The results of the sensory studies conducted by Palgan et al. [10] on reconstituted apple juice exposed to PL at 28 J/cm^2 fluence showed that there was no significant difference in terms of color, sweetness, odor, or acidity of apple juice, but the lowest score was observed for flavor compared to either control or samples PL treated for a shorter time. Off-odor in PL-treated samples remained over the 14 days' storage period due to photophysical changes that occurred on fresh-cut apples [96]. Further, slight changes in flavor were noted by Ignat et al. [87] in apple slices exposed to a fluence of 17.5 kJ/cm^2, which was similar to those detected during the 7-day storage of untreated ones. The effect of PL on grape processing was said to decrease the herbaceous and oxidative smell, so it may be that PL is able to degrade the compounds responsible for green notes and oxidative flavors in wines [107]. UV light is known to induce a series of adverse effects in food products due to the generation of free radicals through diverse photochemical reactions, which can damage vitamins and antioxidants, while also inducing lipid oxidation and color changes [115]. Hierro et al. [97] mentioned that the sensory parameters of ham slices were not altered, whereas for bologna, a difference in odor and flavor profile was observed at fluences higher than 4.2 J/cm^2. In contrast, PL fluences of 8.4 J/cm^2 and ≥4.2 J/cm^2 affected the raw attributes of beef, and tuna *carpaccio* respectively, by inducing the development of sulfur notes [44]. Sensory properties on the chicken breast treated with PL showed no visual color changes, no raw meat flavor, and taste changes, even though there was an increase in the surface temperature up to 38°C after application of 5.1 J/cm^2 UV dose [57]. Most remarkably, unpackaged chicken fillets treated with high fluence PUV (10.8 J/cm^2) showed the highest intensity of sunburnt odor and flavor, which was due to increases in compounds such as 2-pentanone and 1-pentanol [46]. At higher fluence (>6 J/cm^2), thermal effects were induced (54°C), and in turn changes in organoleptic properties of chicken breast meat were perceived [25]. Lasagabaster et al. [100] observed that PL (10.5 J/cm^2) had no effect on the rheological properties of egg and the slight burnt odor was perceived as a sensory parameter, which was not significant. Even PUV application on eggshells had no effect on egg quality in terms of albumen height, egg deformation, eggshell strength, color (L*, a*, and b* values), and the presence of cuticle [116]. Orange pigments were decreased in egg pasta immediately after PL with intense light dose of 26.2 J/cm^2 [90]. In Gouda and Manchego cheeses, there was a significant difference in the odor and flavor in slices treated with 4.2 and 8.4 J/cm^2, indicating the presence of sulfur notes [103]. In cheddar cheese, PL did not affect the color and lipid peroxidation during refrigerated conditions. However, a dose of 9.22 J/cm^2 had an adverse effect on organoleptic properties of cheese [112]. Sensory analysis of cheddar cheese treated with PL showed hedonic scores for liking, flavor, and appearance nearer to untreated control samples; thus Proulx et al. [112] mentioned that PL can be used for commercial application to minimize the undesirable sensory effects on cheese.

46.5.2 Chemical Properties

The enhancement of extraction in grape flashed by PL was observed by the increase in levels of methanol, which is a consequence of the photothermal effect of PL on the grape skin structure [107]. The total soluble solids (TSS) of mango slices treated with PL (8 J/cm^2) did not decrease as compared to untreated slices [94]. Koh et al. [98, 114] even found that there was no effect on TSS of fresh-cut cantaloupe at 4 ± 1°C due to a decreased respiration rate in chilled storage. The increase in acidity was more pronounced in untreated fresh-cut cantaloupes and avocados compared to PL-treated ones, throughout the storage [41, 116]. Maftei et al. [84] found no change in color, soluble substances, and pH in the apple juice treated with PL (53.3 J/g). PL treatment did not have any effect on the antioxidant activity of fruits and vegetables [26, 96]. Even though the anthocyanin content was higher after crushing, the levels were similar to those of controls at the end of the fermentation [107]. Total ascorbic acid content (AAC) and polyphenolic content were similar in both untreated and PL-treated fresh-cut mango samples during 7 days of storage [109]. AAC was conserved throughout the storage period in cut cantaloupe treated at low fluences of 2.7 and 7.8 J/cm^2 [98]. A slight increase in AAC after RPL treatment in cut cantaloupes was noticed and maintained throughout the storage, which could be due to abiotic stress exerted by PL irradiation [114]. IPL applied to spinach and RPL on fresh-cut cantaloupes led to an increase in total phenolics concentration and antioxidant capacity, which may be due to free radical formation by PL stress response that increases the antioxidant production [73, 114]. However, during refrigerated storage, the polyphenol content and antioxidant capacity decreased drastically, and PL-treated spinach was similar to control at the end of storage [73]. The PL treatment of fresh-cut mangoes increased polyphenol oxidase (PPO) activity after 3 days and maintained phenylalanine ammonia lyase activity [109]. IPL treatment did not affect AAC in fruits and had a negligible effect on total phenolic content (TPC) in fresh fruits and vegetables [26, 65, 98, 109, 113]. Similarly, even the mushroom samples treated with 28 J/cm^2 reduced in vitamin-C content and antioxidant capacity compared to 4.8 and 12 J/cm^2 flashing [113]. The TPC of WPL-treated blueberries and water-assisted control samples were significantly higher than the dry control samples immediately after the treatment. However,

blueberries treated with PL showed a lower level of anthocyanin content than dry control samples after 3 days' storage at room temperature [92]. The total anthocyanin content (TAC) of raspberry was not influenced by PL at 5 s and 15 s; surprisingly PL-treated berries showed higher TAC compared to the control at the end of the 10-day storage. However, PL at 30 s increased the TAC by 10.1 mg cyanidin-3-glucoside equivalents/100 g fruit, when compared to 5 s treatment which could be due to stimulation of color and anthocyanin accumulation by PL [65]. Higher concentrations of β-carotene were observed after PL processing of carrot slices (fluences of 2.26 and 4.52 J/cm^2) as compared with control samples, and this behavior was also partly associated with the intense color noticed in the cortex tissue of samples [117]. Further, the carotenoid content of PL treated fresh-cut mangoes was four times higher than the control mangoes on the 7th day of storage [109].

The respiration rate of endive salad, spinach, and fresh-cut cantaloupe was increased by production of CO_2 and O_2 consumption at a higher rate when PL was applied [56, 73, 98]. Similarly, partial pressures of O_2 decreased (by ~5 kPa) and that of CO_2 increased (by ~0.7 kPa) inside the packages of tomato slices on PL processing [78]. These changes could be associated with physiological stress or even physiological damage caused by the IPL treatment, which could affect the metabolic activity of the vegetable/fruit tissue. The changes in headspace gas of the food products were influenced by the fluence applied, storage period, and spectral distribution of IPL treatment [58]. The fresh-cut avocado treated with 305–1100 nm exhibited higher CO_2 concentration than those treated at the 400–1100 nm range, indicating that the UV portion of light led to the generation of anoxic conditions in the headspace of the avocados [58]. The UV part of PL was primarily responsible for a hastened quality loss due to greater respiration rate [56]. IPL treatment increased the respiration rate and gas concentration of lettuce and fresh-cut mushroom at the end of the storage. The O_2 level was less than 2%, indicating anaerobic respiration which affected the sensorial properties of the product [40, 102]. During storage, the respiration rate of IPL-treated fresh-cut avocados increased due to an increasing wounding response and thus caused an undesirable anaerobic condition triggering anaerobic metabolism in the fruit [41]. This anaerobic metabolism leads to a fermentation process, increasing the ethanol production, and inhibits ethylene production in treated fruits [41]. In contrast, PL application on cantaloupe and mung bean sprouts did not result in any significant effect on CO_2 production [56, 114].

One of the disadvantages of continuous UV light is the induction of oxidation processes in meat, which changes its sensorial properties [25, 57, 89]. Ham and bologna treated with PL (above 2.1 J/cm^2) were found to reflect very low lipid oxidation [97], whereas, PUV light treatment induced an oxidation process in sliced ham thus making slices rancid during the storage time (14 days), which may be due to the oxidation process stimulated by the heat generated during the process [89]. PL treatment of egg pasta did not affect peroxide value; however the treatment helped to decrease the formation rate during the storage period [90]. Chicken breast meat flashed with PL showed slightly higher lipid peroxidation (0.16 mg MDA/kg meat) than the control samples [25, 116]. Lipid peroxidation in PL-treated vacuum-packed fermented sausage slices and samples packed in modified atmosphere were not significantly different from the control [40]. These findings showed that light-based processing of food products with proper packaging has an application in food industry to increase the shelf life and to maintain the organoleptic properties of food during storage.

46.6 COMBINED TREATMENTS

The limitations of PL processing are uneven exposure, shadowing effect, browning, and product heating. As a result, many hurdle technology strategies have been developed to address and challenge the limits of PL processing [118]. Combinations of processes have been attempted to increase the microbial inactivation rate and overall process efficiency of PL-based processes [55].

46.6.1 Ultrasound and Pulsed Light

A combination of US and PL resulted in 5.8 and 6.4 log reductions in *S. cerevisiae* KE 162 population, in naturally squeezed and commercial apple juice, respectively [63]. When PL (12 J/cm^2) was applied prior to US treatment, a 6 log reduction in *S. cerevisiae* population was observed in the above two juices. Another study reported that a combinational process provides a synergistic effect on microbial inactivation [119]. US in combination with PL (continuous mode) treatment on commercial apple juice exhibited a synergistic effect that was higher than any of the individual treatments can achieve, i.e. 6.3, 5.9, and 3.7 log reductions for *S. enteritidis*, *E. coli*, and *S. cerevisiae*, respectively [33]. The combination of US and PL (i.e. continuous mode) exhibited the lowest luminosity, decrease in a*, and increase in b* values with respect to control apple juice immediately after the treatment. Additionally, color retention was observed after the combination treatment by preventing apple juice from turning darker and brownish, and also delaying the mold and yeast recovery during the 10 days' storage period [33]. The apple juice treated with US+PL (continuous mode) showed adequate acceptability and fresh natural apple flavor as the main attribute that was highlighted by consumers during sensory evaluation [33].

Muñoz et al. [120] reported that the combination of high-intensity light pulses (HILP) and thermosonication (TS) regardless of the sequence applied had an additive effect on inactivation of *E. coli* in orange juices when compared to either of the processes as a stand-alone. Moreover, TS technology used as a first hurdle, followed by HILP, achieved a significant reduction in *E. coli* population in orange juice when compared to untreated juice or TS as an individual treatment [120]. The combination of PL and TS on apple juice led to significant inactivation of *E. coli* by 4.9 and 5.9 log units when TS was applied at low (14 ml/min, 40°C) and high (8 ml/min, 53°C) settings, respectively. This additive effect on

microbial inactivation could be due to the impact of treatment on different targets, that is, DNA for PL and cell membrane for TS [32]. The combination of PL+TS induced the maximum decrease in L* and b* values and minimum decrease in a* values compared to the reverse treatment, TS+PL [32]. Muñoz et al. [120] reported that there was no sign of sublethal injury to cells with HILP, both at low (4.03 J/cm^2) and high (5.1 J/cm^2) intensities and TS applied individually or in combination. Sublethal damage was detected by Muñoz et al. [32] when PL (low) was applied as the first hurdle, as compared to PL (high) treatment.

46.6.2 Pulsed Electric Field and Pulsed Light

The sequence of HILP/pulsed electric field (PEF) resulted in a slight lowering of *E. coli* K12 cells in apple juice compared to PEF/HILP, but a combination of HILP and PEF suggested a synergistic effect on the inactivation of *E. coli*. This combination had no effect on quality parameters like pH, Brix, browning index, and total phenolics, except for slight color changes [31]. The combination of HILP and PEF treatment had a significant effect on sensory attributes such as flavor and odor of the non-thermally treated apple juice, as compared to thermally pasteurized control [31]. Light-based technology (UV/HILP) combined with PEF had no effect on color, flavor, non-enzymatic browning, TPC, and TAC of the apple and cranberry juice blend and received a similar sensory score to pasteurized samples [121]. The combination of UV/HILP with manothermosonication adversely affected overall acceptability of the apple–cranberry juice blend by increased darkening, lowered flavor/odor values, and changing the overall color of the product [122].

46.6.3 Coatings and Pulsed Light

The combined application of edible coating (gellan-gum based [0.5% w/v] coating enriched with apple fiber) and PL (12 J/cm^2) treatment on fresh-cut apples retarded the microbiological deterioration, and reduced softening and browning during 14 days of storage at 4°C [123]. The combination of PL and gellan gum-based prebiotic edible coating on fresh-cut apples showed the antagonistic effect by hindering the microbial inactivation caused by PL. The uncoated fresh-cut apples treated with PL exhibited lower microbial count after 14 days of storage. Fresh-cut apples treated with PL and edible coating incorporated with apple fiber reduced the signs of oxidation by losing 68% of antioxidant value, while the sample only treated with PL showed a decrease of 83% which was similar to untreated samples [123]. Untreated and PL-treated apple slices showed higher L values than the samples with gellan gum coatings, whereas firmness was better maintained in gellan gum-coated apple slices. Overall, the combination of PL and gellan gum coating on apple slices lowered the sensory acceptability in terms of aroma and flavor during 14 days of storage [123]. In a similar study, pectin-coated fresh-cut apples that were exposed to PL were found to have the highest reduction in yeast and mold, mesophilic and psychrophilic aerobic counts during storage [96]. Pectin-coating of apple cubes (incorporated with apple fiber) was found to inhibit browning and lead to slightly higher antioxidant activity than in the untreated ones during storage [96]. Fresh-cut apple wedges dipped in quality-stabilizing solution (N-acetylcysteine dip) when treated with PL (16 J/cm^2) showed reduced mesophilic and psychrophilic microbial counts by 1.55 log units and molds and yeast loads by 2.3 log units [124]. To minimize the browning on PL-irradiated apple surface, an ascorbic acid (AC)/calcium chloride solution was used as an anti-browning dip prior to PL treatment [125]. The application of AC at 1% on sliced mushroom and apple cubes before flashing with PL significantly reduced browning during storage [113, 123]. The dipping of fresh-cut apples in AC/calcium chloride solution before pectin coating, followed by PL treatment was more efficient in minimizing browning, retaining antioxidant activity, and even did not have any effect on microbial loads and sensory acceptability of apple cubes. Firmness was also maintained in fresh-cut apples when treated with AC/calcium chloride solution as it actually helps in crosslinking the polymer matrix and delays softening of apple surfaces [96]. It is also reported that PL treatment of fresh-cut apple tissues promotes the development of browning, especially after the application of high-energy dosages. The firmness of fresh-cut apples treated with PL of 4 J/cm^2 doubled during 15 days of storage compared to those flashed with 12 J/cm^2 [124]. Llano et al. [124] also observed that fresh-cut apples exposed to the highest fluence (8–16 J/cm^2) retained better antioxidant capacity, and total phenolic and flavonoid content throughout the 16 days of the storage period compared to the samples only dipped in quality-stabilizing solution.

Fresh-cut mushrooms dipped in AC solution exhibited 1.29, 1.03, and 0.72 log reductions in aerobic mesophilic, psychrophilic, and yeast and mold counts, respectively [113]. Application of non-thermal PL treatment against *L. innocua* inoculated on modified chitosan (MC) containing a nanoemulsion of mandarin essential oil-coated green beans (1.2×10^5 J/m^2 per bean side) resulted in a 2 log reduction. Further, PL did not show any synergistic antimicrobial effect against *L. innocua* during storage, and there was a slight detrimental impact on color with the formation of browning spots [126]. The combination of MC coating and PL treatment reduced *E. coli* population on fresh-cut cucumber slices by 1.4–3.8 log CFU/g at 4–12 J/cm^2 [127]. Meanwhile, a combination of PL with MC plus carvacrol essential oil at 3% coating was also more effective in the inactivation of *E. coli* on cucumber slices by 1.9–5.9 log CFU/g respectively for the fluence of 4–12 J/cm^2 [127]. The treatments combining PL (12 J/cm^2) and malic acid (MA) of 2% v/v resulted in significantly greater inhibition of *L. innocua* and *E. coli* populations than either PL or MA alone, by achieving a more than 5 log reduction for fresh produces such as fresh-cut avocado, watermelon, and mushroom throughout the storage period [48]. Even TEM observations confirmed that damage, especially to *E. coli* cells, was caused by a combination of treatments due to agglutination of cytoplasmic content and disruption of cell membrane causing cell death [48]. The application of PL-alginate coating

(ALC)-MA, and ALC-MA-PL treatments on fresh-cut mango led to 3.92 and 3.03 log reductions of *L. innocua* counts, respectively, whereas a combination of MA and PL showed an additive effect on *Listeria* reduction by 4.49 log units compared to PL alone (2.5 log CFU/g) [94]. This difference can be explained by the antagonistic action attributed by ALC, that limits the effect of MA and PL. Meanwhile, the highest inactivation of molds, yeast, and psychrophilic bacteria was obtained with PL-ALC-MA treatment which showed the best microbial quality of mango slices during storage, and ALC helped to maintain the integrity of fruit by reducing the presence of exudates. Therefore, PL should be applied before ALC and MA treatment to overcome the interference caused by ALC [94]. The treatment of mango slices with PL individually was not found to cause any change in pH, but ALC-treated samples increased in pH values and decreased in L values of color in comparison with control samples [94].

The application of anti-browning dipping treatment in combination with IPL would increase the shelf life of minimally processed vegetables and fruits [102]. The coating application after PL treatment would have more influence on the surface texture than if applied alone, since PL may improve the permeabilization of the cell wall of the fruit prior to coating application [94]. The application of PL-ALC-MA and ALC-MA-PL treatments on fresh-cut mango resulted in the highest radical scavenging activity (RSA) of about 42.2 ± 0.4% RSA at the end of 14 days of storage [128]. The PL and MA treatments on fresh-cut mango slices did not show any significant effect on phenolic content compared to the untreated ones; contrarily, mango slices treated with ALC and ALC-MA-PL showed higher content of phenolic compounds immediately after processing as well as at the end of the 14-day storage period [128]. Even, the color of the mango slices was retained after the application of PL, ALC, and MA treatments in combination, with a fresh-like color throughout the 14 days by avoiding browning due to the higher phenolic content achieved [128].

46.6.4 Other Treatments

Research findings have indicated that studies should be aimed at evaluating strategies based on the combination of PL treatments with other processing technologies, e.g. addition of natural preservatives or mild heat treatment, in order to successfully tackle safety issues for clarified juices treated with PL technology. The combined effect of PL+nisin treatment in RTE sausages resulted in a significantly higher reduction (4.03 log CFU) of *L. innocua* compared with individual treatment (PL alone: 1.37 and nisin dip alone: 2.35 log CFU). This combination of PL and nisin was said to cause damage to DNA and membrane pore formation, respectively, thus preventing the recovery of sublethally injured cells [14]. The combination of WPL and 1% hydrogen peroxide (H_2O_2) was found to be the most efficient treatment for inactivating *Salmonella* on raspberries and blueberries by >5.6 log CFU/g [91]. Raspberries treated with WPL (60 s) in combination with 100 ppm sodium dodecyl sulfate (SDS) or 1% H_2O_2 (60 s) inactivated *E. coli* by 5.1 and 5.3 log CFU/g, respectively, whereas 100 ppm SDS or 1% H_2O_2 individually reduced *E. coli* by 2.5 log CFU/g [129]. For strawberries and raspberries, WPL and WPL-H_2O_2 achieved higher log reductions of *Salmonella* (2.4–4.9 log units) than chlorine water washing (2.1 log units), proving the antimicrobial efficacy of WPL [129]. A significant synergistic effect on the inactivation of *B. subtilis* spores (>5 log reduction) was achieved with simultaneous treatment with PUV and H_2O_2 photosensitizer solution on both surfaces and aqueous solutions compared to sequential treatment [51]. Dip-inoculated green onions were treated with PL (60 s), surfactant (SDS) sanitizer combination washing (10 ppm chlorine + 1000 ppm SDS and 300 ppm H_2O_2 + 1000 ppm SDS), as well as a PL–surfactant–sanitizer combination (10 ppm chlorine + 1000 ppm SDS + 60 s PL and 300 ppm H_2O_2 + 1000 ppm SDS + 60 s PL). The combination of chlorine washing and WPL treatment had an additive effect on the inactivation of *E. coli* on green onions by about 2.4 log reductions when compared to chlorine washing or PL treatment alone [85]. H_2O_2 was slightly more capable of inactivating *E. coli* on green onions (0.7 to 2.6 log CFU/g) than citric acid and thymol in combination with 60 s PL treatment. The PL–surfactant–sanitizer combination did not show any synergistic effect on the inactivation of *E. coli* on green onions when compared to the PL–surfactant combination. However, PL in combination with SDS was more effective compared to PL with chlorine washing, thus recommending the application of a surfactant–PL combination treatment in the decontamination of fresh produce [85]. The combination of PL and heat (40 and 45°C) had a significant influence on *B. cinerea* fungal development, but the treatment sequence and temperature level didn't have any effect on the fungal growth [55]. However, a UV-C and PL combination did not show any significant effect on *B. cinerea* fungal growth. In apple juice, a combination of cold storage and PL maintained the log reduction of *S. cerevisiae* over 9 days and retarded the yeast recovery until the third day of storage [54]. The combination of post-cold storage (5°C) with PL had a significant synergistic effect on the decontamination of *L. innocua* and *S. enteritidis* in apple juice, achieving a 5–8 log reduction, and thus, PL coupled with low-temperature storage can provide microbial safety in fruit juices [54]. PL is more effective in decreasing microbial loads on a fresh-cut salad compared to similar treatments with electrolyzed water (40 ppm free chlorine) or chlorine dioxide (15 ppm). PL may, therefore, be an appropriate measure to reduce the required amount of fresh water in fresh produce processing and to keep microbial loads in the wash water at a low level [43, 130]. Thus, PL in combination with other hurdle technologies can be a novel tool for producing microbially safe foods without compromising the nutritional and sensorial quality of foods.

46.7 CONCLUSION

PL technology is a promising non-thermal technique for the decontamination of foods. The mechanism of action of PL for microbial inactivation is reported to have a combined effect of photophysical and photochemical properties (i.e. damage of the cell membrane, cytoplasm, and DNA). The efficacy of

microbial inactivation depends on several parameters, such as light pulse/energy dose, thickness/morphology of food, type of microorganism, and properties of food. The limitations of PL processing are (i) poor penetration of light, and (ii) non-uniform (i.e. inhomogeneous) decontamination. These limitations can be overcome to some extent by employing multidirectional IPL or even sample rotation. Most of the researchers have reported batch-type PL processing units for surface sterilization of products, such as meat, fruits, and vegetables, while a continuous PL system was applied to decontaminate liquid foods. Vegetative bacteria are sensitive to PL as compared to spores, viruses, and fungi. PL technology when combined with other nonthermal technologies like PEF and US could enhance microbial reduction and increase nutrient retention.

47 Irradiation Preservation of Foods

Mohammad Shafiur Rahman

CONTENTS

47.1 FOOD IRRADIATION PROCESS

The irradiation process involves exposing the food, either prepackaged or in bulk, to a predetermined level of ionization radiation. In this process, it is important to know sources of ionization radiation, how energy is quantified, and its scope with advantages and limitations.

47.1.1 Action of Ionization Irradiation

Ionization radiation interacts with an irradiated material and ionizes molecules by creating positive and negative ions by transferring energy in the electrons [1]. The radiation effects on biological materials are direct and indirect. In direct action, the chemical events occur as a result of energy deposition by the radiation in the target molecule, and the indirect effects occur as a consequence of reactive diffusible free radicals formed from the radiolysis of water, such as the hydroxyl radical OH^-, hydrated electron (e_{aq}^-), H atom, hydrogen peroxide (H_2O_2), and hydrogen [1]. Hydrogen peroxide is a strong oxidizing agent and a poison to biological systems, whereas the hydroxyl radical is a strong oxidizing agent and the hydrogen radical is a strong reducing agent. These two radicals can cause several changes in the molecular structure of organic matter [2].

47.1.2 Sources of Ionization Irradiation

There are two classes of ionizing radiation: electromagnetic and particulate. These are γ-rays from radionuclides ^{60}Co or ^{137}Cs, X-rays generated from machine sources operated at or below 5 MeV, and electrons generated from machine sources operated at or below an energy level of 10 MeV [1, 3]. The characteristics of different irradiation sources are summarized in Table 47.1. Although both isotopic and machine sources result in identical impacts on foods, consumers react more favorably to machine sources than isotope sources because of the association of isotopes with the nuclear industry [4]. All three source types require a large plant for economic viability. Much of the high cost is associated with the need for heavy concrete shielding to protect the external environment when the source is in use. In addition, the plant must comply with hygiene and safety legislation relevant to such plants [5].

TABLE 47.1
Characteristics of Irradiation Sources

Radiation Source	Characteristics
Cobalt-60	1. High penetrating power 2. Permanent radioactive source 3. High efficiency 4. Source replenishment needed 5. Low throughput
Electron beams	1. Low penetrating power 2. Switch on–switch off capability 3. High efficiency 4. High throughput 5. Power and cooling needed 6. Technically complex
X-rays	1. High penetrating power 2. Switch on–switch off capability 3. Low efficiency 4. High throughput 5. Power and cooling needed 6. Technically complex

47.1.3 Dose and Dosimetry

The radiation dose (level of treatment) is defined as the quantity of energy absorbed during exposure [6]. Traditionally the dose of ionizing radiation absorbed by irradiated material has been measured in terms of the *rad*, but recently it has been superseded by the *gray* (Gy), which is equal to 100 rad [1]. One gray represents one joule of energy absorbed per kilogram of irradiated product, and the energy absorbed depends on mass, density, and thickness of food [6].

Food irradiation doses are generally characterized as low (less than 1 kGy), medium (1–10 kGy), and high (greater than 10 kGy). Different levels of dose are required to achieve the desired results for products [6]. The energy level used for food irradiation to achieve any technological purpose is normally extremely low, e.g., 0.1 or 1.0 kGy, which would be equivalent to a heat energy of 0.024°C or 0.24°C. The Codex Alimentarius Commission recommended 10 kGy as the maximum energy level or dose of ionizing radiation [7]. At 10 kGy the absorbed energy is equivalent to the heat energy needed to increase the temperature of water by 2.4°C. One gray is equivalent to one joule of energy absorbed per kilogram of material [4]. Loaharanu and Murrell [3] calculated on the basis that 10 kGy of ionizing energy is equivalent to a heat energy of 10 J/g and heat capacity of water is 4.2 J/g °C, i.e., 10/4.2 = 2.4°C. Thus, it is a cold method of food preservation. The absence of noticeable change and small rise in temperature leads to difficulty in detecting whether food has been irradiated [4, 5].

47.1.4 Scope of Irradiation

The potential applications of irradiation are [8, 9] disinfestation, shelf-life extension, decontamination, and product quality improvement.

47.1.4.1 Disinfestation

Disinfestation is one of the important postharvest treatments in food processing, and chemicals are usually used for this purpose. Disinfestation, the control of insects, in fruits can be achieved by doses up to 3 kGy [6]. A low dose of 0.15 to 0.50 kGy can damage insects at various stages of development that might be present on food. Irradiation can damage an insect's sexual viability or capability to become an adult [9].

47.1.4.2 Shelf-Life Extension

One form of shelf-life extension is to inhibit sprouting of potatoes, yams, onions, and garlic at 0.02 to 0.15 kGy [10]. Another form is to delay the ripening and senescence of some

tropical fruits such as bananas, lychees, avocados, papayas, and mangoes at 0.12 to 0.75 kGy [11]. The irradiation also extends the shelf-life of perishable products like beef, poultry, and seafood by decontaminating spoiling microorganisms. Usually, fruits progressively lose their resistance to phytopathogens with ripening. When a low irradiation dose is used to delay ripening, a higher level of resistance is retained in fruits, and microbial development is also delayed as an added benefit [6].

47.1.4.3 Decontamination

Irradiation can reduce microbial load and destruction of pathogens. One form of decontamination could be the use of a low dose (1.0–2.0 kGy) to pasteurize seafood, poultry, and beef. Another form could be a higher dose (3.0 to 20 kGy), such as sterilization of poultry, spices, and seasonings [9].

47.1.4.4 Product Quality Improvement

A higher juice yield could be obtained if fruits are first irradiated at a dose level of several kilograys, thus improving product recovery. Another study showed that the gas-producing factors in soybeans could be markedly decreased with a sequence of soaking, germination, irradiation, and subsequent drying of the beans. This required a dose of 7.5 kGy for maximum effect [12]. It also facilitates reduction of chemicals used in food, such as nitrite and salts. Moreover, irradiation does not leave any chemical residues in the foods [13]. The extent of doses and their purposes are summarized in Table 47.2.

47.1.5 Advantages of Irradiation

Hasegawa and Moy [12] identified at least three distinct benefits of using irradiation to preserve foods. Five advantages of irradiation are discussed next.

47.1.5.1 Minimize Food Losses

Radiation disinfestation and shelf-life extension can reduce the food losses of fresh foods. A great deal of the postharvest losses due to insect infestation can be controlled and minimized by irradiating foods such as grains, pulses, tubers, and fruits. In addition, the shelf life of tubers and some fruits can be extended through sprout inhibition or delayed ripening. Especially in the Third World irradiation has high potential where in many cases food spoils during the postharvest stage [12]. A potential added benefit of the application of irradiation to fruits is the higher juice yield during processing of several commodities [6].

47.1.5.2 Improve Public Health

Foods, especially muscle foods, are contaminated with pathogenic microorganisms or parasites. The decontamination of these fresh foods by irradiation can improve public health concerns. *Salmonella* is a prime source of foodborne illness from poultry products. The use of irradiation up to 3.0 kGy to decontaminate poultry and up to 1.0 kGy to control *Trichinella spiralis* in pork carcasses are approved in the United States [9]. Irradiation is also a method to ensure hygienic quality of solid food [14].

47.1.5.3 Increase International Trade

Many fresh foods are not candidates or not qualified for international trade due to (i) infestation by insects, (ii) infection by microorganisms, and (iii) their limited shelf life, which restricts long-distance shipments. Irradiation can increase or improve the trade of fresh foods over the international market by providing an effective quarantine procedure for infested or infected foods, or helping to prolong the shelf life [9, 14].

47.1.5.4 Alternative to Fumigation of Food

Various chemicals, such as ethylene dibromide, methyl bromide, and ethylene oxide, are used for the fumigation of food and food ingredients. The use of chemical disinfestation treatments is rapidly diminishing due to their toxic nature and environmental impact. For example, the toxic nature of ethylene oxide and the ozone-depleting effect of fumigant ethylene dibromide [5, 14]. Low-dose irradiation of 0.2–0.7 kGy can control insect infestation of grain and other stored products [14]. Irradiation of a dose of 70 Gy led to 99.99% mortality of *Bactrocera invadens* [15].

47.1.5.5 Increase Energy Saving

The energy used for irradiation of food is small compared to canning, refrigeration, and/or frozen storage. The total energy used for refrigerated raw cut-up chicken is 17,760 kJ/kg, for

TABLE 47.2
Extent of Dose and Purpose of Food Irradiation

Dose Limit	Purpose	Dose Limit (kGy)	Examples
Low dose (<1 kGy)	Sprouting inhibition	0.05–0.15	Potatoes, onions, garlic
	Insect and parasite disinfection	0.15–0.50	Cereals, pulses, dried fruit, pork
	Delay of ripening	0.50–1.00	Fresh fruits and vegetables
Medium dose (1–10 kGy)	Reduction of spoilage microorganisms	1.0–3.0	Fish, strawberries
	Reduction of nonspore pathogenic	2.0–7.0	Poultry, shellfish
	Microbial reduction in dry products	7.0–10.0	Herbs, spices
High dose (10–50 kGy)	Sterilization	25–50	Sterile diet meals
Very high dose (10–100 kGy)	Reduces or eliminates virus contamination	10–100	

Sources: Kurstadt [139], WHO [127].

frozen is 46,600 kJ/kg (3–5 weeks frozen storage), and for canned chicken meat is 20,180 kJ/kg. In comparison, refrigerated and irradiated raw cut-up chicken requires a total of 17,860 kJ/kg [16]. Moreover, bans on CFC refrigerants could result in higher costs for refrigerated food in the future, thus combining irradiation and chilling has high potential in the saving of energy during food processing [14]. The reduction of energy requirements can also contribute toward the overall reduction of pollution caused by combustion products of traditional fuels [13].

47.2 EFFECTS ON MICROORGANISMS AND FOOD COMPONENTS

47.2.1 Effects on Microorganisms

Similar to other preservation methods, irradiation affects microbial growth and changes the food components. Ionization irradiation affects microorganisms, such as bacteria, yeasts, and molds, by causing lesions in the genetic material of the cell, effectively preventing it from carrying out the biological processes necessary for its continued existence [17]. Stability of food components also needs to be known to determine their functionality and safety.

47.2.1.1 Mode of Action

The principal targets of irradiation are nucleic acids and membrane lipids. Alteration in membrane lipids, particularly polyunsaturated lipids, leads to perturbation of membranes and to deleterious effects on various membrane functions, such as permeability. The activity of membrane enzymes may be affected as a secondary effect of membrane lipid degradation [6]. Ionization radiations act through changes induced in the DNA structure of the irradiated cells, which result in the prevention of replication or function [3]. The energy levels used are sufficient to disrupt certain bonds in the molecules of DNA, thereby making cell reproduction impossible [4]. Nucleic acids, because of their large size, are the main targets of free radicals generated by irradiation [6]. Chromosomes of bacteria are intrinsically very sensitive and lethal damage occurs as a result of exposure to irradiation. The ability of bacteria to repair a limited amount of such damage gives them considerably greater resistance to such radiations. The efficiency with which different bacteria repair the radiation-induced damage to their DNA varies considerably. The most sensitive vegetative bacteria is *Pseudomonas*, and the most resistant one is *Deinococcus* by a factor of about 100 [1].

47.2.1.2 Level of Dose

Murano [17] reviewed the factors that affect the susceptibility of microorganisms to irradiation, and these are (i) dose level, (ii) temperature, (iii) atmosphere (presence or absence of oxygen), (iv) medium, and (v) type of organism (size, the smaller the target organism, the more resistant it is to ionization radiation; cell-wall characteristics and gram-positive or gram-negative in nature; number and relative age of the cells). In general, the higher the dose applied, the lower the number of survivors and the lower the temperature and the rate of reactions, such as the formation of radicals from water molecules. These radicals can have an indirect effect, by interfering with normal cellular functions such as membrane transport. Table 47.3 shows that minimal doses can achieve significant gains in food safety. If the product is

TABLE 47.3
Effect of Irradiation on Foodborne Parasites

Parasite	Minimum Effective Dose (kGy)	Effect of Irradiation
Protozoa	0.09–0.7	Parasite killed or elimination of infectivity
Toxoplasma gondii	0.251	Killed cyst stage
Entamoeba histolytica		
Trematodes	0.03	Inhibits maturation
Fasciola hepatica	0.15–0.20	Inhibits maturation
Clonorchis sinensis	0.10	Inhibits maturation
Opisthorchis viverrini	0.10	Inhibits maturation
Paragonimus westermani		
Cestodes		
Taenia	>3.00	Complete inactivation of larvae
	0.40	Prevents development in humans
	0.30	Elimination of infectivity
Taenia solium	0.20–0.70	Elimination of infectivity
Echinococcus granulosus	0.50	Elimination of infectivity
Nematodes		
Trichinella spiralis	0.10–0.66	Elimination of infectivity
	0.11	Sterilization of females
Angiostrongylus cantonesis	2.00–4.00	Decreased infectivity
Gnathostoma spinigirum	7.00	Reduced larval penetration
Anisakis species	6.00	Reduced larval penetration

Source: Loaharanu and Murrell [3].

frozen, radical formation is practically inhibited [17]. The *D* value increased from 0.16 kGy at 5°C to 0.32 kGy at –30°C when *Campylobacter jejuni* was inoculated into ground beef [18]. In general, bacteria become more resistant to ionization radiation in the frozen state as well as in the dry state. In both states it is assumed that the contribution of indirect effects from the radiolysis of water is significantly reduced [1]. Off-flavor development in products irradiated in a dry state is less than that of moist products. This is due to the low formation of free radicals at reduced moisture content [2]. The irradiation atmosphere may have an effect, but this may only occur under specific conditions [17]. The composition of the irradiating medium will affect the resistance of microorganisms to irradiation. As a general rule, the simpler the life form, the more resistant it is to the effects of irradiation. For instance, viruses are more resistant than bacteria, which are more resistant than molds, which are more resistant than human beings. Also, within bacteria, some genera are found to be more resistant than others [17]. Bacterial spores are more resistant than their corresponding vegetative cells by a factor of about 5 to 15 [19].

The effectiveness of irradiation to control the infectivity of foodborne parasites is summarized in Table 47.3 from Reference [3]. Low-dose irradiation (below 1 kGy) offers a unique opportunity for controlling the infectivity of a number of foodborne parasites without changing the character of the food. Among the groups of foodborne parasites, trematodes appear to be the most sensitive to irradiation, followed by cestodes and protozoa [3]. The *D* values of various foodborne pathogens in fresh meat are given in Table 47.4.

47.2.2 Effects of Irradiation on Food Components

In addition to microbial growth, the effects of irradiation on other nutritional components need to be identified before using the technology. The effects of irradiation on nutritional qualities of foods are reviewed by Graham [2]

47.2.2.1 Effects on Proteins

Low doses of irradiation may cause molecular uncoiling, coagulation, unfolding, and even molecular cleavage and splitting of amino acids. Apparently, peptide linkages were not attacked, and the main effects were concentrated around sulfur linkages to hydrogen bonds [2]. The sequence of protein bonds attacked by ionizing radiation as follows: -S-CH_3, -SH, imidazole, indole, alpha-amino, peptide, and proline [20]. At 10 kGy radiation, an overall increase in total free amino acids was observed mainly due to the rise in the levels of glycine, valine, methionine, lysine, isoleucine, leucine, tyrosine, and phenylalanine [2]. Irradiation is thought to bring about unfolding of the protein molecule, leading to the availability of more reaction sites [2].

Irradiation also affects the functional properties of proteins. In the case of egg, the doses required for effective *Salmonella* reduction give undesirable side effects, such as loss of viscosity in the white and off-flavors in the yolk [5]. An egg irradiated with 6 kGy showed a thin, watery condition that may be due to the destruction or alteration of ovomucin, the main thickening compound of egg albumin. The casein in milk resulted in an increase in rennet coagulation time and reduced heat stability [2].

The off-flavor development at high doses is due to the presence of benzene, phenols, and sulfur compounds formed

TABLE 47.4
Susceptibility of Various Foodborne Pathogens to Irradiation in Fresh Meat

Organism	T (°C)	Product	D_{10} value (kGy)
Listeria	—	Meat	0.40–0.60
Salmonella	—		0.40–0.50
Escherichia coli O157:H7	—		0.25–0.35
Campylobacter	—		0.14–0.32
Yersinia	—		0.14–0.21
Aeromonas	—		0.14–0.19
Staphylococcus aureus	5	Turkey breast meat	0.45
Campylobacter jejuni	30	Ground turkey	0.16
	5		0.19
	–30		0.29
Salmonella heidelberg	0	Poultry (air packed)	0.24
	0	Poultry (vacuum packed)	0.39
Salmonella enteriditis	5	Egg powder	0.60
	3	Ground beef	0.55–0.78
Salmonella spp.	5	Turkey breast meat	0.71
Listeria monocytogenes	5	Beef	0.45
Escherichia coli O157:H7	5	Ground beef patties	0.27–0.38

Source: Radomyski et al. [140], Smith and Pillai [128].

from phenylalanine, tyrosine, and methionine, respectively. Flavor changes and off-flavors resembling a burnt flavor was observed in the irradiated milk [2]. Irradiation of cheese usually produces smoky off-flavors. Irradiation of soft cheeses at a dose of 1–2 kGy is sufficient to reduce food pathogens and does not impair flavor quality, thus careful dose application is certainly key for off-flavor components [5].

47.2.2.2 Effects on Carbohydrates

Irradiation can break high molecular weight carbohydrates into smaller units leading to depolymerization. This process is responsible for the softening of fruits and vegetables through breakdown of cell wall materials, such as pectin. However, softening may have advantages or disadvantages depending on the requirement. For example, it may be advantageous for juice yield and reduced drying and cooking times of dehydrated products [5]. Sugars may be hydrolyzed or oxidized when subjected to gamma irradiation [6]. The irradiation of wheat at 0.2–10 kGy increased the initial levels of water-soluble reducing sugars by 5–92% compared to untreated samples [21]. Such an overall increase in initial total reducing sugars resulted from the stepwise and random degradation of starch. These changes are highly advantageous in the generation of bread flavor and aroma by reducing sugar–amino acid reactions [2]. Irradiation of pure carbohydrates produced degradation products that have mutagenic and cytotoxic effects. However, these undesirable effects were produced using very high doses of irradiation [2].

47.2.2.3 Effects on Lipids

Irradiation initiates the normal process of autooxidation of fats, which gives rise to rancid off-flavors. Highly unsaturated fats are more readily oxidized than less unsaturated fats. This process can be slowed by the elimination of oxygen by vacuum or modified atmosphere [5]. In lipids, particularly unsaturated fatty acids, radiolytic decomposition is via a preferential break at the level of the carbonyl function of the double bond [22]. This decomposition induces the formation of some volatile compounds responsible for off-odors [23]. The formation of peroxides, volatile compounds, and development of rancidity and off-flavors have been reported [24, 25]. The peroxide formed can also affect certain labile vitamins, such as vitamins E and K [2].

The lipids in cereals degraded only at high doses of irradiation, and no significant effects on iodine value, acidity, or color intensity of wheat flour lipids were observed. At 10 kGy, a 20% increase in total free lipids and a 46% decrease in bound lipids were observed [26]. Lipid–protein complexes, critical in baking, were not noticeably affected at low doses up to 2 kGy.

The volatile oil content of spices has a dose-dependent reduction effect in black pepper [27] and ginger [28] above 6 kGy. A similar reduction was also observed in the case of Ashanti pepper berries when 47 essential oil compounds were analyzed individually at a dose of 10 kGy [29].

47.2.2.4 Effects on Vitamins

The extent of vitamins C, E, and K destruction depends on the dosage used, and thiamine is very labile to irradiation. The losses are low with low dose. Ascorbic acid in solution is quite labile to irradiation, but in fruits and vegetables seems quite stable at low doses of treatment [2]. Vitamins, particularly those with antioxidant activity, such as A, B_{12}, C, E, K, and thiamine, are degraded when irradiation is carried out in the presence of oxygen [6].

Irradiation can also partially damage vitamin C and B_1. Kilcast [5] mentioned that literature referring to vitamin loss is misleading in many cases. Vitamin losses are often quoted at unrealistically high irradiation doses or under unrealistic conditions. In particular, vitamin C loss is often equated with ascorbic acid loss, ignoring the fact that irradiation converts ascorbic acid into dehydroascorbic acid, which is also active as a vitamin [5, 6].

47.2.2.5 Effects on Enzymes

Enzymes in foods must be inactivated prior to irradiation because they are much more radiation-resistant than microorganisms. Usually, enzyme inactivation is accomplished thermally. Generally, it may be said that complete inactivation of enzymes requires about 5 to 10 times the dose required for the destruction of microorganisms [2]. The *D* values of enzymes can be 50 kGy and almost four *D* values would be required to complete destruction [20]. Thus, irradiated foods can be unstable during storage due to their susceptibility to enzymatic attack than nonirradiated foods [2]. High resistance of enzymes to irradiation has been demonstrated with milk phosphatase, which was not destroyed by irradiation doses sufficient to sterilize milk [30]. Enzymes are affected by the indirect effects of the formation of free radicals in the solvent phase, thus dilute solutions of enzymes are relatively more sensitive to irradiation than are concentrated solutions. Moreover, enzymes in their natural environments, as in foods, are relatively very resistant [2]. The activity of enzymes is unaffected at normal doses and thus it limits the achievable shelf-life extension of fruits and vegetables [5].

47.3 APPLICATIONS OF IRRADIATION IN FOODS

47.3.1 Plant Foods

Plant tissues showed a transient increase in respiration and ethylene production even at low doses. The rate of respiration increased linearly with increasing dose of irradiation. The transient rate of respiration decreased back to preirradiated levels within 24 h for 0.3 kGy, but slower with an increasing dose. Ethylene production also increased after irradiation and it reached a maximum at 1 kGy. It has been suggested that irradiation beyond 1 kGy caused membrane damage since ethylene production is membrane-associated [6]. There was a shift from glycolysis toward the pentose phosphate shunt in bananas and toward the glyoxylate cycle in bananas and

mangoes [31]. At higher doses, climacteric fruits may not ripen normally and may develop uneven coloring and skin discoloration [6].

Fruits suffer physiological disorders when exposed beyond their limits of tolerance. These undesirable symptoms are mainly tissue softening and enzymatic browning [32]. Tissue softening is caused by (i) partial depolymerization of cell wall polysaccharides, mainly cellulose and pectins [33]; and (ii) damage to the cell membrane [34]. Enzymatic browning is an indication of cell decompartmentation due to damage of membranes, thus bringing phenolic substrates in contact with polyphenoloxidases [35]. The damage to the cell membrane may result in (i) loss of intracellular water, (ii) cell turgescence, and (iii) oxidative attack on polyunsaturated fatty acids of membrane lipids [6]. The oxidation can be minimized by irradiating in an atmosphere with reduced oxygen content, but treatment efficiency is reduced. Voisine et al. [36] mentioned that a high carbon dioxide atmosphere was shown to protect tissues from irradiation- induced loss of membrane proteins. Thus, low-dose irradiation combined with a modified atmosphere is increasingly considered for control of microorganisms and delayed ripening. Couture and Willemot [37] showed the synergistic action of irradiation combined with high carbon dioxide for control of mold development on strawberries. A decay incidence of *Rhizopus stolonifer* and *Botrytis cinerea* on strawberries packaged under 7% oxygen and 20% carbon dioxide and irradiated at 1 kGy was reported [38]. Table 47.5 shows the response of a number of fruits to irradiation. The applications of irradiation in specific plant materials are discussed next.

47.3.1.1 Spices

There is an increasingly important use of irradiation for decontamination of spices. Spices imported into Western Europe are often heavily contaminated by pathogenic microorganisms as a consequence of open air drying procedures [5]. The prevalent microorganisms of pepper are *Clostridium*, *Staphylococcus*, *Bacillus*, *Aspergillus*, and *Fusarium* species. Doses of 2.5 kGy reduced the fungal and bacterial load by 2 log cycles and 7.5 kGy eliminated the fungal population of ground or whole pepper.

Yang et al. [39] found that the treatment of garlic bulbs with 0.15 kGy can inhibit sprouting and reduce weight loss during storage. The irradiation affects the flavor compounds of garlic. Kwon and Yoon [40] reported that the content of diallyl disulfide in garlic was slightly reduced by irradiation of 0.05–0.10 kGy. There was no difference in the contents of diallyl disulfide upon comparison of 0.05 kGy irradiated with unirradiated bulbs during storage [41]. The irradiated bulbs showed no difference in odor during storage when compared with untreated [42]. The dose of 0.15 kGy affected the volatile compounds in garlic bulbs during storage at room temperature [43]. The content of diallyl disulfide decreased immediately after irradiation. At the end of 8 months of storage both irradiated and untreated samples showed a significant increase in diallyl disulfide. The quantities of some major volatiles were significantly decreased in irradiated ginger rhizome after 3 months of storage when 0.05 kGy irradiation was applied [44].

47.3.1.2 Fruits and Vegetables

47.3.1.2.1 Berries

The postharvest shelf life of cherries, blueberries, and cranberries can be extended at low doses of irradiation [45]. Blueberries irradiated at 0.25, 0.5, 0.75, or 1.0 kGy can be stored at 1°C for 1, 3, and 7 days, and 2 additional days at 15°C, respectively, [46]. The firmness of Sharpblue blueberries was slightly affected by dose, but firmness of Climax blueberries was not affected by irradiation. Flavor and texture were negatively affected as dose increased for berries of both cultivars. Weight loss, decay, peel color, total soluble solids, and titratable acidity were not affected by dosage. Irradiation at or below 0.75 kGy was determined not to be detrimental to the postharvest quality. This treatment can be an effective alternative quarantine treatment to methyl bromide [46].

47.3.1.2.2 Mangoes

Mango preservation would greatly benefit from irradiation treatment. The effects of irradiation depend on the degree of maturity [6]. The optimal dose was 0.75 kGy for three-quarter ripe fruits at room temperature [11]. Combined with a mild heat treatment by hot water dip or vapor for 5 min at 55–55°C yielded even better results [47]. The surface scalding is a limiting factor,

TABLE 47.5
Response of 23 Fruits to Irradiation

Effect	Results	Materials
Beneficial	Ripening delayed	Bananas, mangoes, papayas
	Senescence delayed	Sweet cherries, apricots, papayas
	Storage decay controlled	Tomatoes, strawberries, figs
Not beneficial	Lack of tolerance	Pears, avocadoes, lemons, grapefruits, oranges, tangerines,
	Ripening accelerated	cucumbers, summer squash, bell peppers, olives, plums, apples, table grapes, cantaloupes
		Peaches, nectarines
	Irradiation tolerance only	Pineapples, lychees, honeydew melons

Source: Akamine and Moy [11].

since at 0.25 kGy scalding occurred on the mature green fruits, and tolerance increased with maturity [11].

47.3.1.2.3 Carrots

Doses up to about 0.1 kGy had little effect on the firmness of apples, carrots, and beets, but rapid softening occurred at higher doses [48, 49]. The effective range for control of rotting and sprouting is 0.1–1 kGy, which means substantial softening can occur [50]. Bourne [50] studied the kinetics of softening of carrot with doses from 0 to 50 kGy. Two distinct regions were observed: a steep negative slope for doses up to 15 kGy and a shallow negative slope beyond 15 kGy. A two-stage softening rate curve is qualitatively similar to that for thermal softening of carrot.

47.3.1.2.4 Papaya

Papaya can tolerate up to 1 kGy γ-radiation before surface scald occurs. The surface color development is not disrupted by up to 2 kGy, flavor and aroma up to 4 kGy, and tissue breakdown up to 5 kGy [11, 51]. A dose of 0.75 kGy was considered the optimum dose for retention of fruit firmness with only slight reduction of storage decay [51]. A hot water dip at 48.9°C for 20 min in combination delayed ripening with optimum dose of 0.75 kGy [11, 47]. A hot water dip alone accelerated ripening, while irradiation alone provided only slight control of decay, and a hot water dip was preferable to vapor heat treatment [6]. The respiratory activity was initially elevated immediately after irradiation and then returning to the level of untreated fruit within 24 h [52]. Paull [53] studied the effect of 0.25 kGy on papaya and found irradiated fruit softened more uniformly than nonirradiated fruit.

Zhao et al. [54] found irradiation had no effect on the skin and flesh color development of ripening papaya. Irradiation induced immediate depolymerization and demethoxylation of papaya pectic substances indicated by an increase in water-soluble pectin, and decrease in chelator-soluble and alkali-soluble pectin with a significant decline in methanol content. The linear decrease in firmness up to 1.5 kGy was parallel to the change of pectin fractions. Pectin methylesterase was not affected either immediately after irradiation or during ripening, by irradiation at doses up to 1.5 kGy.

47.3.1.2.5 Strawberries

Irradiation at doses of 1, 2, and 3 kGy effectively prolonged the shelf life of strawberries stored at 4°C for 5, 13, and 16 days, respectively [55]. Maxie and Abdel-Kader [56] indicated that strawberries may tolerate an irradiation dose up to 2 kGy for reducing fungal infection without quality changes. The softening of strawberries occurred after irradiation [31, 57, 58]. The softer texture above 2 kGy may limit use of higher doses. The firmness of strawberries decreased as irradiation doses increased 0.5, 1, and 2 kGy [59, 60]. Success depends on cultivar: the firmer Tioga strawberries tolerated radiation better than the softer Brighton strawberries [47]. Several studies indicated that irradiation-induced texture change was associated with changes in pectic substances [49, 61, 62]. Water-soluble pectin increased and oxalate-soluble pectin decreased at 0 and 1 day after 1 and 2 kGy irradiation. Fruit firmness correlated with oxalate soluble pectin content. Total pectin and nonextractable pectin were not affected by irradiation. The oxalate-soluble pectin content and firmness of irradiated strawberries increased slightly at the beginning of 2°C storage and then decreased as storage time increased [60]. Irradiation enhanced the sweetness of strawberries by reducing titratable acidity in comparison with untreated sample [63]. The depolymerization of carbohydrate polymers, such as starch and cellulose, may slightly increase the sugar content [33].

47.3.1.3 Cereals and Grains

Grains and cereals are treated with low doses of irradiation to eliminate fungi since some of these organisms can produce mycotoxins [2]. Irradiation doses in the range of 0.2–1.0 kGy are effective in controlling insect infestation in cereals [64]. Increasing the dose to 5 kGy totally kills the spores of many fungi surviving the lower doses [65]. In addition to its protective role from insects and microorganisms, irradiation also affects various quality criteria of cereal grains [66]. The amylograph peak viscosity and falling number values of flour decreased with the increasing irradiation dose [67, 68]. Rao et al. [69] also found that amylograph peak height and dough stability decreased with the increasing dose. At 10 kGy, loaf volume and crumb grain were impaired. The overall bread quality of wheat was greatly reduced at a medium dose of irradiation 1–10 kGy [70]. Loaf volume and baking quality deteriorated above 5 kGy irradiation irrespective of the baking formula [71].

Increased cooking losses and inferior scores in sensory were observed in Japanese noodles when wheat was irradiated in the range of 0.2 to 1.0 kGy [72, 73]. Koksel et al. [66] studied the effects of irradiation up to 5.0 kGy on durum wheat and semolina properties and spaghetti cooking quality. The falling number and sedimentation values of wheat meals decreased with increasing dose levels. This indicated the alterations in both starch and gluten components. Irradiation also caused important changes in the spaghetti cooking properties. Total organic matter and solid substance lost values of both cultivars increased with irradiation. Koksel et al. [66] mentioned that irradiation may be useful at 1 kGy dose for treatment of grain for insect control without adversely affecting quality. Above 1 kGy dose, irradiated samples exhibited lower scores for stickiness, firmness, and bulkiness compared to unirradiated samples due to deterioration in both starch and gluten. Cowpeas can be preserved in polyethylene bags (100 μm) after ionizing treatment at doses of less than 0.10 kGy without causing unfavorable nutritional consequences [74].

47.3.2 Animal Foods

In 1997, the U.S. Food and Drug Administration (FDA) approved the use of ionizing radiation to inactivate pathogenic bacteria in red meat [75]. The irradiation is effective in preventing or delaying the microbial spoilage of fresh meats and poultry. As Mitchell [4] mentioned, early studies indicated that irradiation at doses between 0.25 and 1 kGy under aerobic

conditions increased microbiological shelf life but accelerated rancidity [76]. A tallowy odor and flavor developed during storage. The fat was noticeably bleached, and peroxide accumulated more rapidly in the irradiated than in the control fat. In the case of meats, doses up to 2.5 kGy control *Salmonella*, *Campylobacter*, *Listeria monocytogenes*, *Streptococcus faecalis*, *Staphylococcus aureus*, and *Escherichia coli* in poultry and other meats. The doses in excess of 2.5 kGy may change flavor, odor, and color, but these changes can be minimized by irradiating at low temperature or in the absence of oxygen [4].

Irradiation treatment is not effective to stop the changes in meats that adversely affect consumer acceptance, such as oxidation of pigment to yield brown or gray discolorations by atmospheric oxygen; drip loss from the cut surface of lean meat; and oxidation of meat lipids, which causes off-flavors by atmospheric oxygen [4]. Thus, irradiation coupled with vacuum packaging has the potential to extend the shelf life [4]. Table 47.6 shows the threshold dose for an identifiable irradiation flavor in meats.

Hydrogen generated during the irradiation of frozen meats is a promising marker for distinguishing between irradiated and unirradiated frozen food [77]. Poultry meat in particular is known to be susceptible to color changes following irradiation [78]. A pink color is produced in fresh poultry when it is treated with irradiation [79]. Irradiated chicken breasts were found to exhibit increased greater redness (a* values) when compared with the unirradiated controls [80].

47.3.2.1 Poultry

At a low dose of radiation, not all microorganisms are destroyed and survivors such as *Moraxella*, *Acinetobacter*, *Lactobacillus*, and *Streptococcus* can cause spoilage [81]. A mixed microflora to a predominant gram-positive microflora usually exists during the postirradiation stage [82]. Doses of 2–2.5 kGy are effective in controlling *Listeria* [83, 84] and a dose of 1.0–2.5 kGy is adequate to eliminate *Pseudomonas aeruginosa*, and 2.5–5.0 kGy to eliminate *Serratia marcescens* [85]. A dose of 1.50 kGy was effective for *Staphylococcus aureus* in deboned chicken when irradiated in vacuum at 0°C and held at 35°C for 20 h [86]. In the case of *Escherichia coli* in deboned chicken meat, a 90% decrease of viable cells can be achieved by doses of 0.27 kGy at 5°C and 0.42 kGy at –5°C [87].

TABLE 47.6
Threshold Dose for an Identifiable Irradiated Flavor for Meats

Meat	Temperature (°C)	Threshold (kGy)	Reference
Pork	5–10	1.75	Sudarmadji Urbain [141]
Beef	5–10	2.50	Sudarmadji Urbain [141]
Chicken	5–10	2.50	Sudarmadji Urbain [141]
Lamb	5–10	6.25	Sudarmadji Urbain [141]
Lamb	—	2.40	Dempster [112]

In the Netherlands, a maximum dose of 3 kGy is permitted on an unconditional basis in case of poultry irradiation [88], and in Israel and South Africa, a dose of 7 kGy is allowed to eliminate pathogenic bacteria [89]. Mulder [82] recommended a dose of 2.5–5 kGy since this can extend shelf life at chill temperatures from 6 days up to 14 days without insignificant organoleptic quality change. However, doses as low as 0.5 kGy can induce a radiation odor and a 2.5 kGy can induce flavor changes, which may be removed on subsequent cooking [82, 85]. Table 47.7 shows the changes in odor of irradiated chicken carcasses during storage at 1.6°C.

The color of meat depends on three factors: concentration of heme pigments, the chemical state of these pigments, and the physical light scattering properties of the meat structure [90]. Patterson [81] studied the sensitivity of irradiation under air, carbon dioxide, vacuum, and nitrogen on seven bacterial species inoculated onto sterile poultry meat. *Streptococcus faecalis* and *Staphylococcus aureus* were not sensitive to atmosphere, and others such as *Pseudomonas putida*, *Salmonella typhimurium*, *Escherichia coli*, *Moraxella phenylpyruvica*, and *Lactobacillus* were more sensitive in atmospheres other than air. In general, a vacuum or carbon dioxide atmosphere during irradiation had the most lethal effect, and bacteria may be more resistant to irradiation if packaged under nitrogen than carbon dioxide or air [4, 81].

47.3.2.2 Mutton Lamb

Irradiation of vacuum-packaged mutton backstraps at 4 kGy prevented the growth of bacteria for at least 8 weeks at 0–1°C [91], while *Brochothrix thermosphacta* and gram-negative bacteria grew on telescoped lamb carcasses irradiated at 2.4 kGy and stored at 5°C. The total population did not exceed 10^5 cfu/cm^2 during 16 weeks storage [92]. However, at these high doses, adverse effects on sensory attributes and increased volume of weep released were observed. Meat chunks irradiated at 1.0 kGy and 2.5 kGy were acceptable for 3 and 5 weeks, respectively, whereas for minced meat it was 2 and 4 weeks [93]. In contrast, unirradiated meat chunks and mince spoiled within 1 week of storage at 0–3°C [4].

47.3.2.3 Beef

Pseudomonas, Enterobacteriaceae, and *Brochothrix thermosphacta* were strongly inhibited beef meat on irradiated samples and sensory properties were not altered [4]. Rodriguez et al. [94] studied the effect of 2 kGy irradiation on fresh top round beef, packed aerobically in polyethylene film. Psychrotroph counts on the untreated samples reached 10^7 cfu/cm^2 after storage between 8 and 11 days, while similar counts were not observed in irradiated samples until 28 days of storage. The shelf life of vacuum-packaged raw meat can be extended considerably at doses of 1–5 kGy, which also yielded satisfactory sensory quality [95, 96]. Grant et al. [97] studied the effect of 2 kGy irradiation on growth and toxin production by *Staphylococcus aureus* and *Bacillus cereus* on roast beef. Irradiation resulted in a 3–4 log reduction in the numbers of both pathogens. Toxin production by both pathogens was also delayed by irradiation. Roast beef and gravy samples

TABLE 47.7
Changes in Odor of Irradiated and Unirradiated Chicken Carcasses Stored at 1.6°C

Storage Time (Days)	Unirradiated	Irradiated	
		2.5 kGy	5.0kGy
0	Fresh chicken	Slight irradiation odor	Irradiation odor
4	Fresh chicken	Fresh chicken odor	Slight irradiation odor
8	No odor	Fresh chicken odor	Fresh chicken odor
11	Slight off-odor	Chicken odor	Chicken odor

irradiated at 2 kGy and stored at 5°C and 10°C showed similar growth rates of *Listeria monocytogenes*, with a lag period of 6–9 and 2–4 days, respectively, compared to 1–2 days and less than 0.1 days in nonirradiated samples [98].

Postmortem aging of beef is typically done by holding carcasses or cuts between –1°C and 4°C for up to 3 weeks. During that time, tenderness improves and a distinctive flavor develops. Snyder [99] suggested that carcass aging at high temperature followed by irradiation can reduce microbial numbers. Irradiation in conjunction with modified atmosphere packaging containing 25% carbon dioxide and 75% nitrogen could be used for an accelerated aging process of beef at 30°C for 2 days [100]. Their result was based on tenderness, chemical, visual, and microbiological effects. Moreover, if irradiated beef were chilled immediately after aging, this process could improve tenderness without excessive microbial growth and would be more efficient than aging carcasses at high temperatures followed by irradiation [100].

In a summary by Sommers [75]:

- Irradiation can inactivate pathogenic bacteria occasionally found in ground beef, such as *Escherichia coli* O157:H7, *Salmonella*, *Staphylococcus aureus*, and *Listeria monocytogenes*.
- Irradiation does not make food radioactive. (iii) Irradiation, when used appropriately, does not change the aroma, taste, aftertaste, texture, or overall liking of ground beef, including frozen ground beef supplied as part of the U.S. National School Lunch Program.
- There is no detectable increase in the risk of cancer associated with long-term consumption of radiation pasteurized meat as determined by multispecies, multigeneration feeding studies conducted in animals.
- Irradiated ground beef is nutritious and wholesome.
- Irradiation is only effective as part of a comprehensive program designed to improve the microbiological safety of ground beef, not to clean up unacceptable product.

47.3.2.4 Pork

Sivinski and Switzer [101] mentioned that a low-dose irradiation treatment between 0.30 and 1.0 kGy may be used to inactivate the parasite *Trichinella spiralis* in pork. The effect of 1 kGy irradiation on vacuum-packaged pork stored up to 21 days at 4°C reduced the numbers of mesophiles, psychrotrophs, anaerobic bacteria, and Staphylococci throughout storage. The effects of irradiation on sensory characteristics of pork loin were minimal. Irradiation of pork striploins (vacuum packaged, pH 6.2–6.6) at 2.5 and 4.3 kGy reduced by 3 and 5 logs in the number of viable bacteria present [102]. Significant organoleptic (color, odor, and flavor) changes occurred up to 1.0 kGy. Shelf life increased from 8 to 11.5 days for vacuum-packaged ground pork irradiated at 1 kGy when stored at 5°C [103, 104], while from 4 to 6 weeks at 0°C [102]. The storage life of vacuum-packaged pork at 0°C and 5°C was doubled by 2.5 and 4.3 kGy treatment, but produced undesirable side effects of changes in color and odor of uncooked meat [105]. The odor resulting from a dose of 2.5 kGy was sufficient to make the meat unacceptable. Treatment using a dose of 1.0 kGy was effective in extending storage life and produced only slight changes in color and odor [105]. After 12 days of refrigerated storage, *Lactobacillus* and coryneform bacteria predominated in the irradiated meat [103]. The microbial shelf life of vacuum packaged pork lions stored at 2°C was extended from 41 days to 90 days when treated by 3 kGy [106]. Samples of vacuum-packaged ground fresh pork were irradiated at doses from 0.57 to 7.25 kGy and stored at 2°C for 35 days and analyzed. Surviving microflora were not detected in any sample that received an absorbed dose of 1.91 kGy or higher. *Staphylococcus*, *Micrococcus*, and yeast

species predominated in samples that received a dose of 0.57 kGy [107]. There is no significant difference between irradiated samples and controls on lipid oxidation of irradiated pork chops during storage [108].

After reviewing the literature on irradiation in combination with modified atmosphere packaging, Mitchell [4] mentioned that substantial extensions in sensory shelf life can be achieved using doses from 0.5 to 1.75 kGy and modified atmospheres with 25% to 50% carbon dioxide (balance nitrogen). The product must be stored at 5°C or less to achieve extended shelf life. Irradiation in the presence of oxygen has a detrimental effect on chemical and sensory characteristics, resulting in rejection of the product [18, 109]. A list of shelf life of irradiated and unirradiated pork loin in 100% nitrogen is given in Table 47.8. The shelf life can be different depending on the quality attributes, such as microbial and color. The microflora of irradiated modified atmosphere packaging of pork is almost exclusively lactic acid bacteria [110]. Inoculation studies showed that *Clostridium perfringens* was the most resistant and *Yersinia enterocolitica* the most sensitive of the pathogens *Clostridium perfringens*, *Yersinia enterocolitica*, *Escherichia coli*, *Listeria monocytogenes*, and *Salmonella typhimurium* [111].

47.3.2.5 Processed Meats

The amount of nitrite required in cured meats possibly can be reduced by irradiation, thus the chance of nitrosamine formation can be lowered [95, 112]. The nitrite levels in irradiated bacon can be reduced from normal levels of 120–150 mg/kg to 20–40 mg/kg without loss of organoleptic quality [113]. Moreover, the load of spores in additives, such as herbs and spices frequently used in meat products need higher doses of radiation [114]. Wills et al. [6] treated vacuum-packaged sliced corn beef with radiation doses of 1, 2, and 4 kGy. The initial microbial load reduced by 1, 2.5, and 5 log cycles; however, slight changes in aroma and flavor at 2 kGy were observed and storage life was doubled to about 5 weeks. Enterobacteriaceae was effectively inactivated by irradiation with doses of 1 or 2 kGy when sensory effects were minimal. The product can be stored up to 5–7 days when treated at 2 kGy. Ground beef patties irradiated at 2.0 kGy under vacuum remained unspoiled even after 60 days of refrigerated storage [115]. In the case of minced meat, a slight reduction of pH to 5.2–5.3 was observed on vacuum-packed products at a dose of 2 kGy. Lactic acid bacteria were more resistant to radiation and became the dominant species during storage. The combination of pH reduction and irradiation prevented growth of Enterobacteriaceae even at 10°C incubation [116].

The sensory characteristics (flavor, texture, juiciness, and aftertaste) of ground beef patties irradiated at 2.0 kGy and stored under refrigerated conditions were studied by Murano et al. [115]. After one day, irradiated patties were significantly more juicy and tender than nonirradiated patties, while after 7 days no significant difference was observed.

TABLE 47.8
Shelf Life of Irradiated and Unirradiated Pork Loin in 100% Nitrogen

Irradiation Dose (kGy)	Storage Temperature (°C)	Shelf Life (Days)			
		Microbial	Color	Odor	Overall
0	5	14	9	16	9
1	5	21	35	26	21
0	25	2	<2	<2	<2
1	25	10	>14	2	2

47.3.2.6 Fish and Fish Products

Singh [117] and Nickerson et al. [118] reviewed the irradiation of meats and fish and their shelf life. The control of pathogenic organisms and the extension of shelf life of fresh fish can be achieved with relatively low doses less or equal to 2.5 kGy [117]. However, *Clostridium botulinum* (A, B, E, and F) present in fish and fish products remained unaffected by the low doses of irradiation. Thus, precautions to storage under 3°C and making oxygen available to the product need to be taken. In the case of dried fish (moisture <20%), a dose of 0.3 kGy is sufficient to control insect attack and their larvae [119], but at higher levels of moisture from 20% to 40%, a dose of 0.5 kGy is required.

Mold growth can also contribute to spoilage depending on the moisture level in the fish. Control of the mold growth by irradiation alone requires doses of 3 to 5 kGy [119]. Bacterial spoilage is also a problem in semidry and fresh fish, and fish products [117]. Typical doses up to 2.5 kGy are generally adequate to control the spoilage bacteria and extend the shelf life of fresh fish. The optimum irradiation doses and shelf lives of freshwater and marine fish, and shellfish were compiled by Singh [117]. In general, the shelf-life extension on irradiation is dependent on the conditions of irradiation and storage, and seem to vary from species to species of fish.

Al-Kahtani et al. [120] studied the effects of gamma irradiation (1.5–10 kGy) and postirradiation storage up to 20 days at 2°C on tilapia and Spanish mackerel. They found that (i) total volatile basic nitrogen formation was lower in irradiated fish than in the unirradiated; (ii) a larger increase in thiobarbituric acid values continued gradually during storage; (iii) some fatty acids ($C_{14:0}$, $C_{16:0}$, and $C_{16:1}$) decreased upon irradiation, while others ($C_{18:0}$, $C_{18:1}$, and $C_{18:2}$) increased; (iv) thiamin loss was more severe at higher doses ≤4.5, whereas riboflavin was not affected; and (v) doses higher than 3.0 kGy caused a decrease in alpha and gamma tocopherols.

Chen et al. [121] studied low doses (2 kGy or less) in reducing pathogenic and spoilage microorganisms, and the sensory quality of crab products (white lump, claw, and fingers) through 14 days of ice storage. Irradiation effectively reduced spoilage bacteria extending shelf life by more than 3 days beyond control samples. Fresh crab odor and flavor were similar for treated and control samples, while off-flavors and odors developed more rapidly in controls during storage.

Overall, acceptability scores for irradiated crab samples were higher than for control samples through 14 days ice storage.

47.4 TECHNOLOGICAL PROBLEMS AND LIMITATIONS OF IRRADIATION

47.4.1 Major Problems of Irradiation

47.4.1.1 Investment Cost

Successful implementation of a new technology depends on the availability of a proper infrastructure within a given country [14]. Irradiation has high capital costs and requires a critical minimum capacity and product volume for economic operation [13, 122], although irradiation has a low operating cost and requires low energy [123].

47.4.1.2 Risk–Benefit Analysis of Dose

There are threshold doses above which organoleptic changes and off-flavors development occur. But at low doses, all microorganisms and their toxins will not be eliminated. Willemoti et al. [6] mentioned that variability of the effects leads to difficulty in standardizing irradiation treatment. The success of treatment depends on commodity and cultivar, dose of radiation, degree of maturity, physiological status of fruits, temperature and atmosphere during and after treatment, pre- and postharvest treatments, and susceptibility of the microorganisms to be controlled [6]. Tolerance changes with the degree of maturity. Physiological status, such as mechanical injury, season, and humidity at time of harvest, also plays a role. The response of each individual batch of fruits is therefore difficult to predict, thus generalized dose levels and their consequences in quality are difficult to develop.

47.4.1.3 Damage of Packaging Materials

The packaging materials used during irradiation should not cause the production and release of undesired substances that may migrate into the food. Irradiation may affect different packaging materials in different ways. At doses of 60 kGy and higher, some damage may occur in tin-coated steel and aluminum containers, but at the level of sterilizing doses there should not be any affect. The enamels usually used in the interior must also be of the proper type. For example, for high-fat-content foods, oleoresin enamels are unsuitable but are suitable for enzyme inactivation of foods. Irradiation apparently depolymerizes butyl-rubber sealing compounds used in cans [2]. The shape of the container is also very important. A cubical form is the most satisfactory for optimum dose distribution during irradiation [2].

The effect of irradiation on plastic films depends on the nature of the packaging film, layers of packaging film and additives in formulation, temperature and oxygen content during treatment, treatment dose, dose actually absorbed, and contact with foods [124]. At doses less than 20 kGy, physical changes in flexible containers are negligible. High doses above 30 kGy cause brittleness in cellophanes, saran, and plioform, while 20 kGy or more can cause inconsequential physical changes in mylar, polyethane, vinyl, and polyethylene plastic films [2]. The physical damages can be considerably reduced by the addition of aromatic additives. At strong doses at 50 kGy, mechanical properties of polymers can be improved by cross-linking [125]. At the doses generally applied from 3 to 25 kGy, the migration of water increases [123]. Properties of polyethylene terephthalate (PET) are well preserved during irradiation [126]. Table 47.9 shows the FDA-approved levels of irradiation dose for different packaging materials.

An important problem in the irradiation of foods in plastic containers is the production of gas and volatile compounds, which may migrate to the food and cause off-flavors. At sterilizing doses, nylon gives rise to little off-odor production, whereas in the case of polyethylene, short fragmentations of the polymer are produced and enter the food [2]. Some food packaging materials produce volatile compounds under certain conditions. Volatile compounds are formed in polyethylene, polyester terephthalate, and oriented polypropylene after irradiation dose from 5 to 50 kGy. Twenty-two compounds were identified for polyester terephthalate; 40 for oriented polypropylene; and only acetone was identified for polyethylene, which can be good candidate for irradiation of packaged food products. Hydrocarbons, ketones, and aromatic compounds are able to migrate into a packed food product and affect its quality [124]. The kinetics of degradation showed that some compounds remain trapped in the polymer and can be used as irradiation detectors. Irradiated foods should be properly handled and stored after treatment to avoid deterioration, spoilage, and loss of nutritive value. Thus, handling, storage conditions, and packaging are also important postirradiation considerations [2].

47.4.2 Legal Aspects and Safety Issues

A joint FAO/IAEA/WHO Expert Committee on Food Irradiation (IJECFI) concluded that irradiation of food up

TABLE 47.9
Packaging Materials Approved by FDA for Use during Irradiation of Food Packaged Materials

to an overall average dose of 10 kGy causes no toxicological hazards and introduces no special nutritional or microbiological problems [127]. Later, other organizations, such as Health Canada, FDA, Codex Alimentarius Commission, and the European Commission's Scientific Committee on Food also supported this limit [128]. In 1993, the American Medical Association's Council on Scientific Affairs endorsed food irradiation as a safe and effective tool to increase food safety and reduce the incidence of foodborne illness, a view expressed earlier by the U.S. Department of Agriculture [3].

Irradiation of food and agricultural products is currently allowed by about 40 countries and approximately 60 commercial irradiation facilities are operating in the United States [75]. The most common irradiated food products for commercial use are spices and dry vegetable seasonings [3]. Loaharanu and Murrell [3] mentioned that the recent ban by the European Union on the use of ethylene oxide for food could increase the quantity of spices and vegetable seasonings processed by irradiation in the near future. The fumigant ethylene oxide is reported to be carcinogenic and methyl bromide could be harmful to the ozone layer [129].

The safety issues of irradiated foods can be grouped as [9] (i) residual radioactivity, (ii) free radicals and radiolytic products, (iii) carcinogenic and mutagenic properties, (iv) nutrient quality, (v) polyploidy, (vi) toxicity, (vii) microbiological safety, and (viii) operator safety during processing. A complete review of the above aspects of safety is provided by Smith and Pillai [128]. The safety for human consumption of irradiated products has been frequently questioned [13]. The vast majority of toxicological studies and feeding trials have showed no evidence of toxic effects. However, some studies claimed to find evidence of polyploidy in irradiated wheat fed to children [5]. There is already a wide experience in the design, building, and operation of irradiation plants. Therefore, the plants must be controlled and inspected by authorities in order to ensure the national and international radiological safety standards, for example, the health and safety of workers, and environmental pollution from radioisotopes [130].

Relatively small doses of irradiation can reduce the number of pathogenic organisms to very low levels. This may cause a rise in the growth of secondary microflora, such as *Moraxella*, lactic acid bacteria, and yeasts. Thus, Mitchell [4] expressed concerns about in the absence of competing spoilage microorganisms postirradiation, toxin production by surviving pathogens may occur more quickly making the food unsafe to eat before it is visibly spoiled [131]. Irradiation is not an excuse for poor hygiene and is not to be used for reducing unacceptably high levels of microbial contamination [5]. Smith and Pillai [128] identified two major concerns expressed by anti-irradiation groups: misuse to avoid plant sanitation and environmental concerns. The volume of irradiated foods is increasing and the future of irradiated foods is as bright as ever [132].

47.4.3 Consumer Attitudes

The application and cost-effectiveness of irradiation as a method to control foodborne pathogens will depend on consumer attitudes, regulatory actions, economics, and logistics associated with different situations. Moy [9] mentioned four reasons for the slow commercialization of food irradiation: antinuclear activists, the industry's hesitation, time-consuming approval process, and insufficient consumer education. Griffith [133] mentioned that the major factors that will determine the future of food irradiation are the development of a simple and reliable detection method, the harmonization of legislation, the commitment of the food industry, and consumer attitudes. Similar to genetic engineering techniques in food production, it is essential that consumer education and consultation with consumers are an integral part of future developments. Loaharanu [14] reviewed the results of consumer attitude surveys in different countries. He concluded that in advanced countries, consumers at large are still not knowledgeable about food irradiation. They need accurate information about safety, benefits, and limitations of food irradiation.

Hashim et al. [134] also reviewed consumer attitudes toward irradiated poultry and recommended ways to increase the acceptance of irradiated foods: (i) educational programs to increase consumer understanding about irradiation;, (ii) propagate information about safety of irradiation through labels and/or posters; (iii) television shows, children interactions, and/or pamphlets or brochures; and (iv) in-store sampling of cooked irradiated poultry. Recently, the importance of consumer education is also identified [135–137]. Pohlman et al. [138] also showed that audiovisual presentation affects consumers' knowledge and attitude toward food irradiation. Kilcast [5] mentioned three methods have been developed that can currently be used for detection purposes. These are electron spin resonance, thermoluminescence, and detection of lipid breakdown volatiles. However, all these methods require specialist expertise.

48 Pulsed Electric Fields in Food Preservation

Humberto Vega-Mercado, M. Marcela Gongora-Nieto, Gustavo V. Barbosa-Canovas, and Barry G. Swanson

CONTENTS

48.1 INTRODUCTION

There are many different forms in which to apply electric energy for food pasteurization. These include ohmic heating [1–3], microwave heating [4–6], low electric field stimulation [7, 8], high-voltage arc discharge [9–12], and high-intensity pulsed electric field (PEF) application [13–15]. Ohmic heating is one of the earliest forms of electricity applied to food pasteurization [1]. This method relies on the heat generated in food products when an electric current is passed through them. Getchell [2] described the ohmic heating method in milk pasteurization. A 220 V, 15 kW alternating current supply was applied to milk through carbon electrodes in an electrical heating chamber. The milk was heated to and held at 70°C for about 15 seconds. It has been reported that ohmic heating is suitable for viscous products and foods containing particles, and this method is considered to be a promising technique for the aseptic processing of foods [3].

Microwave heating has been extensively applied in everyday households and the food industry [4]. Many food materials possess very low values of static conductivity. However, when they are subjected to microwave fields, they exhibit very high values of alternating field conductivity and consume considerable energy [5]. The heat generated by microwaves is used for heating processes. Studies on microbial inactivation using microwave energy have concluded that microbial death is caused solely by thermal mechanisms [6].

Low electric field stimulation has been explored as a method of bacterial control of meat. In electrical stimulation of meat, an electric field of 5–10 V/cm is applied as alternate current (ac) pulses to the sample through electrodes fixed at opposite ends of the long axis of the muscle [7]. Recently, a very low field (0.4 V/cm) was applied in a 6 liter treatment medium in search of an easy, safe, and practical method to eliminate bacteria for food-processing purposes. Several species of bacteria in saline solution were inactivated [8]. Salt solutions and their concentrations play a very important role in this method.

Inactivation of microorganisms and enzymes contained in food products by electric discharge began in the 1920s with the Electropure process for milk [16], which consisted of passing an electric current through carbon electrodes and heating milk to 70°C to inactivate *Mycobacterium tuberculosis* and

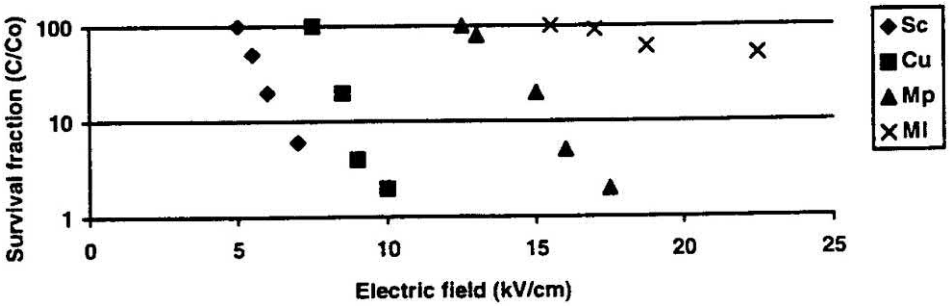

FIGURE 48.1 Relationship between survival fraction and electric field strength (1020 μs pulses) (Sc: *Saccharomyces cerevisiae*; Cu: *Candida utilis*; Mp: Motile pseudomonad; MI: *Micrococcus lysodeikticus*). (Adapted from Hamilton and Sale [27].)

Escherichia coli. Beattie and Lewis [17] demonstrated the lethal effect of electrical discharges on microorganisms when the applied voltage used to treat food was increased 3000–4000 volts. The electrohydraulic treatment was introduced in the 1950s to inactivate microorganisms suspended in liquid foods. The inactivation of microorganisms was attributed to a shock wave generated by an electric arc that prompted the formation of highly reactive free radicals from chemical species in food [14]. Gilliland and Speck [18] applied pulsed electric discharges at different energy levels for the inactivation of *E. coli*, *Streptococcus faecaiis*, *Bacillus subtilis*, *Streptococcus cremoris*, and *Micrococcus radiodurans* suspended in sterile distilled water as well as for trypsin and a protease from *B. subtilis.*

Sale and Hamilton [19] demonstrated the nonthermal lethal effect of homogeneous electric fields on bacteria such as *E. coli*, *Staphylococcus aureus, Micrococcus iysodeikticus*, *Sarcina lutea*, *B. subtilis*, *Bacillus cereus*, *Bacillus megaterium*, and *Clostridium welchii*, and yeasts such as *Saccharomyces cerevisiae* and *Candida utilis.* In general, an increase in the electric field intensity and number of pulses was found to lead to an increase in the inactivation of microorganisms (Figure 48.1 and Table 48.1). Other factors that influence microbial inactivation by pulsed electric fields are the treatment temperature, pH, ionic strength, and conductivity of the medium containing the microorganisms [9, 20–26].

The formation of pores on cell membranes by high-intensity pulsed electric fields (HIPEFs) is not entirely understood.

TABLE 48.1
Activity of *Staphylococcus aureus* after Pulsed Electric Field Treatment

Electric Field (kV/cm)	Survivors (%)	Protoplasts Not Lysed
0.00	100	100
9.25	100	100
14.25	35	43
19.50	0.9	16
24.00	0.3	3
27.50	0.6	2

Zimmermann et al. [28], applying the dielectric rupture theory, concluded that membrane rupture is caused by an induced transmembrane potential approximately 1 V larger than the natural potential of the cell membrane. The reversible or irreversible rupture (or electroporation) of a cell membrane depends on factors such as intensity of the electric field, number of pulses, and duration of the pulses [29–32]. The plasma membranes of cells become permeable to small molecules after being exposed to an electric field; permeation then causes swelling and the eventual rupture of the cell membrane (Figure 48.2).

In September 1996, the U.S. Food and Drug Administration (FDA), based in Washington, D.C., released a "letter of no objection" for the use of pulsed electric fields to treat liquid eggs. To meet FDA requirements [33] in filing a new and a novel process, it is necessary to (i) establish an active and continuous dialog with the FDA during process development, (ii) meet with the FDA to describe the process, (iii) invite the FDA to a site visit (pilot and production facility), and (iv) draft and provide the FDA with an outline of the proposed filing.

The objective of the FDA is to conduct a scientific evaluation of the process to determine if the aseptically produced product poses a potential public health hazard and if all of the critical factors necessary to render the product commercially sterile are monitored and controlled. The filing information of the new process must contain

1. Equipment design: a description of the system, control mechanisms used and fail safe procedures
2. Product specifications: a full description of the product, including physical/chemical aspects, critical factors, and influence of processing on the critical factors
3. Process design: a complete description of the critical/processing conditions used in the manufacture of the product
4. Validation: a physical demonstration of the accuracy, reliability, and safety of the process

In the area of pulsed electric fields, there are many possible project-development designs related to (i) unknown destruction kinetics of microbial pathogens (e.g., *Clostridium botulinum*), (ii) identification of proper indicator organisms, (iii)

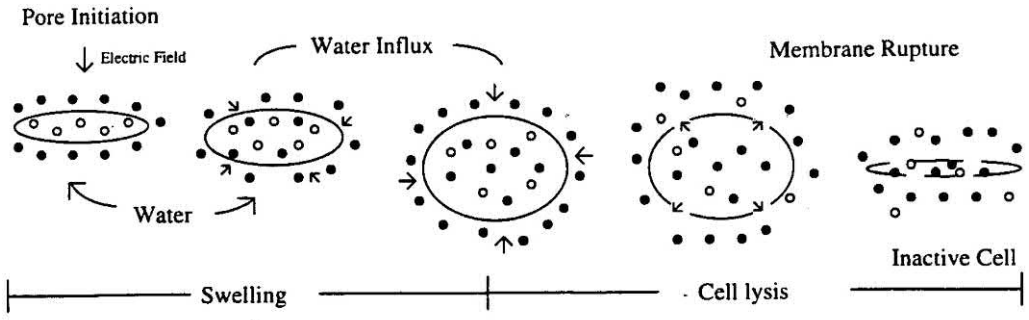

FIGURE 48.2 Mechanism of cell inactivation. (Adapted from Tsong [31].)

uniformly delivered treatment, (iv) impact of processing conditions (e.g., temperature, pH, moisture, and lipid content), (v) identification/monitoring of critical factors (e.g., surface, intensity), and (f) food additives.

48.2 ENGINEERING ASPECTS OF PULSED ELECTRIC FIELDS

The concept of pulsed power is simple: electric energy at low power levels is collected over an extended period and stored in a capacitor. That same energy can then be discharged almost instantaneously at very high levels of power. The generation of pulsed electric fields requires two major devices: a pulsed power supply and a treatment chamber, which converts the pulsed voltage into pulsed electric fields.

48.2.1 Bench-Top Unit

A commercial electroporator (i.e., GeneZapper, IBI-Kodak Company, Rochester, New York) may be used as a bench-top pulsed power supply. This unit provides a maximum of 2.5 kV pulses. The instrument consists of a capacitor (7 μF), charge and discharge switches, and a wave controller. The wave controller may be connected to the electroporator to improve the discharge pattern. Treatment cuvettes with a 0.1 cm electrode gap and l00 μl volume may be used for PEF treatments, which give a maximum intensity of approximately 25 kV/cm. Appropriate voltage and current monitors should be attached to the GeneZapper to measure the pulsed electric field treatments. Figure 48.3 illustrates the major components of the GeneZapper. This bench-top unit provides a convenient method for determining the inactivation kinetics for selected microorganisms.

48.2.2 Lab Scale Pulser

Exponential decay electric pulses can be generated by discharging a capacitor into a chamber containing the food (Figures 48.4–48.6). Current designs for power supplies are able to provide up to 40 kV. Capacitors of 5 μF are used to store the electric energy that is discharged across metal electrodes, creating the electric field used to inactivate microorganisms and enzymes. A mercury ignitron spark gap may be used as the discharge switch. This type of unit may be employed for inactivation studies in a continuous mode. Pulsed voltage across the treatment chamber may be monitored by a resistance voltage divider. Electric current may be monitored by a Rogowski coil connected to a passive integrator. Both voltage and current waveforms may be monitored using a digital oscilloscope.

48.2.3 Treatment Chambers

A static PEF treatment chamber consists of two electrodes held in position by insulating materials that also form an enclosure containing food materials. Uniform electric fields can be achieved by parallel plate electrodes with a gap sufficiently smaller than the electrode surface dimension. Disk-shaped, round-edged electrodes can minimize electric field enhancement and reduce the possibility of dielectric breakdown of

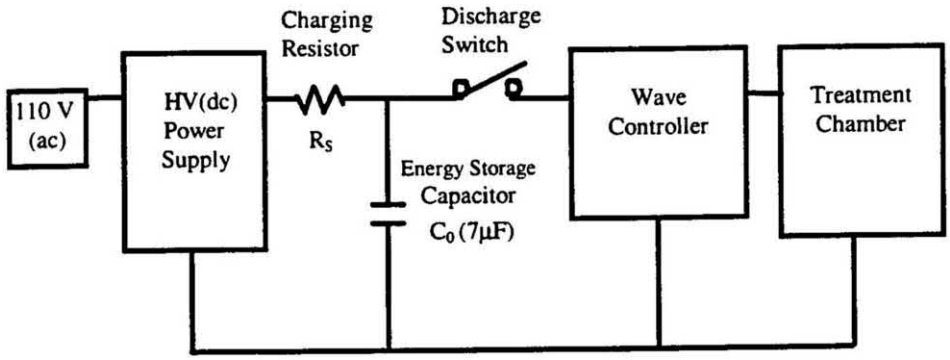

FIGURE 48.3 Major components of commercial electroporator GeneZapper.

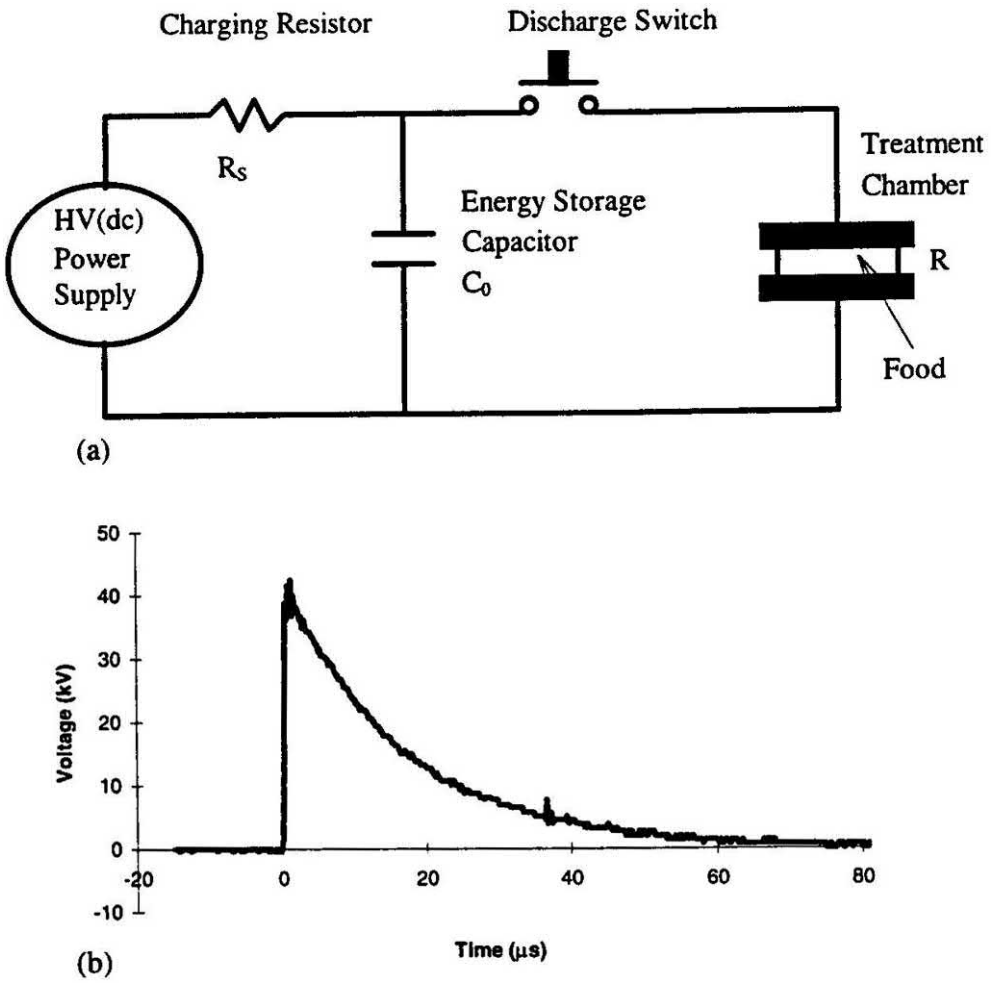

FIGURE 48.4 (a) A simplified circuit for producing exponential decay pulses and (b) a voltage trace across the treatment chamber.

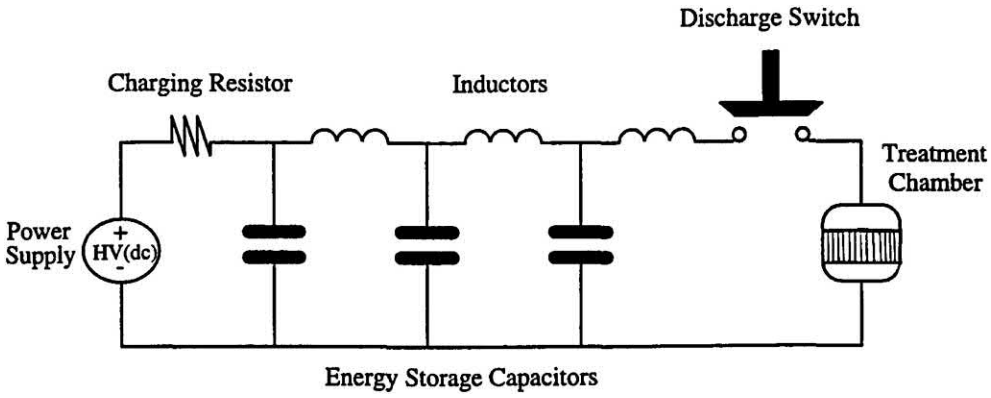

FIGURE 48.5 Typical pulser configuration for high-intensity pulser electric fields.

fluid foods. A continuous flow-through treatment chamber (Figure 48.7) was developed at Washington State University (WSU) to test the flow-through concept using low flow rates. The chamber consisted of two electrodes, a spacer, and two lids. Each electrode was made of stainless steel, whereas the spacer and lids were made of polysulfone. A flow channel was provided between the two electrodes to eliminate dead corners as well as to ensure uniform treatment.

The operating conditions for the parallel plate continuous chamber were as follows: chamber volume, 20 or 8 cm^3 electrode gap 0.95 or 0.51 cm; PEF, intensity 35 or 70 kV/cm; pulse width, 2–15 μs; pulse rate, 1 Hz; and food flow rate, 1200 or 600 cm^3/min. Cooling of the chamber was accomplished by circulating water at a selected temperature through jackets built into the two stainless steel electrodes. It should also be pointed out that a completely sealed treatment chamber

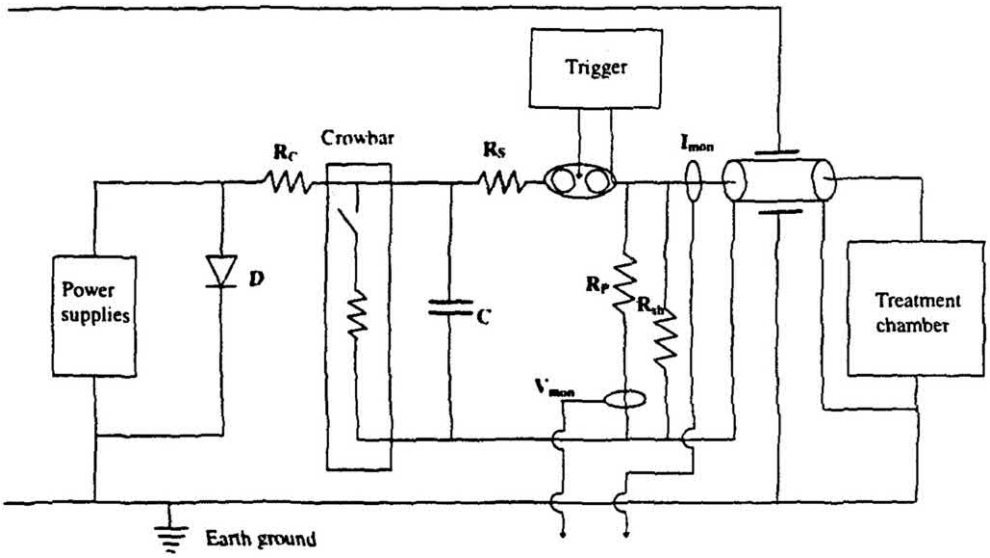

FIGURE 48.6 Current setup of the PEF facility at Washington State University. The pulser has a 16 kJ/s charging power supply, 40 kV peak charging voltage, and 10 Hz pulse repetition rate. C: storage capacitor; D: power supply protection diode; R_c: charging resistor; R_s: series resistor; R_{sh}: shunt resistor; R_p: voltage-measuring resistor; I_{mon}: current monitor; V_{mon}: voltage monitor.

is dangerous. When the test fluid experiences a spark, high pressure develops rapidly and the chamber may break apart. A pressure-released device must be included in the treatment chamber design to ensure the safety of the operation.

A coaxial treatment chamber (Figure 48.8) with a uniform field distribution along the fluid path was designed at WSU. The fluid is fed into the chamber through the bottom region and the treated product exits at the top of the chamber. The protruded surface, located at the outer grounded electrode, enhances and makes uniform the electric field within the treatment region while it reduces the field intensity in other regions of the fluid path. Cooling fluid is circulated to control the temperature between the inner high-voltage electrode and the outer grounded electrode. The gap in the coaxial electrode or the liquid food thickness along the direction of the electric field can be selected by changing the diameter of the inner electrode.

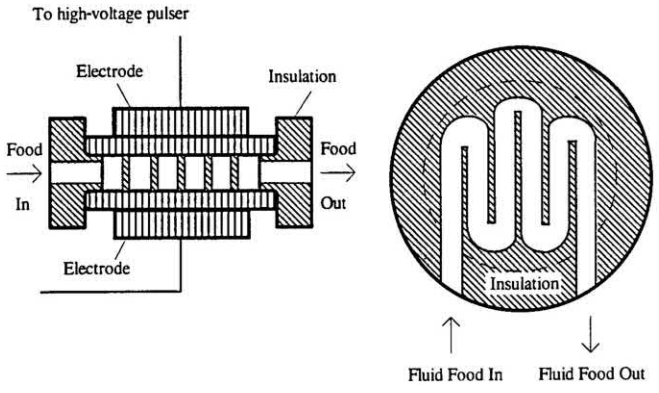

FIGURE 48.7 Schematic drawing of a flow-through treatment chamber. Fluid inside the chamber is baffled to avoid dead spots.

48.2.4 Pulsed Electric Field Process Design

48.2.4.1 HACCP Principles and PEF Technology

The PEF process is summarized in Figure 48.9. The key operations are the receiving of raw materials, PEF treatment, aseptic packaging operation, and finished product storage and distribution. The following analysis [34] is based upon the seven principles of hazard analysis and critical control points (HACCP).

48.2.4.1.1 Hazard Assessment

Microbial hazards are the main concern throughout the PEF operation. Raw materials contain spoilage microbes and

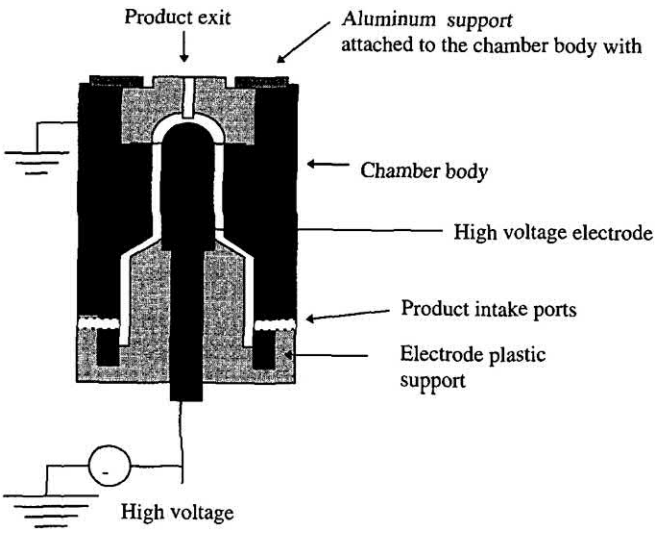

FIGURE 48.8 Schematic of the REF continuous treatment chamber.

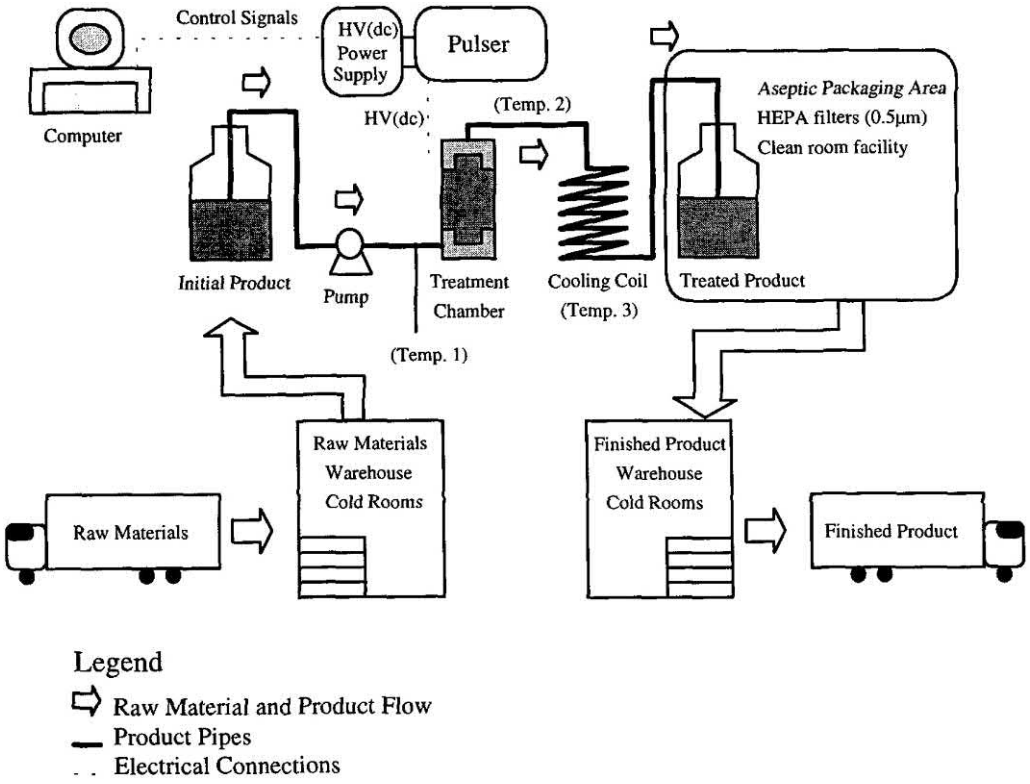

FIGURE 48.9 Pulsed electric field unit operations layout.

pathogens that may spoil the ingredient or raw material, or may be harmful to the consumer. Storage facilities for raw materials may increase the risk of microbial contamination from soil and water deposits. The cleanliness of processing equipment plays a key role in preventing microbial contamination, thus the multiple assembly parts must always be properly sanitized. Inappropriate aseptic packaging operations and storage conditions may result in spoilage of the product.

Chemical hazards to consider are the presence of antibiotic and pesticide residuals on raw materials, electrically induced chemical reactions, and excessive detergent/sanitizer residues from processing and packaging equipment. Physical hazards include foreign matter in raw materials (e.g., stones, rubber, plastic, metal, and eggshells), metal particles from the treatment chamber after a spark, and plastic or rubber pieces from seals.

The final risk classification may be defined in terms of the product (milk, apple juice, eggs, soups, etc.). Six microbiological hazard characteristics, as well as chemical and physical hazard characteristics, are defined by the National Advisory Committee on the Microbiological Criteria for Foods (NACMCF) and will be used to classify PEF products. In general, the final hazard classification should occur between risk categories IV and VI as defined by the NACMCF.

48.2.4.1.2 Critical Control Points: Determination, Limits, Procedures, and Corrective Actions

The following critical control points (CCPs) should be selected to ensure the safety of PEF products: receiving and storage section, PEF treatment section, and aseptic packaging section. The main factors considered and monitored for each CCP are handling and processing time, temperature of material, and cleanliness of equipment and utensils. The treatment conditions (electric field intensity, pulsing rate, input voltage, input current, and chamber temperature) should be monitored and recorded on a continuous basis. Uniform PEF treatment requires the design and construction of a pulser that accomplishes variable pulsing rates, charging rates, voltage settings, pulse widths, and pulse shapes. Pulser components such as power source, computerized controls, triggering mechanism, overloads, dummy loads, and treatment chamber should comply with defined specifications and characteristics such as maximum operating temperature, maximum voltage and current outputs, and reliability (mean time between failures, yields, etc.). The reliability of the pulser may be measured in terms of number of pulses with correct energy level per unit of time as well as total pulses per unit of time. Monitoring devices may include oscilloscopes for voltage and current measures, and pulse counters.

Standard operating procedures (SOPs) should be in place to define aspects such as reception, storage, and preparation of raw materials to ensure proper handling and to reduce the risk of contamination. The pulsing and packaging units must have procedures to specify the assembly and disassembly of the machinery. Cleaning specifications such as frequency and type of detergents and sanitizers to use should be established to prevent contamination between products. The operational parameters for PEF treatments must be specified for each food product based upon its microbial risk, initial microbial counts,

physical and chemical characteristics (e.g., pH, ionic strength, composition), and the maximum time to complete the processing of each food (i.e., time from initial discharge of raw materials to the end of the packaging operation). Alternative procedures must define the corrective actions associated with deviations from process specifications or CCP limits. Quality assurance procedures must be developed for the approval or rejection of PEF-treated products based on the CCP limits and corrective actions.

48.2.4.1.3 Record Keeping

Record keeping is a key aspect not only in a PEF operation but in any successful manufacturing operation. The status of raw materials, process and packaging sequence, and storage and shipping procedures must be reflected in the batch or lot documents. Proper design of the documents is an important and difficult task because the documents must provide enough space for critical measurements without confusing the operator.

48.2.4.2 Hazard and Operability Study (HAZOP) Principles and PEF Technology

The main concern of individuals working in a PEF facility is the voltage intensity, which reaches the kilovolt range. A typical pulser configuration is presented in Figure 48.10. A high-voltage power supply is selected to charge the capacitor (eventually more than one) and a discharge switch releases the stored electric energy from the capacitor through the product in the form of an electric field. The power supply, capacitor, and treatment chamber must be confined in a restricted access area with interlocked gates. The gates will turn off the pulser if they are opened while the power supply is on. Emergency switches must be accessible in case of a process failure. Also, discharging bars must be provided to discharge the elements in the circuit before maintenance or inspection of the unit occurs. To prevent the leakage of high voltage through any fluid (food or refrigerant) in contact with the treatment chamber, all connections to the chamber will be isolated and the pipes carrying materials to or from the chamber connected to the ground.

Electrical and mechanical devices such as pumps, computers, and packaging machines must be protected using safeguards. Proper warning signs must be in place regarding the safety hazards (high voltage, high-intensity electric field) in the processing area. The information related to the operation and maintenance procedures must be contained in standard operating procedures (SOPs). The personnel involved in the PEF operation must be trained and instructed in these SOPs.

The selection of appropriate detergents and sanitizers must comply with the FDA and U.S. Department of Agriculture (USDA), Food Safety and Inspection Service (FSIS) regulations, or regulations of equivalent organizations in other countries. Proper protection devices such as face masks or goggles, aprons, boots, and gloves must be used by employees while applying and removing the cleaning solutions. A complete procedure must be in place to define what kind, when, where, and how to use the cleaning and sanitizing solutions. Proper record keeping is required to avoid contamination of the products with detergent or sanitizer solutions. A complete layout of the facility including details about location of utilities, location of equipment, and emergency exits must be available. Changes in the configuration of the facility must be reflected in the layout.

48.2.5 Currently Used PEF Technology

PurePulse Technologies Co., a subsidiary of Maxwell Laboratories in San Diego, California, owns three U.S. patents to preserve fluid foods such as dairy products, fruit juices, and fluid eggs by treatment with high-intensity electric

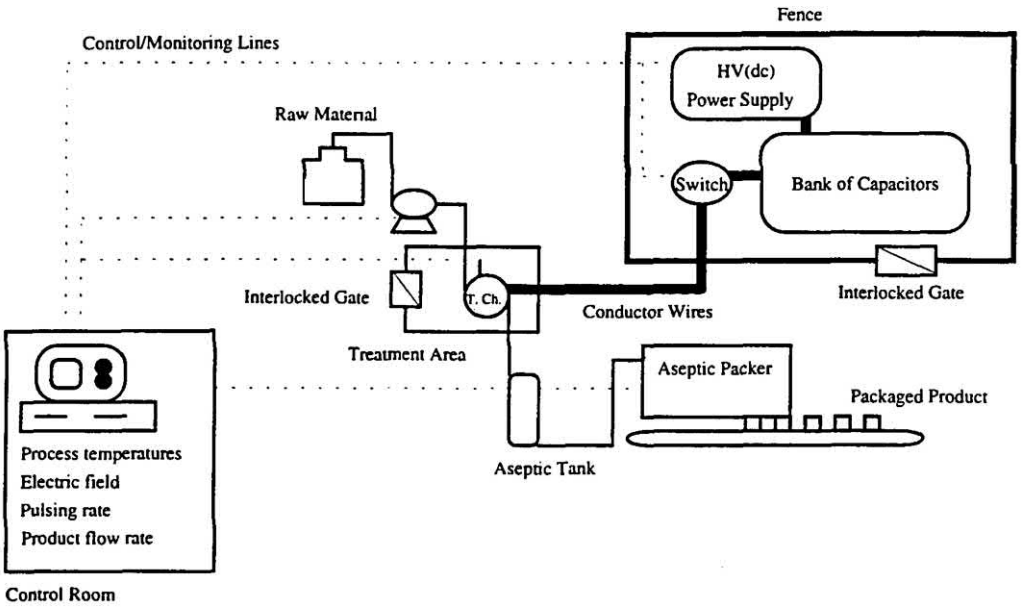

FIGURE 48.10 Schematic diagram of a PEF equipment configuration.

discharges from about 5 to 100 kV/cm with flat-topped exponentially decaying pulse shapes. Pulse duration is controlled to prevent electrical breakdown of the food product; the typical duration is between 1 and 100 μs with repetition rates between 0.1 and 100 Hz [11, 35]. The patents describe both a batch and continuous processing system and recommend that HIPEF treatments be applied to preheated liquid foods, which enhance microbial inactivation and shelf-life stability.

Dunn and Pearlman [11] reported more than five logarithmic cycles of microbial count reduction (5D reduction) of naturally occurring microorganisms in orange juice after 35 pulses of 100 μs at a voltage intensity of 33.6–35.7 kV/cm and a process temperature of 42–65°C. The shelf life of orange juice was increased from 3 days to one week with no significant change in odor or taste. A 3D reduction of *E. coli* (ATCC-10536) inoculated in homogenized and pasteurized milk exposed to 23 pulses of 100 μs at 28.6–42.8 kV/cm was also reported. When a similar test run was carried out using milk seeded with *Salmonella dublin* prior to treatment with 36.7 kV/cm and 40 pulses of 100 μs at 63°C, no *Salmonella* and only 20 cfu/ml of milk bacteria was found. These results may suggest that deactivation from the PEF treatment process is selective and that *S. dublin* are preferentially deactivated over the milk bacteria. Yogurt inoculated with *Streptococcus thermophilus*, *Lactobacillus bulgaris*, and *Saccharomyces cerevisiae* was treated with 20–100 μs pulses at 23–38 kV/cm at a process temperature of 63°C, resulting in a 2D reduction of the lactic acid bacteria and *S. cerevisiae* [11].

The *ELSTERIL* process, developed by Krupp Maschinentechnik GmbH (Hamburg, Germany) in the late 1980s and early 1990s, is used for the sterilization and pasteurization of liquid and electrically conductive media [13, 36, 37]. Krupp Maschinentechnik GmbH, in association with the University of Hamburg, reported microbial inactivation when PEF was applied to fluid foods such as orange juice and milk [37]. A microbial inactivation exceeding 4D has been found for *Lactobacillus brevis* inoculated in milk and treated with 20 pulses of 20 ps at 20 kV/cm, *S. cerevisiae* inoculated in orange juice and treated with 5 pulses of 20 μs at 4.7 kV/cm, and *E. coli* inoculated in sodium alginate and treated with 5 pulses of 20 μs at 14 kV/cm [36, 37]. However, no inactivation of the endospores of *B. cereus* or the ascospores of *Bacillus nivea* was reported [37]. A substantial reduction in ascorbic acid and lipase activity was observed in milk treated with the ESTERIL process [37]. The taste of milk and orange juice did not significantly change after the electric field treatments [37].

The disruption of cell membranes to release fat from animal cells was conducted using a process called *ELCRACK* (Krupp Maschinentechnik GmbH, Hamburg, Germany). The ELCRACK process consists of the exposure of a slurry of comminuted fish or slaughterhouse offal to high-intensity electric pulses that break down cells, leading to increased fat recovery during the separation step after it is pumped through one or more treatment chambers [36]. Washington State University has a patent for the design and development of a static PEF chamber and has filed another for the design and development of a continuous PEF chamber intended for processing liquid foods with PEF treatments [38–41].

48.3 APPLICATIONS OF PEF IN FOOD PROCESSING

The application of PEF as a food-processing tool is gaining popularity since it represents a nonthermal alternative to conventional pasteurization and sterilization methods. The PEF approach, which does not involve the use of added preservatives, is expected to be more appealing to consumers who are skeptical about the use of chemicals in foods. Furthermore, the PEF treatment, being a nonthermal process, may also have no significant detrimental effect on heat-labile components present in foods such as vitamins. The major disadvantage of PEF operation is the initial investment. A pilot plant-size pulser may cost around $250,000. Other units for industrial use are available at prices that range from $450,000 to $2,000,000.

48.3.1 Inactivation of Microorganisms

Raw and reconstituted apple juice, peach juice, skim milk, beaten eggs, and pea soup exposed to PEFs of 25–45 kV/cm were treated using the chamber designed at Washington State University. *E. coli* inoculated in skim milk and exposed to 60 pulses of 2 μs width at 45 kV/cm and 35°C was reduced by 2D [25]. A reduction of 6D was observed in liquid egg inoculated with *E. coli* and treated with an electric field of 25.8 kV/cm and 100 pulses of 4 μs at 37°C [42]. *E. coli* and *B. subtilis* inoculated in pea soup and exposed to PEFs of 25–33 kV/cm (10–30 pulses of 2 μs) provided a limited inactivation (<1.5D) when the process temperature of pea soup was below 53°C, while microbial inactivation was 4.4D with process temperatures between 53°C and 55°C [26].

48.3.1.1 Simulated Milk Ultrafiltrate (SMUF)

The inactivation of *E. coli* varied as a function of the electric field intensity, number of pulses, and pH. Low field intensity (20 kV/cm) resulted in insignificant inactivation of microorganisms independent of temperature and pH ($p > 0.05$). Meanwhile, inactivation of *E. coli* increased with an increase in the number of pulses and an increase in the electric field from 40 to 55 kV/cm. The inactivation was more significant at pH 5.69 than at pH 6.82 ($p < 0.05$) (Figures 48.11A and 48.11B). The temperature effect (10°C or 15°C) on the inactivation for these experiments was not statistically significant ($p > 0.05$). Table 48.2 summarizes the inactivation results after eight pulses for each of the experimental conditions.

The role of pH in the survival of microorganisms is related to the ability of the organisms to maintain the cytoplasm pH near neutrality [43]. Membrane permeability increases due to the formation of pores in the cell wall during PEF treatment [31] and the rate of transport of hydrogen ions may also increase due to the osmotic imbalance around the cell. Thus, a reduction in cytoplasm pH may be observed because a higher number of hydrogen ions are available than at a neutral pH. The change in pH within the cell may induce chemical

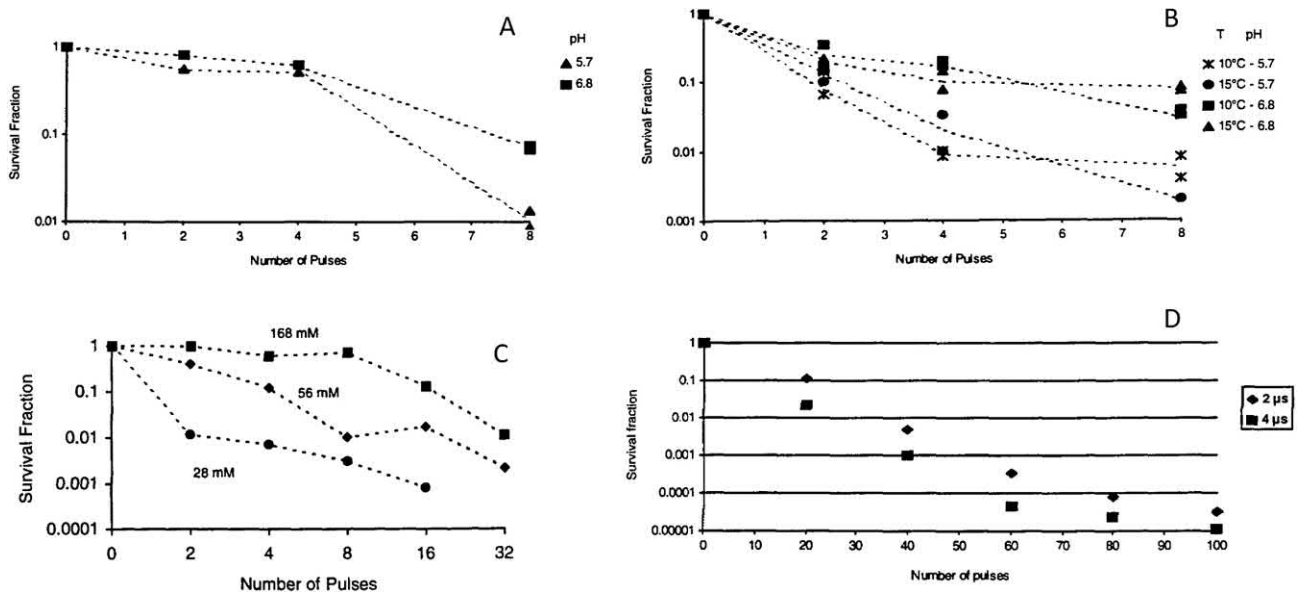

FIGURE 48.11 (A) Inactivation of *E. coli* suspended in SMUF, using 40 kV/cm at 10°C, two samples per each experimental condition. (From Verga-Mercado et al. [26].) (B) Inactivation of *E. coli* suspended in SMUF, using 55 kV/cm, two samples per each experimental condition. (From Verga-Mercado et al. [26].) (C) Effect of ionic strength on the inactivation of *E. coli* suspended in SMUF, at 40 kV/cm and 10°C, two samples per each experimental condition. (From Verga-Mercado et al. [26].) modifications in fundamental compounds such as DNA or ATP, as discussed by Wiggins [44] and Dolowy [45]. Also, oxidation and reduction reactions such as those proposed by Gilliland and Speck [18] may occur within the cell structure induced by the PEF treatment.

The ionic strength of the solution also plays an important role in the inactivation of *E. coli*. An increase in the ionic strength increases the electron mobility through the solution, resulting in a decrease in the inactivation rate. The reduced inactivation rate in high-ionic strength solutions can be explained by the stability of the cell membrane when exposed to a medium with several ions [31]. The effect of ionic strength can be observed in Figure 48.11C, where a difference of 2.5 log cycles was obtained between the 0.168 and 0.028 M solutions.

The growth stage of *E. coli* affected the effectiveness of PEF treatments (36 kV/cm at 7°C, two and four pulses). Cells in the logarithmic phase were most sensitive to the electric field treatments compared to cells in the stationary and lag phase (Figure 48.12) as reported by Pothakamury et al. [46]. Figures 48.13A and 48.13B present the effect of temperature on the log-cycle reduction of *E. coli* using exponentially decaying pulses and square wave pulses of 35 kV/cm. The rate of inactivation increases with an increase in temperature. Coster and Zimmermann [47] suggested synergistic effects of high-intensity electric fields with moderate temperatures. The rate of inactivation increased when square wave pulses were used compared to exponentially decaying pulses. Similar results were reported for *S. aureus* when exposed to PEF at 9 and 16 kV/cm and *L. delbrueckii* and *B. subtilis* when exposed to 9, 12, and 16 kV/cm. Figures 48.13C, 48.13D, and 48.14A present the reported results by Pothakamury et al. for *S. aureus, L. delbrueckii*, and *B. subtilis* suspended in SMUF.

48.3.1.2 Pea Soup

PEF inactivation of *E. coli* and *B. subtilis* suspended in pea soup depends on the electric field intensity, number of pulses, pulsing rate, and flow rate [49] (Table 48.3). The maximum bulk temperature of the peak soup achieved during the PEF treatment was 55°C and is a function of both flow rate and pulsing rate. PEF treatments with a bulk temperature below 53°C resulted in limited microbial inactivation (<1.64D). Microbial inactivation dependence on process temperature may be explained by changes in the sensitivity of the microorganisms to PEF when the temperature exceeds 53°C. Thermal inactivation of microorganisms was avoided by cooling treated pea

TABLE 48.2
Effect of Processing Parameters on the Inactivation of *E. coli* Suspended in SMUF after Eight Pulses

Description	pH	Number of Log-Cycle Reduction	
		10°C	15°C
20 kV/cm	5.7	0.00[a]	0.20[a]

soup to 20°C. Thermal inactivation of *E. coli* requires up to 10 minutes at 61°C when suspended in bouillon [50].

PEF inactivation of B. *subtilis* and *E. coli* decreased almost 2D when the microorganisms were mixed together in pea soup. Figures 48.14B, 48.14C, and 48.14D summarize the inactivation of *E. coli, B. subtilis,* and the mixture of organisms suspended in pea soup and exposed to selected treatment conditions [49]. There is a significant difference in the inactivation levels ($p < 0.05$) between *E. coli* alone and *E. coli* mixed with *B. subtilis.* PEF inactivation of *E. coli* alone reached 6.5D after 30 pulses at 30 kV/cm and flow rate of 0.5 liters/mm, while an inactivation of 4.0D was observed when *E. coli* was mixed with *B. subtilis. B. subtilis* alone had 5.0D when exposed to 33 kV/cm at 4.3 Hz and 0.5 liters/mm, while only 2.0D were observed when mixed with *E. coli* and exposed to 20 pulses at 30 kV/cm, 4.3 Hz and 0.75 liters/mm or 3.5D after 30 pulses. The results for the inactivation of *E. coli* and *B. subtilis* using PEF demonstrate the feasibility of the technology for preservation of foods containing suspended particles and gelatinized starch.

48.3.1.3 Liquid Eggs

High-intensity PEF (26 kV/cm) treatment in continuous flow systems (continuous recirculation and simple pass) inactivates *E. coli* inoculated in liquid egg 6D with a peak processing temperature of 37.2 ± 1.5°C (Table 48.4, Figures 45.15 and 48.16). PEF treatments with 4 μs pulses were more effective than 2 μs pulses (Figure 48.11D and 48.17A), which may be explained by the amount of energy applied to the liquid egg [42]. Figure 48.18 illustrates the effect of energy input in the inactivation of *E. coli,* with energy input (in joules) calculated as follows:

$$\text{Energy/pulse} = 0.5\ C\ V^2$$

where C is the capacitance, 0.5 μF for 2 μs pulses and 1.0 μF for 4 μs pulses; and V is the measured potential across the treatment chamber (15.6 kV). The total energy input (in joules) after n pulses is calculated by

$$\text{Total energy} = n * \text{Energy/pulse}$$

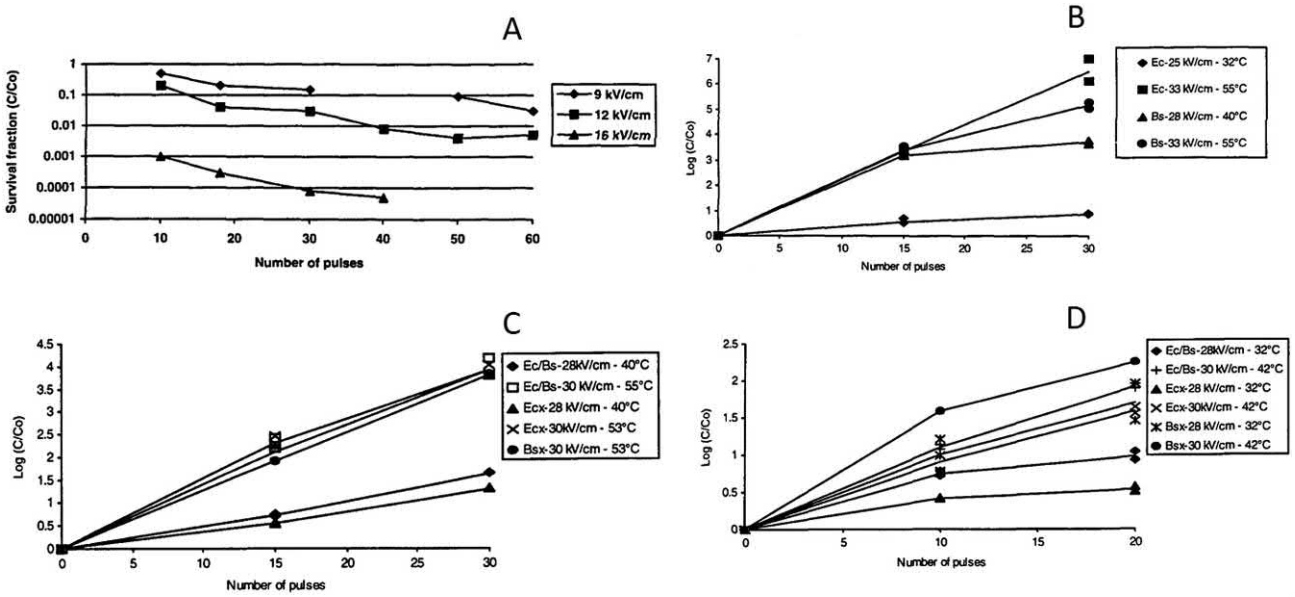

FIGURE 48.14 (A) Inactivation of *B. subtilis* suspended in SMUF. (From Pothakamury et al. [47].) (B) Inactivation of microorganisms suspended in pea soup using PEF at 0.5 liter/min and 4.3 Hz (Ec is *E. coli*; Bs is B. *subtilis*). (From Verga-Mercado et al. [49].) (C) Inactivation of mixture of microorganisms suspended in pea soup using PEF at 0.5 liter/min and 4.3 Hz (Ec is *E. coli*; Bs is B. *subtilis*; Ec/Bs is the overall inactivation for the mixture of microorganisms; Ecx is the inactivation of *E. coli* in the mixtures; Bsx is the inactivation of *B. subtilis* in the mixture). (From Verga-Mercado et al. [49].) (D) Inactivation of mixture of microorganisms suspended in pea soup using PEF at 0.75 liter/min and 4.3 Hz (Ec is *E. coli*; Bs is B. *subtilis*; Ec/Bs is the overall inactivation for the mixture of microorganisms; Ecx is the inactivation of *E. coli* in the mixture; Bsx is the inactivation of *B. subtilis* in the mixture). (From Verga-Mercado et al. [49].)

The survival fraction of *E. coli* in liquid egg is reduced almost 6D with 12,000 J applied in pulses of 4 μs (Figure 48.17A). Grahi et al. [37] nearly reached 5D by exposing *E. coli* suspended in sodium alginate to an electric field of 14 kV/cm with five pulses of 20 μs. Zhang et al. [53] observed a 6D reduction in *E. coli* suspended in potato dextrose agar and exposed to 64 pulses of 40 kV/cm at 15°C and a 9D reduction using 70 kV/cm and *E. coli* suspended in simulated milk ultrafiltrate (SMUF) [54].

Protein, an important nutrient for microbial growth, diminished the effectiveness of the PEF treatment [18, 55]. The inactivation of microorganisms using PEF is more difficult in food materials than in buffer solutions [53]. In general, the bactericidal effect of PEF is inversely proportional to the ionic strength and increases with electric resistivity [5, 26]. The electric resistance of liquid egg (1.9 Q) is low compared to other foods and makes necessary the exposure of liquid egg to a large number (100) of pulses.

Input pulse rate (Hz)	1.25, 2.5	1.25, 2.5
Peak voltage (kV)	15.5	15.5
Peak current (kA)	8.0	8.0
Electric field intensity (kV/cm)	26	26
Pulse energy (J)	60	120
Maximum temperature (°C)	37	37

Source: Martin et al. [42].

There was no significant difference ($p > 0.05$) in the effectiveness of PEF treatment when the pulse rate varied from 1.25 to 2.50 Hz, as the inactivation of E. *coli* in liquid egg was at least 4D if the number of pulses and pulse width remained constant. There was also no significant difference ($p > 0.05$) between the inactivation of *E. coli* using continuous recirculation or stepwise treatments.

48.3.1.4 Apple Juice

Commercial apple juice ultrafiltrated and exposed to different PEF treatments showed no changes in pH, acidity, vitamin C, glucose, fructose, and sucrose content [56] as summarized in Table 48.5. The inactivation of *S. cerevisiae* suspended in apple juice is affected by the intensity of the electric field, treatment time, and number of pulses [51, 57]. Figure 48.19 illustrates the microbial count of S. *cerevisiae* as a function of peak field intensity when two pulses were used and the selected field intensities were 13, 22, 35, and 50 kV/cm. The rate of inactivation increases with an increase in field intensity [51]. Microbial inactivation is a function of the number of pulses, as illustrated in Figure 48.17B. An inactivation of 6D is reported after 10 pulses of 35 kV/cm at 22–34°C. The shelf life of PEF-treated apple juice increases over 3 weeks when stored at either 4°C or 25°C, as illustrated in Figure 48.17C.

48.3.1.5 Skim Milk

48.3.1.5.1 Treatment in a Static Chamber System

PEF treatment inactivates *E. coli* in skim milk at 15°C. The principal parameters influencing the microbial inactivation are the applied electric field intensity and treatment time, which can be expressed by the number of pulses (n) when the width of each pulse is fixed [15]. The *E. coli* survival fraction decreases when milk is treated with an increasing number of pulses at a constant field intensity (Figure 48.17D). The rate of inactivation of *E. coli* increases with an increase in the electric field intensity at a constant number of pulses (Figure 48.20A). Less than one log reduction in *E. coli* population was observed for PEF treatments of 20, 25, and 30 kV/cm and 64 pulses at 15°C. However, PEF treatments at 45 kV/cm, 64 pulses, and 15°C lead to a nearly 3 log cycle reduction [52]. The reported results are consistent with those of Dunn and Pearlman [11], but these authors mentioned that the treatment temperature increased up to 43°C.

Similar *E. coli* inactivation was obtained with 20 kV/cm PEF in saline solution [27]. Hulsheger et al. [21] reduced the population 4 log cycles by applying 20 kV/cm PEF for *E. coli* inoculated in phosphate buffer, and Grahl et al. [37] reached a nearly 5 log cycle reduction by treating *E. coli* suspended in sodium alginate solution with 26 kV/cm PEF. The inactivation

of *E. coli* in potato dextrose agar by applying 64 pulses of 40 kV/cm at 15°C resulted in a 6 log cycle reduction. Notice that PEF inactivation kinetics in semisolid products are different from the PEF inactivation kinetics in fluids because *E. coli* cells are fixed in a gel matrix, which increases uniformity of inactivation [53]. Inactivation of *E. coli* in skim milk by PEF treatment in a static chamber satisfied Hulsheger's model (Table 48.6) because the destruction of this microorganism in skim milk followed a first-order kinetic for both the electric field intensity and number of pulses.

[a] Treatment in a continuous chamber.

Martin et al. [52] reported that the minimum number of pulses (n_{min}) necessary to inactivate the microorganisms in skim milk at 45 kV/cm using a static chamber is 11 and 15 pulses at 35 kV/cm, respectively. The critical electric field (E_c) is 19.9 kV/cm with 64 pulses at 45 kV/cm, which is higher than the value reported by Grahl et al. [37] for *E. coli* suspended in sodium alginate solution (14 kV/cm). Zhang et al. [53] calculated 17.5 kV/cm E_c for *E. coli* in semisolid model foods.

It is more difficult to reduce the survival fraction of microorganisms present in skim milk than in buffer solutions and model foods because the composition of skim milk is complex (i.e., high protein content 33–40 g/liter) [58]. These substances diminish the lethal effect of PEF in microorganisms because they absorb free radicals and ions, which are active in the breakdown of cells [18, 55]. Moreover, the inactivation of bacteria by PEF is a function of solution resistance, which is inversely proportional to ionic strength. Survival fractions decrease when medium resistance increases and ionic strength decreases [26, 59]. The measured resistivity of skim milk is 310 Ω cm and that of buffer solutions is even higher. Since dilution of milk increases the resistivity and decreases protein concentration, the effectiveness of PEF treatment is improved. The inactivation rate of *E. coli* suspended in skim milk:water (1:2.3) and exposed to 40 kV/cm in a static chamber at 15°C is higher than when less diluted skim milk (1:1) is used (Figure 48.20B).

48.3.1.5.2 Treatment in a Continuous System

PEF treatment in a continuous-flow chamber also inactivates *E. coli* inoculated in skim milk. An increase in field intensity or number of pulses produces greater bacterial inactivation (Figures 48.20C and 48.21) and microorganism death follows first-order kinetics with both field intensity and number of pulses (Table 48.7). The E_c when PEF treatment was carried out in a continuous system at 30 kV/cm maximum electric field intensity was between 12.34 and 14.62 kV/cm, and n_{min} ranged from 1.9 to 5.4 pulses. These values were lower than those obtained in the same treated product using the static system.

In general, PEF treatment in continuous systems is more effective in terms of microorganism inactivation than in static systems due to the treatment uniformity being greater. Moreover, in this study even though both chambers are of the parallel plate type, the treatment volume in a static chamber is higher (14.5 ml) than the continuous-flow chamber (8 ml). Therefore, the energy density (defined as energy divided by volume) is higher in continuous systems.

The effectiveness of PEF treatment also depends on pulse duration, which increases the *E. coli* inactivation because the energy applied in each pulse is higher. Applying 25 pulses of 0.7 μs each at 25 kV/cm in a continuous-flow chamber reduces the survival fraction of *E. coli* inoculated in skim milk less than one log cycle, but a treatment in the same chamber with the same number of pulses and field intensity and a 1.8 μs duration pulse reduces the survival fraction by more than 2 log cycles (Figure 48.20D).

48.3.2 Denaturation of Proteins

48.3.2.1 Alkaline Phosphatase

The activity of alkaline phosphatase (ALP) in pasteurized milk products has public health significance since the presence of active ALP indicates inadequate pasteurization or cross-contamination with raw milk [60]. In fresh raw milk, ALP is present in association with the membrane of fat globules; in skim milk, it is in the form of lipoprotein particles.

The inactivation of ALP by PEF is a function of the field intensity, the fat content of the milk, and the concentration of ALP. The activity of ALP decreases with an increase in field intensity [60]. A reduction of 43–59% in ALP activity is reported when the enzyme is suspended in 2% milk and exposed to 70 pulses of 0.40–0.45 ms at 14.8–18.8 kV/cm (Figure 48.22A). Seventy pulses of 0.74 msec of a field strength of 22 kV/cm applied to 2 mg/mi ALP in SMUF reduced the ALP activity by 65% (Figure 48.21B). The activity of ALP dissolved in UHT-pasteurized 2% and 4% milk

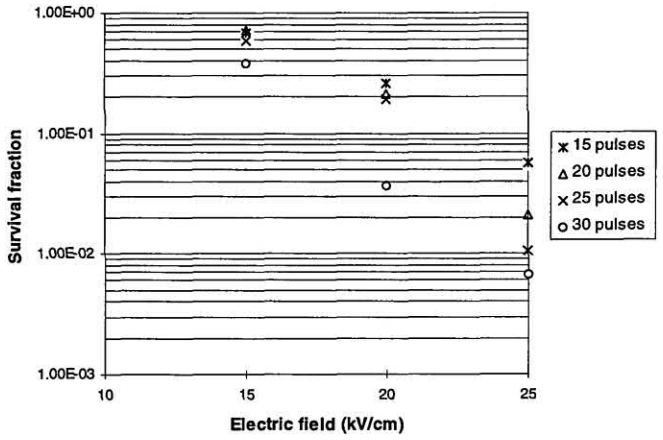

FIGURE 48.21 Inactivation of E. *coli* in skim milk at 15°C in a continuous chamber with different number of 1.8 ms pulses. (From Martin et al. [52].)

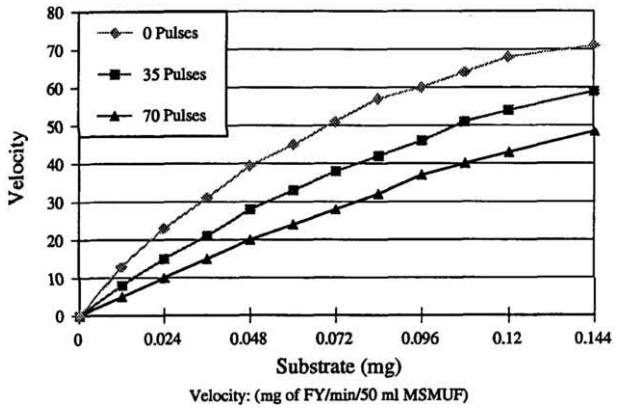

FIGURE 48.23 Initial velocity of fluoroyellow (FY) producing reaction of ALP in MSMUF treated with 0.78 ms pulses of 22.3 kV/cm.

was reduced 59% when exposed to 70 pulses of 0.40 msec at 18.8 kV/cm, while a 65% reduction was observed in nonfat milk as illustrated in Figure 48.22C. ALP suspended in milk (1 ml raw milk in 100 ml 2% milk) using 13.2 kV/cm and 43.9°C after 70 pulses showed a reduction of 96% in activity, whereas heat treatment at 43.9°C for 17.5 min showed only a 30% reduction (Figure 48.22D). Castro [60] demonstrated a reduction in initial velocity of fluoroyellow production of ALP as a function of number of pulses, as illustrated in Figure 48.23. Castro also found that PEF-treated ALP is more susceptible to trypsin proteolysis (70 pulses of 0.78 msec at 22.3 kV/cm), as illustrated in Figure 48.24. The inactivation of ALP is attributed to conformational changes induced by PEF [31, 60].

48.3.2.2 Plasmin and a Protease from *Pseudomonas fluorescens* M3/6

The proteolytic enzyme plasmin and a protease from *Pseudomonas fluorescens* M3/6 were also inactivated using pulsed electric fields. A 90% inactivation of plasmin activity was observed during 30 and 45 kV/cm, 10–50 pulses of 2 μs duration, and a process temperature of 10°C and 15°C [60] as presented in Figures 48.25A and 48.25B. Meanwhile, 80% inactivation was found for a protease extracted from

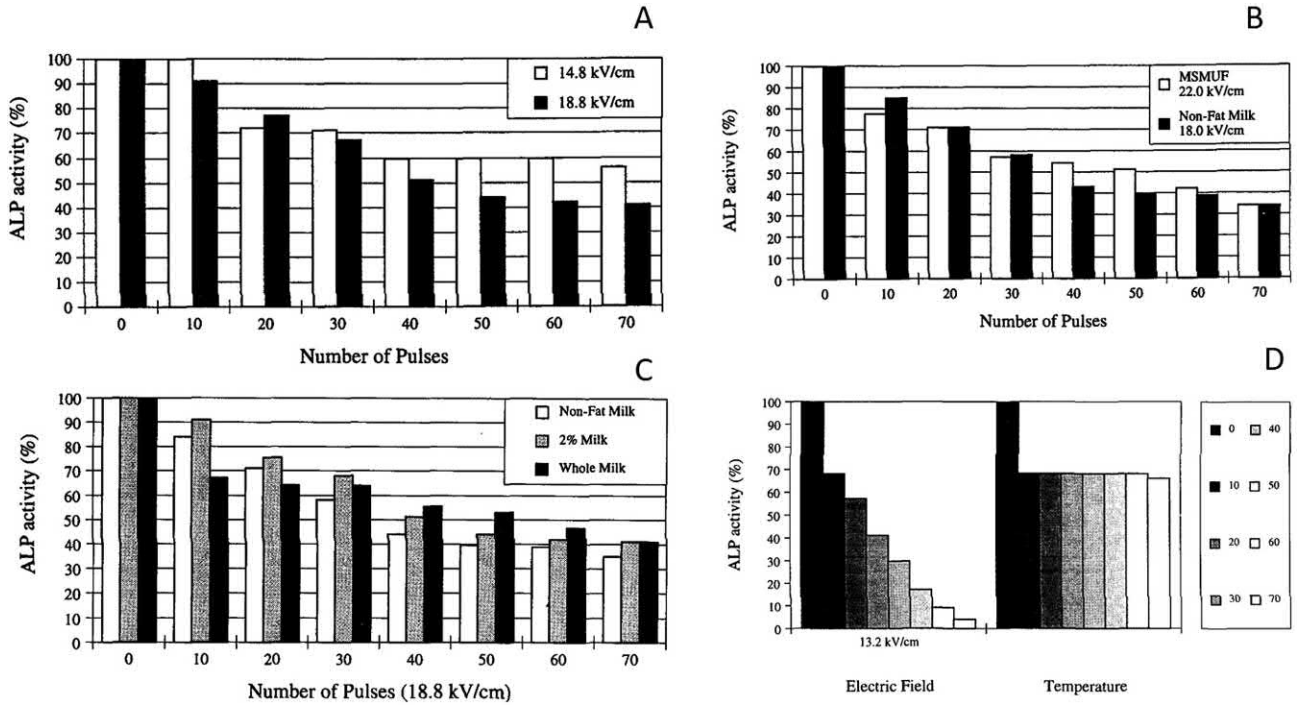

FIGURE 48.22 (A) PEF inactivation of ALP diluted in UHT pasteurized 2% milk. (From Castro [60]) (B) PEF inactivation of ALP diluted in MSMUF or nonfat milk. (From Castro [60].) (C) PEF inactivation of ALP diluted in UHT pasteurized nonfat, 2% and whole milk. (From Castro [60].) (D) Inactivation of alkaline phosphatase by PEF or heating at 44°C for 17.5 minutes. (From Castro [60].)

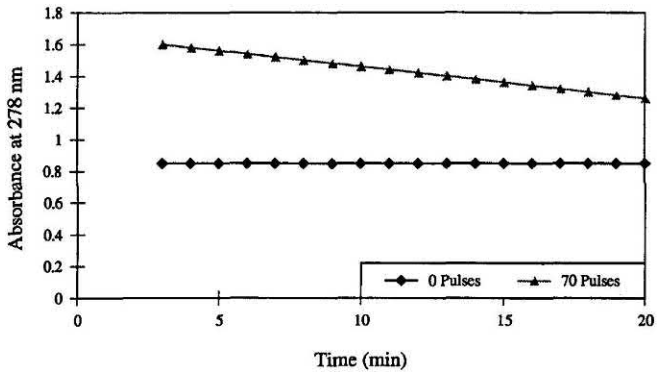

FIGURE 48.24 Trypsin digestion of native and PEF treated alkaline phosphatase. (From Castro [60].)

P. fluorescens when dispersed in Tryptic Soy Broth and exposed to 20 pulses of 2 μs at 11–18 kV/cm and 20–24°C. A 60% inactivation was detected when inoculated in sterilized skim milk and exposed to 98 pulses of 2 μs at 15 kV/cm and 50°C (Figure 48.25C); no inactivation was detected when inoculated in a sterilized casein-Tris buffer and exposed to a PEF treatment similar to that for skim milk. The decreased effectiveness of PEF in the inactivation of the protease in skim milk and the casein-Tris buffer may be attributed to a protective role of the substrate (i.e., casein) against conformational changes of the enzyme induced by the electric fields [61].

The susceptibility of casein to proteolysis varies as a function of treatment conditions [61]; a HIPEF treatment of 25 kV/cm at 0.6 Hz and 30°C was found to increase the proteolytic

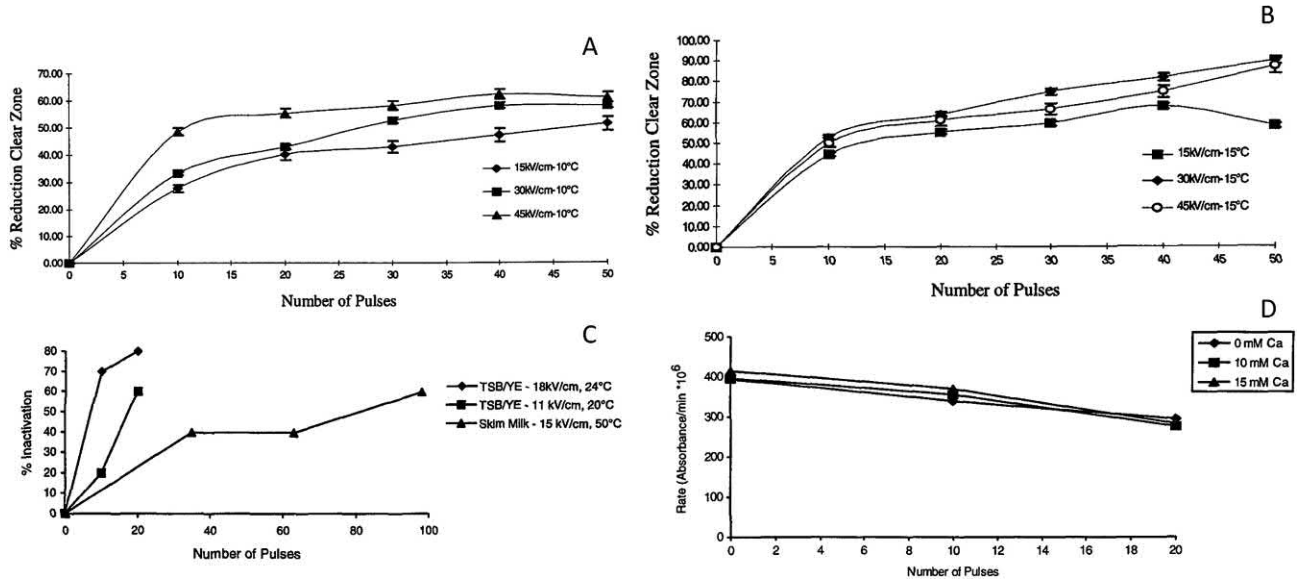

FIGURE 48.25 (A) PEF inactivation of plasmin at 10°C. (From Verga-Mercado et al. [62].) (B) PEF inactivation of plasmin at 15°C. (From Verga-Mercado et al. [62].) (C) Inactivation of a protease from *P. fluorescens* M3/6 in Tryptic Soy Broth enriched with yeast extract (TSB/YE, pulsing rate of 0.25 Hz) and skim milk (pulsing rate 2 Hz) using 2 μs pulses. (From Verga-Mercado et al. [61].) (D) PEF inactivation of protease from *P. fluorescens* M3/6 at 6.2 kV/cm. (From Verga-Mercado [63].)

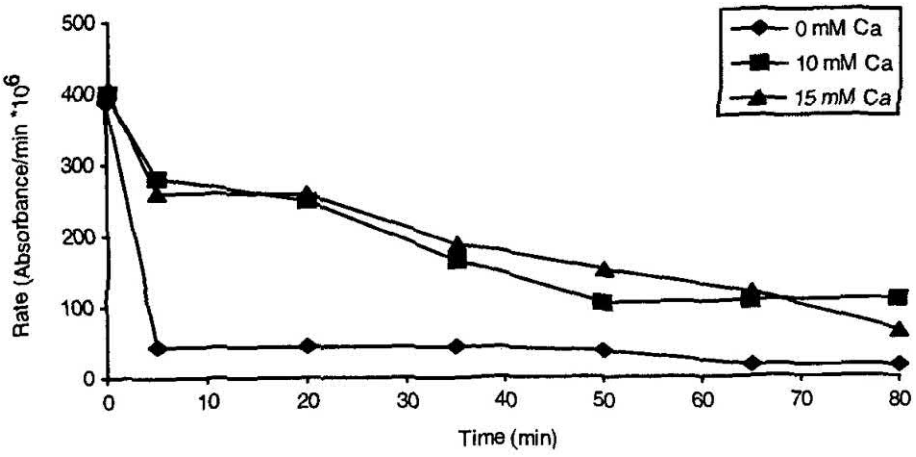

FIGURE 48.26 Thermal inactivation of protease from *P. fluorescens* M3/6. (From Verga-Mercado [63].)

activity in skim milk inoculated with a protease from *P. fluorescens* M3/6. However, 14 or 15 kV/cm at 1 or 2 Hz and 30°C had no significant effect on the susceptibility of casein in skim milk proteolysis, and no significant change was observed in the susceptibility of casein suspended in a casein-Tris buffer when exposed to treatment conditions similar to those for skim milk [61].

The inactivation of the protease from *P. fluorescens* M3/6 when exposed to PEF does not depend on the presence of calcium in the media containing the protease (Figure 48.25D). The inactivation is the same for the three solutions containing 0, 10, or 15 mM calcium. The proteolytic activity of the protease was reduced 30% after exposure to 20 pulses of 700 μs at 6.2 kV/cm and 15–20°C [63].

In contrast to PEF, thermal inactivation of the protease suspended in SMUF does vary with calcium content. Heated samples containing either 10 or 15 mM calcium retained 71% of the original activity compared to 12% retention on samples without calcium after 5 min of heating, followed by a steady decrease in activity as a function of the heating time (Figure 48.26). The analysis by HPLC using the hydrophobic interaction column (HIC) of PEF (20 pulses, 15 mM Ca^{2+}) and heat-treated (5 min, 15 mM Ca^{2+}) samples showed differences in the retention time and peak high of the eluted protein when compared to nontreated samples (Table 48.8). EDTA has a significant inhibitory effect on the proteolytic activity of the protease (Figure 48.27). This result is similar to reported data for the protease from *P. fluorescens*. PEF treatment of samples containing EDTA enhanced the inactivation of the protease in SMUF (Figure 48.28).

48.4 FINAL REMARKS

The research on pulsed electric fields as a nonthermal process needs to include not only the inactivation of microorganisms, but the inactivation of enzymes, retention of vitamins, and the effect of PEF treatments on other food components. The reported inactivation of enzymes, as well as the increased

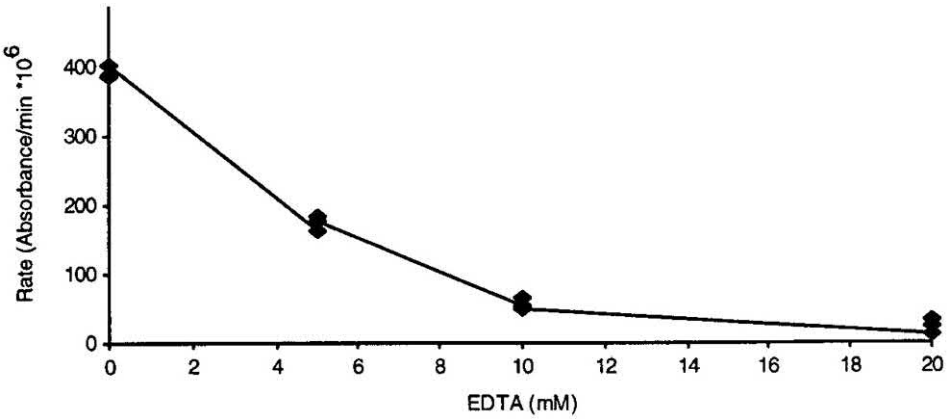

FIGURE 48.27 Inhibitory effect of EDTA on a protease from *P. fluorescens* M3/6. (From Verga-Mercado [63].)

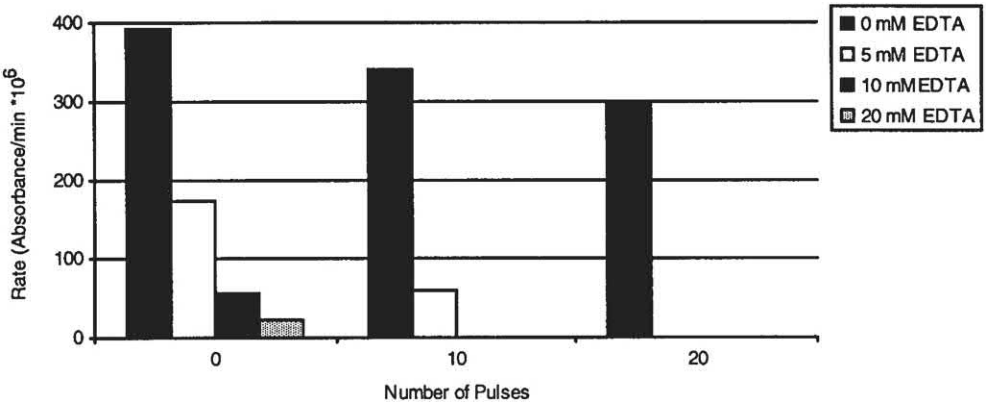

FIGURE 48.28 PEF inactivation of a protease from *P. fluorescens* M3/6 in SMUF with EDTA. (From Verga-Mercado [63].)

proteolysis of casein following exposure to PEF, suggests that detailed research is needed in areas other than preservation. Pulsed electric fields could be utilized as an effective hurdle when used in combination with other preservation factors such as pH and water activity, or as a complementary step with mild thermal processes.

49 High-Pressure Preservation of Foods

Enrique Palou, Aurelio López-Malo, Gustavo V. Barbosa-Cánovas, Barry G. Swanson, and Mohammad Shafiur Rahman

CONTENTS

49.1 INTRODUCTION

The food characteristics that must be attained in response to modem consumer demands are more freshness or fresh-like; fewer preservatives; less heat and chill damage; less acid; and less salt, sugar, and fat as well as foods without extreme treatments [1, 2]. Safety and quality of foods should be based on substantial improvements in traditional preservation methods or the use of "emerging technologies." One "new" or emerging technology receiving a great deal of attention is high-pressure (HP) processing. Studies examining the effects of high pressure on foods date back to the end of the 19th century, but renewed research and commercialization efforts worldwide could place HP-treated foods in several markets [3–6]. In April 1990, the first high-pressure product, a high-acid jam, was introduced to the Japanese retail market. In 1991, yogurts, fruit jellies, salad dressings, and fruit sauces were also introduced, and two Japanese fruit juice processors installed semicontinuous high-pressure equipment for citrus juice processing [7]. The unique physical and sensory properties of food processed by HP technology offer new chances for food product development, such as minimally processed or raw meat and fish, long shelf-life convenience foods with fresh and natural colors, new types of food gels, and frozen foods with improved quality [8].

At the deepest point in the ocean, the pressure is about 100 MPa and at the center of the earth it is 360 GPa [9]. In commercial applications, the highest pressure used is around 5–6 GPa, which is applied for diamond grit production [9]. High-isostatic-pressure technology is the application of pressure uniformly throughout a product, and it is essentially applied for isostatic pressing, quartz growing, chemical reactors, and simulators [10]. Quartz crystals are grown from a strong alkaline solution of sodium hydroxide at a pressure of up to 200 MPa and a temperature of up to 420°C. Some chemical reactions are carried out at high pressure to increase the yield of the reaction. For example, low-density polyethylene is synthesized at a pressure of 200 MPa and a temperature of 350°C. High-pressure vessels are also used as simulators to test equipment that would be used in a high-pressure environment, e.g., deep in the ocean [11]. The food industry employs the technique of isostatic pressing for applying high pressures to foods.

49.2 ADVANTAGES AND DISADVANTAGES OF HIGH PRESSURE

Figure 49.1 describes the factors affecting the selection of a technology for food processing. There are advantages and disadvantages of high-pressure processing in foods. Therefore, the selection of high pressure needs to be decided considering its advantages and disadvantages when applied to a specific food product. The advantages are (i) it operates at a low temperatures as compared to the conventional thermal treatments, thus retains nutrients, sensory, and improves food quality [12, 13]; (ii) its treatments are independent of product size and geometry, and their effect or action on foods is uniform and instantaneous [14–17]; and (iii) it is useful when other methods are impossible to use, for example, commercial pasteurization or sterilization of nonacidic foods is very difficult or impossible without using some additional factors or methods to enhance the inactivation rate.

49.3 PRINCIPLE AND OPERATION OF HIGH PRESSURE

The basis of high hydrostatic pressure is the Le Chatelier principle, according to which any reaction, conformational change, or phase transition is accompanied by a decrease in volume (i.e., high pressure), while reactions are inhibited by an increase in volume (i.e., low pressure) [5, 18]. With the principle of isostatic processing, as shown in Figure 49.2, the food product is compressed by uniform pressure from every direction and then returns to its original shape when pressure is released [19].

Pressure is an important thermodynamic variable and can affect a wide range of biological structures, reactions, and processes [8]. Pressure primarily affects the volume of a system [20]. The influence of pressure on the reaction rate may be described by the transition state theory: the rate constant of a reaction in a liquid phase is proportional to the quasi-equilibrium constant for the formation of the active reactants [20, 21]. Based on this assumption, it was reported that at constant temperature, the pressure dependence of the reaction velocity constant (k) is due entirely to the activation volume of the reaction (ΔE_v) [20–22]:

$$\left(\frac{\delta \ln k}{\delta P}\right)_T = -\left(\frac{\Delta E_v}{RT}\right) \tag{49.1}$$

where P is the pressure, R is the gas constant (8.314 cm^3 MPa $K^{-1}mole^{-1}$), and T is temperature (K). Water is the most important food ingredient in many food products, thus, its

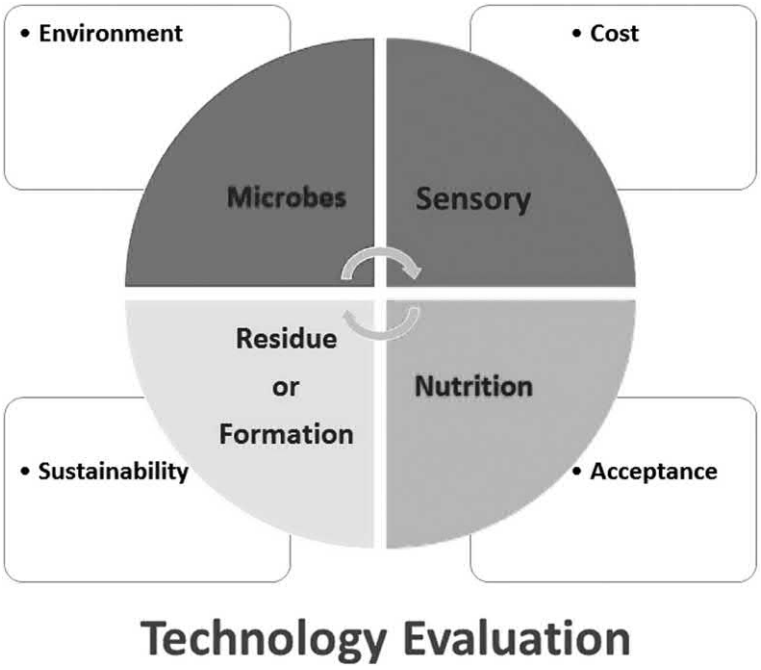

FIGURE 49.1 Factors affecting any technology to be used in food processing.

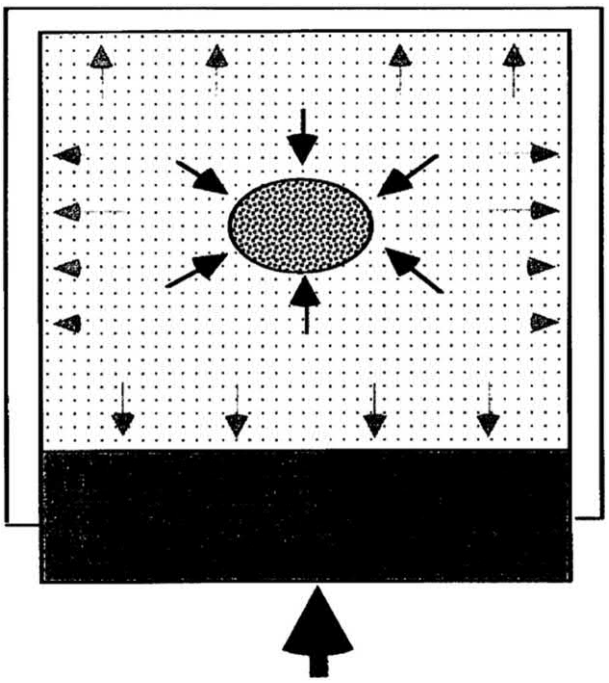

FIGURE 49.2 The principle of isostatic processing. (Adapted from Olsson [19].)

characteristics under pressure are very important. Compared to gases, water is nearly incompressible; adiabatic compression of water increases the temperature by about 3°C per 100 MPa [22]. Self-ionization of water is also promoted by high pressure. The water-freezing characteristics can be changed by the application of pressure [23]. At approximately 1000 MPa, water freezes at room temperature, while the freezing point decreases to –22°C at 207.5 MPa. This event promotes opportunities for subzero storage of foods without ice crystal formation, fast thawing of frozen foods by pressurization, and increasing food freezing by decompression of pressurized foods held below 0°C [8]. In an aqueous system, water molecules surrounding an ionized group align themselves according to the influence of the electrostatic charge, giving a more compact arrangement. Ionization of the acidic or basic groups found in many biomolecules, such as proteins, involves a volume decrease, therefore, chemical reactivity is enhanced by higher pressure [4, 24]. Microorganisms, chemical, biochemical, and enzymatic reactions, as well as some functional properties of biomolecules are affected, to some extent, by high pressure.

49.3.1 Components of High-Pressure Process

A high-pressure system consists of a high-pressure vessel and its closure, pressure-generation system, temperature-control device, and material-handling system [25]. Once loaded and closed, the vessel is filled with a pressure-transmitting medium. Air is removed from the vessel by means of a low-pressure fast-fill-and-drain pump, in combination with an automatic deaeration valve, and high hydrostatic pressure is then generated. High pressures can be generated by direct or indirect compression or by heating the pressure medium [10].

The pressure vessel is the most important component of high-hydrostatic-pressure equipment. Crossland [9] mentioned several considerations that must be taken into account in vessel design: it is necessary to design the high-pressure vessel to be dimensionally stable in a safe-fail way. The vessel does not yield in service; if it fails it should fail by leaking before fracturing. There is also the problem of fatigue, which at the highest pressure cannot be avoided, but an acceptable economic lifetime must be achieved. It is also necessary to establish the minimum number of cycles to failure in order to determine the desired frequency of inspection.

49.3.2 Equipment and Operations of High Pressure

Direct compression is generated by pressurizing a medium with the small diameter end of a piston (Figure 49.3). The large diameter end of the piston is driven by a low-pressure pump. This direct compression method allows very fast compression,

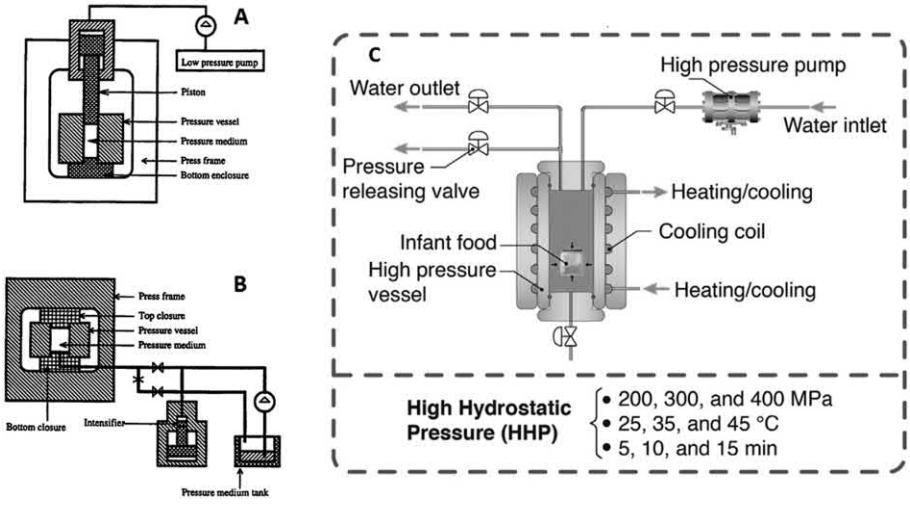

FIGURE 49.3 High pressure system. (A) Direct compression of the pressure transmitting medium, (B and C) Indirect compression of the pressure transmitting medium. (Adapted from Barbosa-Cánovas et al. [11]; Kultur et al. [80].)

but the limitations of the high-pressure dynamic seal between the piston and the vessel internal surface restrict the use of this method to small-diameter laboratory or pilot plant systems.

Indirect compression uses a high-pressure intensifier to pump a pressure medium from a reservoir into a closed high-pressure vessel until the desired pressure is reached (Figure 49.3). Most industrial isostatic pressing (cold, warm, or hot) systems utilize the indirect compression method.

Heating of the pressure medium utilizes expansion of the pressure medium with increasing temperature to generate high pressure. Heating of the pressure medium is therefore used when high pressure is applied in combination with high temperature, and it requires very accurate temperature control within the entire internal volume of the pressure vessel [11]. The isostatic pressing systems may be operated as cold isostatic, warm isostatic, or hot isostatic systems [26] depending on the application.

Cold isostatic pressing is essentially a forming technique used in the metal, ceramics, carbon, graphite, and plastic industries. Powdered materials are filled in an elastomer mold and subjected to high pressure. High-pressure machines work at ambient temperature and use as pressurization fluid a liquid such as water, emulsified water, or oil. Applied pressure is in the range of 50–600 MPa. The cold isostatic pressure process uses "wet bag" or "dry bag" configurations. In the wet bag method, the mold is filled outside the pressure vessel. The mold is then placed in the pressure vessel, which is filled with the pressure medium. In the dry bag method, the mold is fixed in the pressure vessel and separated from the pressure medium by an elastomer tool [11]. The cycle time in a wet bag method is a few minutes, whereas the cycle time in a dry bag method varies between 20 and 60 seconds. Cold and warm isostatic pressure systems are most similar to future food applications. Both the dry bag (in bulk) and wet bag (in container) process options are of interest for food processing [25]. The cold isostatic pressing equipment originally developed for ceramic application was modified to meet additional requirements for food processing. Although the pressure medium used in the vessel is water containing an anti-rusting agent or synthetic oil to protect the pressure vessel against corrosion, food processing requires use of potable water or emulsified potable water [11].

Warm isostatic pressing is also a forming technique. Isostatic pressure is applied in combination with temperatures between ambient and 250°C. A warm isostatic pressure system is used in situations where a chemical reaction develops during pressurization. Hot isostatic pressing is used primarily in the metallic and ceramic industries. The material is uniformly heated and pressurized. The temperature employed is as high as 2000–2200°C, while pressure is 100–400 MPa. The pressure medium used is a gas such as argon, nitrogen, helium, or air. The cycle time typically varies between 6 and 12 hours [10].

49.3.3 Processing Parameters

The processing cost depends on the time of exposure. Processing at 400 MPa with a holding time of 10 minutes is twice as expensive as processing at 800 MPa with no hold time [19]. The combination of pressure, time, and temperature at which the product is processed must therefore be evaluated carefully. A low maximum operating pressure can cause drastic reductions in the fabrication costs. High-pressure processing may be combined with moderately high temperatures, so the operating pressures required are not extremely high [27]. Figure 49.4 shows the pressure and temperature range used for pasteurization and sterilization.

A sterile container filled with food is sealed and placed in the pressure chamber for pressurizing. Ethylene-vinyl alcohol copolymer (EVOH) and polyvinyl alcohol (PVOH) films are recommended for packaging food for high-pressure treatment [28]. Also, the existing multilayer plastic and some aluminum packages may be used for high-pressure processing.

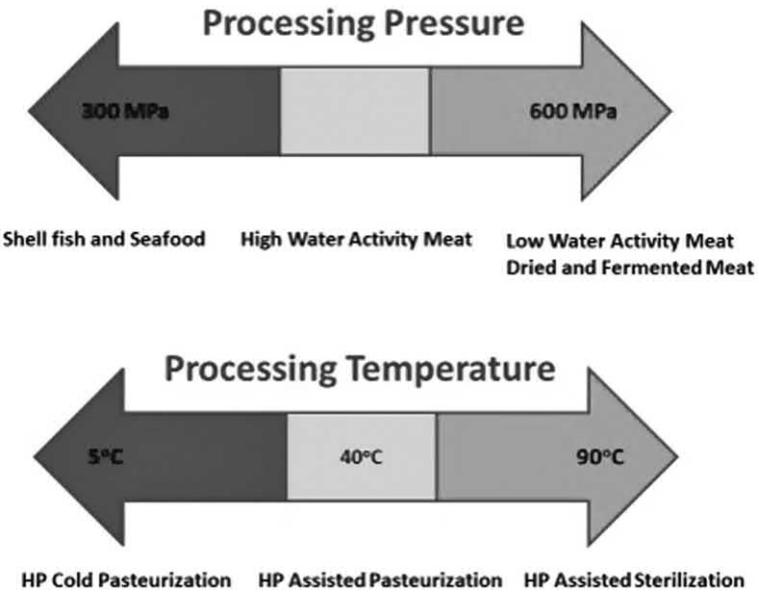

FIGURE 49.4 Pressure and temperature range used for pasteurization and sterilization.

No deformation of the package occurs because the pressure is uniform [29]. The shape of the package needs to be designed to fill the vessel volume as far as possible to increase the economic feasibility of the process. The basis for applying high pressure to foods is to compress the water surrounding the food. At room temperature, the volume of water decreases, as presented in Figure 49.5 [3, 30]. Because liquid compression results in a small volume change, high-pressure vessels using water do not present the same operating hazards as vessels using compressed gases [3].

The capacity of a high-pressure plant depends on three factors: the number of cycles that can be done in a given time, the volume of the product, and the number of high-pressure vessels available. The cycle time is determined by the time needed to handle the food product, including loading, unloading, opening and closing the high-pressure vessel, the pressure holding time, and the pressurization and decompression rates. The productivity of the batch system is increased by a reduction in the pressurizing–decompressing cycle. The pressurizing time is reduced by increasing the delivery rate of the pump [11]. When the required operating pressure is attained, the pumping rate is reduced. At the end of the specified holding time, the pressure vessel is decompressed in two stages to avoid sudden release of pressurized water [31]. Batch processing reduces the risk of large quantities of food becoming contaminated by the lubricants or wear particles from the machinery. Different types of food can be processed in a batch system, without the danger of cross-contamination or the need to clean the equipment after each run [11]. The technical advantage of the batch-type pressure vessel is the simplicity of fabrication when compared to a continuous flow pressure vessel operating at pressures as high as 400–900 MPa [6, 11, 26]. A batch system pressure vessel with a processing capacity of 600 liters/h of liquid food at a maximum operating pressure of 420 MPa was used to commercially produce grapefruit juice in Japan [31]. The production rate of the batch process can be increased by operating pressure vessels in sequence with no lag in the processing times so the system operates sequentially.

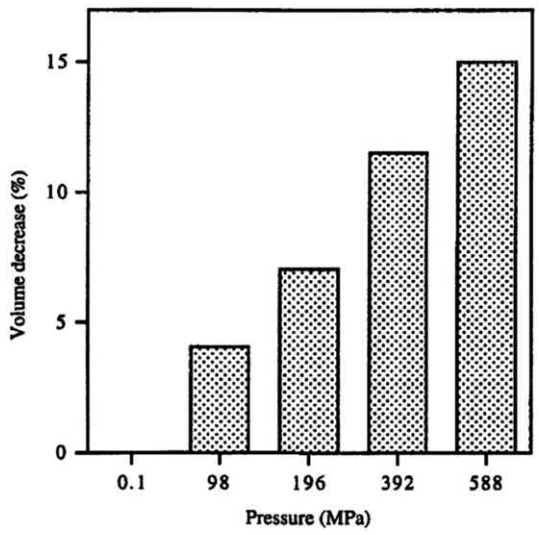

FIGURE 49.5 Decrease in water volume with pressure. (Adapted from Farr [3]).

Food is subjected to high pressure for a specified time period. The holding time in the pressure vessel depends on the type of food and process temperature. At the end of the processing time the chamber is decompressed to remove the treated batch. A new batch of food is placed in the pressure vessel and the cycle begins again [32]. As in heat sterilization of packed products, the water in contact with the product should be of drinking quality, and the lubricating and rust-protecting products should be able to be used in food processing. For bulk processing, the high-pressure equipment should be part of an aseptic line. Parts in contact with the food product should be clean and sterile. The engineering challenges of the application of high pressure in the food industry are primarily the construction of pressure vessels to handle large volumes of food and withstand the high pressures; the pressure vessel should have a short cycle time, be easy to clean, and be safe to operate with accurate process controls. It is desirable to develop a continuous process of pressurization for industrial purposes at reasonably low capital and operating costs [6, 10, 11].

Most of the energy of HP processing is consumed during pressure come-up time when electrical energy is used to achieve the desired pressure by the electric motor in the pump-intensifier systems. At present, the energy required to compress the vessel is mostly lost upon decompression. However, synchronizing the compression and decompression phase in twin-vessel systems could recover half of the decompression energy. In addition, heat could be recovered by chilling or preheating treatment. Maximum product load in the vessel could avoid the loss of compression energy in the transmitting fluid [33].

49.3.4 Commercialization of High Pressure

The Japanese are the leading manufacturers of high-pressure vessels. The major Japanese companies manufacturing high-pressure vessels are Mitsubishi Heavy Industries Ltd., Kobe Steel Ltd., and Nippon Steel Ltd. Other manufacturers of high-pressure equipment include Engineered Pressure Systems, ABB Autoclave Systems Inc., ACB, NKK Corp., Flow International, and Autoclave Engineers [6, 11, 34]. Table 49.1 provides specifications of some commercially available high-pressure systems and some details on pressure vessels and maximum operating pressures. As indicated in the table, the larger the vessel, the lower the maximum operating pressure [6]. The first high-pressure food-processing vessel was manufactured by Mitsubishi Heavy Industries (Tokyo, Japan). The pressure vessels manufactured by Mitsubishi Heavy Industries varied in capacity from 0.6 to 210 liters and the maximum working pressures from 400 to 700 MPa [35]. The increase in the high-pressure unit capacity generally reduces the maximum pressure that can be achieved. To minimize the reduction of equipment life due to repeated use of the pressure vessel, the Mitsubishi pressure vessel is made

TABLE 49.1
Specifications of Selected Commercially Available High-Pressure Vessels

up of double cylinders. The inner surface of the pressure vessel is preloaded with high compression stress. The parts of the vessel that come in contact with the pressurizing medium are made of stainless steel. The pressurizing and decompressing cycle is fast. Maximum pressure is attained in 90 seconds. High pressure and a long holding time imply that a great load is applied to the seal of the vessel cover. Self-seal packing with high durability and reliability is used. The seals can withstand repeated opening and closing of the pressure vessel and application of high pressure without leakage. A piston driven by a hydraulic cylinder is used to generate the required pressure [31].

Kobe Steel Ltd. developed a small test pressure vessel and one of the largest pressure vessels available today, with an internal volume capacity of 9400 liters and a maximum working pressure of ~200 MPa. The small test pressure vessel uses a piston for pressurization, and the oil hydraulic system and operational panel are compactly packaged as part of the equipment. Operation is fully automated, and the temperature inside the pressure vessel can be recorded. The equipment also allows the use of a pressure-control program [36].

The research high-pressure food-processing system developed by ABB Autoclave Systems Inc. (Vasteras, Sweden) consists of two components: the process module and the control module. The process module consists of a cabinet, which contains the Quintus prestressed wire-wound pressure vessel, the electrohydraulic pumping system, and a hot water circulation system. The system can reach 900 MPa within 4 minutes. Temperature is maintained by circulating water in channels between the wire winding and the cylinder wall of the pressure vessel. The programmable control module in the ABB high-pressure research vessel monitors and controls the process time, pressure, and temperature. A microprocessor is used to control food loading into the press, press cycling, and downloading to a conveyor [37]. The cost of treating foods in 100- and 500-liter systems is approximately $0.25 and $0.07 per batch, respectively [29]. The high-pressure system Quintus models from ABB Autoclave Systems vary in their dimensions from 0.09 to 0.5 m (internal diameter) and from 0.225 to 2.5 m (internal length) with an internal capacity up to 500 liters and a maximum operating pressure of 900 MPa. Pressure vessels with other dimensions available from ABB Autoclave Systems include 0.045 m diameter × 0.3 m length with a maximum pressure of 1200 MPa; 0.11 m diameter × 0.26 m length with a maximum pressure of 830 MPa; 0.32 m diameter × 1.25 m length (100 liters) with a maximum pressure of 900 MPa; and 0.50 m diameter × 2.50 m length (500 liters) with a maximum pressure of 900 MPa. The fatigue value can be maintained infinitely by replacing a shrunk wear-liner every 30,000 cycles. Changing the liner is convenient and inexpensive. ABB Autoclave Systems is designing and constructing a high-pressure vessel to work in batch mode with a maximum operating pressure of 1700 MPa. The internal diameter of the pressure vessel will be 0.076 m, and the height will be 0.18 m [38].

A warm isostatic pressing system is available from Engineered Pressure Systems Inc. (EPSI), a subsidiary of National Forge Co. (Andover, Massachusetts). The system consists of a double-ended, lined pressure vessel with plug closures. The design parameters of the high-pressure systems constructed by EPSI are listed in Table 49.1. Recently EPSI developed a laboratory-scale pressure vessel with the following specifications: 0.1 m (internal diameter) × 2.5 m (internal height) with maximum operating pressure of 680 MPa and maximum operating temperature of 90°C. While the design pressure is 750 MPa, the maximum operating pressure is 680 MPa. An electrohydraulic intensifier pump with a motor pressurizes the vessel to the operating pressure in 5 minutes or less [39]. An advanced laboratory-scale pressure vessel with a useful diameter of 0.024 m, length of 0.04 m, and maximum pressure of 800 MPa is also available from EPSI.

Current industrial applications of high hydrostatic pressure are presented in Table 49.2. Hayashi [20] presented a list of pressure-processed foods in the Japanese market. The first pressure-processed foods in human history were strawberry, kiwi, and apple jams (Meidi-ya Food Co.). The jams were produced using high-pressure treatment without application of heat. The jams were vivid and natural in color and taste. The list includes fruit sauces and desserts (Meidi-ya Food Co.), mandarin (Wakayama Co.) and grapefruit juices (Pokka Co.), and unrefined rice wine called "nigori-sake." The new sake

has a white color and fresh flavor, instead of a brown color and cooked smell. Cheftel [18] mentioned that many of the products presented in Table 49.2 are acidic foods, hence they have an intrinsic safety factor. In addition, some of the products are stored and sold refrigerated, consequently, oxidative reactions are retarded. Hayashi [40] reported that at least seven food companies now sell high-pressure-processed foods, including salted raw squid and fish sausages. Knorr [16] mentioned that progress in various additional products is underway, but information is not available due to its confidential nature. In the United States and Europe, developments are being made in fruit products, ready meals, dairy products, meats, fish, and others. Avocado paste (guacamole) is now produced in Mexico using high pressure. Several new industrial applications are expected soon.

49.3.5 Consumer Perception of HP Processing

Consumers' acceptability of a technology is important for its successful applications. Consumers (in the United States, the UK, Europe, and Australia) are more positive toward HP processing due to environmental benefits, improved food safety, and quality [41–45]. European consumers (Slovenia, Hungary, Serbia, Slovakia, Norway, and Denmark) linked HP processing with irradiation and genetically modified organisms and perceived that HP-processed foods have unknown consequences [44, 45]. US consumers are aware and willing to pay additional (39% of respondents) when an explanation for HP and corresponding benefits are given [46]. Chinese consumers could accept the technology, however, consumer education is needed to increase the awareness of the advantages, and specific communication strategies need to be applied [47].

49.3.6 Challenges of HP Processing

Most of the experiments are reported from laboratory- or pilot-scale equipment. Validation from large-scale applications for energy efficiency with reduced wear and abrasion are needed [13]. Commercial feasibility must include research on the design and construction of plant and equipment for the high-pressure processing of foods. Integration of the large amount of available information to design an efficient process is necessary.

Identification of commercially feasible applications is probably the most difficult of the challenges for high-pressure technology [25]. Products processed by high pressure need to have inherent added value or increased profitability due to the expensive process cost. Two important questions need to be answered: Will consumers accept a high-pressure-processed product? Are they prepared to pay an extra cost for a high-pressure-processed food? The commercial application of high-pressure technology in the food industry depends largely on the economic feasibility of the process. The capital cost associated with the equipment purchase and installation is an important obstacle for its commercial implementation [25]. The cost of the high-pressure vessel represents the main fraction of the total cost of an industrial high-pressure processing plant and will depend on the maximum working pressure and the vessel dimensions and processing capacity.

Earnshaw [8] mentioned that it is unlikely that pressure processing will replace canning or freezing; nevertheless, it could find applications for expensive foods with short shelf lives and high-value ingredients such as flavors, vitamins, and functional biopolymers that are heat-sensitive. In Europe, Japan, and the United States there is significant commercial interest in the development of high-pressure food processing, and millions of dollars have been invested in research and development.

High hydrostatic pressure is not a cheap technology, and a systematic approach must be taken to search for processing options to ensure that high-pressure treatments can be successfully and economically applied to a wide range of products [48]. The feasibility studies must include effective equipment design solutions and precisely defined minimum required pressures and time cycles. Continuous operation is also a major task. To optimize high-hydrostatic-pressure preservation techniques, the combined effects of stress factors on the growth of key microorganisms, the storage-dependent changes in food systems after high-pressure treatments, and their shelf-life limiting factors must be clearly understood [49].

49.3.7 Packaging Challenges of HP Processing

The packages should have a sufficient degree of flexibility and resilience to compensate for the reduction in volume [50]. HP treatment produces much less damage than do conventional

thermal treatments in the barrier properties of hydrophilic materials. Gavala et al. [51] found no significant changes in tensile strength of packaging between control and HP-treated samples. The heat seal strength is critical in packages since if a void is present or generated then safety is seriously compromised. In general, thermoplastic materials have stability and can withstand high pressure without significant losses in seal integrity. High headspace volume needs to be avoided since high pressure induced seal damages, delamination and large deformation are observed in flexible packages made of composite materials. The low headspace volume could maximize the use of vessel volume. It is known that gases reduce their volume much more than food or packaging materials, and promotes tensions and failures. In addition, more processing fluid need to be pumped in the vessel for large headspace.

If the polymeric material is layered or coated aluminum, delamination and blistering could be observed since aluminum possesses low compressibility as compared to a polymeric layer. The extent of this effect depends on the pressure exposure time and temperature. In general, the permeability to oxygen, carbon dioxide, and water vapor is not affected by HP treatment. However, damage in the barrier properties is observed in the case of metalized plastic film, especially in the aluminum layer. The reduction of plasticization and subsequent loss of barrier properties occurs at low temperature with HP due to lower water sorption capacity of polymers. HP reduces the voids and free volume of polymer and it causes lower solubility with lower molecular diffusion. These two factors are related to the food–packaging interaction [50, 51]. Packaging must withstand a change of volume up to 18% followed by a return to its original size without losing package and seal integrity and barrier properties (gas permeability, seal and mechanical properties, global migration of packaging components).

49.4 MICROBIAL EFFICACY

The pressure sensitivity of microorganisms varies with the type of microorganism. Gould [1] reports that as high-pressure targets, microorganisms may be divided into those that cause food poisoning and those that cause food spoilage. Microorganisms can be further divided into those that are relatively pressure-sensitive and those that are pressure-resistant. Regarding the pressure sensitivity, the most important categories are the vegetative and spore forms of microorganisms; in general the vegetative forms are inactivated by pressures between 400 and 600 MPa, while spores of some species may resist pressures higher than 1000 MPa at ambient temperatures. Gram-positive bacteria are more pressure-resistant than gram-negative ones [52–54]. Among the gram-positive bacteria, Earnshaw [52] reported that *Staphylococcus* is one of the most resistant and can survive treatment at 500 MPa for more than 60 minutes. Figure 49.6 shows the effect of pressure on microbial lethality.

49.4.1 Vegetative Cells

The relative pressure sensitivity of the vegetative forms of microorganisms has made them the obvious first targets for

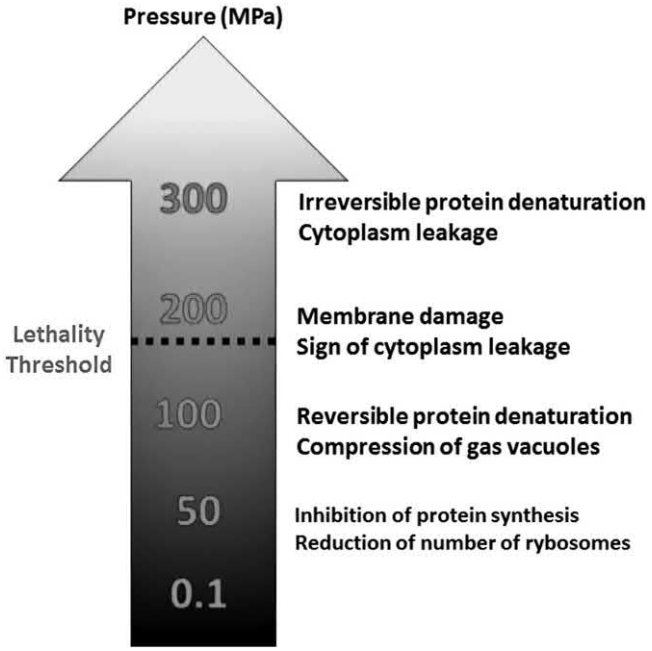

FIGURE 49.6 Level of pressure on microbial lethality. (Adapted from Lado and Yousef [159].)

the preservation of foods by high pressure, and particularly for low pH foods and other foods in which the intrinsic preservation systems already operating ensure that the pressure-resistant food poisoning or spoilage spore-formers that may survive are unable to grow [1]. Increased opportunities must originate when combinations of pressure with some of the other already well-established inhibitory food-preservation techniques are applied using the hurdle technology approach. High-hydrostatic-pressure treatments can be considered as a new hurdle that can be used in combination with other traditional microbial stress factors such as pH, water activity (a_w), and preservatives [55, 56]. However, if high pressure is to be used instead of other stress factors, the kinetics of microbial pressure inactivation must be known as well as the spore resistance of toxigenic bacteria [1]. The extent of microbial inactivation achieved at a particular pressure treatment depends on a number of interacting factors, including type and number of microorganisms, magnitude and duration of high-pressure treatment, temperature, and composition of the suspension media or food [49, 53, 57]. Other experimental variables that must be taken into account include the compression and decompression rates [52].

49.4.1.1 Type and Number of Microorganisms

Zobell [58] reported that most bacteria are capable of growth at pressures around 20–30 MPa; barophiles are organisms that can grow at pressures higher than 40–50 MPa, and those that survive for prolonged periods at pressures >200 MPa are named baroduric or barotolerant. The pressure effects on several pathogenic and spoilage microorganisms inoculated in a pork slurry can be used to illustrate the microbial response to high hydrostatic pressure and the differences among species and microbial forms [54]. *Escherichia coli* counts were almost

unaffected at pressures lower than 203 MPa, but treatments at 304 MPa or higher pressures drastically reduced the initial inocula (10^6–10^7 cfu/g). More than 6 log cycles of *E. coli* were reduced at pressures higher than 405 MPa for 10 minutes. For *Saccharomyces cerevisiae*, less than 2 log cycle reductions were observed at pressures lower than 304 MPa and more than 6 log cycles at pressures higher than 405 MPa. The *Bacillus cereus* spore counts were not reduced considerably (less than 1 log cycle) even in treatments at 608 MPa for 10 minutes.

Patterson et al. [53, 59] reported important information about the effect of high pressure on foodborne vegetative pathogens. The gram-negative bacteria are pressure sensitive [60, 61]. Among these, *Vibrio parahaemolyticus* is one of the most sensible; a 6 log reduction in the initial population can be attained in treatments at 200 MPa for 20 minutes. On the other hand, gram-positive pathogens such as *Listeria monocytogenes* and *Staphylococcus aureus* require a 6 log reduction in the initial inoculum treatments 20 minutes at 340 and 400 MPa, respectively [53]. Another pressure-resistant pathogenic bacteria is *E. coli* 0157:H7; Takahashi et al. [61] reported that for a 6 log cycle reduction, the treatment must be at 700 MPa for 13 minutes. The more complex membrane structure of gram-negative bacteria is more susceptible to environmental changes like those caused by high-pressure treatments [54].

Earnshaw [52] reported that little difference was observed in the overall rates of *Staphylococcus carnosus* inactivation for treatments at 650 MPa with different initial populations ranging from 10^7 to 10^3 cfu/ml. When 10^2 cfu/ml were initially inoculated, a faster inactivation rate was observed. It is obvious that with a great number of initially inoculated microorganisms, the effects of specific high-pressure treatments can be observed, but studies with realistic numbers of microorganisms are also needed. The pressure sensitivity of microorganisms may vary with the species and probably with the strain of the same species and with the stage of the growth cycle at which the organisms are subjected to the high-hydrostatic-pressure treatment. In general, cells in the exponential phase are more sensitive to pressure treatments than cells in the log or stationary phases of growth [52, 53, 58, 62]. Isaacs et al. [63] reported that freshly inoculated *E. coli* cultures growing rapidly were more sensitive than *E. coli* cultures that had reached the growth stationary phase. No effect after 7 minutes at 200 MPa with cells in the stationary phase and around *5* log cycle reductions with young cells from the log phase were observed. Also, it has been established that the cell age distribution in inoculation studies might be an important factor in the result obtained after high-pressure treatments. Bacteria in the stationary phase are smaller and more spherical than in the log phase, when they are rapidly growing, rod-shaped, and exhibit an accelerated metabolism. Isaacs et al. [63] stated that the greater resistance to pressure when the cell metabolism slows down may reflect the accumulation of cell components, which can reduce the effects of high pressure.

Considerable variation in pressure sensitivity between strains isolated from different foods or culture collections has been reported for the same microorganisms. Patterson et al. [53] reported a 3 log reduction for *L. monocytogenes* from a culture collection after 30 minutes at 375 MPa. The same pressure treatment reduced the initial population >10^4- and 10^7-fold, for strain Scott A and a chicken isolate, respectively. Cheftel [18] reported that when the pressure resistance of various microorganisms is compared, the survival fractions determined by different investigators vary by a factor of 1 to >8 for different species of the same genus (*Salmonella*) or by a factor of 1.5–3.5 for different strains of the same microorganism (*L. monocytogenes*).

49.4.1.2 Extent and Duration of High-Hydrostatic-Pressure Treatments

Generally, an increase in pressure increases microbial inactivation. However, increasing the duration of the treatment does not necessarily increase the lethal effect. Above 200–300 MPa, the inactivation ratio of vegetative cells increases with pressure or process time [53]. Table 49.3 presents some results about the effects of high pressure level and exposure time on several microorganisms. As mentioned before, the microbial response to high-pressure treatments depends on the type of microorganism. For each microorganism, there is a pressure-level threshold at which no effects of increasing the exposure time are detected. There also exists a pressure level at which increasing treatment time causes significant reductions in the initially inoculated microbial counts. The intrinsic conditions of the suspension media such as pH, a_w, and nutrients may influence the pressure threshold, which can increase or decrease depending on the microorganism and variation of intrinsic, extrinsic, and processing factors. Kinetic studies at pressures over the pressure threshold are needed. With reliable kinetic data, the pressure sterilization or pasteurization of foods can be predicted and achieved.

49.4.1.3 Temperature

The temperature during pressurization can have a significant effect on the inactivation of microbial cells. Several authors [18, 64–67] observed that the resistance to pressure of an endogenous or inoculated microbial strain is maximal at normal temperatures (15–30°C) and decreases significantly at higher or lower temperatures. Freezing temperatures (–20°C) in treatments ranging from 100 to 400 MPa for 20 minutes enhance microbial inactivation when compared with high-pressure treatments at 20°C [61]. Hashizume et al. [68] reported that *S. cerevisiae* cells were more effectively inactivated by high-pressure treatments at elevated (40°C) or subzero (–0 and –20°C) temperatures.

The decrease in pressure resistance of vegetative cells at low temperatures (<5°C) may be due to changes in the membrane structure and fluidity, weakening of hydrophobic interactions, and crystallization of phospholipids [18]. On the other hand, moderate heating (40–60°C) may also enhance the pressure microbial inactivation, resulting in some cases in a lower minimal inactivation pressure [18, 64]. Ogawa et al. [69, 70] reported an enhanced inactivation of natural flora and inoculated microorganisms in mandarin juice treated at 40°C in combination with pressures in

the range 400–450 MPa. The psychrotrophic bacteria (i.e., *Pseudomonas fluorescens* and *Listeria innocua*) were more sensitive to the effects of pressure at low temperatures, and thermotolerant bacteria (i.e., *Citrobacter freundii*) was more sensitive at 35°C and 50°C. For the three bacteria, the greatest inactivation was obtained when combining the pressure treatment with 50°C [64].

Zobell [58] observed that the maximum microbial growth temperature at increased pressure is generally a few degrees higher than the optimum growth temperature at atmospheric pressure. Sale et al. [71] reported an increasing sensitivity to pressure of *Bacillus coagulans* spores with temperature. Roberts and Hoover [72] evaluated the effect of combinations of pressure at 400 MPa with heat against spores of *B. coagulans* and at 25°C observed less than 1 log cycle reduction in the initial inocula. As the temperature during pressurization increased, the effectiveness of the high-pressure treatment increased; 2 and 4 log cycle reductions were observed at 45°C and 70°C, respectively.

49.4.1.4 Composition of Suspension Media or Food

The effect of pressure on inhibition or inactivation of microorganisms in combination with major environmental variables should be analyzed for a better understanding of the mode of action of this preservation technique. The extent of microbial reduction achieved by a high-hydrostatic-pressure treatment depends on a number of interacting factors including the composition of the media or food [49, 57]. Many food constituents appear to protect microorganisms from the effects of high pressure [4, 6, 49, 53, 57, 73]. Therefore, it is important to evaluate high-hydrostatic-pressure treatments for each individual case.

Dring [74] observed that nonnutritive solutions reduce the microorganism's barotolerance. Marquis [75] reported that an enriched media protects microorganisms against pressure and suggested that free amino acids and vitamins are available and therefore the cells are protected. The pressure resistance of fungi increases as the sugar (sucrose, fructose, and glucose) concentration on the media increases [68, 70, 73].

A baroprotective effect of reduced water activity for organisms that can grow at reduced a~ has been reported [15, 16, 49, 57, 76, 77]. Oxen and Knorr [73] observed that high-hydrostatic-pressure treatment at room temperature and 400 MPa for 15 minutes inactivated the yeast *Rhodotorula rubra* when the a~ of the suspension media was higher than 0.96, while the number of survivors was higher when the a_w was depressed. Similar treatment at 30°C achieved 7 log cycle reductions in the initial inocula at a_w 0.96; 2 log cycles were reduced at a_w 0.94, and no reductions were observed when the a_w of the suspension media was 0.91 [15]. At higher temperatures (45°C) the yeast was inactivated even at low a_w values. Oxen and Knorr [73] demonstrated that pressure–temperature combination treatments result in faster and greater yeast inactivation in comparison with treatments where only temperature or pressure is applied. For heat inactivation, treatments for 15 minutes at 70–80°C and atmospheric pressure were required to inhibit *R. rubra*.

Palou et al. [49] reported the effect of reduced a_w (or increasing soluble solids concentration) on *Zygosaccharomyces bailii* inhibition suspended in laboratory model systems adjusted to pH 3.5. The effect of the model system with soluble solids concentration on the viability of *Z. bailii* without (0.1 MPa) and with a high-pressure treatment of 5 minutes at 345 MPa was studied. *Z. bailii* grew without the pressure treatment in the range of sugar concentration studied (2–59% w/w), rapidly reaching high counts (~$l0^7$ cfu/ml). This yeast is osmotolerant and its growth occurs in media containing up to 60% (w/w) glucose, with a_w 0.85. The soluble solids concentration in the model systems considerably affects the recovery counts after high-pressure treatment, being higher as the soluble solids concentration increased. Greater counts were observed for the experiments with sugar concentrations >40%. In experiments with less than 20% soluble solids, complete inhibition (<10 cfu/ml) of *Z. bailii* was observed. Ogawa et al. [69] reported that for *S. cerevisiae* inoculated in concentrated fruit juices, the number of surviving microorganisms depends on the juice-soluble solids concentration and observed that the inactivation effect at pressure ≤200 MPa decreased as juice concentration increased. Hashizume et al. [68] also reported an increase in the number of surviving *S. cerevisiae* cells with increasing concentrations of sucrose (0–30% w/w) when pressurized at 260 MPa for 20 minutes at 25°C.

Palou et al. [49] reported a linear decreased relationship between the water activity depression factor $(1 - a_w)$ and log of Z. *bailii* survival fraction (N/N_0) after a high-pressure treatment at 345 MPa for 5 minutes. As a_w of the model system decreased, the number of surviving *Z. bailii* increased. The results obtained by Palou et al. [49] without pressure treatment demonstrate that *Z. bailii* was adapted to grow at the selected a_w values, therefore the observed high-pressure effects can be attributed to this variable and not to the effects of reduced a_w on the extension of the lag phase or on the reduction of the growth rate. At $(1 - a_w) > 0.07$, reductions smaller than 1 log cycle were observed [49]. In comparison, Pandya et al. [78] reported for *Z. bailii* suspended in buffer solutions (a_w ~1.0) with pH 4.0, 5.0, and 6.0 that 7 log cycles were reduced in treatments at 304 MPa for 10 minutes, resulting in the total inhibition of the initial inocula. The resistance to inhibition at reduced a_w values may be attributed to cell shrinkage, which probably causes a thickening in the cell membrane that reduces membrane permeability and fluidity [49]. The increased baroresistance of microorganisms at low a_w may also be attributed to a partial cell dehydration due to the osmotic pressure gradients between the internal and external fluids, which may result in small cells and thicker membranes and an increased pressure resistance [15]. The baroprotective effect of reduced a_w reveals that inhibition of microorganisms by high pressure depends not only on pressure level and extent of the treatment but also on the interactions with other intrinsic and extrinsic variables that influence the microbial response [49]. The design of effective pressure treatments that assure microbial stability of foods will depend on an understanding of the relationships between microorganisms and food components.

49.4.1.5 Microbial Cell Recovery after Pressurization

The high-hydrostatic-pressure effects on microorganisms are often determined by plate counts, and usually dilution and plating are made just after treatment. Survival, as measured immediately after pressure release, may differ from that determined after a repair period in the food or in an enriched medium [18]. Recovery after pressure treatment is a very important consideration for process efficacy and death kinetics assessment [53]. Metrick et al. [79] suggested that the lack of nutrients in phosphate buffer prevents the recovery of the pressure-damaged cells. The ultimate fate of the injured cells will depend on the conditions after pressure treatment. However, the fact that pressure can cause injury may be advantageous when high hydrostatic pressure is combined with other preservation methods [53].

The possibility of cell recovery exists, and in many cases, pressure-treated microorganisms may not be detected in plate count methods because of their failure to initiate growth when they are plated immediately after treatment. However, if the repair mechanism remains intact, the microorganisms may be capable of regeneration and growth. Isaacs et al. [63] observed that for *E. coli* suspensions treated at 200 MPa for 0–6 minutes and plated on selective (Mac-Conkey and Eosin Methylene Blue agars) and nonselective (Tryptone Soya agar) media, the survival fraction was greater for bacteria plated on the nonselective agar. This was attributed to the inhibitory ingredients contained in the selective media, indicating that there is a proportion of microorganisms which, after pressurization, can repair and reproduce, whereas the added stress caused by culturing on selective media inhibits the repair process.

Pressure treatments lead to significant reductions in the initial population of *Z. bailii*, but not enough to inactivate the initially inoculated cells, further incubation reveals that the survivors can grow [57]. Yeast cells subjected to physical or chemical hurdles may become injured or sublethally stressed; the recovery of these cells requires generally more incubation time and the injured survivors are capable of growth even in systems with 1000 ppm potassium sorbate and reduced a_w. In treatments rendering complete inhibition of 10^5 *Z. bailii* cfu/ml after 48 hours, the same result was obtained with a longer (120 h) incubation period [57]. Carlez et al. [65] demonstrated that minced meat inoculated with *Pseudomonas* strains treated for 20 minutes at 300 or 450 MPa results in no microbial growth detected after 2 or 6 days of storage, respectively, when stored at 3°C. However, the *Pseudomonas* counts increased with a longer storage. The lag time before reappearance of microbial growth was related to the intensity of the pressure treatment. Carlez et al. [65] defined two different pressure levels: a lower one that causes microbial injury and delays growth, and a higher one that induces complete inactivation of vegetative microorganisms.

Kultur et al. [80] studied the inactivation of total mesophilic aerobic bacteria (TMA) and total yeasts and molds (TYM) during HP processing (pressure: 200, 300, and 400 MPa; temperature: 25°C, 35°C, and 45°C; treatment time: 5, 10, and 15 min) in the case of vegetable-based infant food. Pressure, time, and temperature had a significant influence on both TMA and TYM inactivation depending on the types. Synergistic effects were observed between pressure, time, and temperature in the reduction. HP processing at 400 MPa resulted in a complete inactivation of TMA as well as TYM after 15 min of treatment at 45°C.

49.4.2 Microbial Spores

Bacterial spores have demonstrated pressure resistance [71, 81], and it has been suggested that spore proteins are protected against solvation and ionization. The structure and thickness of the bacterial spore coats are believed to account for this high resistance. Microbial spores suspended in foods and laboratory model systems could be inactivated by high-pressure treatments, but compared with the requirements for vegetative cells the treatment conditions must be extreme: higher pressures and long exposure times at elevated temperatures [82]. Hydrostatic pressure can cause spore germination. Some authors suggested a high-pressure treatment to induce spore germination and a subsequent treatment to inactivate the germinated microorganisms [16, 76]. Gould and Sale [81] studied the germination of *Bacillus* spores and demonstrated that treatments at 25 MPa and 50°C for 30 minutes cause the germination of 50–64% of the initially inoculated spores.

Crawford et al. [83] reported a decrease in viable *Clostridium sporogenes* spores with increasing pressure up to 690 MPa; higher pressures were ineffective in further reducing the spore counts. Crawford et al. [83] postulated that spore germination occurred at pressures lower than 690 MPa and the germinated cells were inactivated by the pressure treatment, leading to a maximum reduction in the initially inoculated spore counts. At higher pressures, a small fraction of the spore population may have remained highly resistant and capable of resisting pressures of 830 MPa. When pressure and temperature were combined at 690 MPa and 80°C for 20 minutes, the treatment was more effective, with a significant reduction in the *C. sporogenes* spore count [83]. Mallidis and Drizou [84] confirmed the extraordinary pressure resistance of *Bacillus stearothermophilus* spores and concluded that the simultaneous application of moderate pressure (up to 30 MPa) and heat cannot be used as a preservation method, since the effect of pressure on the reduction of heat resistance is low at high temperatures. Nakayama et al. [85] observed no appreciable reductions in the spore viability for six *Bacillus* strains, including *B. stearothermophilus*, *B. coagulans*, *B. subtilis*, *B. licheniformis*, and *B. megaterium*, in pressure treatments at 5–10°C for 40 minutes up to pressures of 981 MPa or at 588 MPa for 120 minutes. Therefore, there is no possibility of pressure sterilization of low-acid foods at low temperatures. Hayakawa et al. [86] reported successful treatments for *B. stearothermophilus* spores when pressure treatments were combined with moderate temperature (70°C). Pressure treatments were four to six compression–decompression cycles at 600 MPa with 5 minutes of holding time. These treatments reduced by 6 to 7 log cycles the initial inocula. Lechowich [87] mentioned that there are no published reports on the

high-pressure resistance of *C. botulinum* spores, and their ability to support high pressure at low or high temperatures is unknown. There is a need for data concerning the high-pressure resistance of *Bacillus* and *Clostridium* spores. With this information, the safety aspects of high-hydrostatic-pressure treatment of low-acid foods can be documented [87].

Spores from yeast and molds are easily inactivated at pressures of 300 (*Aspergillus oryzae*) or 400 MPa (*Rhyzopus javanicus*) at ambient temperatures [18]. However, Butz et al. [88] demonstrated that ascospores of heat-resistant molds such as *Byssochlamys nivea* are extremely pressure resistant. For the inactivation of *B. nivea* ascospores, pressures above 600 MPa and temperatures above 60°C were needed. No effects on spore viability after treatment at 70°C and 500 MPa for 60 minutes were observed; a 3 log cycle reduction was observed at 600 MPa after 60 minutes; approximately 5 log cycles were reduced at 700 MPa; and total and rapid inactivation of *B. nivea* within a few minutes (<10) were observed at 800 MPa.

Bacterial spores represent a challenge for high-pressure technology, and more information about their resistance is required. Data are needed on the destruction of *C. botulinum* spores and the most resistant spore-forming species, and studies of the high-pressure process need to include inoculation and challenge testing.

49.4.3 Kinetics of Microbial Inactivation

The patterns of high-hydrostatic-pressure inactivation kinetics observed with different microorganisms are quite variable. Some investigators indicate first-order kinetics in the case of several bacteria and yeast [64, 67, 68, 89]. Other authors observed a change in the slope and a two-phase inactivation phenomenon: the first fraction of the population being quickly inactivated, whereas the second fraction appears to be much more resistant [18]. The pattern of inactivation kinetics is also influenced by pressure, temperature, and composition of the medium [66]. For a broader use of high pressure in food processing, it is of special interest to determine the process conditions for pressure pasteurization in view of industrial applications [18]. To increase microbial safety and ensure microbial stability of foods processed by high pressure, the pressure treatment must ensure a satisfactory reduction in the initial microbial counts, thus kinetic analysis and the pressure dependence of microbial-inactivation rates are needed.

Several scientific reports [54, 60, 79] demonstrate the efficacy of high-hydrostatic-pressure treatments against different microbial species. However, few of them reported kinetic data, which would be necessary for product and process design. For low-acid foods in particular, the kinetic information for pathogenic bacteria and spores will be indispensable in terms of food safety. The kinetic nature of high-pressure inhibition and inactivation may be different from that detected in heat treatment and other food-processing methods. Deviations from first-order kinetics, occurrence of survivor "tails" in death kinetics, and the possibility of cell recovery after pressurization have been observed [52, 53].

Earnshaw [52] stated that there is clear evidence from his and other laboratories that pressure-mediating death is not first order, and inactivation curves often present pronounced survivor tails. Thus the *D* and *z* concepts commonly used in thermal processing cannot be usefully applied to describe pressure processes. However, there is a difference with heat-treatment kinetic evaluation and sampling, and therefore the survivor enumeration is not continuous. Determination of microbial pressure-inactivation kinetics depends on pressure increase and decrease rates since it includes a decompression step to perform sampling. The pressure increase and decrease are not always reported, and the come-up time to reach the pressure is therefore not always taken into account in the logarithmic representation of the number of survivors. Cheftel [18] also mentioned that some publications do not precisely and fully indicate the experimental variables such as pressure, temperature, and time conditions. Moreover, Earnshaw [52] notes that in experiments that evaluate high-pressure-inactivation kinetics, the starting population must always be given. Cheftel [18] suggested that only inoculation with high numbers of a specific strain permits precise determination of the extent of inactivation as a function of processing conditions.

In many reported survival curves, it is unclear if time-zero experiments are growth controls without pressure treatment or are pressure treatments that only take into account the come-up time to reach the pressure level. Figure 49.7 presents the come-up times for pressure treatments ranging from 241 to 517 MPa [90]; the time to release the pressure was less than 15 seconds. The pressure come-up times exert an important

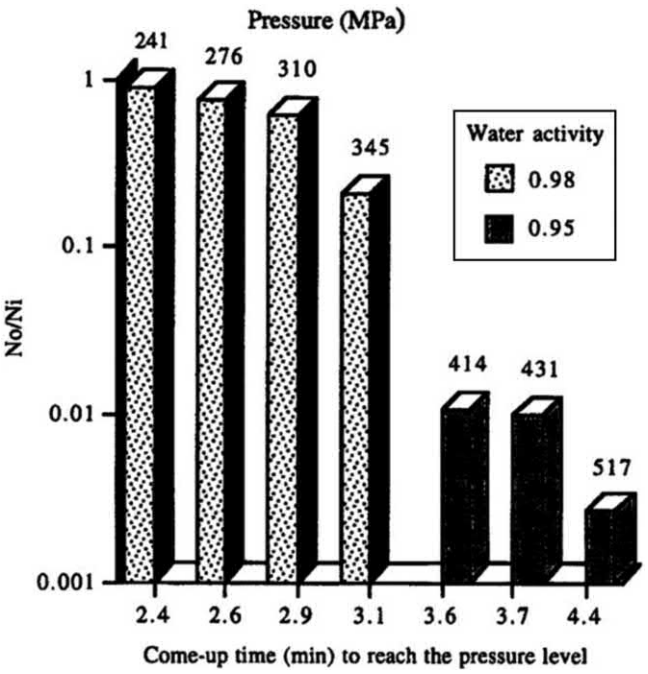

FIGURE 49.7 Effect of initial water activity (a_w), pressure, and pressure come-up time on *Zygosaccharomyces bailii* initial population reduction (N_o/N_i). N_o = yeast count (cfu/ml) after the come-up time for the working pressure; N_i = yeast initial population (cfu/ml). (From Palou et al. [90].)

effect on the yeast survival fraction. *Z. bailii* counts decreased as pressure increased, and at pressures greater than 414 MPa, 2 log cycle reductions were observed. Cheftel [18] reported that the rate of pressure increase and decrease is often neglected as an experimental variable in high-pressure microbial-inactivation studies, and the initial population (N_1) can be notably reduced during the come-up time (Figure 49.7). Palou et al. [90] reported an important effect of the come-up time at pressures of 345 and 517 MPa on *Z. bailii* log reductions in a food model system (a_w 0.98 and 0.95; pH 3.5), furthermore, total inhibition of the initially inoculated cells was achieved when only the time to reach 689 MPa was applied. Therefore, the effects of the rate of pressure increase and decrease need to be evaluated and reported.

Palou et al. [90] observed first-order kinetics for *Z. bailii* inoculated in food model systems with pH 3.5 and a_w 0.98 and 0.95. The logarithm of the survival fraction decreased linearly with time, and yeast cells were inactivated more rapidly with increasing pressure treatments (Figure 49.8). The experimental points with a pressure treatment duration of "0 minutes" express the effect of the come-up time to reach the working pressure and correspond to the initial population (N_o) for the kinetic analysis. Hashizume et al. [68] observed that pressure inactivation kinetics for *S. cerevisiae* at 25°C and a_w 0.99 follows a first-order kinetic model. The death velocity constants or inactivation rates (k) can be calculated from the reciprocal of the slope of the survival curves following a traditional kinetic analysis. Table 49.4 presents the velocity constants reported by Palou et al. [57] for *Z. bailii* and those calculated from the data reported by Hashizume et al. [68]. As can be seen, the k values suggest that *S. cerevisiae* is more pressure-resistant than *Z. bailii*. To compare the effectiveness of pressure treatments and to optimize process conditions, the calculation of D values can be used to compare the resistance

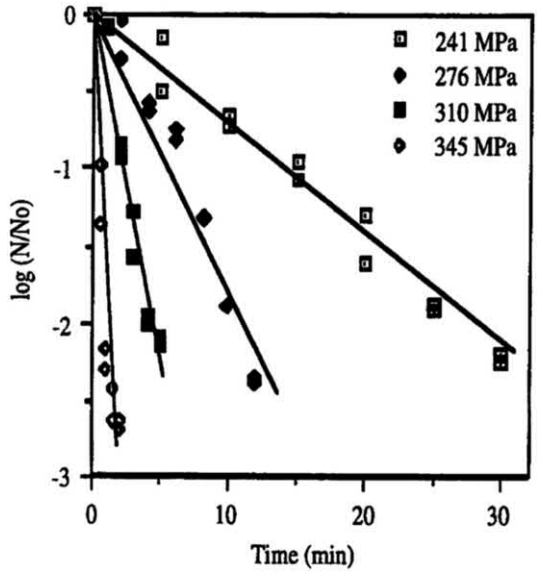

FIGURE 49.8 First-order pressure-inactivation kinetics of *Zygosaccharomyces bailii* in a laboratory model system with water activity 0.98 and pH 3.5. (Adapted from Palou et al. [90].)

of microorganisms. By analogy, with the analysis of thermal destruction or inactivation of microorganisms, a decimal reduction time (D value) can be defined as the time needed to reduce 90% the initial population and can be calculated as $D = 2.303/k$.

Calculated D values for *Z. bailii* [90] and *S. cerevisiae* [68] are presented in Table 49.4. Other reports detected first-order inactivation rates and decimal reduction times for bacterial inactivation with high hydrostatic pressure. Carlez et al. [64] observed that the number of surviving *Pseudomonas fluorescens*, *Citrobacter freundii*, and *Listeria innocua* inoculated in a minced meat product decreased exponentially with process time. Carlez et al. [64] reported decimal reduction times at 20°C of $D_{230\,MPa} = 14.7$ minutes for *C. freundii*, $D_{250\,MPa} = 23.8$ minutes for *P. fluorescens*, and $D_{230\,MPa} = 6.5$ minutes and $D_{360\,MPa} = 5$ minutes for *L. innocua*. Smelt and Rijke [67] reported first-order kinetics for high-pressure inactivation of *E. coli* in a physiological saline solution at 20°C, with D values of 25.9, 8.0, 2.5, and 0.8 minutes for treatments at 200, 250, 300, and 350 MPa, respectively. The pressure resistance of microorganisms depends on the type of microorganism and composition of the suspension media. Many factors that could affect the microbial response under high-pressure treatments, such as temperature, gas solubility, ionic strength, pH, and cavitation, are also modified by pressure. Thus, the microbial inactivation curves that can be obtained during a high hydrostatic pressure treatment also depend on these factors.

Figure 49.9 presents the fit of the experimental data obtained from Palou et al. [57] and Hashizume et al. [68] to Equation (49.1). The positive slope obtained from the plots of pressure inhibition rates (ln k) versus pressure, and therefore a negative activation volume, indicates that a decrease in

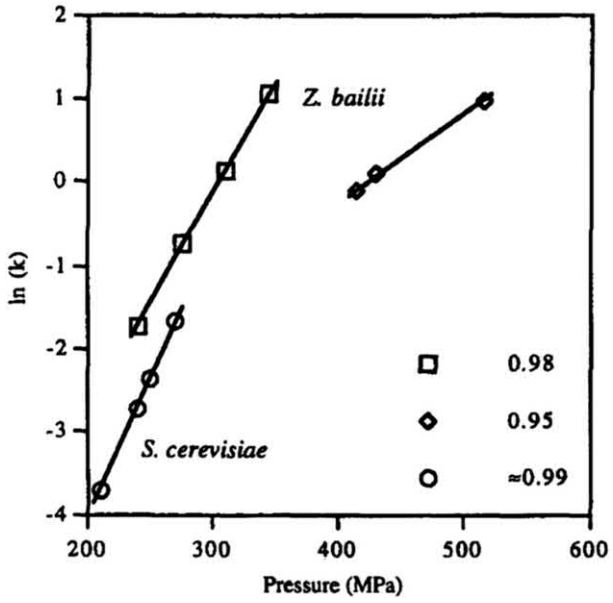

FIGURE 49.9 Effect of pressure and initial water activity on the inactivation rate (k) of *Zygosaccharomyces bailii* at 21°C and *Saccharomyces cerevisiae* at 25°C. (Adapted from Hashizume et al. [68].)

volume is related to the yeast-inhibition process. The activation volumes reported by Palou et al. [57] are presented in Table 49.5. The values obtained are quite different between system compositions and between yeast species. The apparent ΔE_v, calculated considering the activation process of microbial inhibition as one step, indicates the volume variation between the "activated complex" and initial states of the yeast pressure inhibition "reaction" [90]. A negative activation volume represents a reaction favored by increased pressure, so a reaction with a greater absolute ΔE_v value indicates that increments in pressure can accelerate the response, in this case the yeast inactivation rate.

A "pressure z value" can be defined as the pressure increment needed to reduce or increase the *D* value by a factor of 10 and is calculated as the reciprocal of the slope in a plot of log *D* versus pressure. Table 49.5 also presents z values for *Z. bailii* in food model systems at a_w 0.95 and 0.98 [90]. The z value for yeast inactivation in media with a_w 0.98 was 2.6 times smaller than that obtained for media with a_w 0.95, showing that *Z. bailii* was more pressure sensitive in the former condition. These results indicate that the composition of the media influences the microbial response under high-hydrostatic-pressure treatments and demonstrates the baroprotective effect of high sugar concentration or reduced a~ reported by several authors [49, 57, 68, 70, 73, 91]. The z value (68 MPa) calculated from the data reported by Hashizume et al. [68] indicates that *S. cerevisiae* is more sensitive to changes in pressure than *Z. bailii*, which can be attributed to response differences between microorganisms to high-pressure treatments and composition of the suspension medium.

In biological systems, the volume changes associated with ionization can be involved in the mechanism of microbial inactivation [57]. Enhanced ionization under high-pressure treatments is reported for water and acid molecules [52]. Palou et al. [57] mentioned that in the conditions of their work, and knowing that during pressurization a decrease in the pKa of the acids and pH reduction is expected, a temporary reduction in pH and an increase in the dissociated form of the acid can be present during pressurization. The pH changes could enhance the effects of high-pressure treatments on microorganisms and favor the first-order kinetics observed for pressure inactivation of *Z. bailii*.

In several process conditions and different microorganisms, the inactivation curves do not follow a first-order kinetics pattern [52, 53, 63, 79]. Figure 49.10 presents a comparison of high-pressure treatments at 20°C for *Yersinia enterocolitica* suspended in a pH 7.0 phosphate buffer [53]. Similar exponential decay curves have been reported for *E. coli*, *L. monocytogenes*, *S. typhimurium*, and *S. enteritidis* by the same authors at relatively high pressures. As can be seen for treatments at 275 and 300 MPa, the survival curves cannot be described by linear relations; various authors have proposed

TABLE 49.5

the logistic model to describe this pattern. However, the reliability of the logistic model for other organisms under different conditions and process variables needs to be investigated [92]. If the logistic model describes the experimental data, the time required to reduce the initial population by a factor of 10 (D value) can be calculated and used as a comparison parameter.

There are a number of possible theories to explain the tail effect [52]: tailing is a normal characteristic associated with the inactivation or resistance mechanisms, is independent of the mechanisms of survival and/or inactivation, and is the result of microbial population heterogeneity or is the result of experimental errors. Another possible reason for tailing is microbial adaptation and recovery during and after pressure treatment.

49.4.4 High-Pressure Mechanism of Action

In the inactivation of microorganisms by high pressure, the membrane is the most probable key site of disruption [53]. Inactivation of key enzymes, including those involved in DNA replication and transcription, is also mentioned as a possible inactivating mechanism [4]. The lethal effect of high pressure on vegetative microorganisms is thought to be the result of a number of possible changes taking place simultaneously in the microbial cell [53]. Shimada et al. [93] suggested that the structural impact of the high hydrostatic pressure on yeast cells occurred directly in the membrane system, particularly in the nuclear membrane. Besides membrane damage, a decrease in pH due to the enhancement of the ionic dissociation resulting from electrostriction (pressure causes the separation of electrical charges because the electrical charges "organize" water molecules around them, with a resulting decrease in the total volume of the system) during high-pressure treatments was reported by Cheftel [18]. Smelt [94] observed that the intracellular pH decreased under pressurization and associated the pH drop with the loss of ATPase activity and the reduction of the proton efflux from the cell interior. Knorr [16] reported that the reduced Na/K ATPase activity during and after pressurization can be related to a decrease in the bilayer membrane fluidity. Smelt [94] postulated that to maintain the internal pH homeostasis, membrane-bounded ATPase acts as an ion pump. High pressure can denature the enzyme or cause a dislocation in the membrane, thus microbial cells could die by internal acidification.

Microbial death is attributed to permeabilization of the cell membrane after a high-pressure treatment [3]. Pressure affects several biochemical reactions, and this kind of disturbance may be attributed to volume changes during compression, thus any biological process would be affected when high pressure is applied [4]. Farr [3] established that protein denaturalization can be attributed to changes in the chain conformational arrangement. Water pH is reduced from 7.00 (0.1 MPa and 25°C) to 6.27 when 101 MPa is applied [75], and water volume is also reduced as shown in Figure 49.5. These effects can also contribute to microbial inactivation by high pressure.

High-hydrostatic-pressure treatments can alter the membrane functionality such as active transport or passive permeability, and therefore perturb the physicochemical balance of the cell [95]. The physical state of the lipids that surround membrane proteins plays a crucial role in the activity of membrane-bound enzymes, and there is considerable evidence that pressure tends to loosen the contact between attached enzymes and membrane surfaces as a consequence of the changes in the physical state of lipids that control enzyme activity [20]. Jaenicke [96] reported that pressures in the range of 101–304 MPa denature several enzymes and treatments at 304 MPa make the phenomena irreversible. The activity of succinate, formate, and malate dehydrogenases in *E. coli* decreases with an increase in pressure. The dehydrogenases are completely inactivated when subjected to a pressure of 100 MPa for 15 minutes at 27°C [97]. Thus, the microbial inactivation mechanism by high pressure can be attributed, at least partially, to enzyme inactivation [4].

Perrier-Comet et al. [95] observed that yeast cell volume variations during a pressure treatment at 250 MPa for 15 minutes can be divided into three phases. A first phase of volume decrease occurs during the come-up time to reach the pressure; a second phase occurs during the holding time when the cell volume still decreases although pressure remains constant. The volume decrease is attributed to mass transfer between external and cellular media. A third phase of volume variation is attributed to membrane compression. The initial cell volume was not recovered during decompression or after returning to atmospheric pressure. An irreversible mass transfer (mainly water) occurs during the holding time of a pressure treatment.

High-pressure treatment also induces morphological changes in microbial cells. Separation of the cell wall and disruption in the homogeneity of the intermediate layer between the cell wall and the cytoplasmic membrane occur. Isaacs et al. [63] demonstrated with electron microscopy studies that ribosomal destruction in cells of *E. coli* and *L. monocytogenes* results in metabolic malfunctions that can cause cell death. Mackey et al. [98] also observed by electron microscopy that the nuclear material appearance changes considerably in *L. monocytogenes* and *Salmonella thompson* after being treated at 500 MPa for 10 minutes. Hayakawa et al. [86] reported morphological changes in the *B. stearothermophilus* spore surface after pressurization for six cycles of 5 minutes each under 600 MPa at 70°C and observed that every spore was completely ruptured after this process. These observations were attributed to a weakening of the physical strength of the spore coat and rupture of the coat as a result of the pulsed pressure treatment. For *Schizosaccharomyces pombe*, after a treatment at 100 MPa the nuclear membrane was damaged and fragmented [99]. In the same study, a pressure treatment above 250 MPa dramatically changed the cytoplasmic substance, the cellular organelles could hardly be detected, and the fragmented nuclear membrane was barely visible. The outer cell shape, observed by scanning electron microscopy (SEM), of *S. cerevisiae* was almost unaffected by high-pressure treatments up to 300 MPa, but at pressures higher

than 500 MPa there was disruption and damage to the cell wall [93]. Transmission electron microscopy (TEM) revealed that the inner structures were damaged, especially the nuclear membrane, even at 100 MPa [93]. The damage profile of high-pressure treatments revealed that *S. pombe* cells were more affected at low pressure stresses than were *S. cerevisiae* cells [99].

Isaacs et al. [63] observed that pressure treatments at 200–400 MPa cause leakage of ultraviolet (UV)-absorbing materials from *E. coli* cells. Shimada et al. [93] reported that leakage of intracellular UV -absorbing substances from *S. cerevisiae* began to be released at relatively low pressures (100 MPa). When pressure was 200 MPa for 10 minutes, the leakage gradually increased. Leakage of internal substances was related to cell viability, and at 300 MPa most of the *S. cerevisiae* cells were inactivated, corresponding to the great concentration of UV-absorbing substances. This can be attributed to increased permeability and fluidity, and might also provide evidence about the mechanism of high-pressure inactivation [100].

To explain the response of microorganisms to different pressures, high-pressure effects on several biological molecules have been studied; protein denaturation, lipid phase change, and enzyme inactivation can perturb the cell morphology, genetic mechanisms, and biochemical reactions. However, the mechanisms that damage the cells are still not fully understood [95].

49.5 EFFECTS ON ENZYMES

Exposure to high pressure may activate or inactivate enzymes. Pressure inactivation of enzymes is influenced by pH, substrate concentration, the subunit structure of the enzyme, and temperature during pressurization [4]. Pressure effects on enzyme activity are expected to occur with the substrate–enzyme interaction. If the substrate is a macromolecule, then the effects may be on the conformation of the macromolecule, which can make the enzymatic action easier or more difficult [20]. Pressure enzyme inactivation can also be attributed to an alteration of intermolecular structures or conformational changes at the active site. Inactivation of some enzymes pressurized to 100–300 MPa is reversible. Reactivation after decompression depends on the degree of distortion of the molecule. The chances of reactivation decrease with an increase in pressure beyond 300 MPa [96, 101].

Earnshaw [8] mentioned that of particular significance is the apparent lack of pressure effect on some food enzymes, including those that affect food quality, such as proteases, lipases, esterases, and oxidases. Some enzymes, such as phosphatase, are relatively pressure-sensitive and can be inactivated by pressures in the range of 400–800 MPa. The enzymes alkaline phosphatase and lactoperoxidase have been successfully used as process markers in milk heat treatments. Quality control markers such as these enzymes will be needed for high-pressure processing of dairy products. Figure 49.11 presents the effect of 20-minute pressure treatments on alkaline phosphatase in raw milk; the enzyme activity decreases

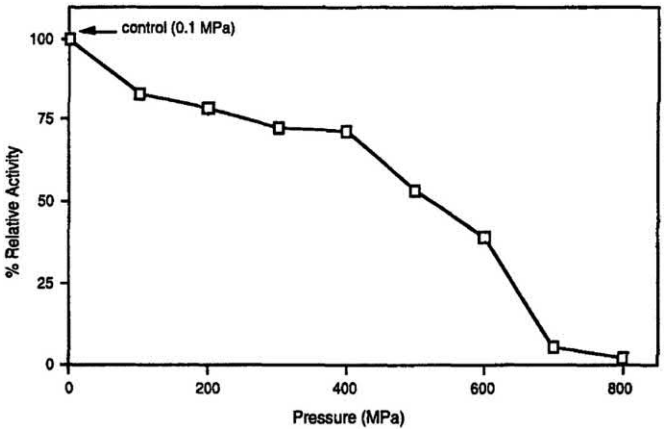

FIGURE 49.11 Relative activity of enzyme alkaline phosphatase in raw milk after 20 minutes of pressure treatment. (Adapted from Johnston [117].)

as the pressure level increases. However, there is a need to establish microbial-quality marker relations to ensure, for example, the destruction of *Mycobacterium tuberculosis* [24].

Heremans and Heremans [102] reported that chymotrypsin is an enzyme that exhibits a pressure-induced conformational change. Its optimal activity is at neutral pH, and the activity disappears at pH 10, which is attributed to rupture of the salt bridge in the vicinity of the active site. Raman spectroscopy studies indicated that pressure inactivates the enzyme due to the destabilizing effects of pressure on the salt bridge and revealed that below 400 MPa the conformational change is reversible [102].

Homma et al. [103] mentioned that high hydrostatic pressure is one of the new technologies that can be used for tenderizing meat or accelerating meat conditioning. Pressure induces changes in the muscle that could be derived from the physical force and/or increase in the proteolytic activity of meat enzymes. The proteolytic activity of enzymes in meat is enhanced by the application of high pressures [103]. The total activities of cathepsin B, D, L, and acid phosphatase in the muscle increase when subjected to pressures ranging between 100 and 500 MPa for 5 minutes at 2°C. Cathepsin H and aminopeptidase B are resistant to pressure treatment. An increase in the activity of cathepsin B1 may account, in part, for the tenderization of meat by pressure-heat treatment [104]. Ashie et al. [105] reported a reduction in the proteolytic activity of fish muscle enzymes with increasing pressure in the range of 100–300 MPa (30 mm) and increasing crude inhibitor (α_2-macroglobulin) concentration (0.1–0.3%) at constant pH (5.5, 6.0, or 6.5). The combination of treatments could enhance the texture of fish muscle, since it favors the inactivation of proteolytic enzymes. This kind of result could have widespread use in surimi and other minced fish products, which have the problem of undesirable protease activity resulting in gel softening.

Enzymes are generally inactivated in vegetables by hot water blanching. Disadvantages of blanching include thermal damage, leaching of nutrients, and possible environmental

pollution due to the production of high biochemical oxygen demand effluent. High-pressure treatment can fulfill the requirements of hot water blanching while avoiding mineral leaching and accumulation of wastewater. High-pressure treatment produces less effluent because less water is required than in hot water blanching [106]. Quaglia et al. [107] reported that pressure treatment at 900 MPa for 10 minutes reduces the peroxidase activity 88% in green peas comparable to traditional water blanching. However, the pressurization treatment resulted in greater ascorbic acid and firmness retention. Lower pressure levels decreased the enzyme activity less than 50%, even when pressure was combined with moderate temperatures (39–60°C). Anese et al. [108] also observed in peroxidase from a carrot cell-free extract that a complete loss of enzyme activity was achieved only when the pressure treatment was applied at 900 MPa for 1 minute. Enzyme activation was observed for treatments in the range of 300–500 MPa. For polyphenoloxidase (apple cell-free extract) it was observed that at pH 7.0, 5.4, and 4.5 a significant reduction in enzyme activity occurred in pressure treatments at 900 MPa for 1 minute. For both enzymes a pH dependence on residual activity after the pressure treatment was observed. Eshtiaghi and Knorr [106] reported that the addition of citric acid could lead to increased polyphenoloxidase inactivation since pH reduction enhances the pressure effects on enzyme inactivation. Denaturation and inactivation of enzymes occur only when very high-pressure treatments are applied; the activation effects that could be presented at relatively low pressures could be attributed to reversible configuration and/or conformation changes on enzyme and/or substrate molecules [108, 109]. Seyderheim et al. [110] evaluated the effects of high-hydrostatic-pressure treatments on selected enzymes including catalase, phosphatase, lipase, pectinesterase, lypoxygenase, peroxidase, polyphenoloxidase, and lactoperoxidase, and reported that peroxidase was the most barostable enzyme with 90% residual activity after 30-minute treatment at 60°C and 600 MPa. Therefore, peroxidase could be used as an enzyme indicator for high-pressure treatments.

Pressurization at 100 and 200 MPa causes hardly any inactivation of pectinesterase [70]. Pectinesterase in juices such as Satsuma mandarin juice is inactivated when pressurized to 300–400 MPa. Purified pectinesterase is also inactivated at pressures of 300 MPa or higher. The inactivation is irreversible, and the pectinesterase is not reactivated during storage at 0°C or transportation. The activity of pectinesterase from mandarin juice remains at low levels during 90 days of storage at 0°C after pressure treatments at 400–600 MPa. Soluble solids such as sugars, proteins, and lipids exert a protective action against pectinesterase inactivation by high pressure or heat [70]. Polyphenoloxidase is often described as a soluble enzyme, localized mainly in the cytosol of plant cells, and is associated with particulate cell fractions [111]. It is well established that polyphenoloxidases from different sources may have different molecular sizes and conformations. Thus, it is expected that the polyphenoloxidases may respond differently during and following high-pressure treatments. It is also anticipated that important differences will occur when

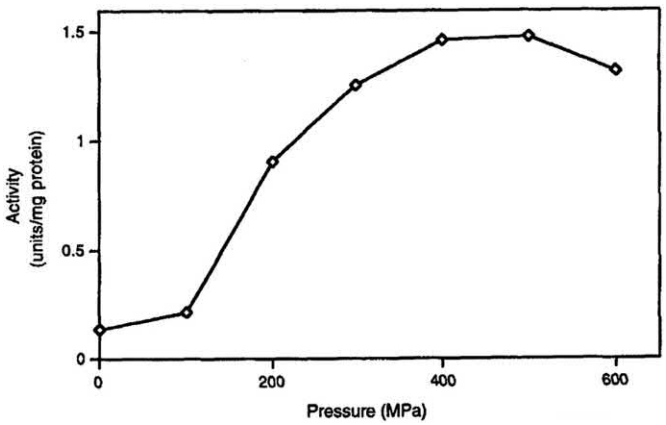

FIGURE 49.12 Activation of polyphenoloxidase from Bartlett pears by high pressure. (Adapted from Asaka and Hayashi [112].)

the enzyme activity is analyzed in whole foods, extracts, or commercial enzymes. In untreated onion cells, phenolic compounds are confined to vacuoles and spatially separated from the polyphenoloxidase by the tonoplast; after pressurization (>100 MPa) the cell and the tonoplast are disrupted and phenolic oxidation products are formed. Polyphenoloxidase is no longer separated from the substrate, and enzymatic browning begins [111]. The activity of polyphenoloxidase increases five times when slices of Bartlett pears are pressurized at 400 MPa and 25°C for 10 minutes (Figure 49.12). A further increase in pressure does not increase enzyme activity. On the other hand, pressurization of homogenates of apples, bananas, or sweet potatoes did not result in the activation of polyphenoloxidase [112]. Gomes and Ledward [113] reported a reduction in polyphenoloxidase activity from a crude potato extract with increasing pressure (400–800 MPa for 10 mm). In contrast, when the crude extract of mushroom was treated at 400 MPa for 10 minutes, an enhancement in the activity was observed. Pressures above 300 MPa inactivated polyphenoloxidase in apple slices [114]. Cano et al. [115] studied the combination of high pressure and temperature on peroxidase, polyphenoloxidase, and pectin methylesterase activities of fruit-derived products. Optimal inactivation of peroxidase in strawberry puree was achieved using 230 MPa and 43°C. Pressurization–depressurization treatments caused a significant loss of strawberry polyphenoloxidase up to 230 MPa. Combinations of high pressure and 35°C effectively reduced peroxidase in orange juice. The effects of pressure and temperature on pectin methylesterase activity in orange juice were similar to those for peroxidase. There is some evidence of changes in the enzyme–substrate interactions during pressurization and, therefore, changes in enzyme reaction kinetics. Some beneficial aspects of enzyme activation or reduced enzyme activity by high pressure can be used to retain or increase food quality.

49.6 CHEMICAL REACTIONS AT HIGH PRESSURE

The application of pressure influences biochemical reactions since most of these reactions involve a change in volume.

Hoover et al. [4] reported that pressure affects reaction systems in two apparent ways: by reducing the available molecular space and by increasing interchain reactions. Thus, reactions involved with the formation of hydrogen bonds are favored by high pressure since bonding results in a decrease in volume [4]. However, Masson [116] reported that hydrogen bonds are insensitive to pressure. Cheftel [18] mentioned that various biochemical studies indicate that pressures above 100–200 MPa often cause (i) the dissociation of oligomeric structures into their subunits; (ii) partial unfolding and denaturation of monomeric structures; (iii) protein aggregation, probably as a consequence of unfolding; and (iv) protein gelation if protein concentration and pressure are high enough.

The functional properties of biological molecules are usually dependent on conformation and conformational changes. The interactions between solvent and solute molecules and inter- and intramolecular interactions of the solute are influenced when subjected to pressure. Therefore, either beneficial or detrimental changes can be produced as a result of a high-pressure treatment [117]. Hydrogen bonding, which stabilizes protein structures (α-helix and β-pleated sheets), is influenced by pressure, but to a lesser extent than ionic or hydrophobic interactions. Hydrogen bond formation results in the shortening of interatomic distances with the corresponding volume decrease and is, therefore, enhanced by high pressure [117].

49.6.1 Structural Change in Protein

High pressure can denature protein molecules. Pressure denaturation of proteins is a complex phenomenon depending on the protein structure, pressure range, temperature, pH, and solvent composition. Oligomeric proteins are dissociated by relatively low pressures (200 MPa), whereas single-chain protein denaturation occurs at pressures greater than 300 MPa. Pressure-induced denaturation is sometimes reversible, but renaturation after pressure release may take a long time. Protein denaturation becomes irreversible beyond a given pressure threshold, which depends on the protein, or at high protein concentrations that enhance aggregation [18]. Figure 49.13 presents a schematic diagram illustrating the effect of temperature on the denaturation of proteins. This kind of diagram delimits regions where the protein is active or denatured; at high temperature, pressure stabilizes the protein against temperature denaturation [18, 20]. Heremans [20] mentioned that the fact that one can "cook" an egg with pressure is the result of the unique phase diagram of proteins. There is evidence that a similar phenomenon occurs with other biomolecules such as polysaccharides [20, 118], microorganisms and bacteriophages [119], and phospholipids [20].

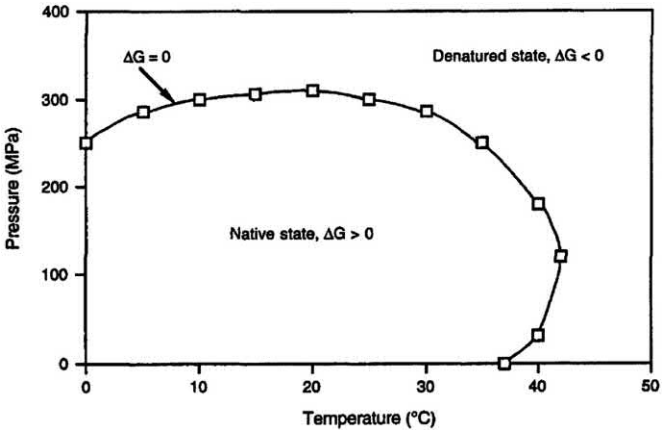

FIGURE 49.13 Schematic diagram illustrating the effect of temperature and pressure on the denaturation of proteins. (Adapted from Heremans [20].)

Pressure may affect the secondary, tertiary, and quaternary structure of proteins. The main targets of pressure are the electrostatic and hydrophobic bonds in protein molecules. High pressure causes deprotonation of charged groups and disruption of salt bridges and hydrophobic bonds, thereby resulting in conformational and structural changes of proteins. Structural transitions are accompanied by large hydration changes. Hydration changes are the major source of volume decreases associated with dissociation and unfolding of proteins [116]. Hydrophobic interactions in proteins can be either disrupted or stabilized according to the magnitude of the applied pressure [24]. The disruptive effect of high hydrostatic pressure on the ionic and hydrophobic interactions and hydrogen bonds of milk casein micelles would allow independent movement of micelle fragments along with caseins and calcium phosphate [24] and cause a conformational change in proteins. In fresh milk, casein micelles are large complex structures consisting of many molecules of different individual caseins and calcium phosphate, maintaining structural integrity. The structural and spatial distribution changes to the micelle components during pressurization would prevent recovery of the micelle original structures after high-pressure treatment [24].

Exposure to high pressure unfolds protein molecules. Unfolding results in alterations of the functional properties of the protein [24]. Foaming, emulsifying, gelling, and water-binding capacity of proteins may be influenced. Proteins treated with high pressures may lead to the development of a range of functional food ingredients prepared from food proteins by controlled unfolding [24]. It is well known that pH and ionic strength influence protein aggregation and gelation under heating conditions; this is also observed when protein solutions are subjected to high hydrostatic pressure. Cheftel [18] mentioned that it is likely, yet not fully demonstrated, that protein aggregation and gelation occur under pressurization as well as after pressure release.

Yogurts (without addition of milk powder) are improved by HP with a high-water retention capacity and without syneresis during storage, and an improved texture as compared to conventionally processed yoghurt. The microstructure and texture of cheeses are improved by retaining whey with higher protein interactions, and partial disruption or aggregation of casein micelles [120].

Low-protein wheat flour does not positively affect the quality of final products of noodles and bread. Lee and Koo [121] observed that high hydrostatic pressure (150 MPa) improved the physicochemical characteristics (i.e., water holding

capacity, and viscosities) of blended low-protein wheat and oat flour, and improved quality (i.e. hardness, gumminess and chewiness) of produced noodles.

49.6.2 Structure in Lipids

Other food components that can be affected by high-pressure treatments are lipids. Ohshima et al. [122] observed that in cod muscles exposed to high-pressure treatments in the range of 202 to 608 MPa for 15 and 30 minutes, the peroxide value of the extracted oils increased with increasing pressure and processing time. The presence of fish muscle accelerates the lipid oxidation after high-pressure treatments, while the isolated oil extract was relatively stable against autoxidation in treatments up to 608 MPa [123]. Cheah and Ledward [124] observed the effects of high-pressure treatments on lipid oxidation in rendered pork fat. Pork samples treated at 800 MPa for 20 minutes and stored at 50°C presented a shorter induction time for lipid oxidation and greater peroxide and TBA (2-thio-barbituric acid) values than untreated pork samples. When pork was stored at 25°C the induction periods were longer than at 50°C, and at 4°C after 8 months of storage the peroxide value was higher than in the untreated samples.

The effects of a_w were also evaluated by Cheah and Ledward [124], who reported that after 4, 6, and 8 days of storage at 50°C, the lipid oxidation in terms of peroxide and TBA values of high-pressure-treated (800 MPa, 20 mm) pork fat was inhibited to some extent at a_w values higher or lower than 0.44. In another study, Cheah and Ledward [125] reported that pressure treatments had little effect on lipid oxidation of minced pork, in terms of TBA value, below 300 MPa but increased proportionally at higher pressures. Pressure treatments in the range of 300–400 MPa appear to be critical for inducing marked changes in pork meat; many structural changes are induced at these pressures. These results may restrict the application of high-pressure technology for meat-based products due to induced oxidation, at least in the mentioned pressure range.

Fat crystallization by high-hydrostatic-pressure treatments is another interesting aspect to be considered. Buchheim and Abou El-Nour [126] observed that fat crystallization increased with the extent of the pressure treatment; maximum changes were found in the pressure range of 300–350 MPa. Dumay et al. [127] stated that this behavior can be used for aging ice cream mixes and physical ripening of dairy cream in butter making. These can be considered as potential applications of high-pressure technology.

49.6.3 Maillard Reaction

The application of high-hydrostatic-pressure treatments, in combination with moderate or elevated temperatures, may influence chemical reactions inherent to food systems such as the Maillard reaction. This reaction, which is manifested by the development of brown color in many processed foods, is known to be highly pH and temperature-dependent. However, few studies have dealt with the effects of high pressure on the Maillard reaction. Tamaoka et al. [128] reported that brown color development was inhibited at pressures in the range of 200–400 MPa in xylose-lysine systems (pH 8.2) when heated at 50°C. They also pointed out that Maillard reactions involving xylose-lysine, xylose-β-alanine, or glutaraldehyde β-alanine are inhibited by high-pressure treatments. Hill et al. [129] compared the rate of browning of glucose-lysine systems at 50°C, in the pH range of 5.1–10.1, with and without the application of high pressure at 600 MPa. Hill et al. [129] reported that at initial pH of 8.0 or 10.1, pressure enhances browning, while at pH 6.5 and 5.1 the effect is the opposite. At 600 MPa the rate of browning was significantly reduced. These observations were attributed to the pH decrease in the systems during pressurization. At pH 6.5 and 5.1 the system buffer capacity is due to the carboxylic acid group of the amino acid, and decreases of about 1.2 pH units occurred. Hill et al. [129] also demonstrated by high-performance liquid chromatography (HPLC) and UV spectra that the composition of the reaction products is similar in samples with the same intensity of browning, whether the samples were treated with high pressure or not. Acid hydrolysis of proteins is enhanced under high-pressure treatment, whereas hydrolysis of corn starch and locust bean gum is unaffected [12, 130]. Pressure treatments at 392–490 MPa at temperatures of 45–50°C enhanced the susceptibility of wheat, corn, and potato starches tα-amylase action [30].

49.6.4 Gelation and Gelatinization Processes

Phase changes in proteins and lipids are accompanied by the application of high pressure; these modifications offer opportunities to develop new products with unique rheological properties [8]. The structure of food proteins and polysaccharides can be changed by high-hydrostatic-pressure treatments and confer different rheological properties and mouthfeel. Earnshaw [8] explained that some Japanese researchers claim that these changes are desirable and that the gel quality of surimi can be improved with high-pressure treatments.

The process of gel formation is the macroscopic consequence of the denaturation, on a molecular level, of proteins and other biomacromolecules such as polysaccharides. The denatured state forms a gel or a precipitate, depending on the physical and chemical environmental characteristics.

Egg yolk subjected to a pressure of 400 MPa for 30 minutes at 25°C forms a gel. While a pressure of 500 MPa renders egg white partially coagulated and opaque, a pressure of 600 MPa causes complete gelation. Pressure-induced gels of egg white possess a natural flavor, displaying no destruction of vitamins and amino acids, and are more easily digested when compared to heat-induced gels. The gels retain the original color of the yolk or the white and are soft, lustrous, and adhesive when compared to heat-induced gels. While the strength of the gels increases, the adhesiveness decreases with an increase in the applied pressure. However, the hardest gel formed by high-pressure (500 MPa) treatment exhibits one-sixth the strength of heat-induced gels. Gumminess of pressure-induced gels is considerably less than gumminess

of heat-induced gels. Gels of egg white produced at 600 and 700 MPa deform readily without fracture. Cohesiveness of pressure-induced gels increases with increases in applied pressure. The force deformation curves of pressure and heat-induced gels of egg yolk and egg white are presented in Figure 49.14 [131]. Ibarz et al. [132] studied the viscoelastic characteristics of egg gels formed under several high-hydrostatic-pressure conditions. For egg yolk samples, gels were formed at pressures above 500 MPa, while for whole egg and egg white samples, gels were formed at pressures over 600 MPa. During amplitude sweep and frequency sweep tests storage modulus ′G and loss modulus "G of gels increased when the treatment pressure increased. ′G was greater than "G in every case studied. ′G values for boiled egg gels were greater than for pressurized gels.

In Japan, a hydrostatic pressure of 400 MPa is used to induce gelation of pollack, sardine, skipjack, and tuna-based surimi. Squid-based surimi is obtained by pressurization of extracted muscle protein at 600 MPa. Pressure-induced surimi gels are organoleptically superior to heat-induced surimi gels [3]. Gelation can be used for adhesion-binding of small size muscles or fish fillets, restructuring of minced fish or deboned meat, and molding of surimi or pieces of gelled surimi into seafood analogs. The possibility of obtaining acceptable gels simultaneously with commercial sterilization at a temperature as low as 0°C is of tremendous practical interest to the surimi industry [34].

The mechanism of high-pressure-induced gelation is different from heat-induced gelation. Gelation by high-pressure treatment is attributed to a decrease in the volume of the protein solution. On the other hand, the application of heat results in violent movement of protein molecules leading to the destruction of noncovalent bonds, denaturation, and formation of a random network. The rearrangement of water molecules around amino acid residues in pressure-induced gels produces glossy and transparent gels compared to opaque gels obtained by high temperatures [131].

Heremans [20] mentioned that important differences in the mechanical properties for temperature- and pressure-induced gels are expected. Hayashi [40] reported that pressure-coagulated food proteins, i.e., egg, soy protein, beef, pork, and fish meat, are more glossy, transparent, dense, smooth, and soft compared to boiled ones. These unique textural properties obtained by the pressurization offer ways to create new food materials.

Gelatinization is the transition of starch granules from the birefringent crystalline state to a nonbirefringent, swollen state. Starch can be gelatinized using pressure or heat. The pressure at which starch gelatinizes depends on the source of starch. Gelatinization may be stimulated by increased temperatures of pressurization [133]. High-pressure may also produce an upward shift of gelatinization temperature of about 3–5°C per 100 MPa. Pressures higher than 150 MPa do not further enhance the gelatinization temperature. The effect of high pressure on gelatinization is due to the stabilization of hydrogen bonds, which maintains the starch granule in the original state [118]. High-pressure treatments on starches produce unique properties, which are different from those formed by heat gelatinization. Pressure-treated starches keep the granular structure intact, whereas heat treatment destroys starch granules and dissolves the starches to give transparent solutions [40].

49.6.5 Vitamin C and Bioactive Compounds Degradation

Su et al. [134] observed that the degradation of anthocyanin and visual color of bayberry juice increased with the increase of HP treatment (pressure: 400, 500, 600 MPa; temperature: 25°C; time: 5–10 min). When stored at 4°C, degradation of untreated and HP treated juice showed similar trends, whereas higher degradation was observed in the case of untreated juice when stored at 25°C. The activation energies (E_v) for anthocyanin and color were observed as –19.85 and –14.92 cm^3 $mole^{-1}$, respectively, and this indicated that anthocyanin was more pressure sensitive than the visual color parameter [134].

HP treatment can increase the extraction capacity of phenolic constituents during juice processing and generally their stability as compared to the untreated is enhanced during storage [135]. The increase in yield is due to enhanced release, mass transfer rates, increased cell permeability, and diffusion of phenolic compounds [136]. The bioactive compound extractability in onion (i.e., increased phenolic and antioxidant and no effects on vitamin C, 100–600 MPa, 1–3 min, 25°C) [136]; carrot (residual PPO 6.9–15.1%) and spinach (residual PPO 21.3–31.1%) (i.e., increased flavonoid and antioxidant) [137]; and strawberry, wild

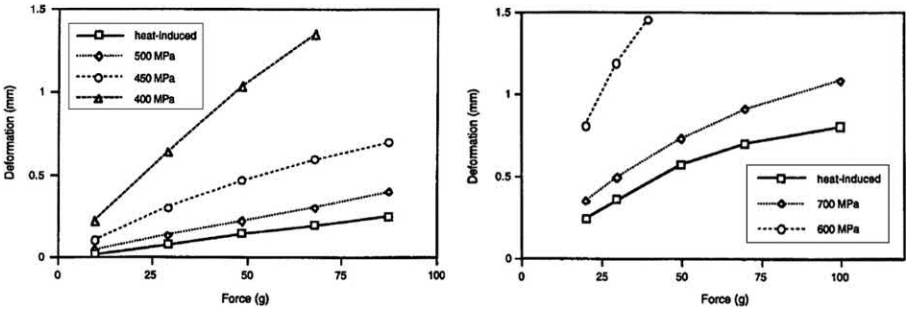

FIGURE 49.14 Force deformation curves of pressure- and heat-induced gels of egg yolk (left) and egg white (right). (Adapted from Okamoto et al. [131].)

strawberry, and pomegranate juice (i.e., polyphenol, anthocyanin and color pigments, 400–500 MPa, 25–50°C, 5–10 min) [138] are enhanced by HP processing. Purple sweet potato nectar treated with HP for a short time (400–600 MPa, 2.5–10.0 min) showed stability of total phenolic, anthocyanin, antioxidant, and color during storage. However, longer shelf life was observed when stored at 4°C as compared to 25°C [139].

HP processing better retained ascorbic acid and carotenoids in carrots and spinach (treated at 100, 300, and 500 MPa for 20 min) as compared to the thermal processing [137]. HP treatment caused a decrease of 10–15% of the initial vitamin C in the case of green pepper, while it increased 10–15% in the case of red peppers (100–200 MPa for 10–20 min) [140]. Similarly, stability of sulforaphane and phenylethyl isothiocyanate in broccoli juice increase in broccoli juice (600–880 MPa, 30–60°C) and these are thermo-labile and pressure stable [141].

49.6.6 Sensory Properties

The principal advantage of high-pressure technology is its relatively small effect on food composition and, hence, on sensory and nutritional attributes. Generally, pressure has little effect on food nutritional characteristics. However, more research is needed before solid judgments can be made [8]. Aleman et al. [142] studied the effect of high hydrostatic pressure on the natural flora present in fresh-cut pineapple. Treatments of 340 MPa for 15 minutes at –4°C, 21°C, or 38°C considerably reduced the initial counts of mesophilic bacteria, yeast, and molds, suggesting an increased shelf life in comparison with untreated pineapple samples. Alteration of the structure of starch and protein by high pressure can be utilized so that rice can be cooked in a few minutes [4]. Grapefruit juice manufactured by high-pressure technology does not possess the bitter taste of limonene present in conventional thermal-processed grapefruit juice [143]. Peaches and pears processed at 410 MPa for 30 minutes remained commercially sterile for 5 years [4]. Pressure treatment of nonpasteurized citrus juices provides a fresh-like flavor with no loss of vitamin C and a shelf life of approximately 17 months [3]. The internal structure of tomatoes becomes tough, tissues of chicken and fish fillets become opaque, and prerigor beef is tenderized [4]. Pressure has an influence on meat ultrastructure with similar changes to those observed during the age-conditioning of meat, therefore the juiciness and tenderness are affected [144].

The jams obtained by high-pressure processing retain the taste and color of fresh fruit, unlike the conventional jams produced by heat. In Japan, high-pressure processing is utilized for the manufacture of jams, marmalades, and sauces from strawberry, orange, and other fruits. The desired plastic container is filled with a mixture of raw materials consisting of fruits, fruit juice, sugar, and acidulants. The container is sealed and subjected to a pressure of 400–600 MPa for 1–30 minutes. Strawberry jam can be obtained by pressurization at 400 MPa for 15 minutes and strawberry puree by pressurization at 400 MPa for 10 minutes. Pressurization allows the permeation of sugar solution into the fruits as well as commercial preservation of the jam [145].

El Moueffak et al. [146] reported that duck foie gras pressurized at 50°C and 400 MPa for 10–30 minutes or at 300 MPa for 30 minutes presents attractive sensory characteristics, with less fat melting, softer texture, less cooked flavor, and a microbiological quality close to that obtained with traditional heat treatment. Pressure treatments up to 150 MPa did not change the sensory and instrumental color of minced beef muscle [65]. However, treatments for 10 minutes at pressures higher than 350 MPa turned the meat surface to a grayish tone, which corresponds to a decrease in the instrumental color a* value. The grayish tone was even more noticeable when 450 MPa was applied for 10 minutes.

Eshtiaghi et al. [147] observed that the color of dried green beans, carrots, and potatoes dried without pretreatment was dark due to enzymatic browning, while pressure or water-blanched pretreated vegetables retained an acceptable color. The pretreatments applied were water blanching in boiling water (carrot and green beans for 7 min and potatoes for 4 min) and pressure treatment at 600 MPa for 15 minutes at 70°C. The texture of dried and rehydrated pressure-pretreated green beans, carrots, and potatoes resulted in textures near that of raw vegetables.

Butz et al. [111] reported that diced onions subjected to high-hydrostatic-pressure treatments lose their typical pungency and characteristic odor due to an intense decrease in dipropyldisulfide content and an increase in 2-methyl-pent-2-enal. Dipropyldisulfide is the compound associated with the odor of fresh onion. Diced onions presented no major changes in appearance immediately after a 30-minute pressure treatment at 300 MPa and 25°C [111]. However, a slight glassy appearance, typical of steamed onions, was observed. In the same study, onions treated at 350 MPa and stored for 24 hours at 20°C exhibited an intense brown color. Onions treated at 300 MPa started to brown, whereas samples pressurized at 100 MPa remained unchanged. Any pressure treatment above 100 MPa induces browning of diced onions, and the rate of browning increases with increasing pressure. Microscopic evaluation of high-pressure-treated (300 MPa) onions revealed severe damage in the vacuoles of the epidermis cells, with the liberation of substrates for polyphenoloxidase activity [111].

Takahashi et al. [148] evaluated the effect of high-hydrostatic-pressure treatments on Satsuma mandarin juice and reported that juice pressurized up to 600 MPa for 5 or 10 minutes at 20–22°C did not change in chemical composition including soluble solids, acidity, amino nitrogen, vitamin C, and essential oil contents. The pressure-treated juices presented no off-flavor, and dimethyl sulfide, the characteristic compound found in off-flavor juices, was not detected. High-pressure-treated juices had very high scores in the sensory evaluation. Hayashi [40] reported some characteristics of food proteins treated by high-pressure technology: (i) Beef muscle pressurized at 400 MPa for 10 minutes looked like raw ham and the taste of pressurized beef was intact, even when the surface seemed slightly baked. (ii) In shrimp treated at 400 MPa for 10 minutes, no apparent changes in color or shape were observed. However, shrimp meat was coagulated as in boiled shrimp.

There are few studies regarding high-pressure effects on nutritional characteristics of pressure-treated foods. Elgasim and Kennick [149] reported that a pressure treatment at 103 MPa for 2 minutes improved the apparent digestibility of meat protein and had no adverse effect on the apparent biological value, net protein utilization, or protein efficiency ratio. A wide variety of effects and changes in food flavor, texture, physical appearance, and structure could result after the application of pressure, and these changes will depend on the type of food and its composition and structure.

Plant structures containing entrapped air will be affected by high pressure when the air volume is compressed. However, in some cases, the vacuoles and pores can be filled with the surrounding fluid, after which the material can maintain its structural integrity with increased density [8]. Adiabatic heating occurs in most food materials subjected to high pressure, and this is proportional to the compressibility of the food:air ratio. Entrapped air in the food matrix and cell vacuoles is very compressible and will increase the food or system temperature [8]. Some vegetable structures are resistant to pressure, while others can exhibit significant softening and severe color changes after pressurization. The effect of high-pressure treatments will depend on the kind of vegetable or fruit, physical characteristics, and maturity. Dumay et al. [127] evaluated the effects of high-hydrostatic-pressure treatments on the physicochemical characteristics of dairy creams and oil–water model system emulsions. Pressure treatments at 450 MPa did not affect the structure of the emulsions. Coalescence or emulsion breakdown was not observed. In the case of model emulsions, important rheological changes were observed, depending on the surface-active protein present and the effects of high pressure on unfolding and/or aggregation. Emulsions containing sodium casinate remained unchanged after treatment, while in those containin β-lactoglobulin the pressure treatment induced changes in their rheological behavior.

49.6.7 Volatile Formation

Chemical reactions in HP processing cause formation of different volatiles as compared to the thermal processing. In the case of carrot, Kebede et al. [150] studied the volatiles formation of thermal (heat sterilization and blanching) and HP–high-temperature treatments. They observed that the type of volatile varied as a function of treatment, and multivariate analysis could clearly classify the products based on the treatments. The volatiles from carrots are formed mainly by oxidative degradation and Maillard reaction. HP–high temperature enhanced oxidative degradation of terpenes, free fatty acids, phenylpropanoids, and carotenoids; and reduced Maillard reaction (i.e., lower furans) and Strecker degradation (i.e., lower aldehydes) products.

49.6.8 Low or Absence of Toxic Compounds

In many cases thermal treatment causes toxic compounds, such as acrylamide and furan. Furan (heterocyclic organic compound) is formed during thermal treatment of food products and it has been shown to be carcinogenic in animal laboratory studies [151]. Kultur et al. [80] studied the formation of furan during HP processing (pressure: 200, 300, and 400 MPa; temperature: 25°C, 35°C, and 45°C; treatment time: 5, 10, and 15 min) of vegetable-based infant food. At the end of processing the furan content in all HP-treated samples was found to be below the limit of detection. The allergenic effects of nuts could be reduced by HP treatment. HP treatment of walnuts (256 kPa, 138°C) were able to diminish the IgE cross-linking capacity more efficiently than heat treated walnuts [152]. HP treatment (200–600 MPa) showed any significant changes in the IgE binding in the case of beef extract [153], whereas bovine gamma globulin decreased [17]. In the case of apple allergen Mal d 3 neither thermal treatment alone (115°C) nor HP (700 MPa) alone caused any change, however, a combined treatment was most effective [154].

49.7 HIGH PRESSURE IN HURDLE TECHNOLOGY

The increasing demand for foods with reduced amounts of chemical additives and less physical damage is opening new opportunities for the hurdle-technology concept of food preservation [52, 56]. The commercial challenge of minimally processed foods provides a strong motivation to study food-preservation systems that combine traditional microbial stress factors or hurdles, while introducing "new" variables for microbial control, such as high pressure. High pressure presents unique advantages over conventional thermal treatments [76]. However, much of the reported data indicate that commercial pasteurization or sterilization of low-acid foods using high pressure is very difficult without using some additional factors to enhance the inactivation rate. Factors such as heat, antimicrobials, ultrasound, and ionizing radiation can be used in combination with high pressure. These approaches will not only help to accelerate the rate of inactivation, but can also be useful to reduce the pressure level and hence the cost of the process while eliminating the commercial problems associated with sublethal injury and survivor tails.

High pressure can be used to reduce the severity of the factors traditionally used to preserve foods. The use of high pressure in combination with mild heating has considerable potential [53]. Studies have shown that the antimicrobial effect of high pressure can be increased with heat, low pH, carbon dioxide, organic acids, and bacteriocins such as nisin [57, 72, 84, 155, 156]. Mackey et al. [62] observed that *L. monocytogenes* cells were sensitized to pressure by butylated hydroxyanisole, potassium sorbate, and acid conditions. Therefore, if the hurdle concept could be applied to the optimization of high hydrostatic pressure for low-acid foods, a combination of moderate treatments including pressure can lead to a food-preservation method effective against bacterial spores [72].

Enhanced pressure inactivation of microorganisms was observed when combining pressure treatments with additives such as acetic, benzoic, or sorbic acids; sulfites; some polyphenols; and chitosan [16, 76, 155, 156]. These combination treatments allow lower processing pressure, temperature, and/

or time of exposure. Roberts and Hoover [72] evaluated the effect of combinations of pressure at 400 MPa, heat, time of exposure, acidity, and nisin concentration against *B. coagulans* spores. Sublethally injured spores by the pressurization in combination with heat and acidity caused *B. coagulans* spores to become more sensitive to nisin. Acidic foods could be protected from spore outgrowth with the combined treatment. Hauben et al. [51] studied the lethal inactivation and sublethal injury of *E. coli* by high pressure and combinations of high-pressure treatments with lysozyme, nisin, and/or EDTA. High-pressure treatments from 180 to 320 MPa disrupted the outer membrane of bacterial cells, causing periplasmic leakage and sensitization to lysozyme, nisin, and EDTA, demonstrating that sublethal injury can be usefully applied in a hurdle technology approach as an effective food-preservation method.

Crawford et al., [83] evaluated the combination of high hydrostatic pressure, heat, and irradiation to eliminate *C. sporogenes* spores in chicken breast. These authors reported no significant differences in the number of surviving spores between samples that were first irradiated and then pressurized or vice versa. However, there was a significant difference between samples exposed to combined treatments and those that were only irradiated, with the combined processes being more effective. No survivors of the initial inoculated spores were observed with a 6 kGy irradiation dose followed by pressurization at 690 MPa and 80°C for 20 minutes. Crawford et al. [83] concluded that a combination of lower doses of irradiation and high pressure is more useful in eliminating *C. sporogenes* spores than the application of either process alone.

Earnshaw et al. [100] mentioned that there is no synergistic antimicrobial action between sorbic acid and pressure up to 400 MPa when applied to *Z. bailii* and attributed this lack of synergy to the modification of sorbic acid dissociation constant under pressurization. Tauscher [22] mentioned that the carboxylic acids commonly used as food preservatives show enhanced ionization when subjected to high pressure. However, Palou et al. [90] demonstrated that increased antimicrobial effects can be obtained when combining high pressure and potassium sorbate to inactivate *Z. bailii* in laboratory model systems with reduced a_w and pH. The initial inoculum (10^5 *Z. bailli* cfu/ml) was completely inactivated in systems with a_w 0.98 in the presence of potassium sorbate with pressures ≥345 MPa for more than 2 minutes; without potassium sorbate the pressure had to be applied at 517 MPa for 4 minutes. In laboratory systems with a_w 0.95 and without potassium sorbate, the pressure must be ≥517 MPa for 10 minutes. With potassium sorbate the treatment time could be reduced to 4 minutes [57].

Citric and sorbic acids were included in the laboratory model systems used by Palou et al. [90]. Thus, a temporary reduction in pH and an increase in the dissociated form of the acids could be present, which will depend on the pressure level. This effect could decrease the antimicrobial effectiveness of potassium sorbate during the time of exposure, since the major antimicrobial action is attributed to the undissociated form of the acid. However, the result of high-hydrostatic-pressure treatments would depend not only on the previously mentioned effects but on the consequences of high pressure in the biological systems involved. A synergistic antimicrobial action was observed between potassium sorbate and high pressure at both a_w [49]. For the same pressure level, the holding time required to inhibit *Z. bailii* is shorter in the presence of the preservative. High-pressure damage to *Z. bailii* renders cells more susceptible to other antimicrobial agents (low pH, potassium sorbate), probably due to the exposure of critical cell surface targets.

There is theoretical evidence about the pH shift during pressurization, but accurate models relating to microorganisms in food systems and direct measurement of pH are not available [100]. A detailed understanding of pH modification in foods might allow the design of food formulation that maximizes effective reversible antimicrobial pH shifts during pressurization [100]. The volume changes associated with ionization can be involved in the action of high hydrostatic pressure in biological systems. Earnshaw et al. [100] mentioned that water and acid molecules show increased ionization under high pressure. Thus, during the pressurization and holding time of a high-pressure treatment, an increase of proton concentration and a pH reduction are expected. High pressure decreases the pKa of certain acids that correspond to a decrease in the pH of solutions or buffers containing these acids [157]. Decreases in the pKa are more important for phosphoric acid than for citric acid. The pH of water or phosphate buffers decreases reversibly by 0.2–0.3 pH units per 100 MPa of applied pressure [158]. These effects can contribute, in a cooperative manner, to enhance the pressure effects on microorganisms, and the knowledge and understanding of their effects may aid to design effective pressure-combined processes. For most of the possible combined processes, the primary goal consists of identifying the factors or treatments that could sensitize microorganisms to pressure [18] or recognize the factors or treatments that could cause the microbial death in sublethal pressure-injured microbial cells. However, the protective effects that could exert food components made necessary the assessment of each combination process in each particular food product.

Cheftel [18] mentioned that potential applications of high pressure include decontamination of raw milk and some curds and cheeses made from raw milk; reduction of the intensity of thermal processing for prepared chilled meals containing thermosensitive food constituents; and the sanitation and increase of the refrigerated shelf life of spreads, emulsified sauces, essential oils, aromatic extracts, and herbs.

49.8 REGULATORY ASPECTS OF HIGH PRESSURE

No specific official requirements are needed in some countries that relate to the control of new food-processing technologies [8]. However, the regulations of food safety are relevant, and there are still several important questions about safety and nutritional value that need to be answered.

Earnshaw [8] mentioned that it is unlikely that pressure processing will replace canning or freezing, nevertheless it

could find applications for expensive foods with short shelf lives and high-value ingredients such as flavors, vitamins, and functional biopolymers that are heat-sensitive. In Europe, Japan, and the United States there is significant commercial interest in the development of high-pressure food processing, and millions of dollars have been invested in research and development.

High hydrostatic pressure is not a cheap technology, and a systematic approach must be taken to search for processing options to ensure that high-pressure treatments can be successfully and economically applied to a wide range of products [48]. The feasibility studies must include effective equipment design solutions and precisely defined minimum required pressures and time cycles. Continuous operation is also a major task.

50 Applications of Magnetic Field in Food Preservation

Jasim Ahmed and Hosahalli S. Ramaswamy

CONTENTS

50.1 INTRODUCTION

Thermal energy induces various biochemical reactions, leading to quality deterioration in foods resulting in undesirable changes in nutritional and sensory characteristics [1, 2]. Therefore, emerging and novel technologies can overcome the limitations of thermal processing and draw significant attention from food processors as well as consumers. Increasing consumer demand for newer food products with health benefits, desirable sensory characteristics, and higher quality retention has also led to the development of mild preservation technologies or minimally processed foods.

In the past, several mild preservation techniques have been developed and tested. Gamma irradiation is one of those. Although the technique has been successful in decontaminating food, consumer acceptability is significantly low for this process. In recent years, the advents of some nonthermal processing technologies that pasteurize and/or sterilize foods have been emerging as alternatives to conventional thermal processes. Most of these novel process technologies focus on energy-saving and eco-friendly applications. These processes have a similarity as they are mild for the food, and kill only the targeted spoilage and pathogenic microorganisms. The food product in question retains most of its natural appearance. In addition, these technologies are of specific interest to the food industry, because they provide attractive alternatives to conventional methods of thermal processing, which often cause undesirable changes in foods. These alternatives could also provide high quality with improved processing economy without compromising safety, and offer

opportunities for creating new ingredients and products due to their specific actions on biological materials and food constituents [3].

Some of the potential mild preservation techniques are (i) high hydrostatic pressure, (ii) pulsed electric fields, (iii) oscillating magnetic fields, (iv) high-intensity light pulses, (v) electron-beam radiation, (vi) microwave and radiofrequency, (vii) ohmic and inductive heating, (viii) high-voltage arc discharge, (ix) ultrasound, (x) X-ray. Among these listed, some of these technologies are now commercially exploited, and few of them are still in the developmental stages. The application of magnetic fields to process food products is one of these novel non-thermal processing methods, and so far a limited number of studies have been carried out on the application and commercialization of this technology. The process could produce fresh-like attributes of foods by retaining thermo-labile nutrients with reduced energy requirements, and could be applied in flexible packages [4]. In the last few years, electromagnetic freezing has received tremendous attention because of its claim of good quality by producing the finest ice crystals. The application of magnetic fields in the food fermentation industry could be a major success by controlling cellular growth and inhibition.

50.2 BASICS OF MAGNETISM AND MAGNETIC FIELD

50.2.1 Magnetism

Magnetism is a phenomenon by which materials exert an attractive or repulsive force on other materials. The origin of magnetism lies in the orbital and spin motions of electrons, and how the electrons interact with each other. The understanding of materials' responses to magnetic fields is important to apply different types of magnetism. The materials are mostly classified as diamagnetic, paramagnetic, and ferromagnetic according to their responses to magnetic fields.

Diamagnetism is a fundamental property of all matter, though it is usually very weak. It results from the non-cooperative behavior of orbiting electrons during exposure to a magnetic field. Diamagnetic substances are made of atoms that do not have any net magnetic moments (all the orbital shells are filled and there are no odd electrons). Water is a good example of a diamagnetic material/fluid. However, when exposed to a field, a negative magnetization is produced; thus the susceptibility is negative. In paramagnetic materials, some of the atoms or ions have a net magnetic moment due to unpaired electrons in a partially filled orbital. Oxygen is the best example of unpaired electrons. However, the individual magnetic moments do not interact magnetically, and similar to diamagnetism, the magnetization becomes zero when the field is taken out. In the presence of a field, there is now a partial alignment of the atomic magnetic moments in the direction of the field in ferromagnetic materials, resulting in a net positive magnetization and positive susceptibility. Unlike paramagnetic materials, the atomic moments in ferromagnetic materials exhibit very strong interactions. These interactions are developed by electronic exchange forces resulting in a parallel or antiparallel alignment of atomic moments. Exchange forces are very large, equivalent to a field in the order of 1000 Tesla, or approximately 100 million times the strength of the earth's field. The exchange force is a quantum mechanical phenomenon due to the relative orientation of the spins of two electrons. Ferromagnetic materials exhibit parallel alignment of moments resulting in large net magnetization even in the absence of a magnetic field. The most common examples of ferromagnetic materials are iron, nickel, cobalt, and some steels.

50.2.2 Magnetic Fields

A magnet is surrounded by an invisible force field. A magnetic field is a region of magnetic force generating out from a permanent magnet. Magnetic fields are created by moving charged particles: in electromagnets, electrons flow through a coil of wire connected to a battery; in permanent magnets, spinning electrons within the atoms generate the field (Figure 50.1). The strength of the magnetic field is a direct function of current passing in the wire. An electromagnetic (EM) field contains both an electrical and a magnetic field. In the case of a fluctuating magnetic or EM field, the field is characterized by its rate, or frequency of fluctuation (e.g., one fluctuation per second is equal to 1 Hz, the unit of frequency). Lines of magnetic force can be seen around a magnet by sprinkling iron filings onto a sheet above it and tapping the sheet. The strength of the magnetic force is strongest nearest to the poles and gets weaker while the poles move away from each other. A magnetic field can also be created by the spin magnetic dipole moment, and by the orbital magnetic dipole moment of an electron within an atom. A magnetic field is a vector field: it associates with every point in space and a vector may vary in time.

50.2.3 Magnetic Field Lines

Magnetic field lines can be used to visualize the magnetic field clearly. The magnetic fields generated by a single magnet are illustrated in Figure 50.2. The distance between those lines indicates the strength of the field when drawn properly. The closer the distance, the more strong the field. The number of lines per square centimeter measures the strength of the magnetic field. Technically, 1 Gauss is equivalent to one

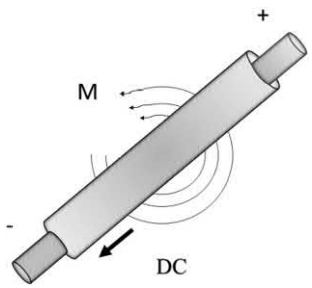

FIGURE 50.1 Current flowing through a wire produces a magnetic field (M) around the wire.

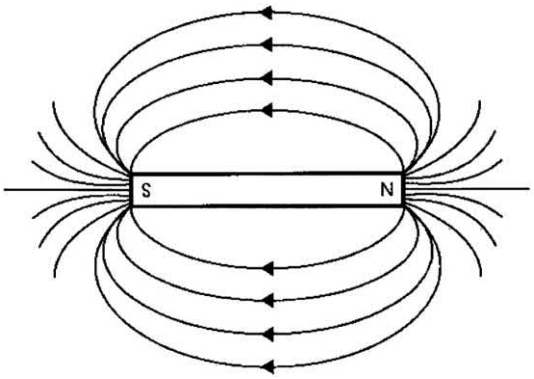

FIGURE 50.2 Single magnet exhibiting magnetic field.

magnetic field line within 1 square centimeter, and the direction of the tangent to the field line is the direction of the magnetic field at that point.

50.2.4 Symbols and Terminology

The fundamental vector quantities describing a magnetic field are the magnetic field strength H and the magnetic flux density B (also called the magnetic induction). The relationship between magnetic flux density, B, and the magnetic field strength, H, is given by $B = \mu H$ which is used to describe the magnetic field generated by currents that flow in conductors. The value of μ (the magnetic permeability) is determined by the properties of the medium. For most biological materials, the permeability μ is equal to μ_0, the value of permeability of free space (air) (1.257×10^{-6} H/m). Thus, for biological materials, the values of B and H are related by the constant μ_0.

Magnetic fields, like electric fields, are produced by electric charges, but only when these charges are in motion. Magnetic fields exert forces on other charges but, again, only on charges that are in motion. The magnitude of the force F acting on an electric charge q moving with a velocity v in the direction perpendicular to a magnetic field of flux density **B** is given by:

$$\mathbf{F} = q\mathbf{v} \times \mathbf{B} \tag{50.1}$$

Equation 50.1 is known as the Lorentz force law. The direction of **F** is perpendicular to both those of **v** and **B**. If, instead, the direction of **v** was parallel to **B**, then **F** would be zero. This indicates an important characteristic of a magnetic field: it does no physical work, because the force, called the Lorentz force, generated by its interaction with a moving charge is always perpendicular to the direction of motion.

Magnetic fields, like electric fields, are produced by electric charges, but only when these charges are in motion. Magnetic fields exert forces on other charges but, again, only on charges that are in motion. The magnitude of the force F is acting on an electric charge q moving with a velocity v in the direction perpendicular to a magnetic field of flux density.

The basic unit of the magnetic flux density can be obtained from Equation50.1 to be Newton second per coulomb meter (N s/C m). In SI units, B and H are measured in Teslas (T) and amperes per meter (A/m), respectively, or, in cgs units, in gauss (G) and oersteds (Oe), respectively. The conversion between the gauss (G), the cgs unit of flux density, and the tesla is 1 T = 10^4 G. A simpler form of the force equation in a wire current loop is given by:

$$F = BLi = (\text{Tesla}) \times (m) \times (\text{amp})$$

A more complex explanation is that if the moving charge is part of a current in a wire, then an equivalent form of the law is given below:

$$\frac{d\mathbf{F}}{dl} = \mathbf{i} \times \mathbf{B} \tag{50.2}$$

In words, Equation 50.2 infers that the force per unit length of wire is the cross product of the current vector and the magnetic field. In the equation above, the current vector, **i**, is a vector with magnitude equal to the usual scalar current, *i*, and direction pointing along the wire that the current is flowing.

50.2.5 Types of Magnetic Field

Magnetic fields may be homogeneous or heterogeneous and can be in static and pulsed mode. In a homogeneous magnetic field, the field intensity is uniform in the area enclosed by the magnetic field coil, while in a heterogeneous field, the field intensity is non-uniform and field intensity decreases as distance from the center of the coil increases. Static magnetic fields (SMF) show a constant strength over time and are generated by permanent magnets or direct current electromagnets. An oscillating magnetic field (OMF) is applied in the form of constant amplitude or decaying amplitude sinusoidal waves and exhibits an intensity gradient over time depending on the nature of the magnet. OMFs are generated by alternate current electromagnets within pulsed fields, and the field intensity alters periodically depending on the frequency and type of wave generating from the electric current in the magnet [5]. The magnetic fields have been classified again as high- or low-intensity fields as per their relative intensity. Low-intensity magnetic fields show strength in the order of one tenth of a gauss, while high-intensity fields show strength in the order of thousands of gauss or greater [6].

50.3 MAGNETIC FIELD GENERATION

50.3.1 Field Generation by Currents in Wires

The simplest way to create a magnetic field is by supplying current along a long straight wire. The magnetic field from such a current-carrying wire actually wraps around the wire in circular loops, decreasing in magnitude with increasing distance from the wire. The magnitude of the field at a distance *r* from a wire carrying a current *I* is given by:

$$B = \mu_o I/(2\pi r) \tag{50.3}$$

where μ_o is a constant, the permeability of free space and $\mu_0 = 4\pi \times 10^{-7}$ T m/A, T is tesla. The magnetic action to inactivate microorganisms has some required specific field strengths, which vary between 5 and 50 T. The generation of such field strength is carried out by (i) superconducting coils, (ii) coils which generate DC fields, and (iii) coils that can be energized by the discharge of the energy stored in a capacitor [7]. Magnetic fields generated by iron core in coil cannot produce the required intensities for microbial inactivation and therefore are not suitable for this purpose. The air-core solenoids can produce higher intensities, and the intensity is directly related to the flow of current, which is found to be a limiting factor due to huge power consumption and heat generation [5].

50.3.2 Static Magnetic Fields Technique

Superconducting magnets are a good choice for high-intensity magnetic field generation since they avoid heating effects. Magnetic field generation with coils of super-conducting metal has been used by various researchers. Metals behave as super-conductors (electricity passes through the wire with no resistance) in a liquid helium environment (–268.9°C). This generates a magnetic field of about 2 T, which is about 40,000 times stronger than the earth's magnetic field (0.0005 T). The liquid helium is insulated by a dewar (insulated storage vessels) of liquid nitrogen, which helps to reduce the loss of helium from the magnets. The magnets need to be filled with liquid nitrogen regularly (weekly), and liquid helium needs to be filled about once a month, which makes this type of magnet expensive to run. However, it has also some limitation in field intensity, with maximum limits of about 20 T. A hybrid magnet contains a superconducting magnetic coil and water-cooled magnetic coil that can produce 15–30 T. Magnetic fields above 30 T have been generated in a pulsed form by supplying a current of 40 kA for short time period [8].

50.3.3 Oscillation Magnetic Fields Technique

Considerable effort has been made to generate high-intensity magnetic fields to extend the available field range. MAGNEFORM® magnetic forming systems (Magneform, San Diego, CA) have achieved wide acceptance as a proven production method on today's high-volume assembly lines. Magneform machines have been routinely used to form, join, or assemble parts of metals and have been tested for food processing applications. Hofmann [9] was probably the first one to test the Magneform 7000 for food applications, and such equipment has been used more recently by Harte et al. [10]. The working principles and coil circuits have been well-described by Pothakamury et al. [5]. The instrument can store the energy in a capacitor bank. The basic principle of magnetic pulse is the same, as it activates a simple electric motor. An electric current generates a pulsed oscillating magnetic field (OMF) between the plates of the capacitors where the food sample is held in plastic bags. The frequency of the magnetic field is dictated by the capacitor's capacitance and the resistance, and induction of the coil. An OMF of 2–50 T is achieved while a coil has been connected to a capacitor of 8–16 kJ [9].

50.3.4 Ultra-High Magnetic Fields

The generation of higher fields (in the megagauss ranges) is still difficult because of the coil destruction by the higher electromagnetic forces. Miura et al. [11] have developed ultra-high magnetic fields in the megagauss range using the electromagnetic flux compression technique and direct fast current discharge into a single turn coil. The authors have claimed the novel processes can generate 500–1000 T field strength.

Scientists from National High Magnetic Field Laboratory, University of Florida, have recently developed [12] one superconducting magnet, which stands 16 feet tall and weighs more than 15 tons. Now, with its commissioning, scientists from around the world will be able to expand the horizons of scientific investigation using nuclear magnetic resonance (NMR) and magnetic resonance imaging (MRI) technologies. The bore is the space within the magnet that holds the sample being tested. The bore size of this magnet (105 mm) makes it particularly useful for scientific research. The 900 MHz magnet delivers 21 T magnetic fields that vary less than 0.0000002 T over a volume which is roughly equal to the size of a small orange.

50.4 APPLICATION OF MAGNETIC FIELDS IN FOOD PRESERVATION

50.4.1 Pasteurization

The success of food preservation basically depends on the inactivation of enzymes and microorganisms which would produce safe food for human consumption. The microbial growth can either be stimulated or ceased during the exposure to magnetic fields. The retardation of growth and reproduction of microorganisms might be associated with changes in DNA synthesis; a change in the orientation of biomolecules and biomembranes to a direction parallel or perpendicular to the applied magnetic field; or a change in the ionic drift across the plasma membrane [5].

The first approach to food preservation by OMF was initiated by Hofmann [9] with a US patent. The basic requirement for the application of OMF technology for food preservation requires a high electrical resistivity, greater than 10 to 25 ohm/cm. Many foods have electric resistivity in these ranges. One of the most common examples of a food that can be processed by the OMF technique is orange juice. The electrical resistivity of orange juice is about 30 ohm-cm. The field intensity is a function of electrical resistivity and sample thickness. However, no correlation has been observed between magnetic field intensities and food constituents.

The inactivation of microorganisms in food has been reported to occur during exposure to OMFs with intensity higher than 2 T [9]. A single pulse intensity of 5–50 T and frequency of 5–500 kHz reduced the initial number of

microorganisms by two log cycles. The technology could be applied for food pasteurization purposes by placing the sample in a magnetic field and magnetizing. The author reported the application of OMF for selected food products to control specific spoilage microorganisms as (i) milk with *Streptococcus thermophilus*, (ii) yogurt with *Saccharomyces cerevisiae*, (iii) orange juice with *S. cerevisiae*, and (iv) Brown 'N Serve roll dough with bacterial spores. These studies also indicated that the temperature increase during the magnetic field is almost negligible (maximum 2°C), and the reduction of microorganisms ranges between 1.4 and 3.6 log cycles.

50.4.2 Microbial Systems

50.4.2.1 Inactivation of Microorganisms

Almost all living organisms are exposed to magnetic fields from different sources. The geomagnetic field on the surface of the earth is approximately 0.50–0.75 gauss in strength. When a magnetic field is applied to microorganisms in a liquid culture, it is distorted or weakened by that culture. A strong field may significantly affect microorganisms, or even kill them. The effects of magnetic fields on microbial growth have been classified by Yoshimura [13] as inhibitory, stimulatory, and none observable.

Several studies have been carried out on the effects of exposure to magnetic fields, and many of these findings are inconsistent (Table 50.1). Hoffman [9] first advocated that exposure to magnetic fields causes inhibition by reducing the growth and reproduction of microorganisms. Exposing food infected with microorganisms to an OMF at frequencies of 5–50 kHz and with an electro-magnetic strength of 5–50 T reduced the microorganisms' population by 2 to 3 log cycles. The formation of metastable pores by the presence of natural magnetite or contaminant magnetic particles on cell membranes has been considered an effect of magnetic fields [14]. The growth rate of the Burgundy wine yeast has been reported to decrease at an extremely low magnetic flux density of 0.04 T [15]. On the contrary, the accelerated growth rate of Trichomonas vaginalis was reported when exposed to 46–120 T [16]. The growth rate of Bacillus subtilis was also found to increase when exposed to 0.15 T and decrease when exposed to more than 30 T [17]. Similar results were reported for Chlorella; an exposure of less than 400 gauss increased the growth, while exposure to 580 gauss decreased the growth rate [18]. Several studies pointed to the magnetic fields as a factor influencing the growth and survival of living organisms, which vary at different magnetic flux densities [19, 20–22].

The strength of the magnetic field has significant effects on microbial growth and survival. The cellular growth in the stationary phase of *Escherichia coli* under a heterogeneous magnetic field of 5.2–6.1 T was found to exhibit a significant increase in the number of cells by about 10^5 as compared to the geomagnetic field [23]. The authors claimed that such a marked death suppression effect by the high magnetic field had never been reported earlier. The amount of sigma S factor encoded by the *rpoS* gene under a high magnetic field was 20% higher in comparison to control geomagnetic field which might be part of the reason why a large number of cells in the stationary phase were maintained under the heterogeneous magnetic field. Fojt et al. [24] studied biological effects of low-frequency electromagnetic fields using three different bacterial strains, namely *E. coli*, *Leclercia adecarboxylata*, and *Staphylococcus aureus*. The strength and frequency of

TABLE 50.1
Effect of Magnetic Fields on Microorganisms

Type of Microorganisms	Nature of Magnetic Fields	Field Strengths (T)	Major Finding	References
Burgundy wine yeast cells	Static	0.04	Growth retardation during exposure at 5–150 min; no retardation at 10, 15, and 17 min	Kimball [14]
Trichomonas vaginalis	Static	4.60–12	Growth was accelerated	Genkov et al. [15]
E. coli	Oscillation	0.05	Inactivation of cells when concentration was 100 cells/mL	Moore [16]
Streptococcus thermophilus in milk	Oscillation	12.0	Cell population reduced from 25,000 to 970 cells/ml	Moore [16]
Saccharomyces in yogurt	Oscillation	40.0	Cell population reduced from 3,500 to 25 cells/ml	Hofmann [9]
In orange juice	Oscillation	40	Cell population reduced from 25,000 to 6 cells/ml	Hofmann [9]
Mold spores	Oscillation	7.5	Population reduced from 3,000 to 1 spores/ml	Hofmann [9]
E. coli	Static	5.2–6.1	Magnetic field increased viable cells by 150 times after incubation for 48 h	Horiuchi et al. [22]
E. coli, *Leclercia adecarboxylata*, and *Staphylococcus aureus*	Oscillation	0.01	Magnetic field caused the decrease of CFU in all exposed samples. The maximum decrease of CFU was observed for *E. coli*; *S. aureus* strain was found most resistant to the magnetic field	Fojt et al. [23]
Saccharomyces cerevisiae	Static	5–14	Rate of proliferation under the magnetic fields decreased after 16 h of incubation compared to control sample	Iwasaka et al. [34]

the field were 10 mT and 50 Hz, respectively, whereas the residence time was less than 30 min. The low magnetic field caused a decrease in CFU in all exposed samples. Viability decreased with longer exposure time and/or higher induction fields for all strains, but the effect was strain-dependent. The highest decrease of the viability and the largest magnetic field effect was observed with *E. coli* while the lowest magnetic field effect was found for *S. aureus*. From the measurement of the growth dynamics, it was concluded that the decrease of the CFU started immediately after the magnetic field was applied. However, Harte et al. [10] found no significant reductions in *E. coli* under magnetic fields lower than or equal to 18 Tesla generated by both OMF and SMF using a 7000 series Magneform machine (Maxwell Laboratories, CA) and a superconducting magnet (National High Magnetic Field Laboratory, NM), respectively.

The finding of enhanced viability of cells under a high magnetic field implies that the productivity of antibiotics or enzymes by microorganisms is enhanced under a high magnetic field. It is already reported that the high magnetic field has no mutagenic or adverse effect on biological cells [25].

50.4.2.2 Mechanisms of Microbial Inactivation

Several hypotheses have been postulated for the mechanism of microbial inactivation by magnetic action. The inactivation of microorganisms may be based on the theory that the OMF may couple energy into the magnetically active parts of large molecules like deoxyribose nucleic acid (DNA) [9]. Within the 5–50 T range, the amount of energy per oscillation coupled to 1 dipole in the DNA is 10^{-2} to 10^{-3} eV. Pothakamury et al. [5] described two theories on the microbial inactivation process using either SMF or OMF:

(i) A weak OMF could weaken bonds between ions and proteins used in metabolism and membrane integrity. In SMF such as the earth, the biological effects of OMF are more pronounced around particular frequencies, the cyclotron resonance frequency of ions [26].
(ii) The effect of magnetic fields on calcium ions bound in calcium-binding proteins like calmodulin. The Ca^{++} ions vibrate regularly to an equilibrium position in the binding site of calmodulin. A steady magnetic field to calmodulin results in the plane of vibration to rotating, or proceeding in the direction of the magnetic field at a frequency that is exactly similar to the cyclotron frequency of the bound calcium. Adding a "wobbling" magnetic field at the cyclotron frequency disturbs the precision to such an extent that it loosens the bond between the calcium ion and the calmodulin [5].

The results presented in Table 50.1 show that, although not well understood, the effect of magnetic fields on the microbial population of foods may depend on the magnetic field intensity, number of pulses, frequency, and property of the food (that is, resistivity, electrical conductivity, and thickness of the foodstuff). Unfortunately, studies on the effects of magnetic fields on microorganisms have produced conflicting results. Until more consistent and convincing results are produced, the prospects for this technology are questionable.

50.4.2.3 Propagation of Yeast

Studies concerning the use of *S. cerevisiae* as a cell model have reported that proliferation increases more than 25% at 50 Hz, 0.5 mT alternating magnetic fields (MF) during 10 h exposure [27]. Nevertheless, the effect observed by these authors when they used 0.2 mT, 50 Hz, in the exposition is the inhibitory action (16%) of cell proliferation. The cell growth dependence with field frequency found by them exhibits positive responses by a more than 20% increase in the cell number after 10 h of exposure to 15 and 50 Hz. However, conflicting results have been reported by Ruiz-Gomez et al. [28] while studying the growth induced by static and sinusoidal 50 Hz magnetic fields (MF) on the haploid yeast strain *S. cerevisiae*. Magnetic fields were produced by a pair of Helmholtz coils (40 cm in diameter) with 154 turns of copper wire in each and separated by 20 cm. The experiments were carried out at 0.35 and 2.45 mT, and yeasts were exposed to MF for time periods of 24 and 72 h in the homogeneous field area. Growth was recorded by measuring the optical density at 600 nm. They reported that static and sinusoidal 50 Hz MF (0.35 and 2.45 mT) did not induce changes in the growth of *S. cerevisiae*.

50.4.2.4 Yeast under High-Gradient Magnetic Field

Superconducting technology has provided new methods for studying the application of strong magnetic fields in biological systems and dia- or paramagnetic materials. Room temperature bores of superconducting magnets have given opportunities to explore the importance of the diamagnetism of biological materials [29, 30] as well as that of strong (ferro-) magnetism in solid-state materials. A new approach using superconducting technology involved gradient magnetic fields in the horizontal direction which led to several interesting phenomena. It was reported that the surface of water bent downward under the magnetic field of 10 T or so at the center [31]. The parting of water has been termed as the "Moses Effect," a phenomenon in which the surface of water has been separated under high magnetic fields [32]. The horizontal gradient magnetic force and the vertical gravitational force generate a sloping gravity-like field for living organisms [33], in which the sloping field is considered to be the actual direction of gravity. In the case of the parting of water, the water was pushed to lower magnetic fields from higher fields, and localized in the middle part of the space forming a "water-wall." However, the applied field should be high and steep enough in order to clearly observe these effects.

The effects of gradient magnetic fields on the behavior of yeast (*S. cerevisiae*) proliferation and mass distribution have been reported also by Iwasaka et al. [34] using strong static magnetic fields (flux density 14 T). When yeast was exposed to 9–14 T magnetic fields with a maximum flux density gradient of $dB/dx = 94\,\mathrm{T}/m$, where x is the space coordinate, the

rate of yeast proliferation under the magnetic fields decreased after 16 h of incubation as compared to that of the control. The results indicated that the gas pressure inside a flask with 6 T, 60 T/m gradually increased in comparison to the pressure inside a control tube. Due to the diamagnetism of medium water and yeast, the liquid surface clearly inclined under gradient magnetic fields, and the hydrostatic force in suspension was strengthened by the diamagnetic forces. In addition, magnetophoresis of the yeast cells in the medium solution exhibited localization of the yeast sedimentation pattern. The mechanisms for deceleration of yeast proliferation by magnetic fields have been proposed and well-described by Iwasaka et al. [34].

50.4.3 Sterilization by Magnetic Fields

Complete sterilization is possible by exposure of magnetic fields to more than one oscillation sequence [35]. Microorganisms tested are viruses, bacteria, mold, protozoa, and algae. In this technique [35], a low electrical conductivity material is passed through a high-intensity, moderate-frequency oscillating magnetic field for a very short residence time, which is adequate for inactivating a major portion of the microorganisms within or upon the material to achieve substantial sterilization without detectably altering the material itself. The decaying magnetic oscillations can be produced by discharging voltage from a capacitor into a coil so that the capacitor and coil are in an electrical loop so that no other components will deter from the natural back-and-forth oscillations. An output of approximately ten magnetic pulses (five each from north and south poles) is significant in strength because each pulse becomes weaker than the one before due to energy dissipation in the wire, coil, and capacitor. The best range of initial magnetic field strength is 5 to 50 Tesla, but anywhere between 2 and 100 will work [35]. Generally, higher electrical conductivity of the infected matter requires less magnetism strength to inactivate the microbes. Foods with minimal electrical conductivity need to be exposed to 10–100 oscillation sequences for complete sterilization. It is believed that some microbes are killed while the majority are just devitalized so that they can't reproduce [35].

50.4.4 Effects of Magnetic Fields on Food Freezing

Magnetic freezing has received serious attention both from the food industry and academics, recently, as a commercial reality. in the last two decades, plenty of patents have been filed, and many companies marketed electromagnetic freezers that apply different types of magnetic fields to improve the quality of frozen food [36]. A few commercial companies are marketing electromagnetic freezers including ABI Co., Ltd. (Chiba, Japan) which sells "CAS (Cells Alive System) freezers" combining static and oscillating magnetic fields; and Ryoho Freeze Systems Co., Ltd. (Nara, Japan) which sells "Proton freezers" that use static magnetic fields and electromagnetic waves.

In electromagnetic freezers, permanent magnets and induction coils are used to produce a weak oscillating magnetic field within the freezing chamber [37]. CAS is not a refrigeration process itself, but is employed to assist in improving existing freezing processes (both in terms of process speeds and product quality). A typical CAS freezing system is illustrated in Figure 50.3 as described by Otero et al. [36]. The freezer consisted of a cooling unit, two fans, a control panel, and a freezing cabinet (Figure 50.3). The cabinet consisted of 10 equidistant rails with a rack that can accommodate up to 10 trays for food freezing and the magnetic field generators. The static and oscillating magnetic field generators are employed to assist the freezing process. The static magnetic field is produced by a number of permanent magnets embedded in the front door and in the ceiling, the floor, and the left and rear walls of the freezing cabinet; the OMF is generated by four rectangular magnetic coils located inside the cabinet. The patent literature pertaining to CAS indicated that the oscillating magnetic field acts on polarized water molecules to delay the formation of ice crystals [38, 39]. Furthermore, it is claimed that oscillating magnetic field–induced freezing is able to generate fine ice crystals throughout the frozen product, prevent cell destruction, improve heat transfer, and retain

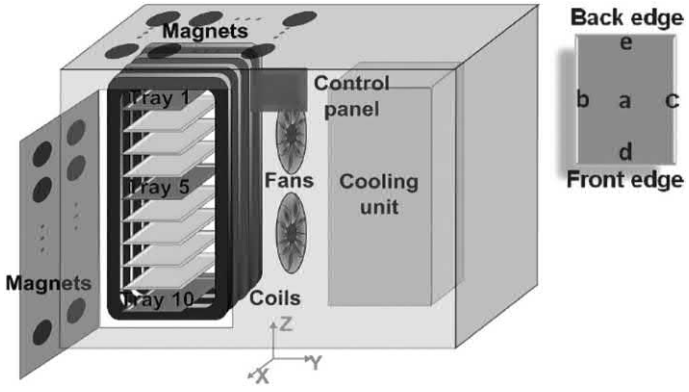

FIGURE 50.3 Typical schematic diagram of the CAS freezer: the main component (left) and the points at which magnetic field measurements were done in selected freezing trays 1, 5, and 10.

the quality of fresh food after thawing [39, 40]. However, it is still in question whether the extremely low strength of the OMFs commonly applied in commercial freezers (<2 mT) has this capability on a substance with a low magnetic susceptibility such as water. Additionally, the mechanisms cited in the patents to explain the effects of OMFs on water molecules are ambiguous, not scientifically proved, and, according to Kobayashi and Kirschvink [41], "do not agree with basic biophysics."

Otero et al. [36] assessed the effectiveness of OMFs in preserving crab sticks in a commercial electromagnetic freezer, both with (<2 mT, 6–59 Hz) and without OMF application. It was found that the OMFs did not have any effect on the drip loss, water-holding capacity, toughness, and whiteness of the crab sticks frozen in the electromagnetic device, and stored for a year. A similar study was carried out by James et al. [42] on individual cloves within whole garlic bulbs using CAS, and its effect on the degree of super-cooling and characteristic freezing curve as compared to freezing under the same conditions without OMF. Overall, it was observed that freezing under the OMF conditions had little significant additional effect on the freezing characteristics, or degree of super-cooling of garlic bulbs, in comparison with freezing under the same environment without OMF. More experiments at higher magnetic field strength and wider frequency ranges should be carried out to establish the potential benefits of OMFs on food freezing.

Magnetic resonant freezing (MRF) is considered as another potential freezing technique that could possibly increase the quality of food material due to uniform flash freezing of the entire food volume by producing fine ice structure in food. The MRF process consists of two stages: (i) food undergoes continuous magnetic wave vibrations, which impede the crystallization, and (ii) instantaneous removal of the magnetic field, which leads to freezing [43, 44]. Changes in the ultrastructure and quality of beef muscle during frozen storage by MRF and air blast freezing and the changes in the quality characteristics after thawing were compared by Choi et al. [45].

It was observed that the size of the ice crystal was minute and evenly formed in the initial freezing period; however, the size was increased as the storage period elapsed. The beef stored by the electro-magnetic resonance freezing exhibited a lower rate of growth in the ice crystal size as compared to the air blast freezing during the frozen storage. The thawing loss of beef stored by the MRF was significantly lower than the air blast freezing, and it showed that the thawing loss of the round was higher than the loin. The sensory evaluation indicated that the beef stored by the MRF did not show the difference until 4 months, and it showed higher acceptability in comparison with the beef stored by the air blast freezing. Therefore, the freezing method has an effect on the change in the ultrastructure and quality characteristics of the beef.

50.4.5 Biological System

Henry Lai and colleagues [46] at the University of Washington have discovered a method of treating malaria with magnetic fields that could prove revolutionary in controlling the disease which the World Health Organization calls one of the world's most complex and serious human health concerns. Researchers claim the malaria parasite *Plasmodium* appears to lose vigor and can die during exposure to oscillating magnetic fields, which may cause tiny iron-containing particles inside the parasite to move in ways that damage the organism. The oscillating magnetic field may affect the parasites in two ways. In organisms still in the process of binding free heme molecules into stacks, the alternating field likely "shakes" the stacked heme molecules, preventing further stacking. That would allow harmful heme free reign within the parasite. If the parasite is further along in its life cycle and has already bound the heme into stacks, the oscillating field could cause the stacks to spin, causing damage and death to the parasite.

50.4.6 Isolation and Separation of Protein by Magnetic Technique

The isolation and separation of specific molecules is common practice in almost all areas of biosciences and biotechnology. Various techniques have been used to achieve this goal. Recently, increased attention has been paid to the development and application of magnetic separation techniques, which employ small magnetic particles. Safarik and Safarikova [47] recently reviewed magnetic techniques for the isolation and purification of proteins and peptides.

The basic principle of batch magnetic separation is simple. Magnetic carriers bearing an immobilized affinity or hydrophobic ligand or ion-exchange groups, or magnetic biopolymer particles having an affinity with the isolated structure, are mixed with a sample containing the target. Magnetic separation techniques have several advantages over standard separation techniques. This process requires only a few handling steps. The separation can be carried out directly in crude samples containing suspended solid material. Due to the magnetic properties of magnetic adsorbents (and the diamagnetism of most of the contaminating molecules and particles), they can be relatively easily and selectively removed from the sample. In fact, magnetic separation is the only feasible method for recovery of small magnetic particles (diameter of 0.1–1 μm) in the presence of biological debris and other fouling material of similar size. In addition, the power and efficiency of magnetic separation procedures are useful in large-scale operations. Several automated systems for the separation of proteins or nucleic acids have become available recently.

Magnetic separation is usually a very mild operation on the target proteins or peptides. Even large protein complexes may remain intact when using the very gentle magnetic separation procedure [48]. The separation process has been significantly influenced by both the reduced shearing forces and the higher protein concentration throughout the isolation process. Appropriate magnetic particles can be used for their concentration instead of ultrafiltration, precipitation, etc. [49].

50.5 APPLICATIONS OF OTHER MAGNETIC PROPERTIES IN FOOD QUALITY SYSTEMS

50.5.1 Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a unique technique for real-time and in-situ measurements due to its non-invasive and non-perturbing nature, which makes it suitable for quality control of food products. This is of particular advantage for in vivo measurements, and also for the assessment of phenomena that occur during the processing and storage of food products. MRI is based on the principles of nuclear magnetic resonance (NMR), a spectroscopic technique used by scientists to obtain microscopic chemical and physical information about molecules. However, the tremendous potential of magnetic resonance systems in other fields has not been fully explored yet. The technique was called magnetic resonance imaging rather than nuclear magnetic resonance imaging (NMRI) in order to avoid negative connotations associated with the word nuclear in the late 1970s [50].

50.5.2 Application of MRI in Quality Control of Food Products

MRI is an attractive tool for temperature mapping (distributions) induced in water-based foods by microwave and conductive heating. Additionally, it can measure quantitatively in three dimensions all aspects of the mass transport of water and/or fat in foods to give direct information about the effects of process engineering, including flow, mixing, and heating.

MRI has been proven efficient as an in-line sensor for detecting defects and measuring the quality of fruits and vegetables. MRI can predict the structure and dynamics of foods and other heterogeneous materials during and after processing. MRI has been used efficiently as a viscometer; MRI measurements of the fluid velocity profile in tube flow are coupled with a pressure drop measurement to yield shear viscosity. Each measurement yields a range of shear viscosity data for a single flow rate, as compared to most conventional viscometers that produce only one data point under the same circumstances. This technique has the potential to significantly enhance process control of industrial processes.

50.5.3 Application of NMR in Quality Control of Food Products

NMR is used extensively as an analytical tool in the characterization and quality control of food products. NMR profiles can detect overall food compositions by assessing the effects of agricultural production and harvesting, storage, and processing [51]. The water mobility in food products can be traced through relaxation spectra involving the NMR-active nuclei in water (^{1}H, ^{2}H, and ^{17}O). The amorphousness and crystallinity of starch can be detected by the solid-state NMR techniques. Mostly, dissolved or extracted samples are measured by liquid-state NMR, but in several cases the use of semi-solid-state ^{1}H HRMAS has also been applied to intact food materials. In several cases, site-specific natural isotope fractionation (SNIF)-NMR has become the method of choice for the detection of adulteration of food products with synthetic ingredients, such as flavors, sugars, and alcohols. The most significant application of NMR is the determination of authenticity of foods. This is a particular issue where biological or geographical origin, often in combination with artisanal manufacturing, has added significant value to food products [51].

50.6 CONCLUSION AND FUTURE RESEARCH NEEDS

The use of magnetic fields as an alternative food processing technology has been unable to gain full commercial acceptance, possibly due to inconsistent results on microbial growth and death kinetics. In addition, there is a significant lack of information on the field and the development of machinery. First, food scientists need to confirm that magnetic fields could effectively deactivate microorganisms. The application of magnetic fields could be effective and beneficial for biomass production at controlled growth rate using superconducting technology. This would help the growth of the fermentation and pharmaceutical industries. The structural modifications of proteins and fats could be achieved by exposing those constituents to magnetic fields. There is a significant lack of research in the food processing areas, and it is hoped that future development will provide answers to nagging questions. However, significant progress has been made in using NMR for quality assessment of foods, such as molecular mobility and structural changes, as well as identifying the effects of processing causing the changes in food materials.

Part VI

Enhancing Food Preservation by Indirect Approach

51 A Glance at Nutrition

Mostafa Waly and Vickie A. Vaclavik

CONTENTS

51.1 INTRODUCTION TO PRESERVATION AND NUTRITION

This chapter focuses on the various preservation techniques and their effects on nutrition. Effective preservation of fresh food helps to ensure that foods contain desirable, nutritious components, and that these are safe and wholesome for consumption later. Precisely, the nutritive value of foods must be maintained during the process of preservation. Overall, in order to receive the health benefits of foods, nutrients must be present in the foods. Undoubtedly, each of the processing variables offers its own set of challenges. Cold preservation techniques result in less nutrient loss than heating as a means of preservation.

The two terms of preservation and processing are unique, and they could be interrelated. Briefly stated, food processing certainly includes preservation, and processing may include the use of specific food additives, some of which are known as "preservatives." Processing also includes food packaging treatments, which of course may assist in preserving food. Food preservation and processing could have beneficial or detrimental effects to the nutrients. For example, vitamin C is significantly lost by heating while the bioavailability of lycopene in tomato is higher when heated or processed as compared to fresh tomato.

51.2 NUTRITION

The inherent nutrient content of raw and fresh produce items declines with the passage of time. This decline could be due to improper handling, such as variations in post-harvest conditions, and preservation methods. Cooking or slow freezing of fresh food may typically result in nutrient loss but increases palatability and nutrient availability. "Nutrients" are chemical substances obtained from food, used for growth, maintenance, and repair of our body. The human body needs nutrients, and malnutrition may result from an under- or over-consumption of energy and nutrients. Cultural factors may influence the consumption of specific types of *foods* although populations of all cultures need the same *nutrients.*

The nutrients are grouped into six classes as macronutrients (i.e., water, 0 kcal/g; carbohydrate, 4 kcal/g; protein, 4 kcal/g; fat, 9 kcal/g), and micronutrients (i.e., vitamins, and minerals, with zero calories). The breaking of the structure of a macronutrient molecule produces energy, which may escape as heat, or build new compounds, as well as transport within the body.

The "essential" nutrients are those nutrients that cannot be made by the body at all or the amount produced is not enough. These essential nutrients are normally obtained from food and should not be dependent upon pills or other supplements. Personal preference is the most important reason why people choose their foods when different options are available. The Institute of Food Technologists reports that people choose foods based on appearance, texture, and flavor. Even children honestly give their opinions regarding these three attributes, as they remark on the foods before consumption. The nonnutrients are not included in the six classes, for example, the

phytochemicals. The six nutrients are discussed in the following sections of this chapter.

Foods may be nutritious with high levels of nutrients per calorie, or foods, many referred to as "junk foods" (a name often used since the 1950s), may have with low levels (or no amount) of nutrients per calorie. Among the six nutrients three offer calories, and three do not contain calories. Foods may be enriched or fortified with nutrients, as defined: enriched food contains added nutrients that are lost during processing, and fortified food contains added nutrients that are not present originally, for example, fortified breakfast cereals, and orange juice fortified with calcium.

51.2.1 Carbohydrate

Carbohydrates are the most important single source of food energy and their intake varies among countries depending on the culture and food recipes. Carbohydrate-containing foods provide up to 60% of total food energy, and these foods are root crops, pulses, vegetables, fruits, and milk products. Carbohydrates have the formula $C_n(H_2O)_n$, with a molar proportion of C:H:O of 1:2:1. Based on the number of monomeric units, carbohydrates are classified into sugars (1–2 units: monosaccharides, disaccharides, polyols), oligosaccharides (3–9 units: maltodextrins, raffinose, stachyose, fructooligosaccharidises), and polysaccharides (>9 units: amylose, amylopectin, cellulose, hemicellulose, and pectins) [1].

The major dietary carbohydrates are starch, sucrose, and lactose. Small amounts of free glucose and fructose are also present in the diet, in addition to glycogen and indigestible polysaccharides such as cellulose. Salivary α-amylase cleaves starch and glycogen by breaking at random the α-1,4 linkages between glucose residues within the chain leading to α-dextrins. α-amylase in saliva and the pancreas cannot hydrolyze: α-1,6 linkages, terminal α-1,4 linkages, and the 1,4 linkages next to branching points. Carbohydrates (a hydrated carbon—CH_2O) is one of the six nutrients used by the human body. It consists of numerous glucose units held together by glycoside bond linkages. Carbohydrates are known as either simple or complex carbohydrates. The simple carbohydrates are (i) three monosaccharides, which contain single units of either glucose ($C_6H_{12}O_6$), fructose, or galactose, and (ii) three disaccharides, which contain one of the three monosaccharides paired with a glucose unit.

Specifically, disaccharides consist of a glucose unit, paired with either fructose to yield sucrose, or glucose paired with lactose to yield galactose, or glucose paired with another glucose to produce maltose. The chemical reaction needed to form disaccharides is condensation, and the by-product of that reaction is the release of water. The opposite reaction needed to split disaccharides is hydrolysis, "hydro" (H_2O), "lysis" (split), by the addition of water. A glyosidic bond forms between the carbonyl and hydroxyl groups of two monosaccharides (in this case, glucose and fructose combine and form the disaccharide sucrose). An OH and a H (H_2O) are released with the formation of the disaccharide. The opposite reaction occurs when the bond is readily hydrolyzed (for example, by heat, acid, and enzymes, such as amylases, sucrase, or invertase) [1].

In addition to the simple carbohydrates of mono- and disaccharides, as well, carbohydrates include the polysaccharides. These are the complex carbohydrates, which consist of three constituents, i.e. three polysaccharides: glycogen, starch, and fiber. Glycogen is the glucose stored/found only in humans and animals (i.e. muscle, liver), not in plant material and not a source of dietary carbohydrate. Starches are the storage form of glucose for plants, grains, and legumes (beans, peas). Starches may be made of one or both of the two starch forms: amylose (i.e. glucose units arranged linearly with β-1,4 glycosidic linkages) and amylopectin (i.e. glucose units 1,4 linkages, with α-1,6 branching every 15 to 30 units). Fiber is found only in plant material, not animal, and unlike starch, it contains a 1,6 bond between glucose units rather than a 1,4 bond. The human enzymes can digest alpha starch bonds and cannot digest the beta fiber bonds of cellulose. Fiber exists as both soluble and insoluble fiber [2].

Soluble fiber dissolves in water to form a viscous, gel-like substance which is readily digested/fermented by bacteria in the colon. It lowers cholesterol, slows glucose absorption, and slows passage through the colon (preventing diarrhea). Foods such as fruits, oats, barley, legumes, some vegetable and plant fiber, and psyllium contain soluble fiber. Examples of soluble fiber are pectin, gum, mucilages, and some hemicelluloses. It aids in protecting against (i) heart disease by reducing cholesterol in the body (it is eliminated in the stool and is prevented for uptake into the body), and (ii) diabetes by reducing blood glucose levels. As well, blood pressure reduction (less hypertension), less risk of atherosclerosis, and less coronary heart disease are also apparent in association with good fiber intake. Soluble, viscous fiber provides a slow gastric emptying of food, and thus fiber intake proves to be a helpful strategy in weight loss [2].

Insoluble fiber is different from soluble fiber. This type of fiber increases the movement of material through the digestive tract and increases stool bulk. Insoluble fiber does not form gels. It increases stool bulk, softens stool, delays glucose absorption, and it speeds up passage through the gastrointestinal tract (thus, it prevents constipation). Insoluble fiber delays starch breakdown (good in the case of diabetes). These are included in the vegetables, wheat, and grains, for example, cellulose, lignin, and many hemi-celluloses. It assists in promoting "regularity" of the stools and is included in vegetables, whole wheat foods, bran, nuts, seeds, and the skin of some fruits and vegetables.

Fiber, carbohydrates that have not been digested in the small intestinal tract, is digested to a variable extent when it enters the large intestine. The bacterial flora metabolize these compounds anaerobically to carbon dioxide, methane, and short-chain fatty acids (acetate, propionate, and butyrate) which are rapidly absorbed and metabolized primarily by the colonocytes. Indigestible polysaccharides such as cellulose (which consists of glucose units linked by β-1,4 linkages) are part of dietary fiber that passes through the intestine without full digestion and absorption [2].

Fiber provides the human body with the "roughage" needed to sweep the intestine clean of the build-up of materials, and thus it serves a valuable purpose. Fiber helps with motility, which is the ability of the gastrointestinal tract to move. Fiber does not provide the same number of calories as other carbohydrates, and it is not processed in an identical fashion. The recommended intake of fiber ranges from 20 to 35 grams/day for women and men, respectively. Fiber promotes the health of the large intestine and protects against both constipation and diarrhea, as well as appendicitis, diverticulitis, hemorrhoids, and cancer such as colon cancer.

The milling technique for removing fiber from whole grain flour (which began in the 1890s) produces white flour. The health benefits of higher fiber intake lowered the risks of metabolic disorders, such as obesity and diabetes, and cardiovascular diseases, such as heart disease and high blood pressure. The processes of chewing coupled with enzyme action and enough digestive fluids change fiber. However, it is not by these actions, rather it is by the trillions of bacteria living in the large intestine, that the true transformation of fiber occurs.

Specifically, fiber aids in reducing sensations of hunger and the subsequent intake of food. However, it must be noted that too much fiber, consumed in a relatively short time, may lead to binding minerals, leading to nutrient deficiencies or diarrhea and bloating. The acceptable macronutrient distribution range (AMDR) for carbohydrate intake, according to the Institute of Medicine, is 45 to 65 g, indicating that 45–65% of daily calories should come from carbs. The AMDR for adults is 10 to 35% for protein and 20 to 35% for dietary fat. Fiber content remains similar in fresh and frozen, as well as heat-processed fruits and vegetables.

Glucose is absorbed through portal blood to the liver. Fructose and galactose are converted to glucose in the liver. The only sugar utilized by the body is the glucose. Most of it is taken by the liver to be stored as glycogen or oxidized by glycolysis for acetyl Co A and lipid synthesis. A minimal amount passes through systemic circulation to maintain the blood sugar level in fasting conditions (the fasting blood glucose level is 60–110 mg/dl) [3]. As a general rule, carbohydrate-containing foods rich in free glucose, oligosaccharides are easily digested and absorbed and have a relatively high glycemic response (increase in blood sugar level). Low-glycemic index foods (legumes, pearled barley, grains) are a good choice for chronic diseases including cancer and diabetes [4]. It has been suggested that cooking and food processing (degree of starch gelatinization, food form, particle size, and food structure) play an important role in determining the glycemic index foods. In summary, the human body benefits from the consumption of complex carbohydrates as well as simple carbohydrates.

51.2.2 Protein

Proteins are polypeptides (polymers of amino acids). Sources of dietary proteins include animals (milk, fish, and meat) and plants (cereals and beans). Protein as a biomolecule is found in DNA, RNA, glycoproteins, and glycolipids [5]. It is the building unit for skeletal muscles as well as being an integral part of different cell membrane receptors, ions channels, and hormonal transports. Proteins as a peripheral on integral spanning molecules in the cell membranes play a vital role in cell membrane fluidity and hence the signal-transduction pathways which are essential for cells' normal function and homeostasis [5]. The biological functions of protein are classified into transport functions (albumin that transports some drugs, calcium, bile pigments, and free fatty acids, and hemoglobin that transports oxygen, and transferrin that transports iron and lipoproteins), metabolic control (enzymes and hormones, e.g. insulin and glucagon), skeletal proteins (actin and myosin), immune function (i.e. immunoglobulins, epitopic determinants), blood clotting factors (i.e. fibrinogen, thromboplastin, and thrombin), essential components of cell membrane and receptors, structural functions (collagen, elastin, keratin, and rhodopsin) [6].

Protein is composed of amino acids, linked together by peptide linkages. The side group "R" is the amino acid component that varies from one amino acid to another**.** There is a variety of 22 possible amino acids, nine of which are called essential amino acids as the human body does not make them. Proteins exist as either animal- or plant-based and yield 4 calories per gram when broken down. The acceptable macronutrient distribution range (AMDR) for proteins is within 10 to 35% of the diet. In some severe cases of a protein energy malnutrition (PEM) disease, kwashiorkor may appear. Kidney disorders may result from overconsumption. It is predominantly proteins to which a person shows negative food allergy symptoms. Labeling for a food's eight major allergens is required in the U.S., as guided by the FDA.

The eight most common food allergies, accounting for 90% of food allergic reactions, are listed herein, yet over 160 foods can cause allergic reactions in people with food allergies. These foods are also the food sources from which numerous food ingredients, thus perhaps allergens, are derived (FDA). The eight foods are (i) milk, (ii) eggs, (iii) fish (e.g. bass, flounder, cod), (iv) crustacean shellfish (e.g. crab, lobster, shrimp), (v) tree nuts (e.g. almonds, walnuts, pecans), (vi) peanuts (peas, not nuts), (vii) wheat, and (viii) soybeans. Regarding food allergies, these eight foods, as well as any ingredient that contains protein derived from one or more of them, are referred to as "major food allergens." Knowledge continues to expand about the physiology of protein and amino acid metabolism in the mammalian organism and especially in relation to human protein and nutrition metabolism; accordingly, to help Americans avoid the health risks posed by food allergens, the U.S. Congress passed the Food Allergen Labeling and Consumer Protection Act of 2004 (FALCPA). Food labels must identify these allergens prominently on the ingredients label. Other countries, such as others in North America, outside of the U.S., report differently [7].

51.2.3 Fat

Lipids are important dietary constituents. They are present in the diet mainly in oils, butter, liver, brain, and egg yolk.

Dietary lipids are ingested in the form of triglycerides, cholesterol, phospholipids, and free fatty acids. Lipids are the major source of energy in the body; 1 gram of fat yields 9.3 kcal [8]. Also, oxidation of fat stores provides energy which is enough to allow several days of survival during total food deprivation, while glycogen oxidation gives energy enough to sustain the functions of the body for 24 hours of fasting. They serve as structural components of the cell membrane (phospholipids and glycolipids). They provide an adequate supply of essential fatty acids and fat-soluble vitamins (A, D, E, and K) [8]. In addition, lipids represent a source of steroid hormones and prostaglandins. Adipose cells are specialized for synthesis and storage of triglycerides in their cytoplasm (in fed state) and for their mobilization into fatty acids and glycerol that are transported to other tissues by blood (in fasting state) [9].

Fats consist of triglycerides, phospholipids, and sterol as triglycerides contain glycerol and three fatty acids, phospholipids contain glycerol, two fatty acids, and phosphorus, and have sterol rather than fatty acids in the structure. Fat content in food increases when it is cooked in a fat-soluble medium. Fats and water do not mix well in food without adequate emulsification [8].

51.2.4 Vitamins and Minerals

Micronutrients are the vitamins and minerals, and these are non-calorie-containing nutrients. These may exist in foods as naturally occurring nutrients, or as added nutrients through the process of either enrichment or fortification. Vitamins are the primary nutrient capable of being lost in the process of preserving foods. Vitamins are either water- or fat-soluble. Water-soluble vitamins include the B vitamins and vitamin C and are easily oxidized in steam. In order to maintain these water-soluble vitamins, the cooking water should be minimal, and product size kept large with less surface area than if cut small-sized. The four fat-soluble vitamins, A, D, E, and K, are not lost in external watery environments, but rather in external cooking fat. Minerals generally remain intact when food is preserved.

51.2.5 Water

Water is the sixth nutrient, and consists of hydrogen and oxygen. It is either added to foods or it is removed. Removal is either deliberate through the process of dehydration, or inadvertent. In fact, very low or high moisture may render a food unacceptable to the palate. An appropriate amount of water aids in retaining high-quality foods with nutritive value, taste, appearance, and textural quality.

51.2.6 Phytochemicals

Plants manufacture chemicals known as phytochemicals that have multiple functions. Some attract insects to encourage fertilization; others provide defenses against predators such as viruses and animals. Phytochemicals exhibit diversified physiological and pharmacologic effects. Active derivatives extracted from leaves, stems, roots, flowers, and fruits of plants may be classified into three main categories: (i) toxic and of no therapeutic use, such as pyrrolizidine alkaloids, nicotine, and hydrazine derivatives, (ii) toxic but useful for treatment of disease when used in controlled amounts or defined chemical conditions, such as morphine, digitalis, vinca alkaloids, (iii) chemo-preventive activity, compounds useful against diseases, such as atherosclerosis, cancer, and diverticular disease [10].

Medicinal plants have vast potential in the treatment of various ailments due to the presence of therapeutically important phytochemicals. Flavonoids are one of such groups, belonging to the superfamily of polyphenols, which have been investigated broadly for their medical properties. Fruits, vegetables, grains, wine, and teas, which are rich in flavonoids, seem to have the ability to prevent or even reverse human chronic diseases by numerous mechanisms including the primary prevention of oxidative stress [11].

Flavonoids and the other phenolic compounds are commonly known as plant secondary metabolites that hold an aromatic ring bearing at least one hydroxyl group. More than 8000 phenolic compounds as naturally occurring substances from plants have been reported [12]. It is very interesting to note that half of these phenolic compounds are flavonoids presenting as aglycone, glycosides, and methylated derivatives [12]. These phytochemical substances are presented in nutrients and herbal medicines; both flavonoids and many other phenolic components have been reported on regarding their effective antioxidant, anticancer, cardioprotective agents, anti-inflammation, and immune system-promoting properties, for skin protection from UV radiation, and as interesting candidate for pharmaceutical and medical applications [11, 12].

51.3 EFFECTS OF FOOD PRESERVATION METHODS ON NUTRIENTS

As far as possible, when food safety is considered, foods should be consumed raw and at the peak of freshness, in order to maximize nutrient intake. Follow food safety rules such as avoiding the consumption of uncooked meats, poultry, fish, and eggs. Cook for a shorter time if it is safe to do so (again, not usually meat, poultry, and fish). Minimize exposure to air, heat, cold, and water. Reuse cooking water containing water-soluble nutrients that have leached out during cooking. When possible, cut produce into large pieces rather than small, for preservation and nutrient retention in the cooking process. For comparison purposes, we will look at fresh foods first—fresh foods are generally consumed prior to postharvest nutrient degradation. This is optimal for maximum availability of nutrients. Cooking in water makes the water-soluble vitamin C from fresh fruits and vegetables susceptible to losses during cooking and thermal processing. Heat, light, and oxygen also cause nutrient losses. Minimal storage time and the correct temperature are crucial to the maintenance of vitamin C and overall nutritive value. Vitamin C content rapidly diminishes during greater than minimal storage, as illustrated in Table 51.1.

TABLE 51.1
Typical Maximum Nutrient Losses (as Compared to Raw Food)

Vitamins	Freeze	Dry	Cook	Cook + Drain	Reheat
Vitamin A	5%	50%	25%	35%	10%
Retinol equivalent	5%	50%	25%	35%	10%
Alpha carotene	5%	50%	25%	35%	10%
Beta carotene	5%	50%	25%	35%	10%
Beta cryptoxanthin	5%	50%	25%	35%	10%
Lycopene	5%	50%	25%	35%	10%
Lutein + zeaxanthin	5%	50%	25%	35%	10%
Vitamin C	30%	80%	50%	75%	50%
Thiamin	5%	30%	55%	70%	40%
Riboflavin	0%	10%	25%	45%	5%
Niacin	0%	10%	40%	55%	5%
Vitamin B_6	0%	10%	50%	65%	45%
Folate	5%	50%	70%	75%	30%
Food folate	5%	50%	70%	75%	30%
Folic acid	5%	50%	70%	75%	30%
Vitamin B_{12}	0%	0%	45%	50%	45%
Minerals	**Freeze**	**Dry**	**Cook**	**Cook + Drain**	**Reheat**
Calcium	5%	0%	20%	25%	0%
Iron	0%	0%	35%	40%	0%
Magnesium	0%	0%	25%	40%	0%
Phosphorus	0%	0%	25%	35%	0%
Potassium	10%	0%	30%	70%	0%
Sodium	0%	0%	25%	55%	0%
Zinc	0%	0%	25%	25%	0%
Copper	10%	0%	40%	45%	0%

Table 51.1 represents maximum nutrient losses in freezing, drying, cooking, cooking (and draining), and reheating, based on USDA data. The table compares the typical maximum nutrient losses for common food processing methods. This table is included as a general guide only. Actual losses will depend on many different factors, including the type of food and cooking time and temperature. For additional data on specific preparation methods, please see the USDA Table of Nutrient Retention Factors. Decidedly, there are additional, numerous ways in which foods can be preserved besides freezing, drying, cooking, and so forth [13].

The preservation of fresh foods is needed in order to prevent quality degradation, including nutrient losses. The end desired result of food preservation is food safety and a similarity to the fresh counterpart. Nutrients are lost during harvest to processing and during storage until foods are consumed. Preservation of nutritional value in fresh, frozen, and canned products is reported by Barrett. Some highlights of preservation of nutritional value in fresh, frozen, and canned products are reported by Barrett [21, 22].

"The USDA provides the most current data on nutrient retention. In this report 290 foods are referenced about their nutrient losses that are typical with common food processing methods such as freezing, drying, cooking and reheating." It explores "The specific factor representing the amount of the food component retained during the specified treatment."

51.3.1 Drying/Dehydration

Nutrient loss occurs immediately after the food item is cut and exposed to the surrounding air and dried. The vitamin A precursor beta-carotene and vitamin C are lost during drying. Commercial losses are 10–50% and 30–80% for these vitamins, respectively, and greater if preserved at home. Pretreatments may either save or cause loss of nutrients upon drying. For example, pre-treatment with sulfur dioxide (not used for organic produce) protects vitamins A and C yet causes a loss of vitamins B [14]. The nutritive value of freeze-dried foods was shown to be retained and higher than that of other drying methods. For example, with freeze drying, vitamins A and C level changes were not significantly different as compared to fresh. Freeze drying also shows a less negative effect on food shrinkage and taste as compared to the common dehydrating techniques. Potential nutrient losses in the dried green, leafy vegetables were observed. The beta-carotene is retained in the range of 20–69%, vitamin C up to 14%, and thiamin is retained in the range of 22–72% in the case of steam-blanching for 5 minutes followed by oven drying [15, 16]. Other diminished levels of nutrients such as polyphenols

were reported. [17, 18]. Upon rehydrating, and cooking with excessive heat, some water-soluble vitamin C and minerals may leach out, and be lost.

51.3.2 Heating. Mild (Blanching, Pasteurization)

Fewer nutrient losses occur through preservation techniques involving cold than through techniques involving heat [19]. Food preservation may involve mild techniques of heat treatment such as blanching or pasteurization. Even mild blanching, usually by steam or water, may result in a reduction of nutritive value via loss of some water-soluble vitamins (vitamin Bs [thiamin, riboflavin, and niacin of the B complex] and vitamin C). Fruit juices high in vitamin C, such as lemon, orange, or pineapple, ascorbic acid, or commercial products containing ascorbic or citric acid may be used for dipping new surfaces of cut fruits to prevent browning [20]. If added, there is an increase in nutritive value.

51.3.3 Heating (Canning)

As previously mentioned, the heat treatment of canning is classified as "severe," not mild. As a result, some water-soluble vitamins are destroyed. Canning is more deleterious to the structure and nutritive vitamin value of foods, such as fruit and vegetables, than if the food were untreated and eaten at the peak of freshness, soon after harvest. Canning exposes fruits and vegetables to high temperatures which degrade vitamin C and may cause leaching into the brine in the can. Vitamin C decreased by 10–90% during the canning of various vegetables, but there was little change in content during the storage of canned products [21]. The canned food processing treatment results in the loss of water-soluble nutrients such as vitamins C and B, and polyphenols, as these may leach out into the cooking water or canning medium. The actual cooking time and use of water of a canned product are less than those needed for a fresh or frozen product. This results in less vitamin C loss in cooking canned foods [21] As far as the B vitamins, thiamin and vitamin B6 specifically, which are very sensitive to heat and light, canning nutrient losses vary from 7 to 70%, depending upon the vegetable canned. Freezing and canning processes may relatively preserve nutrient value as compared to drying [22].

Heating may increase the presence of some antioxidant levels in fresh produce. This is true of the antioxidants beta-carotene and lycopene in tomatoes and carrots. A frozen vegetable company states the following: "Although freezing and canning may reduce the nutritive value of fruits and vegetables to a degree, they extend the length of time they are available. Once the products are processed, nutritive losses in the canned or frozen products are minimal if the products are stored and handled appropriately" [22].

Food processing may be achieved by heat, cold, or other means. The nutritive value of foods must be considered and maintained during food preservation [21–23]. Of the plethora of foods available for consumption, for example, fruits and vegetables, grains, dairy, meat, poultry, and fish, beverages, and so forth, many have been well-received worldwide. Food composition, including flavor, may be altered in the process of preservation. Preserving herbs (herbaceous, leafy part of plants) in cooking oil or vinegar aids in retaining/imparting flavor. Also, lactic fermentation compared with unfermented food may impart nutritive (and enzymatic) benefits of a more robust level. In food preservation, the nutrients must also be retained. More can be explored about the effects of processing on some nutritionally significant compounds in foods. Proper storage and timely consumption should occur for all consumers interested in healthy diets.

51.3.4 Refrigeration

Consumers may not detect that many fruits and vegetables rapidly lose their nutritional value when stored for more than a few days. After being purchased and stored in the refrigerator, some fruits and vegetables can lose as much as 50% of their vitamin C and other nutrients, depending on the temperature [23].

51.3.5 Freezing

Published studies comparing the nutritive value of fresh, frozen, and canned fruits and vegetables are limited. Noted more prevalently in studies are changes to color, texture, and flavor attributes. More inert, unchangeable nutrients such as minerals and fiber levels were similar in fresh, frozen, and canned fruit and vegetable products. These are not sensitive to the heat and subsequent degradation of food preservation. Sensitive to heat, light, oxygen, and pH, vitamins A, E, and lycopene may be lost in processing and preservation treatments. An advantage of cooking is that there is better bioavailability of some nutrients, and preservation may be better assured with some level of cooking foods (parboiling, and so forth). Cooking can both positively and negatively affect foods—a vegetable's color (pigment), texture (hemi-cellulose, starch, etc.), flavor (stronger or milder), and nutritive value (B vitamins, vitamin C, calcium, and so forth).

A more comprehensive discussion is based on a review of literature by Rickman et al., using the nutritional value of fresh, canned, and frozen fruits and vegetables [24, 25]. The conclusion regarding produce is that "Exclusive recommendations of fresh produce ignore the nutritional value of canned and frozen products and may conceal the sensitivity of fresh products to nutrient loss. "Although fresh-picked produce stored for a short time under optimal conditions and consumed raw will most likely provide maximal nutrition, the availability of such produce is limited by region and 'seasonality'."

Vitamin C losses during freezing were slightly lower as compared to canning. Losses were strongly influenced by the individual commodity, and the blanching and freezing methods utilized. If the storage temperature was well-maintained, the frozen fruit and vegetable products showed little change in nutrient content [24].

The short heating time, i.e. blanching pretreatment prior to freezing, inactivates enzymes and results in only a minor

TABLE 51.2
Factors That Remove Nutrients from Food

Vitamin C	X	X	X	
Thiamin	X		X	
Riboflavin			X	
Vitamin B_6	X	X	X	
Folate	X	X		
Vitamin B_{12}	X		X	
Biotin			X	
Pantothenic acid	X			
Potassium			X	

loss of the foods' nutritive value. The various B vitamins were shown to lose 20–60% upon blanching and freezing [25]. Table 51.2 illustrates the typical maximum nutrient losses as compared to raw food and compares the typical maximum nutrient losses for common food processing methods. This table is included as a general guide only. Actual losses will depend on many different factors, including the type of food and cooking time and temperature. For additional data on specific preparation methods, please reference the USDA "Table of Nutrient Retention Factors." In it can be seen that the preservation processes that expose foods to high levels of heat, light, and/or oxygen cause the greatest nutrient loss [25].)

51.3.6 Pickling

The amount of fiber in fresh-pickled vegetables is usually similar to fiber in cooked vegetables. Fat-soluble vitamins, such as A, D, E, and K, are similar during pickling and when cooked. Korean researchers have found that kimchi (a spicy pickled cabbage), has up to twice as much of some B vitamins as compared to fresh cabbage. Certain vitamins are lost during pickling. For example, the heat necessary for canning pickled vegetables destroys much of the vitamin C. Light destroys riboflavin. The storage of pickled vegetables in a cellar or dark room serves to reduce exposure to light, and the subsequent destruction of riboflavin [26].

51.3.7 Radiation: Microwaving and Irradiation

It is reported that microwave heating inactivates vitamin B_{12}, which is found in animal products and fortified vegetarian products [27]. The study compared microwaving or steaming vegetables, such as cabbage, carrots, cauliflower, and spinach, to pressure cooking. It was found vegetables that were pressure cooked lost more insoluble fiber, which is good for gut health, than those that were microwaved or steamed. A key nutrient usually destroyed when cooking vegetables is vitamin C, a severe lack of which can lead to conditions like scurvy [28]. But microwaving accounts for greater nutrient losses than irradiating. This is because water-soluble nutrients are readily destroyed when they are heated, in microwaving [28].

51.4 CONCLUSION

Food provides the ideal mix of vitamins, minerals, and other nutrients. But the nutrients in foods begin to decrease as soon as the fruit or vegetable is picked and continue to decline until the food is eaten. The sooner you eat the food, the lower the chance of nutrient loss. Water-soluble vitamins, especially thiamin, folic acid, and vitamin C, can be destroyed during improper storage and excessive cooking. Heat, light, exposure to air, cooking in water, and alkalinity are all factors that can destroy vitamins. If food is not eaten within several days, freezing is the best method to retain nutrients. The handling, storage, and preservation of food often involve changes in nutritive value, most of which are undesirable. The freezing process, if properly conducted, is generally regarded as the best method of long-term food preservation when judged on the basis of retention of sensory attributes and nutrients. The freezing process is, however, not perfect, as is apparent from the fact that substantial amounts of the more labile nutrients can be lost. Vitamin losses during freezing preservation vary greatly depending on the food, the package, and the conditions of processing and storage. Losses of nutrients can result from physical separation (e.g. peeling and trimming during the pre-freezing period, or exudate loss during thawing), leaching (especially during blanching), or chemical degradation. The seriousness of these losses depends on the nutrient (whether it is abundant or meager in the average diet), and on the food item (whether it generally supplies a major or a minor amount of the nutrient in question).

52 Packaging as a Preservation Technique

Mohammad Shafiur Rahman

CONTENTS

52.1 INTRODUCTION

Packaging has been with humans for thousands of years in one form or another. Packaging dates back to when people first started moving from place to place. Originally skins, leaves, and bark were used for food transport. Mesolithic humans used baskets and Neolithic humans used metal containers and discovered pottery. Four thousand years ago sealed pottery jars were used to protect against rodents, and in 1550 B.C. glass making was an important industry in Egypt. Tin plating iron became possible in A.D. 1200 and as steel replaced iron, this method became useful after A.D. 1600. In 1825 Oersted first extracted aluminum [1]. The Greek and Roman times saw the rise of pottery and the start of the use of glass. In the 1400s timber chests were first used, and after 1850 paper and glass started to be used substantially as processes were developed for mass production. Napoleon Bonaparte was involved in the invention of canning. More recently plastics were developed, particularly the first commercial plastics in the United States in 1935–42 [1].

One hundred years ago there was little use for packaging in the food industries. Now tremendous progress has been made in the development of diversified packaging materials, package design, packaging equipment, and environmental safety and sustainability. Over the last three decades, packaging has grown in volume and importance into one of the most significant areas of food production. This chapter provides an overview of food packaging.

52.2 PURPOSE OF PACKAGING

In addition to the direct approach to food preservation, such as drying and freezing, other measures such as packaging and quality management tools need to be implemented in the process to avoid contamination or recontamination. Although these measures are not preservation techniques, they can play important roles in producing high-quality and safe food [2]. Packaging performs five main functions: product containment, preservation and quality, presentation and convenience, protection, and provide storage history—the 5Ps.

52.2.1 Product Containment

The first function of packaging is its capability of containment. The primary purposes of packaging are containment and protection. It is self-explanatory; liquids, semiliquids, and powders, as well as bulk solids, cannot be marketed without suitable containers. According to the size of the package, different amounts of the product can be delivered

to consumers suiting their choice and convenience [3]. In certain circumstances, quantification is mandatory, as in the case of medical pills or capsules that are marketed individually in a blister-type package. Containment refers to holding goods in a form suitable for transport, whereas protection refers to safekeeping goods in a way that prevents significant quality deterioration.

52.2.2 Preservation by Maintaining Quality

The second function is to control the local environmental conditions to enhance storage life and safety. The main purpose of food packaging is to protect the product from the surroundings and to maintain the quality of the food throughout the product's shelf life. Packaging is one means of spreading product availability over time. Product shelf life is controlled by three factors: product characteristics, properties, and storage and distribution conditions of individual packages [4]. Reactions causing deterioration in foods include enzymatic, chemical, physical, and microbiological changes. Additional problems include insects, pests, and rodents.

52.2.2.1 Nutritional Quality

Packaging affects the nutritional quality of foods. Examples include peroxidation of polyunsaturated fats and destructive oxidation of nutrients such as ascorbic acid, tocopherols, vitamin A, folate, and riboflavin. Fatty acid peroxides are well established as causing health problems. As antioxidative nutrients such as vitamins C and E are lost, other food components become even more vulnerable to oxidation. Carotenoid pigments can also be oxidized, leading to loss of color as well as loss of their beneficial effects in the body. Lipid hydroperoxides can also result in the formation of aldehydes and other compounds with off-flavors. Such peroxides can act as free radicals, which, in turn, can damage other food components such as proteins [5].

Light induces photodegradation and causes loss of vitamins, especially riboflavin (which also acts as a photosensitizer), β-carotene and vitamin C; production or degradation of free amino acids; increases peroxide value; formation of sensory unpleasant volatile compounds (methional, aldehydes, and methyl ketones); and color changes [6]. Oxidative rancidity occurs when oxygen reacts with unsaturated fatty acids either spontaneously on exposure to air (autoxidation) or in the presence of light and sensitizers (photosensitized oxidation) such as chlorophyll or myoglobin. Among all other functions of packaging, the protection of foodstuffs against light plays a key role, particularly during storage, transport, and sales display. Visible light covers a wavelength range of 380 to 700 nm and ultraviolet (UV) light a range of 200 to 380 nm. Photodegradative processes induced by UV light should be given priority because of its high energy content, which is capable of splitting certain chemical bonds. Fluorescent light can initiate photooxidation in foods. In addition to light barriers, use of UV absorbers in the packaging material can decrease lipid oxidation [7].

52.2.2.2 Barrier Properties

Many packaged foods contain living systems in the form of active enzymes and the respiration process. Indeed, the benefits of controlled atmospheres with less oxygen and more carbon dioxide result in part from slowing the effects of these enzyme systems. The carbon dioxide is sometimes generated within the package by enzymatic action. If there is gas exchange across the packaging plastic, the benefits of the effect are diminished [5]. Ethylene affects the physiological processes of plants. As a plant hormone, ethylene regulates many aspects of growth development and senescence, and is physiologically active in trace amounts (<0.1 ppm). It is a natural product of plant metabolism and is produced by all tissues of higher plants and by some microorganisms. Moreover nonethylene and nonrespiratory organic volatiles may also have physiological and/or quality efficiency [8]. Thus packaging can also play a part either by absorbing ethylene (or other volatiles) or preferential transmission of this gas.

To achieve optimum packaging performance, it is important to know product characteristics, properties of the individual package, and storage and distribution conditions [9]. The knowledge of product characteristics and conditions of storage and distribution dictates the required barrier properties of the packaging materials used for a specific application. Barrier properties include permeability of gases (oxygen, carbon dioxide, nitrogen, ethylene, etc.), water vapor, aromas, and light. These are vital factors for maintaining the quality of food. However, packaging materials cannot be chosen solely on the basis of their barrier properties. Factors such as processability, mechanical properties (tensile strength, elongation, tear strength, puncture resistance, friction, burst strength, etc.), and chemical resistance and interaction with the product must also be taken into account [9]. Environmental factors, such as temperature, relative humidity, and light intensity to which the product is exposed during storage and distribution must also be taken into consideration when selecting packaging materials. Transportation damage may happen to the product due to the vibration and other stresses during transport. The extent of such damage can be reduced by proper packaging, such as introducing padding and support and by adjusting the distribution pattern according to the transported product [9].

Current packaging techniques perform more on the preservation by direct interaction with the product. Earlier food packaging materials used to provide only barrier and protective functions. Now various types of active substances can be incorporated into the packaging material to improve its functionality and give it new or extra functions. Such active packaging technologies are designed to extend the shelf life of food while maintaining nutritional quality and safety. Active packaging technologies involve interactions between the food, the packaging material, and the internal gaseous atmosphere [10]. In some cases, the new concept of active or life packaging material allows a one-way transfer of gases away from the product or the absorption of gases detrimental to the product.

Smart packaging with antimicrobials adds a dimension to safety [11]. The extra functions they provide include oxygen

scavenging (absorbing oxygen gas in the package and preventing rancidity, and are being developed as forms of sachets or polymer additives), antimicrobial activity, moisture scavenging, ethylene scavenging, and ethanol emitting [12]. Floros et al. [13] reviewed existing active packaging products and patents. Now it is possible to tailor the atmosphere to suit the needs of the food product inside the package. Indeed, the package itself can be the main regulator of atmospheric conditions within the headspace. The modified atmosphere could provide consumers benefits including quality retention, additive reduction, and fumigant elimination, and match today's busy lifestyle by providing fresh, ready-to-eat take-home meals.

52.2.2.3 Antimicrobial Packaging

Antimicrobial packaging is a promising form of active food packaging. When antimicrobial agents are incorporated into a polymer, the material limits or prevents microbial growth. This application could be used for foods effectively, not only in the form of films but also as containers and utensils. The incorporation of antimicrobial agents with polymeric packaging provides an economic and labor-free way to solve food surface contamination problems [14]. Food packaging materials may obtain antimicrobial activity by common antimicrobial substances, radiation, or gas emission/flushing. Radiation methods may include using radioactive materials, laser-excited materials, UV-exposed films, or far-infrared-emitting ceramic powders. Irradiation sterilization of food packaging materials is not yet permitted by the U.S. Food and Drug Administration (FDA) [12]. A variety of films can be made with antimicrobial activities and various degrees of clarity for use as food packaging. An extensive list of antimicrobial agents used in packaging materials is given by Han [12]. One of the new technologies expected to enhance plastic film barriers to gases and vapors is glass (silica)-coated plastics or the use of other ultrathin coatings such as diamond or other chemically treated surfaces [15]. The development of coated packaging materials, which absorb or block the ingress of taints during container transport of food to export markets, will be of particular benefit. Active and intelligent packaging is still largely a research field, but some manufacturers have already developed sachets of substances that can change the atmosphere inside the package, such as oxygen scavengers. Oxygen removal is not always easy. Oxygen removal can be mechanical, but air in the packaging materials or residual oxygen cannot be effectively removed in many cases. Conventional oxygen scavenging is too slow to retard the changes in many products. Oxygen scavenging systems can also be incorporated in a plastic package, thus forming an integral part of its structure. There are significant technical and commercial advantages in not having to insert sachets or attach labels to trays or bags. They can be activated just prior to use. The package can be manufactured and stored under standard conditions, then triggered to an activated state prior to filling. Inhibition of lipid oxidation in fish muscle can be done by packing antioxidant-incorporated polyethylene film [16]. Oxygen scavengers can also be added in the cap of a glass container.

Different foods require different packaging solutions. For example, the deterioration of product quality in bakery products is due to crystallization of starch granules, causing staling; moisture uptake, causing a reduction in crispness; mold growth, as bakery products typically have a high moisture content; rancidity from exposure of lipids to oxygen; and drying out of the interior (crumb) of a loaf of bread. The main forms of packaging for bakery products have distribution rather than protection as their primary objective. Product quality is ensured by specifying a short shelf life. For example, bread should be consumed as quickly as possible. It is difficult to specify a packaging material for bread that could meet the competing requirements of keeping the crust dry and the crumb moist. Furthermore, moisture movement from starch to protein within the crumb leads to texture changes as the bread ages. Since the shelf life is short, the goal of bread packaging is partially moisture control, but its main purpose is to allow the product to be distributed safely and hygienically. The material used should be inexpensive, as bread is a staple. Materials such as waxed paper, cellophane, and polyethylene are commonly used in bread packaging. Bread was one of the first mass products to be packaged in plastic bags, and it is the largest single domestic consumer product to go into plastics packaging. For many bakery products, even this level of packaging is excessive. Cakes and pastries are often distributed in cardboard boxes that are not airtight, made possible with a waxed paperboard support. Packages containing pies must have air holes, so that the package can "breath" moisture during heating or cooling, preventing crust uptake of moisture [1].

52.2.2.4 Edible Film

Edible antimicrobial films are a particularly promising development. Edible coatings can inhibit the growth of microflora themselves, and these films also offer the opportunity to provide high concentrations of antimicrobials at food surfaces. Edible films may also be used to overcome some of the difficulties in maintaining modified atmospheres around packaged ripening produce. The ratio of the permeability values of the film to carbon dioxide and oxygen can be crucial [15]. Enzyme-generated biofilms for packaging fresh food can be developed from cross-links of proteins [17]. The most important properties to be evaluated in an edible coating are its microbiological stability, adhesion, cohesion, wettability, solubility, transparency, mechanical sensory properties, and permeability to water vapor and gases [18]. Recent approaches of edible coatings are to develop active envelopes to include oil consumption reduction in deep-fat fried products, transport of bioactive compounds, and shelf life extension of highly perishable products [18].

52.2.3 Presentation and Convenience

The third function of packaging is presentation and convenience. In many cases, these are the most important factors for consumers.

52.2.3.1 Presentation

Food labels are intended by law to provide the information that consumers need in order to be able to make the necessary decisions about food purchases. It is important to display the product in an attractive manner to the potential buyer. A cleverly designed and beautifully produced packaging can help sell a product, which is an essential ingredient of an effective marketing campaign. The packaging helps in distinguishing products on the shelf, which is a trait especially important when marketing low-fat or nutritional products. Furthermore, packaging must address communication, legal, and commercial demands. For a package to be effective, it must present the product well and should do its own publicity. The protective packaging may have flaps that can be opened to give a ready-made display for the product, whereas some stores may remove the protective packaging to display the product directly on the shelves, leading to a preference for rectangular containers. The clarity (haze) and gloss optical characteristics are important in packaging presentation. Design based on marketing includes apparent size, attention-drawing by giving an impression of quality, and clear innovative readability of the packaging label [19].

52.2.3.2 Convenience

In many instances, consumers have limited time to shop, cook, and clean; and they prefer prepared or ready-to-eat meals that taste homemade [20]. Different types of packaging design could include various forms of conveniences, such as easy opening, microwaveable packaging, tamper-proofness, and smart barcodes.

52.2.3.2.1 Easy Opening

In many cases, packaging provides convenience to consumers, for example, paper cartons for milk or juice with an ease-open and easy-pour cap, and thus could also increase consumption. Semirigid packaging containers, such as stand-up flexible pouches and stick packs for unit portion sizes, are shifting toward thin, light, and flexible plastics. The closures of any rigid and semirigid package are key for a real competitive advantage. Zippers, slides, and pressure-sensitive adhesive flaps with different designs are being used [21].

Convenience takes different forms [22]: easy to hold, use, open, and close; handheld consumption, such as in a car or at a desk enabling multitasking; easy to prepare, cook, and reheat; and ready-to-eat microwaveable meals. Other conveniences could be smaller portions, reclosable, and tamper-proof options.

Value-added packaging allows in-package cooking and facilitates on-the-go consumption. Self-heating containers are also being developed. In a system described by Webb [23], an exothermic reaction takes place with crushed limestone and starts the heating process. Users would push a button on the bottom surface of the can, and the container fully heats within 5 minutes.

52.2.3.2.2 Microwaveable Packaging

Changes in society, such as diminishing population patterns, increasing average age, smaller families, and more leisure time, as well as improvements in the quality of life, standard of living, and general level of education may also demand specific functions from packaging [24]. Eating styles, such as ready-to-eat meals, snacks, and microwaveable ready meals have been changed over the years, which need innovation in packaging. For children, the packaging might represent innovation or fun [25].

Today's consumer wants to buy food that is ready-to-eat or needs a minimum of preparation, and is good value for money [26]. With microwave food preparation increasing, there is a need for the packaging industry to confront the particular problems in designing packages that deliver microwave products to the dinner table. Food processors can accelerate the usage of microwave ovens by designing products and packages that allow microwave heating or cooking to provide quality [27]. Three types of materials—transparent to microwave, reflective to microwave, and absorbent—can affect the cooking [28]. The transparent materials are nonmetallic substances such as ceramics that are coated or filled with microwave absorbent materials. The reflective category is composed of all devices that are metallic and absorb heat [27]. Aluminum is often used to selectively shield microwaves or redirect microwave energy from certain areas or locations of food. For example, portioned meals need to be heated at different rates, and sensitive portions need to shielded so that the entire meal can be heated more evenly [29]. In the case of frozen foods, such as lasagna, microwave energy needs to be redirected from the edges to the center. Absorbent materials are used to generate localized heating. For example, surface heating using absorbent materials could mimic browning and crisping. Absorbents (i.e., subsectors) are commonly available as flat pads, sleeves, and pouches with various patterns [28]. Arcing between foils needs to be prevented, which could be achieved by foil components that recede from the edge of the package to avoid arcing with the oven walls [30].

The critical design aspect of microwaveable ready-to-eat meals is the safe release of internal steam buildup in packages after microwaving. The build-up pressure could injure the consumer during opening. In extreme cases, pressure could expand and explode the package in the microwave oven (a hazardous situation), and at least a mess to be cleaned up. The internal pressure could be relieved by a weak heat seal that fractures from excess steam pressure during microwave heating, or the incorporation of shrink-film covered vent spots that melt or fail as a result of steam pressure. Films with laser scored or perforated weaknesses are being designed, which would fail and release the internal pressure inside the microwave. These microperforations or partial cuts remain intact during distribution and initial heating, and fail only above extreme pressure [21].

52.2.3.2.3 Tamper-Proof Packaging

Consumers want to tamper-evident closures to avoid packaging being opened unnoticed. In general, tamper-proof packaging makes products more difficult to open so there is clearly a need to balance safety with consumer accessibility [24]. The tamper-resistant package is to alert the consumer that tampering has taken place and to provide visible evidence of

tampering. In many cases, consumers are willing to pay more for tamper-resistant packaging. Tampering can be classified into four categories: two for type of tampering and two for location of tampering [31].

Casual tampering or grazing happens in the store. People sometimes open a product to taste or smell it. Or people attempt to change a price by switching caps. These people usually intend no harm. Malicious, surreptitious tampering usually occurs outside the store. The tampered package is then placed on store shelves. For normal routes of entry, the casual tamperer opens the package and recloses it using the cap or the tear strip or the tear out easy-open end. A malicious tamperer often finds uses an evasive route of entry and the package is reclosed by any means other than the cap or the tear strip. The intended route of entry and therefore the tamper-resistant feature is left undisturbed [31].

Holograms provide good security for labels and they can guard against forgery because they cannot be copied successfully and are difficult to duplicate. A generic self-adhesive hologram tape with tamper-evident properties may be used on various substrates to protect, secure, and authenticate products. Hologram tape can easily disclose whether cartons or boxes have been tampered with. Another tool is holographic shrink sleeves that are reverse printed and attached with tamper-evident holographic stripe inside the sleeves [22].

Covert taggants are unique, hard-to-replicate particles that can be added to inks, paper, films, and other materials, and they can be detected with a specialized reader. Beyond barcodes and optical authentication systems, covert taggants are used to include additional security features on applications ranging from passports to packaging. In the food industry, they are used on premium wines and spirits. Other high-tech covert taggant uses include surface-enhanced Raman scattering (SERS), a nanoscale phenomenon, to generate robust, unique, secure optical fingerprints. SERS materials provide a unique signal that can be detected using specialized readers, and therefore provide highly counterfeit-resistant security solutions for a broad range of applications including brand security [22].

Cases of extortion or sabotage have also been reported. In the mid-1970s, child-resistant packaging became an issue, leading to the development of childproof lids for poisonous products. Tamper-resistant refers to the ability of the packaging to resist tampering (or opening), for example, for child protection, whereas tamper-evident refers to the ability of the packaging to reveal that it has been opened.

52.2.3.2.4 Smart Barcodes

Radio-frequency identification (RFID) tags increase convenience and efficiency in supply chain management and traceability. They can be read via radio, meaning without any specific orientation and at greater distances than what is required for barcodes. Whereas a barcode indicates the type of item it is printed on, an RFID tag indicates not only the type of object it is attached to, but also a unique serial number, and thus can distinguish a given package from every other one in the world [22]. RFID uses radio waves to track items wirelessly. It makes use of tags or transponders (data carriers), readers (receivers), and computer systems (software, hardware, networking, and a database) [19]. The working principles of an RFID system are [32] (i) data stored in a tag are activated by a reader when an object with an embedded tag enters the electromagnetic zone of a reader, (ii) the data are transmitted to a reader for decoding, and (iii) the decoded data are transferred to a computer system for further processing.

2D bar codes are capable of being scanned by smartphones to deliver additional information to users. The ScanLife™ solution goes a step beyond the ability to gather data and analyze by using a camera phone into an all-in-one 2D bar code reader to quickly access websites for product pricing and more. This type of technology could also be used for marketing campaigns. SnapTags™ delivers interactive functionality and traceability to mass marketing by making any logo a gateway to mobile marketing [22].

52.2.3.2.5 Design Simplicity

Packaging design has a strong impact on the point-of-purchase decision. Favier et al. [33] investigated simplicity/complexity through a multidisciplinary approach by mobilizing the fields of semiotics, art history, and marketing. They identified that simplicity/complexity of a package design has a significant impact on brand perception. Simplicity is associated with modernity, reliability, authenticity, success, and sobriety; and complexity with seniority, joy, imagination, charm, femininity, and sophistication.

52.2.4 Protection during Distribution and Processing

The fourth function of packaging is to protect the product during transit to the consumer. Packaging is part of the distribution process necessary to deliver goods to the consumer and facilitate handling and transportation. It also has affected international trade by making shipping of food products possible, allowing seasonal products to be more accessible out of season. Packaging can handle challenges in the food distribution chain, such as heat, humidity, and dew. It is important to aware of the distribution challenges when designing packages.

In the case of prepacked products, they should have the ability to withstand the severity or type of process conditions, such as flexible packaging during canning, and microwavable, ovenable, and retortable foods. Irradiated foods are usually prepacked prior to treatment by ionizing radiation, which prevents recontamination. Packaging materials are also exposed to radiation during treatment, though in this instance it can lead to radiation-induced degradation of the packaging material, followed by interaction between the material and food product [24].

Protective packaging is a term applied to packaging that is primarily designed to protect the goods, rather than for appearance or presentation. Generally protective packaging is applied to the outer containers used for transporting goods from the manufacturer to the point of sale, and filling materials inside the outer containers, e.g., nylon barrier-sealed

bubble packaging (computer parts), urethane expanding foam, polyethylene (PE) foam package "cushions," and polystyrene (PS) loose-fill packaging. The most widely used protective package is the outer carton. All packaging is protective as one of its primary functions, so it is more accurate to call this transport packaging or tertiary packaging (on the basis of the primary packaging being in contact with the product, secondary for grouping units together for single purchase, and tertiary being for grouping secondary packaging for convenience distribution). A pallet is the frame base for carrying the transport packs [1]. The primary packages are put into cartons and the sealed cartons are transported through specialized conveyors, allowing products from different processing lines and sorting onto individual product pallets.

52.2.5 Provide Storage History

A time–temperature indicator (TTI) is effective for predicting microbial concentrations and other parameters of food quality during shipping and storage. It helps ensure proper handling and provides a gauge of product quality (i.e., microbial conditions or ripening status) for sensitive products in which temperature control is imperative to efficacy and/or safety. TTIs are tags that can be applied to individual packages or shipping cartons to visually indicate whether a product has been exposed to time and temperature conditions that adversely affect the product quality. TTIs could be used in chilled foods to identify temperature abuse during storage, display, and distribution.

According to the response mechanisms, TTIs can be divided into three groups: (i) biological, (ii) chemical, and (iii) physical systems. One of them is the use of enzyme-based TTIs to monitor and predict shelf life of products. The tags are available in a one-dot version and a three-dot version with the three dots changing color at different rates. The change of color of the dot indicates the exposed time and temperature of the product [34].

There is considerable potential for the use of TTIs in the food distribution chain, but there are two issues to be considered. One is economics. When using a TTI for a relatively low-cost product, such as lettuce, the indicator also has to be relatively low in cost. This should be considered or addressed by the manufacturer of the indicator. The other issue is knowledge of the food product. The food processor must know the degradation kinetics of the product—how the quality characteristics of the product are changing with time and temperature exposure—in order to select the indicator that matches it [34].

The intelligent ripeness indicator (such as RipeSense™) responds to the aroma released as fruit ripens, giving consumers a better way to determine the ripeness of fruits before opening the pack, and thus provide optimum quality when consumed and reduce waste [22]. The gas concentration indicators in a pack could create tremendous applications, especially in modified atmosphere packaging. The most common oxygen indicator is pink when the ambient oxygen concentration is $\leq$0.1%, then turning blue when the oxygen concentration is $\geq$0.5%. The presence of oxygen is indicated in 5 minutes or less, although the change from blue to pink may take 3 hours or more. "Intelligent ink" has developed by using light-sensitive nanoparticles, such as titania (TiO_2) that can only detect oxygen [35]. The ink is blue in air and ambient room light, but the color changes to white if irradiated with a pulse of UV light. The color can revert to blue under normal room light. In an oxygen-free atmosphere, the ink remains colorless after the UV pulse. This type of ink could be inexpensive and could also be used to indicate if the original modified atmosphere inside a package has changed. Similar novel carbon dioxide intelligent pigment can be incorporated into a thermoplastic polymer to create a long-lived, carbon-dioxide-sensitive plastic film [36].

52.3 IDEAL PACKAGING

There is no such thing as the ideal packaging. Packaging should be such that we could come close to the ideal. The criteria of ideal packaging are [1]

- Zero toxicity
- High product visibility
- Strong marketing appeal
- Ability of moisture and gas control
- Stable performance over a large temperature range
- Low cost and availability
- Suitable mechanical strength (i.e., strength in compression, wear, and puncture characteristics
- Easy machine handling and suitable friction coefficient
- Closure characteristics, such as opening, sealing and resealing, and pouring
- Ability to include proper labeling
- Resistance of migration or leaching from package
- Protection from loss of flavor and odor,
- Controlled transmission of required or unwanted gases

52.4 TYPES OF PACKAGING MATERIALS

From skins, leaves, and bark, tremendous progress has been made in the development of diversified packaging materials and in packaging equipment. In general, packaging materials may be grouped into rigid and flexible structures. Plastic film, foil, paper, and textiles are flexible materials, whereas wood, glass, metals, and hard plastics are examples of rigid materials.

52.5 ENVIRONMENTAL ISSUES

Recently, ecological concerns about packaging have emerged. This means that packaging has to satisfy the required physical, chemical, and biological criteria during their life cycle as packaging (active protection function); and once the original function has been fulfilled, the packaging should decay without polluting the environment (passive protection function).

The presence of plastics in the habitat of wildlife on both land and sea has created issues, which are being vigorously exploited by the environmental lobby to demand solutions from the plastics industry [37]. Landfills are an important outlet for the disposal of packaging waste. Currently, modern facilities are designed to address two environmental concerns [38]. First, is to control the leachate (toxic polluting compounds) to the ground and surface water, and second is the control and use of landfill gases (carbon dioxide, methane, small amounts of nitrogen and oxygen, and a wide range of other gases). These gases are produced during biodegradation of waste from bacterial action, and these may be toxic or explosive. The composition of the mixture depends on the composition, temperature, moisture content, and age of the waste. Most modern landfills use a gas capture technology where the landfill gas is either fired to convert methane into carbon dioxide, or collected and used as a substitute fuel or to generate energy (i.e., energy recovery) [38].

Overall, environmental safety is demanded from packaging material disposal, thus the industry needs to develop easily reusable, recyclable, disposable, or environment-friendly packaging. It is also termed as sustainable, eco-friendly, environmentally-friendly, and green packaging [39]. In 2005, the U.S.-based Sustainable Packaging Coalition defined sustainable packaging by listing eight business and environmental criteria related to the life cycle of packaging [39]. Robertson [39] explained optimum packaging considering "useful" and "wasteful" and both "under-packaging" and "over-packaging" can have an environmental impact at different stages of the life cycle. Although under-packaging is less expensive as compared to over-packaging, environmental impacts are higher if packaging does not provide protection and spoilage occurs [40]. Food package functionality remains paramount; if the package does not function effectively and economically, all efforts are superfluous. Sustainability is collateral to food delivery [41].

Russell [42] emphasized that the whole value chain has a responsibility toward sustainability, including recycling and biodegradability of packaging. The overall resource efficiency of the supply chain should be the main priority. Heller et al. [43] defined a "Food-to-Packaging (FTP)" ratio for explaining the environmental impact. It is defined as greenhouse gas (GHG) emissions or cumulative energy demand for agricultural production and food processing divided by GHG for packaging material production based on a kilogram of food consumed. They reported FTP ratios for GHG emissions ranging from 0.06 for wine to 780 for beef. The high FTP for the foods such as cereals, dairy, seafood, and meats suggest greater opportunity for net impact reductions through packaging-based food waste reduction. Robertson [39] also pointed that the focus on recycling rather than overall sustainability also risks distorting outcomes.

52.5.1 Reduce

An important consideration could be the reduction of the amount of packaging used for foods. In many cases, the efficient design for preservation and the distribution chain could reduce the amount of excessive packaging required for food. It is important to use packaging in the optimum level in addition to only reuse and recycle. For example, the main purpose of packaging for bakery products have distribution rather than protection as their primary objective. Product quality is ensured by specifying short shelf life since bread should be consumed as quickly as possible. Since the shelf life is short, the goal of bread packaging is partially moisture control, but its main purpose is to allow the product to be distributed safely and hygienically. The excessive use of packaging could be avoided if the purpose of the packaging is known.

For many bakery products, even this level of packaging is excessive. Cakes and pastries are often distributed in cardboard boxes that are not airtight but made possible with a waxed paperboard support. Packages containing pies must have air holes, so that the packages can "breath" moisture during heating or cooling, preventing crust uptake of moisture.

There is a constant effort in the packaging industry to reduce the amount of material used for packaging. Glass containers now are on average 30% lighter than in 1980, the weight of cans now approximately 40% less than in 1970, and 2 liter polyethylene terephthalate (PET) soft-drink bottles are 25% lighter than in 1977 [38].

52.5.2 Reuse

Reuse refers to the use of the same material again and again ad infinitum or for an indefinite time. Reuse is the application of a structure for an extended period of time or until it wears out [44]. Some packages, such as glass bottles and jars, can return to the original supply chain and be reused [38]. Sand [45] pointed out that the "milk bottle approach" (i.e., reuse) is a diversion when sustainability of packaging is considered and painful to think about since these resources are much needed to combat climate change. She mentioned that reusable packaging may resonate with consumers, but it is not environmentally or economically sustainable. The life cycle assessment (LCA) and economics are far from favorable for a system that delivers and collects packages from scattered consumer residences and returns these to manufacturers far away for refilling. LCA may be more viable if returnable packaging is aligned with existing systems of garbage and recycling collection. It would be one step forward if integrated collection and consumer sorting of compostable, recyclable, reusable, landfillable, and incinerable packaging are considered.

52.5.3 Recycle

Recycle means to recover and reprocess something into the same or similar product or something useful so that the molecules are not lost in space. Recovering is the act of identifying, finding, and retrieving materials that could be returned to the sender for eventual recycling [44]. The present and future focus is to use materials that can be either recycled or burned without producing noxious fumes, and use of printers' ink without containing heavy metals or biodegradable inks [22, 46].

Contamination is the main concern in the case of recycling and reuse of post-consumer plastics. One of the many difficulties with recycling is that there is no control over how the consumer uses the container (e.g., for pesticides, chemicals), and the container may become contaminated. The ink on labels is also difficult to remove during recycling [1]. In the case of recycling, lamination could be utilized whereby the food contact surface is a virgin layer placed over the recycled material means the virgin layer free of contaminants acts as a functional barrier. Other solutions for recycling are incineration, composting, and environmental degradation. However, this needs to include biodegradable materials. In many cases, the energy requirement during recycling is also an important factor. PET bottles are 25% more energy-efficient than glass and 65% more efficient than aluminum and have less impact on resources at all levels of possible recycling [1]. In many cases, collection costs can be far greater than the potential market of these materials. Auditing recycling can provide an ounce of prevention that can help in avoiding the complications of improper disposal and the resulting liabilities.

52.5.4 Consumers' Attitudes toward Green Packaging

Green packaging has received increasing attention in the logistics industry due to the growing popularity of environmental protection, sustainability, and eco-friendliness [47]. The preference for green packaging varies [48]. Hao et al. [47] identified four principal factors affecting consumers' willingness to pay: environment, green packaging quality, commodity, and packaging price. Even though the majority of consumers have insufficient knowledge regarding green packaging, they have a fairly strong willingness to pay for it. Additionally, consumers would like to attach greater importance to the practicalities of green packaging, such as convenience, reusability, and protective capability [49]. Considering 25 variables related to green packaging, six factorial groups were identified from "theory of consumption values" and "customer value creation framework" in relation to uniqueness to green packaging and influenced buyers' willingness to pay a price premium [50].

The actual environmental impacts (by altering packaging materials) provide other benefits, such as perceived taste and quality in addition to the sustainability perceptions. In addition, consumers' sustainability assessments are highly influenced by mere graphical packaging cues, which have no obvious actual sustainability consequences [49]. In Germany, France, and United States, it was observed that consumers focus predominantly on end-of-life attributes of packaging, although they value recyclability, reusability, and biodegradability differently. There are a number of discrepancies between consumer perception and the environmental impact of different packaging options. It was suggested to feature those eco-advantages that pertain to the post-use phase and to apply different packaging strategies across countries [51]. The dimensions of sustainability have an effect on the selection of the optimal design [52].

52.6 CONCLUSION

In the future, industry and research should aim to satisfy most criteria mentioned earlier in the list of ideal packaging. The choice of packaging is always a compromise between the desired objectives. The quality, safety, freshness, and convenience expected to be the future target in the development of food packaging. Future packaging trends are to develop packages with the following characteristics: opening ease, smaller portions, safe to consumers, environmental packaging, bioactive packaging, biodegradable packaging, edible packaging, tamper-proof methods, and reclosable packaging. Oxygen scavenging technology is merely in its infancy and it has the potential of becoming one of the most revolutionary advances in the packaging industry. The packaging should also give lifestyle benefits. Packaging plays an indispensable role in modern society, for without it many products could not reach consumers in sound condition. In all cases, the amount of packaging used should be optimum, thus avoiding overpackaging. Collection and sorting are issues in reusable packaging, and the economic evaluation may not support then. Better management of product shelf life can reduce excessive packaging. Efficient distribution systems also need to be developed for optimum packaging. The whole value chain needs to be considered when evaluating green packaging including sustainability, recycling, and biodegradability. There is a need to educate the consumer for understanding all aspects of food packaging, and making them a partner for future development. This could help in making the progress smooth and steady to achieve the target of safe packaging technology for consumers.

53 Types of Packaging Materials Used for Foods

Robert H. Driscoll and Mohammad Shafiur Rahman

CONTENTS

53.1 INTRODUCTION

Originating from natural materials such as skins, leaves, and bark, tremendous progress has been made in the development of diversified packaging materials and packaging equipment. Packaging materials are commonly grouped into rigid and flexible structures. Plastic film, foil, paper, and textiles are flexible materials, whereas wood, glass, metals, and hard plastics are examples of rigid materials.

53.2 PLASTICS

Polymers are the fastest-growing group of materials in food packaging. The first plastic materials used for flexible packaging entered commercial production in 1939, just as World War II started, but the main development took place in the middle of the 1950s [1]. Their foremost advantages are their wide diversity and extremely broad spectrum of properties. Plastics are relatively cheap, light, easily processed and shaped, and easy to seal. The density of most plastics is on par with that of paper or a shade higher, but less than half of the density of glass or aluminum or about one-eighth of the density of steel. Plastics do not shatter like glass or buckle like metals [1]. However, two major drawbacks of plastics are their permeability to gases and vapors, and the possibility of their interacting with the product [2]. Polymers (or, as they are commonly called, plastics) are compounds of very high molecular weight. They are constructed of many repeating units or building blocks, combined together via a chemical reaction. These building blocks, called mers or monomers, are gases or liquids at room temperature and pressure, whereas polymers are normally solids under these conditions. Polymers can be either natural (familiar examples are starch, proteins, and rubber) or synthetic, the latter being those used in packaging. Reviews on types of plastic packaging materials are given by Driscoll and Paterson [3], Stollman et al. [4], and Miltz [2]. Other components in plastics are residual monomer and oligomers, additives such as heat and light stabilizers, antioxidants, plasticizers, and UV absorbers, as well as processing aids such as lubricants, slip agents, and antistatic agents.

Since no single film can satisfy all packaging requirements, plastic films may be combined by lamination or coextrusion. Lamination is a technique for bonding films together to give a film the properties of both constituents. By combining the qualities of choice from the raw material films, a laminate can be tailor-made for its particular application. Each layer in the resulting laminate may exhibit different properties from its free state, such as mutual layer reinforcement in which cracks in a brittle layer are prevented from propagating by high elongation (elastic) layers. For package sterilization, the material of choice is polypropylene, which is used as the outer and inner plies of the laminate with polyvinylidene chloride as the middle layer to provide an oxygen barrier. Intermediate between these main functional layers will be other plies to contribute appropriate bulk and strength. Polypropylene has the additional advantage that it can be heat sealed [5].

53.2.1 Background

The first type of packaging material to be discussed is plastic, which is technologically a complex class of materials. Packaging materials may be grouped into rigid and flexible structures. Plastic film, foil, paper, and textiles are flexible materials, whereas wood, glass, metals, and hard plastics are examples of rigid materials. The volume of plastics produced each year now exceeds the amount of steel consumed, and practically none of it is recycled. Plastics now account for about 25% of household waste, although less than 20% of the containers we use are plastic. Half of these are used for milk and various carbonated drinks. However, using other forms of packaging would double packaging costs, quadruple the amount of waste products, would take more energy to produce, and reduce the number of new jobs per year created by the growing packaging industry (e.g., 2500 in Australia). There is increasing recognition of the need to recycle. The main difficulties are the separation of plastics (manual labor) and the purity of the final product (energy problems).

Because of their lower unit cost and lower energy consumption during manufacture, plastics have tended to replace the traditional packaging materials—glass, paper, and metals—in situations where high barrier properties are not required by the product. Although no ideal barrier plastic exists, developments in laminates and copolymers are slowly reducing the competitive edge of glass and metal containers. The historical developments of plastics are presented in Table 53.1. Since 1953, a range of other important plastics have been developed. The definitions of terms are also presented in Table 53.2.

53.2.2 Manufacturing of Plastic

Polyethylene is a polymer that is produced from oil or coal by the extraction of ethylene gas. Ethylene (C_2H_4) is a monomer, a molecule that can combine with itself through breaking its carbon–carbon double bond to produce long-chain macromolecules that are highly inert to the environment. Many other monomers are derived from ethylene.

The chain of mers can twist and kink around the C–C bonds so that the resulting macromolecule can vary from a straight line to a sphere. The degree of linearity has a large effect on the resulting plastic properties. As the polymer is cooled after

TABLE 53.1
Historical Development of Plastics

Year	Plastic Type
1843	Malayan gutta-percha, a shellac molding material, was the first seminatural plastic.
1870	Searching for a substitute for ivory for constructing billiard balls, Hyatt made pyroxylin from cotton and nitric acid and then reacted this with camphor, producing celluloid.
1909	Leo Baekeland reacted phenol with formaldehyde with a catalyst, hexemethyleneteramine, under pressure (to stop foaming), producing the first synthetic resin, called bakelite.
1919	Casein was developed as a film.
1927	Cellulose acetate and polyvinyl chloride were developed.
1935	ICI reacted ethylene under high pressure with trace O_2, giving LDPE, which suited the newly developed technique of blow-molding.
1953	Karl Zeigler produced HDPE from ethylene using the catalysts titanium tetrachloride and triethyl aluminum.

melting or manufacture, the chains will link to each other, either by van der Waals forces, by ionic attraction, or by cross-link bonding. If the macromolecules are straight and regular they will fit well together, giving higher density and crystallinity.

The kinked and twisted molecules are stretchable, sometimes to many times their unstretched length, so the plastic can be *oriented*. Branching can occur along the chains but is relatively rare, requiring reaction to occur at a C–H bond. Higher temperatures permit more of these random branching reactions to occur. Branching reduces crystallinity by preventing ordered molecular arrangements. Most polymers are from difunctional monomers; a few are tri- or multifunctional, leading to three-dimensional configurations instead of long chains. These structures are more rigid at high temperatures.

The plastics are divided into two groups: thermoplastic and thermoset. Thermoplastic means that the plastic may be heated and cooled without losing its structure, while thermoset plastics, once cooled, cannot be reheated without breakdown of the macromolecule. When a thermoplastic material is heated, it becomes pliable and can be shaped as required. Linear polymers tend to be thermoplastic, whereas cross-linked polymers are thermosetting. Cross-linking occurs when atoms join across polymers, e.g., sulfur, which is used to cross-link isoprene to give us the rubber used in car tires, or oxygen, which causes aging in the same rubber by cross-linking and so reducing the rubber flexibility. The structure of natural rubber (isoprene) is leaving out irrelevant hydrogen atoms.

The C after the double bond can point up or down, leading to isomers (isoprene and gutta-percha) with different properties. By analogy with isomers, the basic units can also combine in different orientations, leading to isotactic polymers with ordered structures, which can more easily be crystalline, and atactic structures, where the orientation continuously varies along the chains, preventing crystallinity. For example, polyethylene (PE) varies from atactic PE with a density of 900 kg/m^3 to crystalline PE with a density of 1000 kg/m^3. Common forms of PE are low-density PE (LDPE, 920 kg/m^3), linear low-density PE (LLDPE), medium-density PE (MDPE), and high-density PE (HDPE, 960 kg/m^3).

Bonds can be broken in a number of ways (degradation of the polymer). A C–C bond has an energy of 6.1×10^{-19} J. Ultraviolet (UV) light at 300 nm has an energy of 6.1×10^{-19} J/photon, so is close to the same energy. Visible light at around 600 nm has about half as much energy. If thermal or strain energy is also present, then visible light will also degrade plastic (but more slowly than UV).

Glass temperature refers to the temperature at which individual molecular energy is too low to allow the macromolecules to slide past each other. The melt temperature is the transition temperature from a solid to a free liquid and is higher than the glass temperature. Below the glass temperature, the plastic is brittle, so some plastics cannot be used for freezing, but between the two temperatures, the plastic can be shaped and bent more easily. A plasticizer acts by reducing the average molecular size, acting as a lubricant between the large macromolecules so that they slide over each other. Methods of polymerization are given in Table 53.3.

TABLE 53.2
Definitions of Terms

Terminology	Definition
Mer	A unit, e.g., a basic unit in a chemical structure polymer: many units
Plastic	Deforms, can be shaped by a shear force in excess of a plastic yield minimum
Thermoplastic	Shaped by reducing the yield stress by heat softening
Thermosetting	Initially shaped by heat, but shape is then set permanently crystalline: regular, periodic shape
Amorphous	Opposite to crystalline, random shape
Isotactic	Possessing a preferred orientation of molecules (same feel) atactic: molecules in structure are randomly oriented (no feel)

TABLE 53.3
Methods of Polymerizing

1. Addition: unsaturated compounds open their double bonds under heat and pressure. The macromolecule forms in three stages: initiation, propagation, and termination. Initiation is the initial rupture of the C=C bond to produce energetic combination sites. In propagation, further monomers react with a growing chain. In termination, two growing chains meet each other and combine, preventing any further reaction. For high molecular weights, this should be delayed as long as possible.
2. Condensation: after initiation, molecules combine, releasing low molecular weight compounds such as water.
3. Ionic (either anionic or cationic polymerization): initiation occurs through the introduction of ionic compounds, which become integrated into the polymer, producing a class of plastics called ionomers (surlyn).

Ethylene is the main monomer used in the production of plastics (CH_2=CH_2). The hydrogen atoms can be replaced by halides (chlorine, fluorine, and bromine), phenyl, or other such groups to produce further monomers, all containing the central ethylene double bond. These polymers are generally thermoplastic and are called polyolefins.

Large chemical companies usually manufacture plastic in the form of small plastic beads or resins. These granules as bulk are transported to factories for manufacture into either rigid or flexible materials. In either case, the resin is fed into the hopper of an extruder, which brings the resin temperature to above its plastic melting point but below its degradation temperature. It is then ready to be shaped by passing through a die plate, containing die inserts that shape the product as required.

53.2.3 Construction of Rigid Plastics

53.2.3.1 Blow Molding

Many plastics are shaped using the process called blow molding. This is a process for producing hollow parts in one operation and is primarily used to make plastic bottles. A hot plastic tube, called a parison, is inflated against a cold mold. The final shape will have a thin neck, ideal for many packaging applications. The parison is produced by extruding the plastic at high temperature and pressure. Variations on blow molding include coextrusion blow molding, injection blow molding, and injection stretch molding. Labeling can also be done in the mold.

53.2.3.2 Injection Molding

Injection molding involves the direct injection of molten plastic into a shaped space between two dies. The dies separate after the plastic cools to allow the final shape to fall out. This is used for making solid plastic objects such as caps, closures, and plastic toys.

53.2.3.3 Thermoforming

Many plastic containers are formed by thermoforming. This involves heating a plastic sheet until it softens and then shaping it by stamping it between two cooled molds. A growing requirement of molded plastics is that they be microwaveable, i.e., have a softening point well above 100°C. They must also be shelf-stable. Plastics are generally slow to degrade under ambient conditions, but they may discolor or become brittle.

53.2.4 Construction of Plastic Sheets and Films

Approximately 10 different polymers account for the majority of packaging films. In general, a film is defined as a layer of a thickness of less than 0.010 inch (0.25 mm). Thicker plastic is referred to as a sheet. Films may be used as liners, wraps, or overwraps, depending on how they are applied to the product. Liners are plastic films applied to the inside of the container, often to protect the container from the product, such as plastic linings sprayed into the inside of metal drums or cans. Wraps are applied directly to the product, usually by making a tube from the film, sealing one end, filling the tube with product, then sealing the top end. An overwrap is applied around the carton, often heat shrunk onto the carton to provide barrier protection.

Films may also be used for bags, envelopes, and pouches. A common method of closing plastic bags is with plastic clips that can also double as price tags, as in bread packaging. Envelopes are bags sealed on three sides, with the last side folded over and sealed after filling with product, used mainly for flat items. Pouches are constructed and filled on the processing line automatically. A typical pouch is a complex laminate, possibly of oriented polypropylene (outside), LDPE, aluminum foil, adhesive, and a copolymer film on the inside.

Films are manufactured using an extruder. The plastic resin granules and other ingredients are fed into the extruder, compressed, and heated until the plastic flows out of the die. The two main die shapes are slit circular and slit rectangular. The extruded plastic may then be stretched while still hot and flexible.

53.2.4.1 Monoaxially

Die is designed to give a wide sheet of plastic film. This can then be stretched in the machine direction by up to 80 times its original length, which has the effect of thinning the sheet and orienting the molecular structure. The result is that the plastic can be stretched easily in one direction after cooling, but not in the other. The thickness of the film is checked, the film cooled, and then wound onto the mill roll.

53.2.4.2 Biaxially

Jaws and rollers are used to stretch the film apart in both directions at once (Tenter process). The molten film is poured onto a casting wheel and then through a series of rollers, which stretch the film in the machine direction. The film then passes through the Tenter section oven, where jaws are used to grip the softened plastic and pull it apart in the transverse direction. The result is a stiff plastic. A second method is called the bubble method, where the plastic is extruded as a continuous cylinder, and a bubble of air is blown up the center of the cylinder, forcing biaxial expansion. As the plastic heat-sets, it will shrink slightly before assuming a fixed shape.

The plastic may then be coated prior to the mill roll in several ways to enhance its properties. A common example is coating a plastic that is difficult to print with a printable plastic on one or both sides. Coating will be discussed in more detail later.

Another common coating produces metallized plastic. For this technique, the plastic passes quickly through an evacuated chamber in which aluminum is vaporized. This deposits a metal layer several molecules thick (~200 Å), resulting in a metallized appearance. This material is often used to replace foils as it is cheaper but does not have the same barrier properties as foil (although there will be some improvement over untreated film). The metal coat also substantially reduces UV light reaching the product. Metallized films are a common base for eye-catching graphics. However, the metal does not attach firmly to the plastic and may be scraped off (a surface

lacquer prevents this), and the plastic is not sealable on the metallized side. Metallized plastics also suffer from metal oxidation, affecting print adhesion, giving a maximum effective lifetime of about 3 months.

The film may also be pearlized, a technique that distributes fine air bubbles throughout the plastic (or cavitating the surface) resulting in a pearly white opaque appearance. This is useful for preventing "show-through," the wet appearance where fats directly contact the plastic, and a particular problem with chocolate wrapping. Pearlized plastics also tear more easily. The ideal film should have good barrier properties; be chemically stable, temperature resistant, and heat-sealable; resist grease; be strong; not allow migration; have good transparency and gloss; be printable; and be inexpensive to make. Since no plastic will satisfy all of these requirements, the actual plastic chosen for a particular function will be a compromise.

53.2.5 Properties of Plastics

Most of the properties discussed in the following sections are explained where first used. One key property relevant to packaging equipment, slip, is not covered in detail, so will be explained here. From the perspective of machining, plastic film must have the right friction coefficient to pass smoothly through the packaging equipment. If the slip is too high, the result is different package sizes in tube-formed packaging due to the film sliding past the forming rollers as well as a loss of registration in printing (see later). The product slides easily inside the package, interfering with sealing the pack. On the other hand, too low a slip can cause the film to stick to hot surfaces or folding box surfaces and can cause the product not to slide down to the bottom of the pack, also affecting pack sealing and presentation. The product should be able to slide back and forth in the pack relatively easily for tight sealing at both ends. This section also serves to introduce and describe the primary packaging plastics.

53.2.5.1 Polyolefins

53.2.5.1.1 Polyethylene

Polyethylene (PE) is the result of the polymerization of ethylene gas and has the formula $(CH_2)_n$. It was invented by ICI in the 1930s. Two main manufacturing processes result in different polyethylene products. The first is called low-density polyethylene (LDPE), and the second is high-density polyethylene (HDPE).

LDPE is formed at high pressures (1000–3000 atm). This results in long branched chains, weakly linked to each other by van der Waals forces (but strong overall force due to length). The branching is random, and so LDPE is an atactic polymer. Thus neighboring chains can slip past each other, allowing the material to bend easily (be flexible). As a result, the printability of LDPE is poor. However, many plastics with poor printability can be made printable by corona treatment, in which an ionic discharge is used to sensitize one side of the plastic.

LDPE has low density, as the long chains exhibit branching, so that the molecules are not able to fit closely together. This irregularity in structure also results in a lower melting point and a less crystalline (ordered chain) structure. LDPE is tough, semitransparent (poor clarity), flexible, and has a waxy feel. It resists most chemicals below 60°C, and it resists water moderately but not gases (poor O_2 barrier). LDPE is usually used as thin sheets or laminated to other packaging materials. It is used for bag manufacture (bread, diapers), for low-temperature storage (due to its low barrier properties), and for packaging rice. The melting point of LDPE is 105°C.

HDPE is produced at low temperatures and pressures of about 10 atm. This gives rise to an ordered molecular structure, which is called an isotactic polymer. The Ziegler process is used, employing a catalyst. HDPE is stiffer, harder, less flexible, and waxy. Higher temperatures are required to produce thermoplasticity (melting point = 134°C). HDPE is used for making containers, e.g., crates, bottles, bags, tubs, and plastic knives and forks. It can be steam-sterilized, whereas LDPE cannot. HDPE bottles are opaque and can be used to contain detergent and milk. HDPE resists fats and oils better than LDPE. However, it does not seal easily.

This description simplifies the total PE picture. Available PEs include low-, medium-, and high-density PE, linear low (LLDPE) and medium densities (with twice the hot-tack strength), copolymers of PEs, copolymers with vinyl acetate (EVA), and ionomer film (surlyn). PE may be coextruded with nylon, saran, and ethylene vinyl alcohol (EVOH) sandwiched inside. Such films have high strength, flexibility, clarity, and especially barrier properties, and these are used for bag-in-the-box, pouches, cups, and lids. The form of PE used will usually be a trade-off between barrier properties required and cost.

53.2.5.1.2 Polypropylene

The monomer polypropylene (PP) has the formula $CH_2CH–CH_3$. PP was developed using polymerization catalyst technology by Guilio Natta in 1954. PP forms a regular, highly ordered polymer at low pressures in the presence of certain catalysts called isotactic polypropylene. It has high crystallinity (high clarity and gloss), is hard, heat resistant (higher softening point, 150°C), exhibits good memory, flex crack-resistance, puncture-resistance, and stiffness. It is resistant to chemicals (except aromatic and chlorinated hydrocarbons).

PP has excellent moisture and relatively good gas barrier properties. It can be printed on and is ideal for reverse or surface printing. Cast polypropylene has excellent heat sealability. PP is used for injection-molded containers and blister packs, laminations, carton overwraps, snack food bags, and confectionery bags. It may be coated (e.g., with polyvinylidene chloride or acrylic) and may contain additives. PP has poor heat stability, so precise heat control is required in the packaging equipment.

PP film may be stretched during production yielding an oriented (OPP) or biaxially oriented film (BOPP) of high clarity, strength, and resistance to water vapor and gases (e.g., for wrapping snack foods), and coated with saran or acrylic for better barrier and heat sealability. PP causes contact transparency ("show-through") and is available in thicknesses from 15 to 75 μm. It may be pearlized ($CaCO_3$ + heat generates CO_2 bubbles, resulting in reduced barrier properties and strength,

but no show-through) or white (pigmented, better print density, saves undercoat, reduced show-through). It is used for confectionery, especially chocolate. PP may be coextruded with PE (1.5 μm) for heat sealability.

53.2.5.1.3 Polyvinyl Chloride

The monomer polyvinyl chloride (PVC) has the formula $CH_2CH–Cl$. The term vinyl means that a halogen has been substituted for a hydrogen atom. PVC has low crystallinity (so has good transparency when pure), but higher interchain bonding than PE due to the Cl^- halogen, so it is harder and stiffer. For this reason, plasticizers may be added during manufacture. The Australian Standard 3010—Plastics for Food Contact: PVC allows four plasticizers for food involving flexible sheets and films, e.g., vitafilm (for meat) with particular oxygen diffusion characteristics.

PVC has good feel and printability. It is highly inert. It is glossy and resistant to moisture, fats, and gases. There is a great variety in PVC compositions, e.g., stabilizers, impact aids, lubricants, and other additives are present in large proportions. The stabilizer is necessary because the decomposition point for PVC is close to the melting point. For food products, the extraction of the stabilizer from the PVC must be less than 1 ppm of the stabilizer, and the stabilizer must be a calcium–tin or dioctyl–tin system (not butyl–tin, used for nonfood products), containing tinuvin for UV protection. PVC is used in the biaxial-stressed form, e.g., for shrink-wrapping of cheese and meat. It is also used for thermoformed containers, e.g., for chocolates, as well as for plastic pipes and toys. It heat-shrinks after stretching and can be thermoformed.

53.2.5.1.4 Polyvinylidene Chloride

The polymer polyvinylidene chloride (PVDC) is similar to PVC, except that there is a double chlorine substitution, giving $CH_2=CCl_2$. PVDC has a more ordered structure, with high crystallinity and softness. It has excellent barrier properties (especially to O_2) and it is commonly used as a copolymer with PVC. PVDC possesses reasonable clarity, good feel, good printability, and strength. It is difficult to cut as it lacks stiffness, so it is hard to machine by itself and is too expensive for use as a pure monofilm (except for household use). It resists chemicals; has low water, gas, aroma, and flavor permeability (due to chlorine ions); and high strength. It has high chemical stability and is hygrophobic.

PVDC is used with PVC as a copolymer to coat other packaging materials to provide good barrier properties. It is used in laminates and is an important shrink film, with excellent cling properties. PVDC cannot be reprocessed because it degrades (melt point 162°C). This makes coextrusion lamination difficult as well, although it can still easily be used in coating from solution. When used in coextrusion it must be copolymerized first (for example with vinyl chloride) to give better temperature stability.

53.2.5.1.5 Polytetrafluoroethylene

The formula for the monomer polytetrafluoroethylene (PTFE) is $CF_2=CF_2$. Polymerization produces long, straight unbranched chains, with ionic intermolecular bonding, so PTFE is strong and crystalline. Since the bonds C–C and C–F are strong, this material is extremely inert and has a high softening point (340°C). PTFE possesses a high gloss and is waxy in feel. It is used in coating cookware (nonstick surfaces) where easy-to-clean nonstick surfaces are required.

53.2.5.1.6 Polystyrene

The polymer polystyrene (PS) results when an ethylene hydrogen is replaced by a phenyl radical ($CH_2CH–C_6H_5$). It is a synthetic rubber, which does not degrade over time. PS is amorphous (random packing), low in density, and brittle. In the pure form, it has good clarity and printability. It is often used for loose bulk packaging, especially for packing fragile materials. Originally, this involved aeration of the liquid plastic with fluorocarbons, but environmental aspects have encouraged CFC-free production and reusability of loose packaging materials (also called void packaging).

PS is usually copolymerized, especially with butadiene, to give high-impact polystyrene (HIPS, see later), which has a less brittle structure. Yogurt and ice cream tubs are common examples. Margarine tubs may be made from acrylonitrile buta-styrene (ABS). PS is also used for disposable plates and cups. PS can be foamed with hexane to form expanded polystyrene (EPS), a low-cost, low-density material that is easily formed into holding trays, cups, etc.

Polystyrene is the plastic of choice for thermoforming because it has strength, low cost, formability, and sealability. PE and PP are only used where specifically required; PP containers can be filled at high temperatures. Although PS provides a good barrier to gases, it is permeable to water vapor. It resists grease, acids, alcohols, and alkalis (i.e., chemically stable). Oriented polystyrene is a very useful packaging film and is heat shrinkable. The melting point of HIPS is 100°C.

53.2.5.2 Other Thermoplastics

53.2.5.2.1 Polyesters

Polyesters are plastics formed by the polymerization of esters. In general, they have reasonable clarity and poor feel and printability, but are strong, versatile, with good heat resistance. This is useful for boil-in-the-bag type applications, where the plastic must sustain temperatures of 100°C without deforming or softening. When metallized polyesters are also used for snack and coffee pouches.

Ethylene glycol and terephthalic acid yield polyethylene terephthalate (PET). PET has high strength and chemical stability. It is used for blow-molded bottles and some films, increasingly for thermoformed trays, for shrink-wraps, and for boil-in-the-bag products. It has excellent clarity, comparable to that of glass. It can be printed, metallized, and laminated. It has high barrier properties for a plastic film. Due to efficient recycling, PET is a cheap plastic. It is only used in 12 and 15 μm gauges for film and is commonly used as the outer layer of a laminate structure due to its gloss and temperature stability (melt point 254°C). It is used for microwave pie wraps (microperforated).

Forms of PET include APET (atactic PET), CPET (crystalline PET), OPET (oriented PET), and PETG (copolymer PET/

cyclohexane dimethanol; melting point 265°C). Polyethylene naphthalene (PEN) shows promise due to its low permeability to gases. There is growing interest in recycling polyesters due to their initial high cost. The advent of the PET range has revolutionized the packaging industry, allowing plastic to compete directly with glass bottles. Blow-molded PET bottles have less weight, lower production and energy costs, are droppable, and still have excellent clarity and gloss. The bottle is molded as follows: the closure is first injection molded, producing a little bottle with the screw top already formed, then transferred hot to a blow-mold die. The wall thickness is computer-controlled. The production equipment is specific to PET. Current production rates are about 1/sec. They are not suitable for beer, which requires a light barrier (opacity).

53.2.5.2.2 Cellulose

Cellulose was the first transparent film to be used (invented by Du Pont) in packaging and was widely used until the advent of polypropylene. It is biodegradable. A common name is cellophane, a trademark name of British Cellophane Ltd. Cellulose is clear, stiff, printable, and glossy, but has poor feel and moisture resistance. It has good heat-dimensional tolerance. It is not heat-sealable. It is naturally antistatic, so is good for powders (e.g., milk powder). Cellulose is still widely used today, due to the addition of coatings that have given cellophane great adaptability. Examples of coatings are nitrocellulose (making cellophane flexible and durable), PVC, PE, and PVDC (oxygen-barrier properties).

Cellulose can be laminated to foil, paper, and some plastic films. It is able to retain folds (called *dead fold*), so that if it is twisted, it retains that twist, making it ideal for individual candy wrappings. It is also tearable. It is used for cookies, confectionery, and pastries in situations where vapors may need to "breathe" to prevent surface molding. Cellulose is sold based on weight per unit area, not thickness, due to the variation in thickness that occurs with moisture absorption. It is available in weights of 22–60 g/m^2. Some typical cellulose codes are given in Table 53.4.

53.2.5.2.3 Cellulose Acetate

Cellulose acetate is made from cellulose and acetic anhydride. Cellulose acetate has good clarity and is printable in sheet form, but has poor feel and barrier properties. It is becoming obsolete, although it is still used in laminates and thermoformed blister packs.

53.2.5.2.4 Other Thermoplastics

Other biodegradable biopolymers are being developed but have not yet become competitive. The raw material for the new thermoplastics is usually starch, which is blended with conventional oil-based polymers.

53.2.5.2.5 Polyamides (Nylons)

Polyamides (nylons) are made from condensation of a diacid (e.g., adipic acid) and a diamine (e.g., hexamethylene diamine). Polyamides have high crystallinity, strength, impact strength, puncture and stress-crack resistance, flexibility, and melting (255°C) and softening points. They also have good chemical resistance. Polyamides are used for boil-in-the-bag–type products, frozen foods, fish, meat, vegetables, and processed meat and cheese, always in lamination. They have low water barrier and high gas permeability. A large range of different nylons exists. Polyvinylidene-coated or metallized nylon is about twice the price of pure nylon film. Nylon is available as cast (18–100 μm) and biaxially oriented (BON) nylon (12, 15, and 20 μm). It can be metallized or PVDC-coated for better barrier properties and is usually laminated. As a film, it must be biaxially oriented to give printing and machining stability.

TABLE 53.4
Some Typical Cellulose Codes

Code	Explanation
A	Anchored (describes lacquer coating)
/A	Copolymer coated from dispersion
B	Opaque
C	Colored
D	Coated one-side only
F	For twist wrapping
M	Moisture-proof
P	Plain (non-moisture-proof)
Q	Semi-moisture-proof
S	Heat sealable
/S	Copolymer coated
T	Transparent
U	For adhesive tape manufacture
X	Copolymer coated on one side
XX	Copolymer coated on both sides

53.2.5.2.6 Polycarbonates

Polycarbonates are formed from condensation of carbonic acid in the presence of aliphatic or aromatic dihydroxy compounds. They are amorphous. Most polycarbonates are tough, stiff, hard, and transparent (high clarity), with high softening points, and so can be cook in the oven or sterilized. They also have poor barrier properties and cost three times as much as polypropylene. They are used for plastic tableware and fruit juice containers.

53.2.5.2.7 Acrylonitrile

Acrylonitrile (AN) is an excellent gas barrier (like EVOH and PVDC). It possesses good chemical resistance and has a melting point of 170°C. It is easy to thermoform because of its high stiffness. Acrylonitrile forms copolymers such as Lopac and Borex, which have potential as high barrier plastics. Acrylonitrile buta-styrene (ABS) is still used, but polyacrylonitrile (PAN) has been replaced by PET.

53.2.5.2.8 Plioflim

Pliofilm is a rubber hydrochloride formed by combining polyisoprene (natural rubber) with hydrochloric acid. It is a printable, good-feel, opaque film with good heat-sealing

characteristics and grease resistance. Pliofilm is no longer used much, as it is not easy to machine and is not very durable. However, it was one of the first thermoplastics. It is chemically stable, requires a plasticizer, and has poor barrier properties.

53.2.5.2.9 Ethylene Vinyl Alcohol

Ethylene vinyl alcohol (EVOH) is a film that has high oxygen barrier properties, but hydroxyl groups make it hydrophilic, which increases its permeability. Thus, it must be sandwiched between materials with good water barrier properties, such as polypropylene of low-density polyethylene, to be effective. However, its oxygen barrier properties make it a highly desirable film, competing with PVDC for this role. EVOH is more expensive than PVDC, but it is easier to process and is recyclable. The melting point of EVOH is 185°C.

53.2.5.2.10 Ionomers

Surlyn is the brand name of a range of Du Pont ionomer resins (invented by Rees in 1961). An ionomer resin has both ionic and covalent bonds. The ionic bonds are due to sodium or zinc cations. Surlyn has low-temperature heat sealability (about 90°C), good hot tack (four times better than LDPE, LLDPE, and EVA), formability, toughness, and chemical inertness. Surlyn has some haze. To achieve a coefficient of friction of about 0.2 (as required by modern packaging machinery), slip agents must be added. Surlyn is used for shrink-wrapped meat, cheese blocks, fish, individual candy wrapping, pet food bags, potato chips, snack foods, drink Tetra Pak cartons, margarine tubs, cookies, frozen foods, and nuts as part of a laminate structure, especially as the inner heat-sealing layer.

53.2.6 Processes of Plastics

53.2.6.1 Copolymers

Condensation of combinations of certain homopolymers with each other can produce complex copolymers with properties different from the individual constituents. Depending on how the individual monomers combine, a great variety of properties can result. Let A and B be two monomers: They can combine (i) in strict sequence, e.g., A–B–A–B–A–…; (ii) in blocks, e.g., A–A–A–A–B–B–B–B…; or (iii) in branching chains, with a central chain of one monomer. Some examples are ethylene-vinyl acetate (EVA, a good heat sealant but with poor barrier properties), ethyl–vinyl alcohol (EVOH, a hygrophilic plastic), vinyl chloride copolymers, and polystyrene copolymers.

53.2.6.2 Lamination

Since no single film can satisfy all packaging requirements, plastic films may be combined by lamination or coextrusion. Lamination is a technique for bonding films to produce a film with the properties of both constituents. By combining the qualities of choice from the raw material films, a laminate can be tailor-made for its particular application. Each layer in the resulting laminate may exhibit different properties from its free state, such as mutual layer reinforcement in which cracks in a brittle layer are prevented from propagating by a high elongation (elastic) layer. This effect depends on good adhesion between the layers. Three factors that affect the adhesion between layers are given in Table 53.5.

TABLE 53.5
Factors Affecting the Adhesion between Layers

1. Viscosity/shear rate match during melding. To be coextruded the melt flow viscosities should be similar (a ratio of within 3:1), otherwise one of the plastics will flow with respect to the other, preventing bonding.
2. Temperature, pressure, and period of contact, to build the bond.
3. Functionality of adjacent resin layers, i.e., that they are sufficiently similar in structure to mix at the contact surfaces.

If these factors are not all present, then an adhesive layer is necessary and the plastics may be cold-bonded with a tie-layer of resin adhesive. Adhesives are discussed later. A typical triple-layer film would be composed as follows:

- Properties of outside layer—high gloss, printable, good lamination, possibly metallized, high slip
- Properties of middle layer—strength, stiffness, barrier properties, possibly opaque
- Properties of inner layer—easy to seal (hot seal, good hot tack properties, or good cold seal properties), low migration rates, barrier properties

A laminating machine has the following components:

1. Continuous feed roll with a feeder "on-the-fly" splicer, which can cut off the old roll and join on the new (there may be several rolls feeding film into the machine at once.)
2. Tensioning rollers to give exact control over the tension in the plastic.
3. Lamination stage where the primary and secondary web are combined (web refers to the film as it passes through the machinery).
4. Compression rollers to push the layers together.
5. A take up (rewind) roller to collect the final laminate.

Note that plastics can be laminated with papers and foils as well as plastics. Laminations with paper will tend to use water-based adhesives, since the solvent (water) will absorb into the paper base away from the adhesion zone, allowing the glue to set quickly. Lamination also allows reverse printing, where one plastic layer is printed (in mirror image) before lamination in order to sandwich the printing inside the laminate for greater protection. Lamination of plastic films is achieved by one of four processes:

- Adhesive lamination, where a continuous glue source is fed as a flat film between consecutive layers of the laminate. This may be a hot glue (a plastic resin fed from an extruder, for example) or a pressure-sensitive

glue applied as a high-viscosity liquid to one web, then dried in a tunnel oven to remove the solvent, and then wrapped with the secondary web around a chill roller. The glue may physically bond (e.g., to paper or board) or chemically bond. This technique is also used for labels.
- Extrusion lamination, where extruders replace the feed roll, and the layers are coextruded.
- Thermal lamination, where heat is used to join the webs by partially melting.
- Wax (or hot melt) lamination, where a thermoplastic glue or wax is used instead of a pressure-sensitive glue. The rollers must have the capacity to be heated to a suitable temperature.

Typical speeds for lamination are 100–200 m/min.

53.2.6.3 Coatings

To enhance plastic film properties such as printability, coatings are often used. Aqueous and solvent coatings are applied to the substrate through water dispersions or emulsions, solvent solutions, or waxing. Aqueous and solvent coatings are applied to the substrate using direct roll, direct gravure, or reverse gravure methods. The coating liquid is then dried and cured by infrared heat or a hot-air oven. The coated film is then cooled before being wound onto a roll core. Modern machines allow simultaneous coating on both sides. Examples of coating are foil lidding, reverse gravure, cohesive coating, lacquer coating, and paraffin coating.

Foil lidding is a lacquer coating applied to the foil, which can be heat-sealed to the container but is peelable for convenient opening. On the outer side, a clear nitrocellulose lacquer is applied. PVDC may be coated onto paper or PP by reverse gravure. PVDC does not bond well to other plastics, so a prime coat may be applied first. The prime coat may be nitrocellulose, vinyl, acrylic, or shellac. Cohesive (cold seal, latex-based) coatings are often gravure-coated onto films during printing (on the opposite face). Cold seals are pressure-sensitive, so they can be sealed more quickly than hot seals, which require adequate dwell-time. Colored vinyl lacquers may be applied to outer packaging surfaces, e.g., to give colored aluminum foil. Paraffin waxes are used as coating bases for papers, especially for inner wraps or liners for biscuits or cereals. The wax may be blended with resins, synthetic rubbers, and polymers to meet specific requirements.

53.2.6.4 Adhesives

Adhesive layers are used to bond film layers together to construct a laminate and are polymers. These tie layers will affect the mechanical properties of the final construction. They are usually expensive and must have lower melt temperatures than the layers they are bonding. The adhesives are mostly olefin copolymers, polyurethane, or polyester dissolved in solvents. If no solvent is used, the glue may be extruded hot between the films. Examples of hot-melt adhesives are copolymers of ethylene and acetic acid and surlyn.

Adhesives must "wet" the film surfaces to provide laminate strength, or the laminate will tend to separate into its individual components when used. They may be categorized as liquid, solid, solution, or emulsion [6]. Liquids are monomers that react with trace water to form polymers, such as cyanoacrylate ("superglue"), reactive liquids that combine chemically such as epoxy resins, and pressure-sensitive adhesives (congealed liquid resin in a rubber matrix, with the property that they can be peeled off again). Solids are powder adhesives activated by the addition of moisture, solvent, or heat. Hot melts consist of a polymer, resin, wax, and stabilizers. The hot melt is supplied in solid form, applied in the hot liquid form, and then resolidified as it cools. No solvent is required and they set very quickly. The two main classes of solutions are a water-based (traditional glues with natural polymers such as starch, flour, casein, animal glue, dextrin, gum arabic; and newer synthetic resins in solution such as polyvinyl acetate (PVA), cellulose ethers, and vinyl pyrrolidones), and other solvents (natural, e.g., resin, shellac, bitumen, rubber, and gums, and synthetic, e.g., nitrocellulose, urethanes, nitrile rubbers, epoxies, and cellulose acetate). Emulsions dry faster than solutions and have a greater range of properties. Synthetic resin emulsions now dominate the packaging industry. They include PVA, acrylic resins, and polychloroprenes.

53.2.6.5 Heat Seals

A major requirement of plastic film is heat sealability. A heat seal is the fusion of two surfaces under the influence of heat, pressure, and time. The two surfaces are partially melted by the heat applied by a pair of heated jaws. For plastics such as polypropylene, which has a higher melting point, a copolymer coating may be applied on one or both sides to give heat sealability. Some important terms used in heat sealing are as follows. Dwell time for heat is to penetrate outer films to reach the two layers being bonded, i.e., time the plastic must remain under heat and pressure. Heat seal threshold is the minimum temperature at which a heat seal threshold of 200 g force per 25 mm is obtained. This temperature should be about 80–120° C, i.e., a balance between too high (wrong layers melt) and too near ambient (no melting). The lower the temperature, the faster the sealing, since less heat must be lost before resolidification of the plastic. The pressure applied is about 1 atmosphere. The useful heat seal range is the temperatures over which the films may be sealed. The upper limit is the point where distortion of the plastics starts to occur. Maximum linear film speed is the maximum speed at which film can be passed through the sealing machine. Hot tack is the strength of the initial partially molten seal. If the hot tack is not good, then stresses on the film before cold tack is achieved can reduce the integrity of the seal. Cold tack is the final "cold" strength of the bond.

53.2.7 Plastic Package Types

53.2.7.1 Plastic Bags

Bags are formed from sheet or film plastic by folding and heat-sealing as required. Some bags have folds in the base so that when packed, they expand to a rectangular shape. Handles may be inserted during folding and heat-sealed into the folds.

The bags must be strong enough to resist breakage under the design load, but also must not break when being loaded.

Bags may be preformed, in which case they may be "wicketed," or formed from the source plastic sheet during packaging (usually by forming tubes from the plastic). Wicketing is the process of punching small carry holds at one end of the bag with which to hold the bag during loading. The holes must be carefully designed to carry the load of the product entering the bag, yet must tear off easily so that the next bag becomes available.

53.2.7.2 Plastic Closures

A closure must perform five functions:

1. Contain, to the same level as the remainder of the package.
2. Allow access, so that the consumer can retrieve the product in a convenient way. The ability of the package to be functional in this regard is an important marketing consideration.
3. Restrict access, e.g., tamper-evident and child-resistant caps.
4. Protect the product, such as keeping out dirt and moisture.,
5. Be economic.

The closure may also be used for advertising or barcoding. A plastic screw cap lid has three main components: (i) the cap itself; (ii) a linear (HDPE wad), adhesively attached to the cap in most cases; and (iii) a screw, which interlocks with connecting lugs in the finish of the container but does not provide a good barrier seal.

The closure must be applied with the correct torque. Insufficient torque leads to leakage, whereas too much torque makes removal by the consumer difficult. Tamper-evident attachments to the screw cap are commonly used with plastic beverage bottles, consisting of a ratchet ring under the cap, which becomes detached when the customer removes the lid. A dispensing closure is one that allows the product to be dispensed without removing the closure. Examples of dispensing closures are lids such as flip-tops (e.g., gable-top cartons), pump action, aerosols, and opening pourers, which allow small amounts of the product to be easily removed.

Aerosols are cans containing a liquid product layer and compressed gas propellant. The propellant may also be present as a liquid, which boils as product is used to replenish the driving pressure. The product may be dispensed as a fine spray, mist, dust, or foam. An example of an aerosol application for the food industry is in instant whipped cream. The advantages of aerosols are simple dispensing and complete exclusion of air. They are, however, expensive and an explosion risk, and since 1974 the use of CFCs has been a suspected cause of damage to the ozone layer. There is now an almost total ban on CFC propellants. In Australia, CFCs have been totally replaced by trigger pump packs and inert gas pressure packs.

The advent of flexible packages (replacing rigid containers) has led to a need to develop closures for such packages. Methods include plastic zippers, pressure-sensitive tape, metal bands, plastic clips, and twist ties (e.g., breads). Child-resistant lids have locking devices that either prevent turning unless squeezed or require pressure to open. Tamper-evident seals are discussed in more detail elsewhere.

53.2.7.3 Oven-Safe Containers

Plastic-based food trays that can be heated have become an essential component of convenience foods. The three main plastics used are polypropylene (PP), polystyrene (PS), and crystallized PET (CPET). PP is suitable for microwaves but not for the higher conventional oven temperatures. Foam PS has a still lower melt temperature, but now PS low-density blends have been developed with heat deflection temperatures (HDTs) of 190°C, which is suitable for microwaves. These are cheaper than CPET. CPET is stable from –40°C to 220°C, is clear and resists fats, oils, water, and oxygen on the shelf, but is more expensive. Some instant snack meals have complex laminate structures with metal FAEZO (full aperture easy opening) lids and snap-on plastic cover lids. Aluminum foil trays have good appearance, stack well, have good barrier properties, and can be dual ovenable. Paperboard trays are ovenable in a range of sizes.

53.3 METALS (STEEL, TIN, ALUMINUM)

Steel, tin, and aluminum are used mainly for canned foods and beverages. The most common use of metals for packaging is in tin-coated steel and aluminum cans. The principal advantages of metal cans are their strength providing mechanical protection, effective barrier properties, and resistance to high temperatures providing stability during processing. As regards their opacity, it is an advantage for light-sensitive products, but a disadvantage in that the contents are invisible. Other disadvantages of metal cans are their heavy mass, high cost, and tendency to interact with contents and environment (internal and external corrosion). The critical concepts of canning are to ensure that the product in the can is stable and that the seal provided by the metal is complete. Tin coating or lacquering is an important part of can manufacture. The lacquer is a resin, such as an acrylic (which resists high temperatures), oleoresinous, alkyd, epoxy, phenolic, polybutadiene, or vinyl resin. More than 200 different protective coatings are now in use [7]. The lacquering must be complete. Small gaps in the coating can lead to the iron being exposed. The interior coating has to withstand sterilization temperatures and action of acids, as well as sulfide staining. As iron corrodes, it produces hydrogen gas, which can blow the can. The development of lacquers has meant that tin-free cans are possible. Another disadvantage of steel is the high-energy requirement during manufacture [2, 3].

Aluminum is used increasingly for canning, due to its lightness, low cost, corrosion resistance, availability, and recyclability. Aluminum is also used extensively in many non-canning applications, such as foil packaging, caps, convenience food containers and lids, yogurt tub lids, kitchenware, and laminates. Foil may be used for formed or semi-rigid

containers. Aluminum foil is difficult to use on modern fast-packaging equipment because of creases, tearing, and marking effects. In practice, aluminum foil of fine gauge may have minute pinhole defects due to the tolerances of the rollers, crystal size, and lubricants used, which allow transmission of air and water.

53.3.1 Canning

The most common use of metals for packaging is in tin and aluminum cans. The metal provides a highly effective barrier between the food product and the environment. Thus, the critical concepts of canning are to ensure that the product in the can is biologically stable and that the seal provided by the metal is complete. Food stability for nonpowders is usually achieved by thermal processing. Canning was invented by Appert in the nineteenth century in response to the need to supply Napoleon's army with good-quality food. He used glass bottles, but Durand (English) used metal and pottery at about the same time. The two ideas together gave us tin cans.

Tin cans are made of sheet steel coated with 0.5 mm tin. The coating is applied by tinning, which is electrolytic deposition of the tin at about 10 g/m^2, and hot-dip, which uses about 30 g/m^2. The steel is rolled and ribbed (for added strength) and either sealed with solder (usually 95% lead, 5% tin), or, more commonly, welded. The resulting tube ends are flanged, and the lids at both ends are attached by a double seam without solder. Since steel corrodes rapidly in the presence of acidic substances, the tin acts as a barrier. Some cans are lacquered internally for high-acid products (pH <3) or for products that change color in the presence of tin. Foods that contain sulfur produce a blackening of the tin. The steel can provide almost perfect barrier protection and, due to its structural strength and ability to handle pressure, can be retorted (cooked under pressure) after sealing.

In competition with traditional tin-plated steel cans, modem cans may be made from tin-free steel, aluminum, or laminates. Laminates or composite cans are often fiber–foil containers, such as helical-wound tubes, with metal ends. The fiber may be paperboard. The first layer would be the liner, followed by other layers until finally the printing layer is wound on. The layers are sealed together with adhesives, which generally contribute the majority of the structural strength.

The closure is traditionally the seamed lid, to be opened by the consumer with a can opener. A major development in canning has been the customers' preference for convenience over cost, so that pull tabs (now out of favor because of pollution), zip tops, pop tops, and ring pulls (where the ring remains attached to the can) have been adopted. Other examples are sardine cans (peel-back lids using a key to lever open the lid) and the recently developed full aperture easy opening (FAEZO) cans, where a ring tab is used to peel back the entire top lid. The lid is scored during manufacture to a precise metal thickness; if too thick, the can is difficult to open, and if too thin, the package integrity is endangered.

Not all cans are retorted. The term "general line" is used for containers that are not hermetically sealed for heat processing, which accounts for about 16% of the tinplate market worldwide. The advantages of tinplate are strength (impact, puncture), barrier, formability, printability, and product compatibility. They tend to be used for higher-value products, as the painted tin can look very effective. The processes of manufacturing steel cans are described well in many textbooks and will not be covered here. Aluminum can manufacture is described next.

53.3.2 Aluminum

Aluminum is used increasingly for canning, due to its lightness, low cost, corrosion resistance, availability, and recyclability. Aluminum is also used extensively in many noncanning applications, such as (i) foil packaging, e.g., chocolate, household or industrial foil; (ii) bottle closures and overwraps, e.g., caps, wine bottles; (iii) convenience food containers and lids, e.g., frozen-stored/oven-heated, single portion sizes, yogurt tub lids; (iv) kitchenware, e.g., saucepans, cutlery; (v) special applications, e.g., shrimp freeze blocks; and (vi) laminates.

53.3.2.1 Properties

Aluminum makes up 7.9% of the earth's crust and is attacked by acidic solutions (especially food acids: pH < 4). Special inks had to be developed to work with aluminum, due to its smooth metal surface and high reflectance. A common solution with formed containers is to put all of the print on the lid. The main properties of aluminum are lightness (three times lighter than steel), strength (alloys are as strong as steel), corrosion resistance, electrical conductivity (twice that of copper), appearance, and ease of recycling. It has the barrier properties of steel but without the corrosion problem. It is highly attractive in appearance, as it reflects about 85% of the incident light, and so stands out from other products. It can be bonded with paper (e.g., chewing gum and cigarette wrappers) to allow easier printing. It has excellent strength, so that thin films can be made. It can be extruded into complex shapes, such as roof guttering.

53.3.2.2 Manufacture

Aluminum foil became common after the electrolytic method of extracting aluminum metal from bauxite was developed independently by Hall in the United States and Heroult in France in 1883. Bauxite contains 75% hydrated alumina (Al_20_3) in mono- and trihydrate forms, as well as oxides of iron, silicon, clay, etc.

53.3.2.3 Aluminum Foil

Foil may be used for formed or semirigid containers. Many instant meals are packed in cooking and eating trays made of aluminum, with different compartments commonly formed in the tray to separate the meal components, especially with frozen foods. Aluminum foil is made of solid sheet aluminum rolled to a thickness of less than 0.15 mm and sold on cardboard rolls. For food applications, it is sold at high purity (99.8%) except for formed containers, where it is strengthened (like steel) by the addition of 1–1.5% manganese. After

rolling, the aluminum is work-hardened, so it is brittle and crinkly. The aluminum can be softened by slow heating and slow cooling (annealing, about 24-hour heating at 300°C, which also cooks off the processing lubricating oils, then 24-hour cooling is typical), giving a soft metal of low strength and high flexibility (ductility) suitable for household use and most other food applications—this is called zero temper. By rolling and strain hardening ("quenching" when hot), a more brittle, stronger material is produced. This is called H temper, with a number added according to the degree of hardening. Hard tempers must be used whenever a high degree of forming is required. The metal may also be normalized, a process of air-cooling heated metal that is intermediate between quenching and annealing.

53.3.2.4 Foil Laminates

Aluminum foil is difficult to use on modern fast packaging equipment because of creases, tearing, and marking effects. Thus, additional treatments are common. Lamination can be difficult for the same reasons, but once laminated the resulting plies have excellent machining and visual properties. For example, sodium silicate may be used to glue foil to vegetable parchment (cigarette foil). The foil may be printed, coated, seal applied, and laminated in a step called converting. The web may also be embossed (embossing roller), giving a textured matte appearance, which reduces glare and makes separation in refrigerated storage easier.

53.3.2.5 Rigid Foil Containers

Rigid aluminum foil containers have varying strengths but offer the ultimate in convenience for all food processing, packaging, display, and consumer requirements. They are produced as follows. The foilstock (after hot-rolling) is cold-rolled to 7 μm, the final rolling being two-ply. The plies are separated and annealed (i.e., cold-rolling causes high degrees of work hardening). The foil may then be coated. The web is then slitted to size and then die-formed using complex dies, which control the degree of drawing of the aluminum to retain uniform strength. Lids may be cardboard laminated with aluminum. They are not affected by heat and can be heated, immersed, and frozen.

53.3.2.6 Pinhole Defects

In practice, aluminum foil of fine gauge may have minute pinhole defects. The aluminum foil is graded according to the number of defects as: grade 0, <200 holes/m^2; grade 1, 200–900 holes/m^2; grade 2, 900–3000 holes/m^2; and grade 3, >5000 holes/m^2. The size of the holes is also significant. For this reason, aluminum is commonly bonded with polyethylene for commercial food-packaging applications so that thicknesses of the order of 10 μm can be used. The resulting barrier properties are far superior to those of plastics and plastic laminates,

53.3.2.7 Aluminum Tubing

Aluminum is also used for squeezable tubes (e.g., toothpaste or tomato paste tubes). However, this use is becoming less common due to the following problems: (i) neck finishing is expensive; (ii) inks tend to crack and peel off after squeezing; (iii) some products are affected by aluminum, so a lining may be necessary; (iv) plastic laminates cost about 20% less; and (v) aluminum tubes are more subject to contamination. Plastic laminates (usually including a foil layer) are increasingly being substituted for products such as sauces, peanut butter, and cheese. The main problem with aluminum tubing has been the integrity of the side seam.

53.3.2.8 Aluminum Cans

Cans are made by cutting a blank (a disk of aluminum) from a coiled sheet, the skeletal web being recycled, and then drawing the blank into a cup. The walls may then be ironed by forcing the cup through a series of annular rings (dies) until the cup has the required height (drawn and wall-ironed [DWI] process), with a bottoming die forming a raised dome in the base. Alternatively, the cup may be redrawn, giving a thicker wall (drawn and redrawn [DRD] process). The thinner-walled (DWI) cans are suitable for carbonated beverages, while DRD cans are suitable for steam sterilization and retorting. The body shell is trimmed to length, chemically washed, and then given a chemical etch primer (chromate phosphate) so coatings stick when applied. The lid (two-piece design) is then added.

The can may have a reduced neck diameter for improved appearance, better stacking, and saving metal. Ring-pull tabs or FAEZO openings may be used. Printing may be done before drawing the can (i.e., on the blank), the ink design stretching with the can, or may be applied by offset printing to the final can. Lacquers (e.g., vinyl or epoxy) may be applied internally for acid products to prevent interaction between the product and the can, and externally for protecting the ink and providing the right slip properties on the base. The final can has a base thickness of about 0.020 inch and a wall thickness of 0.0065 inch.

Some areas of current research are dent recovery (using laminates), foil machinability, pinhole defects, closure opening force, and recycling (Australia has the highest recovery rate in the world). Apart from cans, aluminum recycling is difficult due to lamination with other materials, food and moisture contaminants, and the low value and volumes of material, so the trend is to reduce the amount of aluminum required. Foil food containers are difficult to microwave due to arcing and heat energy reflectance. However, there is some interest in developing aluminum food trays for microwave use. All packaging materials either transmit (glass, plastic, paperboard), absorb (susceptors such as metallized polyester laminated to paper, useful for browning and crisping), or reflect (metals). Thus, the tray must be open to the microwave energy at the top, so that the food cooks more slowly but more evenly.

53.4 GLASS

Glass containers used to be and still are considered as a prestigious means of packaging, and serve for the most expensive wines, liqueurs, perfumes, and cosmetics. It is highly

inert, impermeable to gases and vapors, and amenable to the most diverse shaping. In its normal state, it has the advantage of transparency, but where required it can be given different desired colors. It has complete as well as selective light protection properties. Its main disadvantages are its fragility, heavy mass, and high energy requirement during manufacturing. In addition to its marketing strength, glass has other advantages that give it muscle in today's marketplace. It is an excellent oxygen barrier and completely neutral in contact with foods. Glass also fits well into the modern recycling society, since it can be recycled indefinitely. Glass packaging technology has developed to the extent that strength, minimal mass, color, and shape all have been improved. While glass would not supplant metal and plastic in volume, it is finding an increasingly strong niche at the high end of the food spectrum [2].

53.4.1 History

Glass was first manufactured by humans thousands of years ago, possibly as an offshoot of pottery as glazes, and dates to 12000 B.C. Pressing glass in molds to form cups or bowls dates from 1200 B.C. and blow piping was invented by the Phoenicians in 300 B.C. In the third century A.D. clear glass was discovered, for example, cast glass using flat stones, used for church windows. Until the industrial revolution, glass was mainly used for high-quality tableware.

With mass production, however, glass started to become ubiquitous, first through the cork-sealed, narrow-necked bottle, then from about 1850 on the wide-necked jar and from 1920 the screw-top jar. The glass bottle is an almost ideal form of packaging for a large variety of products. It is inert to most substances; the product is visible; the cylindrical shape is good for loading, stacking, and holding; and it is cheap to manufacture and versatile in design.

Glass bottles are used for milk, jams, soft drinks, wines, beer, and spirits, and for many food products. Glass is highly inert, shows the product well, is available, easy to mold, cheap, has almost perfect barrier properties (including barriers to odors), and is recyclable. However, it is brittle, and some product loss will occur through breakage. Because it is fragile, high weights are required per product unit, and for a while, research was directed at reducing the high weight ratios by coatings (e.g., surlyn), which allow the glass to be handled at much higher packaging speeds. The coating reduced breakage, but this research ended when the PET bottle became available. More recently, environmental considerations have revived the idea. Over 75 billion glass containers are used annually by the food industries.

53.4.2 Glass Manufacture

Glass is the result of heating silica, soda ash, and limestone to over 1500°C, with the small addition of minerals for color or strength. As the mixture melts, the compounds fuse and become easy to shape. This may be done by sucking the melt into heat-resistant molds or by blowing semimolten glass into rough shape in a mold and then pressing this into a second mold where a jet of compressed air forces the glass into the final shape. Crystallization is prevented by quickly cooling the final product, so that the final product is amorphous and thus transparent. Annealing is a process of reheating the glass, and then gradually cooling to remove stresses (also used for metals). Safety glass is laminated and toughened.

Special glasses include Pyrex, produced by the addition of borosilicate and having resistance to thermal shock; amber glass, used to inhibit ultraviolet radiation for beer bottles; and crystal with added lead. (Note that wine can leach lead from glass!) Glass may be corroded by the application of hot concentrated alkali. Leaching tests for lead, cadmium, arsenic, and zinc are conducted on glass with high contents of these minerals; but in most cases, the fusion process of glass production prevents traceable amounts of these elements from escaping. In general, glasses are not retortable due to thermal shock and the expense of Pyrex glasses, but if retorted the glass must be cooled under pressure to prevent thermal shock.

53.4.3 Glass Containers

The main components of the container are the cylindrical main part, the bottom, the neck (called the finish), the closure (the screw cap), and the label. The cylinder shape is chosen for maximizing strength for a given volume (the sphere is a better shape, but not convenient for packaging). Glass is not well suited for sharp corners, as stresses tend to concentrate in areas of sharp curvature. The main components of the cap are a lacquer, wad, liner, and cover. Caps may be plastic or metal, and the type of closure might be thread, lug, friction, snap-cap, roll-on, cork, crown, twist-off, etc. The various types of glass containers have a range of names:

1. Bottles (most used)—round, narrow neck to facilitate pouring and closure, for liquids and powders.
2. Jars (wide-mouthed bottles)—neckless, allowing fingers or utensils to be easily inserted. Used for liquids, solids, nonpourable liquids such as sauces, jellies, and pastes.
3. Tumblers (open-ended jars)—shaped like drinking glasses. Used for jams, condiments, and jellies.
4. Jugs (bottles with carrying handles)—short, narrow necks designed for pouring.
5. Carboys (shipping containers)—shaped like short-necked bottles, usually used with a wooden crate holder.
6. Vials and ampoules (small glass containers)—occasionally used for spices, but mainly used by the pharmaceutical industry.

The main uses of glass for packaging are in milk bottles, condiments, baby foods, instant coffee, and drinks. Glass is not used for frozen products or for ground or roasted coffee because of breakage costs and the difficulty of vacuum flushing.

53.5 TIMBER, CARDBOARD, AND PAPERS

Pulp products are widely used in food packaging in the form of different kinds of paper, paperboard, laminates, and corrugated board. The main advantages of paper are its low cost, low mass, relatively high stiffness, and excellent printability; the main disadvantage is its high sensitivity to moisture, reflected in close dependence on the relative humidity of the environment [2].

The basic raw material for papermaking is cellulose. The cellulose molecule consists of a long, straight chain of glucose units. Paper can be classified according to its surface properties into machine-dried, machine-glazed, or supercalendered papers. Great importance must be given to coated and laminated papers, particularly for difficult packaging conditions. All demands regarding special performance as a barrier against water or water vapor, for example, can be met by combining paper and other materials. These are wax-coated, bitumen-coated, and plastic-coated papers. Other special types of paper include glassine, greaseproof paper, vegetable parchment, and waxed papers. Glassine is used extensively because of its inherent resistance to grease, oils, and fats and is the densest paper made [2, 3]. Paper laminations commonly used include paper/aluminum, paper/plastic, and paper/plastic/aluminum.

The use of wood in packaging today is rather limited, confined primarily to crates, large boxes, and pallets. Its major advantage is its strength, but it is quite expensive and cheaper alternatives such as corrugated board have been found adequate for many applications. Even pallets, which used to be made exclusively from wood, are made today in part from foamed plastics [2].

53.5.1 Timber

Wood is commonly used in box construction, but the use of wood for individual packaging (such as cigars) has decreased since the advent of plastics. Examples of timber for packaging are cases, boxes, and casks for long-distance transport.

53.5.2 Cardboard

The next choice of packaging material to be considered is cardboard. This may be a protective package (see previous section) or a presentation package. Folding carton construction consists of taking a two-dimensional flat piece of board (excellent for storage) and cutting, scoring, folding, and then gluing (or locking) it into a three-dimensional rigid box. The cardboard will usually be laminated to paper to allow printing and presentation.

For transport purposes, the fiberboard must resist relative humidity and temperature effects. Relative humidity affects the moisture content of the board (which is hygroscopic), raising it from 6–7% safe moisture (at manufacture) to 14%, at which point the board becomes like a piece of rag. Temperature strongly influences the rates of diffusion of gases and moisture into the package. Thus, the transport requirements will depend on ambient conditions. The board should be designed for the optimum lifetime of the projected job.

The various elements of cuts, tucks, locks, flaps, and folds may be assembled in an endless variety of ways, although the most common is rectangular for packing and storage convenience. Since cardboard is obviously highly versatile, the details for construction vary widely. The actual specifications may include (i) grade of board, ink type, and glue type (e.g., hot-melt glue or water-based); (ii) performance criteria, such as handling strength and crushing strength; and (iii) size.

One of the major uses of cardboard is as corrugated cardboard, a concept developed by Albert Jones in 1871, adopting the method for making ruffles from collars and paper for sweatbands in tall hats. Jones hand-cranked paper, and in 1874 Oliver Long patented gluing paper to both sides of fluted paper. Corrugated cardboard consists of two linerboards covering a central corrugated sheet. The linerboards are made of kraft, test liner, or low-grade pulp covered with kraft. The corrugated paper is made of straw paper or kraft paper. The main factor determining the board properties is the corrugations. A useful modification is the double- and triple-wall container; the corrugations on successive layers are usually parallel. The board is usually printed at the time of manufacture.

Choosing a carton for a specific job depends on the capacity of the carton to meet the requirements for that job. There is a trend to replace subjective tests (e.g., cartons must run on certain packaging machines) with more scientific objective tests (e.g., compression strength). The choice of carton for a specific job will depend on

1. Carton load, both the internal weight of the product and the external load applied.
2. Warehousing conditions, such as stack heights, ambient warehouse conditions.
3. Storage life.
4. Type of handling, e.g., fork, manual, palletizer.
5. In-use conditions (especially RH).
6. Item size, determining critical dimensions of the carton.
7. Maximizing pallet efficiency by using the available space.
8. Size and style—accuracy of the dimensions, which affects packaging machine performance (e.g., 1/64 inch), prefolds, print areas, etc.
9. Protective properties—different cartons protect against different agents, e.g., moisture or odor. These vapors can enter/leave through the cardboard itself, through the creases, through the glue seals or through the gaps between folds. Moisture vapor protection (MVP) is generally achieved through waxing the cardboard and is measured in terms of the resulting water vapor transfer rate (WVTR) measured in $g/m^2/day$.

A waxed board is difficult to print on, so the board may be laminated with white paper. The glue must be chosen that will seal within the time the box is in the packaging machine.

A common glue is dextrin, which is water-based, the water being absorbed into the cardboard as the glue sets. Hot glues may also be used. The inks used must be of the specified hue (and reproducible), resist fading, and resist rubbing.

53.5.2.1 Opening Cartons

For ease of use, some quick reliable method of opening the carton is usually built-in. Examples are perforated thumbnail openings, fold-and-tear openings designed to assist pouring, or designated areas for cutting.

53.5.2.2 Board Strength

The board must be strong enough for packaging, handling, storage, and intended use. It creates a bad impression with the user if the pack bulges, so bulge strength is important. The board must also resist compression and a degree of impact. The strength of the cardboard chosen for the protective package is related to the strength of the product package so that if a weak carton is used, a strong external box is necessary for delivery to the point of sale. Note that the air moisture content (relative humidity) has a large effect on the strength of cardboard. Other problems with cartons include pallet integrity, ropes denting boxes, weak cartons (bottoms fall out), pallet stack collapse (compression), overweight cartons, and forklift damage.

53.5.3 Papers

Paper bags were used in the 17th century. A bag-making machine was developed in 1852 by Wolle in the United States. The gusseted bag (1873) and multiwalled bag (1925) were later important developments. Paper is defined as sheets of material thinner than 0.23 mm and lighter than 220 g/m^2. Paper and board are produced from wood pulp (treated with calcium bisulfite or caustic soda to break down the lignin structure), rags, and other waste. Paper is decomposed by bacterial action over a period. Thus, paper is ultimately environmentally friendly. However, paper has had tough competition as a packaging material over recent years due to the extensive use of plastics. Treatments of paper to make it more competitive include paraffin and waxes (waterproofing) and plastic coating (added strength, and water and gas resistance). Paper can also be laminated with aluminum.

Paper is produced from wood pulp, treated by the addition of soda, calcium sulfite, or calcium sulfate (depending on the end-use). The pulp is milled into a continuous sheet and bleached with chlorine, caustic soda, and sodium hypochlorite. After drying, it may be treated with various chemical coats to enhance its performance. Paper is designated by the weight of a ream of paper of a given size. Usually a ream is 500 pages, but variation in size makes it difficult to directly compare two papers. For printing, the standard size is 24 × 36 inches (6 ft^2 or 0.55742 m^2). Some of the standard papers used are

1. Bond papers (17" × 22"): soda pulp, uncoated bleached, finished to give wet strength and a good printing surface.
2. Tissues (24" × 36"): lightweight semibleached or bleached, finished to give wet strength, with open or closed fiber formation.
3. Litho papers (25"× 38"): smooth printing surface but not as strong as bond paper, used in magazines.
4. Kraft papers (24" × 36"): unbleached equivalent to bond paper, but of heavier basis weight (and hence greater strength), and cheaper.

Other special types of paper include glassine, greaseproof paper (glassine paper that has not been calendered and is free of wood pulp, water-resistant, and heavily milled), vegetable parchment (boil proof and fat impervious, due to treatment with sulfuric acid), and waxed papers. This paper is not moisture-proof, so may be waxed or laminated.

Glassine is used extensively because of its inherent resistance to grease, oils, and fats and is the densest paper made. It is made from straw, which is pulped and purified, then hydrated at high temperature until it partly gelatinizes. The resulting sheet is fed into a calendar, where it is rolled under high-pressure steam to give a transparent paper. It can be laminated. It is used for dry products such as cereals and biscuits after being waxed (paraffin).

Paper laminations commonly used include paper/aluminum (for strength and excellent resistance to moisture and air) and paper/plastic (good for heat sealing as the plastic can bond across the seal, but also good for writing on). Regenerated cellulose is cellulose precipitated out of solution. Cellophane is clear cellulose regenerated from a viscose solution.

53.5.4 Paperboard

Waste paper can be used to produce board for cartons. Some types are

1. Chipboard: waste paper blended with wood pulp to give a flexible gray board (not suited for printing).
2. Manila-lined board: a top liner of ground wood pulp covering newspaper or other waste paper pulp, which can be printed on.
3. Clay-coated board: same as manila-lined, except that the top-liner is coated with white mineral powder bonded to the surface. This important innovation, coupled with fast electrostatic printing, has allowed the carton to be an attractive way of presenting goods.

Waste paper may also be turned into paper pulp for molding, e.g., in egg cartons, molded trays, and vegetable holders. Recycled paper is weak and discolored, making it poor for packaging. It must be used in conjunction with virgin paper. Recycled cardboard does not crease accurately, so boxes cannot be erected as accurately or quickly.

53.6 CERAMICS

The term ceramic describes any nonmetal nonorganic material produced by high temperatures, such as glass and pottery.

The raw material is molded into the required shape and then fired. Once fired, the material cannot be easily modified, as it is brittle and inert. If the material has been applied in a thin coat to another substance before firing, it is called a glaze. The most common use of ceramics in the food industry is, of course, pottery.

The chemical composition of most ceramics is silica (SiO_2), alumina ($A1_2O_3$), and water. Glass is almost pure silica, whereas clays have large amounts of alumina present. The main chemical structure of the fired product is the tetrahedral SiO_4 complex, although other stable structures like this may be present. Most clays are reddish-brown due to the presence of iron, the exception being kaolin (China clay).

During firing the clay shrinks as water is removed. Thus, control of the amount of water in the clay is important, and an initial drying stage is necessary to remove unbound moisture before firing. The firing temperature is also critical. For pottery, it should be above 1000°C. This is well below the melting point of the clay, but is high enough to cause the clay structure to break down into $A1_2O_3$ and SiO_2 molecules, which then react exothermally (sintering). A glass results from complete melting and then cooling.

Vitreous enamel is a finish applied to metals. This is done by coating the metal in powdered glass, and then heating above the melting point of the glass. Legislation nowadays prevents the use of cadmium or lead in vitreous glazes.

53.7 METALLIZED FILMS

Plastic films can be formed by lamination, coextrusion, or impregnation. No single film can satisfy all packaging requirements. Lamination is a technique for bonding films together to give a film with the properties of multiple constituents. By combining the qualities of choice from the raw material films, a laminate can be tailor-made for its particular application. Each layer in the resulting laminate may exhibit different properties from its free state, such as mutual layer reinforcement in which cracks in a brittle layer are prevented from propagating by a high elongation (elastic) layer. The effect depends on good adhesion between the layers [3]. Coatings are often used to enhance plastic film properties such as printability. Aqueous and solvent coatings are applied to the substrate through water dispersions or emulsions, solvent solutions, or waxing.

Aluminum metallized films are extensively used in food packaging applications and compared with films containing aluminum foil. Metallization has the following advantages: (i) lower environmental impact due to a significant reduction in the amount of raw material used and the recyclability of metallized film scrap as part of the base material, (ii) greater flexibility and resistance to flexion, and (iii) impressive presentation. In contrast with polymeric films, the main disadvantage of metallization is its low resistance to flexion and extension [6]. At present there are two other major limitations: foods cannot be cooked in a microwave oven within the package, and the opacity of the finished films can be a handicap for some products in which appearance is as important as quality. Thus, packaging manufacturers are looking for good barrier characteristics without compromising transparency to light and microwaves. Transparent films with excellent barrier properties have been achieved by coatings of aluminum oxide or silicon oxide [6]. Silicon-oxide-coated film helps in extending product shelf life by maximizing flavor, color, and vitamin C retention, and permitting higher filling temperatures.

53.8 BIOPOLYMERS

Bio-based materials are usually termed "environmentally friendly," 'biodegradable," or "earth-friendly." Biodegradable plastics, under appropriate conditions of moisture, temperature, and oxygen availability, lead to fragmentation or disintegration of the plastics with no toxic or environmentally harmful residue [8]. Biodegradable polymers can be classified according to their source as given in Table 53.6 [9]. The production of microbial biodegradable polymers from agro-food waste residues seems a promising route to create an innovative, more resilient, and productive waste-based food packaging bioeconomy [10].

Europe is far ahead of the United States, accounting for nearly 60% of the market for bio-based packaging [11]. Biopolymers are based on renewable raw materials, which can be processed by established plastic processing technologies such as injection and blow molding, blown or cast film extrusion, and extrusion. Components, e.g., cellulose, starch, or oils from plant-based biomaterials, such as corn, rapeseed, and soybean, can be extracted. Similarly, gelatin from animal skin and whey protein from milk can also be extracted [12]. The compostable polymers are biodegraded in an industrial composting environment in fewer than 180 days. It means a defined temperature of about 60°C, a defined humidity, and the presence of microorganisms. These do not leave fragments longer than approximately 12 weeks in the residue, and do not contain metals or toxins, and do support plant life [12]. One of the recently developed ones is compostable polymer polylactide (polylactic acid, PLA), which is typically manufactured by starch from corn. Polylactides are water-resistant

TABLE 53.6
Groups of Biopolymers

Group 1	Extracted polymers	Directly extracted or removed from biomass (i.e., polysaccharides, proteins, polypeptides, polynucleotides)
Group 2	Synthesized polymers	Produced by classical chemical synthesis using renewable bio-based monomers or mixed sources of biomass and petroleum (i.e., polylactic acid or biopolyester)
Group 3	Microbiologically transformed polymers	Produced by microorganisms or genetically modified bacteria (polyhydroxybutyrate, bacterial cellulose, xanthan, curdian, pullan)

Source: Adapted from Sorrentino et al. [9].

and can be formed by injection molding, blowing, and vacuum forming, and at room temperature. An antioxidant agent can be used in the development of biodegradable active packaging from PLA polymer matrix [13].

Polyalkylene carbonate copolymers are a unique family of innovative thermoplastics representing a true breakthrough in polymer technology. These materials are produced through the copolymerization of carbon dioxide with one or more epoxides, and these are amorphous, clear, readily processed, and long-term mechanical stability. In addition, these are considered more environmentally friendly since they consume 50% fewer petrochemicals, as compared to 100% petrochemical-based polymers, and exhibit biodegradable properties [11].

Polypropylene carbonate (PPC) is biodegradable aliphatic polyester reinforced with starch [14], and mango puree nanocomposite reinforced with cellulose nanofibers [15]. Incorporation of low-cost and biodegradable corn starch into PPC provides a practical way to produce a completely biodegradable and cost-competitive composite with good mechanical properties [14]. Improvement in the thermal properties of PPC has been reported by mixing PPC with montmorillonite clay to form a bionanocomposite [16]. Keratin films plasticized by 1,8-octanediol can be applied in food packaging and biomedical materials [17]. Keratin from duck feather without a plasticizer produces fragile films, thus formaldehyde is used for cross-linking and plasticizers to modify keratin films.

The barrier properties of bio-based packaging are crucial in terms of food packaging. Vartiainen et al. [18] reviewed the state of the art of several biopolymers including pectin, starch, chitosan, xylan, galactoglucomannan, lignin, and cellulose nanofibrils. They pointed that in most cases the packaging-related properties of single-layer biopolymer films are inadequate, and thin film coatings, such as sol-gel and atomic layer deposition (ALD), as well as multilayer coatings are applied. Peelman et al. [19] also reviewed different types of biodegradable packaging materials (such as PLA, starch, polyhydroxyalkanoates [PHA], cellulose, and polyhydroxybutyrates [PHB]) and state-of-the-art coating, nanotechnology, and physical and chemical modifications with blending. Optimum formulation was determined for the cassava starch/poly(butylene adipate-co-terephthalate) (PBAT) blown films (i.e., for biodegradable plastic bags) produced via one one-step reactive extrusion using tartaric acid (TA) as a compatibilizer [20]. It measured the tensile strength, perforation force, elongation, and seal strength.

53.9 NANOCOMPOSITES

Nanotechnology presents the packaging industry with opportunities to develop an array of exciting new products with enhanced or fundamentally different performance properties [11, 21]. In addition, it exhibits biocompatibility and biodegradability, and in some cases controlled release capacity of antimicrobial and antioxidant in the cases of active antimicrobial food packaging. Nanocomposites contain a naturally occurring polymer (biopolymer) in combination with an inorganic moiety to be functionalized, and including at least one dimension on the nanometer scale [22]. Challenges remain in increasing the compatibility between clays and polymers and reaching complete dispersion of nanoplates (exfoliation).

The most promising nanoscale size fillers are montmorillonite and kaolinite clays, and crumpled graphite nanosheets [23]. Cellulose biofibers with their highly crystalline building nanoblocks and food contact complying non-MMT (non-montmorillonite) nanoclays have been studied [24]. The reviewed papers indicated that these nanocomposites showed improved physical properties, for example, mechanical strength, thermal stability, gas barrier, physicochemical properties, and recyclability [9, 25]. Azeredo et al. [15] described the use of cellulose nanofibers and glycerol as a plasticizer to improve the mechanical and water vapor barrier properties of edible chitosan films.

In general, there is a need to develop more compatible filler–polymer systems, better processing technologies, and a systems approach to design of polymers, plasticizers, and fillers [21]. Morris [26] has expressed concerns over the long-term fate and disposal of these materials, which might then lead to release of nanoparticles into the environment and back into the food chain, raising debate on the labeling, approval, traceability, and regulation of all these smart or intelligent biomaterials materials.

53.10 CONCLUSION

Conventional packaging materials are glass, metals, paper, and synthetic polymers. Huge expansions of developing new packaging materials are progressing that consider economic, functionality, and environmental issues. These are biodegradable, green, bioactive, nanocomposites, antimicrobial, and edible packaging. In the future, significant progress in these materials will evolve.

54 Food–Packaging Interactions

Shyam S. Sablani, Kanishka Bhunia, and Mohammad Shafiur Rahman

CONTENTS

54.1 INTRODUCTION

Packaging materials are used to protect foods against microbiological, chemical, and physical contamination during storage and distribution. However, most food packaging materials are not inert, and therefore reactions may occur between the food and packaging material. This may change the initial mechanical and barrier properties as well as safety of the packaged foods. Components of the packaging material must be safe to the product as well as to the consumers. This interaction may be classified into three main phenomena: migration, permeation, and absorption. In packaging regulations migration describes the transfer of packaging components from the packaging to the interior of foods. A distinction is usually made between global migration and specific migration. Global migration refers to the total transfer, i.e., the quantity of all substances migrating from the package into the packaged food, whereas specific migration relates to the transfer of one or more identifiable substances contained in the packaging material [1]. When volatile compounds, such as flavors and aromas, are lost through permeation and absorption, food quality may be affected. The permeation in polymeric film depends on the solution and transport behavior of gas and vapor and properties of polymers as well. Packaging materials can also absorb flavor compounds from products, reducing the desired consumer perception of quality.

Although packaging materials are necessary, they can pose risks to human health and/or affect the quality of the contained food. The quality loss of food products can occur with package failure and/or product–package interactions. Package failure can result from inadequate barrier properties for the intended shelf life or from loss of integrity during distribution [2]. Improper use or selection of packaging materials can increase the risks associated with packaged food products. For example, package failure due to loss of integrity

can greatly increase the risk of microbial contamination and potential food poisoning.

Migration of potentially toxic substances from packaging materials in the contact phase is also a major concern in the selection and use of materials for food packaging due to potential effects on human health. The migration of other components from packaging materials, while not harmful to human health, may reduce the quality of food products [2]. The sorption of fats or organic acids by the food-contact layer in a polymer laminate can cause separation (delamination) of different layers of the laminate. Other sorbed compounds can swell the polymer and act as plasticizers, thereby increasing diffusivity and permeability [3].

Product–package interactions can occur in several ways. Figure 54.1 shows a complete scenario. In some cases, product components may penetrate the structure of the packaging material, causing loss of barrier and/or mechanical properties. The migration of low-molecular-weight components from the packaging material to a contained product can result in flavor loss and/or color change. Packaging materials undergoing oxidation can also accelerate the oxidation of products in contact with that material. Packaging can absorb flavor compounds from products, the loss of which decreases the perception of quality. This scalping of flavor compounds is a concern for many aseptic products such as citrus, which contains volatile, highly aromatic compounds. When these compounds are selectively removed by the packaging material, they no longer function as flavor components. Thus, the perceived quality of the product is diminished due to loss of aroma intensity or development of an unbalanced flavor profile [3, 4]. Another problem associated with absorption of flavor components by packaging materials is the influence of that absorbent on the barrier characteristics of the packaging material. Relatively minor increases in the concentration of the organic vapor lead to large increases in permeability of the packaging material. Food-contact material may cause autocatalyzed oxidative reactions in products.

54.2 MIGRATION OF PACKAGE COMPONENTS

54.2.1 Migrating Substances

Substances that usually migrate from polymer-based packaging materials to food are plastic additives, monomers, oligomers, and contaminates. To improve manufacturability, a wide variety of additives is used during the processing of polymeric-based packaging materials. This includes plasticizers, antioxidants, light stabilizers, thermal stabilizers, lubricants, antistatic agents, slip additives, nanoparticles, and photoinitiators. This also includes migrating solvents, such as adipic acid, toluene, butanone-2, ethyl acetate, and hexane, and pigments such as molybdate orange are also used [5, 6].

54.2.1.1 Plasticizers

Plasticizers are a group of additives used in plastic materials to improve their flexibility, stretchability, and workability. The plasticizer also gives the material the limp and tacky qualities found in "cling" films. For example, a commonly used plasticizer for PVDC-based cling-films is acetyltributyl citrate (ATBC). Butyl benzyl phthalate (BBP), di-n-butyl phthalate (DBP), dicyclohexyl phthalate (DCHP), di (2-ethyl) hexyl phthalate (DEHP), diheptyl adipate (DHA), heptyl adipate

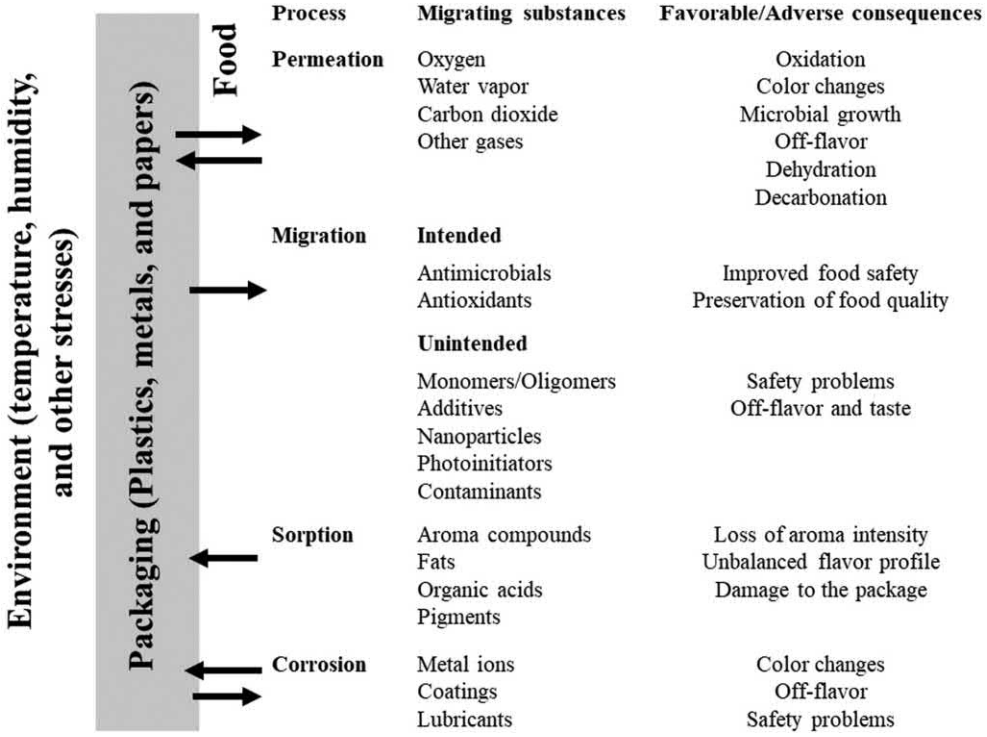

FIGURE 54.1 A complete scenario of product–package interaction resulting from several modes.

TABLE 54.1
Type and Concentration of Plasticizers Found in Some Packaging Materials

Packaging Material	Thickness (cm)	Plasticizer	Concentration of Plasticizer (μg/dm²)
Cellulose acetate	0.003	BBP	1250
		DBP	1840
		DCHP	2090
		DEHP	1620
Cellulose acetate	0.004	BBP	2050
		DBP	3170
		DCHP	3340
Cellulose acetate	0.004	DBP	4840
		DCHP	6480
Polyvinylchloride copolymer	0.002	DHA	2240
		HAD	2550
		HOA	2680

Source: Adapted from Lau and Wong [29].
BBP, butyl benzyl phthalate; DBP, di-n-butyl phthalate; DCHP, dicyclohexyl phthalate; DEHP, di(2-ethyl)hexyl phthalate; DHA, diheptyl adipate; HAD, heptyl adipate and HOA, heptyl octyl adipate

(HAD), and heptyl octyl adipate (HOA) are types of plasticizers commonly used (Table 54.1). About 80% of all plasticizers are used in PVC. Typically, phthalic esters such as dioctyl phthalate (DOP), also known as di-2-ethylhexylphthalate (DEHP), and dioctyl adipate (DOA) or di-2-ethylhexyladipate (DEHA) are used. Epoxidized soybean oil (ESBO) and low-molecular-weight polyesters are also used as plasticizers. PVC may contain 25–45% (w/w) ESBO when used as plasticizer [7]. To address the potential migration of plasticizers into food, the packaging industry has replaced PVC with other polymers, such as PE or regenerated cellulose [5]. In general, plasticizers such as polyadipates migrate at a lower rate due to their higher molar mass (1700–3400 g mol^{-1}) than low-molecular-weight plasticizers including ATBC, DOA, and dibutyl sebacate (DBS) [7–9].

54.2.1.2 Thermal Stabilizers

Thermal stabilizers are used in plastics to slow the decomposition of resins at elevated temperatures, which occurs during thermal processing. Epoxidized seed and vegetable oils such as soybean oil (ESBO), linseed oil, and sunflower oil are used in a range of food-contact plastics as heat stabilizers, lubricants, and plasticizers. Materials such as poly (vinyl chloride), poly (vinylidene) chloride, and polystyrene frequently contain epoxidized oil at levels ranging from 0.1 to 27%. Their toxicity is strongly affected by their purity, since the residual ethylene oxide is quite toxic [6].

54.2.1.3 Slip Additives and Surface Property Modifiers

Polymers such as PVC, polyolefins, and polystyrene tend to stick to metal parts during conversions due to the generation of static electricity on polymer surfaces due to friction. The addition of slip agents (antistatic) such as fatty acid esters and amides, polyethylene waxes, metallic stearates such as zinc stearate, and paraffin can prevent films from sticking together or forming conglomerates, and also reduce the accumulation of electrostatic charge [6, 10]. Slip additives are added to plastic formulations and gradually emerge and bloom on the surface. They also impart useful properties such as lubrication, better mold release, and decreased melt viscosity. Many packaging films tend to stick together because they are nonconductors of electricity. This blocking tendency can be reduced by adding anti-blocking agents such as organic amides as erucamide or metallic soaps such as zinc stearate. In some food packaging applications, moisture condenses as droplets and obstructs the view of contents. This is because polymer has a lower surface tension than water does. This prevents the formation of a continuous layer of water. Adding nonionic ethoxylates or hydrophilic fatty acid esters such as sorbitol and glycerol stearate, also known as antifogging agent, increases the critical surface tension of the polymer surface and promotes the deposition of continuous films of moisture.

54.2.1.4 Anti-Aging Additives

Aging is the process of the deterioration of materials, which results from the combined effects of atmospheric radiation, temperature, oxygen, water, microorganisms, and other atmospheric agents (e.g., gases). Antioxidants are used to slow down oxidation of plastics due to light exposure. BHT, BHA, Irganox 1010, Cyanox 2246, bisphenol A, and Irgafos 168 are the most commonly used antioxidants. Antimicrobials such as algaecides, bactericides, and fungicides can be added to polymers to prevent the growth of microorganisms. UV stabilizers are used to prevent deterioration of polymeric films by photo-oxidation. They act by absorbing high-energy UV radiation and releasing it as lower energy radiation [11].

54.2.1.5 Optical Property Modifiers

Optical property modifiers are used to modify the ability of plastic to transmit light, exhibit color, and reflect surface light (i.e., gloss). Some of the pigments for use as colorants in packaging are red iron oxide, carbon black, white titanium dioxide, yellow cadmium sulfide, ultramarine blue, blue ferric ammonium ferrocyanide, blue and green copper phthalocyanines, molybdate orange, and chrome green. However, a major number of food packaging films do not go through pigmentation. Due to their potential to migrate from plastics into food products, the FDA has questioned the use of some these colorants [10].

54.2.1.6 Monomers and Oligomers

Monomers and oligomers can easily migrate from packaging material into food [5, 6]. Monomers are reactive substances and potentially toxic to living organisms. Therefore, hygiene regulations aim at restricting the content of residual monomers in raw materials and plastics.

Unreacted residual styrene in PS food packaging can migrate into food and may cause adverse and harmful effects on human health. Vinyl chloride monomer is highly toxic;

thus, levels of PVC in food packaging materials are tightly controlled. The epoxy resin of bisphenol A type, such as bisphenol A diglyceride ether (BADGE), is the main component of internal can linings. BADGE has cytotoxic effects in living tissues, and may cause a higher rate of cell division [6]. It may contain unreacted BPA, which is also a major component of polycarbonate-based beverage bottles. However, the FDA found that the current level of BPA/BPA-based materials is safe for food-contact applications, with the exception of baby bottles, sippy cups, and infant formula packaging [12].

Other compounds such as isocyanates used in polyurethane polymers and adhesives are toxic, with well-documented health effects. Polyethylene terephthalate (PET) is commonly used as a packaging material for beverages and edible oils. A standard limit has also been established for the migration of oligomers from PET packaging. Nylon, a frequently used polymer for thermal processing, releases nylon-6 oligomers and caprolactam (monomer) during various cooking methods [13, 14]. These compounds can migrate from polyamides into boiling water and impart a bitter taste to foods.

54.2.1.7 Contaminants

Additional sources of food contamination include decomposed products from additives and monomers that may also migrate into foods. Some of these compounds are diphenylthiurea, benzene dioxins, hydrogen peroxide, and other volatiles [5]. Food can also be contaminated by hydrocarbons, including mineral oil saturated hydrocarbons (MOSH) and mineral oil aromatic hydrocarbons (MOAH) [15]. MOAH is carcinogenic and mutagenic, as well as an endocrine disruptor. Accumulation of MOSH in the human body can cause dysfunction. Potential sources of such contamination are recycled paperboard used as packaging for dry foodstuffs such as noodles, rice, and bakery foods, as well as mineral-oil-based printing inks [16].

54.2.1.8 Nanoparticles and Coating Substances

Nanoparticles are incorporated into polymeric packaging to improve the properties of packaging polymers, such as mechanical strength and barrier properties against oxygen, water vapor, carbon dioxide, and volatiles. Aluminum (Al) and silicon (Si) metal oxide coatings are used to develop high gas barrier and high-performance polymeric packaging for thermal and nonthermal processing technologies. Functional nanoparticles (Ag, ZnO, TiO_2, Se, Cu) with antimicrobial or antioxidant activities are often used in polymeric packaging to increase the shelf life of food. However, nanoparticles and metal from coatings can migrate from food packaging into food and pose risks to human health [17–19]. Nano-silver that is incorporated in food containers and polymer coatings exhibits varying degrees of migration, depending on the type of packaging and food used [19, 20].

54.2.1.9 Photoinitiators

Photoinitiators are a mixture of monomers, oligomers, pigments, and photoactive compounds used in the formulation of UV-curing printing inks, as well as varnishes for food packaging polymers. They can also be found in recycled paper packaging and printed secondary packaging. Photoinitiators such as Irgacure, benzophenone, and isopropylthioxanthone (ITX) can contaminate foodstuff by mass transference [21–23]. The migration of photoinitiators occurs through two mechanisms: set off and/or permeation migration [23]. During "set off," photoinitiators from the external printed surface are transferred to the internal non-printed layer due to contact. Permeation migration occurs when photoinitiators from the external printed surface reach the internal food-contact layer through substrate. Semi-volatile photoinitiators such as benzophenone and its derivatives can contaminate food indirectly through vapor [22].

54.2.2 Prediction of Migration

Migration is a complex process in which substances are diffused from the food-contact layer (higher concentration zone) to the food surface (lower concentration zone). This is dependent on several factors, including the nature of the food, temperature, and the duration of storage [24]. The amount of migration into food can be predicted using a mathematical model based on diffusion. Mathematical models are useful tools for the identification of factors affecting migration and in package design. A better understanding of the migration process will help control the chemical contamination of food from packaging [5]. The diffusion of migrants in polymer and food can be described using Fick's second law:

$$D_p \frac{\partial^2 C_p}{\partial x^2} = \frac{\partial C_p}{\partial t} \tag{54.1}$$

$$D_s \frac{\partial^2 C_s}{\partial x^2} = \frac{\partial C_s}{\partial t} \tag{54.2}$$

where D_p and D_s are the diffusivity of migrant in polymer and food phase (m^2/s); C_p and C_s are the concentration of the migrant in the polymer and food phase (mg/g); x is the space coordinate measured normal to the polymer-food interface (m); and t is time (s). The amount of package components that may migrate into liquid or solid food depends on the chemical and physical properties of the food and packaging. Various factors such as migrant concentration, molecular weight, solubility, diffusivity, partitioning coefficient between polymer and food, time, temperature, polymer and food composition, and structures (density, crystallinity, and chain branching) control migration.

Several semi-empirical diffusion-based mathematical models have been developed and suggested (Table 54.2). Briston and Katan [25] divided migration into three classes based on the limiting control mechanism. Class 1: non-migrating materials with or without the presence of food, Class 2: independent migration, which is not controlled by the food, although the presence of food may accelerate it, and Class 3: leaching, which is controlled by the food, negligible in the absence of food, and significant in its presence. There is

no absolute cut-off between these classes, and the definitions of words like "significant" can influence where the cut-offs are placed [26]. Class 1 is applied for diffusivity of less than 10^{-15} m^2/s. On the other hand, Class 3 systems are those with diffusivity 10^{-13} m^2/s or higher in the presence of food. The migration process is fully described by the kinetics of migrant diffusion in each phase, expressed by diffusivity (D) and the chemical equilibrium, expressed as partition coefficient, K, defined as the ratio of migrant equilibrium concentration in the polymeric material, C_p, to its equilibrium concentration, in the food phase, C_s. K is defined as:

$$K = \frac{C_p}{C_s} \tag{54.3}$$

when $K = 1$, the migrant concentration in food phase equals the concentration in the polymeric phase, at equilibrium. K is higher when more migrant is absorbed into the polymer than into the food. In terms of food safety, a large K limits the migration from packaging material to food. On the other hand, a low K indicates that more migrant is absorbed into the food from the polymer. The food-contact layer is usually made of non-polar polyethylene (PE) or polypropylene (PP), and as a consequence, $K \leq 1$ between the polymer and organic solvents or fatty foods. As the polarity of food increases, the K value also increases. The K value of pure water is over 1000, which eventually limits the migration process. Therefore, K values of 1 and 1000, on either side of the spectrum, are considered as the "worst case" for evaluation of food safety [27].

The partition coefficient is generally estimated by either of three following approaches [27]: the regular solution theory (RST), the unified quasi chemical theory of liquid mixtures functional-group activity coefficients (UNIFAC), and the retention index system. However, to minimize flavor loss in a package, a low K is preferred. Parameters such as the temperature, pH, chemical structure of migrant, molecular size and structure, degree of crystallinity, and polarity of solutes, plastics, and the food can all influence the partition coefficient [27, 28]. Lau and Wong [29] found K values from 2.5 to 250 and D_s from 1.1×10^{-16} to 2.7×10^{-15} m^2/s for three different plasticizers/food systems, with much larger D_s values in fatty foods. Nielsen et al. [30] estimated a K value of up to 22 for four aroma compounds in a water/LDPE system under different storage temperatures.

Several user-friendly software tools, such as MIGRATEST© Lite (FABES GmbH, Munich, Germany), AKTS-SML (AKTS, AG, Switzerland), and MULTITEMP and MULTIWISE (INRA, Reims, France), have been developed for performing migration analysis. MIGRATEST© Lite is based on the Piringer model (Table 54.2), which employs an analytical solution of transport equations to estimate the diffusion coefficients whereas AKTS—SML uses a finite element approach to solve the transient Fick's second law.

54.2.3 Migration Testing and Analytical Methods

Analysis of the migrant in foods can be expensive and time-consuming. This is due to low concentrations of migrated substances and the complexity of the food matrix. Sophisticated analytical methods and protocols have been developed to study the migration of packaging components from packaging or food-contacting material into the food. These procedures are not only important for quantification of migrants, but are also required in order to establish databases for evaluating changing residue levels. They are also used to calculate dietary intakes. These methods and protocols have been approved by regulatory agencies such as the FDA and EC. The analytical procedures involve sample preparation, extraction, cleanup, and a final determination using chromatographic or spectrophotometric analysis.

Various analytical instruments, such as high-performance liquid chromatography (HPLC), gas chromatography (GC), and GC–mass spectrometry (GC–MS), have been used for routine analysis. For example, HPLC methods have been used to measure Bisphenol-A in epoxy resins and diglycidyl ether of DGBPA in tin and 4,4-bis-(dimethylamino benzophenone) in paper and board. GC and GC–MS are used to measure 4,4-bis-(diethylamino benzophenone) in paper and board, styrene dimmers/trimmer in polystyrene cups, and mineral hydrocarbons in polystyrene and wax paperboard. Advanced instruments such as liquid chromatography–tandem mass spectrometry (LC–MS/MS), LC with fluorescence detection, 3D-front face fluorescence, ultra-performance liquid chromatography quadrupole time of flight mass spectrometry (UPLC–qTOF-MS/MS), and inductively coupled plasma mass spectrometry (ICP-MS) are also used to detect and quantify additive(s)/mixture of additives in complex biological materials. Independent component analysis (ICA) has been used to analyze 3D-front face fluorescence spectra of olive oil to analyze packaging–oil interaction [31]. The migration of nano-silvers and silicon from polymer coatings into foods/food simulants has been quantified using ICP-MS [17, 20]. A Fourier transform infrared spectroscopy (FTIR) method has proven useful for analyzing substances on polymer and internal can coatings. Due to the complex nature of foods and the variety of conditions arising from contact with packaging, a series of steps is necessary to quantify specific and overall migration. To simplify the process, regulatory agencies have approved the use of food simulants (Tables 54.3 and 54.4) for migration studies.

54.2.4 Factors Affecting Migration

54.2.4.1 Glass Transition Temperature of Polymers

For contaminants from the surrounding environment, such as naphthalene or other volatile organics, the rate of migration is affected by the glass transition temperature (T_g) of the polymer. In the glassy state (below T_g), polymer molecules/chains are rigid, and migrant molecules have less free volume to diffuse through. This results in a slower migration rate. Above T_g, polymer is flexible due to increased mobility of segmental chains, allowing a higher rate of molecular movement of migrants. Additionally, glassy polymer consists of nanovoids that provide strong adsorption sites to migrating molecules and retard the release rate of migrating compounds [32]. At room temperature,

$C_{F,t} = \frac{A}{m_F}\rho_P C_{P0}\sqrt{D_P t}$	Baner et al. [95]
$C_{F,t}$ = estimated concentration, ρ_P = density of the plastic material, D_P = migrant diffusivity and (A/m_F) = package surface area, $D_P = 10^4\exp(A_P - aM_r - bT^{-1})$ where the coefficient A_P accounts for the effect of the polymer on diffusivity (A_p values for different polymers are 9 for LDPE, 5 for PP and HDPE, ≤0 for non-polyolefins, –7 for PVC, and –3 for PC and PET), M_r = substance relative molecular weight, T = temperature (K), and a and b are correlation constants for molecular weight and temperature effects on diffusivity bearing values of 0.010 and 10450, respectively	
Weibull model $\frac{C_t - C_\infty}{C_0 - C_\infty} = \exp\left[-\left(\frac{t}{\tau}\right)^\beta\right]$	Poças et al. [96]
C_t is the migrant concentration in food at any time t, C_∞ is the concentration at equilibrium, C_0 is the initial concentration, τ is scale parameter associated with process rate, and β is the shape parameter or behavioral index	

polymers such as polyethylene and polypropylene with T_g lower than room temperature have a larger permeability for organic compounds than those with a T_g higher than room temperature, such as polystyrene and PVC. The melting of polymers significantly increases the release of substances from polymers.

54.2.4.2 Molecular Weight and Geometry of Migrants

Migrant molecules with different shapes, sizes, volumes, and weights influence diffusion in polymers, and therefore control the migration process. Substances with higher molecular weight and volume hinder the diffusion process. The volume of molecules, which combines the shape factor and the fractionated volume, correlates with the diffusivities of migrants. For example, the diffusivity of Irganox 1330 in PP at 40°C is two orders of magnitude less than that of Uvitex OB because the Irganox molecule is 1.7 times larger than Uvitex OB [33]. The diffusivity of limonene in PP at 40°C is almost four orders of magnitude higher than Irganox 1010 due to limonene's smaller size and molecular mass (M_r = 136 g/mol) compared to Irganox 1010 (M_r = 1178 g/mol) [34]. Generally, there is a linear relationship between $\log(D_p)$ and molecular weight, and the weighted fractionated volume of molecules [33]. Larger nanoparticles also demonstrate slower diffusion from LDPE film (Table 54.5) [35].

TABLE 54.3
List of Food-Simulating Solvents for Migration Testing, as Defined in the Code of Federal Regulations

Type of Food	Recommended Simulants
Aqueous and acidic foods (types I, II, IVB, VIB, and VIIB)	10% ethanol
Low and high alcoholic foods (types VIA, VIC)	10 or 50% ethanol
Fatty foods (types III, IVA, V, VIIA, IX)	Food oil (e.g., corn oil), HB307, Miglyol 812, or others

Source: 21CFR 176.170(c) [90].
Note: HB307 is a mixture of synthetic triglycerides, primarily C_{10}, C_{12}, and C_{14}.

54.2.4.3 Solubility of Migrants at the Polymer–Food Interface

A migrant with greater solubility into food has a smooth and continuous concentration profile at the polymer–food interface. This facilitates the rate of migration into the food. On the other

TABLE 54.4
Types of Raw and Processed Foods

Food Category	Description
Type I	Nonacid, aqueous products; may contain salt or sugar or both (pH above 5.0)
Type II	Acid, aqueous products; may contain salt or sugar or both, and including oil-in-water emulsions of low- or high-fat content.
Type III	Aqueous, acid or nonacid products containing free oil or fat; may contain salt, and including water-in-oil emulsions of low- or high-fat content
Type IV	Dairy products and modifications: (A) water-in-oil emulsions, high- or low-fat and (B) oil-in-water emulsions, high- or low-fat
Type V	Low-moisture fats and oil
Type VI	Beverages: (A) containing up to 8% alcohol; (B) nonalcoholic; (C) containing more than 8% alcohol
Type VII	Bakery products other than those included in type VIII or IX: (A) moist bakery products with surface containing free fat or oil; (B) moist bakery products with surface containing no free fat or oil
Type VIII	Dry solids with the surface containing no free fat or oil (no end test required)
Type IX	Dry solids with the surface containing free fat or oil

		Meat tray	Cooking oil	70–150	4.6×10^{-11}–4.2×10^{-9}	
Low-molecular-weight compounds	Acetaldehyde	PET	Carbonated mineral water	23–50	4.4×10^{-12}–4.59×10^{-11}	Welle and Franz [104]
	Benzene	PET	Carbonated mineral water	23–50	3.11×10^{-12}–5.76×10^{-14}	
Catalyst	Antimony	PET bottle for carbonated drink	Milli-Q water	25–70	3.6×10^{-21}–5.9×10^{-18}	Rungchang et al. [105]
			4% acetic acid	25–70	5.5×10^{-20}–3.8×10^{-17}	
			50% ethanol	25–70	5.5×10^{-20}–3.6×10^{-17}	
Nanoparticle	Titanium nitride (dia = 1–10 nm)	LDPE film	-	40	4.3×10^{-9}–1.1×10^{-35}	Bott et al. [35]

Note: T is the temperature at which the experiment was conducted; D_p is the diffusion coefficient of migrants in packaging.

hand, if the migrant partitions poorly into the food, the migrant concentration profile may be discontinuous at the interface, slowing the rate of migration. Since most polymer additives and contaminants are fat-soluble, contamination of food by migrating chemicals is more serious in fatty foods than in aqueous foods.

54.2.4.4 Polymer Swelling

Swelling of polymeric materials may occur when foods/food simulants such as organic solvents, lipids, or water are absorbed by polymers. This absorption may create structural changes in polymers that can increase the D_p of additives by several orders of magnitude. Reynier et al. [36] reported a one to two order of magnitude increase in D_p in swollen PP at 40°C for a wide range of additives, including Irganox and Irgafos. The swelling-dependent diffusion coefficient, $D(C)$ can be expressed in three mathematical expressions [37–39]:

$$D(C) = D_0 + B \times C \tag{54.4}$$

$$D(C) = D_0 \times \exp(B \times C) \tag{54.5}$$

$$D(C) = D_0 \times \exp\left(B \times \frac{C}{1+C}\right) \tag{54.6}$$

where D_0 is a constant, B is the "swelling constant," and C is the concentration of the substance causing swelling.

54.2.4.5 Dispersion into Bulk Food

Once the migrant molecules are solvated, they diffuse away from the interface and move into the bulk food. Migration at this stage and in the two previous stages is driven mainly by entropy, a measure of randomness. Limm and Hollifield [40] found that mixing can increase migration into food since it enhances kinetically migrant solvation by removing migrants from the interface, thus reducing re-precipitation. However, migrant solubility and diffusion coefficients are the prime factors governing the dispersion of migrants into food, thus affecting the rate of migration as whole.

54.2.4.6 Temperature

Molecular mobility increases with increasing temperature and accelerates the molecular diffusion of chemical substances (Table 54.5). Thermal processing involves higher temperatures, resulting in a higher migration rate from polymeric packaging into food. The diffusion coefficient of packaging material components can increase six- to seven-fold if the material is exposed to extreme temperature fluctuations (e.g., freezer temperatures to cooking temperature) [24]. Such increases in temperature may also cause the transition of polymers from the glassy to rubbery state, further increasing the migration rate. Brandsch et al. [41] modified a correlation to predict the diffusion coefficient of migrants as a function of the molecular mass of migrant and absolute temperature:

$$D_p = D_0 \exp\left(A_p - 0.1351 M_r^{2/3} + 0.003 M_r - 10454 / RT\right) \text{cm}^2/\text{s} \tag{54.7}$$

where D_0 is the pre-exponential factor, $A_p = A_p^{'} - \tau / T$, M_r is the relative molecular mass of the migrant, and $A_p^{'}$ and τ are specific parameters of the polymer matrix. R is the gas constant, and T is the absolute temperature.

54.3 FOOD AND PACKAGING INTERACTION

54.3.1 Metal–Food Interaction

Metal containers provide absolute protection to food from ambient conditions and environmental contamination, ensuring food safety and quality retention with long-term storage stability. In the market, metals are mainly in the form of cans and flexible pouches for shelf-stable foods, as well as containers for beverage packaging and household usage. However, metal packaging may fail due to stress and corrosion. Corrosion is the destructive attack on a metal through chemical or electrochemical reaction with the environment. Since steel corrodes rapidly in the presence of acidic substances, the tin acts as a barrier. Some cans are lacquered internally for high-acid products (pH < 3) or for products that change color in the presence of tin. Containers made of tinplate are resistant to corrosion by high-acid foods, and can be used unlacquered. However, foods that contain sulfur can cause the tin to blacken. Therefore, metal containers usually come with internal organic coatings or enamel coating. Since steel provides nearly complete barrier protection and has the mechanical strength to handle pressure, it can be retorted (cooked under pressure) after sealing [42]. Cans are susceptible to corrosion at the stressed areas, called stress corrosion cracking (SCC), as well as rapid iron dissolution at fractures/pores in the organic coatings, which causes product blackening known as pitting corrosion. They are also susceptible to sulfide black corrosion, which is a blackening of the internal part of cans and discoloration of foods, and rust formation on the external damage of the cans known as filiform corrosion. Blistering of flexible pouches containing aluminum foils may also cause contamination in foods. The chances of such failure increase considerably in the high temperatures and pressures of retort processing. Furthermore, important factors causing corrosion are enamel properties (porosity, corrosion resistance, and adhesion), the nature of the coating (polyester, epoxy resins, acrylic, oleoresins), the thickness and porosity of coatings, the nature of aqueous or fatty foods, including acidity, oxygen, nitrates, sulfur compounds, trimethylamines, anthocyanins, and dihydroascorbic acid as well as the severity of heat treatment and storage conditions [7, 43, 44].

The major corrosion products in food cans are mainly limited to three metals, tin, iron, and lead, which are liable to dissolve from the container. Of these, only the lead is toxic and cumulative in body tissues, and hence poses a hazard. Lead content varies widely within and between food products. Even the raw material may contribute some of it, although generally the level is well below the regulatory limits, which is 2 ppm for most foods, 0.5 ppm for baby foods, and 0.2 ppm for soft drinks [44]. Consumption of lead may lead to reduced

intellectual performance of children and increased cardiovascular diseases in adults. In a survey, the lead content of 168 samples of acid foods was found to be in the range of 0.02–8.16 ppm, the average for lacquered cans being 1.45 ppm and for plain cans 0.46 ppm [44]. The shift from three-piece soldered cans to three-piece welded or cemented cans, or to two-piece cans, has eliminated possible lead migration from cans to foods [44]. However, commercial tin–lead alloys used for soldering the seams of tin cans contain almost 98% lead. Thus, the possibility of lead migration into canned foods still exists [44]. The lead content in a wide variety of canned fishes has been measured below 0.20 ppm [45]. Canned infant foods are soldered with pure tin to avoid lead contamination, and welding is increasingly used instead of soldering for the same reason [44]. According to the recent FDA guidelines, maximum allowable lead contents of 0.1 ppm in candy for small children, 0.005 ppm in bottled water, and 0.05 ppm in fruit juices are safe for consumption.

Iron, an essential constituent of our diet, does not constitute a toxicity problem, and a limit of 50 ppm is usually considered acceptable. However, rapid dissolution of iron due to pitting corrosion darkens the color of canned foods, such as blackening of olives and brine [46]. Most of the tin in canned foods is insoluble in gastric and intestinal fluids, and is not absorbed during digestion. In solid foods, high levels may occur. Metallic tin and its salts are considered to have low oral toxicity, whereas alkyl derivatives are highly toxic. Outbreaks of poisoning manifested by nausea, vomiting, and other gastrointestinal disturbances have been traced to solid foods and drinks containing high levels of tin (hundreds of ppm). The 250-ppm level quoted in the past as a permissible upper limit in canned foods is based not on toxicological evidence of safety, but on the fact that higher levels produce off-taste and are rarely found under normal conditions of processing and storage. This value is 150 ppm for canned beverages. In lacquered cans, the tin content of the food rarely exceeds 100 ppm [44]. Cans with a lacquered inner wall showed tin migration almost ten times lower than that of non-protected or partially protected cans for a wide range of fruits and vegetables [47]. Recent studies also reported the migration of other trace elements including cadmium (Cd), copper (Cu), zinc (Zn), chromium (Cr), manganese (Mn), and nickel (Ni) into foods from cans and stainless-steel containers [48–50].

Migration in metal cans is primarily associated with the transfer of compounds from solvents used for coating. Mesityl oxide, a solvent used to coat side seams, imparts a "catty" flavor defect to packaged pork products. It interacts with free sulfhydryl groups of meat proteins and trace amounts of free hydrogen sulfide present in meat. Inophorone, a contaminant of can coating solvents, causes a "chemical" defect in canned milk beverages. Epoxy coatings are responsible for anomalous flavors in canned beers [51]. Soft drinks and especially beer are very delicate products, and their flavor and clarity are easily affected if in contact with tin, iron, or an unsuitable varnish. The taste of beer, for example, is adversely affected by dissolved iron above 0.1 ppm [44]. Another major concern is the migration of BPA from epoxy coatings on internal can surfaces. Although the presence of BPA in food does not alter taste significantly, it may pose serious health concerns due to its severe toxicity above the specific migration limit. Some chemical substances that can migrate from metals into food are listed in Table 54.6.

Lubricants are normally used with tinplate to prevent abrasion and facilitate handling during conversion into containers. Typical lubricants contain fatty acids and esters prone to oxidation, and some oxidation products may be transferred to packaged food [51]. Lubricants can result in stale, rancid, woody, and cardboard-like off-flavors in canned beer [52]. Such a compound is 2-nonenal, which has a sensory threshold of about 1 ppb.

54.3.2 Paper–Food Interaction

Paper and board serve as primary, secondary, and tertiary packaging. Migration mainly occurs during primary packaging, i.e., when paper and board come directly in contact with dry foods. Nevertheless, food contamination due to the transfer of volatile and semi-volatile substances from secondary packaging may also occur. Most documented cases of migration from paperboard or paperboard/plastic laminates pertain to components transferred from solvents and adhesives used for material and/or package fabrication, or those transferred from inks used for printing [52–54]. The major migrating components from paper and board packaging are diisobutyl phthalate (DiBP), diisopropyl naphthalenes (DIPNs), di(2-ethylhexyl) phthalate (DEHP), benzophenone (BP), triclosan (TRCL), and fluorochemicals (Table 54.6).

Recycled paper and paperboard are used for many commercial applications due to environmental concerns. However, recycled paper materials contain adhesives, printing inks, trace elements, bleach, paper straightening agents, and inks. Benzophenone, a photoinitiator in UV-cured inks used for printing on cardboard and paper, may also be present in recycled papers. In one study, 17 packages containing recycled materials were analyzed for BPA, DEHP, nonylphenol monoethoxylate (NMP), and nonylphenol di-ethoxilate (NDP) and their migration into salt, sugar, and Tenax [55]. BP and ink compounds can also migrate from carton board to food during microwave heating, and even at frozen storage at –20°C. [56]. Four of the seven carton boards were found to contain BP in the range 0.4–3.0 mg/d m^2. When potato chips and hamburger were heated in a microwave after 1 year of frozen storage, nearly 17 and 8% of the BP present in the carton board migrated, respectively. In Australia, UHT milk packaged in HDPE bottles was recalled due to the metallic taint of benzaldehyde (25 ppb) and BP (10 ppb) that migrated from printing inks on the external surface of the bottles into the milk [10]. Hydrocarbon-like off-odors have been reported in doughnuts packaged with wax-coated paperboard dividers [54]. Benzophenone (BP) solvents used for printing paper have been implicated in the migration of solvent residues into packaged yogurt, resulting in a chemical taste [54]. The compounds migrated from the adhesive layer of aluminum-baked paperboard packaging have been found to cause off-flavors.

TABLE 54.6
Migrating Components from Packaging Materials (Other Than Polymers) to Food

Packaging Material	Migrating Component	Food	Reference
Wooden packaging	1-propanol	Apples	Mousavi et al., [106]
Tin	DGEBA	Canned foods	Biles et al., [107]
Metals/plastics/glass/aseptic	DIPNs	Tomato	Casp et al., [108]; UK, [109, 110]
Recycled paper and board Cans coated with lacquer	Epichlorohydrin		
Paper cardboard and board	Metals (Zn, Sn, Al, Mn, Ba)	Test foods	Knezevic, [111]
Cartons (Al-laminated)	Al	Skim milk, yogurt drink	Eklund and Brenne, [112]
Aseptic	H_2O_2	Milk	Satyanarayana and Das, [113]
Aluminum foil paper laminates	Phthalate esters (DBP, BBP, DEHP)	Butter, margarine	Page and Lacroix, [114]
Cans	BADGE (lacquer)	Water-based simulants	Paserio et al., [115]
Aluminum	Al	Food and drinks	Muller et al., [116]
Paper-based food packaging	2378-TCDD/2378-TCDE (polychlorinated dibenzofurans)	Fatty and non-fatty foods	LeFleur et al., [117]
Ceramic containers	Pb, Cd	Dairy products	Cabrera et al., [118]
Aluminum	Al	Milk	Sieber and Daniel, [119]
Cans	BADGE	Canned foods	UK, [109]
Aluminum	Al	Dairy products	Sieber and Daniel, [120]
Paper and board	4,4-bis(dimethylamino benzophenone((MK), 4,4-bis-(diethylamino benzophenone((DBAB)	Dairy products	Castle et al., [121]
Recycled paperboard, printed packaging	Photoinitiators	FSL, dry foods	Biedermann et al., [122]; Sanches-Silva et al., [23]

A variety of odor-active (low sensory threshold) phenols and cresols, such as p-chloro-m-cresol, have been identified [57]. Similarly, pentachlorophenol and methyl chloroform have been traced to adhesives used for paperboard package fabrication [52]. Pentachlorophenol is used as a biocide in certain adhesives, and causes a moldy off-flavor in food products. Moldy off-flavors due to the migration of 2,4,6 trichloroanisole into cocoa power packaged in paper board containers have also been reported [52]. The paper or paperboard manufacturing process itself can result in the formation of potential migrants. These are chlorophenols, such as 2,4-dichlorophenol, 2,4,6-trichlorophenol, and 2,3,4,6-tetrachlorophenol, two nitrosoamines (morpholine and N-nitrosomorpholine) [52, 58]. The first group is formed during blanching, and the second carcinogen group is used as a corrosion inhibitor for boiler feed water. Other odor-active compounds that may be formed and released during heating of certain types of paperboard packages include acetone, 2,3-butadine, chloroform, furan, furfural, methylene chloride, carbon disulfide, and acetaldehyde. These compounds may be formed during bleaching and/or the lignin removal phases of paperboard manufacturing [51].

54.3.3 Plastic–Food Interaction

Polymers are not absolute barriers to gases such as oxygen, water vapor, aromas, and odors in packaged foods. The degree of sorption is highly dependent on types of polymer and aroma compound present in the food. Other important factors include the crystallinity of polymer, glass–rubber transition, environmental conditions, compositions of packaged food (fat content, pH, pulp content, and type of aroma compounds present) [59], free volume of polymers, sensory threshold level, intensity of aroma compounds, time and temperature of storage, diffusion rate of component in packaging and food, partition of gas phase/packaging and gas phase/food, and ratio of packaging materials to the amount of food [60].

In the case of plastics, the major source of concern is the component migration. Migration from plastics is mainly due to (i) residual components and reactants from the manufacturing process, (ii) compounds formed during conversion into packaging materials and/or packages, (iii) additives incorporated for functionality, (iv) adhesives used during conversion, and (v) time and temperature of processing and storage [24, 51, 61]. Studies show that chemical compounds in food-contact plastics migrate at a higher rate in fatty foods than in aqueous foods. The migration rate further increases with the swelling of polymers, temperature, and duration of exposure [62–66].

The toxicological implications of component migration from packages into foods are another serious problem. Thus, research on food–package interaction is growing [51]. Most plastics contain unreacted residual monomers, oligomers, and other additives, some of which are suspected carcinogens (acrylonitrile, vinyl chloride, etc.) (Table 54.7). Several

TABLE 54.7
Migrating Components from Polymer Packaging Materials to Food

Packaging Material	Migrating Component	Food	Reference
PS	Styrene dimmers/trimmers	Instant food	Kawamura et al. [123]
PS cups	Styrene	Yogurt	Nerin et al., [124]
PS	Styrene	Water, milk, cold and hot beverages, olive oils	Tawfik and Huyghebaert, [125]
Polyester cookware	Benzene	Olive oils	Jickels et al., [126]
PVC films	DEHA	Cheese	Mercer et al., [127]
LDPE, HDPE, PP, microwave packaging	Irganox 1010 (I-1010)	Food simulant liquids (FSL)	Goydan et al., [128]

PS	Styrene	Food oil	Lickly et al., [103]
PS	Styrene	Cheese, dessert, meat products	Hammarling et al., [143]
PVC	DEHA	Cheese	Page and Lacroix, [144]
LDPE	Naphthalene	Milk	Lau and Wong, [145]
ABS	Mineral hydrocarbons	Dairy products	Jickels et al., [146]
PC	Bisphenol-A (BPA)	FSL	Biles et al., [68]
PVC films	DEHA	Bread, olive oil, cheese, meat	Petersen et al., [147]
PVC	DEHA	Microwave fatty foods	Lau and Wong, [65]
PE	Nano silver	Butter, orange juice, bread, cheese	Metak et al., [19]
Ny//Coated PET//CPP	Silicon-metal oxide high barrier coating	FSL	Dhawan et al., [17]

monomers have been linked with health problems, the most significant being vinyl chloride. The National Health and Medical Research Council standard in Australia is <50 ppb vinyl chloride for utensils, <10 ppb in film, and 0 ppb in foods [42]. Symptoms of vinyl chloride monomer poisoning are now well-documented. If it is present in the air at a greater concentration than 500 ppm, poisoning occurs [42]. The residual monomer styrene from PS cups and trays has been shown to migrate into food, including dairy products. Estimated daily styrene exposure is 18.2 to 55.2 μg for individuals, with an annual exposure of 6.7 to 20.2 mg [24]. Depending on the type of food product, the threshold values for styrene monomer vary. The styrene threshold amount is very low in water (taste threshold: 0.022–0.37 mg/kg) and air (odor threshold: 0.050 mg/kg), whereas it is 0.2 to 0.3 mg/kg for orange fruit juice drink, 1–3 mg/kg for oil-in-water emulsions of 15–30% oil, and cocoa powder (10–20% fat), and greater than 3 mg/kg for butter, cream (33% fat), and condensed milk (10% fat) [67].

Polycarbonate plastic is used in the manufacture of food storage containers, and bisphenol-A is a principal reactant in its preparation. Residual bisphenol-A in polycarbonate bottles migrates to liquid foods, and can be determined at low ppb levels [68]. Low-molecular-weight oligomers can migrate from PET trays into foods [6, 69]. The cyclic oligomers of butylene terephthalate can be used only in PET, PC, PS, rigid PVC, and PBT plastics with the maximum concentration of 1% (w/w) [5]. In general, packaging materials can alter the flavor profile of packaged foods by absorbing flavor compounds, chemically reacting with food components to produce off-flavors, and/or releasing components that produce off-flavors into food. Taint is defined as odor or off-flavor in food and is the major reason for consumers' rejection of food. Taint in food and beverages can come from contact polymers containing PS, PA, polyolefins, PVC, and epoxys, noncontact substances such as printing inks, coloring agents, antioxidants, and recycled materials [70]. Nestle's Central Packaging Laboratory found that taint in food is related to solvents used in packaging (28%), degraded PE (24%), halogenated phenols (15%), styrene (15%), degraded paper (3%), and other sources (15%) (EU/2011).

Migration in plastics packaging refers to the transfer of compounds from the plastic to the food product by leaching

or diffusion. Direct contact between plastic and a food product can result in leaching of packaging components into the product, changing the flavors of the food. The main problematic components are amides (slip agents), monomers and oligomers, heat-degradation products from the polymer base, and ink components. Migration may also occur from the food to the plastic, which can result in plasticizing of the package if the vapors are water or certain solvents. This can decrease mechanical strength. The food may lose valuable volatiles, such as odors, carbon dioxide, water, or flavors that increase with higher temperatures. For example, a fruit juice in polyethylene will lose limonene to the plastic (scalping) and increase ascorbic acid degradation [42]. A study shows that PET at 37°C absorbs limonene almost seven times more than at 5°C [71]. Limonene is a nonpolar unsaturated hydrocarbon with a high affinity for nonpolar polymers. Citrus and apple aroma compounds can be scalped by polymers [72]. Dye materials from foods may be scalped by nylon-6 polyamides, altering the color of foods [70]. More details on flavor–food packages interaction are given by Linssen and Roozen [73] and Sajilata et al. [72].

Instead of testing for each possible migratory compound, a test for the total migration of all compounds from a packaging material is usually used. The migration of small molecules in plastic under high-temperature conditions is known to pose problems [74]. The transfer of aromas or flavors leads to tainting of beverages filled for the second time. The single largest groups are monomers and oligomers with molecular weights up to 1000 [61]. The chemical nature of monomers and oligomers depends on the polymers. Vinyl chloride monomer, acrylonitrile monomer, and styrene are three monomers that have received substantial attention [51]. Their migration is very important because of potential toxic and carcinogenic effects. Monomer- and oligomer-mediated flavor problems or off-flavors are equally important. Styrene monomer has a very low sensory threshold and imparts strong odors to foods [75]. In general, high-molecular-weight (around 1000) oligomers found in polyolefins are paraffinic in nature and impart oily off-flavors to foods [61]. Polystyrene in plastic cups has been reported to produce off-flavors [76]. Coffee creamer and condensed milk packed in PS portion packs have exhibited styrene taint [67]. Changes in flavor and odor of butter packaged in waxed parchment paper during refrigerated storage have also been attributed to styrene migration [77].

Other compounds that are produced during plastics manufacturing and cause flavor problems due to migration include aldehydes, ketones, carboxylic acids, hydroxyl acids, catalyst residues, and solvents [51]. Solvents used during polymerization reactions are present at very low levels in the raw resins, but some foods are sensitive to them at the ppb level [78]. A common catalyst 2,2'-azobisisobutyronitrile used during the polymerization of polyvinyl chloride, acrylonitrile, and polystyrene decomposes into tetramethylsuccinonitrile at around 100°C [79]. Migration of this is extremely undesirable, since it is an acute central neurotoxin [80, 81]. During extrusion of the plastic material, temperatures may reach 250°C and higher. At these temperatures, the antioxidants in the polymer are rapidly lost. Free radicals may form on the surface of the material and in food contact. These oxidizable sites or contact points may cause autocatalyzed oxidation of food products [2].

Polyolefins give a variety of thermal degradation (oxidation) products, including aldehydes, ketones, and acrolein [61]. Unsaturated carbonyl compounds present in PE can give "PE-odor" ranges from stale, stuffy, candle-like, musty, to rancid or soapy [82]. A wide range of odor descriptors are used to depict the off-flavor characteristics of foods and beverages, e.g., a "musty" odor in orange juice packed in PP materials [83], a stale and fruity flavor in milk packed in HDPE [84], and a "plastic" odor in corn chips packed in HDPE packages [85]. Compounds associated with the "plastic"-type off-odor of HDPE are usually 1-alkenes. The "plastic"-type off-odor may also relate to other chemical compounds, including styrene, benzothiazole, methylacrylate, trans-2-nonenal, and methylmethacrylate. However, plastic-like off-flavors developed in foods do not necessarily originate from packaging materials. For example, a plastic-like off-flavor in sorbic acids is generated from their degradation products [60]. Polyvinyl chloride contains allylic chlorine atoms that are readily released during exposure to minimal heat and render the material thermally unstable. Polystyrene is relatively heat-stable, but evolves about 0.2% styrene monomer during extrusion [61].

A study on the thermal decomposition of low-density polyethylene at similar conditions during extrusion revealed 44 degradation by-products, representing hydrocarbons, alcohols, aldehydes, ketones, acids, cyclic esters, and cyclic ethers [86]. The major degradation products were formic acid, formaldehyde, acetic acid, and acetaldehyde. Formaldehyde and acetaldehyde are odor-active compounds associated with strong off-odors in packaged foods [78]. The migration of acetaldehyde from PET is of primary concern with respect to migration and off-flavor development in foods [52, 60].

Adhesives are used with some multilayer packaging materials to bond dissimilar materials together and to fabricate (seal) certain types of packages. Many adhesives contain solvents that may migrate into foods [61]. Solvents are also part of ink systems used for printing packaging materials and can impart off-flavors to packaged foods [78]. However, the proper drying of printing materials may completely eliminate solvent migration from adhesives and printing inks [78]. Most solvents are volatile and highly odor-active. Off-flavor problems due to the migration of solvent residues in various products have been reported, including toluene, p-tertiary butylphenol, ethyl acetate, ethanol, isopropanol, toluene, acetone, methyl ethyl ketone, and hexane [51, 67]. For example, the relative threshold value of toluene in coffee is 100–500 and 10–20 mg/kg for odor and taste in order to receive consumers' acceptance [67]. Volatile compounds can be generated when packaged food in plastic is heated in microwave ovens [87]. Different local and international regulatory authorities provide a lower limit to migration from packaging materials below which regulations would be deemed not to apply. An interaction product between packaging and food may also impart an off-odor to food. For example, cooked ham packed in a PA/inomer has been reported to have a "cat-urine"-like odor associated with

methylmercaptopentane, which forms during food-packaging interaction [82].

54.3.4 Stickiness and Packaging

When food sticks to packaging surfaces, this can be either desirable or undesirable to both the processor and the consumer. For example, retaining the quality of sausage products is known to be closely related to the degree of adhesion of meats to the casing. On the other hand, the adhering of a food product to the contact surface can result in product loss, and in some cases, poor product appearance [88]. Adhesiveness or stickiness between the foodstuff and the packaging surface is a complex phenomenon. The word adhesion is broadly used to denote the sticking together of two materials, with or without an intermediate layer. It is an interfacial phenomenon in which the food packaging system generally involves a liquid–solid interface or solid–liquid interface. There are various theories or mechanisms of adhesion described in the literature. These include electrostatic, diffusion, mechanical, chemical, surface energetic, adsorption, and wetting [88]. Some materials and additives for polymers are designed to be effective at the surface of the material. Examples include antifogging agents, some anti-static agents, slip agents, and anti-block agents. Such materials were developed to have an inherent incompatibility with the polymer matrix. Gibb's free energy considerations lead to these types of materials accumulating at the surface, where total energy is minimized, producing the most stable configuration. There may be other cases where surface effects are not intended, but incompatibility with the matrix or other factors leads to an accumulation of the material at the surface [26].

54.4 SAFETY AND LEGISLATIVE ASPECTS

In recent years, consumer awareness about the safety and wholesomeness of foods has increased dramatically. Food contaminations and safety are a subject of intense study by many scientists. Consumer concerns pertain to food additives, both those added intentionally and those ending up in the food from, for example, the packaging material or processing equipment. The variety of substances used in food packaging is considerable. Many of these substances are potentially toxic, harmful, and can migrate into foods. In the early 1980s, numerous toxicological studies of several commonly used plasticizers demonstrated carcinogenic effects in rodents and potential estrogenic effects in humans. From a food safety point of view, it is critical to understand the toxicity of such substances at the concentrations at which they appear in the food from the packaging material.

In order to protect consumers from the migration of harmful substances from packaging to food, different countries have developed various regulations. The approaches adapted by the USA and the EC will be discussed here, since they account for the larger proportion of food packaging materials used. The FDA and the Center for Food Safety and Applied Nutrition (CFSAN) provide guidance and regulatory aspects for food. Regulatory guidelines for food-contact materials and allied aspects are documented in Parts 174 to 178 in Title 21 under the CFR [89, 90]. The regulations specify the limits of global migration of polymeric resins from packaging. The time/temperature/solvent conditions for the short-term extraction tests used to test compliance are also noted in the CFR. The likelihood of a substance posing a health hazard depends on its dietary concentration and toxic potency. The agency considered both factors in establishing a threshold of regulation level. Hence, the extent of migration of harmful substances to food that is trivial to food safety concerns is also proposed. For example, the use of BPA-based PC resins and coatings in baby food containers and infant feeding bottles is completely prohibited due to BPA migration. The FDA and CFSAN estimated new daily BPA exposures for infants and adults are 0.2 to 0.4 μg/kg body weight/day and 0.1 to 0.2 μg/kg body weight/day, respectively [24].

The Europe Commission of the European Communities (CEC) has implemented Directives for packaging materials. The first relevant CEC Directive was issued in 1976, which also proposed analytical test methods to enable limits. The EC has listed thousands of additives and monomers as potential migrants. Many are authorized with restrictions or specific migration limits, and several analytical methods have been standardized. The Directives adopted by the EU member states concerning migration can be divided into three groups: (i) Directives applicable to all materials and articles, (ii) Directives applicable to one category of materials and articles, and (iii) Directives related to individual substances [5]. In general, the Directives introduced limits upon the overall migration from plastics into food and food simulants. In addition, specific migration or composition limits for free monomers in the final article have been set for some monomers.

Currently, the limit for overall migration is set at 10 mg/dm^2 or 60 mg/kg of food simulants, assuming that a standard package has a food-contact area-to-volume ratio of 6 dm^2/L. It also includes the lists of permitted monomers, with restrictions for specific monomers. The FDA has determined that most known carcinogens pose less than a one in a million lifetime risk if present in the diet at a level of 0.5 μg/kg. In Australia and New Zealand, Food Standard Australia New Zealand (FSANZ) provides regulatory standards for food and food safety. The Australian Standard AS 2070-1999 provides guidelines for plastic materials in food-contact use, which are based on regulatory guidelines provided by the FDA and EU. In Canada, food inspection standards are monitored by the Canadian Food Inspection Agency (CFIA) and the Health Products and Food Branch (HPFB) under Health Canada, which is responsible for implementing the standards and policies.

54.5 FINAL REMARKS

The migration of package components is a time–temperature dependent phenomena. Packaged food processed and/or stored at higher temperatures for a longer duration shows higher migration. Additionally, the polarity of foods and

food-contact materials, polymer swelling, and initial concentration, molecular weight, and molecular size of components influence migration adversely. Commercial software is helpful in determining migration into food. However, systematic study and experimental work with appropriate analytical techniques are necessary to determine overall migration and migration of compounds of particular interest, depending on the toxicity level of those compounds. These factors must be considered for intelligent selection and design of food packaging for safe human consumption.

55 Bioactive Food Packaging

Ida Idayu Muhamad and Nozieana Khairuddin

CONTENTS

55.1 INTRODUCTION

Nowadays, food security has become a major issue; hence the introduction of active and bioactive packaging, particularly antimicrobial (AM) food packaging, could play a role in food safety and security assurance. Packaging plays an important role in the whole food chain "from the field to the consumers' tables." Furthermore, food packaging has developed strongly during recent years, mainly due to the increased demands on product safety, shelf-life extension, cost efficiency, environmental issues, and consumer convenience [1, 2]. Packaging is the technology of enclosing or protecting products for distribution, storage, sale, and use. The principal function of packaging is the protection and preservation of food from external contamination. This function involves the retardation of deterioration, extension of shelf life, and maintenance of quality and safety of packaged food. Biodegradable polymers fulfill most of these functions without causing any threat to the environment. Owing to increasing urban lifestyles and global population trends, the demand for packaged, frozen, and ready-to-eat foods has witnessed a significant surge in recent times. With the supply of exotic fruits and vegetables, meat products, and frozen foods transcending geographical boundaries, the packaging industry has been focusing on the development of solutions that provide maximum food security while maintaining nutritional value at competitive prices [3].

Packaging poses new challenges to satisfy its safety requirements as compared to traditional packaging due to its deliberate interaction with the food and/or its active environment (i.e. migration of substances from packaging to food, incorrect use of the packaging due to insufficient labeling, non-efficacious operation of the packaging) [4, 5]. Food and beverage packaging has dramatically shifted from traditional to advanced packaging. Traditional packaging only addresses issues related to protection from external factors. However,

advanced packaging interacts internally (i.e. active packaging) and externally (i.e. smart or intelligent packaging) with the environment and enhances the visual appeal of the products. Therefore, foods and beverages and packaging manufacturers are looking for ways to effect physical, chemical, and microbial textures changes inside the packaged food. The requirement for active and smart or intelligent packaging is changing rapidly due to global awareness of environmental issues. The concerns are not only on the materials and production, but also on legal aspects related to environmental concerns. The focus of packaging in the past has been on the appearance, size, and integrity of the package. A greater emphasis on safety features associated with the addition of functional active agents and natural, often bio-based components used for food packaging explains the current development in bioactive packaging technology.

55.2 ACTIVE AND BIOACTIVE PACKAGING

55.2.1 Concept of Packaging

55.2.1.1 Active Packaging

Active films can be considered an evolution in food packaging since these interact with food by releasing some substance or absorbing at a constant rate over time, and improve food quality and safety. Based on the European Union Guidance to the Commission Regulation (EUGCR) No 450/2009, active packaging is a type of food packaging with an extra function, in addition to that of providing a protective barrier against external influence [6]. Surveys conducted by Brody (2001) have shown that active packaging technologies involve interactions between the food, the packaging material, and the internal gaseous atmosphere [7]. Previously, food packaging materials used to provide only barrier and protective functions. However, various kinds of active substances can be incorporated into the packaging material to improve its functionality and to give it new or extra functions. Such active packaging technologies are designed to extend the shelf life of foods while maintaining their nutritional quality and safety [8–10]. The main objective is to extend the shelf life or to improve the quality and safety of the packed food. They use antioxidants, antimicrobials, and other natural/synthetic molecules to achieve this goal. For example, when anti-microbial systems, such as silver-based compounds, are incorporated into conventional polymers such as polyethylene and polypropylene, it is called active packaging.

55.2.1.2 Bioactive Packaging

Suitable bioactive compounds incorporated into the package wall include phenolic compounds, such as phytoestrogens, carotenoids, organosulfur compounds, plant sterols, suitable dietary fiber, prebiotics, and enzymes [11, 12]. Similar to the active packaging concept, when bio-substances, such as oils, chitosan, and flavonoids, known for their antimicrobial, antithrombotic, antioxidant, anti-inflammatory, cholesterol-lowering, and anticancer properties are incorporated into packaging materials, it constitutes bioactive packaging. Bioactive packaging is expected to create a biological mechanism or interaction between its components and develop synergistic effects toward prolonging the shelf life of packaged food while simultaneously being able to communicate with the consumer on unexpected changes of the packed food leading to spoilage and quality changes. This is a novel concept in technologies intended to help in the production of functional foods, whose bioactive principles and actuators are devised within packaging or coating materials [13]. Therefore, it gives rise to a novel conceptual approach to developing functional foods, while setting the roots of a new packaging technology, in which a food package or coating is given the unique role of enhancing the food impact on the consumer's health [14]. The technologies include novel integration technologies, micro- and nano-encapsulation, and enzyme encapsulation and/or immobilization. Moreover, novel nanocomposite structures can play a role in the controlled release of active and functional compounds from the polymeric or biopolymeric structures, and available techniques can be used to characterize the release kinetics of the various compounds [15].

55.2.1.3 Active and Smart Packaging or Intelligent Packaging

Active and smart packaging systems can provide several benefits to the quality and safety of food. The active systems aim at the shelf-life extension of the food products by keeping their quality for a longer time; the smart systems aim to monitor the quality of the food product or its surrounding environment to predict or measure the shelf life better than a best-before date [16, 17]. Han et al. [18] stressed that "smartness" in packaging can have many meanings, and covers a number of functionalities, depending on the product being packaged, such as food, beverage, pharmaceutical, or household products [18]. Han et al. [18] elaborated the examples of current and future functions of "smartness" [18]: (i) retain the integrity and actively prevent food spoilage (i.e. extend shelf life), (ii) enhance product attributes (such as look, taste, flavor, aroma), (iii) respond actively to changes in the product or in the package environment, (iv) communicate product information, product history, or other conditions to the user, (v) assist with opening and indicating seal integrity, and (vi) confirm product authenticity and act to counter theft.

Smart packaging, which is also known as intelligent packaging, was invented to improve the quality and value of the product [16, 19]. There are several types of intelligent packaging technologies: (i) time temperature indicators (TTI's), (ii) radio frequency identification tags (RFID), (iii) electronic article surveillance (EAS) tags, (iv) electromagnetic identification (EMID) tags, (v) digital watermarks, and (vi) freshness indicators

55.2.2 Types of Bioactive Packaging

Types of bioactive packaging are based on the function of the incorporated bioactive agents [20]. These aspects are discussed in the following sections.

55.2.2.1 Inhibition of Microorganisms or Antimicrobial Packaging

This type prevents pathogenic spoilage/microorganism growth using antimicrobial agents. The introduction of antimicrobial agents into food packaging material could help to prolong the shelf life of food products by inhibiting the growth of microorganisms. Antimicrobial polymers can be used in several food-related applications including packaging [21–23]. They can extend the shelf life and promote safety by reducing the growth rate of specific microorganisms from direct contact of the package with the surface of solid foods (e.g. meats, cheese) or in the bulk of liquids (e.g. milk or meat exudates).

To prevent the development and spread of spoilage and pathogenic microorganisms via meat foodstuffs, antimicrobial packaging materials could be a potential alternative solution. Instead of mixing antimicrobial compounds directly with food, incorporating them in films allows the functional effect at the food surface, where the microbial growth is mostly found to be localized [10]. Antimicrobial packaging includes systems such as adding a sachet into the package, dispersing bioactive agents in the packaging, coating bioactive agents on the surface of the packaging material, or utilizing antimicrobial macromolecules with film-forming properties or edible matrices. The potential of these technologies is evaluated for the preservation of meat and meat products [10].

Additionally, antimicrobial packaging materials could also be self-sterilizing. If the packaging materials have a self-sterilizing ability because of their own antimicrobial activity, these may eliminate chemical sterilization of packages using peroxide and simplify the aseptic packaging process [24]. The self-sterilizing materials could be widely applied for clinical uses in hospitals, biological labware, biotechnology equipment, and biomedical devices, as well as food packaging. Such antimicrobial packaging materials greatly reduce the need for decontamination of processed products and simplify the treatment of materials in order to eliminate product contamination. Antimicrobial (AM) polymers might also be used to cover the surfaces of food processing equipment so that these are self-sanitized when used (e.g. filter gaskets, conveyers, gloves, garments, and other personal hygiene equipment) [25].

The effectiveness of AM film to inhibit microbial growth has been reported by many researchers [26–29]. The application of AM agent into food packaging could be effectively used not only in the form of film but also as containers and utensils [8]. AM packaging materials need to extend the lag period and reduce the growth rate of microorganisms to prolong the shelf life and maintain food safety. They have to reduce microbial growth of non-sterile foods or maintain the stability of pasteurized foods without post-contamination. The basic principle of these traditional preservation methods and AM packaging is hurdle technology [30]. Figure 55.1 illustrates the comparison between conventional packaging and AM packaging.

Figure 55.1 shows that the extra function of AM packaging relative to conventional packaging is as another hurdle in preventing the total quality degradation of packaged foods while satisfying the conventional function of moisture and oxygen barriers, as well as physical protection. The AM packaging system may not contribute to the protection function from physical damage; however, it provides tremendous protection against microorganisms, which is difficult to achieve by conventional (i.e. moisture and oxygen) barrier packaging materials.

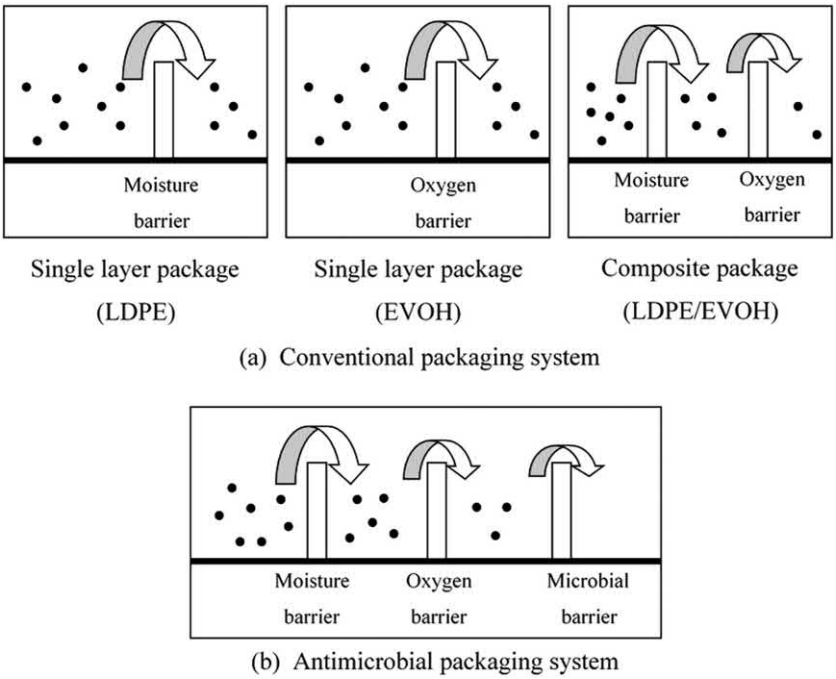

FIGURE 55.1 Hurdle technology in AM packaging system compared to the conventional packaging systems.

55.2.2.2 Inhibition of Oxidation or Antioxidant Packaging

This packaging prevents oxidative deterioration of fat components in food products responsible for off-flavor and rancidity. The addition of antioxidants blocks the oxidative chain reactions of oxygen with unsaturated fatty acids, which results in preservation. Oxygen scavenger: a. iron-based; b. metal/acid; c. metal (e.g. platinum) catalyst; d. ascorbate metallic salts; e. enzyme-based bread, cakes, cooked rice, biscuits, pizza, pasta, cheese, cured meats and fish, coffee, snack foods, dried foods, and beverages.

55.2.2.3 Gaseous Scavenging

Oxygen scavenging is necessary due to the presence of oxygen, which facilitates the growth of aerobic bacteria, yeast, and molds, discoloration, and loss of nutrient value. Ethylene scavengers used are potassium permanganate, activated carbon, and activated clays/zeolites. These are used in fruit, vegetables, and other horticultural products. The fruit crate "fruit fresh," made of corrugated cardboard, uses the hollow spaces between the corrugations to apply active materials such as kaolin clay and zeolite. Other scavenging methods include conversion of sugars, removal of cholesterol, suppressed enzymatic borrowing, juice de-bittering, nutrient etherification, aroma release, and insect repellence.

55.2.3 Sources of Bioactive Compounds

55.2.3.1 Botanical or Plant

Sources of bioactive compounds could be obtained from plant extracts, such as essential oils and phytochemicals (such as flavonoid, betel oil, cinnamon oil, clove oil, catechins, rutin, and quercetin), soy protein hydrolysate, corn protein hydrolysate, and plant-derived enzymes. Bioactive food packaging is an innovative approach for the prevention of the growth of food-spoilage microorganisms [16]. Previous researchers reported that antioxidant extracts from agro-industrial by-products exhibited antimicrobial activity and were suitable for incorporation into edible films for bioactive packaging systems. For example, a bioactive film composed of agar, green tea extract, and probiotics was applied to hake and managed to increase beneficial lactic acid bacteria but reduce the microbial growth, especially the H_2S-producing bacteria, which caused a decrease in the biochemical indexes of fish and reduced the shelf life of hake [31]. Moreira et al. (2016) reported that eucalyptus wood extract was the most active, with only 2% (v/v) necessary to inhibit *Pseudomonas aeruginosa*, *Listeria monocytogenes*, and *Staphylococcus aureus*; whereas almond shell extract was less active, requiring 4% (w/v) to inhibit the growth of *Escherichia coli* and *P. aeruginosa* [32]. However, the extract from corn cobs was bactericidal against *E. coli* and *S. aureus* at a concentration of 4% (w/v). The antioxidant extracts incorporated into sodium alginate films and the maintenance of their antimicrobial properties were confirmed.

55.2.3.2 Animal

These include animal-derived peptides, enzymes, lactoferrin, hepcidin, milk protein hydrolysates, polysaccharides, or biopolymers from animal sources. Chitosan is one of the most common polysaccharides in crab shells, lobsters, shrimps, and insects. It is a β-1,4-linked polymer of 2-acetamido-2-deoxy-glucopyranose (GlcNAc) and 2-amino-2-deoxy- glucopyranose (GlcN), and is investigated as a non-toxic, biodegradable, and biocompatible material. The inhibitory activity of chitosan-based edible coatings was assessed against two food pathogens (*S. aureus* and *L. monocytogenes*) and one strain involved in food alteration (*P. aeruginosa*) on model agar medium, and these showed 100% inhibition of the development of selected Gram-positive bacteria and 77% inhibition on *Pseudomonas* growth. However, the method later proved to be effective on a real cheese food product [33].

55.2.3.3 Bacteria

Gialamas et al. (2010) developed bioactive packaging based on the incorporation of *Lactobacillus sakei* into sodium-caseinate films for the control of *L. monocytogenes* [34]. The rapid growth of *L. sakei* immobilized in the film following contact with the wet medium or the food surface, and significant inhibition of the pathogen growth was observed as compared to the controlled samples under both constant and dynamic storage temperature protocols. This indicated that biopolymer-based antimicrobial films containing cells of a protective culture can be used as an effective packaging technology for improving food safety. Soukoulis et al. [35] developed a new strategy to include probiotics in baked cereal products and reported that the sodium alginate-based surface-coated edible films effectively protected *Lactobacillus rhamnosus* GG on pan bread, and during *in vitro* digestion, whey proteins reduced probiotic loss during drying and storage [35]. Meanwhile the incorporation of lactic acid bacteria [36] as probiotics [37] in edible films successfully obtained high viability of the bacteria throughout the storage study, while their physical properties were maintained stably throughout the storage period.

55.2.3.4 Synthetic or Chemical Sources

These mainly applied to moisture absorbers, oxygen scavengers, and ethylene scavengers such as potassium permanganate, activated carbon, activated clays/zeolites, glucose oxidase and catalase, lactase, alcohol oxidase, and catalase. There are numerous bioactive agents, and these are widely used in a variety of applications in the food, pharmaceuticals, and cosmetic industries. Han [30] affirmed that in the use of antimicrobial agents in the food, pharmaceuticals, and cosmetics products, the industry must follow the guidelines and regulations of the country that they are going to use them in, for example, the FDA and/or EPA in the United States [30]. This implies that new bioactive packaging materials may be developed using only agents which are approved by the authorization agencies, for example by the FDA, or notified-to-use within the concentration limits for food safety enhancement

TABLE 55.1
Some Typical Natural and Synthetic Antimicrobial (AM) Agents Used in Food Packaging

Class of AM Agents	Examples
Antibiotics	Natamycin
Bacteriocin	Nisin, pediocins
Chelating agents	Ethylene diamine tetra acetate, purophosphate, citrates
Enzymes	Lactoperoxidase, lysozyme, lactoferrin
Essential oils	Eugenol, thymol, salicylaldehyde, cinnamic acid
Fatty acids and esters	Monolaurin
Fungicides	Benomyl, imazalil
Gas	Ethanol, Hinokithiol, $Cl0_2$
Inorganics	Sulfites, sulfur dioxide
Isothiocyanates	Allyl isothiocyanate, hypothuiocyanate
Metals	Silver, copper
Mineral acids	Phosphoric acid
Organic acids	Propionic, benzoic, sorbic, acetic, lactic, malic, succinic, tartaric
Oxygen absorber	BHT
Parabens	Methyl, propylparaben
Phenolic antioxidants	Butylated hydroxyanisole, butylated hydroxytoluene 2-terbutylhydroquinone
Proteins	Conalbumin, cathepsin
Others	Reuterin (3-hydroxypropionaldhyde), hydrogen peroxide, ozone, sulfur dioxide

or preservation [30]. There are various types of bioactive agents such as those shown in Table 55.1 which could be incorporated into the packaging systems including chemicals with antimicrobials, antioxidants, biotechnology products, AM polymers, natural AMs, and gaseous [38, 39].

55.2.4 Methodology of Preparation and Mechanism of Actions

Bioactive polymer systems may be classified as migratory bioactive polymers and non-migratory bioactive polymers according to the release and their mechanism of actions and the biodegradable polymer system [33, 40]. Moreover, bioactive agents can be incorporated through immobilization depending on the mechanism of action of the agent.

55.2.4.1 Non-Migratory Bioactive Polymer System (NMBPS)

Polymer bioactivity is devoid of active components migrating from the polymer to the substrate. NMBPS is used as a moisture absorber, oxygen scavenging system, and ethylene scavenger, and it is under investigation in the area of in-package enzymatic processing and non-migratory antimicrobial packaging. NMBPS can generally be divided into two main groups [40].

Inherently bioactive polymers (e.g. polymers containing free amines) have antibacterial activity. Polymers that belong to this group are naturally bioactive themselves without any additional compound. At present, various polymers display inherent antimicrobial properties such as chitosan and UV-treated polyamide. Chitosan is a polysaccharide based on chitin and is widespread in nature, and more effective against spoilage yeast and some Gram-negative bacteria including *E. coli* and *P. aeruginosa*. Chitosan acts through binding to the cytoplasmic membrane surface, and it is possible that the outer membrane protects the Gram-negative cells. Moreover, epifluorescence microscopic results showed a possible chitosan action during a short time duration on the synthesis of nucleic acids and especially on the relative proportion of RNA compared with DNA [33]. This impact was followed by an adaptive mechanism of the cells. Polymers with immobilized bioactive compounds (i.e. polymer modified with bioactive agents) hold specific properties.

55.2.4.2 Migratory Bioactive Polymeric System (MBPS)

Bioactive agents can be released from the polymeric system as these are incorporated in the polymer matrix by different methods [41]. For example, direct incorporation methods and coating techniques allow the migration of bioactive agents. MBPS may be divided into volatile or non-volatile groups depending on the nature of the bioactive agent. Non-volatile MBPS or non-volatile active agents are incorporated directly into packaging material or placed between the package and the food. In the case of compounds attached to the packaging material, these transfer from the polymeric system to the food surface through diffusion.

55.2.5 Methods of Incorporation of Bioactive Substance

Anti-microbial (AM) packaging is part of bioactive packaging, which combines the food packaging materials with AM substances to control microbial surface contamination of foods. Appendini and Hotchkiss [25] characterized the forms of bioactive packaging accordingly by:

i. Incorporation of bioactive substance into a sachet in the package
ii. Direct incorporation of bioactive substance into the package wall
iii. Coating the packaging material with a matrix that serves as a carrier of a bioactive substance
iv. Use of either inherently bioactive polymers that exhibit film-forming properties and are chemically modified or polymers that can be chemically modified to produce bioactive properties
v. Use of bioactive edible coatings directly applied into the food

Manipulating the solvents and/or polymer structures can enhance antimicrobial adsorption. Poly(ethylene-co-methacrylic acid) films treated with sodium hydroxide and swollen with acetone showed an increased absorption and

TABLE 55.2
Antimicrobials Covalently/Ionically Immobilized in Polymer Supports

Functional Support	Antimicrobials	References
	Lysozyme	Hanusova et al. [43]
Low-density polyethylene	Bacteriocin	Storia et al. [96]
Ethylene vinyl acetate (EVA) Ionomers	Surface pre-reacted glass-ionomer (S-PRG)	Nagai et al. [97]
Polystyrene (styrofoam)	Lysozyme	Wu and Daeschel [98], Moringo et al. [99]
	Silver nanoparticles	An et al. [100]
Polyvinyl alcohol	Lysozyme	Conte et al. [101] Feng et al. [102]
Polyvinyl alcohol	Lysozyme-essential oil	
Polyvinyl alcohol poly(methyl vinyl ether-alt-maleic anhydride)	Lysozyme	Najafi et al. [103]

diffusion of benzoic and sorbic acids compared to non-treated films [25]. Immobilization of AMs by ionic or covalent linkages to polymers requires the presence of functional groups on both the antimicrobial and the polymer. Table 55.2 summarizes a few examples of ionic and covalent immobilization of antimicrobials onto polymers or other materials.

There are AMs that cannot tolerate the temperatures used in polymer processing, and these are often coated onto the material after forming or are added to cast film. For example, cast edible films, have been used as carriers for AMs and applied coatings onto packaging materials and/or foods. Previous research discovered the lytic effect of adsorbed nisin on *L. monocytogenes* cells and thus further supported the hypothesis that the use of adsorbed nisin as an antimicrobial agent on food contact surfaces may indeed be feasible [42]. Other examples include adsorption of nisin on polyvinyldichloride (PVdC), [43], polylactic acid [44], hydroxypropyl methylcellulose (HPMC) [45], acrylic/vinyl acetate-ethylene [46], and nisin/EDTA/citric solutions coated onto PVC, nylon, and LLDPE films [47]. The potential reduction in AM activity due to immobilization must be considered. Changes in conformation and denaturation of protein and peptides may result in low activity per unit area. The protection of active sites during film formation and the incorporation of dendrites are a selected way to increase the activity. Conte et al. [48] suggested that the immobilized lysozyme has the potential to reduce bacterial activity of *Micrococcus lysodeikticus* [48]. Other AM enzymes that could potentially be covalently immobilized for packaging applications include lactoferrin, sulfhydril oxidase, and bite-salt stimulated lipase [25, 49, 50].

Some synthetic polymers or natural polymers are inherently AM and have been used in films and coatings. Among natural polymers, chitosan exhibits AM activity [25, 30, 51]. It has been found that the use of agricultural biopolymers that are easily biodegradable, such as chitosan, would solve the problem of waste disposal and un-degraded polymers caused by synthetic polymers [51]. In addition, chitosan-based antimicrobial films have been used to carry organic acids and spices [52]. UV or excimer laser irradiation can excite the structure of nylon and create AM activity. A subsequent study on UV-treated nylon films showed that the surface amino groups were bactericidal, and bacterial cells were adsorbed to the surface and diminished the effectiveness of the amine groups [53].

Incorporation of AM substance into polymers has been commercially applied in drug and pesticide delivery, household goods, textiles, surgical implants, and other biomedical devices [25]. The commercialized antimicrobial compounds include silver substituted zeolite, chlorine dioxide, carbon dioxide, ethanol, glucose oxidase, and allylisothiocyanate. The rationale for incorporating AMs into the packaging is to prevent surface growth in foods where a large portion of spoilage and contamination occurs [25]. Common AM chemicals for food products are preservatives such as organic acid and their salts, sulfites, nitrites, antibiotics, and alcohols [8]. These are mixed into a wax layer for natural cheese [54]. The AM mechanism/kinetics and the controlled-release profile of potassium sorbate from starch-based film into cheeses were examined and mathematically simulated by [55]. Santonicola (2017), on the other hand, reported the release of natamycin from chitosan/methylcellulose film into the same food product [56].

Biodegradable polymers are being studied as edible coatings or film materials [57]. Ramos et al. [58] reported on the AM activity of essential oils in corn zein films. Trombetta et al. (2005) concluded that the antimicrobial effect of (+) menthol, thymol, and linalyl acetate may be due, at least partially, to a perturbation of the lipid fraction of bacterial plasma membranes, resulting in alterations of membrane permeability and in leakage of intracellular materials [59]. Besides being related to physicochemical characteristics of the drugs (such as lipophilicity and water solubility), this effect appears to be dependent on the lipid composition and net surface charge of the bacterial membranes lead to the cross of the cell membranes, penetrating the interior of the cell and interacting with intracellular sites critical for antibacterial activity [59].

A previous study showed that thymol has successfully inhibited the growth of various microorganisms. Ramos et al. [60] found the decrease of viable counts of *S. aureus* on nutrient agar upon the addition of either the carvacrol of thyme or

its constituent thymol. Klarić et al. [61] in their study of antifungal activity of thyme essential oil and thymol against molds reported that essential oil of thyme, which is rich in thymol and other antifungal components, could be used for the disinfection of moldy walls in the dwelling in low concentrations. Corbo et al. [62] suggested the use of thymol as an ingredient for producing fish hamburgers. Their study revealed that thymol in combination with modified atmosphere packaging showed the greatest inhibitory activity against *Shewanella putrefaciens* and *Photobacterium phosphoreum* [62].

A study of antibacterial activities of nisin, thymol, and eugenol against four strains of common spoilage bacteria named *E. coli*, *S. auereus*, *Bacillus cereus*, and *L. monocytogenes* concluded that thymol appeared to be the most preferable agent for research in active packaging in terms of its antimicrobial benefit [63, 64]. An ordinary feature of plant volatiles is their hydrophobic nature, and studies addressing the mode of antimicrobial action of such compounds commonly point to the cell membrane as primary target [65, 66]. Bio-actives directly incorporated into packaging polymer matrices need plasticizers and additives. These are small molecular weight (M_w) compounds, which can interfere with protein chain-to-chain hydrogen bonding, and extend, dilute, and soften the structure, increasing chain mobility, e.g. glycerol, propylene glycol (PG), polyethylene glycol (PEG), sorbitol, and water; they are generally used to improve mechanical properties of protein films [67–69]. Plasticizers are generally added into film-forming solutions to prevent film brittleness or cracking caused by intermolecular forces [67]. These illustrate how bioactives are combined with packaging to suppress microbes and improve the quality of packaged food products.

55.2.5.1 Micro- and Nano-Emulsion

Bioactives, in particular natural pigments or natural dyes with multifunctional properties such as anthocyanins, betalaine, catechin, and chlorophyll, can be prepared with microencapsulation or nanoencapsulation techniques and incorporated into biopolymer films to provide the desired functional properties of a pH indicator, antimicrobial effect, and antioxidant benefits [70–72]. In a smart packaging system, color indicators could provide information about product quality by surrounding conditions and headspace gases of packages; it can also be attached to the package surface or integrated into packages that are improved for determining metabolite residue formed during storage [73]. Temperature, microbial spoilage, package integrity, physical shock, and freshness of the packaged product can be controlled. Anthocyanins are secondary metabolites widely distributed in fruits and vegetables (e.g. red cabbage, sweet potato, bean husk, grapes), making them a promising source of natural indicators that exhibited greater color spectrum as a function of pH and also antioxidant [14, 17, 74, 75]. Several studies investigated the use of biopolymers and anthocyanins for the production of pH indicators. However, studies related to the evaluation of time, temperature, and light effects on the stability of pH indicators, especially those developed with natural colorant, need to be further detailed.

55.2.5.2 Bioactive/Enzymes Immobilization Technology

In the encapsulation or immobilization techniques, tiny substances are encapsulated in food at nanoscale range having diameters of 3 to 800 micrometers. In such a context, their efficacy is guaranteed due to their significantly improved stability and/or release of the bioactive compounds incorporated [76, 77]. This is based on their interactions with the polymeric material and on the environmental conditions of their applications such as temperature, relative humidity, and so on. The significant potential of using nanotechnology tools to improve the performance has made polymers and biopolymers the material of choice as carriers of the bioactive compounds for those types of applications [13, 78, 79].

55.2.5.3 Controlled Release of Bioactive Compounds

In controlled release technology, a migratory bioactive system can be designed as a controlled release system that plays an important role in sustaining a constant concentration of bioactive agents in food and pharmaceutical products without waste of the bioactive agent for a long period. Therefore, the migration rate of active agent from the packaging must be controlled specifically [80–82]. If the migration rate of antimicrobial agent is faster than the growth of microorganisms, the incorporated antimicrobial agent can be weakened to less than the effective critical concentration before the expected period. Several types of biopolymers including kappa-carrageenan, polylactic acid, polyglycolides, and polyorthoesters have been important in controlled release.

55.2.6 Controlled Release System in Bioactive Packaging

In food packaging, migration is used to describe the transfer of a substance from the packaging materials into a food, and it is essential in order to effectively inhibit the growth of microorganisms on the surface of food products. There has been great interest in developing AM packaging materials, which slowly release AM agents to the surface of food and inhibit microbial contamination on the food surface during food storage [12, 83, 84]. Extensive research has been conducted to develop strategies in association with controlled release. Mathematical models play a vital role in accommodating polymeric network design by identifying active compound release mechanisms and key parameters.

Most food packaging systems consist of packaging material, food, and the headspace in the package. Diffusion between the packaging material and the food and portioning at the interface are the main migration phenomena involved in this system. AM agents may be incorporated into the packaging materials initially and released into the food through diffusion and partitioning. Han's description of the migration phenomena is shown in Figure 55.2 [8].

Control of the release rates and migration amounts of the AM substance from food packaging is very important. In principle, the extractability of a compound from a plastic by a foodstuff can be determined by placing the plastic (of known

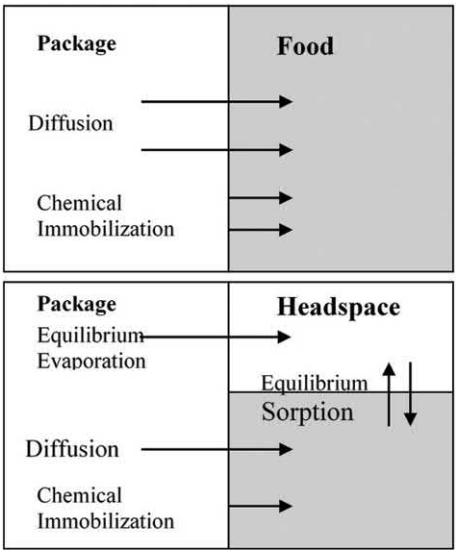

FIGURE 55.2 Food packaging systems and migration phenomena. (Adapted from Han [8].)

surface area) in contact with the food under defined conditions of temperature and time [68]. In practice, the test faces difficulties for the following reasons:

(i) The compounds present in the plastic under test may be unknown and may have been degraded during processing.
(ii) In many instances, such compounds are difficult to determine analytically in a matrix as complex as food, particularly where only small amounts are present in the extract.
(iii) Compounds other than the one of interest may also be extracted and subsequently interfere with the analytical determination.
(iv) Most of the foodstuffs are stable for short periods of time only, whereas extractability data may be required from long-term studies.
(v) Appropriate test conditions are not easy to define as a result of the wide variation in possible contact conditions likely to be encountered in practice in warehouses, supermarkets, corner shops, and household larders.

While it is always desirable to use foods themselves for extractability testing, in practice, it is seldom possible, and so food simulants have to be used instead [68]. The extractability of a compound from plastic can be determined by placing the plastic (of known surface area) in contact with the food or food simulant under defined conditions of temperature, time, and static/dynamic mode [68, 79].

55.3 HISTORY AND DEVELOPMENT

55.3.1 History and Development of Bioactive Packaging

The global nano-enabled packaging market size was USD 23.73 billion in 2015 and is expected to witness significant growth over the forecast period as shown in Figure 55.3 [85]. The key drivers impacting the demand growth include favorable food safety regulations and increasing demand for effective packaging solutions in the food and beverage and pharmaceutical sectors. Nanotechnology is one of the most rapidly growing industries, which is contributing to the growth of several industries; one such industry is the active packaging industry. Increasing usage of nano-enabled packaging in the bakery, meat, fruit and vegetable, and other processed food products is anticipated to boost demand from 2016 to 2024.

The most widespread use of active agent in the industry is synthetic chemical substances, which include alcohol, antibiotics, fungicides, and organic acid. Organic acids and their mixtures possess strong AM activity and have been used as food preservatives, food-contact substances, and food-contact material sanitizers [30]. The use of antibiotics as package additives is not approved for the purpose of AM functions and is also controversial due to the development of resistant microorganisms. However, antibiotics may be incorporated for short-term use in medical devices and other non-food products [30, 38]. Chlorine oxide, allyl isothiocyanates, and ozone are examples of the gaseous AM agents that have been successfully incorporated into packages, which offer protection in the headspace of food packaging. Ethanol vapor generation consists of ethanol absorbed or encapsulated in carrier materials and enclosed in polymer packets. The ethanol permeates the selective barrier and is released into the headspace within the package [25]. Various AM agents could be incorporated into the packaging

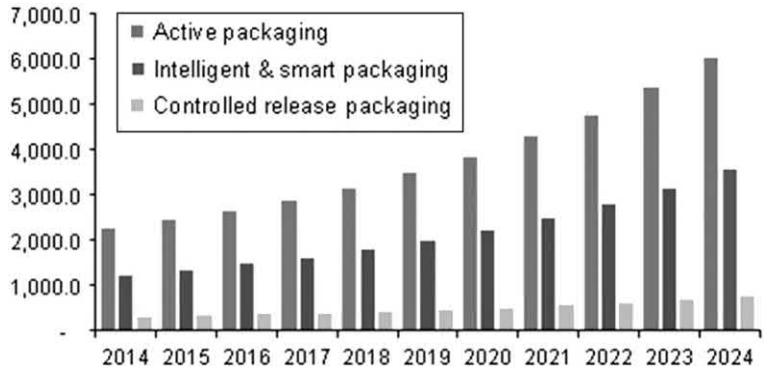

FIGURE 55.3 U.S. nano-enabled packaging market revenue by application, 2014–2024 (in USD million).

systems including chemical AMs, antioxidants, biotechnology products, AM polymers, natural AMs, and gas [16, 38, 39, 86].

Therefore, research on bioactive packaging in general is also, more widely, research on natural compounds as bioactive agents. Pandey and Kumar [87] and Abdallah [88] elaborated on the plant products that can be used as antimicrobial agents, and their review describes the current state of plant antimicrobial compounds worldwide. It studies extracts commonly in use, their structure, mode of action, stability, possible technologies by which they can be delivered, and substances being explored and tested by researchers and clinics back in 2011. Plant essential oils are a potentially valuable source of AM agents that have been shown to possess distinct AM activities against many pathogenic microorganisms [64, 89–92]. For example, the AM effects of essential oils and their active constituents against pathogenic microorganisms including *E. coli* [64, 90–93], *S. aureus* [64, 90, 91, 93], *B. cereus* [64, 91], *E. coli* O157:H7 [94], *Penicillium roqueforti*, *Endomyces fibuliger*, *Penicillium corylophilum*, *Aspergillus flavus* and *Eurotium repens* [95], *Staphylococcus epidermidiis*, *Bacillus subtilis*, *Bacillus* spp., *Micrococcus luteus*, *P. aeruginosa*, and *Klebsiella* spp. [91] have been studied.

55.3.2 Law and Regulations

Active and intelligent packaging is based on a deliberate interaction of the packaging with the food and/or its direct environment to improve food quality and safety. Such technology includes advances in delayed oxidation and controlled respiration rate, microbial growth, and moisture migration. Other examples are carbon dioxide absorbers/emitters, odor absorbers, ethylene removers, and aroma emitters, while intelligent packaging includes time–temperature indicators, ripeness indicators, biosensors, and radio frequency identification. An amendment to the EU Framework Directive for food-contact materials 89/109/EEC has led to the adoption of a new Framework Regulation (1935/2004/EC). The new Framework Regulation for Food Contact Materials (1935/2004/ EC, which was published on 27 October 2004 (5), authorizes the use of active and intelligent packaging, provided the packaging can be shown to enhance the safety, quality, and shelf life of the packaged foods. Based on the definitions laid down in Regulation (EC) No 1935/2004 and in Regulation (EC) No 450 /2009, "active materials and articles" means materials and articles that are intended to extend the shelf life or to maintain or improve the condition of packaged food. These are designed to deliberately incorporate components that would release or absorb substances into or from the packaged food or the environment surrounding the food. Nevertheless, due to its deliberate interaction with the food and/or its environment, the migration of substances could represent a food safety concern.

55.3.3 Industrial Applications and Benefits

Factors to be considered in the manufacturing of active/bioactive films are (i) the chemical nature of the film, (ii) process conditions and residual antimicrobial/antioxidant activity, (iii) characteristics of antimicrobial/antioxidant substance and specific foods, (iv) chemical interaction of additives with film matrix, (v) mass transfer coefficients, (vi) physical properties of packaging material, and (vii) environmental conditions such as storage, temperature, and RH. These could be the industrial benefits of enclosing bioactives within packaging or coating materials.

55.4 CONCLUSIONS AND FUTURE DIRECTION

The purposes of packaging technology are to maintain sensory quality and extend the shelf life of food whilst at the same time maintaining nutritional quality and ensuring microbial safety. Bioactive packaging is an emerging trend and exciting area of food packaging technology with improved quality and safety resulting in innovations in packaging techniques that can confer many preservation benefits on a wide range of food products. The new advances have mostly focused on delaying oxidation and controlling moisture migration, microbial growth, respiration rates, and volatile flavors and aromas. Bioactive packaging is thus a novel set of technologies designed to give response to a number of issues related to the feasibility, stability, and bioactivity of functional ingredients for the food industries. These technologies aim to integrate bioactives within new packaging and coating material concepts and can greatly benefit from previous developments in the pharmaceutical and biomedical sectors and from the unique properties of synthetic and biomass-derived biopolymers. Research and development in response to consumer preferences gave rise to active, smart, and bioactive food packaging techniques that are purely innovative. These innovative packaging technologies contributed toward the improvement of food quality, safety, feasibility, and bioactivity of functional components. The applicability of novel and innovative packaging techniques is growing widely because of their health impact, thus resulting in reduced consumer complaints. In the near future, conventional packaging could be completely replaced by innovative food packaging techniques as these techniques are rapidly making their way into the global market.

56 Hygienic Design and Sanitation

Mohammad Shafiur Rahman, Md. Jiaur Rahman, and Nasser Al-Habsi

CONTENTS

56.1 HYGIENIC DESIGN

The food industry is a diversified and large sector that produces, processes, and supplies much of the foods consumed by the world population. However, proper hazard management, food safety, and hygiene practices are crucial in food production and handling in protecting public health. Hygiene is a key discipline in the area of food safety and public health management. Lack of adequate hygienic practices at all stages of harvesting, post-harvesting, processing, and storage drastically increase the risk of contamination with food poisoning and food infection [1]. Therefore, hygienic design is essential to ensure safe goods supply for consumers. Sanitation is an applied science that states the creation and maintenance of hygienic and healthful conditions in an industry. Its applications refer to hygienic practices designed to maintain a clean and wholesome environment for food production, preparation, and storage [2]. This includes not only cleanliness in foods, but also improved food processing environments that prevent chemical, physical, and biological hazards from causing illnesses and injuries to consumers. One of the keys to operating a clean and sanitary facility is the design of the building and equipment. It is important to do it right the first time, as it is always much harder and more expensive to retrofit or rebuild [3].

56.1.1 Factory Facility Design

A new and renovated food factory facility should be well planned and emphasized with effective functionality, hygienic design, and construction principles to ensure sanitary operations. A hygienically designed facility can boost the healthfulness of all foods and facilitate a sanitation program effectively ([4]. Therefore, it is important to consider hygienic factors when designing food processing factories and equipment in order to ensure food safety and quality.

56.1.1.1 Factory Site

Factory site selection is pivotal in the development of hygienic operations. The design, construction, and maintenance of the factory site and buildings need special considerations from a hygienic point of view. To maintain a good standard of hygiene, a well-planned and adequate waste disposal system is essential [5]. Attention to the design, construction, and maintenance of the site surrounding the factory provides an opportunity to set up the first (outer) of a series of barriers to protect production operations from contamination. These barriers start at the site perimeter boundary, and moving inward, ending with the walls of high-care and low-care regions [6]. Thorpe [6] reviewed the number of steps that can be taken for a factory site. The important ones are as follows:

i. A food factory should not be built up near chemical plants that emit toxic odors, or near salvage yard or water disposal operations. Foodstuffs that are high in fat may pick up bad odors and flavors spontaneously during production, preparation, and processing. In addition, foodborne pathogens can contaminate the

manufactured products by air blown across them, unless special filters are added to the intake air systems [4].

ii. Use of two lines of rodent baits located every 15–21 mm along the perimeter boundary fencing and at the foundation walls of the factory, together with a few mouse traps near building entrances [7].
iii. Keeping areas immediately adjacent to buildings grass-free and covered with a deep layer of gravel or stones, which helps weed control and assists inspection of bait boxes and traps [8, 9].
iv. Making the factory site unattractive by denying birds food and harborage. This means clearing up any spillages of raw materials, avoiding keeping waste material in uncovered containers, and avoiding big trees around the site [10].
v. Premises should be purpose-built to a sanitary design with modern, easy-to-clean materials and sited in surroundings that are free from potential harborages for rodents, birds, and insects [5].
vi. Preventing the unauthorized opening of doors and windows, and using protective screens against flying insects.
vii. Use of high-pressure sodium lights in preference to mercury vapor lamps for lighting of warehouses and outdoor security systems to avoid attracting flying insects at night [7, 10].
viii. Use of good landscaping, which can reduce the amount of dust blown into the factory. Entrances into the plant and areas surrounding it should be well paved to reduce the amount of mud and dirt brought in by workers and clients [1].
ix. Use of orientating buildings so that prevailing winds do not blow directly into manufacturing areas. Doors and windows of the plant should be screened tightly to prevent the entrance of flies and other insects [1].
x. Use of proper layout of vehicular routes around the factory site to avoid soil blown into buildings [6].
xi. Plant premises and areas surrounding it should be kept completely free of all decomposing materials and pools of stagnant water that generate foul odors and are ideal breeding grounds of flies and other insects [1].
xii. Avoid the presence of flowering plants to prevent attracting flies and other insects.
xiii. The air circulated within the factory needs to be controlled, since pests, insects, rodents, and birds carry pathogens.

56.1.1.2 Floors

The floor design of a food facility is an important factor in hygienic design and sanitation. The selection of floor surface depends on the plant and its operations such as raw material collections, food production, preparation, processing, and food materials from the process falling onto the floor. The most critical hygienic issues in a food facility design are the junctions among different construction components, especially between floor finishes and stainless-steel drainage components. For designing of floors, alongside flooring materials, some important aspects such as gullies, channels, junctions, joints, and falls should be carefully considered. Junctions and joints are prone to microbial contamination. The fewer the joints, the less the hygienic risk. Intensifying the hygiene-enhancing qualities of specialist safety flooring is an important aim in safety flooring manufacture. The main characteristics of an ideal floor required are as follows:

i. The floor must be strong, fast, and abrasion-resistant.
ii. The floor must be impervious to water, nonabsorbent, and corrosion-resistant.
iii. The floor should be free of cracks, pits, and crevices.
iv. The floor must be resistant to oil, grease, chemicals, and skid-resistant
v. The floor must be a high-density type. A less porous material reduces moisture absorption and reduces microbial growth.
vi. Resistant to cleaning and sanitizing chemicals.
vii. The floor must be durable, easily maintained, and wear-resistant.

A bacteriostat in the formulation is integral to the flooring and gives the exposed surface strong antibacterial activity against gram-positive and gram-negative microorganisms [11]. A slip-resistant floor is another safety aspect in the prevention of injury-causing slips, trips, and falls. As the problem of floor surface-slip performance is relatively complex, there are many other factors involved than simply the flooring material. Thus, there is a broad range of polymeric shoe-sole materials used today as well as flooring materials. Today a wide variety of flooring solutions are available. These include safety floors studded or formulated with hard mineral additives (fine grain chemicals, for example, silicon carbide) that provide hard coefficient of friction (for strong grip) under wet and contaminated, for example, greasy, conditions [11]. Studded tiles are not recommended because of the greater difficulty of cleaning such surfaces. Ideally, surfaces that offer the greatest ease in cleaning should be used. However, the final choice should reflect a balance between ease of cleaning, slip resistance, and other factors. Joints should be grouted in proper ways. Cementitious grouts are not considered suitable hygienic applications. Epoxy, polyester, and furan resins can be used. Epoxy resins have limited resistance to very high concentrations of sodium hypochlorite and soften at temperatures above 80°C. Polyester and furan resins are more resistant to chemical attack. Floor finishes with either tiles or a synthetic resin should be considered. The choice of flooring surfaces can be broadly grouped into three categories: (i) concretes, (ii) fully vitrified ceramic tiles, and (iii) seamless resin screeds. Concrete flooring, including the high-strength granolite finishes, may be suitable in different parts of the factory. However, concrete is not recommended for high-care production areas due to its ability to absorb water and nutrients. This allows microbial growth below the surface, where it is extremely difficult to apply effective sanitation cleaning [6]. Pressed or extruded ceramic tiles are still extensively used in processing areas. In recent years, these have

been partially replaced by various seamless resin floors due to cost and wide availability. The waterproof membrane of floors should be extended up walls to a height above the normal spillage level [6].

All floors in the factory should be regularly cleaned and must be properly constructed with good drainage. Water should not be allowed to remain stagnant on the factory floor or drain because this breeds unwanted insects and flies [1]. A correct slope on the floor is also important [5]. Drainage should be accounted for in the proposed layout of equipment. Ideally, the layout and siting of production equipment should be finalized before the floor is designed to ensure that discharges can be fed directly into drains. In reality, this may not be possible for the food industry since the layout of lines may be frequently changed. Drainage should be in the middle of the factory and equipment should be placed on both sides of the drain. Equipment should not be located directly over drainage channels as this may restrict access for cleaning [6].

56.1.1.3 Walls

The wall of a food facility should be installed and maintained to ensure all food safety issues are met from the floor to the ceiling. A number of technical factors such as hygienic characteristics, insulation properties, and structural characteristics need to be taken into consideration for walls. A U-shaped channel between the floor and wall junction should be used for easily cleanable and watertight junction. The walls must be constructed of impervious, nonabsorbent, washable, nontoxic materials, and have smooth crack-free surfaces [6]. Schmidt and Erickson [12] suggested some important characteristics of an interior wall of a food facility in hygienic design and sanitation. A cleanable and sanitary ideal wall for a food facility is one that should have the following criteria:

i. The wall should be flat, smooth, and made of concrete/insulated metal panels (IMPs).
ii. The wall must be a high-density type. Less porous material reduces moisture absorption and reduces microbial growth.
iii. The wall must be free of pits, bangs, checks, and crevices.
iv. Junctions between walls and ceilings should be rounded.
v. Joints between walls and floors should be covered.
vi. Wall should be impervious, nonabsorbent, and corrosion-resistant.
vii. The wall should be resistant to cleaning and sanitizing chemicals.
viii. The wall should be durable, easily maintained, and wear-resistant.
ix. The wall must be precisely installed, stuck down, and covered.

56.1.1.4 Doors, Windows, and Ceiling

Doors, windows, and ceiling also need to be properly designed from the point of sanitary operations. Doors allow direct entry of pests and flies that may spread foodborne pathogens in the working area of a food plant. A double-access door installed with automatic opening and closing could reduce pests and fly contamination. Although windows are essential for an effective environment and adequate lighting within a food plant, they may pose a sanitation hazard because of their breakage and contamination from pests, dust, and other sources [4]. However, if it is essential to install windows in a factory facility design, it is best if they are made of unbreakable polycarbonate material [13]. Widows must have nets to prevent insect entering into the production areas. The ceiling of a factory facility must be a smooth concrete slab of exposed double tees with caulked joints. It should be enclosed in concrete, granite, or the equivalent to avoid overhead areas that collect dust and debris, or provide rodent runways or insect harborage [4].

56.1.1.5 Lighting

Lighting in all areas of the plant should be sufficient for the adequate performance of all assigned duties. Areas where cleaning, sanitizing, sorting, picking, and product inspection are done should be provided with sufficient nonglazing light to enhance work performance [1]. Lighting should be used in such a way to avoid attraction of insects. Electro-blades could also be used to trap and kill insects and flies. Lighting stuffs, for example, LED light bulbs should be equipped with break-resistant lenses or shatterproof shielding and designed to be moisture-resistant and cleanable.

56.1.2 Equipment Design

Good hygienic design of equipment, which should be installed in such a manner as to minimize the chances of contamination occurring and to facilitate housekeeping and sanitation programs [6]. All equipment must be designed and constructed so that all internal contact points and external surfaces may be cleaned. Each piece of equipment has its own peculiar areas where microorganisms might proliferate, and hazard analysis of any weak points should ensure their removal, and indicate control and monitoring [5].

Legislation on the hygienic design of food-processing equipment or the hygienic maintenance of this equipment is rather vague [14]. In Europe, the most important legislation giving criteria for hygienic design of equipment is the Council Directive on the approximation of the laws of member states relating to machinery (89/392/EEC, revised 98/37/EC), which contains safety requirements and the basic principles of hygienic design [15]. National standards and/or directives applicable to the hygienic design of food machinery are available, but only a few international standards exist, directed mainly at the dairy industry [16]. A basic standard about hygiene requirements for the design of machinery is ISO 14159:2002 (ISO, 2002). The European Committee for Standardization (CEN) issues standards for equipment manufacturers to be able to fulfill the requirements of the directive. One important basic standard is Standard EN 1672-2 "Food-processing machinery—Safety and hygiene requirements—Basic Concepts—Part 2; Hygiene requirements" [17]. However, there are also guidelines and methods published,

e.g., by the European Hygienic Engineering and Design Group (EHEDG, www.ehedg.org), 3-A Sanitary Standards Inc. (3-A, www.3-a.org), and NSF International (www.nsf.org) available for helping in the design of new hygienic equipment. According to the EHEDG guidelines, constructions that cause problems include dead ends, sharp corners, low-quality seals, and joints [18, 19].

Equipment can be classified into three groups:

i. Aseptic equipment (high demand): Equipment that can be cleaned in place (CIP) and freed from microorganisms and spores (sterilization in place, SIP) without any dismantling.
ii. Hygienic equipment class I: Equipment that can be cleaned in place and freed from relevant microorganisms without dismantling.
iii. Hygienic equipment class II: Equipment that can be cleaned after dismantling and that can be freed from relevant microorganisms by sterilization, pasteurization, or chemical treatment after reassembling [20, 21]. It needs greater care in the location of adjoining equipment to prevent inefficient discharge of product from one unit to the next.

Valves are essential components of all food processing plants, and the quality of the valves used strongly influences the microbiological safety of the food production process. Valves for food contact use must therefore comply with strict hygienic requirements. It is important to keep the following conditions in mind: (i) pits and crevices must always be avoided; (ii) sharp edges should be avoided; (iii) screw threads should not be used; and (iv) dead ends, which may trap product or prevent adequate cleaning, should be avoided. Valves must be as short as possible and must be installed in a drainable and cleanable position if dead ends are unavoidable, and there should be as few seals as possible in a valve. During processing, the compressibility of the sealing should not be exceeded. More details are given in the European Hygienic Equipment Design Group Report [20]. In Europe, the valve design must meet the criteria as shown in Table 56.1 [22].

The guidelines for basic design and safe use of double-seat mix-proof valves in food processing, along with an outline of its benefits and applications are provided by EHEDG [23]. This type of valve prevents intermixing of ingredients or cleaning fluids during normal use. Other EHEDG [23] updates provide general hygienic design criteria for the safe processing of dry particulate materials. Figure 56.1A shows the possible design faults for a liquid holding tank and a better design is shown in Figure 56.1B. The design criteria for handling dry materials must consider (i) the eventuality of disassembly/accessibility for cleaning and inspection, (ii) the moisture content of the product, and (iii) safety aspects, including the formation of dust and exposure to it.

Mechanical seals are commonly used for pumps, agitators, mixers, and other types of rotary equipment. Dynamic sealing takes place at the interface between a stationary seal ring and a rotating ring. It is accomplished by using perfectly flat face surfaces and using the product pressure along with spring force to press the components together. Inappropriate design of mechanical seals can cause contamination of a food product by microorganisms and/or residues, which may be toxic or allergenic. The EHEDG [21] update presents the details of the design of mechanical seals for hygienic and aseptic applications. The general design criteria are presented as

i. The parts of the seal in contact with product must be suitable for CIP and SIP according to EHEDG guidelines.
ii. The nonproduct side of the seal shall be cleanable and capable of being disinfected and shall not contaminate or have any adverse influence on the food.
iii. Product-contact surfaces have to be smooth and crevice-free.
iv. The nonproduct side must be as smooth and as crevice-free as possible.
v. Dead ends are not permitted on the product side.
vi. Springs are not permitted on the product side.
vii. Designed corners must have a minimum radius of 3 mm.

Materials used for components in mechanical seals must (i) be nontoxic; (ii) be anticorrosive; (iii) be crevice-free; (iv) be

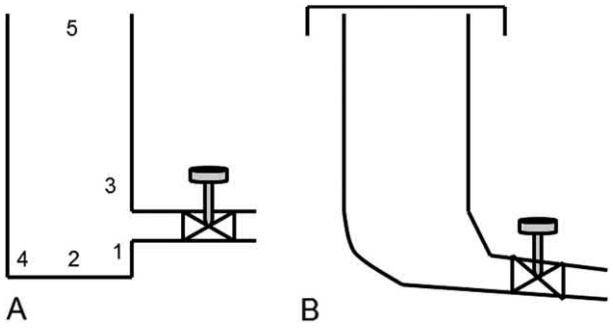

FIGURE 56.1 Design of a liquid holding tank. (A) Poor design (1: dead end, 2: no slope on the bottom, 3: sharp exit, 4: sharp corner, 5: no cover). (B) Hygienically improved design.

nonabsorbent; (v) not transfer undesirable odors, colors, or taints to the product; (vi) not contribute to the contamination of food nor have any adverse effects on the food; and (vii) have surfaces and coatings that are durable, cleanable, and capable of being disinfected; without breaks, and resistant to cracking, chipping, flaking, and abrasion; and prevent penetration of unwanted matter.

All equipment must be rinsed and sanitized on a daily basis and whenever there is a change in shift, if this is appropriate [1]. All surfaces in contact with food and outside surfaces of equipment must be cleanable. Surface roughness has a significant influence on cleaning ability. A greater surface roughness requires longer cleaning time [20]. Geometry appeared to be one of the main factors in hygiene, emphasized by the way the equipment is connected to the CIP circuit [24, 25].

56.2 GOOD HYGIENIC PRACTICE

Practicing good hygiene is an important part of hygienic design and sanitation in a food facility. Good hygiene is essential to ensure the products manufactured by a food plant and sold are safe to consume and free from contamination. Poor worker and equipment hygiene is the potential contributing factor in the contamination of the products causing foodborne illness outbreaks.

To ensure food industry staff members conform to personal hygiene requirements, two issues must be considered: (i) the environment within which the staff operates and (ii) the quality of the staff members. From a food hygiene point of view, the quality of the working environment depends on the facilities or equipment provided, which include toilets and protective clothing. The quality of staff depends upon their health, hygiene, habits, attitude, beliefs, and education or knowledge level on hygiene [26].

56.2.1 Purpose of Sanitation

Sanitation is important from legal, economic, quality, and food safety standpoints. Sanitation programs should be integrated with a company's hazard analysis and critical control points (HACCP) or food safety programs [3]. Giese [3] mentioned that good sanitation is much more than just good common sense; sanitation also entails getting the message across to all plant personnel and not just those involved with handling food. Sanitation consists of two parts: (i) cleaning and (ii) sanitizing. Cleaning means the removal of the residue of food, dirt, dust, foreign material, or other soiling ingredients or materials. Sanitizing means the effective bactericidal treatment of clean surfaces of equipment and utensils [1, 27]. Ideally, disinfectants should have the widest possible spectrum of activity against microorganisms (viruses, bacteria, fungi, and spores) in a time relevant to application contact times [28].

The purpose of sanitation are that it (i) increases the chance of complying with regulatory requirements, (ii) can prevent a catastrophe, (iii) enhances or facilitates an effective quality assurance program by increasing the acceptability and storage life of food by suppressing microbial population, and (iv) can save energy and retard the spreading of flora throughout the establishment [29]. There is an increasing trend in food production toward products with a short shelf life with low severity of processing. This demands higher standards of hygiene [30].

Cleaning and sanitizing are also important elements of any sanitation program. Good cleaning compounds must be economical, nontoxic, noncorrosive, noncaking, nondusting, easy to measure or meter, stable during storage, and easily and completely dissolved. The selection of these compounds depends on the area and equipment to be cleaned, soil types, and their attachment characteristics [29]. Different types of cleaners and sanitizers are available. There is value in working with suppliers not only to select the best materials to meet industry needs, but also to use this resource to ensure that employees have been properly trained in their use [3]. Surface-attached organisms were generally found to be less susceptible to disinfectants than suspended organisms. In practice, however, many factors are present in the factory environment that may affect the resistance of bacteria prior to disinfection [28]. The cleaning compounds are classified by Marriott [29] as alkaline cleaning compounds (strongly alkaline, heavy-duty alkaline, and mild alkaline cleaners), acid cleaning compounds (strongly acid cleaners, mildly acid cleaners, and solvent cleaners), synthetic detergents, alkaline soaps, phosphate substitutes for laundry detergents, solvent cleaners. More details about cleaning compounds and sanitizers are given by Marriott [29].

56.2.2 Strategy for Establishment of Sanitary Practices

A planned sanitation maintenance program is essential to meet legal requirements; to protect brand and product reputation; and to ensure product safety, quality, and freedom from contamination. All phases of food production and plant sanitation should be included in the program to supplement the cleaning and sanitizing procedures for equipment and factory facilities [29].

56.2.2.1 Reduction of Food Contamination Sources

Foods not handled in a sanitary way may become contaminated from processing equipment; employees; soil, air, and water; sewage; and insects and rodents. Contamination can be reduced through effective housekeeping and sanitation, protection of food during storage, proper disposal of garbage and litter, and protection against contact with toxic substances [29].

56.2.2.2 Personal Hygiene and Food Handling

Hygiene can be effectively controlled in the food industry through good manufacturing practice (GMP) and involves everyone. Good personal hygiene practices of personnel working in or visiting the production area are important. Additional requirements apply to personnel working in high-care areas. Personnel in the production area must maintain a

high standard of personal hygiene and appearance, be in good health, and adopt hygienic manufacturing principles. Personal hygiene refers to the cleanliness of a person's body. The health of workers also plays an important part in food sanitation. People are potential sources of microorganisms that cause illness in others through transmission of viruses or through food poisoning [29]. Personal hygiene means reasonably clean hands, forearms, neck, hair, and clothing that is liable to contact with food [26].

The education of food handlers is a crucial line of defense in the prevention of most types of foodborne illnesses [31]. Using questionnaires and microbial surveys, Aarnisalo et al. [14] investigated the hygienic working practices of maintenance personnel as well as the hygiene of the equipment in the Finnish food industry. The protective clothing, washing of hands and tools, and avoiding foreign bodies left on the production lines should be targeted when the hygienic working practices are developed for maintenance personnel. Based on the questionnaire to food processors, packaging machines, conveyors, dispensers, and slicing and cooling machines were considered the most problematic pieces of equipment hygienically mainly because of poor hygienic design. In order to improve food safety, both the training of maintenance personnel in food hygiene and equipment design should be more emphasized. Similarly, Nel et al. [32] interviewed workers from a deboning room of a high throughput abattoir by means of a structured questionnaire to ascertain the knowledge, attitude, beliefs, and practices regarding personal and general hygiene applied specifically in the deboning room. Basic hygiene practices were found to be in place and the workers adhered to the majority of these. The results highlighted a need for improved communication between management and workers as well as a need for more training in personal and general hygiene. Although basic personal and hygiene practices such as the wearing of overalls and gumboots, as well as the cleaning and disinfection of equipment are adhered to, they need to be optimized in order to be effective. The basic rules of personal hygiene are [1, 11, 27, 29]

i. Washing hands in hot water using plenty of soap and drying hands on a clean cloth or paper towel. Soap and water act as emulsifying agents to solubilize grease and oils on the hands. Increased friction through rubbing the hands together or using a scrub brush with the use of soap can reduce many transient and more resident bacteria than a quick handwash. Approximately 25% of food contamination is attributable to improper washing. Handwashing is conducted to break the transmission route of microorganisms from the hands to another source and reduce resident bacteria. Antimicrobial soaps are recommended for food preparation and handling areas. A fast-acting bactericidal skin cleanser kills most skin organisms on contact within 15 seconds. Proper washroom hygiene demands effective hand drying. A cloth towel system is hygienic, environmentally friendly, and cost effective. There is a lot more to skin cleaning than just soap and water. Inadequate or incorrect cleaning can lead to chronic skin disease. Skin cleaning must be done thoroughly, but also gently. The choice of cleaner depends largely on the type of contamination. The wrong choice could lead to skin irritation, dermatitis, and even more severe skin conditions.
ii. Washing hands after using the toilet, handling garbage or other soiled materials; handling uncooked muscle foods, egg products, or dairy products; handling money; smoking; or coughing and sneezing.
iii. Maintaining skin protection. Maintaining skin involves a three-point program: (i) correct skin protection for use before contact with various skin irritants and for under gloves; (ii) effective nonaggressive skin cleaning, which minimizes the loss of natural fats and oils from the skin; and (iii) after work, skin care to recondition the skin and support the healing of existing dermatitis or damage. A protective cream is also used in many cases. The types of materials handled dictate which type of protective cream to use. Protective creams do more than protect the skin. These functions include strengthening the outer layer of the skin, supporting the skin's ability to repair itself, stimulating skin growth, and make cleaning easier.
iv. Keeping fingernails short and clean, using a hairnet or cap, daily bathing, using deodorants, and washing hair at least twice a week.
v. Using protective clothing, footwear, and headgear, and these must be changed regularly. Beards must be kept short and trimmed, and a protective cover worn over them when considered appropriate by management.
vi. Avoiding use of nail varnish, false nails, and makeup; and avoiding wearing false eyelashes, wristwatches, and jewelry or ornaments. These items are places where more microorganisms can grow. These items are also difficult to clean.
vii. Avoid counting money during food handling.
viii. Avoiding consumption of food and drink in areas other than the tea bars and staff restaurant.
ix. Avoiding consumption of sweets and chewing gum in production areas.
x. Avoiding smoking or taking snuff in food production, warehouse, and distribution areas.
xi. Avoiding spitting in all areas on the site.
xii. Staying away from food when a person has an infected cut, boil, or other infection of the exposed skin; covering sneezes and coughs by means of a tissue or handkerchief.
xiii. Reporting all cases of diarrhea, fever, etc., and having periodic checkups.
xiv. Avoiding using bare hands to touch foodservice equipment and utensils. Disposable gloves should be used when contact is necessary.

All personnel should receive basic training in food handling and hygiene. This should include personal hygiene and an appreciation of the HACCP or GMP to implement HACCP. Management must select clean and healthy employees and ensure that they conduct hygienic practices. Sick workers should take sick leave and be properly treated before starting to work again.

Hand hygiene is the most important means of reducing the spread of infection. Peden and Vaughan [33] identified an improvement in the compliance rate of hand hygiene within a hospital when visual reminders, education, and positive reinforcement are used. Similarly, hand hygiene education and reminders to staff continue to maintain increased compliance and guarantee success [34]. Surveillance is a complex task that requires many elements to be addressed for data to be correctly reported. This includes the consistent application of data collection criteria by appropriately educated persons [35].

56.2.2.3 Cleaning of Factory Facility

Cleaning is an essential part of hygiene activities in a factory facility. Cleaning and disinfection prevent the contamination of food products from the factory facility and equipment surfaces. In the case of high-risk chilled foods, this is often a critical control point [30]. Recently, the usage of water became ever expansive and that economic reality must be acknowledged. Therefore, recycling water in food factories could be a solution to this problem. However, to apply this technique there must be a guideline to be followed. EHEDG and Codex Alimentarius have provided some hygiene legislation to this development, but it is not yet approved. Water recycling is still being evaluated in terms of consequences of the development, negative impacts that might be encountered, and emerging technical innovation that can be considered as a solution [36]. Napper [36] gave an example of removing organic material at the point where it comes into process water and before it gets contaminated with bacterial growth and chemicals. The observation was the level of chemical oxygen demand, which is the basis for cost of discarding of waste, which can be highly reduced. Moreover, this waste material can be also sold as a product. New technologies are proposed for disinfection, such as killing by adding metal ions to process water whether by chemicals or electrochemical process, and killing by creating chlorine and/or free radicals from tap water.

Cleaning and disinfection of surfaces in food factories is a big challenge. Titanium oxide added to the surface has a powerful oxidation ability that can be used to decompose materials, which can cause trouble even in small amounts. Titanium oxide is now widely used as a material for antibacterial tiles and in air-cleaning systems. When titanium oxide is coated on a glass, it shows it is superhydrophilic.

Effective cleaning is essential for the following purposes:

i. To remove materials on which foodborne pathogens might grow and spread easily through various carriers.
ii. To facilitate the effective disinfection process on the various compartments of a facility to reduce levels of foodborne pathogens.
iii. To prevent the risk of contamination/spreading of bad smell and odors, especially in the seafood and margarine industries.
iv. To promote a good image to visitors, including customers.
v. To offer a pleasant and hygienic working environment to industry workers.

56.2.2.4 Cleaning of Equipment

All equipment must be washed and rinsed. Frequent cleaning of plant equipment should be maintained at all times, and all parts should be continually washed by well-located continuous water sprays. Equipment should be cleaned as soon as possible after use, and disinfected or sterilized just before it is used again. If there is an appreciable time lag between uses, the equipment should be washed and disinfected or sterilized after use, and disinfected or sterilized again before use. The frequency will depend upon the hazard risk to the product being produced [5].

All equipment should be designed for easy cleaning. If the product is cleaned in place, the detergent used and the flow rates and angle or efficiency of the spray balls must be validated to ensure the soil is effectively removed from all areas with no blind spots. Hand cleaning depends upon operative training as well as the correct use of detergents [5]. All utensils used must be absolutely clean. Buckets, knives, and drain pans should be cleaned and rinsed whenever empty or not in use [1].

Evans [37] studied microbial contamination of food refrigeration equipment in chilled rooms in 15 plants processing a variety of foods (raw meat and salads, Chinese ready meals, dairy products, slicing and packaging of cooked meats, and catering establishments). An initial survey found microbes at a total 891 sites on evaporators, drip trays, and chilled room walls and was followed up with a more detailed examination of 336 sites with high counts, selecting for *Listeria* spp., coliforms, enterococci, *Staphylococcus aureus*, and *Bacillus cereus*. Although evaporator cleaning procedures were carried out in some factories as part of routine maintenance, these were not shown to be effective at maintaining low levels of bacteria on evaporators. To maintain evaporator hygiene, it was suggested that regular cleaning procedures, possibly by means of automated cleaning systems, should be considered [37].

Knowledge of adhering microflora on process equipment would also be valuable information in designing cleaning and disinfecting procedures, and is essential in the good hygienic practices program of food processing plants, as the development and design of improved cleaning and disinfecting procedures should target the microorganisms persisting and potentially contaminating the product. Many food pathogenic and spoilage bacteria are able to attach to food contact surfaces [38] and remain viable even after cleaning and disinfection [39]. Such adhered bacteria can detach during production and contaminated food as it passes the surfaces. Microorganisms attached to and growing on a surface are called microbial biofilms. The microbial fouling or biofouling causes problems in

the food industry. Hygienic problems in equipment are caused when microorganisms become attached to the surfaces and survive on them [40] and later become detached from them contaminating the product. Microflora adhering to the processing equipment during production and after cleaning and disinfecting procedures was identified in four different fish processing plants [41]. A total of 1009 microorganisms were isolated from various agar plates and identified. A stepwise procedure using simple phenotypic tests was used to identify the isolates and proved a fast way to group a large collection of microorganisms. *Pseudomonas*, Neisseriaceae, Enterobacteriaceae, coryneform, *Acinetobacter*, and lactic acid bacteria dominated the microflora of cold-smoked salmon plants, whereas the microflora in a plant processing semi-preserved herring consisted of *Pseudomonas*, *Alcaligenes*, and Enterobacteriaceae. *Psychrobacter*, *Staphylococcus*, and yeasts were found in a caviar processing plant. Overall, many microorganisms that are often isolated from fish were also isolated from the fish processing plants. However, some selection depending on processing parameters occurred, since halo- and osmo-tolerant organisms dominate in the caviar processing. After cleaning and disinfection, yeasts, *Pseudomonas,* Neisseriaceae, and *Alcaligenes* remained in smokehouses; yeasts and *Pseudomonas* in the herring plant; and *Pseudomonas*, *Staphylococcus*, and yeasts in the caviar plant. The dominant adhering organisms after cleaning and disinfection were pseudomonads and yeasts independently of the microflora during processing [41].

The ability of spores to adhere differed widely among strains [42]. All the members of the *B. cereus* group are surrounded by a loose balloon-like exosporium whose hydrophobic character could account for their strong adhesion to various materials such as stainless steel, polymers, and glass [43]. Transmission electron microscopy only revealed the presence of appendages [44, 45] on exosporium, but also that exosporium was made of a basal crystalline layer surrounded by a hairlike external layer whose filaments vary in length between species and strains [46]. Exosporium contains proteins, polysaccharides, lipids, and ash [47]. Some of the proteins constitutive of or associated with the exosporium were identified on *Bacillus anthracis* [48, 49] and *Bacillus cereus* spores [50]. A number of these proteins are not structural components but are closely associated with the exosporium, such as EA1 [48, 51], GroEL [48, 52], or InA [52]. Glycoproteins of high molecular weight (over 200 kDa) were identified in extracts from *B. anthracis* [49, 53], *B. thuringiensis* [54], and *B. cereus* [50, 52] spores. Only a few of the proteins and glycoproteins described in the literature have proven to be required for exosporium constitution or stability. Among the latter, BcIA is a structural component of the hairlike structure [53], while ExsFA and ExsFB are essential for the stability of the basal crystalline layer [55], and ExsA for the assembly of the coat and exosporium of *B. cereus* spores [56]. Some differences among spores from various *B. cereus* strains were previously evidenced. The most frequently reported variation is the surface energy, with *B. cereus* spores being moderately to highly hydrophobic [42, 57]. Additionally, the number and length of appendages could also differ among strains [44]. All these variations in spore surface properties could affect spore adhesion. Indeed, current theories on the mechanism by which bacteria adhere to inert surfaces suggest the importance of a cell surface's hydrophobic character [58, 59]. The presence of appendages, presumed to promote spore adhesion by overcoming the potential barrier and initiating contact with surfaces [60], was also believed to play a major role in attachment [2, 43, 61], but these results remained highly controversial [2, 45]. Last, the presence of some surface proteins and glycoproteins was known to play a major role in the adhesion of vegetative cells of various bacteria such as *Enterococcus faecalis* [62] and *Staphylococcus aureus* [63].

Tauveron et al. [64] examined seven strains of *Bacillus cereus* isolated from the environment and from patients with diarrheic symptoms. They were examined from two angles: (i) spore surface properties, and (ii) their ability to adhere to stainless steel and to resist a cleaning-in-place procedure. Their results revealed significant differences in their morphology (size of exosporium, length and number of appendages), hydrophobic character, and surface protein composition. Most of these proteins originated in the vegetative cell and were tightly bound to the external surface of the exosporium such as EAI or alanine racemase. Spore adhesion properties also varied from strain to strain. The ability to adhere was higher when spores were surrounded by long appendages, while the largest spores displayed the least resistance to cleaning. These observations suggested that food processing line contamination might be due to a given type of strain with specific surface properties (long appendages and small exosporium), which would represent an increased threat under the milder processing conditions required by consumers (minimally heat-treated foods for example) and by legal requirements (to limit effluents caused by hygiene procedures).

The dry-ice blasting technique has been widely employed in industry to clean equipment since the 1980s [65]. This process is a form of carbon dioxide cleaning at a temperature of –78.58°C in a pneumatic jet base and operates with dry-ice pellets as the single-way blast medium. The solid blast medium is environmentally responsible and no residue is left after the cleaning process since the dry ice directly sublimates when subjected to the surface of the equipment [66]. The production of the blast medium from other industrial processes is a by-product from industries such as ammonia production, oil and gas refineries, and ethanol production, therefore, no additional greenhouse gases to the atmosphere. This type of cleaning media is approved by the U.S. Environmental Protection Agency (EPA), U.S. Food and Drug Administration (FDA), and U.S. Department of Agriculture (USDA). This technique is also used as a preservative since it leaves behind no toxic residues in food. Moreover, carbon dioxide can act as a refrigerant in modified atmosphere packaging during transport and storage. Further, it inhibits bacterial growth as the dry ice sublimates by displacing the oxygen required by aerobic organisms and lowering the pH of food to bacteriostatic levels by forming carbonic acid [67]. Witte et al. [68] investigated the disinfection potential of dry-ice blasting and parameters

influencing cleaning efficacy. This method proved to remove bacterial cells to a similar extent from several surfaces and components of dairy production equipment, occasionally with a slight abrasive effect. The bacterial removal rate was less than 5 $\log_{10}$ units, therefore, they did not recommend dry-ice blasting as a disinfection method, but it can be used as an efficient cleaning comparable to other conventional methods. In general, dry-ice blasting is regarded as being environmentally friendly and requires less energy and less water [69].

56.2.2.5 Hygiene Monitoring

The evaluation of the effectiveness of a sanitation program may be carried out in several ways: visual inspection, swabbing, and microbiological analysis, contact plates, or ATP (adenosine triphosphate) bioluminescence [30]. Traditional hygiene monitoring using culturing techniques creates a number of difficulties, including it is laborious and time-consuming. Estimation of the total colony count may take 24–48 h. If it is necessary to detect or estimate the presence of specific microorganisms, 4–7 days may elapse before a result is obtained. Results need to be generated sufficiently quickly to take remedial action or to prevent contaminated surfaces from being reused [30]. The technique of ATP bioluminescent involves taking a sample by swabbing a surface and then processing the swab. More details are given by Hawronskyi and Holah [30] and Griffith et al. [70]. These methods can be divided into three different types: cuvette-based, pen-based, and swab-based. The speed of this method enables remedial action to be taken in the case of poorly cleaned equipment. The disadvantages are that (i) it cannot currently give any indication of the presence or absence of pathogens, only a total level of ATP contamination on a surface; (ii) the presence of detergents or other chemicals may interfere with bioluminescent reaction; and (iii) it is expensive compared to the low-cost conventional culture techniques [30].

56.3 CONCLUSION

Hygienic and sanitary design of a food facility is essential during construction and renovation to ensure effective hygienic operations. A functioning sanitary design begins with the selection of a best-suited site that is free of environmental hazards such as polluted air, pests, and foodborne pathogens. An appropriate site planning with effective sanitary principles, such as having raw material and final product storage, and a proper drainage system and waste disposal, can reduce contamination from the environment. All other aspects of sanitary design and operations such as equipment design, good manufacturing practice (GMP), HACCP, personal hygiene and food handling, cleaning of the factory facility, cleaning of equipment, and hygienic monitoring must be followed thoroughly to offer a hygienic environment and ensure food safety. However, it is essential to install a hygienic flow diagram through the production and processing lines that facilitates the safe production of a final product by preventing contact with raw materials and unprocessed items.

57 Hazard Analysis and Critical Control Point (HACCP)

Titus De Silva

CONTENTS

57.1 BACKGROUND

57.1.1 Need for an Effective Food Safety Assurance System

Food safety has been of concern since the Middle Ages, and regulatory measures have been enforced to prevent the sale of adulterated or contaminated food. Many rules and recommendations advocated in religions or historical texts are evidence of a concern to protect people against foodborne diseases and food adulteration. Motarjemi et al. [1] summarized the present concern and emphasized the need for an effective food safety program [1].

Technological progress in food processing has brought about greater awareness of problems associated with food preservation. With the expansion of global food trade, food safety has become a worldwide issue. According to the World Health Organization (WHO), "thousands of millions" of cases of foodborne illnesses occur every year and two million children die each year from diarrhea. These cases relate to the microbiological contaminants only, and when chemical and physical contaminants are taken into consideration, the number of cases is much higher [2].

International food trade contributes to the spread of foodborne illnesses in five ways [2]: (i) new threats arise as a result of the introduction of pathogens and contaminants from one country to another, (ii) pathogens that have been controlled in one country can be reintroduced in another country where they have not been controlled, (iii) transportation over long distances and long periods of time provides ample opportunities for contamination and growth of microorganisms, (iv) contaminant food can reach more people resulting in major outbreaks of disease, and (v) the history of the food product may be unknown by the importing country when trans-shipping of food through one or more countries takes place. International and national organizations have enforced laws and regulations to achieve quality and safety in food preparation and preservation in order to safeguard the consumer from foodborne infections and intoxication.

57.1.2 The Development of HACCP

The principles of the Hazard Analysis and Critical Control Point (HACCP) technique were applied to the chemical

processing industry, particularly in Great Britain, more than 40 years ago [3]. The Pillsbury Company, together with NASA and the US Army's Research, Development and Engineering Center at Natick, first developed this system to ensure the safety of astronauts' food [1, 4, 5]. Since then the HACCP system has grown to become a universally recognized and accepted method for food safety assurance. The World Health Organization (WHO) has recognized the importance of the HACCP system for prevention of foodborne diseases for over 20 years and has played an important role in its development and promotion. One of the highlights in the history of the HACCP system was when in 1993 the Codex Guidelines for the Application of the HACCP system were adopted by the FAO/WHO Codex Alimentarius Commission, requiring them for international trade [6]. In the United States, large chemical industries have also adopted hazard control programs. The U.S. Occupational Safety and Health Administration (OSHA) introduced the HACCP technique to reduce accidents.

57.1.3 Benefits of HACCP

Lack of food safety systems costs the food industry millions of dollars annually through waste, reprocessing, recalls, and resulting losses of sales. Foodborne diseases are no longer limited to developing countries. In the United States, the Centers for Disease Control and Prevention (CDC) report that foodborne diseases account for 76 million illnesses, 325,000 hospitalizations, and 5000 deaths each year. According to the World Health Organization, the cost of just five foodborne diseases in England and Wales was estimated at £300–700 million in 1996 [2].

It is now recognized internationally that the most cost-effective approach to food safety is through the application of the HACCP technique. By adopting an effective food safety system based on HACCP, the industry can minimize the potential for things to go wrong and ensure the safety of food products. HACCP is entirely complementary and adds essential safety elements to existing processing systems such as Good Manufacturing Practices and ISO 9000 standards. Food producers as well as retailers and consumers will benefit as a result of an effective HACCP program. The benefits of the HACCP system are summarized in Table 57.1 [1].

57.2 TERMINOLOGY

The terms, such as hazard, severity, risk, and hazard analysis, that are important to the HACCP concept are defined in Table 57.2. It is important to understand the terminology first before applying HACCP in food systems.

57.3 MANAGEMENT COMMITMENT

The design and implementation of a HACCP system is the responsibility of the HACCP team. But the senior management must be aware of the fundamental requirements of the food safety program so that they can commit the necessary resources and have a positive approach to the project. Its role then is to influence the project's success by creating a "buy-in" from every member of the organization. In the absence of total commitment from the senior managers, the organization runs the risk of failure at a critical point [7]. The senior management must acknowledge that a HACCP program is a comprehensive tool that helps everyone in the organization to maintain a safe food production and serving environment. As with a QMS, the food safety program involves suppliers, staff, and customers. In addition, the organization has to comply with regulatory requirements. Therefore, support from the senior management team, regulatory bodies, training institutions, and the industry are all essential in designing an effective food safety program. The suppliers can support the organization's commitment by recommending equipment and procedures that will assist in realizing the long-term food safety goals [8].

57.4 PREREQUISITE PROGRAMS

Prerequisite programs are an essential part of the HACCP program. It is not possible to implement a HACCP program without the prerequisite programs in place. These provide the basic environment and operating conditions that ensure the production and delivery of safe food. The National Advisory Committee for the Microbiological Criteria for Foods [9] has recommended the prerequisite programs shown in Table 57.3 as a foundation for an effective HACCP system in the organization.

Other prerequisite programs might include (i) quality assurance procedures, (ii) product formulations, (iii) glass control,

TABLE 57.1
Benefits of the HACCP System

Ensures safety of food products through preventive measures rather than through final inspection and testing
Capable of identifying all potential hazards
Easy to introduce technological advances in equipment design and processing procedures related to food products
Directs resources to the most critical part of the food-processing system
Encourages confidence in food products by improving the relationships among regulatory bodies, food processors, and the consumer
Promotes continuous improvement of the system through regular audits
Focus on safety issues in the whole chain from "farm to fork"
Complements the quality management system (e.g., ISO 9000)

TABLE 57.2
Terminologies Related to HACCP

Term	Definition
Hazard	A biological, chemical, or physical or other property in a food product that has the potential to harm the consumer or cause illness. It can occur in the ingredients or at any stage in the life of a product. The term can thus be applied to foreign material, chemical residues, and/or microbiological contamination.
Severity	The seriousness or consequence of exposure to the hazard.
Risk	The estimate of the probability of a hazard occurring.
Hazard Analysis	The identification of biological, chemical, or physical and/or other hazards associated with ingredients, production practices, processing, storage, distribution, retailing, and use.
Critical control point (CCP)	An operational step in a manufacturing process that results in injury or risk to consumer if not controlled. At critical control points, controlling measures can be exercised to eliminate or minimize any form of hazard.
Control point	An operational step in a manufacturing and distribution process that may be controlled in order to maintain quality and meet regulatory requirements.
HACCP plan	A document that sets out the procedures based on the principles of HACCP to be followed to assure food safety.
Hazard Analysis and Critical Control Point (HACCP)	A scientific, rational, and systemic approach to identification, assessment, and control of hazards during production, processing, manufacturing, preparation, and use of food to ensure that it is safe when consumed. The HACCP system provides a preventive and thus a cost-effective approach to food safety.
HACCP system	The organizational structure, procedures, processes, and resources needed to implement the HACCP plan.
Critical limit	One or more prescribed tolerances that must be met to ensure that a CCP effectively controls a health hazard.
Sensitive ingredient	An ingredient known to have been associated with a hazard and about which there is a concern.
Validation	A review of the HACCP plan to ensure that all elements of the plan are accurate and correct.
Verification	The use of methods, procedures, and/or tests to ensure that the requirements of the HACCP system have been fulfilled.

TABLE 57.3
Prerequisite Programs

	Prerequisite Program	Scope
1	Facilities and premises	Suitability of production environment including buildings, pathways, drainage, waste management, etc. Provision of adequate space for manufacture, storage, cooling, and refrigeration Provision of ventilation, water supply, and lighting facilities for personnel
2	Supplier control	Program for the approval of suppliers Effective GMP and food safety programs
3	Specifications	Written specifications for all ingredients, packaging, and processes
4	Equipment	Calibration of equipment Preventive maintenance according to an established schedule
5	Cleaning and sanitation	Validation of sanitation methods Availability of documented procedures Regular cleaning and sanitation of equipment
6	Personnel hygiene	Establish a personnel hygiene policy Ensure that all employees follow the required personnel hygiene policy
7	Training	Management of training records in personnel hygiene, GMP, cleaning, sanitation procedures, personnel safety, and their role in the HACCP program
8	Management of chemicals	Proper and safe storage and segregation of food and non-food chemicals
9	Receiving, storage, and transport	Storage of all raw materials and products under sanitary conditions Maintaining appropriate environmental conditions for storage
10	Traceability and recall	Batch coding of all raw materials and products Establish an effective recall procedure
11	Pest control	An effective pest control program

(iv) labeling, and (v) employee food and ingredient handling practices. An HACCP program ensures that the food is safe to consume, and the integration of the prerequisite programs provides assurance that food is safe as well as wholesome. The prerequisite programs have to be regularly audited and reviewed just like any other management program. While these programs can be managed separately from the HACCP program, some aspects such as recall procedure, preventive

maintenance, sanitation, and hygiene may be incorporated into the HACCP plan.

57.5 THE SCOPE OF THE HACCP PROGRAM

In the early years following the introduction of HACCP, concern was focused on microbiological integrity. The basic philosophy was to examine the food ingredients as they are processed until consumption of the finished product. Aggressive competition required organizations to reduce costs while maintaining quality. Increasing consumer awareness and legal liability to produce safe food forced organizations to adopt a broad view of the food safety program. There were other significant changes. Changes in process technology, increased automation, complex packaging solutions, new ingredients and improved formulations, greater emphasis on sensory evaluations, and complex distribution networks leading to reduced delivery times had a major impact on food safety requirements.

The generic requirements of food safety were stipulated in the Codex Alimentarius which is a collection of food standards adopted by the Codex Alimentarius Commission [10]. The HACCP program incorporates the general principles of food hygiene as well as appropriate commodity standards. In 1998, the British Retail Consortium (BRC) developed and introduced the BRC Technical Standards and Protocols for supplying retailer branded food products. Although it was originally developed primarily for the supply of retailer branded products, in recent years it has been used as a basis for developing HACCP programs. It incorporates the management system of ISO 9000, principles of Codex Alimentarius, and Good Manufacturing Practices (GMP) [11]. Thus, a complete HACCP program includes (i) HACCP principles, (ii) management principles, (iii) plant environment standards, (iv) process and product control, and (v) personnel hygiene.

57.6 THE SEVEN PRINCIPLES

The seven principles of HACCP were formulated by the National Advisory Committee on Microbiological Criteria for foods (NACMF) in 1987 [12]. They are now widely accepted as the standard for developing a food safety program.

1. Analyze the hazards and assess the risks.
1. Identify the CCPs.
3. Define critical limits for each CCP.
4. Establish controls to monitor the CCPs.
5. Establish corrective actions.
6. Define record keeping and documentation requirements.
7. Establish verification procedures.

These seven principles form the framework of the HACCP program, and these will be described in the sections that follow. In the future, it is possible that three more principles will be added [13] to the seven already in place: (i) summary and interpretation of each HACCP system (this review briefly summarizes the system, indicates any remaining hazards, and assesses the risks of occurrence), (ii) education and training, and (iii) validation.

57.7 DEVELOPMENT OF THE HACCP PLAN

The development of the HACCP plan goes through four distinct stages. Table 57.4 shows the key tasks associated with each stage. These tasks are applicable to any food processing operation regardless of the size. The program evolves as the HACCP team works through these stages [14]. It is a good idea to carry out a HACCP study for each new product in each plant. Hazard analysis critically examines the quality of all ingredients, processing steps, and the product itself. The CCPs can be identified by analyzing the hazards in each processing step. The HACCP plan is managed by regular monitoring and reviewing of the system through the implementation of corrective action when necessary.

57.7.1 The Team

The HACCP study begins with the selection of a team consisting of members drawn from various disciplines in the food-processing operation. The success of the HACCP program depends on the constitution of the HACCP team [15]. The selection of the team is an important step in the development of the HACCP program. It is not a management team, but a team drawn from all levels depending upon the expertise and experience required. All of the key functions of the organization should be represented in the team, and it may include a project leader, a production manager, a technical expert, an engineer, a secretary, and others as required. Once the team is formed the members will require further training on HACCP principles, and the members should be provided with the necessary tools to perform the tasks. Its objectives [16] will be to (i) define the type of food produced by the organization, (ii) identify how food product ingredients are received, (iii)

TABLE 57.4
Development of the HACCP Plan

Stage	Key Tasks
1	1 Assemble the team
	2 Train the staff
	3 Describe the product and intended use
2	4 Draw the flow diagram
	5 Analyze the hazards (Principle 1)
	6 Establish the CCPs (Principle 2)
	7 Define critical limits (Principle 3)
	8 Establish monitoring methods (Principle 4)
	9 Establish corrective actions (Principle 5)
3	10 Define verification methods (Principle 6)
	11 Establish documentation and record keeping requirements (Principle 7)
	12 Validate the HACCP plan
4	13 Review and improve the program

TABLE 57.5
Responsibilities of HACCP Team Members

Team Member	Responsibility
Project leader	Convenes and chairs meetings
Production manager	Constructs flow charts
	Advises on production issues and process capability
Technical expert	Advises on technical issues
	Identifies hazards and recommends solutions
Engineer	Supplies information on performance of equipment and machinery
	Makes recommendations on new machinery, equipment, or processes that may be required
Secretary	Records proceedings of meetings
Others (as required)	Provide information on specialist areas

define the processes and their controls, (iv) identify how the food is stored and distributed, and (v) identify the hazards and the CCPs. In the absence of in-house expertise, it may be necessary to seek the advice of external consultants. The team leader or coordinator has a significant impact on the outcome of the program, and he/she is responsible for assigning various tasks to the members of the team. The responsibilities of the team are summarized in Table 57.5.

57.7.2 Training

HACCP training has now been accepted as the most cost-effective means of controlling hazards related to microbiological, physical, and chemical contamination of foods. The implementation of the HACCP plan is a team exercise. Training and education are essential if the full benefits are to be achieved [17]. Food producers have the responsibility to produce safe food, and the regulatory bodies need to be competent in monitoring the HACCP programs.

HACCP training should provide (i) knowledge of concepts, principles, and benefits of the HACCP program, (ii) practical skills and knowledge necessary for the implementation of the HACCP program, and (iii) the skills needed for further development of the HACCP program. Regulatory authorities, senior managers, shop floor personnel, and technical managers should be involved in the HACCP training program. The training program itself should target the needs of each of the above groups. For example, regulatory authorities need to have knowledge of the concepts, principles, and benefits of the HACCP programs, and shop floor personnel need to have practical skills. Scientific data should be used to support the training progress. Software on HACCP programs is now available, and the material presented in such programs can be an essential tool for training.

57.7.3 Product Description and Intended Use

The HACCP team needs to have a complete understanding of the product, its intended use, the ingredients used, the composition of the product, and the processing steps. It is necessary to have this information before the analysis of hazards because the food products have to be assessed in relation to the ability of different pathogens to grow. The product description [18] should include (i) name of the product, (ii) end-product features (e.g. pH, preservatives, etc.), (iii) how the product is to be used (i.e. ready-to-eat, further processing, heated prior to consumption), (iv) packaging details (e.g. packaging materials and packaging conditions), (v) shelf-life, (vi) distribution outlets, (vii) labeling instructions, (viii) shipping conditions, and (ix) target consumer group. An example of a product description is shown in Table 57.6.

TABLE 57.6
Product Description of Country Medium Wine

Product Feature	Description
1. Product name	Country Medium Wine
2. Product features	Alcohol 12%v/v, pH, preservatives, SO_2
3. How the product is to be used	Cool before serving
4. Packaging	3-liter plastic bags of special composition which prevent the entry of O_2
5. Shelf life	9 months from the date of packing
6. Distribution outlets	Retail shops
7. Labeling	Alcohol content, preservatives, storage conditions, and the number of standard drinks
8. Shipping conditions	No physical damage or extremes of temperature
9. Target consumer group	None

TABLE 57.7
List of Raw Materials Used in the Production of Wine

Primary Ingredients	Chemicals	Packaging Materials	Non-Contact Packaging
Grapes	See attached list (attach list of chemicals used)	Bottles, glass	Cases, corrugated board
		Bottles, plastic	Labels
		3-liter bags	Muselets
		Metal caps	Shrouds
		Plastic caps	Capsules, PVC
		Corks	Sections, corrugated board

The product ingredients include raw materials, processing aids, and packaging material. Regulatory requirements have to be checked to ensure that the additives and preservatives are permissible and are within specified limits. An example of a list of ingredients and packaging materials is shown in Table 57.7.

The team has to gather further information on processing steps and the formulations used in the production of food. A checklist may include but is not limited to the following: (i) possibility of contamination during preparation and storage, (ii) inactivation of microorganisms and toxins and the possibility of microbiological, chemical, and physical contamination during processing, (iii) pH, water activity (a_w), and/or reduction/oxidation potential, (iv) possibility of the presence of microorganisms in raw materials and packaging, (v) basis of process technology, and (vi) effect of packaging on the survival and/or the growth of microorganisms.

57.7.4 Flow Diagram

A food-processing operation is a continuous process of flow of food ingredients from "farm to fork" (growing, harvesting, receiving, storage, processing, packaging, transportation, and service). A flow diagram breaks up the process into a series of sequential steps that assist further evaluation. It typically commences at the point where the food is received at the operation. Thus, the steps in the flow diagram typically include the entry of ingredients, all processing steps, packaging, storage, distribution, and handling by the consumer. In a simple flow diagram, the process steps are shown inside boxes with arrows indicating the entry and exit points.

In a large food production operation, it is not possible to draw flow diagrams for each of the recipes. However they could be grouped according to the method of processing, for example, baking, cooking, chilling, steaming, cold preparations, etc. Yet another approach is to group recipes according to the category of food—thin cooking, thick cooking, sauces and brews, fruits and vegetables, starches, breads and batter, cold combinations, and hot combinations. In such instances, a single flow diagram would be adequate for each food category [19]. Figures 57.1 and 57.2 show the flow diagrams for the production of chicken and vegetable salad and hot smoked salmon, respectively.

57.7.5 Types of Hazards

Hazards in food processing can be classified into three types: Biological, chemical, and physical.

57.7.5.1 Biological Hazards

Biological hazards are associated with microbiological organisms such as bacteria, viruses, fungi, and parasites. Most foodborne illnesses are caused by pathogenic bacteria, and a certain level of microorganisms occurs in some raw foods. Viruses can be foodborne/waterborne or transmitted by human, animal, or other contact. They survive on living cells and therefore cannot replicate in food but can be carried by it. Parasites are host-specific but can include humans in their life cycle. They occur in undercooked meat products or contaminated ready-to-eat food. Fungi include molds and yeasts, and some produce mycotoxins which are toxic for humans and animals. The survival and the growth of microorganisms depend upon several factors: (i) inadequate time–temperature combination during heat treatment, (ii) slow acid production during fermentation, (iii) holding foods between 7 and 65°C because of processing delays, (iv) storage of foods for long periods at refrigerated temperatures, (v) high water activity (a_w), and (vi) low levels of chemical preservatives

57.7.5.2 Chemical Hazards

Chemicals are used in food products, such as pesticides during the growing stage or as food additives during formulation and processing stages. Types and concentration levels of chemicals are important for safety aspects. Some examples of hazardous chemicals are heavy metals such as lead, tin, cadmium, copper, and mercury; food additives such as certain preservatives, colorings, and conditioners; and others such as solvents, cleaning agents, paints, and additives.

57.7.5.3 Physical Hazards

Physical hazards are caused by foreign matter that can enter into a food product at any stage from the processing of raw materials to the consumption of the finished product. Foreign matter may be visible to the naked eye or may be dissolved or dispersed in the food product. The physical form of the foreign matter can vary from powder to particulate matter, depending upon its type and origin. The detection of foreign matter in a food product is not easy because of the variability and

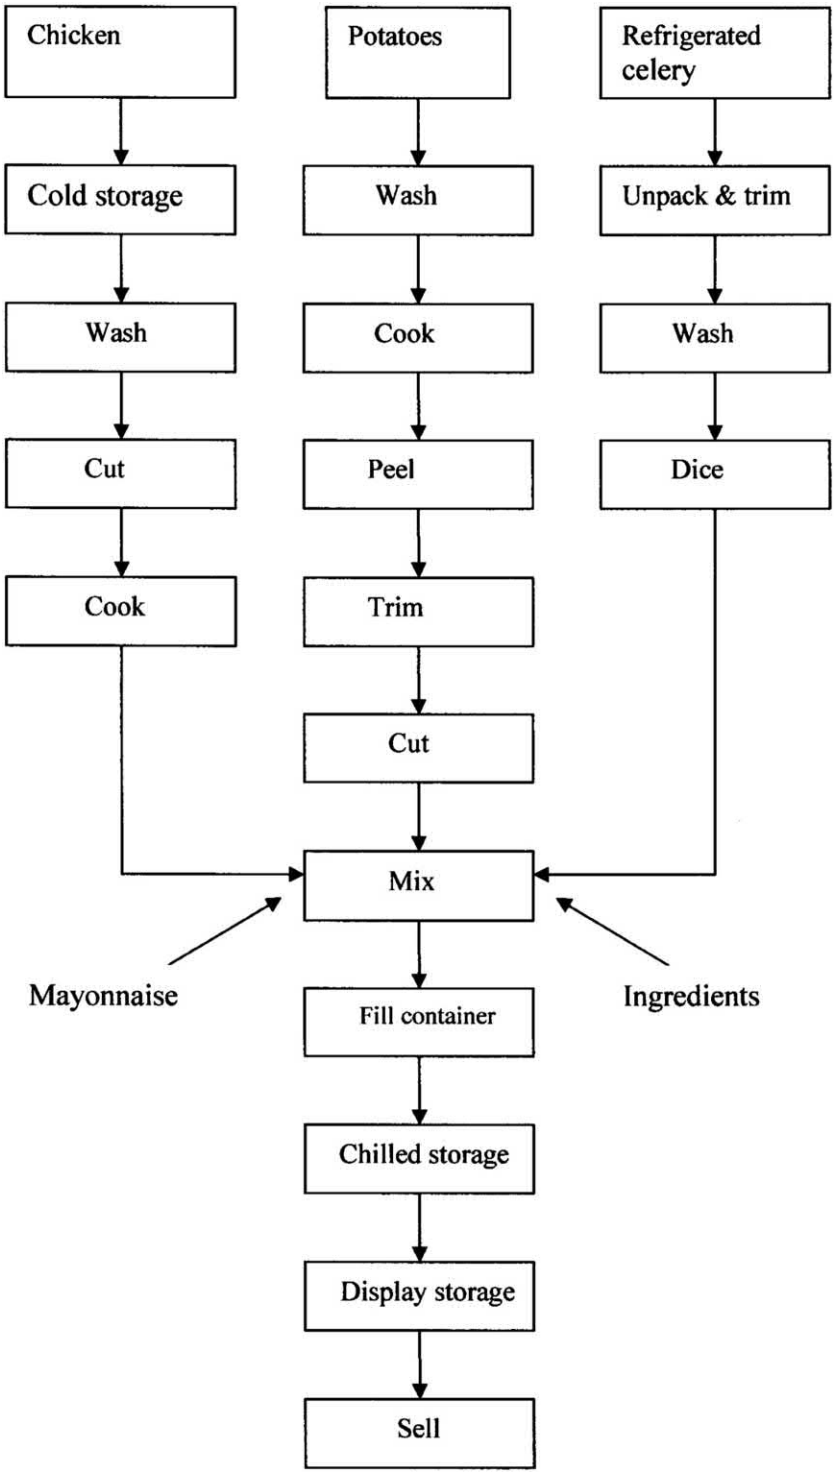

FIGURE 57.1 Flow diagram for the production of chicken and vegetable salad.

infrequent occurrence. Some of the common types of foreign matter associated with physical hazards in food are insects, spiders, worms, etc. (although these organisms are nonhazardous in themselves, they may carry pathogenic microorganisms), parts of animals, birds, metals, machine parts, glass pieces, plastic objects, sand, stones, dirt, cigarette butts, and plastic dressing strips.

57.7.6 Sources of Hazards

57.7.6.1 Raw Materials

Raw materials are the primary source of contamination. Failure to follow basic quality assurance procedures on raw materials may lead to food products that are unsafe for consumption. The common quality assurance procedures carried

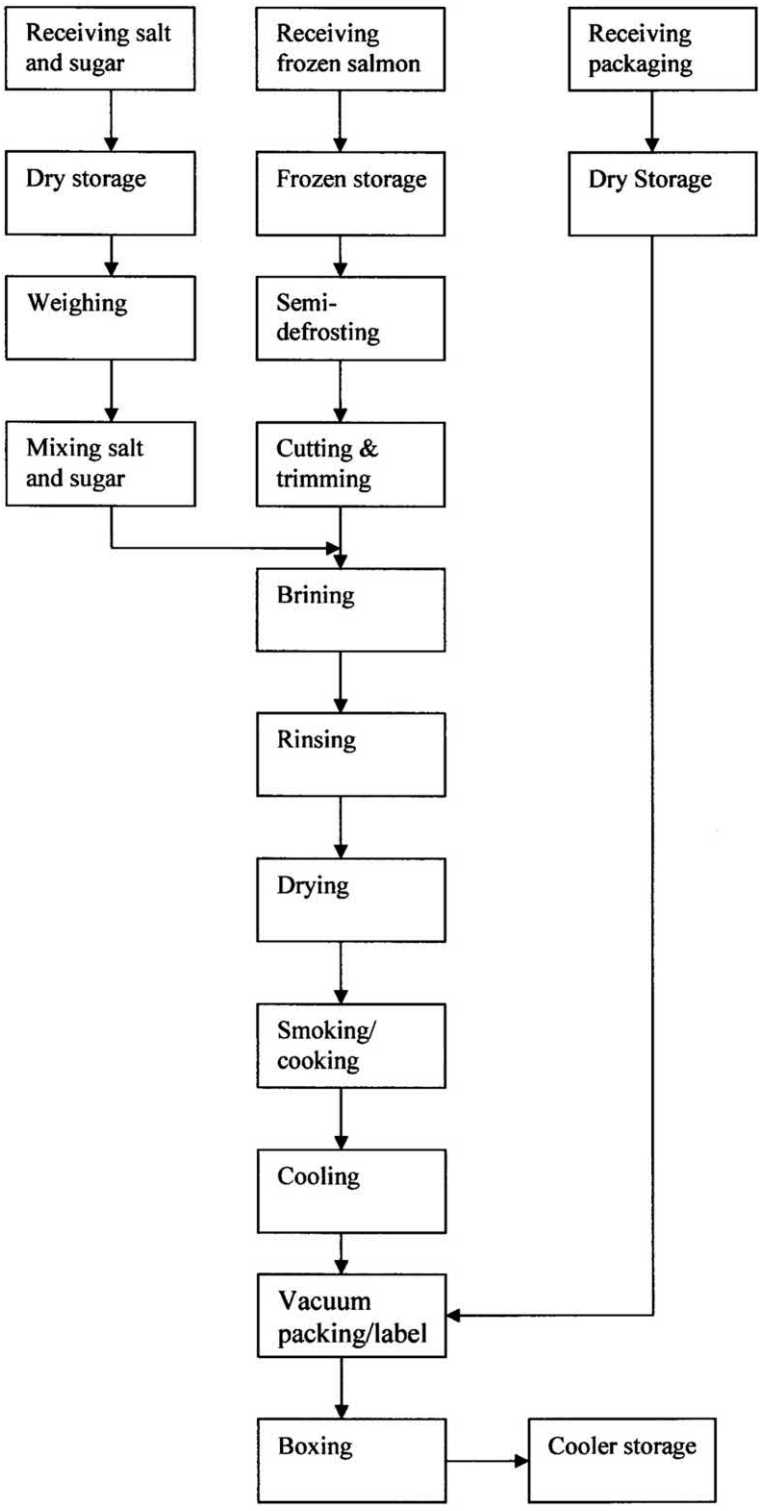

FIGURE 57.2 Flow diagram for the production of vacuum-packed hot smoked salmon.

out on raw materials are related to (i) identification and labeling, (ii) storage conditions, (iii) handling requirements, (iv) preparation and processing, and (v) isolation of unsuitable raw materials. The raw materials that are most likely to cause microbial hazards are meat, poultry, fish, and dairy products. The level of microbial contamination depends upon (i) the source, (ii) the refining and handling process, (iii) the packaging material, and (iv) the storage conditions [20].

The HACCP technique has been closely associated with the protection of the consumer from microbiological hazards. Such a narrow focus has been criticized on the grounds that microbiological hazards account for only one type of hazard

[21]. Raw materials may carry traces of chemicals and foreign matter. Heavy metals such as lead, arsenic, mercury, tin, and cadmium are thought to be of greatest health concern. They occur in vegetables grown in contaminated soils. Packaging materials such as lead capsules in wine bottles and solder from the side seams of cans are potential sources of contamination. Adhesives, coatings, and resins used in packages may cause health hazards unless they comply with the health and safety requirements [22]. Seam defects in cans and seal defects in other packaging designs can lead to microbial contamination.

Cleaning chemicals, solvents, lubricants, and dirty or incompletely washed bottles may contaminate food products. Excessive amounts of sulfur dioxide used in the sterilization process prior to filling bottles result in high levels of sulfur dioxide in the food product (e.g., high sulfur dioxide levels in wine). Preservatives, colorings, flavors, and conditioners are common additives used in food processing, and excessive amounts of these can be harmful. The permissible levels of food additives are governed by the food regulations in each country. Fruits and vegetables sprayed with pesticides can retain high levels of pesticide residues unless the applications are carefully monitored. Foreign objects such as stones and insect parts may also be found in fruits and vegetables. An unhygienic working environment can promote contamination with rodent bait, insecticides, insects, etc. Other sources of chemical and foreign body contamination include glass fragments from broken light fittings and thermometers, stones and particles of wood in sun-dried fruits, herbs, and spices, and accidental contamination with cleaning chemicals or other toxic non-food substances [23].

57.7.6.2 Processing Steps

Uncontrolled processing operations can lead to hazardous situations. Failure to maintain processing conditions such as temperature/time, delay in processing, using incorrect formulations and procedures, and following unauthorized processing techniques may all result in contamination and/or microbial growth. Mercury thermometers in the processing area can be a potential hazard, and most industries prohibit the use of such thermometers in their factories. Poor cleaning practices may leave excess cleaning chemical residues on plant and equipment.

57.7.6.3 Machinery

Unclean and unhygienic equipment can easily promote the growth of microorganisms or other hazards. Failure to maintain the sterility of equipment when it is required results in microbial contamination. Proper setting up of equipment should also be followed. Glass bottles can get chipped at the filler or capping machine if the machines are not properly set up. Imperfectly made containers can also contaminate the food with the material of the container. Metal pieces from meshes or metal parts and nuts and bolts can easily get mixed with the food product if the machines are not regularly maintained. Badly designed or modified plant and equipment can promote the growth of microorganisms in dead-ends of pipework or dirt-traps.

Preventive maintenance of machinery is an important aspect of a safety-management program. If safety requirements are ignored, the layout of machinery and equipment can be a potential hazard. The machinery should be examined at intervals to ensure safe operation. Any change in engineering should be such that it is not hazardous.

57.7.6.4 Handling of Food

With the introduction of highly automated, high-speed machinery, vast volumes of food products are processed, stored, and transported to distribution centers and retail chains. Therefore, food safety depends upon processing characteristics as well as handling during transport, storage, and customer use. Hazards may develop due to inadequate temperature control during storage, transportation, retail handling, and home storage. Products such as chilled/frozen entrees and meal components are preserved by refrigeration. Hazards could be developed if these products are stored at higher temperatures or used beyond their recommended shelf life [24].

Failure to rotate stocks of dated products can result in outdated products reaching the consumer. Abuse by the customer is possible in the absence of clear storage or preparation instructions. Lack of knowledge about handling, cooking, and storage of foods increases the risk of hazard occurrence. Personal hygiene is extremely important in any food-serving establishment. If adequate precautions are not taken, food handlers can transmit pathogenic bacteria. Personal articles such as jewelry can get mixed with foods during preparation.

57.7.6.5 Environmental Conditions

Hazards due to environmental conditions may affect raw materials, processing, and machinery. Pollution of water and soil can have alarming results through the food chain. Through regulatory requirements, most countries monitor and control the disposal of domestic and industrial wastes to prevent the entry of hazardous materials and rodents into the food production environment. Environmental contamination may also be due to foreign matter, chemicals such as sprays, and contaminants in water.

57.7.7 Some Measures for Controlling Hazards

57.7.7.1 Measures at the Processing and Packaging Stages

57.7.7.1.1 Raw Materials

In a food-processing environment, raw materials constitute one of the most important areas that must be carefully controlled. The food producer has no direct control over the quality of incoming raw materials. Until adequate control can be established over the entire range of raw materials to prevent the entry of or eliminate harmful or potentially harmful organisms and residues, constant vigilance must be maintained. This is particularly true of "sensitive ingredients"—those ingredients that have been historically associated with a known hazard, such as eggs, fish, milk, cheese,

TABLE 57.8
Processing Methods to Control Microorganisms in Raw Materials and Packaging

Method	Control Parameter
Heat treatment	Time, temperature, humidity
Filtration	Pore size, filter integrity
Irradiation	Dosage and density of load
Chemical	Concentration, pH, temperature

shellfish, etc. The processes used to remove or destroy microorganisms in raw materials and packaging are shown in Table 57.8 [20]. Some of the controls that can be established in order to ensure that incoming raw materials do not cause a health hazard are summarized in Table 57.9.

Packaging materials can also be a source of health hazards since most users are unaware of the materials used. Controls can be established by specifying the recommended types of packaging materials. Bulk containers that are used to transport food products should have a cleaning program in place, which should be audited. Only permissible products should be transported in bulk containers that are used to carry food products. Other controls include tamper-proof seals, inspection of samples on delivery, and maintaining appropriate storage conditions.

57.7.7.1.2 Processing Steps

A wide variety of methods can be employed to control the hazards that may be encountered during the processing operations. The type of control mechanism depends upon the processing method or methods employed in the plant. Temperature and pressure recorders are common in most food-processing systems. With advances in electronic technology, thermometers are not often used, and if they are employed, mercury thermometers should be avoided. Control charts, log sheets, and other records can be employed to monitor the temperature and pressure in a processing environment. Batch records should clearly state the type and quantities of ingredients used in production. Products that require a use-by date should be controlled at the source. All products including the ingredients used should have batch number or a lot number to enable traceability. Finished products should be maintained at the specified temperature, and products held under quarantine should be clearly labeled to prevent them from being dispatched. Operating storage tanks at positive pressure can create problems of cross-contamination between liquid and gas lines. Such cross-contamination can be avoided by using nonreturn valves at appropriate locations. Changes made in a process should be controlled through a change control procedure, which should include a reassessment of the hazards and CCPs.

57.7.7.1.3 Plant and Machinery

Hazards due to the plant and machinery can be controlled by the development and maintenance of physical equipment and accessories used to manufacture a food product. It is necessary to thoroughly clean and sterilize all equipment and utensils before and after processing. It is also important to recognize the significance of HACCP principles in planning and the layout of engineering equipment. A hazard control program requires that every production line in the plant be correctly laid out showing the operation and interrelation of all machinery and equipment. A preventive maintenance program should be in place that indicates the frequency at which equipment should be checked. When a change in machinery or machine settings occurs, the hazards must be reassessed. Critical measuring equipment such as thermometers, weighing scales, etc. should be calibrated by organizations authorized by the national bodies to do so, so that the measurements can be traced to a national standard. Line lubricants, grease, and chemicals used for cleaning of equipment should be recognized as safe and should be purchased from an approved supplier. The operators are the closest to the machinery, and they should be adequately trained to identify potential hazards. Unusual observations should be immediately investigated.

57.7.7.1.4 Storage and Distribution

Hazards due to storage, dispatch, and distribution are associated with storage conditions, stock rotation, and physical

TABLE 57.9
Control of Incoming Raw Materials to Ensure Safety

1. Be highly selective of sources and suppliers of materials and their ability to produce and deliver a safe product consistently by implementing an approved supplier policy.
2. Establish specifications for raw materials taking into consideration those characteristics that are critical to quality and safety.
3. Avoid using the cheapest price as the sole criterion for purchase. Relate the price to risk assessment.
4. Review any new ingredients introduced into the system. Instruct the supplier to inform you of any changed characteristics of the raw material, since even minor changes may affect the final quality.
5. Carry out periodic audits at the supplier's premises.
6. Instruct the supplier to have a HACCP and a QA program in place. Provide encouragement and support if necessary. Developing a partnership can be mutually beneficial.
7. Inform the supplier to label the raw materials accurately and provide assurance in the form of compliance certificate when they are delivered.
8. Carry out periodic tests on raw materials on a random basis on delivery.
9. Monitor storage conditions of raw materials both at the supplier and the producer.
10. Encourage the raw material suppliers to develop safe packaging of ingredients.

locations. All purchased products should be handled and stored in a manner to ensure protection, preservation, and freedom from contamination, pests, etc. Specific storage conditions can be monitored by the use of temperature/time records, while the physical location can be observed for cleanliness and freedom from vermin and dirt. Schedules for cleaning and vermin control programs should be in place and monitored in the storage area. Products released for dispatch should be physically located away from the quarantine area. The use of status stickers such as HOLD, QUARANTINE, REJECT, and PASSED will prevent substandard products from being dispatched. Electronic records should clearly indicate the status of finished goods in the storage area, and provision must be made to ensure that only released products are available for distribution to customers. The design of food storage areas should take into account access to goods, personnel, and forklifts, ease of cleaning, drainage, lighting, and ventilation.

Refrigerated foods such as sous vide and other chilled foods have gained popularity worldwide. These foods are more susceptible to mishandling than frozen or shelf-stable products and therefore need to be managed carefully. Training of personnel in the safe handling of food during transport, monitoring temperature/time records in refrigerated trucks, maintaining cleanliness and hygiene, and correct delivery procedure are some of the controls that can be exercised to reduce or eliminate the hazards due to transport and storage. Routine inspection and audits can be used to monitor the effectiveness of the storage, dispatch, and distribution system.

57.7.7.1.5 Premises

Control methods that can be used to prevent the occurrence of hazards and for safe operation within the premises of the food production area depend upon the proper design and layout of processing areas. Several control measures can be employed to prevent potential hazards: (i) pest control program in the plant, (ii) a scheduled maintenance program, (iii) regular inspection of vents and overhead pipes, (iv) use of guarded light fittings, (v) filtered air supply in the processing area, (vi) temperature/time records in manufacturing and storage areas, (vii) regular cleaning program for walls, floors, and ceiling, (viii) monitoring the quality of water supply and its temperature when used for sterilizing/ sanitizing of equipment, and (ix) waste disposal program to prevent the entry of rodents and pests. Health and safety regulations also provide some measures of controls over the hazards that originate in a food-processing facility. Regular audits should be carried out to ensure that health and safety regulations are observed.

57.7.7.1.6 Personnel

An HACCP program should take into account the hazards due to poor handling of food in a production facility and at food serving stations. In catering facilities and chilled and frozen food premises, poor physical health and lack of personal hygiene of staff represent a major risk [25]. Food handlers can be a major source of pathogenic bacteria. Incidences have been noted where personal articles such as pens, paper, jewelry, metal items, cigarette butts, and chewing gum have been incorporated into food products. Entry of these hazards can be controlled by introducing a policy covering prohibition of smoking, chewing gum, and wearing jewelry, maintaining personal hygiene, use of clean uniforms, monitoring illnesses, and regular medical care, and regular audits to monitor the effectiveness of documented procedures for handling food. All garments should be clean and free of soil. Freshly laundered garments should be provided for food handlers on a daily basis. Wherever appropriate head covers should be worn. Besides being unpleasant, hair is also a source of microorganisms [26]. Workers who handle food should not have cuts or infectious diseases. Such workers should be prevented from handling food. Touching prepared food with bare hands should be avoided. Suitable hand washing and drying facilities should be provided near work stations.

57.7.7.2 Measures at Postprocessing and Packaging Stages

Contamination of food products can also occur at postprocessing and packaging stages. Food manufacturers and retailers should be aware of the need to handle food in a safe and hygienic manner. Manufacturers and retailers have the responsibility to ensure that food products are not abused by the consumer after purchase.

57.7.7.2.1 Retail

Before food reaches the consumer, the retailer is responsible for maintaining the safety of all food products in his/her care. The retailer must store the food at the recommended temperature, and adequate care has to be taken when food is handled. The control measures therefore relate to monitoring temperature/time records during storage, inspection of equipment and facilities, auditing, training of staff, and use of tamper-proof and tamper-evident packaging.

57.7.7.2.2 Food Service

Food is presented to the consumer in a variety of ways. Some foodservice systems are prone to microbiological and other hazards. The techniques of HACCP that can be applied to food-production systems are also valid in food-service systems. The presence in food of certain microorganisms or their metabolic products in amounts sufficiently large to cause illness when consumed is a major concern. The population is at greater risk in this respect from the food-service establishments [27]. Hazards that need to be controlled are linked with several factors, including the composition of menus and individual food items, particularly raw materials not subjected to further processing, storage, preparation, handling, and holding procedures. The control methods include (i) selection of suppliers, (ii) inspection of raw materials on arrival, (iii) temperature/time control in storage and food-handling areas, (iv) monitoring personnel hygiene and food-handling practices, (v) sanitation of utensils and handling equipment, (vi) provision of adequate covers to protect from insects, and (vii) control of entry of insects

57.7.7.3 The Consumer

57.7.7.3.1 Food Preparation

Outbreaks of food poisoning due to poor handling of food in the home are not uncommon. Food spoilage due to pathogenic microorganisms as well as hazards from foreign objects can occur during the preparation of food. Consumer awareness of the potential hazards of handling food in the household is important in order to ensure the safety of foods prepared at home. The hazards can be controlled by checking containers prior to purchase, handling the product correctly on the way home, properly storing ingredients and food, keeping kitchen equipment clean, preparing food correctly, and managing the pantry appropriately [28].

57.7.7.3.2 Food Usage

Prepared food products such as ham, cheese, and sauces may be consumed directly or incorporated into other foods. Hazards can occur due to consumer abuse. The manner of reconstitution of the food and the consumer groups such as diabetics for whom the food is made should be indicated on the label. Limited control methods are possible in the hands of the consumer. Controls can be exercised through the provision of consumer information as to how the food product should be handled, used, and stored. Warning labels such as use-by dates and storage conditions, use of temperature/time indicators on sensitive and high-risk food items, and packaging design that minimizes abuse by the consumer are also ways in which the food processor can help the consumer minimize hazards.

57.7.8 Hazard Analysis

Hazard analysis is the first principle in the implementation of the HACCP program, and it is necessary to identify those hazards which must be eliminated or reduced to an acceptable level in order to produce safe food. A hazard analysis serves three purposes: (i) to identify the hazards of significance to food safety, (ii) to select critical hazards on the basis of risk to the consumer, (iii) to identify potential hazards that warrant specific preventive measures [29]. When the same product is manufactured by different food-processing organizations, the hazards will depend upon the following: (i) sources of ingredients, (ii) product formulations, (iii) processing machinery and equipment, (iv) processing and preparation procedures, (v) duration of processes, (v) storage conditions, and (vi) experience, knowledge, and attitudes of personnel [18].

All existing and new products must be subjected to hazard analysis, and when raw materials, product formulations, processing or preparation procedures, packaging components, distribution, and/or the use of product changes, the original hazard analysis has to be reviewed. A systematic approach to hazard analysis involves the assessment of biological, chemical, and physical hazards in all facets of the food production operation including delivery to consumers. Biological hazards occur when there is potential for harmful bacteria to contaminate the food. Chemical hazards exist when food is contaminated with substances such as pesticide residues, toxic metals, cleaning agents, and sometimes food additives and preservatives in excessive amounts. Physical hazards can exist when particles such as glass fragments, metal pieces, wood, hair, jewelry, or dirt contaminate the food. A suitable form for hazard analysis is shown in Table 57.10 [30]. The analysis should cover all the steps from receiving raw materials to delivery to consumers as given in the flow diagram.

TABLE 57.10
Hazard Analysis Form

Processing Step	Hazard Type	Significant? (Y/N)	Hazard Description	Control Method
	Biological			
	Chemical			
	Physical			

57.7.9 Assessing the Hazard Potential

An important step in implementing a HACCP program is the assessment of potential hazards. Hazard analysis requires knowledge of pathogenic organisms or any agent that could cause spoilage of the product and be harmful to consumers. A broad understanding of how these hazards could arise is also essential for a complete assessment. An assessment of potential hazards involves a detailed examination of the following: Raw materials, process, product, and end-use. These are assessed on the basis of biological, chemical, and physical hazards. Different systems have been used to assess the hazards associated with food products [31, 32]. Suitable layouts for the assessment of the hazards are described in the sections that follow.

57.7.9.1 Assessment of Raw Materials

The hazards related to raw materials can be grouped under microbial, foreign matter, and those associated with transportation and storage.

57.7.9.1.1 Biological Hazards

Some food products are more prone to microbial contamination that others, e.g., food products such as fish and meat are more likely to be contaminated with microorganisms than are fruits and vegetables. Chlorinated water and food ingredients such as salt generally do not carry microorganisms. Several factors are important for the growth of microorganisms. These factors are discussed in other chapters and must be taken into consideration in assessing the risk potential. Microbial growth may also occur during uncontrolled transport and storage conditions. Products such as salt and sugar do not require special storage conditions, whereas maintaining a prescribed temperature/time is important for chilled food.

57.7.9.1.2 Physical Hazards

Common types of foreign matter that are of concern in a food-production environment are soil, metal objects, personal

articles, etc., and the possibility of such contamination should also be assessed. Some food products may be damaged or undergo deterioration during transport. The extent of damage or deterioration that can occur under uncontrolled conditions of transport should also be considered when the raw materials are assessed.

57.7.9.1.3 Chemical Hazards

The raw materials may also be contaminated with chemicals and other pesticide residues. The possibility of such contamination should be considered during the assessment of raw materials.

57.7.9.1.4 Assessing the Risk

Risk can be high or low. For example, cooked food such as fish, meat, and eggs has a low risk in contrast to uncooked food. Even if the hazard is eliminated at a later stage of the process, any risk associated with raw materials should not be ignored.

57.7.9.2 Assessment of the Process

The assessment of the process involves analysis of each step. At each step of the process, consideration has to be given to the possibility of contamination with biological, physical, or chemical hazards.

57.7.9.2.1 Biological Hazards

Microbial destruction is a critical factor in food processing, and if adequate controls are not in place, microbial contamination is a distinct possibility. During the handling of food items, microbial contamination can occur. However, microbial growth will take place only if the material is a suitable substrate and is stored at a condition suitable for growth.

57.7.9.2.2 Physical Hazards

Processes such as sieving, washing, inspection, and metal detection are designed to remove or reduce foreign matter present in a food product. The assessment is based on the efficacy of the process. New foreign matter can be introduced during certain steps in the process. For example, plastic pieces can become embedded in the food product during a packaging operation, and metal pieces or shavings can get into the product via faulty machinery.

57.7.9.2.3 Chemical Hazards

Any equipment that comes into direct contact with food items can contaminate the food if it has not been thoroughly cleaned. On the other hand, carton closure equipment that does not come into contact with food directly cannot be considered a possible hazard source.

57.7.9.2.4 Control Measures

If the hazard is not eliminated downstream, adequate control measures should be exercised at the step under consideration. If vegetables are washed for the purpose of removing foreign matter and intended to be consumed uncooked, the washing step is critical and needs a high degree of control because of possible microbial contamination. However, if the vegetables are intended to be cooked, the washing step is for the purpose of removing soil and dirt and therefore needs a low degree of control. Displaying raw chilled seafood, poultry, and meat needs a high degree of control because it is important to keep the display temperature below 4°C in order to limit bacterial growth [33]. The consequences of failing to do so can be serious. Process steps such as filling trays and handling of food require a moderate degree of control.

57.7.9.3 Assessment of the Product during Storage and Delivery

The methods by which food should be stored and delivered depend on the characteristics of the food product. The product is evaluated on the basis of hazards associated with its stability. Consideration has to be given to storage conditions, packaging requirements, and delivery instructions necessary to prevent the product from undergoing deterioration or spoilage.

57.7.9.3.1 Biological Hazards

Products such as bottled wine, canned foods, and jam do not require special storage conditions, and hence there are no hazards associated with storage. For perishable foods such as meat, fish, and ice cream, the storage conditions are critical to prevent the growth of microorganisms. Vegetables require special storage conditions, but if abused, the hazards that can occur are less critical. Chilled and frozen foods may be subjected to unfavorable storage conditions (temperature/time) over long periods during transport. These food products require special packaging, and the hazards associated with such products are critical.

57.7.9.3.2 Physical Hazards

Food is transported over long distances and is subject to a wide variety of storage conditions and handling techniques. The hazards that can occur during the transport of food substances are assessed as to the extent of damage or deterioration. Few or no hazards are associated with food products that do not require special storage conditions or handling techniques. Some food products packed in glass or plastic containers require special storage conditions during transport to prevent damage and subsequent spoilage.

57.7.9.3.4 Chemical Hazards

Chemical hazards in a food product during storage and delivery are often caused by unclean containers. Food ingredients are also transported to food producers, and in some instances, contaminated substances may be transported in the same vehicle [34].

57.7.9.3.5 Control Measures

Controls are not necessary for food products such as canned foods, sugar, and salt. When chilled and frozen food products are transported, stringent control measures should be exercised. Some products that are transported over short distances in insulated packaging may not require special storage

conditions, and failure to maintain control over temperature/time may not have serious consequences.

57.7.9.4 Assessment of End Use

During the last few years, food manufacturers have been aware of the increase in the cases of consumer dissatisfaction and complaints about food products [28]. Mishandling of products that leads to deterioration of quality has been cited as one of the causes of consumer dissatisfaction. Hazards can sometimes occur in the hands of the consumer as a result of inappropriate usage and abuse by the consumer.

57.7.9.4.1 Inappropriate Usage

Food products that can be safely consumed by the general population cause no risk. Some food products that can be safely consumed by a section of the population may not be tolerated by others, although the effects of such a hazard may not be significant. The hazards associated with the usage of such foods are classified as low. The hazards that can occur, for example, as a result of incorrect labeling or wrong formulation of food products made especially for certain groups of people, such as the elderly, children with allergies, and diabetic patients, are critical.

57.7.9.4.2 Abuse by the Consumer

Food products that do not require special storage conditions or handling cause no hazards in the hands of the consumer. However, some food products have a low risk of being abused and require moderate care in handling, for example, bread left outside and open to air soon develops mold. Some foods such as cooked meat require special handling by the consumer to prevent spoilage that may not be obvious, and the consumption of such food may cause serious illness (e.g., *Salmonella* poisoning). These food products have a high risk of abuse.

57.7.9.4.3 Control Measures

Controls are not necessary for food products that cannot be abused. Foods that have a low risk of abuse require a moderate degree of control, and other food products that require special handling need strict control measures.

57.7.10 Critical Control Points (CCPs)

The determination of CCPs is the second principle of HACCP. This step follows the hazard analysis which identifies the potential hazards that can threaten the food supply and production. A critical control point in a food-processing system leads to an unacceptable health risk and can be effectively controlled to prevent or eliminate health hazards to an acceptable level of low risk.

57.7.10.1 Classification

Critical control points can be generally classified as CCP1 and CCP2 [35]. CCP1 is defined as a step or location in a food-processing system that on its own effectively eliminates a hazard, e.g., metal detection in food products and sterilization. CCP2 is defined as a step or location in a food-processing system that contributes to the control of a hazard but does not guarantee elimination, e.g., inspection and pasteurization.

It is important to distinguish between CCPs and control points that are less critical in ensuring food safety. Several key points to note in determining the CCPs are (i) CCPs should not be restricted to a minimum or maximum number, (ii) a CCP is specific to a product and process, (iii) CCPs should not be duplicated, (iv) CCPs should only be introduced when it is necessary to eliminate or reduce a health hazard, (v) CCPs should always be developed by consulting an expert when there is doubt about a product or a process, and (vi) development of CCPs requires the use of common sense [15].

The presence of a control downstream should not be considered a reason to neglect controls in proceeding steps. For example, wines are tested for pesticide residues prior to bottling, and even then the grape grower has the responsibility to control the spray program. Any opportunity to eliminate or minimize the occurrence of a hazard should not be overlooked.

57.7.10.2 Location of CCPs

HACCP techniques enable the food processor to identify hazards and risks, focus on where they pose a threat to the safety of food, and develop the means to control them. The actual location of a CCP depends upon the type of hazard, the ingredients, packaging, processing procedures, storage, and handling. Emphasis should be placed on the prevention of entry rather than detection after they have been introduced. CCPs should be introduced as early as possible in the food-processing system and close to the origin of the hazard. All precautions must be taken to prevent the entry of new ones [35]. Hazards associated with raw materials should be controlled at the source, i.e., the supplier. This minimizes the risk of entry of hazards and avoids unnecessary inspection of raw ingredients on receipt. Therefore, preprocessing techniques such as washing and sorting will be more effective in controlling hazards.

Food-production processes are often associated with more than one CCP. For example, in the production of entrees in conventional, cook/chill, and cook/freeze food service systems, time–temperature is a CCP throughout production in each of the models. Equipment and personal sanitation are also CCPs that should be regularly monitored using standards and criteria established by the food-processing system [36]. The inspection of the finished product usually verifies the effectiveness of controls placed so far.

57.7.10.3 Determination of CCPs

True CCPs have often been confused with control points, and as a result, a large number of CCPs are identified, making the HACCP system unworkable. For example, in a commercial process of smoked fish, it is possible to identify many individual steps, but only three can be considered critical: Salt penetration, smoking, and storage [21]. There are two approaches for identifying the CCPs: Decision tree developed by the Codex Alimentarius Committee of Food Hygiene [37, 38] and risk analysis.

57.7.11 Identification of CCPs

57.7.11.1 Decision Tree

The decision tree [30] employs a systematic approach and a logical process at every process step for every hazard identified as significant in the food production operation. It promotes further discussion by the HACCP team and hence improves the quality of the outcome. The principal elements of the decision tree are shown in Table 57.11 as a series of questions.

Q1. Do control measures exist at this or subsequent steps for the identified hazard?

This question refers to the use of control measures such as temperature control, visual inspection, or use of metal detectors at this step or subsequent steps in the food-processing operation to control the hazard. If there are no control measures, the team should indicate how the hazard will be controlled before or after the manufacturing process (outside the control of the organization). For example, pesticide residue in grapes is controlled by the grape grower. Alternatively, the operation, process, or product could be modified to ensure that a control measure exists.

Q2. Does this step eliminate or reduce the likely occurrence of the identified hazard to an acceptable level?

For each operation, the team should define the acceptable levels. Examples of controls that are designed to eliminate or reduce the likely occurrence of a hazard include chlorination of water, pasteurization, use of metal detectors, and cleaning procedures, etc. Question 2 applies to process operations, and it is not applicable to incoming raw materials.

Q3. Could contamination with the identified hazard occur in excess of acceptable levels or increase to unacceptable levels?

This question refers to the likelihood of the hazard having an impact on the safety of the product. The response to this question should be based on the risks, the company's complaint reports, and scientific literature on the subject. If the contamination is not likely to represent a threat to human life, the response to this question is "no."

Q4. Will a subsequent step eliminate the identified hazard or reduce likely occurrence to an acceptable level?

Question 4 is designed to identify those hazards that are known to represent a threat to human health or that could increase to an acceptable level, and that will be controlled by a downstream operation. If the response to this question is a "yes," it is necessary to identify the subsequent step that controls the hazard, thus proceeding to the next identified hazard. The questions given in the decision tree should be asked for each significant hazard at each process operation, including receipt and handling of raw materials. All CCPs identified by the team must be implemented and cannot be replaced by other controls elsewhere in the operation.

57.7.11.2 Risk Analysis

Food safety is a significant public health issue worldwide with major costs to the health authorities. Uncontrolled application of agricultural chemicals, environmental pollution, use of non-permissible additives, and other abuses of food along the food chain can potentially introduce or fail to reduce hazards related to food production, delivery, and service. Therefore, food safety programs designed to protect consumers have to meet several challenges: (i) the emergence of new pathogens and other hazards, (ii) the re-emergence of pathogens and other hazards, and (iii) the threat of bioterrorism with increased awareness of food additives and food safety among consumers, analysis of risks associated with food become extremely important. The level of risk to the consumer depends on the degree of control exercised by growers, suppliers, food processors, and food regulatory authorities to eliminate or minimize the risks to acceptable safe levels. Risk analysis is an evolving discipline, and the methods used for the assessment and management of risks are still being developed [39].

It is important to understand the difference between hazard and risk. A hazard is a biological, chemical, or physical agent in, or condition of food that may have an adverse health effect. In contrast, risk is a function of the probability of an adverse effect

TABLE 57.11
CCP Decision Tree

Question Number	Question	Response "Yes"	Response "No"
1	Do control measures exist at this or subsequent steps for the identified hazard?	Proceed to Q2	If the control is necessary modify the process
2	Is this step specifically designed to eliminate or reduce the likely occurrence of the identified hazard to an acceptable level?	CCP	Proceed to Q3
3	Could contamination with the identified hazard occur in excess of acceptable levels or increase to an unacceptable level?	Proceed to Q4	Not a CCP
4	Will a subsequent step eliminate the identified hazard or reduce likely occurrence to an acceptable level?	Not a CCP	CCP

and its severity of impact on the affected population [40]. The risk analysis process involves three distinct steps: Risk assessment, risk management, and risk communication. The purpose of risk assessment is to identify the hazards and their immediate, interim, and long-term effects on human health. Risk management establishes appropriate controls to eliminate or reduce these risks. The aim of risk communication is to develop methods to communicate this information to consumers.

57.7.11.2.1 Risk Assessment Risk assessment consists of four components.

1. Hazard identification
2. Hazard characterization—quantitative and/or qualitative evaluation of the adverse effects of the hazard on humans
3. Exposure assessment—quantitative or qualitative evaluation of the likely degree of exposure to the hazard
4. Risk characterization—integration of the first three components to arrive at an estimate of the likely adverse effects in the target population

Once the hazards have been identified, they should be assessed on the basis of established data. Each hazard can be assigned a numerical risk level based on the severity of outcome and the likelihood of occurrence of the hazard [41]. Severity is classified at three levels:

High severity (score = 3)

Microbial contamination causing life-threatening illness, e.g. *Clostridium botulinum*, *Salmonella typhi*, *Vibro cholerae*, or contamination with a chemical or foreign object causing life-threatening or permanent illness or injury.

Medium severity (score = 2)

Microbial contamination causing chronic illness, e.g. *Campylobacter*, *Vibrio parahaemolyticus*, or contamination with a chemical or foreign body causing temporary illness or injury.

Low severity (score = 1)

Microbiological contamination causing moderate illness, e.g. *Listeria monocytogenes*, *Staphylococcus aureus*, or contamination of a chemical or foreign body causing discomfort, nausea, etc. [23]. The likelihood can also be categorized as high (score = 3), medium (score = 2), and low (score = 1). High likelihood indicates that the hazard will occur; medium likelihood indicates that there is a reasonable chance of occurrence; and low likelihood denotes that the occurrence will be rare. Risk level = likelihood × severity. Risk level = 1–3: Low risk—establish control measures where appropriate. Risk level = 4–6: Medium risk—establish control measures. Risk level = 7–9: High risk—CCP.

In the canning process, the likelihood of *Clostridium botulinum* surviving retorting is very low (1) but the severity of the illness (botulism) is high (3). Thus, the risk level = 3 and the retorting is a control point and not a CCP. A better approach for risk assessment takes into consideration the severity of the illness as well as customer complaint reports and product recalls [42]. The ratings for severity are as follows: (i) fatality, (ii) serious illness, (iii) product recall, (iv) customer complaint, and (v) not significant. Likelihood ratings for each food hazard are: A, common repeating occurrence. B, known to occur or "it has happened" (own information). C, could occur or "I have heard it happening" (published data). D, not expected to occur. E, practically impossible. Based on the above ratings, significant factors are assigned to various combinations as shown in the matrix in Table 57.12.

Example of an assessment of significance:

> Process step: Receiving salmon for the production of vacuum-packed hot smoked salmon. Potential hazard: Pathogens, parasites in fish. Severity: 2 (serious illness). Frequency: D (not expected to occur in finished product because of subsequent steps).
>
> Significance: 12 (not a CCP). Control measures: Received frozen, supplier HACCP compliant with specifications, control smoking/cooking at subsequent step.

57.7.11.2.2 Risk Management

Risk management is the process of implementing policy alternatives compatible with the results of risk assessment and applying appropriate control options, including regulatory measures. The aims of the risk management program are to (i) establish the significance of estimated risk, (ii) compare the costs of reducing this risk to the benefits gained, (iii) compare the estimated risk to benefits to the consumer, and (iv) promote regulatory and other changes necessary to reduce the risk.

TABLE 57.12
Matrix for the Assessment of Significance of Risk

Likelihood →		A	B	C	D	E
Severity	1	1	2	4	5	11
↓	2	3	5	8	12	16
	3	6	9	13	17	16
	4	10	14	18	21	23
	5	15	19	22	24	25

Note: Shaded areas = CCPs

The outcome of the risk management program is the development of standards, codes of practice, and other guidelines for food safety. Risk management decisions are based on the outcome of the risk assessment process, food processing, quality and food safety requirements, food handling and distribution requirements, and food quality and safety standards to control hazards in food production. These decisions are implemented, and their effectiveness of control measures is monitored to ensure that the food safety objectives are met.

57.7.11.2.3 Risk Communication

Risk communication is the final element of the risk analysis process. According to the Codex Alimentarius definition, risk communication is an interactive process of exchange of information and opinion on risk among risk assessors, risk managers, and other interested parties. The responsibility for food safety rests with all involved at all stages of the food chain, including consumers. They should be provided with appropriate information on potential hazards and precautions to be taken to eliminate or reduce the risks. Consumers also need to be aware of the control measures exercised by the regulatory bodies to ensure food safety.

The purpose of risk communication is to educate the general public and specific target groups such as the elderly, diabetics, etc., on food hazards and their risks to general health and wellbeing. Communication provides information necessary to prevent, minimize, or reduce risks associated with food intake to acceptable, safe levels through voluntary or regulatory control mechanisms. This information also provides consumers with the power to exercise their own control measures to safeguard their health.

57.7.12 Establishing Critical Limits for Each CCP

Establishing measurable limits (specifications) for each CCP is the third principle of HACCP. The critical limits define the criteria for acceptability or rejection and thus are the operational boundaries for each CCP. These limits may be derived through various sources: Experiments through validation, regulatory requirements, codes of practice, or other valid sources. Critical limits should be established for the following food production operations as applicable: (i) distribution processes, (ii) receiving operations, (iii) storage, (iv) thawing, (v) production, (vi) hot holding, (vii) cooling, (viii) processing, (ix) reheating, (x) cold holding, (xi) transporting, (xii) recipe flowcharting, and (xiii) employee training.

The measurable limits are often defined by time, temperature, physical attributes, acidity, pH, moisture content, water activity, salt concentration, and chlorine levels. Purchasing management procedures should include clearly defined specifications, and the control limits may refer to a successful outcome of an audit at the supplier's premises. The person who receives goods must ensure that the food is received in good condition, free from spoilage and tampering, and that it meets the organization's in-house specifications. It is essential that the temperature of perishable products and the cleanliness of the vehicle/container are checked on receipt. Training requirements have to be established for all employees who handle food. These may include proper handwashing techniques, use of clean uniforms and hair covers, communicating company policies on smoking in the workplace, wearing jewelry, etc. Cross-contamination is an important hazard that is sometimes overlooked. Raw and cooked products should be physically segregated in storage. Critical limits for cross-contamination may include storage conditions and proper use of cutting boards. Table 57.13 shows some examples of critical limits [18].

57.7.13 Establishing Procedures and/or Equipment for Monitoring CCPs

Monitoring is defined as planned measurement or observation to ensure that the CCP is under control and is the fourth principle of HACCP. Monitoring procedures should be carefully defined such that loss of control can be detected. It is essential that responsibility is assigned for observation or testing. The test results have to be accurately recorded for future reference. The purpose of monitoring includes the following: (i) to evaluate the effectiveness of the system's operation at the CCP, (ii) to determine instances of deviation from a critical limit, (iii) to provide evidence that the performance level of the operation at the CCP complies with the HACCP plan.

Monitoring can be performed at defined time intervals or continuously. The latter is more reliable and shows deviations from the specified limits, allowing timely corrective action to be taken. When monitoring is done at time intervals, the

TABLE 57.13
Some Examples of Critical Limits

Hazard	CCP	Control Limit
Bacterial pathogens (non-sporulating)	Pasteurization	72°C for at least 15 seconds
Metal fragments	Metal detection	Metal fragments larger than 0.5 mm
Bacterial pathogens	Drying over	A_w less than 0.85 for controlling growth in dried food products
	Acidification step	Maximum pH of 4.6 to control *Clostridium bolulinum*
Excessive nitrite	Curing/brining	Maximum 200 ppm sodium nitrite in finished product
Food allergens	Labeling	Legible label containing a list of correct ingredients
Histamine	Receiving fish	Maximum 25 ppm histamine levels in evaluation of tuna for histamine

frequency of monitoring should provide confidence that the CCP is under control. When monitoring systems are designed it is necessary to consider the time lapse between measurement and the results. On-line measurements are rapid and provide results immediately. On the other hand, microbiological tests provide results after a few days, and therefore, finished products have to be held under quarantine until the test results are known. All monitoring equipment should be subjected to regular calibrations. There are two types of monitoring: Measurement monitoring and observation monitoring [43].

Observation monitoring usually involves the use of checklists and includes visual checks (sight, smell, and taste), visual observations for some physical characteristic (presence of foreign objects), and checks for hygiene and cleanliness. Observation monitoring is generally easy to implement, but there are some disadvantages. Results of observation monitoring often require interpretation, and the operators must be sufficiently trained to make sound judgment.

Measurement monitoring often involves instrumentation and can be automated. The results are straightforward and do not require subjective judgment. Measurement techniques can be designed such that the findings can be easily interpreted. The results will also demonstrate trends and highlight subtle changes.

57.7.14 Establishing Corrective Actions

Establishing a corrective action procedure is the fifth principle of the HACCP plan. Corrective action is necessary when a deviation at a CCP has exceeded the critical limits. A deviation is critical when it results in an unacceptable consumer health risk, which must be resolved promptly. Deviation procedures are a predetermined and documented set of actions to be accomplished when a deviation occurs. Corrective actions enable the cause of the non-compliance to be corrected and the non-compliant product to be managed. Product control includes proper identification, segregation, and disposition of the affected product.

After the appropriate corrective action is taken, it may be necessary to review the HACCP plan. The corrective action procedures should include an investigation to determine the cause of the problem, effective procedures to prevent a recurrence, and verification of the effectiveness of corrective action.

57.7.15 Verification Procedures

The sixth principle of HACCP is the verification of operational procedures. It is the task of application of methods, procedures, tests, and other evaluations, in addition to monitoring to determine compliance with the HACCP plan [18]. The purpose of verification procedures is to assess the effectiveness of the plan and ensure that the HACCP system is compatible with the plan. Although it is carried out at planned intervals on completion of the study, verification may also have to be performed when there is a change in the ingredients, product, or process or when a deviation occurs or a new hazard is identified. Some of the verification activities are (i) audits covering all operations of food production, (ii) reviews of menu and recipes and confirmation that documented methods are followed, (iii) maintenance and calibration checks, (iv) verification of flow charts, (v) cross-contamination possibilities, (vi) all records including relevant training records, (vii) corrective action reports, and (viii) compliance with regulatory requirements

57.7.16 Documentation and Record-Keeping

Record keeping is the last principle of the HACCP plan and is an essential requirement of the HACCP program. Records demonstrate the history of the process, its measurements, deviations at the CCP, and corrective actions taken. Record keeping is also an essential regulatory requirement. Regulations governing food production dictate the type of records to be maintained by the food processor. For example, according to FDA's HACCP regulations, seafood operations are expected to document and follow basic sanitation standards [30]. An HACCP manual includes, but is not limited to, the following documents: (i) profile of the organizations, (ii) policies, e.g., hygiene, cleanliness, smoking, etc., (iii) products manufactured by the organization, (iv) prerequisite program referenced, (v) flow diagrams, (vi) hazard analysis, (vii) HACCP schedule, (viii) consumer complaint procedure, (ix) recall procedure, (x) corrective action and disposal of nonconforming goods procedure, and (xi) recording and documenting control procedure [44].

Records and documents may be in any form, e.g., charts, written procedures, electronic records. The records have to be regularly reviewed to ensure that HACCP controls are effective, correct data are being recorded at specified intervals, and that operators are completing their tasks as instructed. Most of the records associated with the HACCP program are associated with monitoring and corrective actions. They can be simple check sheets or complex control charts. The type of records to be maintained depends on the nature of the food-processing operations. Monitoring the temperature is essential for processes that employ refrigerators, freezers, dishwashers, steam equipment, hot and cold cabinets, and ovens. Some examples of records to be maintained are (i) pest control records, (ii) calibration records, (iii) maintenance logs, (iv) shipping records, (v) premises inspection reports, (vi) release reports, (vii) training records, (vii) calibration reports, (ix) consumer complaint and corrective action reports, and (x) control charts as applicable. Record-keeping should not be treated as mere paperwork. It is the key system to manage, verify, and validate the HACCP program [45].

57.7.17 Validation Procedures

While verification can be performed by audits and other methods at scheduled intervals and as required, the effectiveness of operational processes and methods can be determined only by a proper validation. Validation is the process of ensuring that the procedures are effective [46]. A process can be verified as correct but may not be valid to achieve the

desired result. For example, the process of cooling a stockpot of soup in a refrigerator may comply with documented procedures (verification), but the long time required for the temperature to drop in the center of a large container can permit bacteria to continue to grow (validation). Hence, the validity of the cooling process (refrigerator in contrast to blast chiller) is in doubt. Often equipment or procedures are unique to the organization, and therefore the operating characteristics of the process will become important in the validation of a critical limit. Food science is an evolving discipline, and it is essential that up-to-date scientific references are used in the validation process. Validation is an on-going planned procedure. However, the following factors may cause a review of the validation procedure: (i) when raw materials, product, or processes change, (ii) results of adverse audit reports, (iii) frequent deviation from the specified critical limits, (iv) new scientific data on potential hazards or processes, (v) consumer complaints, and (vi) product recalls.

57.8 CONSUMER PROTECTION

The primary objective of a HACCP system is to protect the consumer from harm caused by hazards associated with food products. A survey carried out by a task force has revealed four causes of consumer dissatisfaction with food products [28]: Unfamiliarity and expectations, price, defects, and mishandling by the consumer.

Food producers have a responsibility to ensure that all food products are adequately labeled. Information such as product description (particularly for new products), ingredients, shelf life, storage conditions, and special preparations, if any, should be provided to create awareness of the nature of the product and to prevent mishandling. Retailers as well as manufacturers can go a step further by providing information in the form of leaflets that explain handling of food products on the way home, storing of ingredients and prepared foods, and the potential hazards involved with handling foods in the household. Food producers, as well as retailers, have an important role to play in educating the consumer as to food safety.

57.9 MANAGEMENT OF THE HACCP PROGRAM

57.9.1 Review, Audit, and Recall Processes

57.9.1.1 Review

The HACCP program, just like the quality management system, is dynamic. With advances in food technology, food producers are constantly looking at new, rapid, and safe ways of processing food. The HACCP program should be flexible enough to adapt itself to changing circumstances. New knowledge gained about microorganisms also presents a challenge to already developed and implemented HACCP programs. An HACCP program should also take into account the variability and adaptability of agents responsible for hazards to human health.

It is easy for organizations that have a quality management system in place to incorporate a HACCP program into the already existing system. Procedures such as management responsibility, management review, and document approval and issue can be applied to the HACCP system. The function of the management representative then is to maintain the system through regular audits and reviews. The management representative responsible for the program should ensure that all new and current product specifications, results of audits, customer feedback, process conformance and product conformity, the status of preventive and corrective actions, actions taken since the last meeting, standards of practice, changes to procedures and equipment, engineering and microbiological data, safety controls, and monitoring systems are reviewed regularly by the HACCP team. It is the responsibility of the team to determine, in relation to current practices or new procedures, (i) the potential hazards in ingredients, products, and risks, (ii) whether the hazard can be eliminated or minimized, (iii) the effectiveness of a terminal heat treatment, (iv) the possibility of recontamination, and (v) the hazards associated with handling, storage, distribution, and product usage.

A hazard identification form (Figure 57.3) can be used to report the results found by the team. All accidents, misuse of ingredients, unsafe environment, and safety issues must be recorded and reported to the appropriate authorities. Authority must also be given to the operators to stop the process if in their opinion it is unsafe to operate. All safety issues must be dealt with immediately, and timely action must be taken to eliminate unsafe practices and equipment.

57.9.1.2 Audit

An HACCP audit can be defined as a systematic and independent examination to determine whether (i) HACCP activities and related results comply with planned arrangements, (ii) these arrangements are implemented effectively, and (iii) the arrangements are suitable to achieve the objectives. A schedule of audits must be prepared and carried out as planned. There is no international standard yet for the HACCP system equivalent to the ISO 9000 standard series. However, the HACCP system can be audited against the specified requirements of the system. To some extent, the British Retail Consortium (BRC) standard for food meets the requirements of a food safety standard [11]. It integrates the relevant section of the ISO 9000 standard, Codex Alimentarius, and GMP. The BRC standard has the following sections: (i) HACCP system, (ii) quality management system, (iii) general documentation requirements, (iv) factory environment standards, (v) product control, (vi) process control, and (vii) personnel.

HACCP audits should provide (i) an assessment of the adequacy of the existing system (ii) a benchmark against which improvements can be made and evaluated, (iii) evidence that contractual and legal requirements have been met, and (iv) feedback on safety issues. HACCP audits are carried out in a manner similar to quality system audits and typically apply to, but are not limited to, records and activities associated with control points and critical control points, training, and reviews. All non-compliances must be dealt with at the earliest

opportunity, and products related to these non-compliances should be kept under quarantine for thorough investigation.

57.9.1.3 The Product Recall Process

A reliable and well-tested method of recall should be in place to deal with a food item that has been established to be contaminated with a harmful ingredient or pathogenic organisms. Government regulations place a legal responsibility on food producers who recall food products for safety-related reasons to notify the authorities in writing within a specific period of initiating a recall (Figure 57.4). The traceability information will enable the affected product in the warehouse, in retail outlets, and in the hands of the consumer to be isolated. A suggested plan for a product recall is shown in Figure 57.5.

The text for the advertisement placed in the daily print media should comply with the statutory requirements and include (i) the name of the product and the producer, (ii) the pack size and a description of the packaging, (iii) any other details necessary for identification, (iii) the reason for recall, (iv) the necessity to identify and quarantine the stock, (v) the manner of disposal, (vi) if the hazard to the consumer is serious, indications of clinical symptoms and advice to consult a medical practitioner, and (vii) a toll-free telephone number to provide assistance to consumers. When the recall has been terminated, the recall team should review the effectiveness of the recall procedure and recommend changes,

if necessary. The recall team should document the following information: (i) the name of the product and pack size, (ii) the reason for recall, (iii) the cause of the problem, (iv) the chronological history of the recall events with actions taken, (v) the effectiveness of the recall, (vi) the total cost of the recall, (vii) the corrective actions taken, and (viii) the effectiveness of the recall.

In the case of a recall, the accuracy of information and speed with which action is taken is important. Although a mock recall may be impracticable, a regular traceability audit of a product should be carried out. This may include an audit of the ingredients used, process employed, laboratory findings, and the product distribution details. A sample recall notice is shown in Figure 57.6.

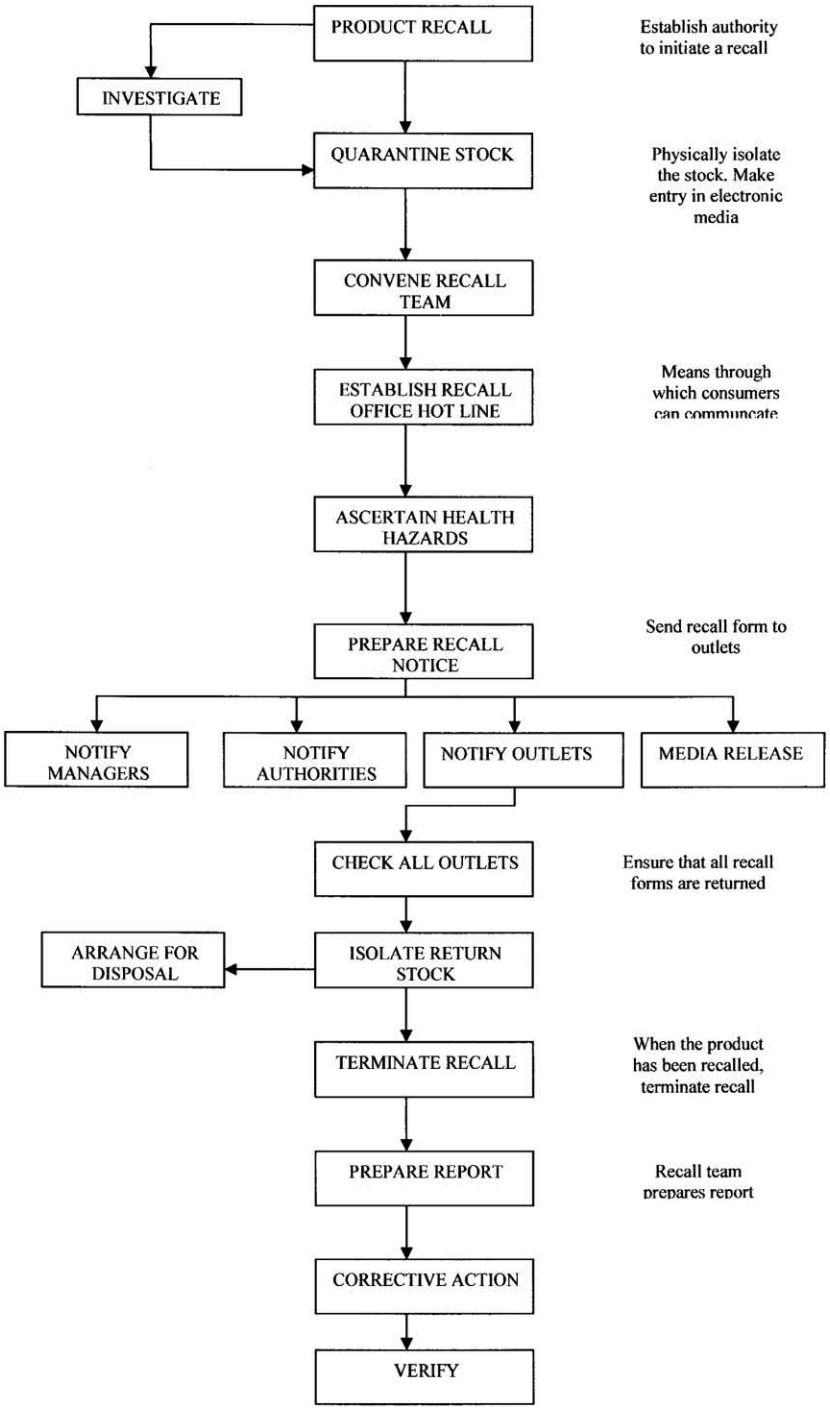

FIGURE 57.5 Recall plan.

57.10 BENEFITS OF IMPLEMENTING A HACCP SYSTEM

The HACCP system is a preventive and cost-effective approach to food safety and is more effective in preventing foodborne illnesses than traditional approaches. The application of an effective HACCP system has clear benefits for consumers, and industry as well as for regulatory bodies [47]. These benefits are summarized in Table 57.14.

57.11 HACCP IN THE OVERALL QUALITY SYSTEM

The survival of a business depends on its ability to satisfy the customer's needs and expectations at an affordable cost, which is achieved through an effective quality management system. It provides a basis for continuous improvement. The effectiveness of a quality management system can be assessed against standards such as ISO 9000. The quality management

FOOD RECALL NOTICE

FOOD PRODUCTS LIMITED STRAWBERRY JAM

FOOD PRODUCTS LIMITED IS RECALLING 375G JARS OF STRAWBERRY JAM, BECAUSE OF THE DISCOVERY OF GLASS IN TWO JARS OF FOOD PRODUCT'S STRAWBERRY JAM. THE RECALL APPLIES TO THE PRODUCT HAVING THE CODE L23A6.

THE PRODUCT HAVING THE ABOVE CODE SHOULD NOT BE CONSUMED.

AS A SAFETY MEASURE WE ARE RECALLING ALL SUPPLIES OF THIS PRODUCT WITH THE ABOVE IDENTIFICATION ON THE LABEL.

THERE HAVE BEEN NO REPORTS OF INJURY OR ILLNESS. HOWEVER, ANY PERSON CONCERNED ABOUT THEIR HEALTH AS A RESULT OF CONSUMING THE PRODUCT SHOULD SEEK MEDICAL ADVICE.

PLEASE RETURN THE PRODUCT TO THE POINT OF PURCHASE FOR A REFUND OR PHONE TOLL FREE……..

THE RECALL DOES NOT APPLY TO ANY OTHER FOOD PRODUCTS LIMITED STRAWBERRY JAM HAVING A DIFFERENT CODE OR ANY OTHER FOOD PRODUCTS LIMITED PRODUCT.

WE SINCERELY APOLOGISE FOR ANY INCONVENIENCE CAUSED BY THIS RECALL.

system should be designed to meet the individual needs of the organization. Food manufacturers, while being aware of the quality of foods, should also realize that food safety is an absolute requirement. Regulatory authorities all over the world enforce laws aimed at protecting the consumer from harmful food. HACCP is a management tool that focuses attention on food safety and complements the quality management system. Implementation of a quality management system and a HACCP program both require teamwork. The requirements of a HACCP program are embodied in the seven principles as defined by the National Advisory Committee on Microbiological Criteria for Food [48].

The procedures relating to the HACCP system can be developed using the seven principles as the basis. An ISO 9000-based quality management system can easily be integrated with the HACCP program [44]. The clauses in the ISO 9000 standard such as responsibility, management review, and audit can be applied while keeping the focus on safety as well as quality. An HACCP system can be incorporated into the quality management system by making references to individual clauses such as product realization, corrective and preventive actions, internal audits, document control, and others common to both systems. The HACCP system should not be limited to the seven principles and should also include procedures relating to HACCP planning, customer complaints, and control of HACCP records, some of which are prerequisites.

TABLE 57.14
Benefits of Implementing the HACCP System

Benefits for Consumers
Lower risk of foodborne illnesses
Greater awareness of food safety
Greater consumer confidence in food supply
Better quality of life through health and socio-economic benefits
Benefits for Industry
Greater confidence in product
Minimize legal and insurance costs
Increase market access
Lower waste, fewer or no recalls, minimum or no reprocessing and corrective action
A consistent product
Enhanced staff commitment to food safety
Lower business risk
Benefits for Regulatory Bodies
Improved health among the community
More efficient food control
Lower public health costs
Trade promotion
Greater confidence of the community in the food supply

57.12 CASE STUDY (I): PRODUCTION OF CHICKEN AND VEGETABLE SALAD

57.12.1 Product Description

Chicken and vegetable salad is a ready-to-eat chilled product prepared with cooked chicken, freshly sliced celery,

and cooked, peeled, and diced potato in a dressing mixture. Chicken breasts (skinless, boneless) and other ingredients are bought at the market. The dressing mixture consists of a pasteurized mayonnaise base blended with spices. The product is put into plastic trays, which are covered with a peelable foil membrane and packed in a cardboard outer package. The product is refrigerated and brought to the refrigerated case as required.

57.12.2 Assessing the Hazard Potential of Chicken and Vegetable Salad

A flow diagram for the production of chicken and vegetable salad has already been described (Figure 57.1). The next step in the HACCP technique is to assess the hazards associated with the raw materials, processing steps, product, and end usage. It will then be possible to determine the raw materials and the processes that are critical. The whole process is then examined in order to establish the critical control points using the decision tree.

57.12.2.1 Raw Materials

Of the raw materials, the most hazardous item is chicken. It may be contaminated with pathogenic bacteria. The storage conditions after collection and during transport are also significant. Therefore, the cooking step is very critical. Potatoes may carry bacterial spores on the skin. If the potatoes are received washed, the washing step is only a control point. Celery may be contaminated with bacteria and spray residues. Although chicken, potato, celery, and other ingredients may be contaminated with foreign matter, washing and/or inspection prior to use will reduce the risk of contamination. Mayonnaise, being acidic, may be contaminated with acid-tolerant bacteria. Tables 57.15–57.18 show the hazards associated with the raw materials used in the production of chicken and vegetable salad.

57.12.2.2 Process

The process assessment of chicken and vegetable salad is given in Table 57.19. Potatoes are washed for the purpose of removing foreign matter from the skin. Cooking chicken in the only lethal step in the whole process and requires careful control of temperature and cooking time. Potatoes are also cooked, but the bacterial spores residing on the skin may not be destroyed. After cooking, there are several steps (peeling, trimming, and chopping) that involve manual handling. All such steps are hazardous, and there are no lethal steps downstream. Washing of celery may reduce the level of vegetative pathogens but will not eliminate them. Microbial contamination can occur during the mixing operations. The salad is hand-filled into trays and exposed to the environment. The frequent manual handling during the filling operation is a health hazard. The temperature of chilled storage and display cabinets must be controlled to prevent the growth of microorganisms. All steps recognized as significant should be considered for the identification of CCPs in the final analysis.

57.12.2.3 Product

Microbial growth can occur if the storage conditions of the salad are not controlled at the food producer's premises and during transport and distribution.

57.12.2.4 End-Use

The chicken and vegetable salad is a food product that is prepared for the general population. However, after purchase, abuse such as leaving the container open or keeping it at a warm temperature can cause the product to deteriorate and become a health hazard if consumed. The label should include specific conditions of storage and the use-by date.

TABLE 57.15
Hazards Associated with Processing Chicken

Processing Step	Hazard Type	Significant Y/N?	Hazard Description	Control Method
Receiving chicken	Biological	N	Pathogenic bacteria (e.g. *Salmonella*, *Campylobacter*, *Yersinia*)	Supplier HACCP compliant with controls and specifications.

	Physical	N		

57.12.3 Application of Decision Tree

Table 57.20 shows the application of a decision tree to the process steps. The four questions in the decision tree allow the identification of hazards that could be reduced at an earlier stage even though a downstream process is capable of eliminating or reducing a further risk. For example, washing potatoes removes or reduces the extent of foreign matter that may be present before they are cooked. The cooking step destroys the microorganisms. Therefore, both washing (removal of foreign matter) and cooking (eliminating microorganisms) steps are CCPs.

The decision tree is applied to all the steps to determine the CCPs. Chicken can undergo spoilage during storage. However, the storage step is not classified as a CCP because it does not eliminate or reduce the microorganisms and there is ample opportunity to inspect for spoilage during the subsequent steps of washing, cutting, and cooking. Cooking the chicken pieces for a sufficiently long period can destroy microorganisms. Hence, it is a lethal step and is classified as a CCP.

The steps of peeling and cutting after cooking can introduce contaminants from hands, knives, and other equipment. However, bacteria cannot multiply in the presence of high-acid ingredients such as mayonnaise, vinegar, pickle, etc. Therefore, the mixing step can give absolute control if sufficiently high-acid ingredients are added and thoroughly blended. Thus, the peeling and cutting steps are not CCPs.

TABLE 57.20
Critical Control Points for Chicken and Vegetable Salad

Process Step	Significant Hazard	Q1	Q2	Q3	Q4	CCP Y/N
Receive chicken	Microbial contamination	Yes	No	Yes	Yes	No
Cold storage	Microbial growth	Yes	No	Yes	Yes	No

TABLE 57.21
Control Schedule for Chicken and Vegetable Salad

Processing Step	Item to Be Controlled	Control Limit	Control Method	Frequency	Action	Responsibility	Record
Receiving Ingredients CCP2	Foreign matter	No foreign matter	Visual inspection	Every batch	Reject Inform supplier	Supervisor	Inward goods record
Cooking potatoes CCP1	Cooking temperature/ time	Cook to a minimum internal temperature of 60°C for at least 15 seconds	Monitor temperature	Continuous	Cook longer	Operator	Temperature chart
Washing Potatoes CCP2	Foreign matter	No foreign matter	Visual inspection	Every batch	Remove foreign matter Wash again	Operator	Check sheet
Trimming, chopping celery CCP2	Equipment cleanliness Foreign matter	Clean equipment No foreign matter	Visual inspection	Continuous	Remove foreign matter Clean equipment	Operator	Check sheet
Cooking chicken CCP1	Cooking temperature/ time	Cook to a minimum internal temperature of 75°C for at least 15 seconds	Monitor temperature	Continuous	Cook longer	Operator	Temperature chart
Storage filled trays CCP1	Storage temperature Labeling instructions	Store below 5°C Correct label	Monitor temperature Inspect label	Every 2 hours	Quarantine product Investigate cause	Supervisor	Temperature chart

Celery may be contaminated with foreign matter and microorganisms. The washing step will remove foreign matter but may not reduce the risk of vegetative pathogens to an acceptable level. While the reduction of foreign matter is an important process step, the trimming and chopping operations after the washing step may provide ample opportunity to ensure that foreign matter is removed. However, if there is sufficient evidence to show that the washing step does reduce the level of microbial contamination and any chemical residues to an acceptable level, the washing step could be considered as a CCP.

The plastic trays into which the salad is filled are new. Although the trays may have foreign matter, they are inspected prior to use, and hence contamination with foreign matter can be eliminated. The processes of chilling and storage of the finished product are CCPs (CCP1), and storage under controlled conditions will prevent the growth of microorganisms.

57.12.4 Overall Risk Assessment and Reduction

It is now possible to consider how risks can be reduced by making some changes to the process. Vegetables are a major source of contamination. Potato and celery can be purchased from an approved grower. Celery may be blanched or washed with chlorinated water to reduce the bacterial load. Potato can be washed, peeled, trimmed, cooked, and diced or diced and cooked. Contamination can occur during the manual handling operations, particularly after the cooking step. The use of disposable gloves during manual handling will minimize contamination. Pathogenic bacteria do not grow in acid media, and contamination during the mixing step can be controlled by adjusting the pH to 4.5 or lower. If this is not practicable, the formulation can be tested and the recipe then followed accurately. Tamper-proof or tamper-evident packs can be used as a precaution against tampering and possible contamination. The risk of abuse by the consumer can be minimized by providing warning labels that give instructions on storage after purchase. Metal detectors can be installed on line to detect metal objects in the food. The finished product can be subjected to microbiological tests to detect the presence of specific microorganisms.

57.12.5 Control Schedule

The steps that have been identified as CCPs are controlled as specified in the control schedule (Table 57.21).

57.13 CASE STUDY (II): PRODUCTION OF VACUUM-PACKED HOT SMOKED SALMON

57.13.1 Product Description

Vacuum-packed hot smoked salmon [49] is a cooked ready-to-eat product. Salmon, packed in ice, are delivered to the production facility within hours of harvesting. Salt, sugar, and

spices are bought from the market. After smoking the smoked salmon are individually packed and vacuum-sealed. They are then packed in outer boxes of polystyrene with corrugated board outside. The finished boxes are frozen at –18°C and delivered in refrigerated trucks. The shelf life of the product is one year from the production date.

57.13.2 Assessment of Hazard Potential of Vacuum-Packed Hot Smoked Salmon

The flow diagram for the production of vacuum-packed hot smoked salmon is shown in Figure 57.2. The hazards associated with the raw materials, processing steps, product, and end usage are examined next. The analysis will show the raw materials and the processes which are critical to the production of a safe product. A risk analysis is carried out to establish the CCPs.

57.13.2.1 Raw Materials

The assessment of hazard potential is shown in Tables 57.22–57.24. Fish is an ideal breeding ground for pathogens such as *C. botulinum*, *L. monocytogenes*, and parasites. Throughout the process, adequate care has to be taken to prevent the growth of microorganisms. The fish should be packed in ice until delivered to the factory. Packaging materials that come into contact with fish may harbor microorganisms. Therefore, the packaging material suppliers should have an effective food safety program in place to ensure that food-contact materials are free from biological, chemical, and physical contaminants.

57.13.2.2 Process

The hazards associated with the smoking process are shown in Table 57.23. The production facility should maintain a hygienic environment, clean and disinfected equipment, and a personnel hygiene program to minimize or eliminate the chances of contamination. The brining process has to be carried out under refrigeration because high temperatures can lead to pathogen growth. Immediately after brining, the product should be maintained below 4°C until further processing. The smoking operation is the most critical step. The smoking process should be designed to eliminate *L. monocytogenes* by holding the product at a suitably high temperature for a sufficiently long period. The internal temperature of fish should be continually monitored and recorded. If an adequate temperature is not reached, bacteria will survive. The smoking temperature of not lower than 65°C for not less than 30 minutes

is based on the coldest part of the fish in the oven. Severe temperature abuse during packaging, storage, and distribution can allow pathogen growth. The storage conditions should be specified on the label so that consumers are aware of the danger of storage outside the stated limits.

57.13.2.3 Product

The drivers must ensure that refrigerating units in delivery trucks are maintained in good working condition. Microbial growth can occur if the storage conditions are not adhered to at the food production facility and during transport and distribution.

57.13.2.4 End Use

The product is intended for general use. The label must comply with regulatory requirements and should specify any colorants or additives added, storage conditions, and the expiry date.

57.13.3 Risk Assessment

Raw fish may carry pathogenic bacteria and parasites. Risk assessment of the hot smoking process depends on the severity of the outcome and the likelihood of occurrence of the hazard in the food product. Throughout the process, the

TABLE 57.25
Control Schedule for Hot Smoked Salmon

Activity	Potential Hazard	Critical Limit	S	L	A	Control Method	Corrective Action	Person Responsible	Record
Receiving salmon	Microbial growth	Received frozen	2	D	12	Product is frozen Supplier HACCP compliant Controlled at smoking	HOLD, inform supplier	Supervisor	Inward goods receipt
Weighing salt and sugar	Microbial contamination	No contamination	3	D	17	Personnel hygiene Disinfect equipment	HOLD product, monitor cleaning and hygiene	Supervisor	Check sheet
Semi-defrosting	Microbial growth	No growth	2	D	12	Defrosting procedure Controlled at smoking	HOLD, investigate	Supervisor	Temperature chart
Cutting and trimming	Microbial contamination	No contamination	2	D		Personnel hygiene Controlled at smoking	HOLD Check cleaning and hygiene	Supervisor	Check sheet
Brining **CCP**	Microbial growth	Minimum 24-hour soaking Minimum salt Content of 6%	2	C	8	Time in brine Salt content Weight of fish and brine Maintain chill room temperature	HOLD longer in brine Investigate	Supervisor	Check sheet Temperature chart
Drying	Microbial concentration	No growth	3	D	17	Correct drying procedure Correct salt concentration	HOLD Investigate	Supervisor	Check sheet
Smoking **CCP**	Survival of microorganisms	No microorganisms	2	C	8	Minimum internal temperature of fish of 65°C for 30 minutes	HOLD product Investigate	Smoke Operator	Temperature chart
Vacuum packing labeling	Growth of microorganisms	No growth	3	C	13	Presence of appropriate label statement on storage Correct packing procedure	Relabel	Packing Supervisor	Check sheet
Cold storage **CCP**	Bacterial growth Toxin production	No growth or toxin	2	C	8	Cooler temperature of 0°C or less	HOLD product Adjust cooler temperature	Supervisor	Temperature chart

Note: S = Severity; L = Likelihood; A = Assessment.

growth of pathogenic bacteria such as *C. botulinum* and *L. monocytogenes* is a potential hazard that can lead to serious illness (severity score = 2). The likelihood of provoking the illness is extremely low [50]. The pathogenic organisms grow at temperatures above 1°C, and they compete with spoilage flora which grows well at temperatures below 1°C. Therefore the fish is likely to be spoiled before the production of toxin or the development of a high number of pathogens. When the products are cooked before consumption, the risk is completely eliminated. Thus, the likelihood at the fish receiving step is classified as D (unlikely to occur).

Brining is an essential part of the whole operation as the salt content in the fish in combination with smoke and heat treatment is necessary to control the growth of microorganisms. There have been reported cases of contamination of smoked salmon with *L. monocytogenes* [51]. Because of the critical nature of brining, smoking, and cool storage operations and reported cases of contamination, the hazard of microbial growth is classified as a likely event (likelihood score = C) and thus, these steps are CCPs. Table 57.25 shows the risk analysis of the hazards identified as significant.

57.13.4 Overall Risk Assessment and Reduction

The fish are a major source of microbial contamination. Raw fish should be examined for freshness and wholesomeness. All eviscerated fish or fish not being used should be kept below 0°C. Frozen fish should be checked for wholesomeness. The production facility should ensure that the cleanliness of plant and equipment, a hygienic environment, and personnel hygiene are maintained to minimize the risks of contamination.

During frozen fish storage, the temperature can be monitored through continuous surveillance using security alarms. The smoking process is critical, and the internal temperature of fish during this process can be monitored using thermocouple probes in the three thickest fish in the coldest part of the oven. A sample from each oven load should be analyzed for water-phase salt (WPS) level. The cooling step after smoking should be controlled because of the possibility of microbial growth if the cooling period is too long.

Time–temperature integrated (TTI) labels may be applied to the finished product to indicate any abuse of temperature over a certain period of time. Tamper-evident packaging will provide further security against intended or unintended contamination. An automatic labeling system with alarms will ensure the application of the label on every pack.

57.13.5 Control Schedule

The steps that have been identified as CCPs are controlled as specified in the control schedule (Table 57.25).

57.14 GOOD MANUFACTURING PRACTICES

In preparing the salad and the hot smoked salmon there are several operations that are control points but not critical control points. These steps can be controlled by implementing good manufacturing practices. Inspection and storage of raw materials, cleaning of equipment, use of food-grade detergents and disposal gloves, training in personnel hygiene, a preventive maintenance program, and the use of status stickers are some of the controls that must be considered to assure the safety of the final product. Regular audits provide a means of verifying the effectiveness of the procedures.

57.15 ISO 22000 STANDARD

The International Organization for Standardization developed the ISO 22000 Food Safety Management Standard [52]. It will define the requirements for a food safety management system for all organizations in the food chain from farmer to catering, including packaging. The standard aims to harmonize the voluntary international standards.

58 Good Manufacturing Practice (GMP)

Titus De Silva

CONTENTS

58.1 INTRODUCTION

Good Manufacturing Practices (GMPs), also known as current Good Manufacturing Practices (cGMPs), are a series of manufacturing and administrative procedures aimed at ensuring that products are consistently made to meet specifications and customer expectations. The regulations governing GMP cover a variety of consumer goods such as human pharmaceutical products and veterinary products (21 CFR 210-211); biologically derived products (21 CFR 600 and CFR 620); medical devices (21 CFR 820); manufacturing, packaging, or holding human food (21 CFR 110); and processed food (21 CFR 100) [1]. In relation to food, the implementation of GMP results in safe and quality food. In the United States, the Food and Drug Administration (FDA) has issued these regulations as the minimum requirements for manufacture. Most countries have their own GMP regulations for pharmaceuticals. The first formal set of GMPs was published by the FDA in 1963 as Part 133 [1].

58.2 GMP ACTIVITIES

Figure 58.1 shows the various activities of GMP. It supports and brings together many programs, systems, and philosophies that lead to an effective food business providing safe and quality products. The three main elements of GMP are

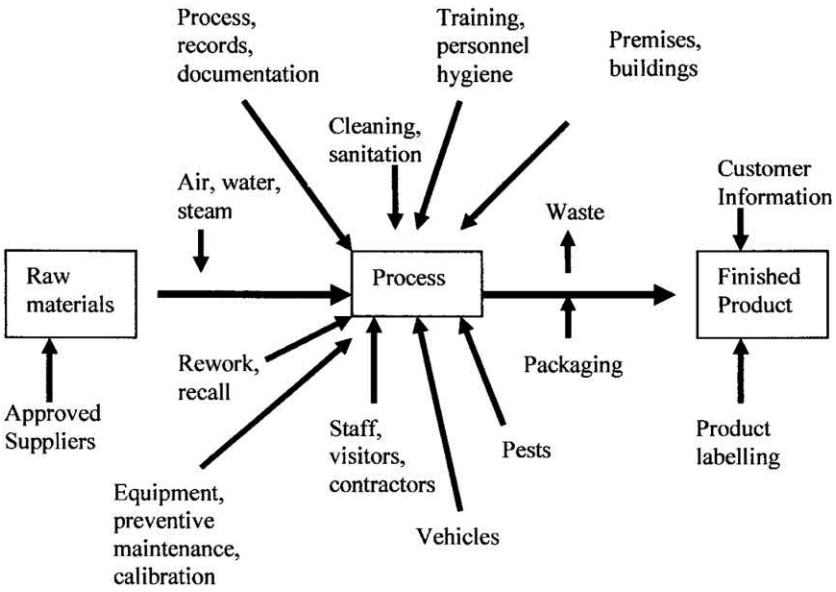

FIGURE 58.1 Activities of GMP.

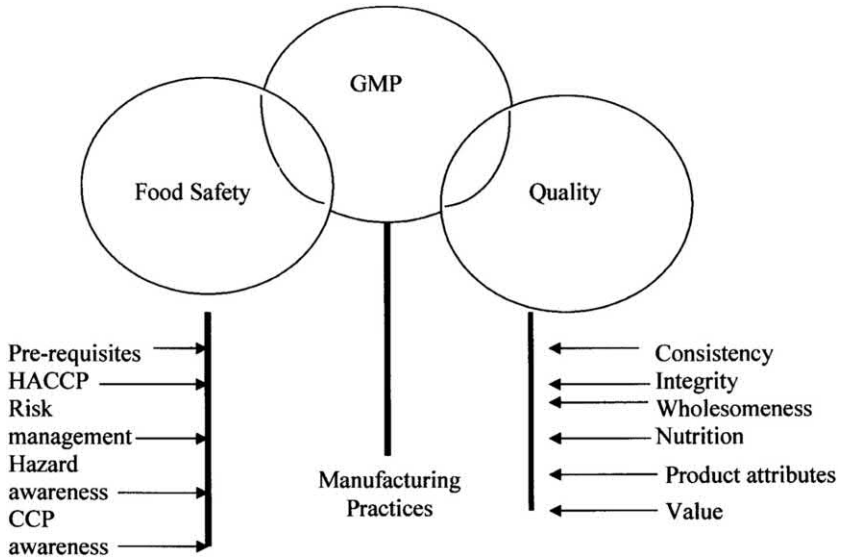

FIGURE 58.2 Core food business.

food safety, good practice, and quality. Their relationship to one other is shown in Figure 58.2. Food safety and quality management systems, and the standards provide a firm foundation for the survival of the business by adding attributes of quality and value to the product. This will enable the food business to gain competitive advantage.

58.3 GMP PHILOSOPHY

The philosophy behind GMP is summarized [2] as (i) GMP is closely aligned with disciplines such as quality, management, food safety, and food quality; (ii) GMP is designed by food manufacturers for food manufacturers; (iii) GMP involves the entire food business operation from establishment of policy to its implementation; (iv) GMP is a proactive and hands-on document; (v) GMP has provision to exceed customer's expectations and provides confidence in the product and consistency in the process; (vi) every activity within the food business impacts on the finished product; and (vii) through GMP, value is built into the product and loyalty to the brand.

58.4 FOUNDATION OF GMP

GMP is based on two complementary and interacting components: effective manufacturing operations and effective food control operations. Complementary to these two components are the management functions of these two components.

58.4.1 Effective Manufacturing Operations

GMP requires that every aspect of the food manufacturing process is clearly defined and effective in achieving the desired result and that all necessary facilities are provided, including [3] (i) adequate premises and space; (ii) correct and properly maintained equipment; (iii) appropriately trained personnel; (iv) correct ingredients and packaging material; (v) suitable storage and transport; (vi) documented procedures for all operations including cleaning; (vii) appropriate management and supervision; and (viii) adequate administrative, technical, and maintenance support. Record keeping is an integral part of the manufacturing operation, and records provide evidence of completed activities in the plant. Procedures are necessary for all processes including training, written in a manner easily understood by the operators.

58.4.2 Effective Food Control

Effective food control can be achieved by having an efficient food control management plan by (i) providing adequate facilities for inspection, sampling, and testing; (ii) monitoring process conditions and the production environment; and (iii) providing prompt feedback to manufacturing personnel to enable them to make adjustments, when necessary. Control mechanisms are established for all tasks from receiving raw materials to the delivery of finished goods or disposal of nonconforming goods.

58.4.3 Effective Management

The achievement of GMP objectives is the responsibility of senior management and requires active participation and commitment of personnel in many interacting departments at all levels within the organization and its suppliers. To accomplish the objectives, there must be a comprehensively designed and effective quality system incorporating the elements of GMP. The basic concepts of quality assurance, GMP, and quality control are interrelated. Senior management must have a formal commitment to compliance with the GMP requirements. Management has to ensure that the key personnel are suitably qualified and trained to carry out their tasks according to the prescribed procedures. Over the past 10 years, there has been a global attempt to formalize the management process that guides the establishment of GMP [4]. The result of this attempt is the ISO 9000 series of standards.

58.5 PRELIMINARY PROCESS

A manufacturing organization adopting the GMP principles is able to (i) consistently meet its own and customers' requirements, (ii) meet industry standards and codes of practice, and (iii) comply with regulatory requirements. In order to achieve this, the organization has to plan its activities. The preliminary process for GMP is shown in Figure 58.3. The scope of GMP is not only the production of a perfect end product but also the demonstration of activities that accomplish the end product.

58.6 GMP ACTIVITIES

GMP is intended to build quality into the product at all stages of the operation, and the activities associated with GMP are [5, 6] (i) organization and personnel, (ii) training and personnel hygiene, (iii) building and facilities, (iv) equipment, (v) control of components, (vi) production and process control, (vii) packaging and label control, (viii) storage and distribution, (ix) laboratory control, (x) documentation, (xi) cleaning and sanitization, (xii) maintenance and calibration, (xiii) pest management, (xiv) foreign matter control, (xv) waste management, (xvi) reworking material, (xvii) audits and review, (xx) customer complaint procedure, and (xxi) recall procedure.

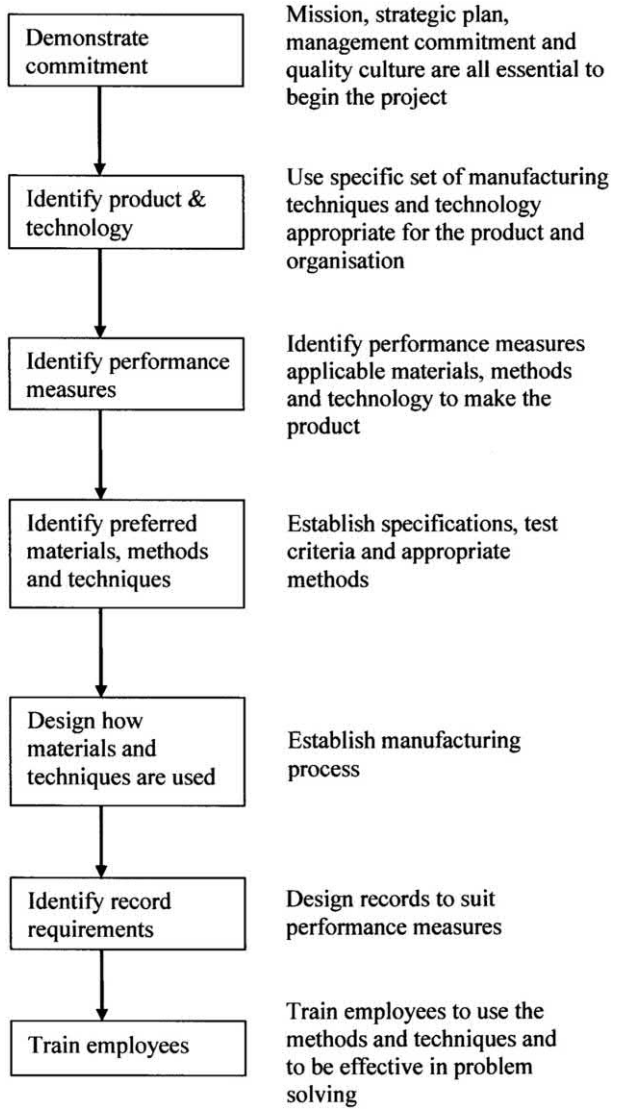

FIGURE 58.3 Preliminary process for GMP.

58.6.1 Organization and Personnel

To implement the GMP program effectively, it is necessary for the organization to establish a structure appropriate for the business. It must have an adequate number of personnel who have the relevant qualifications and training to perform the required tasks. Their duties should be clearly explained before the commencement of the tasks. The training program should cover the principles of GMP, specific tasks, and personnel hygiene.

The three key personnel in a manufacturing organization are the quality control/quality assurance (QC/QA) manager, the production manager, and the purchasing manager. The QC/QA manager has the authority to (i) approve materials and finished goods; (ii) reject, hold, or quarantine nonconforming products; and (iii) recommend suppliers. The production manager is responsible for production, personnel, equipment, operations, and the management of records. It is the responsibility of the production manager to ensure that products are manufactured to the relevant specifications within the budgeted cost. In consultation with the QC/QA manager, the production manager should (i) generate specifications for materials and products, (ii) train manufacturing staff, and (iii) control the manufacturing environment and hygiene.

The purchasing manager has the authority to order raw materials that comply with established specifications and initiate action with the suppliers when the purchased product does not meet product specifications. The management must demonstrate support and commitment to the principles of GMP and create an environment where the employees take ownership. Leadership and motivation are key features of an effective business organization. The managers must adopt a proactive approach and promote a quality culture within the organization so that the employees take pride in their workmanship.

58.6.2 Training and Personnel Hygiene

The organization has to ensure that the employees have appropriate facilities and are trained to promote personnel hygiene and safe food handling. The training program has to reflect the type of operation and the level of education of its employees.

58.6.2.1 Recruitment and Induction

The basis of the recruitment and selection process is the ability to do the task at the time, unless the organization has a program to train the new recruit. The organization has to ensure that the person has the capability to perform the job either after training or with previous experience. The recruitment process and subsequent training are thus critical for food safety. Job descriptions have to be established for all positions. The relevant competence and/or training requirements

are specified for each job. The aim of the induction process is to prepare the new employee for the company culture and the process itself should commence with the introduction of the person to the business, its quality system, organization expectations, and the tasks required of them. The person's responsibilities, reporting structure, and the disciplinary process have to be clearly defined.

58.6.2.2 Competence and Training

Competence is the demonstrated ability to apply knowledge and skills to a task correctly and completely the first time without assistance. The organization should ensure that minimum levels of competence are maintained and that the employees perform the tasks without supervision.

The training program should include the principles of GMP and the demonstration of competence in the company's hygiene practices, its quality management system, and the operating principles of the activity. It is essential that the trainer emphasizes the reason for maintaining food hygiene and compliance with legal requirements. At regular intervals, it is the manager's responsibility to review the training requirements and address the deficiencies.

58.6.2.3 Food Hygiene Requirements

Training in food hygiene is an essential part of the training program. The food hygiene requirements [7, 8] include (i) clean protective clothing; (ii) hair and beard covers where necessary; (iii) washing hands before commencing work; (iv) keeping the body, hands, and clothing clean; (v) prohibition of smoking within the premises; (vi) exclusion of personnel suffering from infectious disease; (vii) covering wounds with waterproof plaster; (viii) first aid material; and (ix) prohibition of wearing jewelry or loose items.

58.6.3 Building and Facilities

Buildings should be located, designed, and constructed to suit the type of operation that permits the separation of individual processing, manufacturing, packing, testing, and storage operations to avoid mix-ups, cross-contamination, and deterioration. At all times the premises should be maintained in a clean and tidy condition. The processing areas should have (i) a ceiling made out of materials that prevent mold growth or build up of dust; (ii) floors made of impervious material free from cracks or open joints; (iii) walls of smooth impervious material to facilitate easy cleaning; (iv) environmental controls such as adequate lighting, ventilation, heating, cooling, and proper washing and sanitary facilities; (v) entry points sealed off to prevent pest access and inhibit waste odors; (vi) drains that allow maximum flow of waste and have trapped gullies and proper ventilation; (vii) changing rooms segregated from processing areas; (viii) provision to contain waste in covered containers regularly disposed; (ix) protection for receiving and dispatch of materials and products in storage from weather; (x) written procedures for cleaning all processing areas; and (xi) pest control devices placed at appropriate locations away from open product.

58.6.4 Equipment

All equipment used in the manufacturing area should be suitable for its intended use and properly maintained and cleaned. It is a good practice to use protective covers on equipment where there is a threat of contamination from external sources. All precautions must be taken to prevent contamination from hands and equipment during maintenance when processing takes place. All surfaces which come into contact with food should be (i) inert to the food and should not contaminate the food; (ii) microbiologically cleanable, smooth, and nonporous; (iii) visible for inspection and cleaning; and (iv) set to enable self-emptying or self-draining. The equipment should be arranged to protect the contents from external contamination from leaking joints, lubricants, and broken metal parts. A program of preventive maintenance should be scheduled for all equipment, and during preventive maintenance it is essential that the engineer reports the missing parts such as nuts, bolts, springs, etc. so that appropriate action can be taken. Before and after every use, it is a good practice to clean all equipment. Documented cleaning procedures should be available at all workstations. Power-driven equipment can sometimes generate fumes and appropriate precautions should be taken to prevent the food from contamination.

58.6.5 Control of Components

To ensure the finished product has the right quality attributes and is safe to consume, the raw materials, including packaging that comes into direct contact with food are purchased from approved suppliers. The criteria for the approval of suppliers should include the following: (i) the supplier should be able to meet the organization's requirements, (ii) the quality is acceptable, (iii) the supplier can meet the delivery needs, (iv) the price is acceptable, and (v) the supplier has an effective food safety program in place.

Adequate precautions should be in place to prevent any contamination before and after delivery to the premises. They are held in a segregated area in quarantine until their status has been determined after appropriate inspection. Segregation should also be extended to electronic documentation to prevent the material from being used in production before their status has been determined. The organization's inspection criteria may include (i) conformance certificates, (ii) provision of test results, (iii) identification on receipt, and (iv) full analysis or any combination of these criteria. While in storage, all raw materials are regularly checked to ensure that they remain in acceptable condition. The storage areas are maintained in hygienic condition and in conditions appropriate for the type of raw material.

During the receipt and issue of raw materials, the organization has to ensure that the details of products are traceable through appropriate record keeping. Further controls may include checking weights/volumes, stock rotation and identification. It is essential that appropriate stickers are applied following inspections. The status stickers generally in use are

HOLD: materials whose status is in doubt
QUARANTINE: materials whose status is yet to be determined
REJECT: materials unsuitable for use
PASSED: materials suitable for use

The reasons for the hold, quarantine, or rejection and the date should be clearly stated on the label.

58.6.6 Production and Process Control

A fundamental requirement of any manufacturing organization is that the processes are capable of consistently producing finished goods, which conform to established specifications, and for food products to be free from contaminants. The effectiveness of the processes have to be determined prior to production by means of controlled trials. Similar evaluations are done whenever there is a change in the raw materials, methods of manufacture, or equipment. Before commencing production, checks should be carried out to ensure that (i) the processing area is free from potential contaminants, (ii) correct materials and methods are used, (iii) correct setup procedures are used, and (iv) all equipment is clean and ready for use. Work instructions are kept at all workstations and are written in a clear and simple style for easy comprehension by the operators.

58.6.6.1 Controls during Production

Accurate records have to be maintained of all production data including the operating conditions and quality parameters. Statistical control charts are used to identify deviations from the normal. Problems that cause stoppages, breakdowns, and emergencies are identified, recorded, and promptly addressed. Process controls specify the type of tests to be conducted, the frequency of checks, and the operating limits. Suitable methods should be used to identify the batches of production, delivery vehicles, container numbers, etc., to enable effective traceability. The controls ensure that the product is not contaminated and is capable of preventing the growth of microorganisms. This is achieved by careful monitoring of physical factors such as time, temperature, humidity, water activity, pH, pressure, flow rate, and others as appropriate. Suitable conditions are maintained throughout the process to prevent the decomposition of the product and/or the growth of microorganisms.

During processing, steps are taken to ensure that food is protected against inclusions of metal and other extraneous material. This can be achieved through the use of magnets, metal detectors, etc. Food processing operations often involve processes such as washing, peeling, cutting, sorting, inspecting, etc., and these are performed in a manner that prevents the food from contamination from hands, equipment, utensils, etc. The processing areas used for food production are not used for the manufacture of nonhuman food.

58.6.6.2 Control of Finished Product

Finished products are not released until they are tested and approved by the authorized person. Nonconforming products are segregated and quarantined. Appropriate storage conditions are adhered to before and during the delivery of finished goods.

58.6.7 Packaging and Delivery

Very often in packaged food items, the packaging material comes into direct contact with the food. The organization must ensure that packaging materials possess the following features: (i) made with approved food-grade material; (ii) capable of protecting the food item during its expected life under normal conditions; (iii) appropriate for the production in terms of moisture absorptions, moisture loss, etc.; (iv) capable of standing up to recommended operations such as microwave heating, pressure, etc.; (v) no interaction between the food and the packaging material; (vi) capable of maintaining the characteristics and the integrity of the product; (vii) correct for the product being manufactured; and (vii) passes the test criteria.

Over the last few years, consumers have become increasingly aware of the characteristics of the products they purchase through effective communication. The regulatory measures ensure that appropriate information is displayed on food products either on the label or on the immediate package. The label is not only a marketing tool but also a source of information to the consumer. The finished product should carry mandatory information and other information such as instructions for reconstitutions, storage conditions, target consumer groups, etc. as applicable. A unique code identifies the food product for recall purposes, if necessary. In many countries, attention is now focused on the declaration of allergens, and whether the food is genetically modified.

58.6.8 Storage and Distribution

Storage and distribution are significant elements in the food supply chain. The primary purpose of storage and distribution of food products, ingredients, and packaging is to protect them against physical, chemical, and microbial contamination as well as against deterioration of the food and the container. The principles of good hygiene practice apply not only to food and the ingredient but also to packaging components that come into direct contact with food. The buildings, grounds, and equipment of food storage warehouses have to be designed, constructed, and maintained in a manner that does not compromise food safety standards.

58.6.8.1 Storage

Storage, transport, and distribution are an important link between the producer and the consumers. Even if sufficient care has been taken to ensure the quality and the safety of food, uncontrolled storage and transport conditions can severely affect food products. The storage conditions have to be appropriate for the type of food production facility, and the controlled conditions include (i) regular inspection of material for signs of deterioration, (ii) maintaining correct storage conditions for the type of product, (iii) regular cleaning

to maintain storage areas in hygienic conditions, (iv) a pest control program, (v) maintaining stock rotation, (vi) maintaining the integrity of the stock during internal and external transport, and (vii) segregation of products that have not been released for distribution.

58.6.8.2 Distribution

It is essential that transport and distribution are carried out by approved suppliers. The organization should ensure that vehicles used for transporting food products are not used for carrying animals, harmful articles, chemicals, or biological products. It is a good practice to ensure that the transporting facility has a good cleaning program, and it is the responsibility of the organization to inspect vehicles for general cleanliness, accumulation of water, presence of foreign material, or damage that could cause contamination of the food product. The inspection checklist may include (i) openings that permit the entry of pests, rodents, birds, and/or insects; (ii) foreign odors; and (iii) presence of nails splinters, oil, grease, dirt, and/or bird droppings. Security precautions should deter any tampering with products during transport. Distributing the load in a uniform manner can avoid damage to the products and people or the vehicle during transport. All instruments necessary to maintain the environmental conditions inside the vehicle should be regularly inspected and maintained.

58.6.9 Laboratory Controls

Laboratory testing is an integral part of the production process and it provides its customers, both internal and external, with accurate test results at all relevant times in order to fulfill the GMP requirements. The minimum requirements for laboratory practice are shown in Table 58.1. It is important to maintain the integrity of the testing laboratory. This may be achieved by the accreditation of the laboratory to a national standard.

TABLE 58.1
Requirements for Good Laboratory Practice

Control Item	Requirement
Personnel	Qualified and competent
	Suitably trained
Sample control	Documented criteria for receiving, accepting, and rejecting samples
	Clear traceability information
	Procedure for handling and storage of samples
	Sampling plans and equipment for sampling
Facilities and environment	Facilities and environment compliant with regulations
	Good housekeeping
	Monitored environmental conditions
	Prevention of cross-contamination
	Appropriate facilities and environment for conducting tests
Equipment control	Suitable equipment for effective performance of tests
	Calibration schedule for equipment
	Maintenance of current equipment
	Procedure for the purchase of new equipment
	Clear operating instructions at workstations
	Reference materials such as weights, thermometers, hydrometers, etc.
Test methods	Validated and documented test methods
	Performance monitoring
	Validated quality control standards such as media, pH, buffers, etc.
	Procedure for "suspect" test results
Record control	Management of records of test results
	Traceability of a record to a standard/sample
	Inclusion of information such as the operator, signature of the authorized person for approval, and amendments and deviations from expected results
	Preserved from deterioration
	Easy retrieval
Test reports	Testing laboratory name and the customer
	Sample details
	Test method
	Accuracy of the test method
	Appropriate dates
	Authorized signature
	Results of tests as required by the customer
Documentation control	Scope of the laboratory function
	Recruitment of staff and necessary qualifications
	Management of samples
	Management of equipment
	Test methods
	Performance reviews
	Reviews of corrective action reports and audits

58.6.10 Documentation

The documents in the production facility provide evidence that a particular activity has been followed and has been successful or failed. The aims of documentation are as follows: (i) define materials, processes, control measures, and products; (ii) record and communicate information needed before, during, and after production; (iii) reduce the risk of error arising from poor communication; and (iv) permit investigations and traceability in case of failures of product or process. Documents fall into three main categories: instruction and procedures, programs, and records and reports.

58.6.10.1 Instructions and Procedures

Instructions and procedures are essential for any plant's effectiveness and efficiency. They provide information about how to perform tasks safely, effectively, and efficiently. They can be used for the training of employees. Instructions and procedures incorporate the best practices that result from previous learning experiences. The user is actively involved in the development of procedures and instructions and they have to be helpful and intelligible. A good procedure (i) describes the purpose of the task, (ii) emphasizes significant steps sequentially, (iii) defines responsibilities, (iv) provides guidance in the case of a problem and identifies decision points, and (v) is supported by flow diagrams, photos, and drawings in color. The documents that provide instructions and procedures are shown in Table 58.2.

TABLE 58.2
Instructions and Procedures

Document	Description
Specifications	Raw materials, packaging materials, in-process controls, finished goods, customer requirements
Procedures	Manufacturing instructions
	Purchase procedures
	Quality policy and quality system procedures
	Product recall procedures
	Standard operating procedures
	Cleaning instructions
	Plant operating instructions
Schedules	Maintenance schedule
	Calibration schedule
	Audit schedule
	Review schedule

58.6.10.2 Programs

Programs are the scheduled activities carried by the organization to meet its targets. These include production programs, training programs, pest management programs, waste disposal programs, and environmental management programs.

58.6.10.3 Records and Reports

The records and reports include data entered before, during, and after manufacture to provide evidence of controls in place for the production of safe food. Some examples of records and reports are (i) records of receipt, inspection, approval, and issue of raw materials; (ii) records of tests and release information on bulk products, finished products, and intermediates; (iii) in-process control charts and calibration records; (iv) weight/volume control records; (v) batch manufacturing records; (vi) customer complaint reports; (vii) quality control records, audit reports, and reviews; and (viii) corrective action reports. Documents and records are maintained for a period after the end of the expected shelf life of the product as specified by the regulatory bodies or as required by the organization. These also include electronic data and documents that should be backed up according to a scheduled program.

58.6.10.4 Document Control System

An effective documentation control system ensures that the documents and critical control records are available, up to date and correct. The following information is essential for a document control system: (i) title, (ii) issue date and issue number, (iii) signature of the authorized person, (iv) reference number of the document, (v) page number, and (vi) changes made.

58.6.11 Cleaning and Sanitation

Cleaning is the complete removal of food soil using appropriate chemicals as recommended. Sanitation is the process of reduction of microorganisms to a safe level. Cleaning and sanitation is the most important aspect of the hygiene program. Detailed procedures have to be established for all surfaces that come into contact with food products as well as for others such as overhead structures, walls, ceilings, etc. The objective of any cleaning and sanitization program is to remove food soil on which microorganisms can grow and kill microorganisms present. The cleaning program has to be evaluated for its effectiveness by carrying out appropriate tests. The procedures should specify the cleaning and type of chemical for each production line.

58.6.11.1 Cleaning and Sanitization Steps

Cleaning and sanitization consist of four steps [9, 10]: (i) Physically remove food particles and foreign matter by sweeping, wiping, or prerinsing in cold water. Rinse any equipment containing high-protein substances with cold water (hot water will cause proteins to be baked onto surfaces). (ii) Wash equipment in hot water and detergent to remove grease and dirt. (iii) Rinse with hot water again to remove dirt and detergent, and air-dry. (iv) Sanitize equipment and surfaces with a chemical or by immersing in water at 82°C.

58.6.11.2 Cleaning Methods

Mechanical cleaning, also referred to as cleaning-in-place (CIP), employs automated programs. It does not require disassembly or partial assembly. The temperature and contact times are automatically controlled. Cleaning-out-of place (COP) allows partial disassembly and involves cleaning in specialized pressurized tanks. Manual cleaning requires total disassembly for cleaning and inspection.

58.6.11.3 Sanitization Methods

Effective sanitization of food product contact surfaces achieves a reduction of contamination level by 99.999% (5 logs) in 30 seconds [10]. Nonproduct contact surfaces require a contamination reduction of 99.9% (3 logs) using the test organisms *Staphylococcus aureus* and *Escherichia coli*. There are two types of sanitization methods: (i) thermal sanitization, which involves the use of hot water or steam at a specific temperature for a specific contact period; and (ii) chemical sanitization, which involves the use of an approved chemical sanitizer at a specified concentration and contact time.

58.6.12 Maintenance and Calibration

Repair, maintenance, and calibration of the plant and equipment are essential for the effective operation of the processes.

58.6.12.1 Repair

When repairs are done by outside contractors, such as electricians, fitters, builders, plumbers, etc., the standard of service required has to be specified. The organization must ensure that they comply with food hygiene and other requirements, and that the work has been carried out to the expected standard.

58.6.12.2 Preventive Maintenance

An effective preventive maintenance program will avoid unnecessary downtime due to machine breakdowns. Suitably

qualified and skilled personnel have to be employed to carry out maintenance activities. In addition to the preventive maintenance schedule, the management must respond to breakdowns or unusual occurrences observed or detected by the operators.

58.6.12.3 Intrusive Maintenance

Intrusive maintenance is the activity of carrying our maintenance while production is in progress. When intrusive maintenance is carried out, the safety of the product is not compromised. Adequate precautions have to be taken to ensure that the product in progress is carefully controlled and protected to prevent any contamination as a result of maintenance or change in environmental conditions.

58.6.12.4 Calibration

It is necessary to calibrate measuring equipment to maintain the integrity of the measurements. Calibrations are carried out by certified organizations to enable traceability to a national standard. The calibration schedule has to reflect the critical nature of the measurement, the environment in which the instrument is placed, and the previous history of deviations. The equipment and instruments that are out of calibration should be promptly removed from use.

58.6.13 Pest Management Program

The most effective method of controlling infestation is by maintaining good housekeeping standards. Control of pests is important to prevent the spread of disease and contamination of the product. To maintain the pest management program, it is essential to have appropriately trained personnel or employ a professional pest control organization. A documented pest management program contains the following information: (i) location of baits; (ii) the date when the baits are placed; (iii) record of use (quantity, areas, frequency) of pesticides; (iv) chemicals used for rodents, birds, and insects; (v) record of signs of pest activity; and (iv) procedure for updating the program when the system or building changes.

The program manager ensures that all materials, products, packaging, utensils, and surfaces in contact with food are protected from contamination by pest control substances. An effective system of internal communication is essential so that the production personnel can prepare the plant for pest control. Products and equipment are stored at a distance of 50 cm from adjacent walls to facilitate cleaning and inspection for infestation. Site inspections are carried out at regular intervals and records of inspections are maintained as evidence.

Pest control devices include electric fly killers, rodent traps, nets for birds, scaring devices, shooting of birds, baits, and insecticides. The entry of pests can be prevented by (i) careful design and maintenance of buildings to prevent any access, (ii) clearing of nesting sites, and (iii) providing appropriate screens on doors and windows. A good housekeeping program reduces the risk of infestation. This is achieved by (i) effective waste management, (ii) inspection of food products on receipt, (iii) proper storage in pest-proof environment, and (iv) closing all possible entry points.

58.6.14 Foreign Matter Control

Foreign matter can originate from incoming goods and during processing operations. In order to minimize the risk of contamination, controls are applied at various locations in the production chain, i.e., supply, manufacturing, packaging, storage, and distribution.

58.6.14.1 External Sources of Contamination

The external sources are often associated with contaminants such as pests. Similarly, methods of handling, production, and packaging can give rise to foreign matter, for example, stones in peanuts and pieces of wood in herbs. Since raw materials are the primary source of contamination, the specifications should be designed to include limits on the exclusion of foreign matter.

58.6.14.2 Internal Sources

There are several internal sources of foreign matter: (i) building, installation, plant, and equipment; (ii) surface coatings and finishes; (iii) maintenance tools; (iv) personnel; and (v) recovered product.

58.6.14.3 Foreign Matter Control

Plant, equipment, and buildings are regularly inspected to detect and address any deterioration, soiling, or detachments. During processing, precautions can be taken to minimize the risk of contamination with foreign matter and such precautions include (i) the use of metal detectors; (ii) sieving, filtering, sifting, washing, inspection, and sorting; (iii) magnetic grids and plates; (iv) keeping containers not in use inverted; and (v) closely monitoring glass breakages and implementing an effective clean-up procedure.

Implementing a Hazard Analysis and Critical Control Points (HACCP) program minimizes the potential for contamination of food with foreign matter, chemicals, and microorganisms.

58.6.15 Waste Management

With the global focus on environmental management, waste and effluent disposal have become important issues for organizations as well as for regulatory bodies. The organization has to ensure that waste is controlled to ensure that there is no contamination to the finished product. Contamination could occur from spills, waste plastic drums/containers, harmful chemicals, etc. Food scraps are also a major source of food for bacteria, insects, and rodents. Packaging may be a source of food. A well-planned waste management program with procedures, accountabilities for those managing waste, and accurate records will minimize not only regulatory noncompliances but also chances of contamination. ISO 14001 [11], the Environmental Management System, is an ideal standard to manage the environment. Table 58.3 provides guidelines for managing waste [12].

TABLE 58.3
Guidelines for Managing Waste

Item	Guideline for Managing
Waste bins	Require covers and locate well away from food production and storage areas
	Easily accessible for removal
Wet refuse	Metal or plastic containers with tight-fitting lids
	Collected from the premises daily or if this is not possible, precautions are taken to prevent rotting and pest access
	Regularly cleaned in suitable washing areas
Dry refuse	Metal or plastic containers with tight-fitting lids or in paper or plastic sacks held firmly with a close-fitting lid
Yard areas	Kept clean and dry
	Areas designated for storage of waste are included in the cleaning schedule
Waste on the floor	Cleaned immediately
Raw material packaging	Not used for storing food products
	Empty packaging disposed immediately
Old food containers	Not used for storing chemicals or nonfood items
	Label contents of the container
Emergencies	Establish emergency response procedures
	Contact numbers readily available
Environmental spills	Environmental spill kits

58.6.16 Reworking Material

Defective products may be reworked or reprocessed provided the resultant product complies with relevant specifications and is safe for consumption. Procedures should clearly define the standards for reworking or reprocessing. If defective products cannot be reworked, rejection may be the only viable option. All rejected products must be clearly labeled and physically segregated. The manner of disposal depends on the nature of the rejected product, but the organization has to consider (i) the means of recovering the cost, (ii) safeguarding the reputation of the company, (iii) protecting the consumer, and (iv) compliance with regulatory requirements.

58.6.17 Customer Complaint Procedure

Governments have enforced regulatory controls to ensure the rights of consumers. Customer complaints can be a valuable source of information on food quality and safety. A customer complaint procedure covers (i) written instructions to deal with complaints, (ii) authority to decide on the extent of the investigation and subsequent corrective action, (iii) documented recall procedure, (iv) process for investigating and responding to the consumer within the shortest possible time, (v) procedure to prevent a recurrence, if the complaint is justified, (vi) regular reviews of complaint reports for trends or any specific process requiring attention. A customer complaint involves the customer, the organization, and sometimes the regulatory authority. The organization has to ensure that all complaints are resolved promptly to avoid possible harm to the consumer.

58.6.18 Audits, Reviews, and Recall Procedure

Audits and reviews are used to verify whether the GMP activities are working correctly as planned. Audits are systemic and independent examinations involving on-site observation, interviews with staff involved with operations and review of records. On-site observation includes the inspection of documents, processes, and records. Records of monitoring activities, corrective actions, audits and calibration of equipment are checked for compliance with the GMP plan.

Reviews are carried out regularly to ensure that activities of the GMP plan are still relevant. It gives the opportunity for the organization to make any changes in the manner in which food is prepared or handled, leading to continuous improvement.

An effective recall procedure ensures that harmful food products are not available for consumption. The organization should ensure that effective procedures are in place to deal with food safety hazards to enable the complete and rapid recall of any defective products from the market. When a product has been withdrawn because of a health hazard, the recall of other products made under similar conditions should be seriously considered. Recalled products should be held under quarantine until the manner of disposal has been established and the product disposed of. These are discussed in Chapter 57 on HACCP.

58.7 ISO 9000 STANDARD, GMP, AND HACCP SYSTEM

The ISO 9000 standard is a management system for controlling and improving the performance of the organization. On the other hand, GMP is a code of practice that controls all aspects of manufacture. ISO 9000 provides a management structure for the effective implementation of the GMP program. The revised FDA Medical Devices GMP [13] places considerable emphasis on quality management systems. Quality policy, quality objectives, and management commitment are all essential features of this program [14]. The current regulations were designed after the publication of the ISO 9000 series (1994 version) [15] and 17 clauses have been adopted by the Medical Devices GMP regulations. HACCP system is a food safety program that provides an effective structure to GMP by providing a system that identifies, evaluates, and controls hazards that are significant to the production of safe food. Prior to the development of HACCP plans, it is necessary to review the existing programs and verify that all good manufacturing practices are in place and effective. The GMP program ensures that HACCP plans focus specifically on critical control points for product safety. If a GMP program is not adequately implemented, the HACCP plan will be less effective in ensuring product safety. ISO 9000, GMP, and HACCP systems are thus complementary to each

other and together they contribute to the production of safe food while making a profit for the organization by minimizing waste and having effective systems.

58.8 BENEFITS OF GMP

GMP is a dynamic program that enables the organization to make and maintain quality improvements. The principles of GMP offer greater assurance of food safety and quality through broad-based prerequisite programs and emphasize prevention and control of processes throughout the food chain. They are designed to introduce on-line process controls that can quickly respond to potentially hazardous situations and provide continuous measures of quality that can uncover problems and fluctuations as they happen and before the product is released. Combined with an effective HACCP plan, the safety of the food being processed can be readily detected and corrected at critical locations before the product is completely processed and packaged. Because of the generic nature of GMP, it is flexible enough to be adapted to different industries. An effective GMP program can offer several benefits to the organization, and some of the benefits are summarized in Table 58.4.

58.9 APPLICATION OF GMP PRINCIPLES

A GMP program ensures favorable conditions for the production of safe food. In combination with a proper HACCP plan, a robust food safety program can be developed. The generic principles behind the management of GMP activities listed in Section 58.6 can be conveniently applied to all food processing operations. However, control of components, production and processes, packaging and labeling, and storage and distribution may require specific consideration depending on the nature of the food product. These are discussed in the following applications.

58.9.1 Production of Fresh Produce

The production of fresh produce involves growing, harvesting, packing, processing, and transporting to the facility. The FDA has published [16] eight guidelines to ensure the microbial food safety of fresh produce: (i) Prevention of microbial contamination of fresh produce is more important than corrective actions following contamination. (ii) Growers and packers should adopt good agricultural practices in areas over which they have control while not increasing risks to the food supply or the environment. (iii) Human or animal feces in the orchard are a major source of contamination. (iv) When water is used for agricultural purposes and processing, its quality must be considered in order to minimize the risk of contamination. (v) Use of manure or municipal biosolids should be closely monitored to minimize the potential for contamination. (vi) Personnel hygiene and sanitation practices in the processing areas play a critical role in minimizing the potential for microbial contamination. (vii) Growers and packers must adhere to all regulatory requirements. (viii) Define authorities and responsibilities of personnel involved in all operations from growing to transporting fresh produce.

TABLE 58.4
Benefits of GMP

	Benefit
1	Creates awareness of food quality and safety among the staff
2	Increased confidence in product safety
3	Provides a starting point for HACCP program
4	Recognition internationally
5	Prevents regulatory noncompliances by meeting regulatory requirements
6	Prevents expensive failures
7	Reduces customer complaints and recalls
8	Improves profits

58.9.2 Production of Unpasteurized Apple and Other Fruit Juices

A variety of pathogenic organisms have been known to cause illness as a result of consumption of juice [17]. The most likely source of contamination is from fruits coming into contact with animal feces, water, containers, workers, or contaminated processing equipment. Therefore, GMP principles have to be applied to all stages from harvesting to the delivery of finished goods.

58.9.2.1 Orchard Management

A means to exclude domestic and wild animals should be used to prevent access of animals to the orchard. In locations where bird roosting is a problem, a means to scare birds should be used. To reduce the risk further, it is advisable to avoid animal manure. Water used to dilute pesticides can be a source of contamination and therefore orchard owners should be aware of the water quality. Records of pesticide and fertilizer applications have to be maintained.

58.9.2.2 Harvesting Practices

Sound, ripe fruits should be picked in clean bins and transported directly to the storage facility, sorting station, or juice processing plant, as appropriate. Drop fruits or rotten fruits should not be used for further processing. All bins should be labeled to show the orchard location, picking date, and picking crew.

58.9.2.3 Transportation

The vehicles used for transportation should be kept clean, and care should be taken to avoid damage and contamination during transport. The vehicle must be inspected prior to loading to ensure cleanliness and suitability.

58.9.2.4 Fruit Storage

Ideally, fruits should be pressed as soon as possible to prevent an increase of pH, which would favor pathogen growth during storage. However, if fruits need to be stored, rapid cooling to

0°C will maintain fruits in good condition. During storage and subsequent operations, fruits should be gently handled to minimize physical damage.

58.9.2.5 Fruit Sorting and Cleaning

Inspection for sorting should be done in a clean, dry, well-lit environment, and decayed, damaged, or otherwise spoiled fruits should be removed to prevent contamination of juice.

Fruit cleaning is done by effective washing, brushing, and rinsing. Food-grade sanitizers can be used for washing, and sanitizer levels are monitored during use. Sanitizers are rinsed from fruits unless otherwise instructed by the manufacturer's instructions. The water used for washing and rinsing should be free from pathogens and maintained at least 5°C warmer than the temperature of fruits. Wash and rinse water should not be recycled, and records of water quality have to be maintained in the facility.

58.9.2.6 Fruit Inspection and Processing

Processing apples in cold storage should be kept between 0°C and 4°C, or at the recommended atmosphere and temperature for the variety. Pressing, filling, and sealing areas have to be enclosed to prevent access to pests. The processing areas should be separated from areas where fruits are sorted and washed. Appropriate filter cloth and tubing should be used in production, and tubing should be sanitized and cleaned before commencing the operations. Pomace residue is disposed of after each day's production.

58.9.3 Production of Fermented Dry and Semidry Sausage Products

Dry sausages are meat products with a pH of 5.3 or less that are chopped or ground and dried to remove 25–50% of the moisture. Semidry sausages are dried to remove 15% of the moisture. In their manufacture, special attention is paid to the microbiological condition of the products [18]. Testing requirements for *E. coli*, *Listeria* sp., *Salmonella* sp., and *S. aureus* are part of GMP.

58.9.3.1 Raw Material Treatment

Because of the potential microbiological contamination, a strict, comprehensive sanitation program is necessary. The control program begins at the source of raw products and the sanitization procedures must ensure that containers shipping raw product to the factory, including cartons, boxes, tankers, and trucks, are kept clean.

58.9.3.2 Processing

During slaughter and processing, product flow must prevent cross-contamination between raw and finished products. Possibilities of cross-connection, including human, equipment, water, air, or piping arrangements, should be investigated to eliminate potential cross-contamination. pH and time–temperature are essential controls for fermentation and direct acidulation, and these are maintained at levels that inhibit the growth of microorganisms. Separate wash areas have to be established for raw and ready-to-eat (RTE) products, and they should be located where clean RTE equipment does not cross raw meat areas of the plant.

58.9.3.3 Slicing and Packaging Equipment

Complete mechanical disassembly is required to allow thorough cleaning and prevent contaminants from accumulating. All food contact surfaces have to be cleaned and sanitized daily. During production and breaks, the moisture level of the environment needs to be carefully controlled. Protective covers on control panels, motors, equipment, and other food contact surfaces can be a source of contamination and should be cleaned regularly. Heat shrinking equipment, including exhaust ducts, should be cleaned and sanitized daily to avoid spreading contamination from water and steam to packaging lines.

58.9.4 Poultry Processing

Poultry processing includes the processing of poultry, poultry parts, and other edible materials from poultry that have not yet been treated any way to ensure their preservation [19]. They are chilled or frozen and intended for human consumption.

58.9.4.1 Inspection and Sorting

Different domesticated birds should be processed separately to protect against the risk of cross-contamination. All poultry should be subjected to antemortem and postmortem inspection as required by regulations or established protocols. All unfit poultry should be removed, segregated, and disposed of appropriately.

58.9.4.2 Washing and Other Preparations

After evisceration and inspection, carcasses are washed in clean water. Wash water should not be recycled. The water used during the preparation, handling, packing, and storing of poultry carcasses, poultry parts, and other edible material should be potable.

58.9.4.3 Preparation and Processing

All operations leading to the finished product and packing should be carried out in a timely manner to enable the rapid handling of consecutive operations, which would prevent contamination, deterioration, spoilage, or the development of infectious or toxigenic microorganisms. Bleeding and blood collection, scalding, plucking, and evisceration should be carried out under controlled conditions to prevent any contamination. Bleeding equipment, scalding tanks, plucking machines, and evisceration troughs should be maintained in good condition and cleaned regularly.

Special precautions must be taken with wax-dipped poultry so that set wax and removed feathers fall into suitable containers. Only clean wax should be used for wax dipping. Reclaimed wax should not be reused unless it has been heated to 80°C for at least 20 minutes. Before reuse, the wax is skimmed, washed, and filtered.

58.9.4.4 Cooling and Refrigeration Requirements

After preparation, carcasses are cooled rapidly to an internal body temperature of 4°C or less. When cutting takes place before cooling, it is done within one hour of slaughter. Immediately after cutting, the parts are stored at 4°C. When cutting is done after cooling, the internal body temperature is not allowed to exceed 10°C. Poultry carcasses, poultry parts, and other edible materials are stored in an environment that prevents deterioration and mold growth. They should be regularly inspected and used in strict rotation.

58.9.4.5 Ice-Pack Containers

The ice used in ice packing should be made from potable water and should be manufactured, handled, stored, and used so as to prevent contamination. When poultry carcasses are ice-packed in barrels or other containers, they are wrapped in plastic or other suitable material to protect against contamination. The barrels and containers should have holes to permit the water to drain out and must be covered. Wooden barrels or containers should not be used for this purpose because wood can be a source of contamination.

Part VII

Issues and Technologies Related to Food Preservation

59 Pesticide Residues in Foods: Their Sources and Reduction

Mohidus Samad Khan and Nadira Mustari

CONTENTS

59.1 INTRODUCTION

Pesticides are the substances or mixture of substances used to prevent, destroy, or control pests that may cause harm during production, processing, storage, transport, or marketing of foods and other agricultural commodities [1, 2]. The key objectives are (i) to control pests, plant diseases, and growth of organisms that could harm human activities and tree structures; (ii) to improve yield and quality of crops; and (iii) to save production costs of agricultural products [3, 5]. Globally, pesticide production, distribution, and application is a billion-dollar industry, which also provides job opportunities to millions of people around the world [6, 7]. However, the effects of pesticides and pesticide residues could be nonselective to pests and other living organisms, and may contaminate water bodies, affect nontarget and beneficial organisms, and persist in the environment for years. Populations are at high risk if they are exposed to direct or indirect sources of pesticides and/or pesticide residues. The entry sources could be the food and water chain. Therefore, a proper risk–benefit analysis needs to be done before using any type of pesticide.

To ensure safe pesticide use, regulatory actions have been taken by regulatory and environmental protection agencies of different nations, and hazardous synthetic chemical pesticides are being replaced by safer "organic" chemicals, such as biopesticides, which pose lower or no risk to the environment and human health [8]. However, lack of efficacy, inconsistent field performance, and high production costs are the limiting factors for them to become popular alternative products.

In this chapter, the ingredients of pesticides, classification of pesticides, relevant health concerns for different pesticide families, and management of pesticide handling are discussed. In addition, different pesticide management techniques, such as reduction of pesticide residues in grains and foods, alternatives to conventional pesticides, and prospects of organic farming are also covered.

59.2 HISTORICAL BACKGROUND OF PESTICIDE

The history of using pesticides to control pests is over 4000 years old. It is reported that different elemental compounds, such as sulfur, mercury, lead, arsenic, and copper, have been used as pesticides to control insects and pests [9]. The scopes and applications of pesticides have increased over the centuries to ensure high yield and to meet the demand of defect-free food production [10]. Worldwide, synthetic chemicals have been extensively used for the last few decades to inhibit or control pests, to reduce yield losses, and to uphold high-quality products. In recent years, the market of alternative pesticides, such as biopesticides, is also growing to reduce pesticide-related health and environmental hazards.

Humans have developed mechanisms to control pests since the beginning of agriculture. The earliest pest control strategies were conducted by the Sumerians in 2500 B.C.; they used sulfur compounds to control insects and mites. Greeks and Romans used oil sprays, ash, sulfur ointments, and lime to protect crops [11]. The modern-day chemical pest control era began in the early 1930s. Dichlorodiphenyltrichloroethane (DDT) was discovered as an effective insecticide in 1934 by the Swiss chemist Paul Müller [12]. DDT made a revolution in the world. DDT was used in Switzerland to control potato beetles in 1939 and commercial production began in 1943. It was effectively used in tropical countries to combat the anopheles mosquito, which transmits malaria. In 1946, Switzerland reported the first case of pesticide resistance: houseflies were not being affected by DDT anymore [13]. During the 1950s and 1960s, there were numerous reports of DDT-resistant plagues. In the following years, new types of pesticides were developed [14]. During this time, new approaches such as *integrated pest management* were developed and these are being adopted throughout the world to reduce pesticide consumption and increase efficiency in the control of pests.

The first legislation providing federal authority for regulating pesticides was enacted in 1910 [15]; however, decades later, during the 1940s, manufacturers began to produce large amounts of synthetic pesticides and their use became widespread [16, 17]. Pesticide use has increased 50-fold since 1950 [18, 19]. Seventy-five percent of all pesticides in the world are used in developed countries; however, the use of pesticides in developing countries is also increasing [20, 21].

In the 1960s, it was discovered that DDT was preventing many fish-eating birds from reproducing, which was a serious threat to biodiversity. Rachel Carson wrote the best-selling book *Silent Spring* about biological magnification, which also created an awareness revolution by pointing to pesticides as the reason for the systematic poisoning of the ecosystem [17]. The agricultural use of DDT is now banned under the Stockholm Convention on Persistent Organic Pollutants, but it is still used in some developing nations to prevent malaria and other tropical diseases by spraying on interior walls to kill or repel mosquitoes.

59.3 PESTICIDE INGREDIENTS

Pesticide products contain both *active* and *inert* ingredients. An active ingredient prevents, destroys, repels, or mitigates a pest; it can also be a plant regulator, defoliant, desiccant, or nitrogen stabilizer. All other ingredients are called inert ingredients by federal law of the United States of America [22]; they are important for product performance and usability.

59.3.1 Active Ingredients

Active ingredients are the chemicals in a pesticide product that act to control the pests. Active ingredients must be identified by name and weight percentage on the label of pesticide products. All ingredients other than biological pesticides and antimicrobial pesticides are considered conventional active ingredients. On the other hand, antimicrobial active ingredients are the substances or mixtures of substances used to destroy or suppress the growth of harmful microorganisms (such as bacteria, viruses, or fungi) on inanimate objects and surfaces. Ingredients derived from certain natural materials are called biopesticide active ingredients.

59.3.2 Inert Ingredients

Inert ingredients are combined with active ingredients to make a pesticide product. Inert ingredients are chemicals, compounds, and other substances, including common food commodities (e.g., certain edible oils, spices, herbs) and some natural materials (e.g., beeswax, cellulose). Inert ingredients play key roles in pesticide effectiveness and product performance. Inert ingredients serve the following functions: (i) act as a solvent to help the active ingredient penetrate a plant's leaf surface; (ii) improve the ease of application by preventing caking or foaming; (iii) extend the shelf life of a product; (iv) improve safety for the applicator; (v) protect the pesticide from degradation; and (vi) protect the pesticide from sunlight exposure. Under U.S. law, manufacturers are not required to identify inert ingredients by name or percentage on product labels. In general, only the total percentage of all inert ingredients is required to be on the pesticide product label.

59.4 CLASSIFICATION OF PESTICIDES

Pesticides can be classified according to their chemical structures, origins, working principles, target molecules, and possible health effects [23–29]. Different types of pesticides are briefly discussed in the following sections [23–30].

59.4.1 Inorganic Pesticides

Inorganic pesticides include arsenic, copper, and mercury compounds. Inorganic pesticides have the ability to remain in the environment for extended periods of time. They are generally neurotoxins and even a single dose may cause permanent damage.

59.4.2 Natural Organic Pesticides

Natural organic pesticides are mainly plant extracts, such as nicotine and nicotinoid alkaloids from tobacco; rotenone from the roots of derris and cubé plants; and pyrethrum, a complex of chemicals extracted from *Chrysanthemum cinerariaefolium* [11]. Even if natural, many of these compounds are toxic to humans and other life forms; recently rotenone has been linked to nerve damage and Parkinson's disease [31].

59.4.3 Fumigants

Fumigants are generally small molecules, such as carbon tetrachloride, carbon disulfide, ethylene dichloride, and ethylene dibromide, that easily gasify and penetrate rapidly into some materials. They are used to sterilize soil and prevent degradation of stored grain. These compounds are highly hazardous for workers, and their use has been severely restricted or banned.

59.4.4 Chlorinated Hydrocarbons

Chlorinated hydrocarbons are synthetic organics containing chlorine. They may be persistent in the environment and are subjected to bioaccumulation. Many chlorinated hydrocarbon pesticides have been banned or restricted throughout the world; however, some are still actively used. Chlorinated hydrocarbon pesticides include DDT, chlordane, aldrin, paradichlorobenzene, 2,4-dichlorophenoxyacetic acid, and 2,4,5-trichlorophenoxyacetic acid.

59.4.5 Organophosphates

Organophosphate pesticides are synthetic organics containing phosphorus complexes. These inhibit cholinesterase, an enzyme that regulates the peripheral nervous system. These are degraded easily, so their bioaccumulation is rare. Some examples are parathion, malathion, dichlorvos, dimethyldichlorovinylphosphate (DDVP), and tetraethylpyrophosphate (TEPP).

59.4.6 Carbamates

Carbamate pesticides are derivatives of carbamic acid; they act in the same way as organophosphates and have low bioaccumulation rates. Carbamate pesticides are generally toxic to bees. They include carbaryl, aldicarb, aminocarb, and carbofuran.

59.4.7 Microbial Agents/Biological Controls

Microbial agents are living organisms that control pests. Bacteria, viruses, and insects have been used as "natural" controls. They can act in four ways: as parasites of the pest, as predators, as pathogens, or as weed feeders [30]. Table 59.1 lists different groups of pesticides based on their purposes. Figures 59.1 and 59.2 present pesticide classifications based on pesticide origins and chemical structures, respectively.

TABLE 59.1
Classification of Pesticides Based on Their Purposes

Group of Pesticides	Purpose
Algaecides	Kill or prevent growth of algae
Antimicrobials	Kill microorganisms that produce disease
Attractants	Attract specific pests using natural insect chemicals called pheromones that confuse the mating behavior of insects
Avicides	Control pest birds
Biopesticides	Naturally occurring substances with pesticidal properties
Defoliants	Cause foliage to drop from a plant, typically to aid in the harvesting process
Desiccants	Aid in the drying process of plants or insects, usually for laboratory purposes; promote drying of living tissues, such as unwanted plant tops
Fumigants	Produce vapor or gases to control air or soilborne insects and diseases
Fungicides	Destroy fungi that infect plants, animals, or people
Herbicides	Kill weeds and other plants that are growing or competing with a desired species
Insect growth regulators (IGRs)	Accelerate or retard the rate of growth of insects
Insecticides	Control or eliminate insects that affect plants, animals, or people
Miticides (Acaricides)	Kill mites that live on plants, livestock, or people
Molluscicides	Kill snails and slugs
Nematicides	Kill nematodes, which are microscopic wormlike organisms that live in the soil and cause damage to food crops
Ovicides	Control insect eggs
Piscicides	Control pest fish
Plant growth regulators (PGRs)	Accelerate or retard the rate of growth of a plant; substances (excluding fertilizers or other plant nutrients) that alter the expected growth, flowering, or reproduction rate of plants
Predacides	Control vertebrate pests
Repellents	Repel pests such as mosquitoes, flies, ticks, and fleas
Rodenticides	Kill mice, rats, and other rodents

59.5 HEALTH EFFECTS OF PESTICIDES

Pesticides are designed to control pests, weeds, and other plant pathogens; however, their mode of action is often nonspecific due to the presence of heterogeneous chemicals [32]. Pesticides often kill or harm organisms other than pests, including humans. Because of the improper and irrational use of different types of pesticides, the environment as well as the food chain (e.g. vegetables and fruits) may get contaminated with these chemical substances [33]. Individuals can be exposed to pesticides or pesticide residues through the workplace or due to environmental contamination. Based on the level of toxicity and exposure, these residues can affect different parts of the human body. The hazard of using pesticides depends on the toxicity of the pesticide and the amount of exposure to the pesticide, and it is often illustrated with the following equation:

$$\text{Hazard} = \text{Toxicity} \quad \text{Exposure}$$

The toxicity of a pesticide is a measure of its capacity or ability to cause injury or illness. The toxicity of a pesticide is determined by subjecting test animals to varying dosages of the active ingredient and each of its formulated products. The harmful effects of different pesticide families are briefly discussed in the following sections.

59.5.1 Health Effects of Fungicides

The acute toxicity of fungicides to humans is generally considered as low. Fungicides can be irritating to the skin and eyes. Inhalation of spray mist or dust from these pesticides may cause throat irritation, sneezing, and coughing. Long-term exposures to low concentrations of fungicides can cause adverse health effects [34]. Most cases of human fungicide poisonings have been from the consumption of seed grain. Table 59.2 summarizes the signs and symptoms of acute exposures to commonly used fungicides [34].

59.5.2 Health Effects of Herbicides

In general, herbicides have low acute toxicity to humans. However, there are different herbicides that can be dermal irritants since these are often strong acids, amines, esters, and phenols. Inhalation of spray mist may cause coughing and a burning sensation in the nasal passages and chest. Prolonged inhalation may cause dizziness. Ingestion usually causes vomiting, a burning sensation in the stomach, diarrhea, and muscle twitching [26, 35]. Table 59.3 summarizes the signs and symptoms of acute exposures to commonly used herbicides [26, 35].

59.5.3 Health Effects of Insecticides

59.5.3.1 Organophosphate and Carbamate

Insecticides cause the highest number of pesticide poisonings in the United States. The most serious pesticide poisonings usually result from acute exposure to organophosphate and carbamate insecticides. Organophosphate insecticides include chlorpyrifos, diazinon, dimethoate, disulfoton, malathion, methyl parathion, and ethyl parathion. The carbamate compounds include carbaryl, carbofuran, methomyl, and oxamyl. Organophosphates and carbamates inhibit the enzyme cholinesterase, causing a disruption of the nervous system. All life forms with cholinesterase in their nervous system, such as insects, fish, birds, and humans and other mammals, can be poisoned by these chemicals. Organophosphate and carbamate insecticides inhibit the activity of cholinesterase, resulting in a buildup of acetylcholine in the body. An increase in

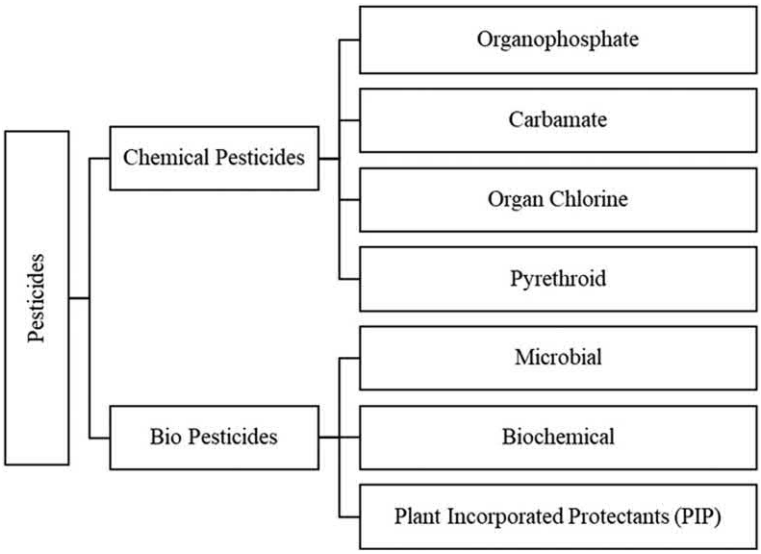

FIGURE 59.1 Classification of pesticides based on their origin. (From Rawtani et al. [28].)

acetylcholine results in the uncontrolled flow of nerve transmissions between nerve cells. The accumulation of acetylcholine causes the continual transmission of impulses across the synapses. The effects of organophosphate or carbamate poisoning can result in both systemic and topical symptoms. Table 59.4 summarizes the signs and symptoms from acute exposures to commonly used insecticides [26, 35, 36].

59.5.3.2 Organochlorine

Organochlorine insecticides are persistent organic pollutants (POPs), a class of chemicals that dissociate slowly in the environment and accumulate in the fatty tissues of animals [36]. Hence, POPs stay in the environment and food web long after being applied. Many POPs are endocrine-disrupting chemicals, which can create subtle toxic effects on the hormonal system of the animal body [37]. Endocrine-disrupting chemicals often mimic the natural hormones of the human body, disrupting the normal functions, and causing adverse health effects [38].

Among its wide variations, the mostly used organochlorine pesticides are DDT and its derivatives, such as hexachlorocyclohexane (HCH), aldrin, and dieldrin. These POPs are widely used in many countries because of their low cost and versatility against pests. Due to their potential bioaccumulation and biological effects, these POPs have been banned in different countries [39]; however, POPs are still available in the natural ecosystem [40]. Some of the names and related health effects of organochlorine pesticides are listed in Table 59.5 [41–48].

59.5.3.3 Pyrethroid Pesticides

Pyrethroid pesticides are potent neuropoisons, endocrine disruptors, and may cause paralysis [41]. Pyrethroids are a synthetic version of pyrethrin, a natural insecticide, and are more stable in sunlight than pyrethrins. Pyrethroid pesticides are popular insecticides as they can easily pass through the exoskeleton of the insect. Deltamethrin and cypermethrin are examples of pyrethroid pesticides [42].

59.5.3.4 Biopesticides

Biorational or biopesticides are considered relatively nontoxic to humans and environmentally safe. The U.S Environmental Protection Agency (EPA) defines biorationals as "certain types of pesticides derived from such natural materials as animals, plants, bacteria, and certain minerals" [42]. The effect

of biopesticides depends on the interruption of natural growth processes of arthropods. These do not selectively attack any arthropod species, but generally have extremely low toxicity for vertebrates, including people. This group includes insect growth regulators (IGRs), chitin inhibitors, plant growth regulators, and chromosterilants.

59.5.3.5 Microbial Pesticides

Microbial pesticides kill arthropods, either by releasing toxins or by causing infections through microbial organisms. Two common microbial pesticides are *Bacillus thuringiensis* serotype *israelensis* (Bti) bacteria and *Bacillus sphaericus* (Bs) bacteria [43]. Products from these bacteria are used to kill mosquito larvae; Bti also kills black fly larvae. Most microbial pesticides are more selective than biochemical pesticides. The organisms used in microbial insecticides offer greater safety since these are nontoxic and nonpathogenic to wildlife, humans, and other organisms [44].

All pesticides have the potential to be harmful to humans, animals, other living organisms, and the environment if used incorrectly. The key to reducing health hazards when using

TABLE 59.4
Signs and Symptoms of Acute Exposure for Several Insecticide Active Ingredients

Active Ingredient	Chemical Formula	CAS No.	Signs and Symptoms
Acephate (organophosphate)	$C_4H_{10}NO_3PS$	30560-19-1	Headache, excessive salivation and tearing, muscle twitching, nausea, diarrhea; respiratory depression, seizures, loss of consciousness; pinpoint pupils
Aldicarb (N-methyl carbamate)	$C_7H_{14}N_2O_2S$	116-06-3	Malaise, muscle weakness, dizziness, sweating; headache, salivation, nausea, vomiting, abdominal pain, diarrhea; nervous system depression, pulmonary edema in serious cases
Carbaryl (N-methyl carbamate)	$C_{12}H_{11}NO_2$	63-25-2	Malaise, muscle weakness, dizziness, sweating; headache, salivation, nausea, vomiting, abdominal pain, diarrhea; nervous system depression, pulmonary edema in serious cases
Chlorpyrifos (organophosphate)	$C_9H_{11}Cl_3NO_3PS$	2921-88-2	Headache, excessive salivation and tearing, muscle twitching, nausea, diarrhea; respiratory depression, seizures, loss of consciousness; pinpoint pupils
Endosulfan (organochlorine)	$C_9H_6Cl_6O_3S$	115-29-7	Itching, burning, tingling of skin; headache, dizziness, nausea, vomiting, lack of coordination, tremor, mental confusion; seizures, respiratory depression, coma
Malathion (organophosphate)	$C_{10}H_{19}O_6PS_2$	121-75-5	Headache, excessive salivation and tearing, muscle twitching, nausea, diarrhea; respiratory depression, seizures, loss of consciousness; pinpoint pupils
Methyl parathion (organophosphate)	$(CH_3O)_2P(S)OC_6H_4NO_2$	298-00-0	Headache, excessive salivation and tearing, muscle twitching, nausea, diarrhea; respiratory depression, seizures, loss of consciousness; pinpoint pupils
Phosmet (organophosphate)	$C_{11}H_{12}NO_4PS_2$	732-11-6	Headache, excessive salivation and tearing, muscle twitching, nausea, diarrhea; respiratory depression, seizures, loss of consciousness; pinpoint pupils
Pyrethrins (natural origin)	—	—	Irritating to skin and upper respiratory tract; contact dermatitis and allergic reactions; asthma
Pyrethroids (synthetic pyrethrin)	—	—	Abnormal facial sensation, dizziness, salivation, headache, fatigue, vomiting, diarrhea; irritability to sounds or touch; seizures, numbness

pesticides is to limit the exposure by wearing personal protective equipment (PPE) and to use a low-toxicity pesticide when available. Reading the label and practicing safe work habits can minimize hazards from the use of pesticides.

59.6 MANAGEMENT OF PESTICIDE HANDLING AND USE

Because of the health and environmental hazards, worldwide pest management is facing economic and ecological challenges [45]. To overcome these challenges, regulatory actions have been taken by regulatory and environmental protection agencies of different nations. The manufacturer or the formulator along with the national authority should ensure proper labeling written in the local language(s) with warnings of possible hazards and comprehensive instructions for safe use. The users and producers should use personal protective equipment to prevent the risk of personal hazard [46]. In any pesticide poisoning, the first thing is to avoid further contamination, and it is important to ensure that the victim is breathing so that proper oxygen supply to the body can be maintained. Following this, medical assistance should be sought [47].

59.6.1 Pesticide Registration

Pesticide registration is a scientifically based, legal and administrative process, where a wide variety of effects associated with the use of a pesticide product and its potential effect on human health and the environment is assessed [48]. The registration is an important step in the management of pesticides as it enables authorities, primarily, to determine which pesticide products are permitted to use and for what purposes. Pesticide registration offers control over quality, usage rates, claims, labeling, packaging, and advertising of pesticides, thus ensuring that the best interest of end-users as well as the environment are well protected [1]. The registration process is restricted to the assumption that pesticides are only used for their intended function, and does not promote unreasonable effects either on human health or on the environment. Therefore, before commercial use, several tests are conducted that determine whether a pesticide has any potential to cause adverse effects on humans, wildlife, and aquatic ecosystem. Effects in any nontarget species may translate into ecosystem unbalance and food-web disruption that ultimately may affect human health and edible species.

Pesticide registration is a complex process and takes considerable time, resources, and expertise on the part of the registration authority, the pesticide manufacturing industry, and various public interest groups. An expanding series of tests based on improved technology is required to provide precise pesticide residue detections and toxicological assessments in response to public concern.

59.6.2 Human Exposure to Pesticides

Human exposure to pesticides may occur through occupational exposure in the case of agricultural workers in open

TABLE 59.5
Health Effect of Organochloride Pesticides

Name	Signs and Symptoms
BHC and its derivatives	Can harm the nervous system, β-BHC alters thyroid hormone levels and can affect brain development; may cause cancer [2], photosensitivity, permanent hair loss [1]
α- and ϒ- Chlordane	Inhalation or ingestion may cause toxic effects, such as headaches, depression, anxiety, poor balance, tremors, and mental confusion; may cause cancer in animals [3]
Endosulfan I and II and sulfate	Acutely neurotoxic; acute poisoning includes hyperactivity, tremors, convulsions, lack of coordination, staggering, breathing, nausea and vomiting, diarrhea, and, in severe cases, unconsciousness [4, 5]
DDD, DDE, DDT, and their derivatives	May cause pancreatic cancer, non-Hodgkin's lymphoma, breast cancer, leukemia, skin sensitization, allergic reaction and rash [6], affect nervous system, cause prickling sensation of the mouth, nausea, dizziness, confusion, headache, lethargy, incoordination, vomiting, fatigue, and tremors; causes reproductive problems in rats and birds [7]
Aldrin and dieldrin	Decreases the effectiveness of immune system; increases infant mortality; reduces reproductive success; causes cancer, birth, and kidney problems [8]
Endrin, endrin aldehyde, and endrin ketone	Swallowing large amounts may cause convulsions and lead to death within a few minutes or hours; less serious exposure results in headaches, dizziness, confusion, nervousness, nausea, vomiting [9]

fields and greenhouses, workers in the pesticide industry, and exterminators of house pests [49]. However, irrespective of whether the occupation involves the use of pesticides, the presence of such chemicals in the working environment constitutes potential occupational exposure. Evidently, workers who mix, load, transport, and apply formulated pesticides are normally considered to be the group that receives the greatest exposure because of the nature of their work and are therefore at the highest risk for possible acute intoxications [50]. In some situations, exposure to pesticides can occur from accidental spills of chemicals, leakages, or faulty spraying equipment. People living in close proximity to agricultural farms or places where pesticides are frequently used may be unintentionally exposed to pesticides or pesticide residues. The occupational exposure increases in the case of not paying attention to the instructions on how to use the pesticides and particularly when the user ignores basic safety guidelines on the use of personal protective equipment and fundamental hygiene practices such as washing hands after pesticide handling or before eating [51].

Several factors can affect exposure during pesticide handling. The form of formulation of pesticide products may affect the extent of exposure. Liquids are prone to splashing and occasionally spillage, resulting in direct or indirect skin contact. Solids may generate dust while being loaded into the application equipment, resulting in exposure to the face and the eyes. The type of packaging of pesticide products can also affect pesticide exposure; the size of cans, bottles, or other liquid containers may affect the potential for spillage and splashing [52]. Weather conditions at the time of application, such as air temperature and humidity, may affect the chemical volatility of the product, the perspiration rate of the human body, and the use of personal protective equipment [53]. Wind velocity increases evaporation of spray droplet, loss of pesticide from the target area, spray drift, and resultant exposure to the applicator. General hygiene behavior of workers and proper use of protective clothing during pesticide use also have a substantial impact on pesticide exposure. Furthermore, the frequency and duration of pesticide handling affect exposure. In particular, the exposure of an individual farmer that applies a pesticide once a year is lower than that of a commercial applicator that normally applies a pesticide for many consecutive days or weeks in a season [50].

59.6.3 Minimizing the Negative Impact of Pesticides

In recent days, there is a growing level of concern regarding pesticide use and their impacts on human health and environmental quality [54]. To address the increased concerns, policymakers and authorities are developing and implementing regulations aiming to protect both the environment and human health. Compliance with available standard guidelines for the safe use of pesticides and cautious measures during selling and storing pesticides can minimize most of the hazards related to pesticide exposure.

59.6.3.1 Measures during Selling

The manufacturer, the formulator, or the person responsible for labeling and registering the pesticides with the national authority should ensure proper labeling written in the local language(s) with comprehensive instructions for safe use and warning for possible hazards. The label should additionally specify the ingredients and also provide instructions for first aid in case of poisoning [55].

59.6.3.2 Measures during Applying Pesticides

Users should follow the instructions provided in the label of the container or packaging when using pesticides. The users and producers should use personal protective equipment, such as protective clothing made of butyl rubber, PVC, neoprene, laminated polyethylene fabrics, gloves, eye protectors, and masks to prevent the risk of personal hazard [46].

In the case of pesticides applied in agriculture, integrated crop management (ICM) includes guidelines to be followed by farmer unions to enforce actions for the production of safe agricultural products without contaminating the environment [56]. For pest control, ICM encourages the use of complementary methods of pest management to reduce animal pests or weed population below its economic injury level and to minimize pesticide impacts on the other components of the agroecosystem. Pest-resistant crops against insects and fungi, biological control, and other cultural or physical measures can be used as complementary methods. Pesticide applications on crops should include the following information [56]: (i) identify the appropriate pesticide for the specific pest attack on the plants or crops, (ii) use of a pesticide at the recommended

dose when a pest is found or it requires a precautionary treatment, (iii) optimization of pesticide use for economic saving through adjusted doses according to pest population density, and (iv) minimization of pesticide use by altering the cultivation system to lower the risk of pests.

To ensure the safety of agricultural workers, pesticide handlers and cultivators, the EPA activated the Worker Protection Standard (WPS) in 1995 [57]. The aim of the WPS regulation is to "minimize and mitigate pesticide exposure, and inform agricultural workers about the hazards of pesticides." It requires agricultural employers to notify workers about pesticide treatments and advances [57].

According to a study conducted by EPA, around 85% of the total daily exposure to airborne pesticides comes from breathing air inside the home [58]. Improper pesticide applications should be avoided at homes and offices. For any pest-related issue, alternative measures, such as temperature treatment, biological controls, and the least toxic baits should be applied. Spraying pesticides in lawns and gardens should be avoided [58].

59.6.3.3 Measures after Pesticide Poisoning

The chemicals of pesticides may injure humans in many ways. It is therefore important to take appropriate measures if pesticide poisoning or exposure occurs beyond the permitted limits. In the case of any pesticide poisoning, the following steps may be followed [47, 59–61]. The first step is to avoid further contamination and to ensure that the victim is breathing. There is a good chance of recovery if proper oxygen supply to the body can be maintained. Following this, medical assistance should be sought [47].

If someone swallows pesticides, the victim should be treated immediately. First, the label of pesticides has to be identified. There are two ways to help a victim who has swallowed poison: either (i) inducing vomiting or (ii) diluting the poison by having the victim drink milk or water [59]. Inducing vomiting is the quickest way to get the pesticides out of the stomach, however, it may not be effective in certain cases like when the victim is unconscious, and when the pesticide is highly corrosive or a highly concentrated petroleum product.

If the skin is directly exposed to pesticides, it is advised to wash off the pesticides immediately to prevent further exposure, followed by drenching the skin with soap and water carefully. In the case of chemical burning, cold running water should be used to wash the skin. The affected area then needs to be loosely covered with clean soft cloths. Further treatment should be carried out based on medical advisory [60].

In the case of eye injury, eyes should be washed with clean water immediately for around 15 min since the eye membrane can absorb pesticides faster than any other external part of the body. Eyelids should be kept open while washing with a gentle stream of water. Using any kind of drugs or eye drops are prohibited [47, 61].

The victim needs to take fresh air immediately after inhaling pesticides. An artificial respirator should be used while shifting the victim, and it is more important when the victim suffers from breathlessness. The victim should be kept as quiet as possible. Tight clothing should be loosened. If the victim is becoming unconscious, he or she should be protected from falling and his chin should be pulled forward to ensure proper airflow [47, 60].

59.7 METHODS OF PESTICIDE RESIDUE REDUCTION

Pesticides are used indiscriminately and excessively throughout the globe, and these residues remain in the food materials, water, fruits, vegetables, and total diet [62, 63]. These pesticide residues enter into the human body by consumption of the foods contaminated by pesticides, which leads to chronic disorders. Thus, the removal of these residues from food commodities utilizing different processing methods is very essential. Different household preparations, such as peeling, bleaching, washing plus cooking, parboiling, and saltwater washing, play an important role in the reduction of pesticide residues in foods [64]. Most food processing techniques help to reduce or eliminate pesticide residues on the surface or inside the food [65]. Table 59.6 summarizes common food processing techniques of processed foods [66–70].

TABLE 59.6
Methods of Pesticide Residues Reduction

Types of Pesticide	Food	Removal Mechanism	Reference
Endosulfan	Bitter gourds	Washing (30 s)	World Health Organization [1]
Dichlorvos	Soybeans	Washing (twice)	McNaught and Wilkinson [2]
Phosalone	Golden apple	Washing	Cooper and Dobson [3]
HCB	Tomatoes	Washing (vinegar)	Pimentel et al. [4]
p,p-DDT		Washing (10% NaCl solution)	
Dimethoate		Tap water washing	
Endosulfan	Bitter gourds	Peeling	World Health Organization [1]
Fenthion	Mango		
Dimethoate			
Malathion	Rough rice	Parboiling	Amir et al. [6]
Endosulfan	Bitter gourds	Cooking (10 min open cooking, 10 min steam cooking)	World Health Organization [1]

Each food processing operation collectively reduces the concentration of pesticides present in food commodities [71]. Almost all loose surface residues and polar chemicals are eliminated by washing. Preparatory steps like peeling and trimming remove the residues from outer portions. Various thermal processing treatments, such as pasteurization, blanching, boiling, cooking, steaming, canning, and scrambling, have been found valuable in the degradation of various pesticides depending upon the type of pesticide and length of treatment. A significant portion of nonpersistent chemicals is hydrolyzed and bleached out by hot water washing. Nonpolar chemicals (chlorinated hydrocarbons) are grimly detained in the waxy layers of fruits and vegetables. Peeling of fruits and vegetables completely removes the pesticide residues accumulated in waxy layers, however this process reduces the beneficial phytochemicals in fruits and vegetables [65]. Different methods to reduce or eliminate pesticide residues in food items are briefly discussed in the following sections.

59.7.1 Reduction by Washing

Washing is the most common form of food processing and is a preliminary step in both household and commercial preparation. Loosely held residues of several pesticides are removed during washing with reasonable efficiency [72]. Researchers reported that washing rice grains with water removed approximately 60% of the chlorpyrifos residues [73]. Washing with 2% saltwater demonstrated a very good effect in the removal of the residues below maximum residue limits (MRL)[74].

Chlorinated water and ozonated water are often used for the disinfection of fruits and vegetables. Scientists have demonstrated that washing using chlorinated water and ozonated water reduces pesticide residues, such as azinphos-methyl, captan, and formetanate hydrochloride, on fresh apples and in processed apple products [75, 76]. Acidic solutions (5–10% solution of acetic acid/citric acid/ascorbic acid/H_2O_2) were found to be more effective than other washing solutions to extract organochlorine pesticides from potatoes [77]. It was reported that washing potatoes with tap water or aqueous solutions of acetic acid and/or NaCl followed by blanching or frying of potatoes removed most organochlorine and organophosphorus residues [78]. Washing with soap and acetic acid solutions was found to remove profenofos residues in aubergines; a high percentage of profenofos residues were removed from peppers after washing using acetic acid solution, potassium permanganate, and tap water [79]. Researchers have demonstrated that washing grapes with tap water, tamarind solution (2%), salt solution (2%), baking soda, lemon water wash, or vinegar can effectively reduce organophosphorus residues up to 75% [80].

59.7.2 Reduction by Cooking Process

The cooking process can significantly reduce pesticide residues in food items. To demonstrate cooking effects to reduce pesticide residues, researchers randomly analyzed selected fruits for the initial deposit of pesticides. Each lot of pesticide-treated sample was subjected to different decontamination methods, namely, washing under running tap water, 2% salt solution, direct cooking, or dipping in 2% salt solution and cooking, and then analyzed for final remaining residues after treatment using a validated QuEChERS (quick, easy, cheap, effective, rugged, and safe) method utilizing GC-ECD (gas chromatography–electron capture detector), FPD (flame photometric detector), and GC-MS (gas chromatography–mass spectrometry) [74]. The cumulative effect of all four household processes caused substantial reduction in residues up to 95%. However, cooking in a pressure cooker for 5 minutes reduced pesticides 30–93% [74]. Washing with 2% saltwater followed by cooking demonstrated that the residues were reduced 98–100%; in addition, fat-soluble and water-soluble pesticides can be removed using this process.

59.7.3 Reduction Using Food-Grade Coatings As Processing Aids

Coating hams with vegetable oils or hot lard is a common practice in Spain to control mite infestations in dry-cured ham [81]. Some vegetable oils (including coconut, sunflower, groundnut palm, corn, and sesame) are used to protect cured fish from pests and to give fish a more attractive appearance [82]. A list of animal and vegetable oils (e.g., soybean oil, canola oil, corn oil, olive oil, mineral oil, and lard), sorbic salts (sodium/potassium/calcium sorbate), propionic salts (sodium/potassium/calcium propionate), iodide salts (sodium/potassium/calcium iodide), citrate salts (sodium/potassium/calcium citrate), short-chain alcohols (e.g., 1,2-butanediol, 1,3-butanediol, 1,4-butanediol, 1,2-propanediol, 1,3-propanediol, 1-propanol, 2-propanol), organic acids (e.g., maleic acid, citric acid, 3,3-thiodipropionic acid), butylated hydroxyanisole (BHT), and butylated hydroxytoluene (BHA) have been tested as dippings on dry-cured ham cubes [83]. Among all the tested substances, 100% lard, 50% propylene glycol (1,2-propanediol), and 10% butylated hydroxytoluene (BHT) were found highly effective at controlling mite reproduction under laboratory conditions [83].

59.7.4 Reduction of Certain Pesticides Due to Their Low Solubility

Tea is the most commonly consumed beverage in the world. It is prepared after infusing processed black tea in hot water. During the process of brewing, along with flavor and aroma, the residues of plant protection chemicals may also be transferred into the tea brew or infusion. The leaching of certain pesticides, such as ethion, endosulfan, dicofol, chlorpyrifos, deltamethrin, hexaconazole, fenpropathrin, propargite, quinalphos, and lambdacyhalothrin, from powdered black tea into the brew was studied. The rate of transfer of the pesticide residue from black tea to the hot brew was largely influenced by physicochemical parameters, such as water solubility and the octanol–water partition coefficient. Tea brews prepared from untreated black tea samples were fortified with standard

solutions of the respective pesticides, extracted, and analyzed using GC (gas chromatography) and HPLC (high-performance liquid chromatography) by following standardized methods. Results revealed that the rate of leaching of residues of these pesticides into the tea brew was low due to their low solubility in aqueous medium and high octanol–water partitioning coefficients [84].

59.7.5 Reduction by Organic Agricultural System

Researchers have demonstrated that organic foods contain a lesser amount of pesticide residues. In line with several published literature reviews, the French Agency for Food Safety (AFSSA) performed an up-to-date exhaustive and critical evaluation of the nutritional and sanitary quality of organic food [85] and reported that (i) organic plant products contain more dry matter and minerals (Fe, Mg), and contain more antioxidant micronutrients such as phenols and salicylic acid; (ii) organic animal products contain more polyunsaturated fatty acids; (iii) data on carbohydrate, protein and vitamin levels are insufficiently documented; (iv) 94–100% of organic food does not contain any pesticide residues; (v) organic vegetables contain far less nitrates, about 50% less; and (vi) organic cereals contain overall similar levels of mycotoxins as conventional ones. Therefore, organic agricultural systems have already proved able to produce food with high-quality standards and low pesticide residues [85].

59.7.6 Reduction by Other Techniques

Different processes, like bread making, milling, washing, and infusion, have also been found to cause considerable pesticide residue dissipation. Commercially produced bread is an important component of the every day diet in many countries. In one study, during the bread making process, bread was prepared from wheat flour spiked at different concentrations (1–4 ppm) with endosulfan, hexaconazole, propiaconazole, malathion, chlorpyrifos, and deltamethrin. It was observed that at the 4 ppm level of spiking the degradation of endosulfan, deltamethrin, malathion, propiaconazole, chlorpyrifos, and hexaconazole were 70%, 63%, 60%, 52%, 51%, and 46%, respectively. Yeast-mediated fermentation and baking at high temperature led to the degradation of the pesticides [86].

59.8 ALTERNATIVE PESTICIDES AND ORGANIC FARMING

Increased understanding and awareness of the adverse effects of pesticides on health and the environment is driving the demand for alternatives to pesticides. The alternative approaches consider pest problems within a broad context, which include the presence of natural enemies, the distribution of the pest population, active season of growth, and expected weather patterns [86–89]. Biopesticides can be a replacement for synthetic chemical pesticides. Biopesticides pose lower risk to the environment and human health [90, 91]. Many sustainable farms use integrated pest management (IPM) as an alternative to pesticides [92, 93]. The overall optimization of pesticide handling by following the existing regulations could contribute to the reduction of the adverse effects of pesticides on human health and the environment [94]. A mew major alternative mechanisms of pest management are described next.

59.8.1 Cultural Control

Cultural control is the deliberate alteration of the production system by targeting the pest itself through agronomic practices to avoid or reduce pest injuries to crops. These methods are utilized most frequently to control pest-related issues. Crop rotation, intercropping, sanitation, trap crops, and pest-resistant crop plants are a few examples of cultural control. These individual tactics of cultural control tend to be pest and crop specific [95].

59.8.1.1 Tactics to Prevent, Reduce, or Delay Pest Colonization of the Crop

The site selection, intercropping, trap crops, and altering the time of planting are key alternate approaches to prevent, reduce, or delay pest colonization of a crop. *Site selection* involves locating the crop field in such a manner that pests, from the site of the previous year's crop or from natural overwintering sites, cannot easily find their way there [96].

Intercropping is a practice that involves growing two or more crops in proximity. The most common goal of intercropping is to produce a greater yield on a given piece of land by making use of resources that would otherwise not be utilized by a single crop. Intercropping may concentrate the pest in a smaller, more manageable area so that it can be controlled by appropriate tactics.

Trap crops are grown as a control measure to lure pests away from the cash crop. Pests are either prevented from reaching the crop or concentrated in certain parts of the field away from the main crop. The principle of trap cropping relies on pest preference for certain plant species, cultivars, or a certain stage of crop development [97].

Plantation and harvest dates of some crops can be rearranged to reduce or to avoid potential pest damage [98]. Early planting ensures that seedlings have reached a nonsusceptible or tolerant stage when the pest appears. Planting needs to be done only after the emergence or immigration of the pests leaves the pests without hosts. Early harvest date may prevent pests from reaching damaging population densities or overwintering stage by harvest [95].

59.8.1.2 Tactics to Reduce Survival of Pests by Creating Adverse Biotic and Abiotic Conditions

Source reduction involves eliminating food, water, shelter, or other necessities that are important for pest survival [99]. Animal manure management is an effective sanitation practice used to prevent or to reduce fly-related issues in poultry and livestock operation. Crop rotation interrupts the normal life cycle of pests by placing them in a nonhost habitat. It is

highly effective to prevent different weeds, soilborne plant pathogens, and root-living arthropods. Sufficiently sparse plant and row spacing are important in preventing plant pathogens that usually require a certain moisture threshold to germinate and grow.

Tillage (soil-turning and residue-burying practices) and seedbed preparation reduce the number of soil-living pest stages [100]. Some forms of tillage can reduce pest populations indirectly by destroying weeds and volunteer crop plants in and around crop-production habitats.

59.8.1.3 Tactic to Reduce Injury Caused by Pests to Crop Plants

Plants resistant to pest attack are less preferred by pests as they adversely affect the pests' normal development and survival, or the plant may tolerate the damage without an economic loss in yield and/or quality [100]. Constitutive plant resistance is easy to use, cheap, and compatible with other pest management tactics. Induced resistance to herbivores and pathogens reduces plant exposure to the autotoxic environment of secondary compounds [101].

59.8.2 Physical and Mechanical Control

Physical and mechanical controls either kill insects and small rodents or make the environment unsuitable for them by attacking or setting up barriers. These methods are used for crop growing and household pest management [71, 103–105].

59.8.2.1 Barriers

Row covers, typically used for horticulture crops, are useful to keep insects away from plants. These are knitted tenuously with plastic or polyester fiber so that plants can still absorb sunshine and moisture from the air. Diatomaceous earth, made from fossilized and pulverized silica shells, is used to impair the protective cuticle layer of insects, such as ants. Consequently, the insects become vulnerable to becoming dry. As moisture diminishes the effectiveness of diatomaceous earth, it must be attributed at regular intervals.

59.8.2.2 Traps

Devices like flypaper or sticky boards, covered with a sticky and poisonous substance, are used to attract insects. Insects, attracted by those traps, land upon the surface and get glued. These traps are commonly used for capturing flies or leafhoppers.

59.8.2.3 Fire

Farmers consider fire to destroy insect breeding grounds. Fire burns the soil-top and kills insects present there. However, fire may kill beneficiary insects as well. Besides, some larvae can sustain below the surface of the soil.

59.8.2.4 Temperature

Different thermal conditions can be used to kill insects or to prevent their infestation. Cold storage prolongs the shelf life of agriproducts and retards the development of pests. Heat treatment is also effective in killing insect larvae in certain types of products.

59.8.2.5 Radiation

Gamma radiation kills all stages of pests in storage conditions. This is a common method that is employed to kill insects or insect larvae during export or import of large quantities of grains, fruits, and vegetables.

59.8.2.6 Ultrasonic Vibrations

Moths are often sensitive to bats' ultrasonic signals, quickly escaping from the area. Imitation of the bat's echolocation system helps in driving away the lepidopterous insect pests from the area.

59.8.3 Biological Alternatives

Biological alternatives can be used as a replacement for chemical pesticides to leave the ecosystem undisturbed. Biological alternative options can be broadly classified as (i) biological control, (ii) biopesticides, (iii) semiochemicals, and (iv) transgenic organisms [105]. Biological control, also known as biocontrol, is the use of natural enemies (predators, parasitoids, insects, or other arthropod species) to reduce the damage caused by pests. Biopesticides, also known as biological control, are based on pathogenic microorganisms or natural products that usually kill pests. The term biopesticide may also be used, more widely, to describe the application of biological agents, pathogens, predators, or parasitoids. In addition, botanicals, semiochemicals, and transgenic plants are sometimes described as biopesticides. According to the EPA, biopesticides are certain types of pesticides derived from natural materials such as animals, plants, bacteria, and certain minerals.

59.8.3.1 Biological Control

Biological control involves the suppression of reproductive organisms through the actions of parasites, predators, or pathogens to restrict pest population at a lower average density [106]. There are three different approaches to biological control: *importation*, *augmentation*, and *conservation*.

Importation involves the enforcement of the natural enemies of a pest to a new locale the pest does not naturally inhabit. The process involves determination of pest-origin and consequently collection of appropriate natural enemies associated with the pest. Selected natural enemies are then passed through rigorous assessments, testing, and quarantine processes to ensure their appropriate use. Finally, the selected natural enemies are mass-produced and distributed [107].

Augmentation involves the supplemental release of natural enemies to boost the natural inhabitant population. In addition, the cropping system may also be modified to favor or augment these natural enemies, called habitat manipulation. During the critical time of the season, a small number of natural enemies to a pest are released, which is called inoculative release.

In the conservation method, biological control action is taken to enhance the effectiveness of existing natural enemies

to pests in the ecosystem. As natural enemies are already adapted to the habitat and target pest, their conservation becomes simple and cost-effective.

59.8.3.2 Biopesticides

As mentioned earlier, biopesticides are certain types of pesticides derived from natural materials such as animals, plants, bacteria, and certain minerals. For example, canola oil and baking soda have pesticidal applications and are considered as biopesticides.

59.8.3.3 Semiochemicals

Semiochemicals (from the Greek word *semeon*, meaning "signal") are chemical substances that mediate interactions between organisms. Semiochemicals are attributed to interspecific and intraspecific interactions, which are categorized as allelochemicals and pheromones, respectively [108].

59.8.3.4 Transgenic Organisms

Genes of one species can be modified or can be transplanted to another species. Organisms that have altered genomes are known as transgenic. Genetic modification with recombinant DNA techniques is the newest way of generating pest-resistant plants. The most successful commercial transgenic crops resistant to insects include cotton, maize, and potato[109].

59.9 CONCLUSIONS

Pesticides play an important role in producing reliable supplies of agricultural produce at affordable prices to consumers, improving the quality of produce, and ensuring high profits to farmers. Extensive use of pesticides has caused food and groundwater contaminations, and the destruction of beneficial insects. Pesticides and pesticide residues are an important source of injury and illness among farmers and farm workers. Pesticides have been linked to a number of health problems, including neurologic and endocrine (hormone) system disorders, birth defects, and cancer. To understand the dangers posed by pesticides and pesticide residues, it is important to consider the role of inert ingredients along with active ingredients of pesticides. Inert ingredients may have the potential to be anything but inert; some may have toxicities as high as some active ingredients.

Increased understanding and awareness of the adverse effects of pesticides on health and the environment is driving the demand for alternatives to pesticides. There are proven alternatives to pesticide use. These approaches consider pest problems within a broad context, which include the presence of natural enemies, the distribution of the pest population, active season of growth, and expected weather patterns. Many sustainable farms use integrated pest management (IPM) as an alternative to pesticides. IPM is a growing movement among farms of all sizes that incorporates a variety of techniques to eliminate pests while minimizing environmental damage. IPM strategies hold the key to reduce the deleterious impact of pesticides. In addition, suitable use of pesticides is necessary to protect the environment and, eventually, health hazards associated with it. Before choosing a pesticide, important aspects should be kept in consideration, such as proper identification of the pest, mode of action of the pesticide, and quality and persistency of the pesticide. Proper protection measures should be taken to avoid unnecessary pesticide exposure to the user as well as environment, and the pesticides should be stored in proper storage facilities. There are a number of treatments, such as washing with tap water, chlorinated water, ozonated water and/or acidic solutions; cooking or baking; using food-grade coating; and adopting an organic agricultural system that could be performed to reduce pesticide residue in foods.

60 Biotechnology in Foods

Mohammad Shafiur Rahman

CONTENTS

60.1 INTRODUCTION

Biotechnology is one of the most important technologies affecting food production, processing, preservation, and security as well as nutrients contents. However, there are issues in favor of and against the use of biotechnology in food production. The World Health Organization (WHO) [1] defines genetically modified (GM) organisms as "organisms (i.e. plants, animals or microorganisms) in which the genetic material (DNA) has been altered in a way that does not occur naturally by mating and/or natural recombination." This technology is often called "modern biotechnology" or "gene technology," "recombinant DNA technology," or "genetic engineering (GE)." In this technique, select genes are transferred from one organism into another, either from the same species or from nonrelated species. Foods produced using GM organisms are often referred to as GM foods. Biotechnology covers many contemporary agricultural and food manufacturing tools. In many instances, the use of the term GE over GM is considered more precise.

60.2 HISTORICAL BACKGROUND

The era of GE began in the early 1970s when California scientists discovered how to make recombinant DNA (rDNA) using restriction enzymes to cut and paste DNA, which gives a bacterium, plant, or animal a trait it does not possess naturally [2]. Transgenic crops were first planted commercially in 1995 and have increased rapidly since [2]. The first generation of genetically engineered foods started mostly with disease-insect and herbicide-resistant crops, such as glyphosate-resistant soybeans, insect-resistant corn and potatoes, and virus-resistant squash. The focus was to increase production as well as quality and safety (i.e., environmental and food) due to the reduction of chemicals. The second generation of biotechnology consists of crops to create healthier foods, for example, cereal grains with increased amounts of soluble and insoluble fibers, milk with improved calcium bioavailability, and vegetables with boosted levels of antioxidants [2]. The major concerns of biotechnology are the safety of transgenic crops for human consumption and the environment or ecology. Thus, it is important to know the proper and realistic risk-benefits of biotechnology.

60.3 ENHANCED GLOBAL FOOD SECURITY

A world without hunger is possible if food production is increased sustainably, and food safety is ensured with proper nutrition and distribution [3]. Food security demands sound supply of foods as well as safe and wholesome foods. GM foods could possibly meet the world's future food needs for the growing population by increasing production. This could be achieved by adapting diverse environments and tolerance to stresses. GM technology could provide food security by enhancing genetic diversity, for example, banana production. GM foods may contain nutritious foods, such as golden rice.

60.3.1 Increased Food Production

GE showed great promise for increasing crop productivity, for example, improvement genes in tomato controlled plant architecture, flower production, and fruit size, thereby improving productivity [4]. Molecular breeding programs and genetic engineering using de novo domestication can exploit and boost the genetic diversity of wild plants. Zsogon et al. [5] edited six loci genes that are important for yield and productivity in present tomato crop lines through de novo domestication of wild tomato. The morphology was altered, together with the size, shape, number, and nutritional value of the fruits as compared with the widely cultivated tomato (i.e., threefold increase in fruit size, a tenfold increase in fruit

number, compact growth, and 500% improved in lycopene accumulation, which is noticeable through a deeper red coloring of the juice).

Pests are a major threat to agricultural food production. Around 40% of worldwide crop production is destroyed by pests and pathogens, and 13% due to insect attacks. Among crops, the loss due to pests varied from about 50% in wheat to more than 80% in cotton production. In the cases of soybean, wheat, and cotton, the estimated losses varied from 26% to 29%, and for maize, rice, and potatoes the losses are 31%, 37%, and 40%, respectively [6]. Currently, the control strategies against pests are mainly based on chemical treatments and biological control. Interestingly, major focuses of GM are given to the increased grain yield and crop productivity. The new genome-editing technologies could address major pest and disease problems, reduce the need for chemical pesticides, and make plants more resilient to climate stress [3].

The earliest applications of genetic engineering to agriculture have focused primarily on simplifying pest management in widely planted crops. One major category includes crops for diseases and insect resistance to prevent crop losses (e.g., insect-resistant corn and cotton). The second category encompasses herbicide-tolerant crops, which allow farmers to spray broad-spectrum herbicides over growing crops [7]. One of the most harmful tomato pests is the *Tuta absoluta* (Meyrick) (Lepidoptera: Gelichiidae), and without appropriate management, it can cause production losses ranging from 80% to 100%. Hamza et al. [8] observed tomato defensive responses on this insect when a serine proteinase inhibitor (BTI-CMe) and a cysteine proteinase inhibitor (Hv-CPI2) from barley gens were used. They observed that the proteinase inhibitor 2 (Pin2) gene increased the production of glandular trichomes and altered the emission of volatile organic compounds.

Herbicide-tolerant (HT) GE soybean impaired plant root development and activity of microorganisms responsible for nitrogen fixation. The most substantial benefit of HT crop technology stems from its compatibility with no-till production systems. This benefits conservation efforts by less erosion and sedimentation of waterways, improved soil quality, less fuel and labor use, and better wildlife habitat.

60.3.2 Disease-Resistant GM Crops

In Bangladesh, there is a successful public–private partnership for the development of a commercial release of transgenic insect-resistant eggplant [3]. In Africa, a drought-tolerant variety of water-efficient maize is being developed with the intention to make this available royalty-free to smallholder farmers through African seed companies [9].

60.3.3 Increased Nutritional Value and Functionality

Biofortification is a promising, cost-effective, and sustainable technique to enhance nutritionally enhanced crops, and these could deliver micronutrients to a population with limited access to diverse diets or where micronutrient interventions are limited. Garg et al. [10] reviewed the success stories of biofortification research on different crops through breeding, agronomy, and genetic modification, and these approaches improved the lives of millions of people around the world. The GM approach can be used for the simultaneous incorporation of genes involved in the enhancement of micronutrient concentration, their bioavailability, and reduction in antinutrient concentration in plants. In addition, GM modifications can be targeted to redistribute micronutrients between tissues, enhance the micronutrient concentration in the edible portions of commercial crops, increase the efficiency of biochemical pathways in edible tissues, or even the reconstruction of selected pathways [11–13]. Initially, transgenic biofortified crops involved substantial amount of time, effort, and research investment and development. However, in the long run it is a cost-effective and sustainable approach, unlike nutrition-based organizational and agronomic biofortification programs [14, 15].

Modern biotechnology tools are also being used to develop these more nutritious crops. A lack of dietary diversity directly increases the risk of nutrient deficiencies. There is no single solution to the complex problem. The International Life Sciences Institute (ILSI) [16] reviewed five case-study crops with improved nutritional value. The first one is the "double-embryo maize," a variety being developed through modern biotechnology in which the grain contains two embryos, resulting in high protein and oil contents in maize. The second one is the "orange-fleshed sweet potato," a crop biofortified with β-carotene to control vitamin A deficiency. The third one is the "improved-protein sweet potato," with improved protein content, and it could be for the populations at risk for protein-energy malnutrition. The fourth one is "golden rice 2," with increased provitamin A carotenoid and β-carotene content. The fifth one is the "lysine-maize," with increased lysine content in order to simplify diet preparations. Zhu et al. [17] developed a high-efficiency vector system for transgene stacking and used it to engineer anthocyanin biosynthesis in rice endosperm. It was constructed by containing eight anthocyanin-related genes (i.e., two regulatory genes from maize and six structural genes from Coleus) driven by the endosperm-specific promoters, plus a selectable marker and a gene for marker excision. This transformation of rice generated a novel biofortified germplasm "purple endosperm rice" containing high anthocyanin content and antioxidant activity in the endosperm. The "Cavendish" dessert banana was genetically modified and greatly enhanced provitamin A levels and named the "golden banana" [18]. Cruz-Rus et al. [19] reviewed the efforts of improving the L-ascorbic acid (i.e., vitamin C) content in crop species using GM transformation, quantitative trait loci, and association-mapping-based approaches.

The transgenic approach can be a valid alternative for the development of biofortified crops, and it relies on the access to the unlimited genetic pool for the transfer and expression of desirable genes from one plant species to another. It is independent of their evolutionary and taxonomic status. Furthermore, transgenic approaches remain the only feasible

option to fortify these crops when a particular micronutrient does not naturally exist in crops. Garg et al. [10] pointed out that besides the challenges of biofortified crops, there is a bright future to address the malnutrition challenge thru biofortification. Garg et al. [10] presented the utilization of different genes for biofortification by transgenic means (Figure 60.1). They found that large numbers of genes have been utilized for crop biofortification. The transgenic-based approach has the advantage that once a useful gene discovered, it can be utilized for targeting multiple crops, including important genes like phytoene synthase. They summarized the enhanced crop nutritional level considering different micronutrients, such as vitamins, minerals, essential amino acids, and essential fatty acids. Most of the crops are in the research stage and very few are now released.

60.3.4 Flavor Enhancement

The release of the tomato reference genome when resequenced, considering hundreds of diverse cultivated and wild tomato accessions, showed that genomic changes through the history of tomato breeding [20]. Modern tomato breeding is primarily focused on yield, shelf life, and resistance to biotic and abiotic stresses [21]. Organoleptic and aroma quality traits are commonly ignored, resulting in a decline of flavor-associated volatiles [22]. The narrow genetic diversity of modern tomatoes limits their diversified improvement potential. Gao et al. [20] presented the tomato pan-genome constructed using genome sequences of 725 phylogenetically and geographically representative accessions. This revealed 4873 genes absent from the reference genome. They identified a rare allele in the TomLoxC promoter and observed that transgenic plants revealed a role of TomLoxC in apocarotenoid production, which contributed to desirable tomato flavor.

Freitas et al. [23] reviewed the marine biotechnology advances toward the production of new functional foods and ingredients, such as enzymes, chitin and chitosan, different types of proteins, bioactive peptides, amino acids, omega-3 fatty acids, pigments, phenolic compounds, and polysaccharides. Cruz-Hernandez and Paredes-Lopez [24] reviewed the applications of GM for ripening fruits since it is important to the development of color, aroma, flavor, and texture. These improvements could be attractive to potential consumers.

60.4 POLICY MAKING

In 1992, the US Food and Drug Administration (FDA) adopted a regulatory policy that specified that foods produced through genetic engineering techniques or containing GE substances substantially similar in "structure, function, and composition" to substances already in the food supply (proteins, carbohydrates, fats, and oils) were to be considered

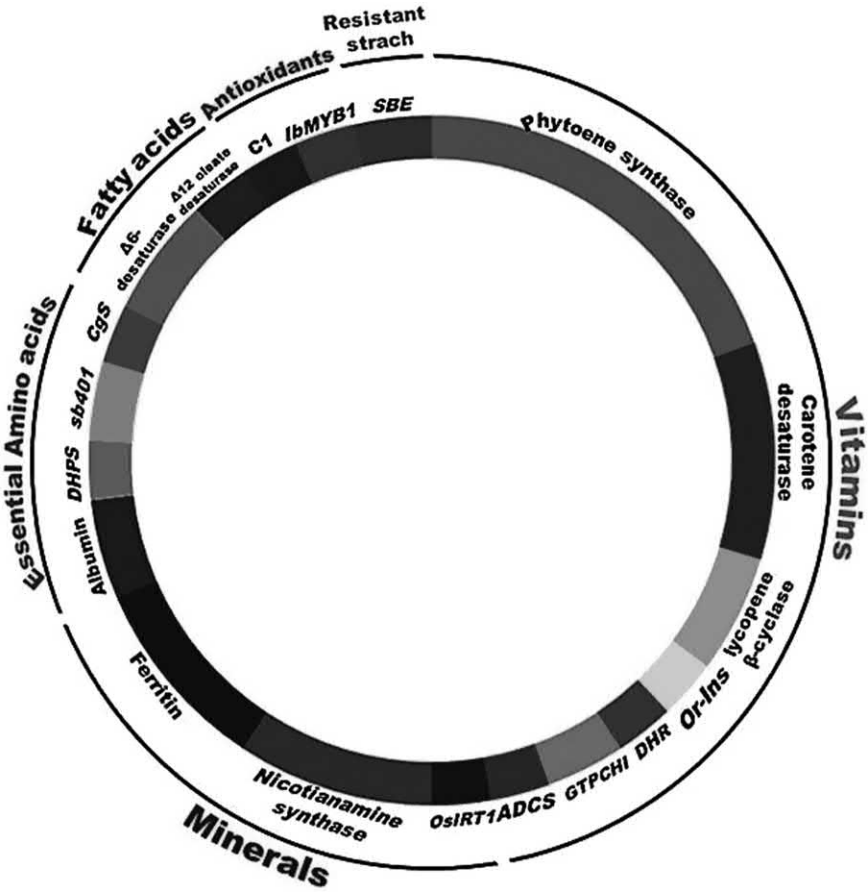

FIGURE 60.1 Utilization of different genes for biofortification by transgenic means. (From Garg et al. 2018 [10].)

"generally recognized as safe (GRAS)" [25]. This terminology was later changed to "substantially equivalent" (SE) [27]. If any food product considered SE is already in food supply (i.e., proteins, carbohydrates, fats, or oils), then it could be considered as GRAS. FDA deemed GM foods as GRAS or SE, and these are not required to undergo mandatory premarket approval [25, 27]. This policy was not accepted by many scientists. In January 2001, the FDA proposed modifications to its regulatory policy and called for a 120-day premarket notification [26].

The National Research Council (NRC) concluded that the US Department of Agriculture (USDA) needs to (i) more rigorously review GE crops before approving them for commercial use, (ii) more actively seek outside scientific peer review of crop applications and advice on changes in regulatory policy, (iii) more actively solicit public comment, and (iv) monitor transgenic crops more closely after their approval [28].

There is little history of safety regarding the structure, function, or composition of GM foods. The function of a food-producing organism could be altered, causing it to produce new allergens or increase the expression of allergenic proteins already present [2]. Scientific uncertainty is a concern owing to the novelty of health and environmental concerns due to the lack of established scientific methods [29]. The four central components necessary to deal with scientific uncertainty are (i) taking preventive action in the face of uncertainty, (ii) shifting the burden of proof to the proponents of an activity, (iii) exploring a wide range of alternatives to possibly harm actions, and (iv) increasing public participation in decision making [7].

In December 2002, the British Medical Association (BMA) supported precautionary principle toward GE foods. The precautionary principle handles at least two types of errors. A desire to minimize type II errors (false-negative) since the potential harm is greater if conclusions commit a type II error compared to a type I (false-positive), since recovery from most harm to ecosystems or human health involve large time lags and are sometimes irreversible. However, type I errors are usually limited to the short-term economic loss for the developers [30]. The second one is to take into account something that is inherent in all biological systems regarding uncertainty to the biological system. The precautionary principle is supported for four reasons [31]: (i) it benefits workers, (ii) it does not impose damaging costs on industry, (iii) it can stimulate technological innovation, and (iv) economic logic supports timely action to avoid substantial health and environmental costs. Criticisms of the precautionary principle include [32] (i) current regulatory processes are already precautionary, (ii) the precautionary principle is not scientifically sound because it advocates making decisions without adequate scientific justification, and (iii) if it were implemented, the precautionary principle would stifle innovation by requiring proof of safety before new technologies could be introduced [33].

A controversy surrounding GE foods stems from whether consumers have the right to know if their food has been bioengineered [2]. The requirements of GM labeling vary from country to country. The moral and ethical concerns depend on the history, traditions, experiences, beliefs, and values of a diverse citizenry. In general, the American national identity is generally not linked to food and food production, and the opposite is true in Europe. Thus, in Europe, GM foods could be a threat to their cultural identity. In some countries there is pressure on land, thus it is difficult to preserve wildlife. Europeans reported placing the highest confidence or trust in international organizations, such as the United Nations (UN) and WHO. In contrast, in the United States most support was reported for US government agencies, including the USDA and FDA. In many instances, local authorities could take quick actions for local outbreaks [7]. Recently, the USDA released "National Bioengineered Food Disclosure Standard" rules and regulations related to GE foods [34]. It is intended to provide a mandatory uniform national standard for disclosure of information to consumers and is effective from February 19, 2019.

The perception of science also varies. In Europe, science is considered a process of debate, thus ethical, social, and cultural factors are valued more highly. This produces lower confidence in the power of science and necessitates the adoption of the precautionary principle. Libertarian sentiment in the United States insists that science be halted only if there is sound scientific evidence of the negative aspects of GM foods [7]. Americans are most often addressed in their capacity as consumers; European often separate their role in society into citizens first and consumers second. Quality of citizen engagement also affects perception of GM foods.

Consumers would be more likely to buy bioengineered foods that taste better or fresher, protect against insect damage or require less use of pesticides, do not involve harm to animals, and do not involve the transfer of animal genes into plants. The lack of consumer acceptance of GE foods and crops is attributed to the public ignorance or misunderstanding of science, stems from the lack of trust between the public and other sectors of society, reports of trusted information from the industry, and skepticism of the government's ability to regulate GE technology [2]. Consumers' education and trust is very important and this could be achieved through labeling and disclosure, as well as exchange of knowledge. One-way exchange of knowledge to the consumers is perceived as passive reception, where only authority provides rules without allowing any feedback from the consumers [2].

More than 30 years of experience with GM crops shows that negative public attitudes in Europe can have a considerable effect on public perceptions and policy in developing countries [35]. The European Court of Justice ruled to regulate GE crops in the same way as GM, and this could stifle international progress in applying genome-editing technologies for crop improvement [36]. The rulings by the United States and Japan on the relaxation of regulations toward genome-edited crops are expected to set the ground for a new paradigm for leading to more efficient regulation internationally [3, 37]. A lower degree of restrictive regulations of genome-edited crops in the European Union could send a positive signal to the developing countries for GM technologies for food security [3]. Still, there is limited public acceptance and adoption of

GM technologies due to the lack of technical, regulatory, and communication capacities to handle transgenic GM technologies locally [38].

The societal risks depend on the public assimilating information from the scientific community. McFadden and Lusk [39] used Bayesian decision theory to explain risk factors of GM foods and global warming. They studied the effects of prior beliefs on the assimilation of scientific information related to GE by the public. Bayesian decision theory assumes that people update and incorporate a belief by allocating weights to a prior belief and new information to form a posterior belief. Information processing does not always conform to Bayesian decision theory and posterior beliefs may converge or diverge by new information. This disconnect implies that the public could place greater weight on other types of nonscientific information with heuristics and cognitive biases. For example, consensus by the scientific community may not be the same since the assimilation process of knowledge is different. It was observed that the extent to which new adapted information accepted depends on the extent to which it conforms to prior beliefs (i.e., factors), such as misinterpreting information, illusionary correlations, selectively scrutinizing information, information-processing problems, knowledge, political affiliation, and cognitive function.

In order to achieve sustainable progress, continued efforts, learning lessons from past, and strategy is necessary to facilitate the use and adoption of genome-edited crops and GE technology. Strategy should be based on transparent communication, and training of researchers and other stakeholders. The development of the evidence-based regulation, communications to build awareness, careful marketing strategy, capitalizing success stories, private–public partnerships, and capacity building (i.e. training, incentives, and facilities) should be emphasized [38].

After analyzing the safety issue, Nicolia et al. [40] pointed out that an improvement in the efficacy of scientific communication could have a significant impact on the future of GE. They concluded that their reviewed collection of scientific records be available to researchers, communicators, and teachers at all levels to help create an informed and balanced public perception on the important issue of GE foods. Implementation of rules related to GM is very challenging [41].

60.5 RISK–BENEFIT ANALYSIS

Participatory approaches are commonly used in risk analysis and risk decision-making. In 1996, NRC proposed three rationales for the broad participation in risk characterization: normative (i.e., participation of citizens), substantive (i.e., participation of people with diverse experience), and instrumental (i.e., participation of governments and international bodies) [42]. It is also emphasized for public–private partnerships and "Safety First Initiative" approaches. GM poses a threat to the values of pluralism or diversity. Intellectual property rights could allow limited access to all users, and thus the law should allow the rights of farmers, the community, and plant breeders.

ILSI [16] provided ten recommendations to assess the safety of GM crops. These are

(i) The new crop's safety assessment should start with an appropriate comparator crop that has a history of safe use.
(ii) It is necessary to develop data on a case-by-case basis, i.e., data for each crop must be developed individually.
(iii) The safety of any novel protein(s) introduced into a crop needs to be assessed carefully.
(iv) Compositional analysis of crops should include known toxicants and antinutritional compounds considering specific metabolites of the targeted metabolic pathway.
(v) The appropriate phenotypic properties need to be assessed, and unintended and unexplained differences need to be identified.
(vi) Laboratory animal studies need to be performed in addition to other safety assessments, and this will provide added safety assurance.
(vii) If GM is used for livestock feed, it is important to demonstrate the expected nutritional benefits.
(viii) Premarket studies in humans should be appropriate on a case-by-case assessment.
(ix) Premarket assessment needs to be checked to identify the impact of nutrient intake by the consumers when the diet is changed with GM crops.
(x) It may be useful to make a risk–benefit analysis of the removal of risk of harm caused by nutritional deficiencies.

All these issues will provide the relevant data required for a meaningful risk–benefit analysis.

Seralini et al. [43] studied the long-term toxicity (2 years) of herbicide (glyphosate: 0.1 ppb in water) used on maize and GM maize using rats. Glyphosate consumption in water above the authorized limits may provoke hepatic and kidney failure, according to the United States Environmental Protection Authority (US EPA). This study showed that concentrations well below officially set safety limits induced severe hormone-dependent mammary, and hepatic and kidney disturbances. Similarly, GM maize gave comparable pathologies that may be linked to abnormal or unbalanced phenolic acids, metabolites, or related compounds. In addition, other mutagenic and metabolic effects of the edible GM maize cannot be excluded, for example, the production of other potentially active compounds such as miRNAs [44] or leukotoxin diols [45]. This indicated that the use of toxic chemicals (i.e., herbicide) could be reduced, but similar toxicity could be developed by different new components in GM foods.

Nicolia et al. [40] reviewed the scientific literature on genetically engineered crop safety for the last 10 years. They built a classified and manageable list of scientific papers and analyzed the distribution and composition of the published

literature from 2002 to 2012. They tried to catch the scientific consensus from the selected original research papers, reviews, relevant opinions, and reports; and pointed that any significant hazards were directly connected with the use of genetically modified crops although the debate is still intense.

Cotter [46] highlighted in his report the unintended effects and potential risks related to GE in agriculture considering observations as reported in peer-reviewed scientific studies. He emphasized that significant research and data gaps in the unintended genetic mutations may impact human health and ecosystems. Many studies evidenced the intended changes that GE might achieve, while there is a complete lack of studies on the unexpected effects arising for the food and environmental safety. The "off-target" (i.e., changes to other genes that were not intended) effects are both a major challenge and a major concern. The off-target effects could unintentionally alter important genes, which can change in chemistry or protein production, and these dynamics and kinetics are important for food and environmental safety. In addition, any implication of the "on-target" effects (i.e., intended changes occur at the intended location, but with a different outcome than expected) needs to be carefully evaluated. For example, a small insertion or deletion of DNA within a gene, even if on target, could change the way a gene is read and processed into proteins in problematic ways causing toxicity. GE may be precise, but outcomes may not always be precise. Overall, regulatory oversight is essential to ensure that potential risks of GE organisms are considered prior to their entry into the environment or food chain.

Many countries in Africa and Asia are hesitant to promote the use of GM crops, largely because of erroneously perceived risks and fears of losing export markets to Europe [3]. The nature of the risk to the environment by GM will vary with the type of organism released. In one study, transgenic manipulation genes in Japanese medaka fish were selected and it was observed that body size reduced their reproductive fitness. It was estimated that the release of even one GE fish could lead to local extinction of the species within 37 generations. Another concern is that insects, which feed on cotton, corn, and other crops, may eventually develop resistance to the naturally occurring insect toxin *Bacillus thuringiensis* [2].

Lassoued et al. [47] provided an expert survey on the added potential benefits of GE or GM crops as compared to those developed by conventional breeding. The survey results revealed a consensus among experts on the enhanced agronomic performance and product quality of GE crops over alternatives. The majority of experts indicated that the regulations for health and safety, potential of export markets, consumers' willingness, and role of media play a major part in determining the development of GE and use in agriculture. They pointed out that further research is needed to gauge expert opinion for the success of GE technology. Recently, consumers of certain countries are more willing to consume GM-derived food [48] and success stories are available.

Moreau [49] studied the ecological risk analysis of GM salmon in relation to its management in the face of uncertainty. He reviewed the available empirical information on the potential ecological and genetic effects and discussed the underlying eco-evolutionary science. The data gaps and irreducible epistemic uncertainties limit the role of scientific inference in support of ecological risk management. The predictive uncertainties are pervasive in complex eco-evolutionary systems, and it is responsibility of those involved in the risk analysis process. These limitations need to be communicated timely, clearly, and cautiously.

60.6 CONCLUSION

Biotechnology could be one of the important technologies to address food security by increasing food production and nutrient content. There are issues in favor and against the use of biotechnology, although its application is progressing. Biotechnology (i.e., GM and GE) can increase crop productivity by affecting plant architecture, and creating insect-resistant, disease-resistant, and harsh-climate-resistant crops. In addition, biofortified crops can be developed for increased nutritional value, sensory quality, and health functionality. Rules and regulations are being developed and implemented to control the use of biotechnology, although lots of concerns and debates exist. Careful risk–benefit analysis needs to be conducted before applying biotechnology in food production.

61 Food Laws, Regulations, and Standards

Rubaba Rahman and Mohammad Shafiur Rahman

CONTENTS

61.1 INTRODUCTION

The regulation of food safety has become more relevant than ever. In just 2018 alone, the world witnessed widespread adulteration of foods: strawberries in Australia were contaminated by small needles leading to a nation-wide trade recall of berries [1], a norovirus outbreak in the Winter Olympics in Korea impacted close to 200 people [2], and a listeria outbreak in South Africa led to over 180 deaths and around 1000 reported incidents [3]. It is such incidents that call for strong legislation and policies with respect to food safety to ensure consumer protection and public health. Indeed, the regulatory framework of food safety plays a crucial role in sheltering the public from economic fraud and preventing the sale of unsafe foods [4]. It is also widely found that inadequate laws relating to food safety result in foodborne illness outbreaks and affect the sale of foods, leading to serious economic consequences. McKeown et al. [5] studied the effects of food safety laws, consumer confidence, and foodborne illness outbreaks on the respective effects on food sales and found that consumer confidence in food safety resulted in losses in sales for many businesses. The increasing role of the media reporting such incidents further exacerbates public distrust. This chapter will accordingly first provide the reader with the principles underpinning legislation and policies concerning food safety.

It will then review how food safety is achieved through the current regulatory and legal framework, both internationally and locally, including in the United States, Canada, Dubai, Oman, Australia, and Europe. A global lens is necessary in an era of globalization and free trade. Alongside international and local laws, the chapter will also discuss how certifications and international standards further foster an environment of safe food production and supply. The chapter will conclude with future challenges that the current regulatory framework of food safety faces, including globalization, health threats, and technologies identified by the European Parliament's Committee on Environment, Public Health and Food Safety [6]. In this regard, using the Novel Food Regulation (NFR), de Boer and Bast [4] emphasized fostering mutual understanding and improving the use of science in regulatory acts. They highlighted that it is of utmost importance to bridge the gap between both fields of expertise.

61.2 ORIGINS OF FOOD LAWS AND REGULATIONS

The key to food safety is the strong and effective enforcement of laws [7]. By way of background, laws are normally a system of rules that are enacted by a governing body and are made up of legal obligations to do or refrain from doing something, whereas regulations are the process of monitoring and enforcing the rules. Guidelines flow from laws and regulations, which are advisory rather than binding [8]. Food law encompasses a wide range of legislation and accompanying regulations and guidelines that govern the way we cook, process, serve, distribute, and eat food. An effective legal framework aims to control the quality and safety of the food we eat, the training and expertise required of the people that provide food to the public, and the type of entity through which food can be served (i.e., a restaurant, a food truck, a food cart, etc.). Food laws affect every single one of us. They impact individuals and organizations, from the family who owns the convenience store down the street to the giant grocery conglomerate, and from the woman running the community kitchen to international food service companies. These laws govern supper clubs, farmer's markets, restaurants, grocery stores, and food festivals, to just name a few.

Food laws are mainly established based on risk and severity. Risk is the chance or probability that a given hazard will

occur, whereas severity is the degree of damage one hazard could cause. "Risk thermostat" is the balancing behavior and cultural filter of the propensity to take risks based on perceived danger, and its consequences could be rewards and accidents. Sperling [9] argued that ethics should play an important role in all three levels of risk analysis of food safety. He found that ethics encourage individuals to reflect on and make value judgments in the process of risk assessment.

61.3 STANDARDS AND CERTIFICATION

61.3.1 Standards

Maidana-Eletti [10] defines standards as being used in all areas of human activity to achieve certain characteristics of goods and their manufacture, thereby reducing risks, fostering trust, and enabling predictability in the market. Indeed, historically, consumers needed to trust the safety and quality of the food products they bought. They particularly required the products to be in accordance with their specifications or the "standards" they set. Before placing an order, the purchasing organization would normally make inquiries relating to the supplier's capability of supplying a product that will meet all its requirements. The purchaser would call for samples from potential suppliers and would carry out inspections and tests to determine whether the samples conformed to specifications. However, the actual shipments would still contain nonconforming products despite the samples having passed all the tests. Major buyers would therefore generally also send their technical experts to assess the quality control systems of the suppliers to ensure that the suppliers were capable of truly producing goods and/or services of consistent quality.

Evidently, the preassessment procedure of the suppliers' quality capabilities meant tremendous costs for buyers, particularly when overseas suppliers were involved. Multiple assessments by different purchasers would likewise be extremely expensive for the suppliers because of the extra labor and money required to prepare for each assessment. Another problem the suppliers faced were the subjective nature of each assessment. Experts from different purchasing organizations, drawing on their company's own experiences, would have different perceptions of an effective quality control system. As a result, suppliers would sometimes receive varying assessment reports from different purchasers for the same product and production system.

As identified by Keener et al. [11], substantial changes in the global economy, paired with increasing relationships between regulatory agencies internationally and a common goal to improve public health, have led to calls for international harmonization of food safety standards. The US Food and Drug Administration (FDA) reports that "such harmonization, potentially, enhances public health protection and improves government efficiencies by reducing both unwarranted contradictory regulatory requirements and redundant applications of similar requirements by multiple regulatory bodies" [11].

A universally accepted standard quality assurance system was deemed necessary to solve the aforementioned issues. It would serve as a reference or benchmark for the assessment of any supplier's quality system. Third-party assessors would also enforce a universal standard, reducing the need for purchasers to carry out individual evaluations and sparing suppliers the burden of multiple assessments.

It is for these reasons that the Codex Alimentarius Commission (CAC), a joint body of the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO), with 188 member countries and the European Union, introduced the Codex Alimentarius (Codex), or "Food Code." Codex encompasses international food standards, guidelines, and codes of practice contributing to the safety, quality, and fairness of the international food trade and protection of public health [12]. Since 1963, Codex has worked to foster harmonized international standards relating to food. Codex has published over 200 standards to date, including general standards for the labeling of prepackaged foods and standards for a variety of food products, from corned beef and canned crab meat to dates, bananas, and infant formulas [13].

Whether Codex is legally binding in nature has been hugely contested among legal academics, without any agreement being reached [10]. When the standards weren't adopted for local legislation, they remained nonbinding and were accordingly ignored for their lack of legal relevance [10]. However, the Sanitary and Phytosanitary (SPS) Agreements, which all members of the World Trade Organization (WTO) adhere to, adopted Codex, consequently upgrading Codex's legal status to semibinding [10]. The adoption of Codex by the SPS Agreements are in the following articles of the SPS Agreements.

> Art. 3.4: Members shall play a full part, within the limits of their resources, in the relevant international organizations and their subsidiary bodies, in particular the Codex Alimentarius Commission … to promote within these organizations the development and periodic review of standards, guidelines and recommendations with respect to all aspects of sanitary and phytosanitary measures.
>
> Art. 12.3: The committee shall maintain close contact with the relevant international organizations in the field of sanitary and phytosanitary protection, especially Codex Alimentarius Commission ... with the objective of securing the best available scientific and technical advice for the administration of this Agreement.

Alongside Codex, the Hazard Analysis Critical Control Point (HACCP) system and the ISO 22000 standard further regulate food quality internationally. HACCP aims to deal with possible risks for food safety [14]. ISO 22000 does not take a preventative approach, but rather a management and systems approach to implement food safety into an organization [14].

However, the rise of a variety of international standards has created more issues. Keener et al. [11] state that predominantly "rich, technologically advanced nations" are involved in the creation and discourse of standards, such as in the CAC. It is argued that poorer countries may struggle to adhere to these standards alleged to be more appropriate

for the wealthier nations [15], leading to a form of *techno-imperialism*, where rich nations impose their standards on the poorer countries, who have had limited to no input in the creation of the standards [11]. An international and collaborative approach to standardization can easily remedy this.

61.3.2 Certifications

Certification refers to the confirmation of certain characteristics of an object, person, or organization. This confirmation is often, but not always, provided by some form of external review, education, assessment, or audit. Accreditation is a specific organization's process of certification. One of the most common types of certification in modern society is professional certification, where a person is certified as being able to complete a job or task, usually by the passing of an examination.

In first-party certification, an individual or organization providing the good or service offers assurance that it meets certain claims. In second-party certification, an association to which the individual or organization belongs provides the assurance. Third-party certification involves an independent assessment declaring that specified requirements pertaining to a product, person, and process or management system have been met. In this respect, a notified body is a third-party, accredited body that is entitled by an accreditation body. Upon definition of standards and regulations, the accreditation body may allow a notified body to provide third-party certification and testing services.

61.3.3 Local Laws and Regulations

Alongside international regulations, local laws also govern food practices and trade. For example, the Food Safety Modernization Act, introduced in 2011, regulates food safety in the US. In 2013, it enacted two main rules to address food safety both domestically and when imported: "preventive controls for human food" and "standards for produce safety" [11]. In Canada, 14 statutes govern food safety, from the Food and Drugs Act to the Safe Food for Canadians Act, and similarly tackle issues relating to food safety and the importation/exportation of food [16]. In the Middle East, for example in Oman, Ministerial Decree No. 2 of 2010 issues regulations on food safety and handling, setting strong standards for hygiene [17]. In Australia and New Zealand, the Food Standards Australia New Zealand Act 1991 establishes a joint food safety standard system between the two countries. Legislation covering all stages of the food chain, termed the "farm to fork" approach [6], is imposed on each member state of the European Union. The European Parliament and the Council adopted Regulation (EC) No 178/2002, covering the basic principles of food law [18]. However, what happens when local legislation clashes between countries? For example, genetically modified foods are treated cautiously under European food laws, but considered safe under US, Argentinian, and Canadian laws [19] (see Figure 61.1, adopted from Lau and Lyon [20]).

Keener et al. [11] highlight that where such conflicts occur amongst local food laws, international agreements, like the aforementioned SPS Agreements, should assist. The SPS Agreements state that where countries impose strict standards, scientific justification must be demonstrated (Art. 2.2). The standards must be "based on a scientific risk assessment" (Art. 5.1). In this way, the Agreements encourage countries to base their food laws and regulations on international guidelines, sound scientific evidence, and public health, in a way that least detriments free trade [11, 19]. After litigation back in 2003 regarding genetically modified organisms (GMOs) in the World Trade Organization, it was found that Europe's stringent standards were not founded on the basis of risk assessment [21].

61.4 FUTURE CHALLENGES AND CONCLUSION

Pederson and Hernandez [6] reported to the European Parliament's Committee on Environment, Public Health and Food Safety on the future challenges of food safety law. They remain relevant and should be carefully considered by future policy makers. The challenges that Pederson and Hernandez flag, alongside other academics, are detailed in the following sections.

61.4.1 Globalization and Increasing Free Trade Agreements

With increasing global trade, the distribution of contaminated food can be extensive, making international standards and global cooperation essential (covered earlier). Menon [22] states that the number of free trade agreements is expected to increase in the future, which should foster international standardization.

61.4.2 Climate Change and Health Threats

Scientists warn that climate change not only means an increased average global temperature, but also comprises trends toward stronger storms, more rain, and prolonged dry periods [23]. Echoing Jaykus et al. [23], Pederson and Hernandez [6] found that such drastic climate changes are likely to affect food safety. Warmer climates augment hygiene risks when storing and distributing food. As such, climate change is expected to, and has actually been well documented in some places to, drastically impact food and waterborne diseases as well as zoonoses (diseases passed between animals and humans). For example, in Australia, notifications for *salmonellosis* increase with decreasing latitude, in other words, with increasing average temperature [24], which draws the connection between warmer climates and diseases. Miraglia et al. [25] found that with more extreme weather conditions, such as heatwaves and flooding, increasing amounts of pathogenic bacteria in foods normally followed. Newell et al. [26] highlight that foodborne pathogens, including *Salmonella* spp. and *Escherichia coli*, thrive in novel conditions, for example in fresh produce, and create more challenges to public health like antimicrobial resistance. This further complicates the effects of climate change.

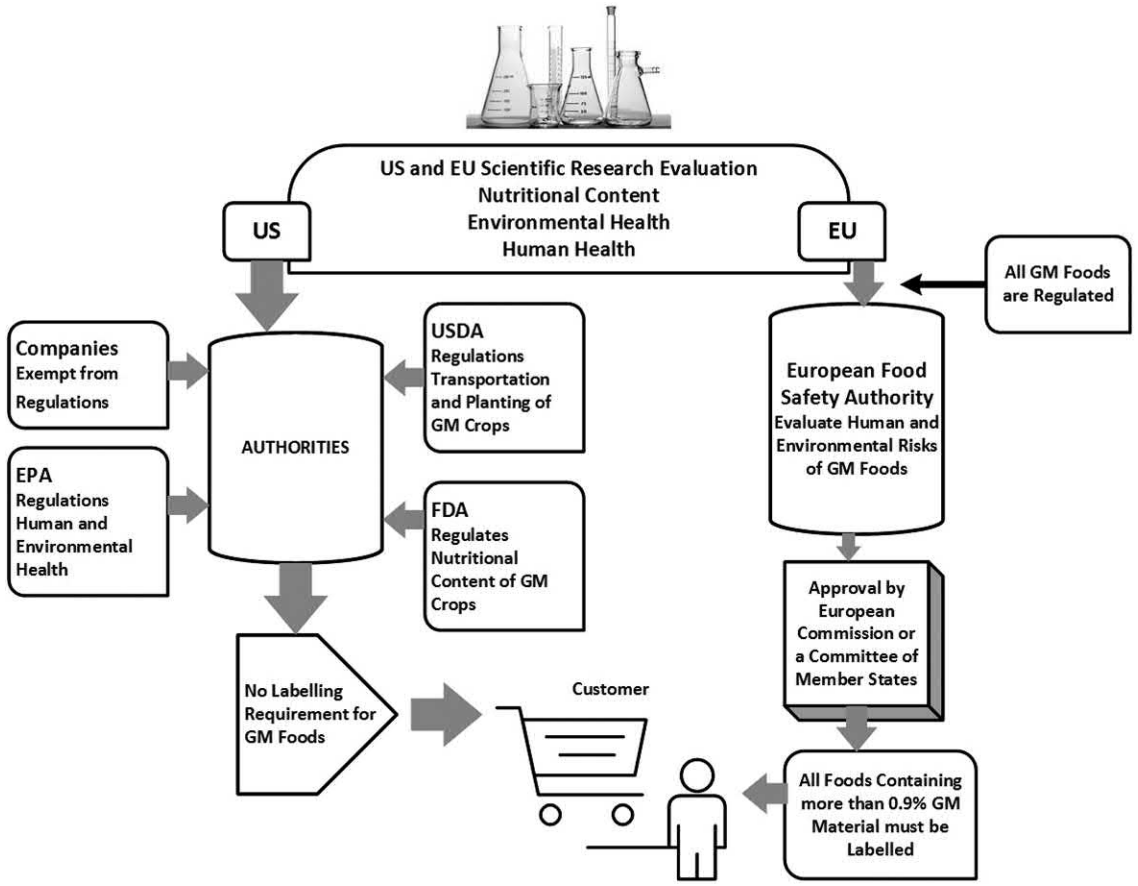

FIGURE 61.1 Differences in food regulation and policies in Europe and America regarding genetically modified foods. (Adopted from Lau [20].)

Jaykus et al. [25] recommend understanding and preparing for the impacts of climate change, as well as constantly monitoring and reviewing the environment, foods, livestock, and wildlife for risks [26], which is important for the early identification and rectification of new issues and trends that climate change and pathogens bring. Early identification will also assist in keeping food safety policies and legislation up to date. Quested et al. [27] relevantly found: "The most important factor in reducing the burden of food-borne disease was identified as our ability to first detect and investigate a food safety issue and then to develop effective control measures."

61.4.3 Technologies

Emerging technologies, such as nanotechnology and biotechnology, serve a number of benefits, inter alia, increasing productivity and the quality of food packaging, production, safety, and taste as well as pest control and disease [6]. However, the current framework will need to be updated as nanotechnology and other technologies remain novel and bear unprecedented risks, such as nanomaterials entering the bloodstream and interacting with organs, causing possible cytotoxic effects [28]. The novelty in emerging technologies like nanotechnology leaves it difficult to define, therefore often difficult to regulate. The European Commission continues to tackle this dilemma as more technologies are adopted [6].

The divergence of international opinion (due to the diverse ethical and cultural values) on biotechnology portrays another difficulty in uniformly regulating such technologies. Article 8(g) of the UN Convention on Biological Diversity (CBD) was introduced to ensure the safety of biotechnologies, particularly where they are a threat to biological diversity and human health. Although the CBD has been ratified by more than 190 countries, only 157 countries have ratified the Cartagena Protocol, Article 19, paragraph 3 of the CBD, which is a legally binding instrument aimed at biosafety [29]. The main reason for this is the effect the protocol may have on a country's trade in GMOs [29]. The protocol has been criticized by some as being ineffective as major players in GMOs, such as the United States and Australia, are not parties to the protocol [29].

McCullum et al. [30] recommend that rather than managing the consequences of new uses of biotechnology after their introduction to the market, dialogue between governments, their citizens, and the private sector should be initiated before research and the development stage. In this manner, resources can be effectively allocated and the wider community can be informed and participate in the progress. Such an approach can also be applicable to the international community.

61.4.4 Conclusion

As food laws and regulations face future challenges, as explored earlier, academics continue to emphasize the importance of monitoring climate change and emerging pathogens. As risks are identified, policies and legislation will need to be updated to reflect these changes, and governing bodies should remain proactive. Food laws will also need to be globally standardized as globalization and international trade increases. In order to avoid conflicts of these international laws and standards with local legislation, international laws should take a legally binding status. International cooperation will also be essential to ensure the enforcement of these food standards globally.

62 Commercial Considerations: Managing Profit and Quality

Anne Perera and Gerard La Rooy

CONTENTS

62.1 INTRODUCTION

While the handbook is essentially a technical publication written for technical people, it is appropriate to keep in mind the book's fundamental purpose, which can be stated in its simplest form as "caring for the customers." Putting caring for the customers in a practical context, we can say that organizations must have the intent and appropriate capability to develop and produce wanted and risk-free products and services. When we say risk-free, we mean not only risk-free for the customer; however important that requirement is, it is also very much applicable to the organization's objectives. Indeed, the proper management of risk is particularly about not endangering the continuity of existence of the business enterprise. In determining the content of this chapter, we had to make a choice between breadth and depth. We felt it was more appropriate to go for breadth in order to provide the reader with a reasonable range of topics so that anyone interested can undertake further reading as they see fit.

When working on the structure of this chapter, we were mindful of the thrust of this part of the handbook, enhancing food preservation by an indirect approach. For us, this means that food-preservation professionals must be prepared to go beyond their traditional fields of expertise and see their contribution in a much wider content. It also reinforces our view that irrespective of the method of preservation employed, the selection of the method must not only be based on sound technical grounds, but also on appropriate business considerations. Please note that while the chapter as a whole was compiled by us jointly, the specialized sections were contributed by either Anne or Gerard individually.

62.2 MANAGING PROFIT

62.2.1 Business Environment

For a business to be successful, it must have sound processes, up-to-date and profitable products, and well-managed services. Successful companies, besides being highly competent in their respective technical fields, also need to be very skilled in business management. While this need for business skill is generally accepted, it should be appreciated that there has been a fundamental change in what business management ought to be about. Many business structures have changed from "tall" structures to ones with few levels and with fewer "functional silos." This means, for example, that food preservation is becoming more fully integrated with marketing, production, and customer service. To illustrate the points made so far, we will look at the case of "flat-earth thinking" versus "round-earth thinking."

62.2.1.1 Management Structures and Practices

Peter Scholtes of Joiner Associates has likened the traditional style of management with the belief that the earth was flat. He explains that people who believed that the earth was flat would ask questions like: "What happens when I sail my ship until I reach the edge?" Once science proved that the earth was round, a sudden shift in thinking occurred, and questions about falling off the edge became irrelevant [1].

What this means is that organizations that are flat-earth based (and we believe that a considerable number still are) will need to undergo some revolutionary rather than evolutionary change. The revolutionary changes required will make their current management practices irrelevant, redundant, and in many cases quite wrong. However, once the big change in thinking has been accepted and the practices implemented, we can employ the process of evolutionary change for further development and improvement [2, 3].

To illustrate how structures and practices have become irrelevant or inappropriate, we can construct a simple comparative table (Table 62.1). Looking at the table, we can observe that some of the items are either one way or the other, e.g., directive driven or direction led. Other items are more continuous (tall versus flat). If we consider the complete table, however, there can be little doubt that we are dealing with a dichotomous situation—the traditional versus the new.

TABLE 62.1
The Changing Business Environment

Traditional (Flat Earth)	New Age (Round Earth)
Executives near CEO	Executives near staff

Expecting "Traditional" organizations to change gradually into "New Age" ones is a bit like expecting an ocean liner to start sprouting wings and gradually change into a 747 aircraft. Putting it another way, we sometimes need revolution before there can be evolution. These changes in business have had, and continue to have, a profound effect on the food-preservation profession, and practitioners need to be fully aware of these changes lest they be left behind with their flat-earth thinking [4].

62.2.1.2 Changing Role of the Food Professional

The science of food preservation is also undergoing much change. It should be appreciated, however, that we are not just concerned with technological change. On the contrary, we believe that the major changes and challenges facing the profession will continue to come from the changes to the business environment referred to earlier [5].

Consequently, there is a need for the profession to become more and more integrated with the totality of the business. What this means in practice is that professionals have to assume a wider role and accept greater responsibility for the success of the companies that employ them. To identify the specific change in emphasis, which we believe is necessary to ensure the profession's further effectiveness and relevancy, it is useful to employ another comparative table (Table 62.2). While most items in the table are fairly self-explanatory, the question of functional (personal) objectives versus company objectives warrants some examination. For many technical personnel, the main work focus tends to be on objectives that are very close to the person in question and on the quality of the actual process. "Doing things right," it could be called. For example, a product development professional will have expectations about the quality of the development process itself and what is to be ready by when. He or she will also

TABLE 62.2
Conventional and Business-Aligned Approaches

Conventional	Business Aligned
Narrow view	Wider role
Advisory	Accountable
Product emphasis	Customer focus (external *and* internal)
Production driven	Market led
Cost unawareness	Profit appreciation
Quality control	Quality management
Risk avoidance	Quantified assessment of exposure
Functional skills	Business knowledge
Functional/personal objectives	Company/organization objectives

be concerned with the robustness of data and with the appropriateness and quality of any tests and experiments. It is our view that this almost exclusive focus on functional objectives is not sufficient in today's commercial environment, let alone in tomorrow's. What is required of the New Age professional is, in addition to technical competence and focus, a marked increase in appreciation of company objectives, overall results, and the commercial "levers" that drive them. We can term this demand for additional understanding and emphasis ensuring that we "Do the right things." The important point is that unless we do the right things as well as doing things right, our efforts may be ill-directed and as a consequence largely wasted.

62.2.2 Commercial Requirements

Most food-preservation technologists are bound to be employed in a commercial enterprise of one type or another at some time during their working lives. Even for those with entirely academic careers, there is still the issue of continuing demand for greater commercialism in the management of academic institutions. Consequently, it is important for professionals in any technical field to have a reasonable appreciation of business fundamentals as well as the commercial and other expectations of the enterprise for which they work. A proper understanding of these fundamentals and expectations will enable the technologist to contribute to the organization's success to the fullest extent possible [6].

The work of technical staff can profoundly affect, both positively and negatively, the financial performance of most organizations. Sound technical developments can open up new business opportunities, lead to greater efficiency, and secure a stronger position in the marketplace. Misdirected efforts, on the other hand, are likely to result in increased and unnecessary complexity, higher costs, poorer asset utilization, and lower profitability. It is perhaps worth noting that profit is not a dirty word but is in fact a vital prerequisite for growth and long-term success. Profitability is a must if funds are to be available for investment in new products, processes, and technologies.

62.2.2.1 Revenue, Cost, and Assets

Of the many factors that impact on a business's financial performance, the following are the most critical:

Revenue
Costs
Assets employed

Food professionals can and often do have a very significant impact on all three. Before looking at how this may come about, it is important to understand the way the factors affect overall financial performance and their interrelationship.

62.2.2.1.1 Revenue

Assume there are two firms, X and Y, with annual sales revenues of \$50 million and \$40 million, respectively (Figure 62.1). Which is the better-performing company? In terms of sales revenue, the answer is firm X, but more information is needed to determine which is the sounder firm, e.g., costs.

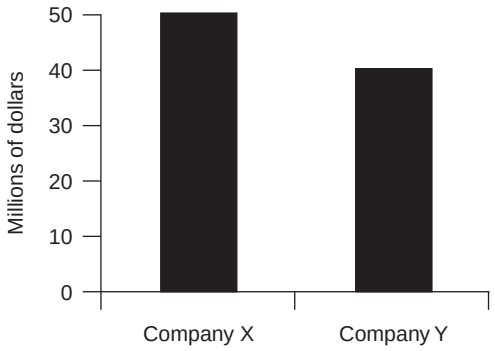

FIGURE 62.1 Revenue of companies X and Y.

62.2.2.1.2 Costs

Assume the costs are \$40 million for company X and \$20 million for company Y (Figure 62.2). With a margin of \$10 million for firm X and \$20 million for firm Y, which is the better company? Looking at just the margin, it is clearly firm Y, but before we award them the annual prize for performance we need to look at the resources employed to generate the \$20 million.

62.2.2.1.3 Assets Employed

When assessing financial performance the resources are considered to comprise the assets employed by the organization, such as buildings, land and plant (fixed assets), and funds tied up in inventories and debtors (current assets—these can be turned into cash reasonably quickly). If the total assets used by the companies are \$20 million for X and \$50 million for Y, which now shows the better performance?

$$\text{Performance} = \frac{\text{Margin}}{\text{Assets}} \times 100\%$$

$$\text{Performance for company } X = \frac{\$10}{\$20} \times 100\% = 50\%$$

$$\text{Performance for company } Y = \frac{\$20}{\$50} \times 100\% = 40\%$$

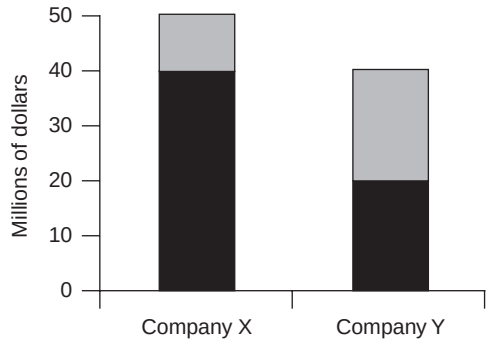

FIGURE 62.2 Costs of companies X and Y.

62.2.2.1.4 Observations

For company X:

The lower margin may mean the business deals in low-value items. Lower use of assets could mean quick turnover of stocks, calculated as follows:

$$\frac{\text{Annual Sales}}{\text{Average Inventory Value}}$$

If, for example, half of the $20 million were tied up in inventories, the stock turnover per year would be 50/10 = 5 times per annum. The low asset figure may also mean low plant book values (plant could be obsolete). The old plant may be costly to operate and hence be the reason for the low margin.

For Company Y:

This company appears to deal in higher-value items. The higher margin may attract competitors to move in on the market. Stock turnover (again assuming half of the assets are tied up in inventory) would be 40/25 = 1.6 times per annum. The company may have a more modern plant, which may mean a lower cost structure and hence the higher margin.

62.2.2.2 Fixed and Variable Costs

Many actions and decisions made by technical staff have a significant effect on costs. It is therefore important for the decision makers to appreciate the difference between fixed and variable costs. Let us consider the basic definitions first.

62.2.2.2.1 Fixed Costs

In brief, fixed costs are those costs not affected by changes in output. An example of a fixed cost would be the cost of monthly machine rental, which we would incur no matter what the output. Note, however, that any production beyond machine capacity would mean a step in our fixed costs, i.e., cost of renting another machine. Also, the passage of time can lead to increases or decreases in fixed costs. Consequently, the earlier statement on fixed costs needs some qualification: Fixed costs are not affected by changes in output within a specified output range, and fixed costs remain constant within a specified period.

62.2.2.2.2 Variable Costs

Variable costs vary with changes in output, and the unit cost is generally deemed to be constant, although that is by no means always the case in reality. For example, bulk purchase may bring the cost per unit down, or in other cases the cost of additional units may be higher than the average. When comparatively small quantity ranges are considered, however, variable costs may be taken as truly variable, i.e., the cost per unit stays constant and total variable cost can be found by multiplying the unit costs by the quantity used.

62.2.2.2.3 Fixed versus Variable Costs

In many business situations, including the technical field, there are often trade-offs to be considered between fixed and variable costs. It is important to have a clear understanding of the difference between fixed and variable costs as well as the relationship between the two. Assume a company wishes to launch a new product and has been given two different manufacturing proposals.

1. Proposal 1: Low fixed cost, high variable cost
   Fixed cost (equipment, etc.) = $100,000 pa
   Variable (material, labor) = $10 per unit
   Selling price = $15 per unit
   Sales volume = 40,000 units pa
2. Proposal 2: Higher fixed cost, lower variable costs: The second proposal is more mechanized and hence requires less expensive material and less labor. Fixed costs are consequently $100,000 higher, but variable costs are lower at $7 per unit.
3. Initial comparison: The two proposals can be readily compared by means of a table (Table 62.3).
4. Comparing profit and break-even points: To determine which of the two proposals is better in terms of the data supplied, we need to calculate (i) total profit for the year and (ii) the break-even point, i.e., the volume at which total revenue equals total cost. Again the two proposals can be compared (Table 62.4).

TABLE 62.3
Comparing Fixed and Variable Costs

	Proposal 1	Proposal 2
Fixed cost pa	$100,000	$200,000
Variable cost per unit	$10	$7
Selling price per unit	$15	$15
Sales volume units pa	40,000	40,000

TABLE 62.4
Comparing Profits and Break-Even Points

	Proposal 1	Proposal 2
Sales revenue = quantity × selling price	600,000	600,000
Fixed cost	(100,000)	(200,000)
Variable cost = quantity × variable cost per unit	(400,000)	(280,000)
Profit	100,000	120,000
Contribution margin = selling price – variable cost	$5	$8
Break-even point = fixed cost ÷ contribution margin	20,000 units	25,000 units

5. Observations: While proposal 2 is more profitable, proposal 1 is less risky. If sales are evenly spread throughout the year, it would take the first proposal 6 months to break even, while for proposal number 2 the break-even point would occur at 7½ months. The break-even analysis, while not a sophisticated tool, is quite useful in illustrating the differences between proposals. Take care, however, as in reality, fixed costs have a habit of going up (or sometimes down), for example, when

needing to rent an extra piece of equipment. Also, variable costs are rarely as linear as assumed here, although as said earlier, they can usually be taken as linear between reasonably small quantity intervals.

62.2.2.3 Price, Margins, and Costs

Before discussing the impact of technical staff on costs, it is necessary to introduce a number of cost-related concepts. The approach to the management of costs in an organization is very much dependent on how costs are viewed—as a starting point or as the endpoint. Figure 62.3 illustrates different ways of considering costs.

62.2.2.3.1 Traditional Cost Plus

The traditional method of determining a selling price was to add up all direct and indirect costs (e.g., overheads) and add a suitable margin. This approach works when there is little or no competition (e.g., due to import control). Unfortunately, some companies will persist with this approach even when, because of changed conditions, it is no longer appropriate (Figure 62.3, method 1).

62.2.2.3.2 Market Price

In a free market, the price is set by that market and has nothing to do with costs or margins. The change from "tradition" to "market price" method took place in some countries during the 1950s and 1960s but in many other countries during the 1970s and early 1980s. The principal effect of the change to a market (and as a rule lower) price was reduced margins, since costs were generally considered as "fixed" (Figure 62.3, method 2).

62.2.2.3.3 Required Margins

The squeeze on margins meant that many organizations experienced unsatisfactory returns on their invested capital. However, to attract new capital, returns and hence margins must be adequate. Since prices are largely beyond the control of the organization and margins must be achieved, the real situation is that:

$$\text{PRICE} - \text{MARGIN} \rightarrow \text{COST}$$

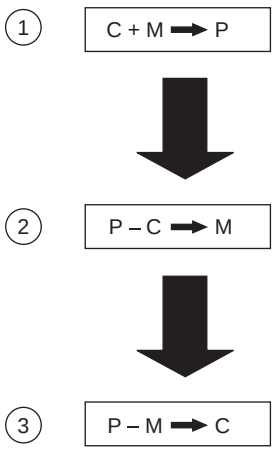

FIGURE 62.3 C, M, P relationships, where C = cost, M = margin, and P = price.

This means that cost is the most important element and one that management needs to focus on constantly.

62.2.3 Technical Impact on Business

Most managers do not fully appreciate the impact that technical resources have (or could have) on the business in general and on revenue generation in particular. What is more, it is quite likely that the majority of technical staff are also not completely aware of their contribution to the success of the enterprise. We will look briefly at four types of impact:

Impact on revenue
Impact on costs
Impact on assets
Impact on cash

62.2.3.1 Impact on Revenue

In many cases, the technical staff provide the lifeblood for the organization's future, as all products and processes require constant renewal and replacement if there is to be security of future revenue.

62.2.3.1.1 Types of Impact

When considering the impact that technical professions have on an organization's revenue generation, it is necessary to appreciate that there are shorter-term and longer-term impacts: (i) Shorter-term impacts (tactical or current revenue): Projects coming under this heading are generally concerned with existing products and processes or new products within existing competencies (e.g., product line extensions, product improvements, ingredient substitutions, etc.). (ii) Longer-term impacts (strategic or future revenue): These are concerned with new technology and products outside current competencies.

62.2.3.1.2 Conceptual and Analytical Soundness

An important point to note is that a project can be analytically correct but conceptually wrong at the same time. In other words, the arithmetic is fine but the underlying premises are flawed. Technical staff should seek advice if required and take particular care in (i) setting out all underlying assumptions clearly, (ii) defining the scope of the project accurately (including in some cases any matters which, while outside the project, may still be relevant), (iii) listing all agreed expectations in terms of both magnitude and probability, and (iv) assessing the economies of the proposal soundly and presenting the justification in a logical manner.

62.2.3.1.3 Reliable Tangible Cost and Benefit Information

Proposals need details about the various types of costs and benefits, that is: One-off costs and benefits (e.g., purchase of new packaging printing dies, the sale of some piece of equipment made possible by the project) and ongoing costs and benefits (e.g., increased production energy costs, reduced labor costs).

62.2.3.1.4 Intangible Cost and Benefit Information

It is important to include all intangibles, even if it is difficult to estimate dollar figures. It may in fact be better not to try to show dollar figures, as it often leads to much argument and debate. Make sure, however, that all intangibles are clearly identified and list them separately, preferably at the end of the presentation. Examples of intangibles include:

Enhanced brand image
Improved competitive position
Increased customer satisfaction
Improved staff morale
Adverse impact on the quality of life of people in the neighborhood
Waste generated by proposed process not suitable for recycling

The point to remember is that intangibles should not be dismissed as of little importance because of our inability to put precise dollar figures on them. On the contrary, with many projects the intangibles (the "soft" issues) are often more important than the "hard" (dollar) issues.

62.2.3.1.5 Technical Revenue Contribution Reporting

When it comes to ongoing management, technical function professionals may assist their cause by ensuring that the revenue contribution is duly reported on and acknowledged (Table 62.5).

62.2.3.2 Impact on Costs

Technical staff can and often do have a very significant impact on costs. Frequently the technical professionals are the members of an organization who make the decisions that affect not only the total costs of a development but which more particularly determine the balance between fixed and variable costs. Understanding that balance is important especially when dealing with new proposals. Some examples are outlined below.

1. Increased R&D costs: Deciding to spend more on R&D (higher fixed cost) in order to gain lower product costs (variable costs).
2. Higher specification levels: Insisting on a higher specification than may be necessary is likely to push up the costs of production (higher variable costs). The decision can also result in higher fixed cost if, for example, the close tolerances specified require a more expensive piece of equipment than would be the case with a less demanding specification.
3. Product line extension: Every time a new product is added to a company's product portfolio, it is likely that production run sizes and frequencies will be affected (usually adversely). Consequently, the set-up cost (a fixed cost) has to be recovered over a smaller number of units, thus driving up the total cost per unit.

62.2.3.3 Impact on Assets

We have already considered briefly the importance of the assets employed when assessing a company's performance. As with costs, the actions and decisions of the technical professional can have considerable impact. Again some examples can illustrate the position.

62.2.3.3.1 Current Assets

When launching a new product, a company invariably needs to increase its working capital (current assets), for example, (i) extra funds tied up not only in finished goods but also in new ingredients and components, and (ii) additional funds required to finance the increased debtors resulting from the sales of the new product.

62.2.3.3.2 Fixed Assets

Technical developments often lead to companies investing in new processes and equipment. It is important that this new investment does not dilute the company's financial performance, that is, the return on the new investment should not be less than the norm for that particular industry and preferably be better than the company's current average return. Exceptions may occur when companies invest in new processes and facilities for strategic reasons, provided of course that this fact is understood and accepted by the decision makers.

62.2.3.4 Impact on Cash

Companies may be profitable but still fail if they run out of cash and cannot pay their bills. While a proper discussion on cash management is beyond the scope of this chapter, it should be noted that profit and cash are not the same things. It is important that the technical professional has some understanding of that difference, since again technical decisions

TABLE 62.5
Sample of Technical Revenue Contribution Report

	Year to Date	Budget	Variance	Last Year	Estimate for Remainder of Year
Net sales $ "old" revenue					
Net sales $ "new" revenue					
Total net sales					
% New revenue of total net sales					
Technical costs					
% Technical costs of new revenue					

can have considerable impact. (If you wish to pursue this topic, we suggest you talk to the financial staff in your organization about how organizations absorb and release cash. You may also like to find out about cash flow evaluations).

62.2.4 Technical Responsibilities

Companies employ food professionals to carry out specific roles in various technical areas, such as research and development, quality assurance, and technical services.

In these roles, food professionals have the opportunity to put into practice what they have learned during academic training. Professional development, recognition, and experience gained are part and parcel of the rewards.

62.2.4.1 Research and Development

Research and development, commonly referred to as R&D, is a vital activity for any progressive company. Failure by companies to develop new products and processes will not only hamper growth, it may lead to the decline and possible demise of the organization. We believe that this is especially so in the case of food companies.

Food companies depend on their technically qualified professionals to carry out the functions of new product/process developments to move their companies forward. This is achieved by identifying products/processes that have the potential to increase the profitability of the company. The research and development function of a food company must thus be closely associated with both marketing and production functions. New product ideas are generated by companies through

Study of market trends
Brainstorming
Requests from customers
Competitive pressures

Ideas that show promise and fit the company's criteria are passed on to the R&D department for development.

62.2.4.1.1 Product Development Processes and Procedures

The product development process will depend on the type of company, the nature of the business, the company philosophy, and management style. Some companies have a formal procedure in place to ensure that product/process development is carried out systematically, while others may develop new products in an informal manner.

As a rule, a more formal approach gives better and more reliable results, especially in larger companies. The main steps comprising a product development procedure are shown in Figure 62.4. Since developing new products is generally an expensive process, companies must subject all new ideas to rigorous screening and prioritizing to ensure that only those ideas with a high probability of success are approved for development. Also, if a partially developed product is no longer likely to meet expectations it is better to abandon the idea. The costs incurred must be considered as "sunk costs," and it would be incorrect to spend any more resources. Another point to note is that products developed at considerable expense principally as technical projects but without a proper input of marketing requirements or with insufficient understanding of business objectives, are unlikely to see the light of day. It is possible to prevent such situations by a formal approach in managing the product development process.

62.2.4.1.2 Product Development Considerations

Food professionals as members of an R&D team need to have access to information on new product launches in their specific product categories, preferably from around the world, and set up a product-awareness library. They also need to build their own networks with other professionals in the areas of ingredients, packaging, and analytical laboratories related to product quality in terms of food composition, and nutrition. Some large food companies have their own technical centers and in-house support services, while others have to depend on outside facilities to provide such services. In dealing with organizations and personnel outside their own company, food professionals involved especially in new product development need to be aware of the importance of maintaining confidentiality about commercially sensitive information.

Professionalism in R&D requires practitioners to be familiar with rules and regulations pertinent to their area of work and to abide by them at all times. There are no universal food regulations, and it is the responsibility of the food professionals to know the food regulations of their own country as well as the relevant information on regulations of countries importing their products. In this regard, it is important to understand that different countries have different labeling requirements. While the artwork on packages is normally handled by the marketing department, R&D personnel have to take an active role in providing and/or approving information that is to be shown on the labels of new products.

In addition to new product development, most food companies carry out continuous product improvement through ingredient substitution and/or process improvement. No matter which R&D activity food professionals are involved in, they need to be aware of the cost implications and try to avoid unnecessary expense. Developing product specifications is a function that R&D staff must carry out with essential input from the marketing and production departments. Such teamwork is necessary to ensure that the marketing expectations are matched by the production capabilities of the company. Once the specifications are developed and approved, they become the basis for quality assurance, which is another area in which food professionals are employed.

62.2.4.2 Quality Assurance

The primary role of the quality assurance (QA) function is to assure that the quality of the products processed and marketed by the company is of the standard required, in other words, that the products are made in accordance with specifications. It is the responsibility of the QA function to ensure that the raw materials received comply with the standards that have been mutually agreed to by the company and the supplier. If

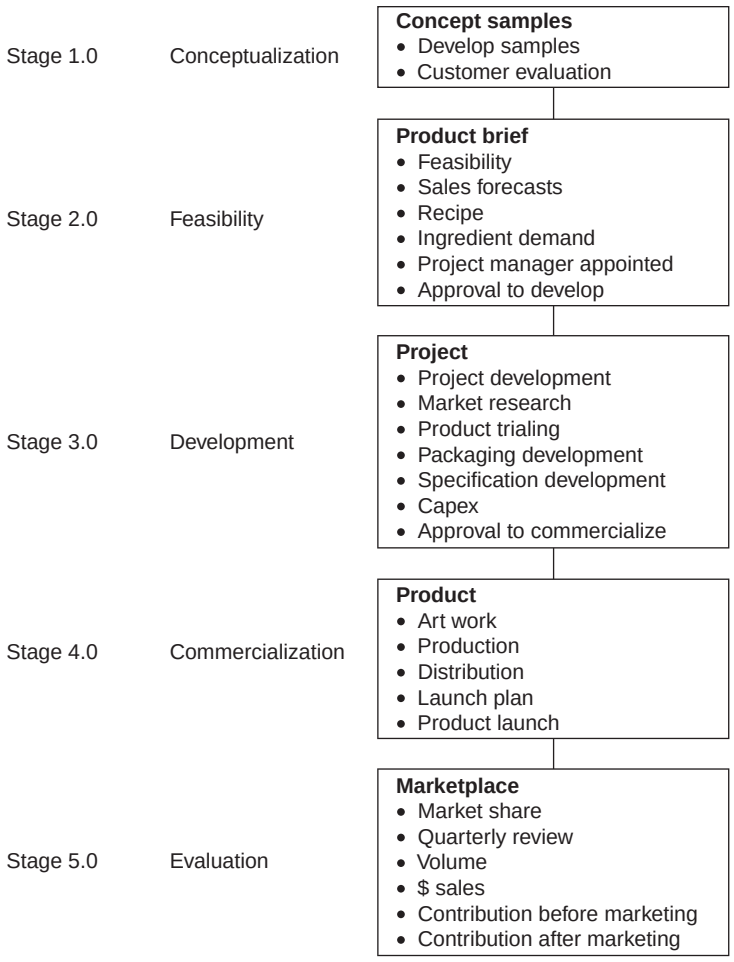

FIGURE 62.4 Main steps in product development procedure.

the incoming material is not of the agreed quality, the QA department should intervene and take the necessary action. In most cases, this means rejection of the incoming material. Only in exceptional circumstances should reworking be considered. In any case, reworking is, as a rule, a costly exercise, which should be avoided if possible.

During processing, samples are generally taken for routine checks of quality. Specific quality parameters of the product in question are recorded on QA forms, which are held in a file. This enables the product history to be traced back if required. Such records also provide valuable process performance information and may serve as evidence when responding to consumer complaints and/or in the event of a product recall. Staff involved in QA must take all precautions and all necessary steps to prevent any problems from occurring. Such problems may be related to the contamination of a product with undesirable substances, be they of physical, chemical, or microbiological origin. Programs such as Hazard Analysis Critical Control Point (HACCP; see Chapter 57 have become increasingly important to food companies in monitoring and preventing potential problems. It should be noted that hazards are not confined to just the actual food products. On the contrary, manufacturing hazards can have significant impact on the environment.

62.2.4.3 Other Technical Services

Research and development with quality assurance are not the only technical functions of food professionals. For example, those with interests in sales and marketing can become technical sales personnel or product managers. Their skills are valuable in providing technical background on the products, ingredients, and equipment/machinery that they sell or market. In addition, they are in a good position to relate to a client company's R&D and QA staff, who generally are the customers for such goods and services.

Although cost is often a considerable factor in decision making, in many instances the decision of a client company to purchase from one supplier and not the other is determined by the type of technical service provided. Leading ingredient companies employ food professionals to work closely with their clients and often produce tailor-made ingredients, products, or equipment so as to suit their specific needs. Some food professionals from supplier companies work in close association with the product development staff of client companies in developing new products. In such cases, the client company may negotiate exclusive rights for the ingredient and or the production system for a given period of time. In situations where new ingredients are not yet permitted by the regulatory

authorities of some countries, the supplier companies or their agents in the countries concerned may intervene and often succeed in obtaining approval. Food professionals play an important role in preparing submissions for approval, which often require substantial technical input by way of research and supporting evidence on the safety of the ingredient in question.

62.3 MANAGING QUALITY

62.3.1 Quality Scene

Over the last two decades, there has been a considerable increase in the understanding and acceptance of the importance of quality. The technical professional needs not only to be in tune with this change in thinking, he or she must also take a proactive stance because it often is the technical area in which one finds the origins of both quality successes and failures as well as the remedies.

62.3.1.1 Importance of Quality

To assess the nature (or the customer's perception) of quality, it is useful to employ Dr. Kano's model of quality, which identifies three different aspects of quality: Basics, satisfiers, and delighters.

62.3.1.1.1 The Basics

The basics are the fundamental aspects and features of a product (or service) that are considered to form part of its inherent functionality. Basics are all those ordinary things that the customer expects to be up to the mark (e.g., size, flavor, functionality). The important point to realize is that failure to meet the basics usually makes the customer angry.

62.3.1.1.2 The Satisfiers

Satisfiers are those aspects and features that make the customer feel happy about his or her purchase. They are important to the customer but are only effective if the basic requirements have been met.

62.3.1.1.3 The Delighters

Delighters are those extra features or services that clearly exceed the customer's expectations. They can, however, be counterproductive if the basics are not met. A faulty product coupled with a delighter will make the customer cynical.

62.3.1.1.4 Points to Note

The following are worth noting: (i) most customer complaints are likely to be concerned with the basics, (ii) remember, failure to meet the basics tends to make the customer angry, and (iii) the quality model is very relevant in all areas of management, be it marketing, product development, or production.

62.3.1.2 Origins, Sources, and Causes of Quality Problems

Quality problems usually manifest themselves when a customer complains or when quality assurance staff detect an out-of-specification product. To find the root causes of complaints we need to dig deep. It is a bit like peeling an onion—each layer needs to be removed before the next one is revealed.

62.3.1.2.1 Origins

First, we need to identify the three fundamental origins of quality failures. These are (i) faulty design (design mistakes, specification shortcomings), (ii) faulty execution (faults in manufacture or assembly, shortcomings in delivery or service), and (iii) incorrect use (intentional or unintentional).

It should be noted that many, if not most, of the quality failures experienced by firms are the result of faulty design, even though they appear to have their origins in faulty execution. For example: (i) in many cases firms settle on design features and specifications without having a proper understanding of what the operational systems are capable of delivering in a consistent manner, e.g., unrealistic mix tolerances, (ii) quite often designs will carry within them the seeds of faulty execution: Parts that can be assembled incorrectly, awkward design that will encourage assembly shortcuts, unwarranted production complexity, and lack of standardization.

62.3.1.2.2 Sources

Once we have identified the fundamental origin of failure, we can look for the source by identifying each specific process, operation, or procedure involved with the failure. In most instances, we will need a concise description of the process or operation concerned. When faulty execution is the origin of failure, two types of sources are possible: Those within the organization and hence under our direct control (internal), and those outside of the organization, usually because of faulty materials or services (external). Even where the source is external, there will always be some contributing internal factor. For example: (i) When a supplier is responsible for poor-quality components (external source), we also need to identify the appropriate internal contributing factors (e.g., inadequate or unrealistic purchasing specification, price-only purchasing policy, or undue emphasis on credit). (ii) Management of the inward goods acceptance process is inadequate. (iii) The line staff is unable to react quickly when faulty materials are encountered.

62.3.1.2.3 Causes

While having an understanding of the origins and sources of quality failures is a necessary first step, there is little we can do about prevention and improvement unless we also understand the cause of our problems. All quality problems arise from a failure to meet customer expectations. Most of the time a failure is the result of variability in one or more processes. While the question of process variability is discussed in more depth in Section 62.3, it is worth noting here that understanding the variability of processes is an essential prerequisite to reducing quality problems. To reduce the variability in processes we need to appreciate what causes it. There are two different types of causes of variability: Common causes and special causes.

Common-cause (statistical) variability includes the random variation in results or performance, which is due to the

system itself rather than any specific action. This variation is considered "normal" for the particular system. As common-cause variability is an inherent feature of the process, improvement in process performance is dependent on making changes to the system. Pep talks to staff, exhortations, or slogans are quite useless in this situation. Unless the actual system is changed for the better, variability will not decrease. Special causes are those extraordinary and often one-time events that cause a temporary increase (or decrease) in variability. There is no need to change the system of operation to avoid variability due to a special cause.

62.3.1.3 Quality Culture and Processes

It is important to note that in the end, improved quality can only come about if there exists in the organization an all-pervading quality culture. This means not quality one day and quantity the next. It means that the entire organization should be quality aligned with regard to management practices and systems. In addition, there needs to be an organization-wide agreement to regard quality issues principally as opportunities for improvement rather than as problems to blame on someone. In practice, it means that all quality issues need to be viewed in terms of origin, source, and cause (as outlined earlier) and that there are in place sound, standard, and accepted process-improvement techniques in the company. It is important to appreciate that it is only when the underlying processes are improved in a permanent fashion that one can expect a sustainable increase in quality performance.

62.3.2 Understanding and Reducing Variability

It is very important for technical staff to thoroughly appreciate the effect process variability can have on business performance. There are two principal impact areas:

1. At the time of product and process development, the R&D specialist has a major role in ensuring that potential process variability is understood and minimized.
2. During production, the quality assurance professional can do much in introducing the right monitoring systems and training so that operational staff can learn about process performance and subsequently work to reduce its variability.

62.3.2.1 Costs Associated with Variability

To introduce how variability can reduce quality and performance, and drive up costs, we will use as an example the costs involved in maintaining a painted house. The lasting quality of paint on a wooden house provides a classic demonstration of the effects of variability in performance and the costs associated with it.

62.3.2.1.1 Variability in Paint Performance

Have you ever had the unenviable task of preparing a clapboard house for repainting? You must have wondered as you toiled away why some of the paint had flaked away while other bits stubbornly remained in spite of vigorous wire brushing and scraping. You may also have seen houses that obviously haven't been repainted for several decades yet still have some paint showing. While some of the remaining paint would be easy to peel off, other remnants would still be difficult to remove.

62.3.2.1.2 Costs of Paint System Performance

Consider the case of a house with painting costs over the first 35 years of its life as shown in Table 62.6. If there was no variability in the performance of the paint, all the paint would last exactly the same length of time. Remember that some small parts of the paint system remain intact for several decades, so if all the paint performed as well as the best parts, a 35-year life could be possible. If there was absolutely no variability, we could predict the life of the paint system with total confidence. We could plan the job of painting (Job A) with precision, as on a given day (known in advance) all of the paint would fall off the house. In addition, there would be no need for scraping and sanding. The table shows that the difference in per m^2 cost between the two scenarios is \$32 (\$48 – \$16), which is the cost due to the variability in performance of the paint system. Even if we take a more modest paint life of 2l years, the cost would still be considerably less. What the example shows very clearly is that there are costs associated with variability and that high variability means high costs.

62.3.2.1.3 Other Costs

While the dollar costs associated with high variabilities are very important, they are in the majority of cases reasonably self-evident and quantifiable. But there can be other important costs.

1. The costs of a poor reputation: Without any doubt the most important of all costs is the detrimental effect variability has on one's reputation in the marketplace.

TABLE 62.6
Costs Associated with Variability in Paint Performance

			$ per m^2 (labor and material)
A. When new: Three-coat finish			8
B. After 7 years: Making good spot failures, spot prime, and two coats			7
C. After 14 years: Making good spot failures, spot prime, and two coats			12
D. After 21 years: Complete repaint including sand back, refill prime, coat			12
Paint life costs:			
Year	Job	$	Accumulated
0	A	8	8
7	B	7	15
14	C	7	22
21	D	12	34
28	B	7	41
35	C	7	48

If there is one thing that annoys customers more than anything else, it is a lack of consistency. Nothing will damage a reputation more quickly and more permanently than a high level of variability in the quality of products and services.

2. Staff-related costs: These costs are associated with pride of workmanship and staff morale. High variability in our processes is likely to cause many internal problems, such as scheduling difficulties, quality-of-fit problems, and reworking—all of which are bound to lead to reduced job satisfaction and, as a consequence, to poorer performance.

62.3.2.2 Managing and Reducing Variability

In many organizations, process variability is given insufficient weight, resulting in quality problems and subsequent loss of customer confidence. It should also be appreciated that variability reduction is not something that happens by itself. On the contrary, it requires focused management attention, sound systems, and properly trained staff.

62.3.2.2.1 Reasons for Variability in Performance

To understand why we often experience quite a large variability in performance, we need to identify the various sources. In the case of the painted house, they can be divided into four categories:

Timber surface: The original timber surface is likely to be a source of considerable variability in the performance of the paint system. Variation in surface finish, moisture, and resin content will all contribute to that variability.

Materials: If you buy paint supplies from a reputable source, you can be fairly certain that the variability will be low. However, in spite of a manufacturer's best efforts to keep paints uniform, there will always be some variability. This is likely to be greater if a particular paint comes from more than one batch. The upshot is that some of the paint will perform better than average and some worse.

Application: The way the paint is applied provides an enormous potential for variability in performance. Using a brush, for example, results in large differences in coat thickness. Even employing different painters for different parts of the job is likely to lead to an increase in variability. In addition, one must take into account the varying painting conditions, such as air temperature and humidity, which will increase variability in performance.

Position: This is a critical factor in how long a paint system is going to last. Areas of paint exposed to wind, rain, and full sun are likely to fail earlier than those protected by porches or eaves.

62.3.2.2.2 Understanding Variability

When advocating the reduction of variability, we should remember that most if not all regular company reporting is about reporting averages. For example, most standard costing systems are designed to report average monthly performance against some predetermined (average) standard. Averages by their very natures will mask variability, so while we may aim to meet a particular better average performance, we could be unwittingly steering our ship in the wrong direction.

Take, for instance, a case involving three teams with the average daily outputs over a month as shown in Tables 62.7 and 62.8: On the face of it, Team B is the best, and if we did not look further we could conclude that Teams A and C should pull their socks up and work like Team B. If we were to dig a little deeper, we would learn that the highest and lowest daily figures were as shown in Table 62.8. If we also learned that production in excess of 1200 units per day was considered to be too hard on the equipment and that such high rates of throughput tended to lead to quality problems, which is now the better performing team? In terms of output variability, it is Team A, because it turns in the most consistent performance. Perhaps Teams B and C could learn something from Team A about how to avoid very low throughput days, while Team A could be encouraged to talk to Team C about what they do to reach 1200. As for Team B, the first aim needs to be "no production beyond 1200 units per day" with the subsequent focus on reducing throughput variability further by improving low-day output.

62.3.2.2.3 Best, Worst, or Average Performance

In the case of the painted house, it is quite obvious that the worst-performing parts of the paint system determine the painting costs over the lifetime of the house. The best-performing parts are those difficult-to-remove bits that we strike when trying to get the house back to bare wood. While the average performance of the total paint system could be 20 years, is this useful information? After all, would a paint system with an average life of say 25 years necessarily be a better proposition? What about if in the latter case the performance range was 5–45 years (rather than 7–33 years)? Averages can be highly dangerous statistics, and while politicians and other public figures can be masters at using and misusing averages, in business we see much misunderstanding as well.

62.3.2.2.4 Accumulation of Effects

Because customers experience the final result of the various processes, one needs to be aware of the potential accumulation

TABLE 62.7
Case Study of Three Teams: Average Output

	Team A	Team B	Team C
Average (units/day)	1000	1100	1000

TABLE 62.8
Case Study of Three Teams: Highest and Lowest Output

	Team A	Team B	Team C
Highest daily	1100	1500	1200
Lowest daily	900	700	800

of the variability effects of all processes. Considering the case of the painted house again, the accumulation of effects can be looked upon as a lottery. Some areas are unlucky, in that they have a combination of all of the worst aspects, while others have a combination of the best with the best. Between the two extremes, we have a multitude of combinations, which provide either better or worse-than-average performance. As a consequence, we see some early failures occurring in quite unexpected places (e.g., away from the weather), while other areas of paint continue to perform well in spite of being much more exposed.

If we apply this concept of accumulation of effects to several business processes, we can see why some customers can be "unlucky" when it comes to customer service. Take, for instance, the following situation. We supply goods to customers and have the following performance statistics: Stock availability 90%, order accuracy 90%, invoicing accuracy 90%. Table 62.9 shows the average effect on our customers (assuming the three statistics are independent of each other). We can observe that we have on average one "unlucky" customer per 1000 orders who experiences the "worst with worst with worst" combination. They are the ones who are likely to tell their friends "Don't deal with that firm, they cannot do anything right." Using this example, it is clear why some people end up with a "lemon" of a car, while other buyers of the same model are very satisfied. In the business of food preservation, the problems are very much the same.

62.3.2.2.5 Improvement Opportunities

The important point to note is that process variability will, generally speaking, not reduce by itself. On the contrary, it requires special effort and attention to detail. There are many techniques available, but any detailed discussion is beyond the scope of this chapter. We will therefore confine ourselves to identifying opportunities to reduce variability and to the principles underlying improved process performance.

62.3.2.2.6 Minimizing Potential Variability

It is by seeking to minimize variability in the first place that the technical professional can make a significant contribution to the ultimate performance of the product. During the development phase, there are many opportunities for this, but unfortunately the opportunities are seldom taken advantage of to their full extent. Some examples include:

TABLE 62.9
Customer Performance Statistics

Problems	Percentage
None	72.9
One	24.3
Two	2.7
Three	0.1
Total	100

Understanding the capability of the processes and developing the product and specifications accordingly. There is little point in specifying a process to ±1°C when the actual variability is ±2°C. Looking for opportunities to standardize materials and processes wherever appropriate. Undue and unnecessary diversity does invariably lead to higher variability of output. Making the definition of the process control methods and information a required part of the product or process design and specification.

62.3.2.2.7 Minimizing Operational Variability

Assuming we have taken all important steps to minimize potential variability, we must now put in place the systems and procedures necessary to understand and minimize operational variability. The main point is that processes must be monitored and properly understood before changes and adjustments are made, as shown in Figure 62.5.

62.3.2.2.8 Benefits of Reducing Variability

In spite of what intuition may sometimes tell you, reducing variability through systematic improvement of the process will invariably lead to reductions in cost, increased customer satisfaction, and other benefits.

Lower costs: The ability to set a lower target weight when packing a valuable product and being sure that that customer is not shortchanged.

Happier customers: Lack of consistency in products and services will harm a company's reputation. Customers will be happy when their expectations are understood and satisfied. If you aim to exceed their expectations, be confident that you can exceed them in a consistent manner. Make sure the statement "exceeding customer expectations" is not just a slogan. Raising customers' expectations without the possibility of consistent delivery is bound to have an adverse effect on your business.

Inventory savings: Reduced product variability also makes possible savings in inventory. Improved consistency is a prerequisite for just-in-time (JIT) management. It should be remembered that "out of spec" products as a rule become a liability to the company, requiring "write-downs" or additional expense or both.

Increased capacity: Processes that are under proper control as a rule operate better with resulting increases in output.

Happier staff: Reduced process variability means fewer production problems, less panic, and fewer complaints, all of which help staff to feel better about their jobs and themselves.

62.3.3 Managing Customer Complaints

It is no secret that many companies do not like receiving customer complaints. They are usually seen as embarrassing, troublesome, and possibly frivolous. But we need to manage them well if we are to maintain good customer relations and turn the complaints into opportunities for improvement. To do this we need to (i) ensure we have the correct culture, (ii) design the right system and operate it properly, and (iii) carry out proper analysis, report, and follow-up.

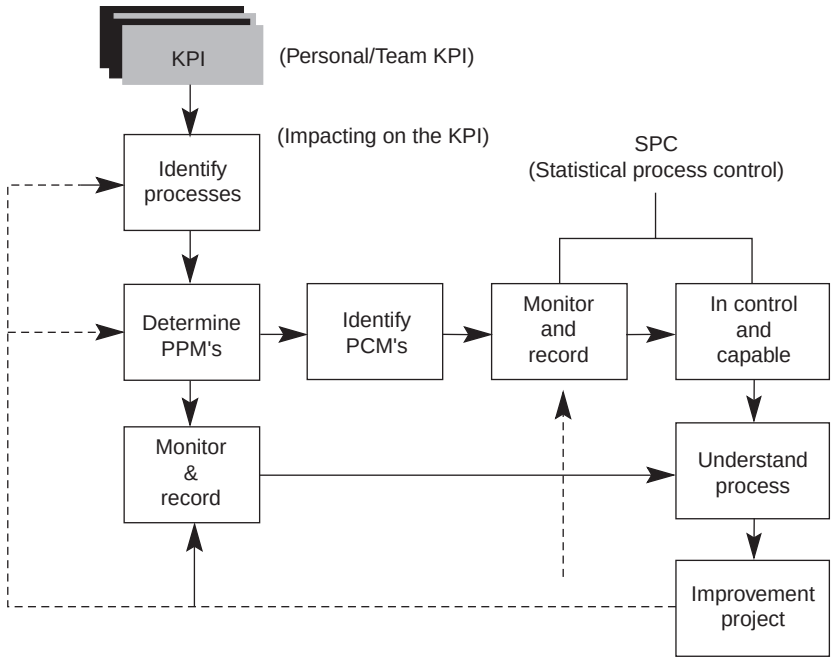

FIGURE 62.5 Systematically reducing variability. KPI = key performance indicator, PPM = process performance measure, and PCM = process control measure.

62.3.3.1 Assessing the Situation

62.3.3.1.1 Correct Culture

Before one designs and implements any system, it cannot be overemphasized how important it is to have the correct culture in place. This means treating a customer who complains as a person doing us a considerable favor. The customer is telling us something about our product or service that we probably did not know but ought to. We should accept that many other customers may have similar feelings about our product or service except that they do not bother to complain. Instead, they decide not to buy the product again, as well as telling their friends about their unhappy experience.

Points to remember include:

- Are customer complaints principally seen as a nuisance?
- Who is responsible for managing complaints, and who actually handles them?
- Are complaints dealt with by some junior and possibly untrained person?
- Is it possible for customers to get "shoved around"?
- Are we sure that complaints are handled professionally every time?
- Are complaints seen as important?

A good check on the perceived importance of customer complaints is to look at how they are reported. Are they included in the monthly report? If yes, are they hidden somewhere at the back, or do they form part of the important summarized results?

62.3.3.1.2 Do We Have the Right System?

Once an organization has accepted that customer complaints are extremely important and introduced the necessary managerial and cultural changes, it should ensure that it also implements a sound customer complaint-management system and related procedures. The most important requirement is confidence that the system and procedures will ensure the appropriate response in every situation. In addition, the procedures should ensure a good standard of recording to provide the organization with a proper source of information for any required follow-up and subsequent improvement of the processes. If they are not up to scratch, redesign them.

Points to consider include:

- Is there in place an up-to-date written procedure for dealing with complaints?
- Does the procedure ensure an appropriate response in every case?
- Can we be confident that all (or at least most) of our customers are happy with the way the organization deals with complaints?
- Does the system ensure proper recording, monitoring, and reporting?
- Do the complaints lead to improvements?

62.3.3.2 Developing a New Approach

If an organization considers customer complaints to be important, it must be prepared to develop, implement, and maintain a sound management system.

62.3.3.2.1 Defining the Rules

A crucial part of any new customer complaint-management system is defining the rules that are to govern its operation. It is important to identify all likely incidents and link each one of them to an appropriate response. A useful tool for doing

this is a decision table, which will enable the organization to define precise rules for action in each case. To construct a decision table it is necessary to identify all situations (conditions). These would include product or service faults (e.g., wrong weight, minor contaminant, serious contaminant, life-threatening fault, rude salesperson, poor after-sales service) and disposition of the customer (e.g., happy, neutral, angry, threatening action). It is also necessary to agree on the appropriate response (e.g., days to respond, call on the customer, etc.).

62.3.3.2.2 Complaint Classification

Once all conditions have been identified, a complaint classification table can be constructed. The classifications are to identify a predetermined response for every situation. Table 62.10 shows five different responses denoted by the letters A, B, C, D, and E. If all of the conditions, actions, and appropriate response rules have been defined, there will be a basis for a sound and reliable procedure.

62.3.3.2.3 Appropriate Responses and Operation

Once there is agreement on the complaint classifications, the appropriate responses need to be linked to them. Table 62.11 shows the general idea: By determining the complaint classification the person dealing with the complaint can select the correct response every time. If required, another column ("else") can be added to meet any situation that does not fit A, B, C, D, or E.

TABLE 62.10
Complaint Classifications

Complaint	Customer			
Wrong weight	A	A	B	C
Minor contaminant	A	A	C	D
Serious contaminant	B	C	D	E
Life threatening	E	E	E	E
Rude salesperson	A	B	C	D
Poor service	A	B	C	D

TABLE 62.11
The Response Rules

	Customer				
Action	**A**	**B**	**C**	**D**	**E**
Days to respond	3	1	1	I	I
Standard letter	Y	N	N	N	N
Special letter	N	Y	O	N	N
Vouchers	2	3	N	N	N
Call on customer	N	O	Y	Y	Y
Retrieve product	N	O	Y	Y	Y
Recall procedures	N	N	N	O	Y
Advise QA manager	N	O	Y	Y	Y
Advise GM	N	N	O	Y	Y

62.3.3.2.4 The Responsibility Matrix

To help define who is responsible for what, one can employ a responsibility matrix. The idea is to relate people and required actions in a single table (see Table 62.12).

62.3.3.3 Recording, Monitoring, and Reporting

To turn quality problems into improvement opportunities, it is essential to record and monitor all relevant information. Depending on the size of the organization and the number of complaints, anything from a simple manual system to a sophisticated computer system may be required. For most organizations, a modest PC-based system will prove the best solution. However, irrespective of whether the system is computer-based or not, the general principles are essentially the same: The system must provide for ease of monitoring, analysis, and subsequent reporting.

62.3.3.3.1 Origins, Sources, and Causes

In an earlier section, we looked at the origin, sources, and causes of quality problems. It is important that the customer-complaint system and procedures and the staff operating them are capable of differentiating between origins, sources, and causes. If there is no such distinction, it is unlikely that the management of customer complaints will lead to process improvement and a subsequent reduction in quality failures. Of particular concern is that many organizations do not appear to appreciate the difference between common-cause and special-cause quality problems.

In organizations where the difference between common and special causes is not understood, one often finds major changes to systems and procedures because of some out-of-the-ordinary failure. Also, failures due to common-cause variability may be explained to customers as one-time problems that are unlikely to recur.

62.3.3.3.2 Recording Details

For a customer complaint system to be effective, the proper recording of all necessary details is essential. Figure 62.6 shows an example of a monthly recording of the details of origins, sources, and causes. Similarly, other information such as complaint classification and the nature of the complaint (basic, satisfier, or delighter) should be recorded. An action and improvement log should also be maintained.

62.3.3.3.3 Analysis and Reporting

If a good recording and monitoring system is in place, subsequent analysis and reporting can be tailored to fulfill particular needs. A company may settle for a simple form of analysis and reporting, in which case the task is fairly straightforward. On the other hand, it may decide to be quite sophisticated and opt to employ advanced analytical techniques and reporting methods. Whatever approach is adopted, it is crucial that the analysis and reporting have some real meaning leading to improvements in performance. The following points should be kept in mind:

More sophisticated reports: The information collected should allow one to identify possible correlations, for

TABLE 62.12
Responsibilities for Customer Complaints

FIGURE 62.6 Origins, sources, and causes of complaints.

example, between (i) complaint classifications and origins; (ii) particular types of complaints such as contamination and origins; (iii) origins and causes; (iv) reductions in complaints and improvement projects. (A word of caution. When embarking on a program of more sophisticated analysis, be sure to employ a suitably numerate employee. Basic conceptual errors can make any analysis at best useless, at worst dangerous.)

Action/improvement reporting: The main source of information for this will be the action and improvement log, although information may also come from other sources such as customers and operations. Control of dates is important (e.g., date items first raised, original agreed completion date, latest agreed completion date).

Place in company reporting: Once the analysis to be done and reports to be produced have been determined, it is necessary to decide on the content of the regular monthly report. It is also necessary to decide who will be responsible for the reporting and where the report should be included.

62.3.3.4 Improving Process

Ensuring the correct customer response in every case is a crucial feature of any complaint system. This part of the system is "outward focused," which is very important to maintaining good customer relations. However, to improve performance and hence the reputation as a quality company, it is necessary to have an inward focus as well.

Customer complaints can provide valuable information about underlying weaknesses. However, the important point to note here is that what shows up as customer complaints are effects or results and that to prevent or lessen complaints we must identify and improve the underlying processes. It may be said that this statement is rather obvious, however it is a fact that many organizations do not bother to search out the processes involved with permanent improvements. It should be remembered that most management reporting (not just customer complaints) is about results with little or no appreciation of what are the relevant processes.

62.3.3.4.1 Managing Improvements

A system of recording and monitoring will identify many areas where improvements are both possible and necessary. Improvements should be managed in a structured and somewhat formal manner. Some points to remember include:

The customer complaint system, if managed correctly, provides information as a basis for improvement rather than emotive assertions such as: We always have the wrong weights; we never deliver on time; or our product is full of contaminants. The emphasis needs to be on prevention and improvement rather than culprit finding. It must be quite clear whether problems are common-cause (systems) or special-cause types. Generally speaking, improvements or a reduction in complaints come about by focusing on and improving the underlying processes. It is necessary to exercise patience. Improvement of the process will take time, but if done properly the improvement will be permanent and hence very worthwhile.

62.3.3.4.2 Identifying Processes

If it is working correctly the system will identify the process that needs to be improved, e.g., staff induction/training, design procedures, specification development, production tolerances, or process monitoring. Of particular interest are complaints that have their origin in product design and development. Design is the start of the sequence of operation, and hence any failings in design will affect all subsequent processes.

As mentioned earlier, a large number of a firm's quality failures have their origin in faulty design, although they may, at first sight, appear to have their origin in faulty execution. If products are designed and developed with problem prevention in mind, many subsequent quality failures can be avoided. Important areas to consider include (i) standardization of ingredients where appropriate, (ii) simplifying processes where possible, and (iii) designing intermediate tests into the process, including statistical process control.

Once a reasonable quantity of data has been collected, it should be possible to identify the specific processes giving rise to particular complaints, such as (i) ingredient quantity control, (ii) mixing, and (iii) cooking. Note, however, that to find the real source of the problem, considerably more investigation is usually needed. For example, complaints may be traced to the cooking process, but the real source may be insufficient operator training, out-of-date manuals, or a lack of maintenance of the temperature-control equipment.

62.3.3.5 Management Commitment

The proper management of customer complaints requires much thought and effort as well as attention to detail. In addition, considerable management support and involvement is required, especially if improvements are to be made. It really comes down to the following questions: (i) is the organization serious about the customer's expectations and the company's reputation? and (ii) is it prepared to make the effort to turn problems into opportunities? Even if not all problems can be solved, we can still benefit from some of the concepts and techniques discussed, provided the organization knows where it wants to go and ensures a consistency of signals.

62.3.3.6 Consistency Is All-Important

Consistency of signals to both customers and staff is vital if one is to succeed in reducing complaints. For example, do not allow quality policies and procedures to be overridden arbitrarily by edicts from above. Be sure to provide ongoing support for the complaint system's operation and resulting improvement projects. In order to ensure that output from the system is given due recognition, it is important to (i) check the company's current culture and practices, (ii) decide what the current shortcomings are and what changes are warranted, (iii) obtain agreement from affected managers and staff to develop a plan of action, and (iv) implement and enjoy the improvements in performance. The process of improving an organization's performance and enhancing its reputation as a quality company is all about doing many things better. Focusing on customer complaints is a good starting point.
