PART II Preservation of Minimally Processed Foods

PART III Preservation Using Chemicals and Microbes

PART IV Preservation by Controlling Water, Structure, and Atmosphere

Acknowledgments

First and foremost, I would like to thank Almighty Allah for allowing me to continue doing what I love most: to learn, teach, and write. I am grateful for the opportunity to present the third edition of this book.

I also express my sincere gratitude to the Sultan Qaboos University for giving me the opportunity and facilities to work on such an exciting project and for supporting all my professional endeavors. I would also like to thank all my earlier employers, including BUET, UNSW, and HortResearch, who built the foundations of my knowledge and expertise. Appreciation is also due to all my teachers, especially Prof. Nooruddin Ahmed, Prof. Iqbal Mahmud, Prof. Khaliqur Rahman, Prof. Jasim Zaman, Prof. Ken Buckle, Dr. Prakash Potluri, Dr. Robert Driscoll, and Mr. Habibur Rahman, for their encouragement and help when I was pursuing higher education and with my academic research. I would like to express my appreciation to Dr. Abdullah Al-Sadi, Dr. Rashid Al-Yahyai, Dr. Zaher Al-Attabi, Dr. Omar Al-Jabri, Dr. Michel Claereboudt, Dr. Said Al-Ismaily, and Prof. Osman Gaafar for supporting me throughout my career, from teaching to conducting research at the Sultan Qaboos University. Special thanks to my colleagues and research team members: Dr. Nasser Al-Habsi, Dr. Mostafa Waly, Prof. Nejib Guizani, Dr. Mohamed Al-Khusaibi, Dr. Ahmed Al-Alawi, Ms. Salha Al-Maskari, Dr. Lyutha Al-Subhi, Dr. Ismail Al-Bulushi, Dr. Amanat Ali, Ms. Intisar Al-Zakwani, Dr. Mohamed Al-Ruzeiki, Dr. Zahra Al-Kharousi, Ms. Farha Al-Naabi, Mr. Rashid Al-Belushi, Ms. Insaaf Al-Marhubi, and Ms. Fatima Al-Amri.

I sincerely acknowledge the sacrifices made by my parents, Asadullah Mondal and the late Saleha Khatun, during my early education. I also thank my relatives and friends, especially Professor Md. Mohar Ali Bepari, Dr. Md. Moazzem Hossain, and Dr. Iqbal Mujtaba, for always inspiring me. I am grateful to my wife, Sabina Akhter (Shilpi), for her patience and support during this project, and to my daughter, Rubaba Rahman (Deya), and my son, Salman Rahman (Radhin), for always keeping me up-to-date with the latest technology and making it easier to work from home. I would also like to thank my other family members, my son-in-law, Nushan Islam, my daughter-in-law, Thasnim Rahman, and my dearest granddaughter, Aiyla Rahman, for their continued support. Most of the work on this book was done at home; thus, without my family's cooperation and support, it would have been very hard for me to complete and finalize this book.

Editor

Mohammad Shafiur Rahman, Professor at the Sultan Qaboos University, Oman, and the author/co-author of more than 400 technical articles, including 149 refereed journal papers, 137 conference papers, 78 book chapters, 36 reports, 18 popular articles, and 13 books. He is the author of the internationally acclaimed and award-wining *Food Properties Handbook*, published by CRC Press, Boca Raton, Florida, which was one of the bestsellers from CRC Press in 2002. The second edition was released with his editorship. He is also one of the editors of *Handbook of Food Process Design*, published by Wiley-Blackwell, Oxford, England, in 2012. He was invited to serve as one of the associate editors for the *Handbook of Food Science, Engineering and Technology* (2006), and one of the editors for the *Handbook of Food and Bioprocess Modeling Techniques*, published by CRC Press, Florida (2008). Since 2015, he has published five more books in the areas of food science, technology, and nutrition.

Professor Rahman has initiated the *International Journal of Food Properties* (Marcel Dekker, Inc.) and has served as its founding editor for more than 20 years. In addition, he has served in the editorial boards of more than ten international journals. In 1998, he was invited and continued to serve as a Food Science Adviser to the International Foundation for Science (IFS) in Sweden. Professor Rahman is a professional member of the New Zealand Institute of Food Science and Technology (NZ), the Institute of Food Technologists (USA), and Member of Executive Committee for International Society of Food Engineering, ISFE. He was involved in many professional activities, such as organizing international conferences, training workshops, and other related activities. In 2014, he initiated and served as the Founding Chair of the International Conference on Food Properties (ICFP) series and initiated the ICFP mentoring program for young scientists and academics. He has been invited as keynote/plenary speaker to more than ten international conferences in the food science and engineering sectors. He earned B.Sc. Eng. (Chemical) (1983) and M.Sc. Eng. (Chemical) (1984) degrees from Bangladesh University of Engineering and Technology, Dhaka, Bangladesh, an M.Sc. degree (1985) in food engineering from Leeds University, England, and a Ph.D. degree (1992) in food engineering from the University of New South Wales, Sydney, Australia.

Professor Rahman is an eminent scientist and academic in the areas of food processing and preservation. He is recognized for his significant contribution to the basic and applied knowledge of food properties related to food structure, health functionality, engineering properties, and food stability. His total SCOPUS and Google Scholar citations are 3,928 (h-index: 37) and 29,436 (h-index: 70), as of 4 July 2019, which qualifies the impact of his research in the international scientific community. Professor Rahman has received numerous awards and fellowships in recognition of research/teaching achievements, including the HortResearch Chairman's Award, the Bilateral Research Activities Program (BRAP) Award, CAMS Outstanding Researcher Award 2003, SQU Distinction in Research Award 2008, SQU Recognition for Scientific and Research Excellence (year 2017–2018), and the British Council Fellowship. In 2008, Professor Rahman ranked among the top five leading scientists and engineers of the 57 OIC Member States in the AgroSciences Discipline.

Part I

Preservation of Fresh Food Products

1 Types of Foods and Food Products

Mohammad Shafiur Rahman

CONTENTS

1.1 WHAT ARE FOODS?

Foods are materials, in a raw, processed, or formulated form, that are consumed orally by humans or animals for growth, health, satisfaction, pleasure, and satisfying social needs. Generally, there is no limitation on the amount of foods that may be consumed (as there is for a drug in the form of a dosage) [1]. However, this does not mean that we can eat as much as we want, thus we need to follow dietary guidelines. There is another category, supplements, which are also consumed as dosages mainly to prevent diseases or are beneficial to treat diseases. Chemically, foods are mainly composed of water, lipids, fats, and carbohydrates with a small proportion of minerals and organic compounds. Minerals in the form of salts and organic substances are present in foods as vitamins, emulsifiers, acids, antioxidants, pigments, polyphenols, or flavors [2].

1.2 TYPES OF FOODS

Raw foods generally originate from two major sources: the plant and animal kingdoms. Some foods hold an intermediate position, such as honey being a plant product but collected and processed by bees [3]. Foods can be classified based on their sources. For example, plant sources (e.g., fruits and vegetables) and animal sources (e.g., meat, fish, and dairy) [3]. A proper classification could be used to identify the generic characteristics found in different classes of foods. Foods can also be classified based on the degree of processing (processing aspects). In many instances, foods we consume pass through different degrees of processing actions. This affects the storage stability, safety, and convenience to consume. Processing adds value to the raw foods and generates a monetary gain. Processing is also important in achieving food security by making it available, safe, and wholesome. Figure 1.1 shows different classes of foods based on the degree of processing (tomato is considered as an example). Similarly, different meat products can be prepared from fresh meats, such as frozen, canned, modified atmosphere packed, vacuum packed, fermented, cured, and smoked meats.

1.2.1 Fresh Foods

Farmers grow or produce fresh foods and look for markets for their raw fresh products. Food processors or manufacturers utilize new technologies and processing or preservation methods in order to produce value-added products from fresh foods harvested by farmers or from their by-products.

Fresh foods have a short shelf life and need to be processed prior to perceptible evidence of undesirable changes. Processing can help foods retain their original state of physical, chemical, microbial, and sensory characteristics. The goal is to preserve the sensitive nutrients of fresh foods.

Harvested foods are items separated from the medium of immediate growth (plant, soil, or water) or meat from the animal after slaughter, eggs laid from birds, or milk from the normal secretion of mammalian glands. They are considered as fresh foods and no processing steps are taken on the products.

1.2.2 Processed Foods

Processing adds value to a food product. Food preservation or processing is an action or way to maintain foods at a desired level of properties or nature for their maximum benefits. Maintaining food properties lies at the heart of food science and technology, and it is the main purpose of food processing. Generally, a process is defined as the sequence of events and equipment systems required in producing a product. In the case of processed foods, steps are taken to improve quality in terms of safety, nutrition, desired sensory characteristics, and convenience as well as shelf life.

It is commonly considered that fresh foods contain more vitamins and functional components, and thus are expected to be the best. On the other hand, processed foods may contain added chemicals and low levels of nutrients. However, other dimensions of processed foods could be their digestibility,

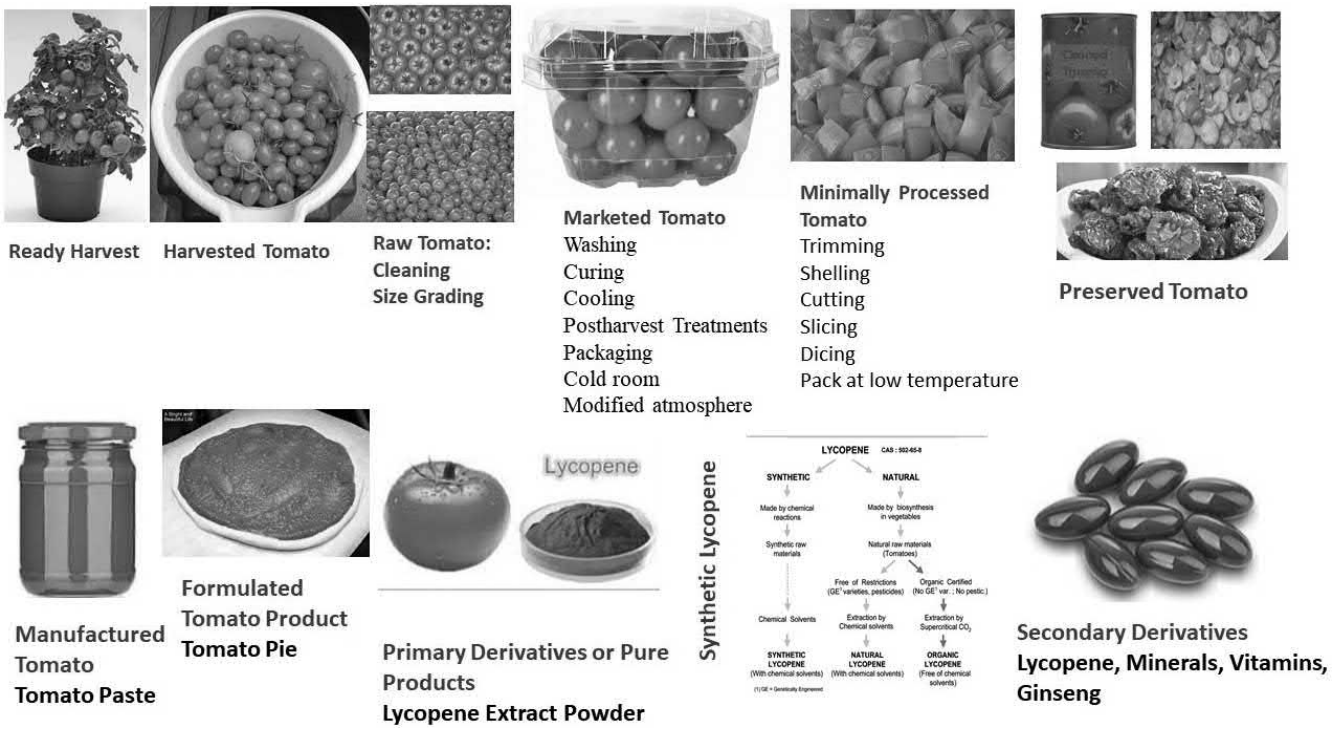

FIGURE 1.1 Different classes of food based on processing severity (tomato as an example).

nutrient bioavailability, and their function. In these cases, processing could play a role. For example, cooking at higher than 90°C or acid washing reduces pesticide residue. In addition to improved sensory perceptions and palatability, cooking improves digestibility. In the case of cassava, processing reduces cyanide (antinutrients). Cooking also releases more nutrients and bioavailability is observed. For example, in heated tomatoes and ketchup, the release of polyphenol and bioavailability of lycopene are observed.

1.2.2.1 Maintaining Original Structural Integrity

In this category, processing does not change the original structure or integrity of raw foods. The following lists foods in this category.

1.2.2.1.1 Raw Foods

Raw foods are in the earliest or primary state, after harvesting, milking, or slaughter, and have not been subjected to any treatment apart from cleaning and size grading.

1.2.2.1.2 Marketed Fresh Foods

Marketed fresh foods are harvested items retaining their complete structural integrity or state as a whole without perceptible evidence of physical, chemical, or microbiological change. The main steps in preparing marketed fresh foods are washing, curing, cooling, postharvest treatments, packaging, and storage in a cold room or modified atmosphere.

1.2.2.1.3 Minimally Processed Foods

In general, minimally processed foods have fresh-like quality and are convenient to prepare, serve, and consume (i.e., minimal steps for the consumers). In the case of minimally processed fruits and vegetables, attempts are made to keep the structural integrity without conventional food preservation techniques, such as freezing, canning, and drying (i.e., minimal processing severity). This adds to the convenience. Similar attempts are also made for meat jerky.

In the case of minimally processed fruits and vegetables, the main steps are trimming, shelling, cutting, slicing, dicing, and usually storage at low temperatures (i.e., chilled condition) to prolong quality and safety. Washing, peeling, and dicing make fruits and vegetables easy to consume.

This category has more risk than fresh or processed foods. Nowadays different product categories are appearing on the market, such as ready-to-eat meals, cook–chill and cook–freeze products, and partially cooked bread and pizza. In these products, the original structural integrity of the raw materials could not be maintained, but attempts are made to make the products appear fresh cooked or fresh baked.

1.2.2.1.4 Preserved Foods

Preserved food products are changed little during manufacturing, that is, the main preservation methods do not significantly change the individual properties of the foods. Examples include canned, frozen, and dehydrated foods.

1.2.2.2 Severity of Processing or Restructuring

In this category, processing changes the original natural structure of food at different degrees or levels. The following describes foods in this category.

1.2.2.2.1 Manufactured Foods

In manufactured food products, the raw substance usually loses its original composition by employing one or more basic methods of preservation. Examples are sausages, cured meats, jams and marmalades, and even wines.

1.2.2.2.2 Formulated Foods

Formulated food products are prepared completely based on mixing and processing of individual ingredients to make shelf-stable products, for example, cakes, biscuits, breads, and ice cream.

1.2.2.2.3 Primary Derivatives or Pure Products

Primary derivatives or pure products are obtained from the raw product through purification, for example, starch from corn or potatoes, sugar from beets, fats and oils from seeds and fish, and lycopene from tomatoes.

1.2.2.2.4 Secondary Derivatives

Secondary derivatives are derived by further steps from basic components. Examples are fat hardened by hydrogenation, cholesterol-free oil, phytochemicals and vitamins, and low molecular weight pectin by hydrolysis from the extracted pectin from fruit skins.

1.2.2.2.5 Synthetic Foods

Synthetic foods are made through microbial or chemical synthesis. Examples are vitamins, nutrients, and functional food components.

1.3 CONCLUSION

The food industry routinely develops a wide variety of food products using new technologies, new formulations, and new raw materials. It is important to understand the classes of foods for their proper production methods, safety, and legal requirements for marketing. For example, in some countries, saffron is permitted for use to color and flavor foods, but crocin extracted from saffron might not be permitted.

2 Food Preservation: An Overview

Mohammad Shafiur Rahman

CONTENTS

2.1 INTRODUCTION

Food preservation involves the action taken to maintain foods with the desired properties or nature for as long as possible. The process is now moving from an art to highly interdisciplinary science. Food preservation methods consider the use of or combination of inactivation, inhibition, and avoidance of recontamination of foods. This chapter provides an overview of food preservation methods, emphasizing the following: (i) use of chemicals and microbes; (ii) control of water, structure, and atmosphere; (iii) use of heat and energy; and (iv) enhanced preservation by indirect approaches. The final section discusses the factors that need to be considered in order to satisfy the present and future demands of consumers and law-enforcing authorities.

Throughout most of the world, innovation, sustainability, and safety have become the focus of modern industry and economy. The United Nations World Commission on Environment and Development defines sustainable development as "meeting the needs of the present generation without compromising the ability of future generations to meet their own needs." A sustainable way of designing and developing food products appeals to consumers, provides a point of differentiation from competitors, and provides a perfect platform for a range of positive public relations activities [1]. Innovation is vital to maintain progress in technology and engineering. Food safety is now the first priority of the food production and preservation industry, incorporating innovation and sustainability. The industry can compromise with some qualities, such as color, to some extent but not with safety.

The preservation and processing of food are not as simple or straightforward as it was in the past. It is now moving from an art to a highly interdisciplinary science. A number of new preservation techniques are being developed to satisfy current demands of economic preservation and consumer satisfaction in nutritional and sensory aspects, convenience, safety, absence of chemical preservatives, price, and environmental safety. Understanding the effects on food of each preservation method has therefore become critical in all aspects. This chapter provides overviews of the new technology, identifying the changing demands of food quality, convenience, and safety.

2.2 CAUSES OF DETERIORATION

Mechanical, physical, chemical, and microbial effects are the leading causes of food deterioration and spoilage. Damage can start at the initial point by mishandling of foods during harvesting, processing, and distribution; this may ultimately lead to a reduction of shelf life. Other examples of deterioration include (i) bruising of fruits and vegetables during harvesting and postharvest handling, leading to the development of rot; (ii) tuberous and leafy vegetables lose water when kept in atmospheres with low humidity and subsequently wilt; and (iii) dried foods kept in high humidity may pick up moisture and become soggy. The four sources of microbial contaminants are soil, water, air, and animals (insects, rodents, and humans) (Table 2.1). The major causes of quality loss are shown in Table 2.2. In preservation, each factor needs to be controlled or maintained at a desired level. Foods are perishable or deteriorative by nature. The storage life of fresh foods at normal atmospheric conditions is presented in Table 2.3.

During storage and distribution, foods are exposed to a wide range of environmental conditions. Environmental factors such as pressure, temperature, humidity, oxygen, and

   b. Indirectly by spreading disease

Source: Borgstrom [3].

light can trigger several reactions that may lead to food degradation. As consequences of these mechanisms, foods may be altered to such an extent that they are either rejected by or harmful to the consumer [2]. Damage is caused by the mishandling of foods during harvesting, processing, and distribution, which will lead to reduced shelf life of foods. Bruising of fruits and vegetables during harvesting and postharvest handling leads to the development of rot. Crushing of dried snack foods during distribution seriously affects their quality. Tuberous and leafy vegetables lose water when kept in atmospheres with low humidity and subsequently wilt. Dried foods kept in high humidity may pick up moisture and become soggy [2]. Condensation of moisture on foods or a damp atmosphere favors microbial growth, occasionally promotes the development of insects, and may indirectly lead to deterioration resulting in destructive self-heating [3]. Mechanical damage is conducive to spoilage. Bruises and wounds are such defects, and they frequently cause further chemical and microbial deterioration. Peels, skins, and shells constitute natural protection against this kind of spoilage [3]. In case of frozen foods, fluctuating temperatures are often destructive, for example, fluctuating temperatures cause recrystallization of ice cream, leading to an undesirable sandy texture. Freezer burn is a major quality defect in frozen foods that is caused by the exposure of frozen foods to fluctuating temperatures. These large fluctuations may cause a phase change by thawing or refreezing foods. Similarly, phase changes involving melting and solidifying of fats are detrimental to the quality of candies and other lipid-containing confectionary items. Shriveling occurs due to the loss of water from harvested fruit and vegetables.

Each microorganism has (i) an optimum temperature at which it grows best; (ii) a minimum temperature, at which growth no longer takes place; and (iii) a maximum temperature, above which all development is suppressed. Bacteria that grow particularly well at low temperatures are called *psychrophilic* (*cryophilic*) or low-temperature organisms. Bacteria with an optimum temperature of 20°C–45°C are *mesophilic*, and those with an optimum temperature above 45°C are *thermophilic* [3]. Microbial growth in foods results in food spoilage with the development of undesirable sensory characteristics, and in certain cases, the food may become unsafe for consumption. Microorganisms have the ability to multiply at high rates when favorable conditions are present. Prior to harvest, fruits and vegetables generally have good defense mechanisms against microbial attack, however, after separation from the plant, they can easily succumb to microbial proliferation. Similarly, meat upon slaughter is unable to resist rapidly growing microbes [2]. The pathogenicity of certain microorganisms is a major safety concern in the processing and handling of foods in that they produce chemicals in foods that are toxic to humans. Their growth on foods may also result in undesirable appearance and off-flavors. Microbial or chemical contaminants are also of concern in food deterioration. Chemicals from packaging materials may also be a source of food contamination.

Several chemical changes occur during the processing and storage of foods. These changes may cause food to deteriorate by reducing its sensory and nutritional quality. Many enzymatic reactions change the quality of foods. For example, cut fruits tend to be brown rapidly at room temperature due to the reaction of phenolase with cell constituents, as it is released in the presence of oxygen. Enzymes such as lipoxygenase, if not

TABLE 2.2
Major Quality Loss Mechanisms

Microbiological	Enzymatic	Chemical	Physical	Mechanical
Microorganism growth	Browning	Color loss	Collapse	Bruising due to vibration
Off-flavor	Color change	Flavor loss	Controlled release	Cracking
Toxin production	Off-flavor	Nonenzymatic browning	Crystallization	Damage due to pressure
		Nutrient loss	Flavor encapsulation	
		Oxidation reduction	Phase changes	
		Rancidity	Recrystallization	
			Shrinkage	
			Transport of component	

Sources: Gould [4, 7].

TABLE 2.3
Storage Life of Some Fresh Foods at Normal Atmospheric Conditions

Food	Terminology	Storage Life
Meat, fish, and milk	Perishable	1–2 days
Fruits and vegetables	Semiperishable	1–2 weeks
Root crops	Semiperishable	3–4 weeks
Grains, pulses, seeds, and nuts	Nonperishable	12 months

denatured during the blanching process, can influence food quality even at subfreezing temperatures. In addition to temperature, other environmental factors such as oxygen, water, and pH induce deleterious changes in foods that are catalyzed by enzymes [2].

The presence of unsaturated fatty acids in foods is a prime reason for the development of rancidity during storage as long as oxygen is available. While the development of off-flavors is markedly noticeable in rancid foods, the generation of free radicals during the autocatalytic process leads to other undesirable reactions, for example, loss of vitamins, alteration of color, and degradation of proteins. The presence of oxygen in the immediate vicinity of food leads to increased rates of oxidation. Similarly, water plays an important role; lipid oxidation occurs at high rates at very low water activities.

Some chemical reactions are induced by light, such as a loss of vitamins and browning of meats. Non-enzymatic browning is a major cause of quality change and degradation of the nutritional content of many foods. This type of browning reaction occurs due to the interaction between reducing sugars and amino acids, resulting in the loss of protein solubility, darkening of lightly colored dried products, and the development of bitter favors. Environmental factors such as temperature, water activity, and pH have an influence on non-enzymatic browning [2].

2.3 PURPOSE OF FOOD PRESERVATION

Preservation methods start with a full analysis and understanding of the whole food chain, including growing, harvesting, processing, packaging, and distribution; thus an integrated approach needs to be applied. Food preservation involves action taken to maintain foods with the desired properties or nature for as long as possible. It lies at the heart of food science and technology, and it is the main purpose of food processing. First, it is important to identify the properties or characteristics one wants to preserve. One property may be important for one product but detrimental to others. For example, collapse and pore formation occur during the drying of foods. This can be desirable or undesirable, depending on the desired quality of the dried product, for example, crust formation is desirable for long bowl life in the case of breakfast cereal ingredients, and quick rehydration is necessary (i.e., no crust and more open pores) for instant-soup ingredients. In another instance, the consumer expects apple juice to be clear, whereas orange juice can be cloudy.

2.3.1 Purpose of Food Preservation

An important question is, why to preserve a food? The main reasons for food preservations are to (i) overcome inappropriate planning in agriculture, (ii) produce value-added products, and (iii) provide variation in diet. The agricultural industry produces raw food materials in different sectors. Inadequate management or improper planning in agricultural production can be overcome by avoiding inappropriate areas, times, and amounts of raw food materials as well as by increasing storage life using simple methods of preservation. Value-added food products can give better-quality foods in terms of improved nutritional, functional, convenience, and sensory properties. Consumer demand for healthier and more convenient foods also affects the way that food is preserved. Eating should be pleasurable to the consumer and not be boring. People like to eat wide varieties of foods with different tastes and flavors. Variation in the diet is important, particularly in underdeveloped countries in order to reduce reliance on a specific type of grain (i.e., rice or wheat). In food preservation, the important points that need to be considered are

- What quality level is desired?
- How long to preserve?
- For whom to preserve?

After storage of a preserved food for a certain period, one or more of its quality attributes may reach an undesirable state. Quality is an elusive, ever-changing concept. In general, it is defined as the degree of fitness for use, or the condition indicated by the satisfaction level of consumers. When food has deteriorated to such an extent that it is considered unsuitable for consumption, it is said to have reached the end of its shelf life. In studying the shelf life of foods, it is important to measure the rate of change of a given quality attribute [2]. In all cases, safety is the first attribute, followed by quality. The product quality attributes can be quite varied, such as appearance, sensory, or microbial characteristics. Loss of quality is very dependent on the type of food and composition, formulation (for manufactured foods), packaging, and storage conditions [2]. Quality loss can be minimized at any stage of food harvesting, processing, distribution, and storage. When preservation fails, the consequences range broadly from the food becoming extremely hazardous to minor deterioration, such as color loss [4].

2.3.2 Period of Preservation

The second question is, how long to preserve? After storage for a certain period, one or more quality attributes of a food may reach an undesirable state. At that time, the food is considered unsuitable for consumption and is said to have reached the end of its shelf life. This level is defined by the manufacturer according to how long the product is saleable. The

"best before" date is set shorter than the shelf life with a good margin. Hence, it is usually safe and palatable to consume a product long after the best before date, provided the product has been stored at the recommended conditions. Products may be marketed with the production date "pack date" and/or a best before date. Alternative markings are "use by date" or "expiration date," which may be closer to shelf life than the best before date [5]. In studying the shelf life of foods, it is important to measure the rate of change of a given quality attribute [2]. The product quality can be defined using many factors, including appearance, yield, eating characteristics, and microbial characteristics, but ultimately the final use must provide a pleasurable experience for the consumer [6]. Loss of quality is very dependent on food type and composition, formulation (for manufactured foods), packaging, and storage conditions [4]. The various stages of food production, manufacture, storage, distribution, and sale are shown in Figure 2.1. Quality loss can be minimized at any stage and thus quality depends on the overall control of the processing chain. The major quality-loss mechanisms and consequences are shown in Table 2.1 and Figure 2.2. When preservation fails, the consequences range broadly from extremely hazardous to color loss [4]. The required length of preservation depends on the purpose. In many cases, very prolonged storage or shelf life is not needed, which simplifies both the transport and marketing

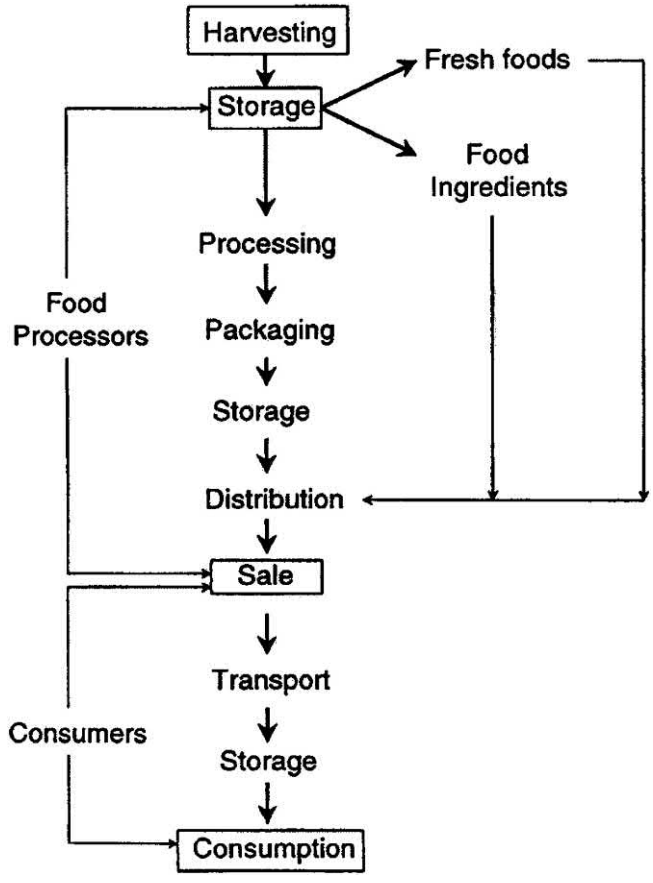

FIGURE 2.1 Various stages of food production, manufacture, storage, distribution, and sale.

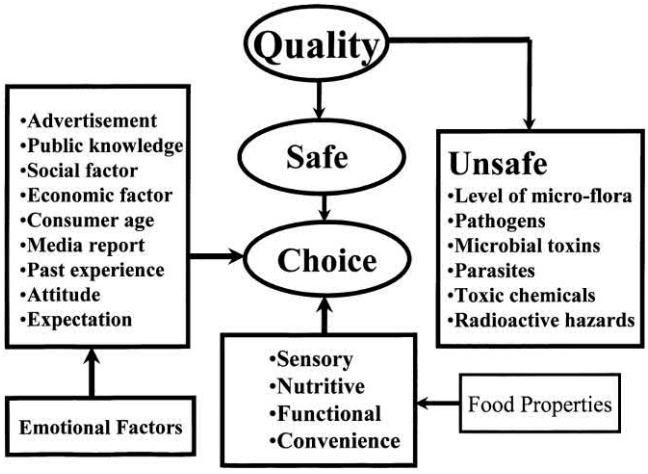

FIGURE 2.2 Factors affecting food quality, safety, and choice.

of the foodstuff. For example, prepared meals for lunch need a shelf life of only one or even half a day. In this case, there is no point in ensuring preservation of the product for weeks or months. In other cases, a very long shelf life, say, up to 3 to 5 years may be required (e.g., foods for space travelers or food storage during wars).

2.3.3 Consumers of Food Products

The third question is, for whom to preserve? It is important to know for whom the preserved food is being produced. Nutritional requirements and food restrictions apply to different population groups. Food poisoning can be fatal, especially in infants, pregnant women, the elderly, and those with depressed immune systems. The legal aspects of food preservation are different in cases of foods produced for human or animal consumption. Thus, it is necessary to consider the group for whom the products are being manufactured.

2.4 FOOD PRESERVATION METHODS

2.4.1 Gould's Classification

Based on the mode of action, the major food preservation techniques can be categorized as (i) slowing or inhibiting chemical deterioration and microbial growth; (ii) directly inactivating bacteria, yeasts, molds, or enzymes; and (iii) avoiding recontamination before and after processing [4, 7]. A number of techniques or methods from these categories are shown in Figure 2.3. Although the currently used traditional preservation procedures continue in one or more of these three ways, there have recently been great efforts to improve the quality of food products, principally in order to meet the requirements of consumers through the avoidance of extreme use of any single technique.

Preservation starts when the harvested foods are separated from the medium of immediate growth (plant, soil, or water) or meat from the animal after slaughter, or milk from the normal secretion of mammalian glands. Raw foods are those

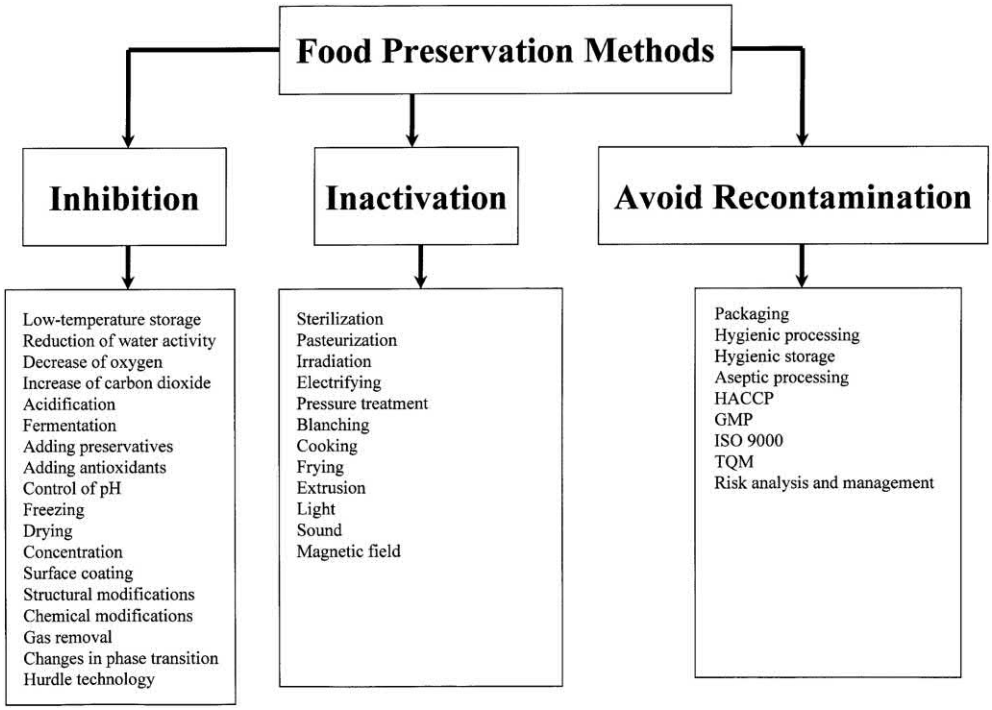

FIGURE 2.3 Major food preservation techniques [4, 7].

in the earliest or primary state after harvesting, milking or slaughter; they have not been subjected to any treatment apart from cleaning, size grading, etc., in the case of foods of plant origin. Postharvest technology is concerned with handling, preservation, and storage of harvested foods, and maintaining the original integrity, freshness, and quality. The methods of preservation depend on the origin of foods—particularly whether they are of plant or animal origin. Postharvest handling of foods of plant origin includes efficient control of environmental atmosphere (such as humidity, gas composition, and temperature), and implementing an adequate packing, storage, and transport system. Physical treatments usually used are curing, precooling, temperature treatments, cleaning, and waxing, whereas chemical treatments are disinfection, fumigation, and dipping. Meat is the edible flesh of any of a number of species of mammal or bird, both wild and domesticated. Postharvest quality is affected by slaughter conditions or stress before death.

In the case of fish, preservation methods include chilling, electrical stimulation, and decontamination methods (e.g., hot water rinsing with or without chlorination; decontamination with phosphate, hydrogen peroxide, chlorine, chlorine dioxide, and ozone; and surface treatment by organic acids). Pretreatments, such as blanching, sulfiting, and other physical and chemical pretreatments are used before applying major preservations methods. The main purpose of pretreatment is to improve product quality and process efficiency. In recent years, altering the processing strategy and/or pretreatment has gained much attention in the food industry.

The methods based on inhibition include those that rely on control of the environment (e.g., temperature control), those that result from particular methods of processing (e.g., microstructural control), and those that depend on the intrinsic properties built into particular foods (e.g., control by the adjustment of water activity or pH value [7]. The danger zone for microbial growth is considered to be between 5°C and 60°C; thus food products chilled and stored at a temperature below 5°C is one of the most popular methods of food preservation.

The steps of cleaning and sanitization are important in food preservation. Chemical disinfectants vary in their ability to kill microorganisms. Effectiveness depends on the types of microorganisms, their attachment mechanisms, and the physical characteristics of the produce. Some disinfectants are appropriate for use in direct contact washes, others only for process water, processing equipment or containers, and facilities. It is important to know disinfectants' mechanisms of action effectiveness, as well as the relevant microbial biochemistry. Several chemicals are utilized, such as chlorine, chlorine dioxide, hydrogen peroxide, ozone, peroxyacetic acid, bromine, iodine, trisodium phosphate, and quaternary ammonium compounds [8]. Although fumigants are not strictly preservatives, they are used for insect control. Methyl bromide is one of the fumigants used, but it has the potential to damage atmospheric ozone and it is being phased out. There is a need for development of new environmentally safe methods of fumigation. In reality it is very difficult to separate food preservation methods as inhibition, inactivation, and avoid recontamination, as proposed by Gould [4, 7]. For example, drying could accomplish inactivation (i.e., heat from air) as well as inhibition (i.e., low moisture). For this reason, Rahman [9] classified food preservation based on the types of applied energy and chemicals, and types of control methods.

2.4.2 Rahman's Classification

Rahman [9] classified food preservation methods into four categories: (i) preservation using chemicals and microbes; (ii) preservation by controlling water, structure, and atmosphere; (iii) preservation using heat and energy; and (iv) preservation enhanced by indirect approaches. This classification could have more rationale than classification based on mode of actions, or conventional and new methods of preservations.

2.4.2.1 Use of Chemicals and Microbes

The use of chemicals in foods is a well-known method of food preservation. Wide varieties of chemicals or additives are used in food preservation to control pH, as antimicrobes and antioxidants, and to provide food functionality as well as preservation action. Some additives are entirely synthetic (not found in nature), such as phenolic antioxidant tertiary butylhydroquinone (TBHQ), and others are extracted from natural sources, such as vitamin E. Irrespective of origin, food additives must accomplish some desired function in the food to which they are added, and they must be safe to consume under the intended conditions of use.

Many legally permitted preservatives in foods are organic acids and esters, including sulfites, nitrites, acetic acid, citric acid, lactic acid, sorbic acid, benzoic acid, sodium diacetate, sodium benzoate, methyl paraben, ethyl paraben, propyl paraben, and sodium propionate [10]. When a weak acid is dissolved in water, equilibrium is established between undissociated acid molecules and charged anions, the proportion of undissociated acid increasing with lower pH. The currently accepted theory of preservative action suggests inhibition via depression of internal pH. Undissociated acid molecules are lipophilic and pass readily through the plasma membrane by diffusion. In the cytoplasm, approximately pH 7.0, acid molecules dissociate into charged anions and protons. These cannot pass across the lipid bilayer and accumulate in cytoplasm, thus lowering pH and inhibiting metabolism [11]. There are several limitations to the value of organic acids as microbial inhibitors in foods [10]:

- They are usually ineffective when initial levels of microorganisms are high.
- Many microorganisms use organic acids as metabolizable carbon sources.
- There is inherent variability in resistance of individual strains.
- The degree of resistance may also depend on the conditions.

Nitrides and nitrates are used in many foods as preservatives and functional ingredients. These are critical components used to cure meat, and they are known to be multifunctional food additives and potent antioxidants. Many plants contain compounds that have some antimicrobial activity, collectively referred to as "green chemicals" or "biopreservatives" [12]. Interest in naturally occurring antimicrobial systems has expanded in recent years in response to consumers' requirements for fresher, more natural, and additive-free foods [7]. A range of herbs and spices are known to possess antibacterial activity because of their chemical composition. Antimicrobial agents can occur in foods of both animal and vegetable origin. Herbs and spices have been used for centuries by many cultures to improve the flavor and aroma of foods. Essential oils show antimicrobial properties, and are defined by Hargreaves as a group of odorous principles, soluble in alcohol and to a limited extent in water, consisting of a mixture of esters, aldehydes, ketones, and terpenes. They not only provide flavor to the product but also preservation activity. Scientific studies have identified the active antimicrobial agents of many herbs and spices. These include eugenol in cloves, allicin in garlic, cinnamic aldehyde and eugenol in cinnamon, allyl isothiocyanate in mustard, eugenol and thymol in sage, and isothymol and thymol in oregano [13].

Rancidity is an objectionable defect in food quality. Fats, oils, or fatty foods are deemed rancid if a significant deterioration of the sensory quality is perceived, particularly aroma or flavor, but appearance and texture may also be affected. Antioxidants are used to control oxidation in foods, and these have health functionality by reducing risk of cardiovascular diseases and cancer, and slowing the aging process. The use of wood smoke to preserve foods is nearly as old as open-air drying. Although not primarily used to reduce the moisture content of food, the heat associated with the generation of smoke also gives a drying effect. Smoking has been mainly used with meat and fish. Smoking not only imparts desirable flavor and color to some foods, but also some of the compounds formed during smoking have a preservative effect (bactericidal and antioxidant).

Hydrogen ion concentration, measured as pH, is a controlling factor in regulating many chemical, biochemical, and microbiological reactions. Foods containing pH <4.5 are low-risk foods; they need less severity in heat treatment. Microorganisms require water, nutrients, appropriate temperature, and pH levels for growth. Below about pH 4.2 most other food-poisoning microorganisms are well controlled, but microorganisms such as lactic acid bacteria and many species of yeast and molds grow at pH values well below this. Many weak lipophilic organic acids act synergistically at low pH to inhibit microbial growth. Thus, propionic, sorbic, and benzoic acids are very useful food preservatives. The efficacy of acids depends to a large extent on their ability to equilibrate, in their undissociated forms, across the microbial cell membrane and in doing so, interfere with the pH gradient that is normally maintained between the inside (cytoplasm) of the cell and the food matrix surrounding it. In addition to weak lipophilic acids, other preservatives widely used in foods include esters of benzoic acid, which are effective at higher pH values than organic acids. Inorganic acids such as sulfate and nitrite are most effective at reduced pH values, like organic acids. While these preservatives are employed at parts per million (ppm) levels of hundreds to thousands, the acids used principally as acidulants are often employed at percentage levels. The following describes the three regimes of pH actions [14]:

- Strong acids do not themselves penetrate the cell membrane. These acids may exert their influence by the denaturing effect of low pH on enzymes present on the cell surface and by lowering of the cytoplasmic pH due to increased proton permeability when the pH gradient is very large.
- Weak acids, which are lipophilic and penetrate the membrane. The primary effect of such acids is to lower cytoplasmic pH and undissociated acid may have specific effects on metabolism that amplify the effects of the weak acid.
- Acid-potentiated ions, such as carbonate, sulfate, and nitrate, which are inhibitors at lower pH.

The pH affects not only microorganism growth; it also affects other components and processes, such as enzyme stability, gel formation, stability of proteins, and vitamins. Antimicrobial enzymes also have current applications and further future potential in the food industry. They play a significant role in the defense mechanisms of living organisms against infection by bacteria and fungi. Many lytic enzymes now used in the food industry to degrade unwanted polysaccharides have potential for use as novel and natural food preservatives. One such enzyme, lysozyme from hen egg whites, has been known for many years and is used against *Clostrial* spoilage in hard-cooked cheese in France [15]. When an enzyme is used, it is very important to maintain its activity for its effect on preservation. Hydrolytic antimicrobial enzymes function by degrading key structural components of the cell walls of bacteria and/or fungi, whereas antimicrobial oxidoreductases exert their effects by the generation *in situ* of reactive molecules. Fuglsang et al. [16] pointed that the potential of these enzymes in food preservation is still far from realized at present.

Antibiotics could be medical and nonmedical. Nonmedical antibiotics (such as natamycin and nisin), either produced by microbes or synthetically, inhibit microbes at very low concentrations. Organisms present in food can become resistant to antibiotics and colonize the gut of animals and man. Antibiotics used therapeutically may then become ineffective. In addition, antibiotics are used in growth enhancement and disease control in healthy animals. However, the increasing incidence of antibiotic-resistance is raising great concern and it is becoming a complicated issue.

When a chemical is used in preservation, the main question is how safe it is. There should be a risk–benefit analysis. Antimicrobial agents or preservatives are diverse in nature, but legal, toxicological, marketing, and consumer considerations have created a trend such that both the number and amount of preservatives in use are diminishing rather than increasing [16].

2.4.2.2 Control of Water, Structure, and Atmosphere

Many physical modifications are made in ingredients or foods during preservation. Such modifications can also improve the sensory, nutritional, and functional properties of foods. Changes experienced by foods during processing include glass formation, crystallization, caking, cracking, stickiness, oxidation, gelatinization, pore formation, and collapse. Through precise knowledge and understanding of such modifications, one can develop safe, high-quality foods for consumption.

Water is an important constituent of all foods. Scott in 1953 clearly identified the activity of water as a medium that is clearly correlated with the deterioration of food stability due to the growth of microorganisms and it is more important than the total amount of water as stability is concerned. This concept helps us to develop generalized rules or limits for the stability of foods using water activity. This was the main reason why food scientists started to emphasize water activity rather than water content. Since then the scientific community has explored the great significance of water activity in determining the physical characteristics, processes, shelf life, and sensory properties of foods. The minimum water activity is the limit below which a microorganism or group of microorganisms can no longer reproduce. For most foods, this is between the 0.6 and 0.7 values of the water activity range. Pathogenic bacteria cannot grow below a water activity of 0.85 to 0.86, whereas yeast and molds are more tolerant of a reduced water activity of 0.80, but usually no growth occurs below a water activity of about 0.62. The critical limits of water activity may also be shifted to higher or lower levels by other factors, such as pH, salt, antimicrobial agents, heat treatment, and temperature to some extent. Removing water, adding solutes, or a change in solute–water interactions can reduce the water activity of a food.

Drying is one of the oldest methods of food preservation, in which water activity is reduced by separating out water. Drying in earlier times was done in the sun, but today many drying methods and many types of sophisticated equipment and methods are used to dehydrate foods. Drying is a method of water removal to form final products as solids, whereas concentration means the removal of water while retaining the liquid condition. The loss of flavor, aroma, or functional compounds is the main problem with drying, in terms of quality. The cost of processing, packaging, transportation, and storage are less for dried products than canned and frozen foods. The concentration of liquid foods is mainly carried out by thermal evaporation, freeze concentration, and membrane separation. Each method has its advantages and disadvantages.

Freezing changes the physical state of a substance by changing water into ice when energy is removed in the form of cooling below freezing temperature. Usually, the temperature is further reduced to storage level at –18°C. Microbial growth is completely stopped below –18°C, and both enzymatic and nonenzymatic changes continue at much slower rates during frozen storage. There is a slow progressive change in organoleptic quality during storage. Freezing is more popular than drying due to its ability to retain relatively fresh-like qualities in the food.

Foods can be considered very stable in the glassy state since below glass temperature, compounds involved in deterioration reactions take many months or even years to diffuse

over molecular distances and approach each other to react. The hypothesis has recently been stated that this transition greatly influences food stability, as the water in the concentrated phase becomes kinetically immobilized and therefore does not support or participate in reactions. The formation of a glassy state results in a significant arrest of translational molecular motion, and chemical reactions become very slow. Many attempts are being made to relate the glass concept to physicochemical changes in foods.

Edible coatings serve many purposes in food systems. Coatings are used to improve appearance or texture and reduce water loss. Examples include the waxing of apples and oranges to add gloss, edible natural polymeric coating of frozen fish to add gloss and reduce shrinkage due to water loss, or coating of candies to reduce stickiness. Other surface treatments for foods include the application of antioxidants, acidulants (or other pH-control agents), fungicides, preservatives, and mineral salts. The formulation of edible coatings depends on the purpose and type of products. Encapsulation has been used by the food industry for more than 60 years. In a broad sense, encapsulation technology in food processing includes the coating of minute particles of ingredients (e.g., acidulants, fats, and flavors) as well as whole ingredients (e.g., raisins, nuts, and confectionery products), which may be accomplished by microencapsulation and macrocoating techniques.

Gums and gels, such as casein, guar gum, agar, carrageenan, and pectin, are also used in food products to provide the desired structure and functionality to the products. These are extremely important for the textural attributes, such as creaminess and oiliness of formulated products, and oral perception of fat-mimicking foods.

Packaging techniques based on altered gas compositions have a long history. The respiratory activity of the various plant products generates a low-oxygen and high-carbon dioxide atmosphere, which retarded the ripening of fruit. Modified atmosphere packaging is a preservation technique that may further minimize the physiological and microbial decay of perishable produce by keeping them in an atmosphere that is different from the normal composition of air. The gas composition and method of this technique depends on the type of produce and purpose. There are different ways of maintaining a modified atmosphere. In modified atmosphere packaging (termed "passive atmosphere") the gas composition within the package is not monitored or adjusted. In "controlled atmosphere packaging" the altered gas composition inside the packaging is monitored and maintained at a preset level by means of scrubbers and the inlet of gases. Active packaging can provide a solution by adding materials that absorb or release a specific compound in the gas phase. Compounds that can be absorbed are carbon dioxide, oxygen, water vapor, ethylene, or volatiles that influence taste and aroma. Vacuum and modified-humidity packaging contain a changed atmosphere around the product. Although this technique was initially developed to extend the shelf life of fresh products, it is now extended to minimally processed foods from plant and animal sources.

2.4.3 Use of Heat and Energy

2.4.3.1 Heat

Earlier, mostly heat was used for inactivation. Thermal inactivation is still the most widely used process for food preservation. The advantages of using heat for food preservation are (i) heat is safe and chemical-free; (ii) heat provides tender-cooked flavors and taste; (iii) most spoilage microorganisms are heat-labile; and (iv) thermally processed foods, when packed in sterile containers, have a very long shelf life. The main disadvantages of using heat are overcooking, which may lead to textural disintegration and an undesirable cooked flavor, and nutritional deterioration results from high-temperature processing. Heat treatment processes include mainly pasteurization, sterilization, cooking, extrusion, and frying. Currently more electrotechnologies are being used and this will expand in the future.

Considering the severity of the heat treatment process, mild processing technologies, such as high-pressure processing, ultrasounds, pulsed electric fields, ultraviolet (UV) light, high-intensity pulsed light, magnetic field, and atmospheric cold plasma can serve as useful alternatives to commercial sterilization and pasteurization, and can be used to destroy foodborne pathogens while retaining nutritional and sensorial properties. Each mild technology has a specific mode of microbial inactivation and their knowledge is of foremost importance in applying and designing quality and safe foods [17].

2.4.3.2 High Pressure and Ultrasound

High-quality fresh foods are very popular; consequently, there is demand for less extreme treatments and/or fewer additives. High-pressure hydrostatic technology gained attention for its novelty and nonthermal preservation effect. Studies examining the effects of high pressure on food date back to the end of the 19th century, but renewed research and commercialization efforts worldwide could soon bring high-pressure-treated foods back to several markets. The basis of high hydrostatic pressure is the Le Chatelier principle, according to which any reaction, conformational change, or phase transition that is accompanied by a decrease in volume will be favored at high pressures, while reactions involving an increase in volume will be inhibited. Predictions of the effects of high-pressure treatments on foods are difficult to generalize due to the complexity of foods and the different changes and reactions that can occur. However, a tremendous amount of information is being developed on microorganisms, chemical, biochemical and enzymatic reactions, development of functional and sensory properties, gel formation, gelatinization, and the freezing process.

Ultrasound is sound energy with a frequency range that covers the region from the upper limit of human hearing, which is generally considered to be 20 kHz. The two applications of ultrasound in foods are (i) characterizing a food material or process, such as estimation of chemical composition, measurements of physical properties, nondestructive testing of quality attributes, and monitoring food processing; and (ii)

direct use in food preservation or processing. The beneficial or deteriorative use of ultrasound depends on its chemical, mechanical, or physical effects on the process or products.

2.4.3.3 Electricity

Many different forms of electrical energy are used in food preservation, e.g., ohmic heating, microwave heating, low electric field stimulation, high-voltage arc discharge, and high-intensity pulsed electric field. *Ohmic heating* is one of the earliest forms of electricity applied to food pasteurization. This method relies on the heat generated in food products as a result of electrical resistance when an electric current is passed through them. In conventional heating methods, heat travels from a heated surface to the product interior by means of both convection and conduction, which is time-consuming, especially with longer convection or conduction paths. Electroresistive or ohmic heating is volumetric by nature, and thus has potential to reduce overprocessing. It provides rapid and even or uniform heating, providing less thermal damage and increased energy efficiency. *Microwave heating* has been extensively applied in everyday households and the food industry, but the low penetration depth of microwaves into solid food causes thermal nonuniformity. *Low electric field* stimulation has been explored as a method of bacterial control of meat. The mechanism of microbial inactivation by electric field was first proposed by Pareilleux and Sicard [18]. The plasma membranes of cells become permeable to small molecules after being exposed to an electric field; permeation then causes swelling and the eventual rupture of the cell membrane. The reversible or irreversible rupture (or electroporation) of a cell wall membrane depends on factors such as intensity of the electric field, number of pulses, and duration of pulses. This new electroheating could be used to develop new products with diversified functionality.

2.4.3.4 Irradiation

Ionization radiation interacts with an irradiated material by transferring energy to electrons and ionizing molecules by creating positive and negative ions. The irradiation process involves exposing the foods, either prepackaged or in bulk, to a predetermined level of ionization radiation. The radiation effects on biological materials are direct and indirect. In direct action, the chemical events occur as a result of energy deposition by the radiation in the target molecule, and the indirect effects occur as a consequence of reactive diffusible free radicals formed from the radiolysis of water, such as the hydroxyl radical (OH^-), a hydrated electron (e_{aq}^-), a hydrogen atom, hydrogen peroxide, and hydrogen. Hydrogen peroxide is a strong oxidizing agent and a poison to biological systems, whereas the hydroxyl radical is a strong oxidizing agent and the hydrogen radical is a strong reducing agent. Irradiation has wide scope in food disinfection, shelf-life extension, decontamination, and product quality improvement. Although it has high potential, there are concerns about legal aspects and safety issues, and consumer attitudes toward this technology.

UV radiation has long been known to be the major factor in the antibacterial action of sunlight. It is mainly used in sterilizing air and thin liquid films due to its low penetration depth. When used at high dosage there is a marked tendency toward flavor and odor deterioration before satisfactory sterilization is achieved. UV irradiation is safe, environmentally friendly, and more cost-effective to install and operate than conventional chlorination. Visible light and photoreactivation are also used in food processing. If microorganisms are treated with dyes, they may become sensitive to damage by visible light. This effect is known as photoreactivation. Some food ingredients could induce the same reaction. Such dyes are said to possess photodynamic action. White and UV light are also used to inactivate bacteria, fungi, spores, viruses, protozoa, and cysts. Pulsed light is a sterilization method in applications where light can access all the important volumes and surfaces. Examples include packaging materials, surfaces, transmissive materials (such as air, water, and many solutions), and many pharmaceuticals or medical products. The white light pulse is generated by electrically ionizing a xenon-gas-filled lamp for a few hundred millionths of a second with a high-power, high-voltage pulse.

In many cases, it would be very difficult to make a clear distinction between inhibition and inactivation. Take, for example, preservation by drying and freezing. Although the main purpose of freezing and drying is to control the growth of microorganisms, there is also some destruction of microorganisms. Freezing causes the apparent death of 10% to 60% of the viable microbial population and this gradually increases during storage.

2.4.3.5 Magnetic Field

Magnetism is a phenomenon by which materials exert an attractive or repulsive force on other materials. The origin of magnetism lies in the orbital and spin motions of electrons, and electron interactions with each other. Magnetic fields have potential in pasteurization, sterilization, and enhancing other factors beneficial to processing in food preservation.

2.4.4 Food Preservation Enhanced by Indirect Approaches

In addition to the direct approach, other measures such as packaging and quality management tools need to be implemented in the preservation process to avoid contamination or recontamination. Although these measures are not preservation techniques, they play an important role in producing high-quality, safe food. With respect to the procedures that restrict the access of microorganisms to foods, the employment of aseptic packaging techniques for thermally processed foods has expanded greatly in recent years both in the numbers of applications and in the numbers of alternative techniques that are commonly available [7].

From skins, leaves, and bark, tremendous progress has been made in the development of diversified packaging materials and in the packaging equipment. Packaging performs three main functions. The first is to control the local environmental conditions to enhance storage life. The second is the display, i.e., preservation of the product in an attractive

manner to the potential buyer. The third function is to protect the product during transit to the consumer. The new concept of active or life packaging materials allows (i) one-way transfer of gases away from the product or the absorption of gases detrimental to the product; (ii) antimicrobial in packaging; (iii) release of preservatives from controlled-release surfaces; (iv) oxygen scavengers; (v) carbon dioxide generators; (vi) absorbers or scavengers of odors; and (vii) absorption of selected wavelengths of light. These systems have capabilities for controlled automatic switching. Another concept of edible or biodegradable packaging has also been evolved for environmental reasons. Processing and packaging can be integrated to improve efficiency.

Food safety has been of concern since the Middle Ages, and regulatory measures have been enforced to prevent the sale of adulterated or contaminated food. Food safety is now the highest priority. Recently the concepts of hazard analysis and critical control point (HACCP), ISO 9000, good manufacturing practices (GMP), standard operating procedures (SOP), hazard and operability studies (HAZOP), and total quality management (TQM) have gained attention. HACCP is a state-of-the-art prevention approach to safe food production based on prevention and documentation and is thus cost-effective. It is a proactive approach based on science. Most of the food industry around the globe is now targeting the implementation of HACCP programs for their processes to ensure safety. HACCP is a scientific, rational, and systematic approach to identification, assessment, and control of hazards during production, processing, manufacturing, preparation, and use of food to ensure that it is safe when consumed. This concept is based on the application of prevention and documentation. The HACCP system provides a preventive and thus a cost-effective approach to food safety. It is important to understand the concept of safety and quality first before planning to implement HACCP in the branch of the food industry or the products being targeted. The concepts of HACCP were initiated in the 1950s by the National Aeronautics and Space Administration (NASA) and Natick Laboratories for use in aerospace manufacturing. This rational approach to process control for food products was jointly developed by the Pillsbury Company, NASA, and US Army Natick Laboratories in 1971 in order to apply a zero-defects program to the food process industry [19]. The World Health Organization (WHO) has recognized the importance of the HACCP system for the prevention of food-borne diseases for over 20 years and has played an important role in its development and promotion. One of the highlights in the history of the HACCP system was in 1993 when the Codex guidelines for the application of the HACCP system were adopted by the FAO/WHO Codex Alimentarius Commission, requiring them for international trade.

ISO 9000 is the generic standard that specifies minimum requirements to be fulfilled by organizations in order to meet a customer's needs. It does not specifically address the issue of food safety, but it addresses the need to identify and comply with regulatory requirements that are applicable to the product and/or process. ISO 9000 and HACCP techniques are complementary. HACCP techniques should therefore be used as a tool to support the quality management system ISO 9000.

In order to meet the requirements of GMP, regulatory bodies provided well-defined guidelines for food-processing operations. GMP could be considered as the building blocks and cornerstones of HACCP. TQM is a management philosophy that seeks continuous improvement in the quality of performance of all processes, products, and services of an organization. HAZOP is a systematic structured approach to questioning the sequential stages of a proposed operation in order to optimize the efficiency and the management of risk. The Food Regulatory Authorities around the world are now very active in implementing these tools in the food industry. A quality management system does not guarantee food safety unless the hazards are identified and controlled.

Recently, the concept of *hurdle technology*, or combined methods of preservation, has gained attention. The microbial stability and safety of most traditional and novel foods is based on a combination of several preservative factors (called hurdles), which microorganisms present in the food are unable to overcome. This is illustrated by the so-called hurdle effect, first introduced by Leistner and his coworkers. He acknowledged that the hurdle concept only illustrates the well-known fact that complex interactions of temperature, water activity, pH, and redox potential are significant for the microbial stability of foods. With respect to procedures that slow or prevent the growth of microorganisms in foods, major successes have been seen and new applications are steadily being made in the use of combination preservation techniques or hurdle technology. This has been supported by a greatly improved understanding of the principles underlying the stability and safety of an enormous number of combination-preserved foods that are traditional and indigenous to different parts of the world. Modified atmosphere packaging has grown rapidly, particularly for the extension of the high-quality shelf life of certain chill-stored foods.

Applications of modern biotechnology with genetic modification will play a more important role in the future for more value-added products, and ease and make efficient the methods of preservation. Biotechnology is a general term for several techniques that use living organisms to make or modify products for a specific purpose. The techniques of biotechnology offer opportunities to address consumer issues of food quality and environmental safety. Biotechnology can be used to make fruit more flavorful; improve nutritional and functional quality of fruits, vegetables, grains, and muscle foods; grow foods in a wider climate zone; and grow foods in a more environmentally benign fashion [20]. The biggest application of biotechnology will be rapid and sensitive diagnostic kits for the detection of pathogens and unwanted xenobiotic compounds in foods. Another application of biotechnology will be on-package sensors that could indicate when a food is spoiled or when a pathogen or its toxic by-product is present at some level of concern [21].

The major driving forces in development and modification of food processing are the desire to reduce the extent of

processing, i.e., the demand for *lightly processed* or *fresh-like* organic and natural foods; the desire to maximize automation, control, and efficiency; the desire to minimize cost; and the need to respond to ever-more strict regulations concerning the environmental impact of various processes [22]. Nonthermal preservation technology is being used to maintain nutrition and quality. There is a tendency to reduce the intake of animal products and to consume more cereal and cereal-based products, fruits, and vegetables. Other technologies being developed to meet the consumer desire for minimally processed foods is the shift from heat treatment for pasteurization and cooking to the use of electromagnetic waves, such as electron-beam and gamma radiation and microwave radiation. Microwave applications are easily accepted by the consumer but are used in few processing applications by the food industry. One of the major problems of this technology is that to permit appropriate textures for the products, the intensity must be high enough to kill all pathogens despite their rapid time–temperature history [21]. Other potential electromagnetic processing techniques that can be used to minimize adverse heat changes due to cooking include pulsed light at high intensity, pulsed magnetic fields, direct current in a particulate stream (ohmic heating), pulsed electric discharge, and radio frequencies such as infrared. Food processing is very energy-intensive, and reducing energy use by using efficient electrotechnology can increase profit as well as reduce environmental impact. In many cases, fast or rapid heating by electrotechnology may not provide enough time to develop desired textures and flavors.

Food habits have been a very important component of human society since its inception. Changing trends and lifestyles demand specific attributes. These include convenience in preparation and consumption, changing taste preferences, attitudes and perceptions about diet and health, more nutritional and functional advances in technology that influence food quality and availability, economic factors, ethnic and geographic regional factors, age, and suitability and convenience for lifestyle [20]. Eating away from home no longer means just sitting down in a restaurant. It can be done while sitting in a car, a train, a park bench, or at an office desk. New types of fast foods are emerging to meet the demand, and safety and innovation are needed. Taste, nutrition, and convenience are the driving forces in today's market. There is also great emphasis on simple meal preparation at home, especially with microwave cooking.

Antinutritional factors in many raw materials need to be considered, and adequate pretreatments should be used before major preservation steps. It is important to reduce pesticide residues in the final products and these must be used as little as possible. There is increasing utilization of integrated pest management (IPM) as a part of growing and processing. Usually, pesticide residues decrease, often dramatically, during processing and preparation. The process of washing and peeling fruits and vegetables generally results in a significant decline of pesticides detected in the food. This is especially true for pesticide residues that are found only on the surface of the commodity [23]. The amount of residue depends largely on the pesticide, the commodity, and the process used. Exceptions may also occur when processing caused degradation of the chemical, creating a chemical that is more toxic than the parent chemical. A stewardship program is used for control of pesticide residues. There is great consumer concern regarding potentially harmful chemicals in the food supply, such as hydrocarbons, dioxin, and heavy metals.

The factors that should be considered before selecting a preservation process are (i) desired quality of the products, (ii) economics of the process, and (iii) environmental impact of the methods. Food industry waste is now also of concern to law enforcement authorities and consumers. Food waste is not only an economic loss but also has an impact on the environment. It is important to make every effort to minimize waste, to set up effective recycling systems, and to implement suitable systems for value-added products. The ultimate success of the food industry lies in the timely adoption and efficient implementation of emerging new technologies to satisfy the present and future demands of the consumer.

2.5 CONCLUSION

Continuous innovation and progress are being made in the development of preservation methods using new technologies and their combinations. Commercial successes of these new technologies are limited due to their cost, complexity, and established evidence of safety. The applications of smart food preservation methods need to be implemented to achieve food security, safety, and sustainability. In addition, consumers are now very concerned about the use of chemicals, sustainability, and environmental safety. Future food preservation methods need to address all issues rather than only considering the technological progress.

3 Methods of Peeling Fruits and Vegetables

Xuan Li

CONTENTS

3.1 INTRODUCTION

Peeling is a common unit process for many fruits and vegetables to produce fresh-cut, minimally processed, and canned food products. The peeling process intends to remove the inedible or undesirable layer of rind or skin from raw produce. Through the peeling process, peeled products are prepared to meet high quality and safety requirements for human consumption or for other forms of subsequent processing, such as dicing, cutting, and canning. In food production lines, the peeling operation represents an important preparatory step, and it is typically performed at the initial stage [1]. After peeling, the appearance, texture, flavor, or nutrient values of the peeled product may be altered from raw materials. Hence, the peeling process can significantly contribute to changes in the storability, palatability, digestibility, and bioavailability of final food products [2].

Historically, manual peeling was the most widely adopted approach for thin skin removal and nowadays is still in practice for certain high-value fruits, such as mangoes [3]. The simplistic goal of manual peeling is to remove peels with as little loss as possible of the usable food materials [4]. Industrial peeling methods that are adaptable to large-scale process operations were successfully developed around the 1940s to 1950s to reduce labor, time, and waste involved in the peeling process [1]. Hot lye peeling and steam peeling are two widely adopted methods suitable for peeling a broad variety of fruits and vegetables, such as potatoes, tomatoes, citrus, sweet potatoes, carrots, pumpkins, pears, peaches, and apples [3]. In recent years, the reduction of energy and water consumption involved in the peeling process has become an important consideration due to the dwindling water supply and ever-tightening environment regulations [1, 4]. Producing high quality peeled products in a cost-effective manner using less water and energy drives the sustainable development of novel peeling technologies.

3.2 PEELING METHODS: CONVENTIONAL

As a unit operation, peeling can be realized by means of mechanical, chemical, or thermal treatments as well as any of their combinations. Common industrial peeling methods and emerging peeling techniques are described in the following sections.

3.2.1 Mechanical Peeling

Mechanical peeling utilizes knives, blades, or abrasive devices to remove the undesirable part directly from raw food materials [5, 6]. Thereafter, skin residuals are washed away using water. Since it is mostly performed in dry form at ambient temperature, mechanical peeling causes the least injury to the freshness and nutritional values of peeled products [3]. As compared to other chemical- and thermal-based methods, mechanical peeling operates using less energy and with lower capital costs, and has the minimum negative environmental impact. But relatively low throughput and high peeling losses (23–30%) limit its application to some high-value fruits and a few root vegetables that are difficult to peel using other means. Common mechanically peeled products include citrus

fruits, pears, pineapples, bulb onions, carrots, squashes, cassavas, and other tubers [7, 8].

Mechanical peeling can be classified as abrasive peeling and non-abrasive knife peeling [9]. In abrasive peeling, food materials, such as carrots and potatoes, are treated in a batch or continuous process equipped with abrasive elements, such as stiff brushes, carborundum rollers, and revolving bowls or drums with abrasive surfaces along the inner wall [10]. The abrasive element removes the outer skins through the shear stress developed at the peel–flesh interface. In the non-abrasive peeling, stationary knives or razor-like blades are used to remove tough-skinned product by pressing the cutting tool against the surface of the rotating materials [3, 4]. Abrasive peeling and non-abrasive knife peeling can be integrated into one single process, which is usually used for tough-skinned vegetables like parsnips, swedes, and turnips. Such a design allows products to be treated in sequence by the abrasive devices and knife tools with adjustable rotating speed and controlled depth of knife penetration, yielding a finished product with a much cleaner cutting surface. Cutting tools and abrasive elements can be custom-designed to match the geometrical characteristics of the food products and the mechanical properties of the skin to be peeled. Variability in product shapes and sizes, the difference in skin thickness, texture, and strength of skin adhesion to the flesh are the key considerations in the design of mechanical peeling devices.

3.2.2 Lye Peeling

Lye peeling, also known as caustic peeling, is a chemical method used for peel removal of thin-skinned products, where raw food materials are exposed to a heated solution containing caustic chemicals (most commonly, sodium hydroxide or potassium hydroxide) that can dissolve the skin. After treatment with lye, the loosened skins can be removed either by high-pressure water sprays or through abrasive peel eliminators, usually a perforated rotary drum or a mechanical pinch roller [2].

Lye peeling can be further divided into two categories: wet lye peeling and dry lye (dry-caustic) peeling. The wet lye peeling is carried out by immersing products into a concentrated lye solution of 8–25% at an elevated temperature from 60 to 100°C for a short residence time (15–30 s) [3]. Fundamentally, the presence of hydroxyl (OH^-) group in lye solution cleaves the α (1–4) bonds of individual galacturonic acid units in polysaccharides of skins [11]. As it moves further into the product's inner tissues through the diffusion mechanism, the lye solution dissolves the pectic and hemicellulosic materials and weakens the network of cellulose microfibrils, thus loosening the skin [12, 13]. In some cases, different chemical additives, such as surfactants or wetting agents, are added to the lye bath to improve peeling efficiency or to reduce lye concentration while maintaining the peeling effectiveness [1, 14].

Dry-caustic peeling is a modification of the wet lye peeling method. Instead of soaking products in a hot lye bath, a lye solution is sprayed onto product surfaces under a high-temperature environment, where thermal energy is utilized to accelerate lye peeling activities [15, 16]. The dry-caustic peeling combines the effects of chemical reaction and thermal shock to soften the skin so as to reduce the use of water and chemicals during the peeling process [17, 18]. As a result, it has fewer waste disposal concerns in comparison with the conventional wet lye peeling method.

Wet lye peeling is by far the most popular technique used in commercial peeling processes, and it has been applied for a wide variety of fruits and vegetables, like tomatoes, sweet potatoes, potatoes, peaches, guava, pears, and apricots. Its great suitability for various products, the ease of process control and automation, high peeling quality, and efficiency are practical advantages for industrial-scale operation [9]. Product immersion time in the lye solution, temperature of the hot lye bath, and lye concentrations are the three major controllable factors that affect the total usage of chemicals and final peeling quality [19, 20]. Lye diffusion coupled with heat penetration may cause cellular injury and discoloration in tissues adjacent to the skin, resulting in a "heating ring" appearance, which can become quite pronounced for certain products such as potatoes, sweet potatoes, and peaches, and considerably harm the sensory quality. Effluents from lye peeling containing organic loads (BOD and COD) with high pH values (11–13) cannot be directly released to the environment without appropriate neutralization treatments [3]. The waste disposal problem and serious salinity contamination inherent to the traditional wet lye peeling process become the major issues for food processors [21].

3.2.3 Steam Peeling

The steam peeling technique involves placing raw fruits or vegetables inside a pressure vessel, and exposing them to high temperatures and pressurized steam for rapid heating in a short period (15–30 s). As the pressure is released, thermodynamic changes at the product surface cause peel detachment [12, 22]. The loosened skins are subsequently removed by pressurized water spray or mechanical pinch rollers [12]. As a chemical-free method, steam peeling has been increasingly adopted by the food industry as a replacement for the lye peeling of potatoes, tomatoes, pimiento peppers, sweet potatoes, and other vegetables [12, 23–25]. The main advantages of steam are the reduction of chemical contamination and the reduced salinity issue in wastewater treatment as compared to lye peeling. Inferior appearance, decreased firmness, and high mass losses are the major drawbacks of the commercialized steam peeling technique. Modifications of the conventional steam method, such as high-pressure steam peeling with flash cooling, lye–steam peeling, and freeze–heat peeling, were investigated in the past number of decades, targeting the minimization of peeling loss and improvement in the quality of peeled products [1, 3].

3.2.4 Flame Peeling

In this thermal-based peeling method, a flame is used to scorch the outer layer of products at extremely high temperatures

(>1000°C) in a controlled short time frame (1–3 s) [3]. Products are passed through a furnace tunnel equipped with gas burners that are designed to provide adjustable and adequate thermal intensity in a uniform manner. Flame peeling is applied mainly to fruit and vegetable materials that contain extremely high moisture content, such as peppers, garlic, and onions [6, 26, 27]. Sufficient heat capacity of materials with high moisture content allows relatively easy burn-off of the outer skin of the material without overheating the product's internal flesh [10]. The main advantages of flame peeling are (1) it can reduce the microbial populations, thus increasing the shelf stability, and (2) it can preserve the ascorbic acid content. Since flame peeling involves the relatively complicated construction, installation, and maintenance of equipment, the high capital outlay precludes its adoption by small-scale food processors [27].

3.3 EMERGING PEELING TECHNIQUES

Over the years, novel and sustainable peeling techniques have been increasingly studied and developed to reduce the usages of chemicals, energy, and water in the conventional peeling methods. Recently reported alternative peeling techniques include infrared dry-peeling, enzymatic peeling, ohmic peeling, and ultrasonic peeling.

3.3.1 Infrared Peeling

Infrared peeling has been developed as a sustainable and promising peeling technique that can eliminate the use of any chemicals and any heating media like hot water or pressurized steam to promote skin separation [2, 28]. Rapid heating of the product surface at a low heat penetration depth (<1 mm) is achieved by utilizing non-ionizing radiation from far- and mid-infrared wavelengths. As a result, only a shallow layer of product surface is subjected to the intense infrared radiation, which causes the skin to loosen enough to be washed away easily. Because of the rapid surface heating characteristics of infrared, the edible inner part of the product stays at a low temperature (<30°C) during infrared peeling, thus maintaining minimal changes in the quality and nutritional values of the peeled product [29, 30]. Since no water is used during infrared heating, this process is referred to as the infrared dry-peeling method [28]. When compared to lye peeling outcomes, infrared dry-peeling produces similar peelability, less weight loss, and comparable product firmness and appearance [31].

Bench-scale and pilot-scale infrared dry-peeling systems were designed, built, and tested for tomatoes, pears, and peaches [21, 32]. Evaluations of a gas-based flameless catalytic infrared peeler and an electricity-based infrared peeler were conducted in pilot-plants and multiple commercial tomato processing facilities over several growing seasons (2010–2018) [9]. The infrared dry-peeler consisted of three major sections: an infrared heating section, a vacuum section, and a pinch roller section [9]. Infrared-peeled tomatoes showed thinner peel-off skin, better product integrity, and firmer texture than steam-peeled tomatoes [9]. Because it is a chemical-free process, tomato skins received from infrared dry-peeling can be reutilized as a byproduct [9, 30]. Further, there is a lower cost in wastewater treatment. Given these competitive advantages, this alternative technique to lye/steam peeling could herald a step-change for the food peeling process. Enhancement of the overall heating rate and uniformity for products varying in shapes and sizes while achieving an industrially acceptable throughput need to be addressed before this novel technique becomes a commercial reality [14, 29, 33, 34].

3.3.2 Enzymatic Peeling

Enzymatic peeling is a biological peeling method. Polysaccharide hydrolytic enzymes such as pectinases, hemicellulases, and cellulases can be used to infuse into the surface of fruits and vegetables, resulting in a weakened adherence of peel to flesh because of the degradation of the pectin matrix and the breakdown of the hemicellulose–cellulose network in fruit epidermal and hypodermal layers [3, 35]. Polygalacturonase (PG) and pectin methylesterase (PME) are commonly used enzymes to hydrolyze the pectin materials in plant cell walls and middle lamella. For different fruits to be peeled, process parameters such as temperature, pH values, enzyme type, and concentrations are the key optimizable variables to achieve successful bioseparation [36]. Enzymatic peeling has been studied in several types of fruits, including citrus, grapefruit, and stone fruit [35–38]. It is advantageous that this method does not require extensively harsh treatments often seen with chemical and thermal methods [34, 36].

3.3.3 Ohmic Peeling

The ohmic heating technique was investigated for the tomato peeling process [14]. Ohmic peeling is achieved by electroheating of the tomato surface by controlling the electrical conductivity of the peeling medium, where the tomato product is immersed in a sodium chloride or sodium hydroxide solution [39]. During the ohmic peeling, each tomato acts as an electrical resistor and generates heat when electricity is passed through it. The dissipation of electrical energy into heat allows rapid and uniform heating throughout the tomato surface. Bench-scale studies showed some promise that the combined lye-ohmic peeling can improve the quality of peeled tomatoes and reduce the peeling losses and lye consumption [9].

3.3.4 Ultrasonic Peeling

Ultrasonic peeling involves using low-frequency ultrasound (20–100 kHz) to treat fruits or vegetables that are submerged in high-temperature water. The ultrasonic cavitation effect through successive compression and rarefaction of high-intensity sound waves is utilized to detach the skin from the flesh [3, 34]. The synergistic effect of power ultrasound with hot water is critical to achieving the desired peeling quality [40]. This method was primarily investigated for the tomato industry to replace the use of lye.

3.3.5 Others

Other peeling methods, such as cryogenic peeling, vacuum peeling, acid peeling, and peeling with ammonium salts or calcium chloride, have been investigated in the past few decades [1]. These methods can be considered as modifications of the above-mentioned conventional methods. Successful commercialization of these other alternatives has been hampered due to the low throughputs and/or high processing costs [3].

3.4 PEELING FUNDAMENTALS

The mode of action associated with any chemical- or thermal-based peeling process usually combines biochemical and biophysical changes occurring at the product's outermost surface and adjacent inner layers. In steam peeling, for example, thermal shock induced by the pressurized steam strikes on the product's outermost surface first, causing the melting and reorganization of cuticle waxes at the product's epidermal layer which is known as the phase transition [9, 12, 41]. As the heat transfers from the surface into the product's inner tissue, the increased temperature leads to the cell wall rupture. This vaporization of cellular fluids moves to the adjacent epidermal layer, thus accelerating various biochemical reactions at the product's inner layers. The occurrence of various biochemical reactions (e.g., hydrolysis of polysaccharides and degradation of pectin) results in microstructural changes in the product's epidermal and hypodermal layers, and finally causes the separation of skin from flesh [11, 12, 31]. After peeling, changes in product quality, such as texture and nutritional content, are attributed to the thermal softening or chemical degradation in the peeling process, where a kinetic modeling approach is typically employed to describe any chemical process within the product's surface tissues [42, 43]. In terms of transport phenomena, many peeling processes involve complex heat and/or mass transport processes inside and outside of the food product that may possess a unique skin structure. Knowledge of the skin anatomy and fruit physiology can facilitate the evaluation of the multi-physicochemical transport phenomena underlying a peeling process.

An integrated approach of experimental observations and predictive modeling analysis has certainly enriched the elucidation of skin detachment behaviors in the peeling process. Numerical simulations of the transient heat transfer inside irregularly shaped tomatoes in conjugation with biomechanical measurements in the skin membrane allow an interpretation of the peel loosening and cracking phenomena (i.e., the case of infrared peeling of tomatoes) [30]. Predictions of temperature, vapor pressure, viscoelastic moduli, and shear stress evolutions in the tomato surface during the infrared heating process were quantitatively proposed and verified [13, 29, 30]. At the cellular level, a microscopic analysis evidenced that the peel loosening was observed as the melting of extracellular cuticles, collapse of surface cellular layers, thermal expansion, and severe degradation of cell wall structures. These factors contribute to the increased peel stiffness and reduced peel adhesiveness [30, 31]. Skin crack behaviors were attributed to the rapid surface heating of infrared radiation, which reduced the skin failure strength and caused a build-up of vapor pressure under the skin membrane. When the vapor accumulated to a certain level, skin cracking can occur as the shear stress in the skin membrane exceeds the critical rupture stress [30].

Mechanistic understandings of a peeling process can provide valuable insights into the development of new peeling processes and the design of new peeling equipment. For example, in the design of the first infrared peeler where the infrared heating section must accommodate tomato populations of various shapes and sizes, curve-shaped infrared emitters were custom-made to match the fruit's geometric features. The curve-shaped infrared emitters promote intensive and uniform surface-to-surface radiation that can rapidly heat the fruit surface from room temperature to boiling temperature in about a few seconds [9, 21]. Immediately after infrared heating, a vacuum chamber was engineered to increase the formation of cracks by enlarging the pressure difference across the skin membrane, which facilitates peel cracking, allows easier subsequent peel removal and results in better peelability. Clearly, the design of peeling processes and equipment would benefit from a sound mechanistic understanding of the peeling fundamentals. Understanding the peeling basics can not only help the successful peel release but also prevents potential loss of nutritional content.

3.5 PEELING PERFORMANCE AND PRODUCT QUALITY

An adequate peeling process must be established to (1) achieve satisfactory peel removal with maximized peeling efficiency, (2) produce premium-quality peeled product, (3) minimize peeling loss, product quality changes, and pollution hazards resulting from a peeling process, (4) reduce the consumption of chemicals, water, and energy, and (5) save time, labor, and economic cost [1, 29]. In practice, reliable assessment of the peeling performance of incoming raw products is a challenge due to the substantial amount of variability in raw product physicochemical properties, cultivars, product defects, seasonal variations, and many other agronomic factors [30, 44]. Peeling evaluation can consist of both objective and subjective quantifications. A general guideline is that using a single grading scale or criterion in peeling evaluation can introduce bias and should be avoided [14, 30]. Instead, the creation of an inclusive metric from different efficiency, quality and product safety perspectives allows better and comprehensive assessments of the peeling process [31]. Some commonly used criteria include the peelability, peeling yield/loss, the ease of peeling, percentage of peel removal, peeled skin thickness, peeling residence time, peeling efficacy, peeling throughput, efficiency of water usage, energy consumption, and so on [11, 21, 31, 45, 46]. Additional consideration may also be given to overall economic efficiency. Different evaluation matrices can be developed to quantify the peeling performance, such as raw materials to be peeled, and the desired final products.

Commercial processors are not concerned with only the peeling performance but also the safety and quality of peeled products. During peeling, removal of the skin induces

mechanical injuries in fruits and vegetables due to cellular damage of the outer pericarp surface that protects the inner edible tissue. Levels of food safety and quality are crucial concerns in peeling processes. Because the increased susceptibilities to deterioration such as enzymatic changes and microbial contaminations can take place at the peeled surfaces anytime during food processing and handling, the quality and shelf-life of peeled products may be compromised [6, 47, 48]. Accordingly, industrial quality controls of peeled products include visual appearance, texture, flesh color, taste, nutrient loss, integrity of peeled product, and so on. A sampling protocol for incoming products and fruit tagging procedures, like the radio frequency identification (RFID) method, are practical options to monitor closely any quality changes throughout the peeling process [14]. Novel techniques for quality control by means of digital imaging analysis, analytical spectroscopic techniques, dynamic thermal analysis, and magnetic resonance imaging have been explored in order to achieve the best quality assurance and management [13, 49, 50].

3.6 PEELING SUSTAINABILITY

Conventional peeling operations can consume extensive amounts of water and energy, and inevitably generate waste that requires additional waste management to avoid contaminating the environment [4]. In recent years, the long-term water supply concerns and the enforcement of wastewater discharge regulations have exerted environmental pressure and financial burden on food processors [28, 34, 51, 52]. Such new challenges for the fruit and vegetable processing industry have created an incentive and strong desire to develop sustainable and cost-effective peeling alternatives that can reduce the peeling wastage, water and energy usage, and overall cost of the peeling process [9, 31]. Overall, the development and appropriate selection of peeling methods need to consider the sustainable aspects in terms of reducing energy and carbon footprints, minimizing chemical contamination, and improving water-use efficiency.

3.7 FINAL REMARKS

Peeling is a widely used process to produce various premium-quality products in the fruit and vegetable industry. As a unit process, peeling can be water- and energy-intensive. The selection of a proper peeling method for different fruits and vegetables can impact the high-level production of finished products: not limited to the product quality and safety, but also the inherent waste management and operating expense. Most popular industrialized processes that were developed a few decades ago may result in enormous amounts of peeling effluents with high costs of wastewater handling and disposal. Future endeavors would be engaged with the development of sustainable and cost-effective peeling alternatives that can reduce water, chemical, and energy consumptions and minimize wastewater generation while producing high-quality products. A holistic approach must be taken to optimize any emerging peeling technique that can be effectively and economically applied to a wide range of food products.

4 Postharvest Physiology of Fruits and Vegetables

V. K. Mishra and T. V. Gamage

CONTENTS

4.1 POSTHARVEST QUALITY

Fruit and vegetables are consumed in fresh and processed forms (canned, frozen, dried, preserves, fermented products) and are valued for their health-promoting potential. Kader [1] defined quality as "a combination of characteristics, attributes, or properties that give the commodity value as a human food." However, the definition varies along the supply chain which consists of producers, handing and distribution agencies, processors, and finally a consumer. Quality attributes normally used for raw materials are: physical (size, firmness, presence or absence of seeds, etc.), compositional (natural sugars, volatiles), nutritional (vitamins, antioxidants, functional components), and sensory (color, texture, taste, flavor, and odor). Specific quality requirements of raw material vary with the nature of the product and processing applied to it. Reasonable storage life of fruits and vegetables before processing is an additional criterion used by processors to assess their suitability as a raw material and to increase the processing season. Minimization of deterioration of quality of plant produce intended for processing is the main aim of suppliers of fruits and vegetables that are stored and handled. Postharvest quality is an important determinant of the quality of fresh and processed fruit and vegetable [2]. As depicted in Figure 4.1, the quality of fruit and vegetables depends on several factors that can be classified as preharvest, harvesting, and postharvest. The physiological status of these live and morphologically diverse products, in addition to diseases and pests, and mechanical injuries, and injury during postharvest handling, impacts directly on quality. Knowledge of postharvest physiology is therefore fundamental to understanding the process of deterioration in order to prevent postharvest losses in terms of both quality and quantity for both fresh and processed product markets.

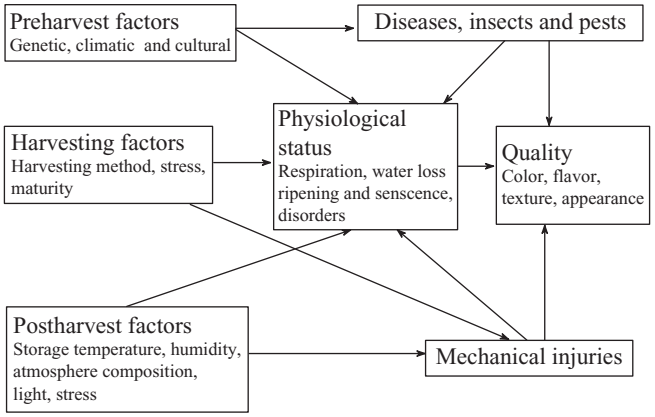

FIGURE 4.1 Schematic representation of factors affecting postharvest quality of fruits and vegetables.

Postharvest period begins at the separation of plant organ used as food from the medium of its immediate growth or production and ends when it enters the process of preparation for final consumption or further preservation and processing. Fruit and vegetables are live tissues harvested at various stages of their growth and development, have tender texture, contain high moisture content (60–95%) and water activity, lose water to the surrounding atmosphere, and continue respiration, which produces heat and water at the expense of food reserves, which were otherwise replaced by photosynthates and nutrients supplied by the plant before harvest. In this chapter, we provide an overview of postharvest physiology processes in relation to the postharvest quality of fruits and vegetables.

4.2 FACTORS AFFECTING QUALITY

4.2.1 Preharvest Factors

Preharvest factors determine most of the quality of plant produce including fruits and vegetables, and postharvest management must ensure that harvest quality deterioration is minimized. In fact, 70% of the quality of fruits and vegetables depends on preharvest conditions [3–5].

4.2.1.1 Genetic

Genetic makeup has a profound effect on the selection of a raw material for a given processing application. Cultivar and rootstock selection influence the composition, quality, storage potential, and response to processing. Fruit cultivars grown for fresh market sale may not be suited for processing and vice versa. The criteria used by breeders in the development of new varieties are high yield, resistance to disease and disorders, improved compositional and nutritional values, reduction in undesired toxic compounds, and improved processing characteristics. Selection of cultivar is important for both enhanced storage life and optimal quality of the fruit or vegetable for processing. Varieties have been identified to suit a particular processing method [6–11]. For example, the Roma variety is more suitable for canning than juicy and acidic varieties of tomato. Fruit and vegetable processors usually contract out growers who grow a particular variety that suits the raw material specifications for a given type of processing.

TABLE 4.1
Transgenic Fruits and Vegetables Released with Improved Quality Claims

Produce	Trait
Apple	Reduction in the incidence of bitter pit, reduction in browning (Arctic apple)
Banana	Delayed ripening, increased bruise resistance
Melon	Altered ripening
Eggplant	Seedless
Cucumber	Seedless
Pepper	Altered ripening, improved flavor
Potato	Reduced bruise sensitivity, increased amylopectin
Strawberries	Delayed softening and ripening
Tomato	Increased solid content, delayed ripening, increased shelf life

There has been a significant amount of work reported on modification of genetic make-up to improve the postharvest performance of fruits and vegetables [7–9]. Table 4.1 lists the transgenic fruits and vegetables released and traits targeted to improve postharvest quality to reduce browning and softening tendencies, increase storage life [7] to enhance processing time, and improve uniformity of the flavor and color to ensure consistency of processed product quality.

4.2.1.2 Climatic

The climatic conditions, such as temperature, humidity, light, wind, soil texture, elevation, and rain fall, significantly influence fruit and vegetable quality [5, 12, 13]. The duration, intensity, and quality of light during cultivation affect the quality at harvest. In tomatoes, leaf shading of fruits results in a deeper red color during the ripening and when grown in full sunlight they contain more sugar and dry matter. Exposure to sun tends to make citrus fruits lighter in weight, with thinner rind, low amounts of juice and acids, and high solid content compared to those that are shaded or those inside a canopy. In purple cabbage and eggplants, formation of anthocyanin pigments is controlled by short wavelengths of light in the blue and violet regions [14]. Thiamine synthesis is stimulated by light and generally occurs in the leaves and increases in concentration until the plant is mature. Turnips harvested in the morning contain more riboflavin than those harvested at other times of the day [13]. Fruits grown in cold climates usually are more acidic than those grown in warmer regions [15]. Moretti et al. [16] reviewed literature on the effect of climate change (increase in temperature, CO_2, ozone) on quality of fruit and vegetables. Temperature can influence photosynthesis, respiration, aqueous relations, membrane stability, plant hormones, and primary and secondary metabolite synthesis through enzyme-mediated biochemical reactions. For plants to have a higher yield, the photosynthetic rate needs to be high and the ratio of photosynthesis/respiration rate should be higher than one. An increase in temperatures will reduce

maturity time [16]. High CO_2 levels result in the malformation of potato tubers, increased incidence of scab, and a change in reducing sugar content. Increase in ozone reduces photosynthesis and alters synthesis of other metabolites. For example, exposure to 0.005 to 1.0 mol/mol ozone results in a transient increase in the β-carotene, lutein, and lycopene contents of tomatoes; a high level of ozone increases vitamin C content and decreases emissions of volatile esters in strawberries [16].

4.2.1.3 Cultural Practices

Soil nutrient and water supply, pruning, thinning, pest control or chemical spray, and density of planting influence the quality of plant produce [12, 17]. Fertilizer addition affects the mineral content of fruit, while other cultural practices such as pruning and thinning may influence nutritional composition by changing fruit crop load and size [18]. The closer the planting, the less sweet will be the fruits. Potatoes grown in sandy, gravelly, or light loamy soils, and low-water or -fertility soils have higher dry matter. A high N/K ratio and phosphorus deficiency in soil increase the tendency of potato to darken after cooking. Pineapple plants receiving undue amounts of nitrogen produce tart, white, and opaque fruits with poor flavor characteristics [18]. Pesticide residues may give rise to flavor taints in fresh and processed products and may even produce harmful metabolites and toxicity. Plant nutrient type and the amount of fertilizer applied have an impact on tomato color, sugar levels, total soluble solids, flavor, and texture and are related to susceptibility to diseases [18].

4.3 HARVESTING FACTORS

4.3.1 Maturity at Harvest

Maturity at harvest is the most important quality criterion for a processor as it directly affects composition, quality, losses, and the storage potential of plant produce. The optimum harvest maturity is vital to achieve maximum postharvest life of the fresh produce [19, 20]. Although most fruits reach peak eating quality when harvested fully ripe, they are usually picked mature, but not ripe, to decrease injury during postharvest handling. Fruits picked either too early or too late in the season are more susceptible to physiological disorders and have a shorter storage life than those picked at mid-season [12]. Harvesting fruits when either immature or overripe can cause extensive loss of the produce; thus maturity indices are used for estimating the correct harvesting stage. The optimum maturity of produce for fresh consumption and processing is determined by the purpose for which it will be used. The maturity stage considered best for canning may not be the best for dehydration, freezing, or making jams or preserves. For example, fully ripened tomatoes should be used for the preparation of dried and concentrated products to achieve the best flavor.

Several indices are used to identify and evaluate the maturity for harvest and for assessing suitability for a processing application. Maturity indices vary among types, cultivars of the produce, and intended processing. The indices are based on: (i) change in visual appearance (size and shape, overall color, skin color, flesh color, presence of dried outer mature leaves, drying of the plant body, development of the abscission layer, surface morphology and structure, and fullness of fruit), (ii) days elapsed from full bloom to harvest, and accumulated heat units during development, (iii) physical changes (ease of separation or abscission, flesh firmness, tenderness, specific gravity or density), (iv) chemical changes (soluble solids, starch, acidity, sugar/acid ratio, juice content, oil content, tannin content), and (v) measurable physiological changes (respiration and internal ethylene concentration). Both objective and subjective methods are used in the measurement of indices. Tables 4.2 and 4.3 show commonly used indices for assessing maturity for harvesting and for assessing suitability for processing for selected fruits and vegetables, respectively. Since each method has its own limitations and advantages the accurate assessment of maturity requires the use of a combination of indices [12, 21].

4.3.2 Harvesting Methods

Harvesting can be done manually or mechanically. The harvesting system used and its management have a direct effect on the incidence and severity of mechanical injuries. Thus, management procedures should include the following for best results: (i) selection of optimum time to harvest regarding fruit maturity and climatic conditions, (ii) training and supervision of workers, and (iii) an effective quality control procedure. Pickers can be trained in methods of identifying produce that is ready for harvest [21].

Harvested vegetables other than root crops should not be placed directly on the soil and exposed to sunlight, heat, and rain. Exposure to sun can lead to a high internal temperature, which is detrimental to the quality. A simple shade or grass coverage can provide protection to the harvested products. Some root crops can benefit from brief exposure to the sun in order to dry off the surface or facilitate removal of adhering soil [18]. The time of day or night and weather conditions during picking also affect the quality. Harvesting during or immediately after rains should be avoided, and harvesting should preferably be carried out during the cooler part of the day (usually early morning) to avoid shriveling and wilting.

4.4 POSTHARVEST FACTORS

4.4.1 Humidity

Fresh fruits and vegetables contain sizable amounts of water, for example, watermelons may contain >95% water of its fresh weight. Since most of the water is free water, the produce will continue to lose water to the surrounding atmosphere. The loss in water manifests as shriveling, wilting, and loss of crispness. The tissue may also become tough or mushy and unacceptable to the consumer. The reduction of saleable weight and loss of sensory characteristics lower the marketing value. The surface area/volume ratio, nature of the surface: presence/absence of cuticle, number of stomata (leaves) and

TABLE 4.2
Harvest Maturity Indices for Vegetables and Specifications for Processing

Vegetable	Harvest	Specifications for Processing
Broccoli	Compact bud cluster	
Cabbage	Compact head	Sauerkraut (mild flavored, sweet, solid white head, Sugar >2%, ascorbic acid 30–60 mg/100 g)
Carrot	Desired length and texture	Canning (tender texture) Juicing (juice yield and sugars >6°B)
Cauliflower	Compact curd	
Cucumber	Size and tenderness	Pickles (ripe with sugar content of 1.5–2.5%)
Eggplant	Desirable size and tenderness	
Lettuce	Desirable size before flowering	
Okra	Desirable size and tips snap off easily	Canning (small, young, and tender)
Olives	Straw yellow to cheery red	Pickling (slightly less mature, size, color)
Onion	Tops beginning to dry	Drying (high solids content)
Peas	Well-filled pods which snap easily	Canning (13.4% AIS, tenderometer reading of 115–125) Freezing (13.4% AIS, tenderometer reading of 95–105) Drying (9–11% AIS, tenderometer reading of 85–95)
Potato	Tops beginning to dry	Chips (dry matter of 21–24%, specific gravity (>1.075), <1.5% sugar) French fries (specific gravity of 1.08–1.12, <0.3% reducing sugar) Frozen chips (total solids 20–22%, <0.2%) Canning (whole tubers of 19–38 mm size, specific gravity of <1.08) Dehydrated diced potatoes (specific gravity of 1.1) Starch manufacture (minimum of 15% starch)
Sweetcorn	Milky sap oozing upon pressing	Canning (slightly immature kernels)
Tomato	Seeds slip upon cutting the fruit	Most processed products (SS >5%)

Sources: Dauthy [22], Holdsworth [11], Kader [19], Kitinoja and Kader [21], Lisinska and W. Leszczynski [23], Maestrelli [24], Ranganna [25], Rodriguez et al. [26].

lenticels (fruits), periderm (tubers and roots); and injury to the plant tissues affect the rate and extent of water loss.

Water loss can be prevented by maintenance of high atmospheric relative humidity (RH), low temperature, reduced air movement, and increased pressure, avoiding product injury, and the use of suitable packaging during storage and transportation. Optimum RH is 85 to 90% for most fruits and 90–98% for most vegetables except dry onions and pumpkins (70–75%). Some roots may require almost 100% relative humidity [27, 28]. Maintaining high RH, in certain situations, may induce decay, surface mold development, and physiological disorders including impaired fruit ripening; however,

TABLE 4.3
Maturity Indices and Specifications for Processing Fruits

Fruit	Harvest	Specifications for Processing
Apple	140–150 days from the bloom, starch content	Sauce and canned products (maximum shear press values of 3.1–3.3 kN for slices, min SS of 10% for sauce)
Apricot	Three-quarters of the area of the fruit should be yellowish green or one-half yellow	Canning (full flavor) Drying (full flavor and ripening)
Grapes	14–17.5% SS, or SS/A of 20 or higher	White wine fermentation (pH 3.1–3.3, TA 0.7–0.9, Brix 19–22°B) Red wine fermentation (pH 3.3–3.6, TA 0.6–0.8, Brix 21–23.5°B)
Orange	SS/A of 8	Minimum juice content of 30–35% Frozen juice concentrate (12.5–19.5 SS/A)
Pear	>13% SS and yellowish green color	Canning (full flavor and firmness measured to 66.7–75.6 N)
Banana	Pulp to peel ratio of 1.35–1.4, or disappearances of angularity, color	Banana puree (complete disappearance of angularity, full flavor, and flesh appears translucent)
Mango	Change of peel color from green to yellow	Canning (full flavor and total sugar/soluble solids ratio close to 1)
Strawberries	>2/3 of fruit surface has pink or red color	Freezing (firmness equivalent to 10–15 N force)

Sources: Bedford [6]; Kader [28]; Maestrelli [24]; Margalit [29]; Matthews [30] Springett [31].

surface condensation of moisture (sweating) over long periods is probably more of significance in enhancing decay than high humidity.

4.4.2 Temperature

Proper temperature management is the most important tool in postharvest handling of plant produce to control both physiological and pathological deteriorations. Provided exposures to temperatures leading to chilling and freezing injuries are avoided, lowering the temperature during handling, transportation, and storage is the most effective means of extending the shelf life and reducing the loss of the quality by lowering the metabolic processes such as respiration and transpiration. Figure 4.2 shows the effect of temperature on the shelf life of selected fruits and vegetables. The difference in the effect of temperature on the shelf life varies due to differences in the physicochemical properties of different types of fruits and vegetables. For example, the most pronounced effect in increasing the shelf life by reducing the temperature is expected for lettuce and green onion rather than for strawberry and raspberry. The effect of temperature on quality is expressed by a temperature quotient, Q_{10}, which is defined as:

$$Q_{10} = \left(\frac{q_2}{q_1}\right)^{\left(\frac{10}{(T_2 - T_1)}\right)} \tag{4.1}$$

where q_2 and q_1 are the rates of quality function at two temperatures, T_2 and T_1, respectively. The Q_{10} values describe the effect of temperature on a particular quality attribute, such as color, texture, flavor, etc. For example, Q_{10} values for quality deterioration in asparagus when expressed as appearance, sugar loss, and fiber increase are 2.7, 5.8, and 10, respectively, between a temperature range 0–10°C [32].

4.4.3 Atmospheric Gas Composition

Atmospheric gas composition, such as oxygen, carbon dioxide, and ethylene, influences the microbial decay and physiological processes such as respiration. The reduction of oxygen and elevation of carbon dioxide through modified or controlled atmosphere storage complement the effects of maintaining low temperatures through the postharvest value chain. For example, transporting banana under 3% O_2 and 5% CO_2 reduces premature ripening and crown rot development by the high carbon dioxide/oxygen ratio [34]. The beneficial or harmful effects of varying gas composition, however, depend upon commodity, cultivar, physiological age, oxygen and carbon dioxide levels used, temperature, and duration of storage [28, 35]. The principles underlying the technology of manipulation of atmosphere and recommended levels of gases for extending the postharvest life of fruits and vegetables have been covered elsewhere [35–39], and in the chapter on controlled atmosphere storage (Chapter 22).

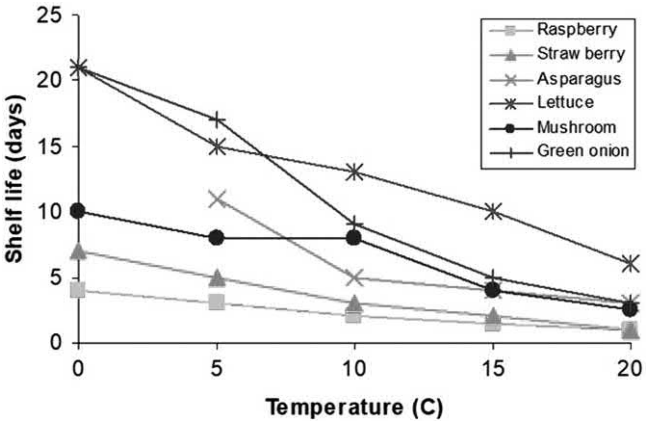

FIGURE 4.2 Effect of temperature on shelf life of selected fruit and vegetables. (Data from Brechet and Brechet [33].)

4.4.4 Light

Light may influence the quality of fruit and vegetables by controlling the synthesis/degradation of pigments responsible for color (chlorophyll, carotenoids), flavor by catalyzing the oxidation of lipids, sprouting, reducing nutritive value by degrading vitamins such as ascorbic acid and riboflavin, and production of toxins. The exposure of potatoes to light during storage may produce green tissues, which contain solanine, a toxin [18]. Thus, light intensity should be minimized. Adverse effects of light can be prevented by storage in the dark and using packaging materials that prevent the transmission of light.

4.4.5 Mechanical Injury

Mechanical injuries expose internal tissue to contamination, increase respiration rate, promote chemical and enzymatic reactions, allow the spread of decay microorganisms, and induce an overall quality decline. The surface cracks, cuts, and punctures that develop during growth or as a result of mechanical injuries weaken the protective outer layers causing water loss. At early stages of maturity, some commodities have the ability to repair and seal off the damaged area. The capacity of wound healing diminishes in most cases as the plant organs mature except some tuber and root crops.

4.4.6 Postharvest Diseases or Infections

The postharvest diseases are initiated at the early stage of development when attached to the plant, by fungi or bacterial invasion through the cuticle or through wounds, and/or natural openings in the surface, and through injuries in cut stems or damage to the surface. While most microorganisms can invade only the damaged produce, a few are able to penetrate the skin of healthy tissue. Postharvest diseases control is based on: prevention of infection, eradication of incipient infections, and retarding the progress of pathogen spread by fungicide or bactericides [40, 41].

The pH of tissue is the major factor that influences the microflora present. Yeasts and molds are often the

predominant microorganisms in fruits and fruit products as they grow well under acidic conditions. Only a few species of yeast pathogenic to man and other animals are common contaminants of fruits and fruit products [40, 41]. Mold-infected raw fruit may become soft during or after processing because pectinases present in molds despite the use of ordinary thermal treatment. For example, patulin is a common mycotoxin in apples [41].

In general, the bacteria that cause diseases in humans are not associated with fruit products due to poor tolerance to low pH of fruits. There are four groups of human pathogens that may be present in fresh fruits and vegetables [42]: soil-inhabiting bacteria (*Clostridium botulinum*, *Listeria monocytogenes*), enteric bacteria (*Salmonella* spp., *Shigella* spp, *E. coli* O157:H7, etc.), parasites (Cryptosporidium, Cyclospora), and viruses (Hepatitis, Norwalk virus, etc.).

4.5 POSTHARVEST PHYSIOLOGICAL PROCESSES

The origin and development of plants influence physiological aspects of fruit and vegetables. From initiation or conception to death (senescence), plants or parts thereof undergo different stages of development having significant differences in their metabolism, impacting on quality. Fruits and vegetables pass through five distinct developmental phases from initiation to: (i) development (morphological and chemical completion of tissue), (ii) young or premature (developmental period before the onset of maturation), (iii) mature (completion or fullness of growth and edible quality; most of the maturation processes must be completed while the produce is still attached to the plant), (iv) ripe (maximum esthetic and edible quality), and (v) senescence (leading to death and making the produce worthless and inedible). The duration and rate of these stages vary with the type and variety of the product and stage of development [1–3 13, 19–21, 28, 35]. Table 4.4 provides examples of plant parts used as fresh or in processed forms. The morphology and the stage of development at which these are harvested vary substantially. When harvested, sprouts and seedlings are in the very early stages of development, followed by stems and leaves, partially developed fruits (cucumber), fully developed fruits (apples), roots and tubers and seeds (dry beans, peas). Tissues that are in the early stage of development have relatively short shelf life as compared to those which are primed for dormancy (e.g. potatoes).

TABLE 4.4
Types of Plant Parts Consumed in Fresh or Processed Form

Plant Part	Example
Seeds and pods	Peas, chick pea, corn, baby corn, beans, okra
Bulbs, roots, tubers, and corms	Potato, beet, carrot, onions, garlic, lotus root, cassava
Flowers	Cauliflower, broccoli, banana flower
Fruits	Tomato, pears, peach, pineapple, olive, eggplant, mango, lychee
Buds	Bamboo shoot
Stems	Asparagus
Leaves	Lettuce, spinach
Seedlings	Bean, alfalfa, onion, radish sprouts

The unwanted sprouting in vegetables, such as onions, ginger, garlic, and potatoes, is related to dormancy and rest. Dormancy is a condition of quiescence due to some internal or external factors, and rest is a phenomenon in which sprouting does not occur in spite of a favorable environment (for example, potatoes have no period of rest) [18]. Rooting in roots and tubers is initiated by high humidity in the environment and may result in rapid decay, shriveling, and depletion of food reserves [13, 35]. Seed germination of mature fruits during storage, such as chayote, tomatoes, papaya, and pod-bearing vegetables, is also a serious problem. Green beans and sweetcorn may toughen due to the development of spongy tissues when storage is unduly prolonged [18]. Elongation of existing structure as in asparagus, carrot, beet, and kohlrabi, and bending of tissues in response to gravity and light reduce the market life.

4.5.1 Respiration

All living organisms convert matter into energy through a fundamental process of life called respiration, which primarily constitutes enzymatic oxidation of substrates, such as carbohydrates, proteins, lipids, organic acids, etc., in the presence of atmospheric oxygen to carbon dioxide and water, and accompanied by a release of energy as follows:

$$C_6H_{12}O_6 + O_2 \rightarrow CO_2 + H_2O + 2872\,kJ \qquad (4.2)$$

The reaction brings about changes in the chemical composition as carbohydrates, proteins, lipids, and organic acids are used as substrates. The respiratory quotient (RQ), which is defined as a ratio of CO_2 produced to O_2 consumed, can indicate the type of substrate being oxidized during respiration. The RQ values for carbohydrates, organic acids, and lipids are 1, >1, and <1, respectively. The prevalence of anaerobic respiration corresponds to high RQ values. The respiration reaction is exothermic as a significant part (about 57%) of the energy produced is dissipated as heat, called vital heat or heat of respiration, which contributes to a further increase in the temperature of the commodity.

Respiration plays a significant role in the postharvest physiology and deterioration of quality of plant foods. The rate of deterioration is generally proportional to their respiration rate, which often is a good index of the storage potential of a fruit or vegetable. The higher the respiration rate the shorter is the shelf life and vice versa. The respiration rate can be used as a criterion to compare the perishability of fruits and vegetables. Kader and Barrett [12] classified fruit and vegetables into five groups based on their respiration rate as shown in Table 4.5, which also illustrates the relationship between the relative perishability and their respiration rates. Commodities such as mushrooms, which respire at rates three times those of dried fruits, are more perishable and have a shorter shelf

TABLE 4.5
Classification of Fruit and Vegetables Based on Respiration Rate

Class	Respiration Rate (mg/kg hr) 10°C	20°C	Examples
Very low	<10	<40	Nuts, dates, dried fruits
Low	10	40	Potatoes, onions, cucumbers, apple, pear, kiwi fruit, pomegranate, Chinese date
Moderate	10–20	40–80	Peppers, carrots, tomatoes, eggplant, citrus fruits, banana
High	20–40	80–120	Peas, radish, apricot, fig, ripe avocado, cherimoya, papaya
Very high	>40	>120	Mushrooms, green onions, cauliflower, dill, parsley, melons, okra, strawberry, blackberry, raspberry

Source: Kader [12].

life than nuts and dried fruits. The effect of respiration on perishability can be explained by (i) coupling of the resultant reducing power and formation of ATP due to respiration with biosynthetic reactions leading to loss of quality, (ii) loss of food reserves, (iii) toxic effects of accumulation of carbon dioxide, and (iv) increase in product temperature due to respiratory heat, which dictates the cooling load requirement during storage [39, 44, 45].

Useful data on experimental respiration rates for different fruits and vegetables are given by several references [45, 47–49]. Experimental data on the production of CO_2 are correlated to temperature by a relationship such as:

$$\dot{m}_{CO_2} = f \times \left[\frac{9T_m}{5} + 32\right]^g \tag{4.3}$$

where $\dot{m}_{CO_2}$ is the rate of carbon dioxide production per unit mass of the product, T_m is the mass average temperature of the product (°C), and f and g are the respiration coefficients for a given product. The coefficients obtained by least square fit of the experimental data are given in Table 4.6 [47]. Similarly, the relationship between the heat of respiration and temperature can be derived from the reaction stoichiometry involving glucose oxidation. Within the physiological range of temperatures (0–30 °C), the rate of respiration increases exponentially (Figure 4.3) and a large amount of heat is produced as heat of respiration (Figure 4.4).

The respiration rate depends on a host of internal and external factors. The internal factors include (i) the quantity of substrate (predominantly sugars), (ii) the size, shape, cell morphology, and maturity, (iii) the structure of the peel, (iv) the volume of intercellular spaces, and (v) the chemical composition of tissue which affects solubility of oxygen and carbon dioxide. The external factors are: (i) temperature, (ii) availability of ethylene, oxygen, carbon dioxide, (iii) light, (iv) water stress, (v) biological activity, and (vi) growth regulators.

TABLE 4.6
Respiration Coefficients (f and g) for Equation 4.3 for Selected Fruits and Vegetables

Fruit or Vegetable	f	g
Apples	5.687×10^{-4}	2.598
Blueberries	0.002724	2.573
Cabbage	6.080×10^{-4}	2.618
Carrots	0.05002	1.793
Grapes	7.056×10^{-5}	3.033
Limes	2.983×10^{-8}	4.733
Onion	3.668×10^{-4}	2.538
Oranges	2.805×10^{-4}	2.684
Peaches	6.361×10^{-5}	3.204
Pears	6.361×10^{-5}	3.204
Potatoes	0.01709	1.769
Strawberries	3.668×10^{-4}	3.033
Tomatoes	2.007×10^{-4}	2.835

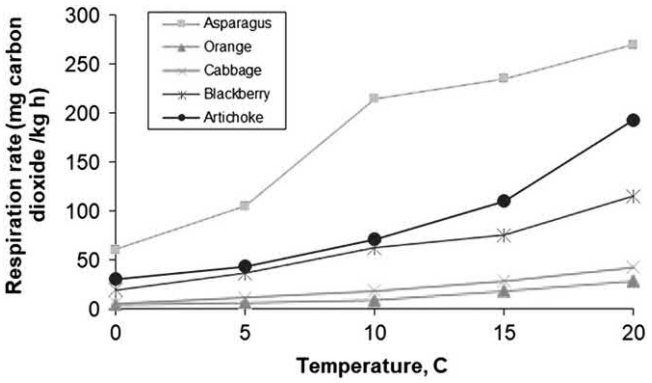

FIGURE 4.3 Effect of temperature on the respiration rates of some fruit and vegetables. (Data from Gross et al. [45].)

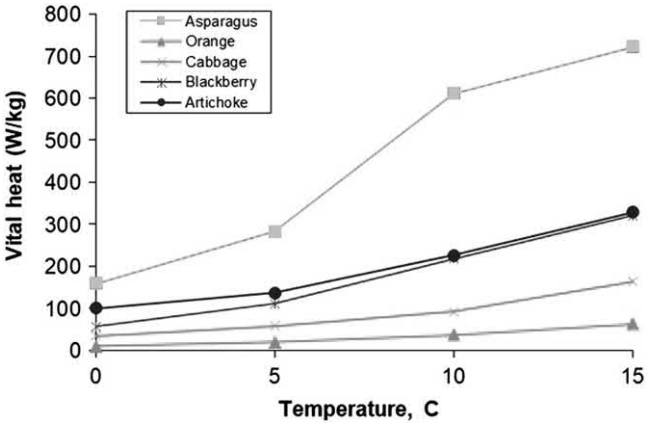

FIGURE 4.4 Effect of temperature on the evolution of vital heat by some fruit and vegetables. (Data from ASHRAE [44].)

Out of these external factors, temperature, atmospheric composition, and physical stress have the most profound effect on respiratory activity, and postharvest management of respiration involves controlling these factors to reduce the deterioration of quality.

As the produce approaches maturity, the rate of respiration declines, and those commodities that are harvested while in the period of active growth (e.g. most vegetables and immature fruits) have high respiration rates. However, fruits show two distinctive respiratory patterns during ripening and are grouped into: (i) non-climacteric, and (ii) climacteric. Climacteric fruits show a dramatic increase in the rate of respiration during ripening. The climacteric peak can be prolonged or delayed by reducing the rate of respiration in order to increase the shelf life. Climacteric fruits can be harvested mature and ripened off the plant. These produce much larger quantities of ethylene in association with their ripening, and exposure to ethylene treatment will result in faster and more uniform ripening [12]. The respiration rate is at a minimum at maturity, and remains rather constant, even after harvest. The rate will rise up abruptly to the climacteric peak only when ripening is about to take place, and then it will slowly decline. The non-climacteric fruits are not capable of continuing their ripening process once removed from the plant. These produce very small quantities of ethylene, and do not respond to ethylene treatment for ripening, except in terms of degreening (degradation of chlorophyll) in citrus fruits and pineapples [12]. Examples of non-climacteric and climacteric fruits and vegetable are given in Table 4.7.

The respiration rate depends on temperature, and the temperature dependence varies among and within commodities. The relationship between temperature and respiration rate can be expressed in the form of Q_{10} values, which allow the estimation of the rate of respiration at an unknown temperature provided the rate of respiration at a known temperature is available. The temperature quotient, Q_{10}, for respiration may be defined by replacing q_2 and q_1 by R_2 and R_1, respectively, in Equation 4.1. R_2 and R_1 are the rates of respiration at two temperatures, T_2 and T_1, respectively. Q_{10} values for respiration rates are not constant and vary between 2 and 2.5 for a temperature range of 5–25°C [32, 35, 48]. As the temperature increases, Q_{10} values decrease, and Q_{10} tends to reduce to less than 1 as the thermal death point of the tissue approaches [48].

Reduction in the O_2 concentration and increasing concentration of CO_2 in the atmosphere surrounding fresh fruits and vegetables reduce the rate of respiration. The extent of the effect depends on factors such as temperature, produce, cultivar, age, and level of maturity at harvest. A 3–5% reduction of oxygen concentration does not have an adverse effect on produce, but a comparable increase in carbon dioxide may suffocate and ruin certain fruits and vegetables. There is considerable variation in the injury threshold of various fruits and vegetables to O_2. Reduction of O_2 concentration below 2–3 % gives a beneficial reduction in rates of respiration and other metabolic processes for most produce. However, complete removal of O_2 is not recommended as an anaerobic environment is detrimental to the quality of the produce as it leads to fermentation, decay and development of off flavor, and change in color and texture.

The stage of development of produce also influences the rate of respiration. The rate of respiration declines with maturity; immature fruits respire at a higher rate than those that have attained full maturity. Actively growing vegetables such as asparagus (floral meristem) have very high respiratory rates compared to storage organs such as potatoes and mature fruits (Figure 4.3). This is the reason why potatoes can be stored for longer periods than asparagus.

Physical stress during cultivation, harvesting, and postharvest handling influences respiratory behavior significantly. Tissue injury increases the rate of respiration and induces ethylene production, which may further catalyze an increase in respiration with consequent loss of quality. While assessing the relationship between respiration, bruising susceptibility, and temperature in sweet cherries, Crisosto et al. [17] found that impact bruising damage was greatest in the tested cultivars when fruit flesh temperature was below 10°C.

4.5.2 Transpiration and Water Stress

Transpiration is mainly responsible for water loss, which leads to a loss of: salable weight, appearance (wilting and shriveling), textural quality (softening, flaccidity, limpness, crispness, and juiciness), and nutritional quality [12]. In most fruits and vegetables, a 5 to 10% loss in moisture content produces visible symptoms of shriveling and wilting due to cellular plasmolysis [18, 35].

Transpiration is a process of mass transfer in which the water vapors move from the surface of the produce to the surrounding atmosphere. The rate is directly proportional to the partial pressure gradient across the transfer surface area and inversely proportional to the sum of the resistances, such as the type of the surface and presence of waxes on the surface. The simplest mathematic model of the transpiration process used in the literature is of the following type,

$$\dot{M} = k_t(p_s - p_a) \tag{4.4}$$

where $\dot{M}$ is the transpiration rate, k_t the transpiration coefficient, and p_a and p_s are the ambient and evaporating surface vapor pressures, respectively. The transpiration coefficient represents the reciprocal of resistances to moisture transfer. The experimental data on transpiration coefficients have been compiled by Sastry et al. [51] and are given in Table 4.8. Such coefficients have limitations in describing the true transpiration process. Further improvements of the transpiration model were suggested by Sastry and Buffington [50] and Becker and Fricke [47]. It may be possible to group fruits and vegetables into three broad ranges of transpiration rates under refrigerated storage conditions: high (500–850 mg/kg hr mm Hg, carrots and parsnips), intermediate (100–250, cabbage and rutabagas), and low (10–80, potatoes and onions). The rate of transpiration depends on both product and environmental factors. These factors include (i) skin structure, (ii) size, shape, and surface area, (iii) water vapor pressure difference, (iv) air movement, (v) heat of respiration, (vi) the level of maturity, (vi) endothermic effects of evaporation, and (vii) the amount of solutes present in the produce.

The main sites of transpiration in plants are the hydathodes, stomata, epidermal cells, lenticels, trichomes (hairs), and cuticle. The number of stomata in the epidermis, type of surface, tissues under the skin, and structure and thickness of wax coating on the surface (cuticle) determine loss of water. The higher the ratio of surface area to volume, the greater is the loss of water by evaporation. Thus, at the same conditions the expected rate of transpiration will be in the order leaf (spinach) > fruit (tomato) > a root or a tuber (potato). Immature fruits tend to encounter higher transpiration rates than mature fruits due to the higher permeability of the skin to water vapors. Since the solute depresses the water activity of solutions, higher solute concentration in the tissue binds water and reduces water loss.

TABLE 4.8
Transpiration Coefficients of Selected Fruit and Vegetables

Product	Mean Transpiration Coefficient (mg/ kg s mPa)	Range of Transpiration Coefficient (mg/ kg s mPa) Reported in the Literature
Apples	42	16–100
Brussels sprouts	6150	3250–9770
Cabbage	223	40–667
Carrots	1207	106–3250
Celery	1760	104–3313
Grapefruit	81	29–167
Grapes	123	21–254
Leeks	790	530–1042
Lemons	186	139–229
Lettuce	7400	680–8750
Onions	60	13–123
Orange	117	25–227
Parsnips	1930	1097–2771
Peaches	572	142–2089
Pears	69	10–144
Plums	136	110–221
Potatoes	25	15–40
Tomatoes	140	71–365

Source: Sastry et al. [51].

The temperature, relative humidity, and air movement are the three most significant environmental factors that affect water loss by transpiration. In general, high surface temperature and low relative humidity increase the rate of transpiration. As is indicated by Equation 4.4, the vapor pressure difference, the driving force for water movement, has a direct relationship with the transpiration rate, and therefore the difference can be used to determine the transpiration rate. Sastry and Buffington [50] reported the following regression equation (Equation 4.5) for the best fit ($R^2 = 0.99$) curve describing the transpiration rate and apparent vapor pressure difference for tomatoes:

$$\dot{m} = 0.038557\,(p_{sa} - p_{\infty})^{0.9536} \tag{4.5}$$

where $\dot{m}$ = the rate of transpiration (mg/cm^2 s), p_{sa} = apparent water vapor pressure at the evaporating surface, and p_{∞} = atmospheric vapor pressure in mm Hg. The relationship for tomatoes has been almost linear. While atmospheric vapor pressure is dependent on both temperature and air relative humidity, the apparent vapor pressure depends mainly on temperature due to saturation conditions prevailing in the tissue. Thus, one practical way to minimize transpiration is to cool the produce quickly under high humidity conditions (hydro-cooling). Respiratory activity produces heat that contributes to higher evaporation of water even under prevailing saturation conditions by increasing the vapor pressure deficit. It is expected that fruits and vegetables, which have higher respiratory activity, will also have higher water loss. The effect of maturation and ripening on transpiration varies significantly amongst fruits. Fruits such as mango and banana show increased transpiration after reaching the climacteric period [14]. The dissolved solutes, particularly simple sugars at higher concentrations, reduce the vapor pressure of water in the solution inside the tissues more and hence reduce the rate of transpiration. Air circulation or velocity increases the moisture evaporation from the surface, particularly in situations where temperature fluctuations persist.

Water loss can be minimized by maintaining higher pressure than atmosphere, maintaining low temperature and humidity during storage, loading density and depth, application of waxes and other water-resistant coatings to the surface, or by appropriate packaging such as with plastic films [35, 47, 52].

4.5.3 Ripening and Senescence

Ripening refers to a stage in tissue development when a fruit reaches an optimal eating quality, as evidenced by favorable change in composition, color, texture, and other sensory

attributes [19, 35]. Many fruits (climacteric) require ripening to be carried out by the processor as fruits have been shipped to processors in the immature stage to avoid tissue injury during transportation and handling. Ripening in fruits follows physiological maturity and precedes senescence, which leads to the death of the tissue. Senescence is genetically programmed and can be induced by common stressors such as tissue injury, deficiency of nutrients and water during production, exposure to insects, pests, and diseases, and adverse environmental conditions. An understanding of the biochemistry of senescence, therefore, provides clues to delay the loss of postharvest quality of fruits and vegetables. King and O'Donoghue [53] identified three main areas of research conducted to unravel senescence, the role of ethylene, structural changes in the cell wall, and metabolic changes when immature after harvest.

Ripening induces changes that are structural, physical, chemical, nutritional, bio-chemical, or enzymatic. These changes are (i) degradative, such as chlorophyll breakdown, starch hydrolysis, and cell wall degradation, and (ii) synthetic, such as formation of carotenoids and anthocyanins, aroma volatiles, and ethylene formation.

The details of compositional and morphological changes during ripening and senescence are given in several references [1, 12, 13, 19, 33, 35, 46, 54]. Carbohydrates, organic acids, amino acids and proteins, lipids, pigments, pectic substances, and volatile components are mostly affected and directly contribute to the pleasant color, aroma and flavor, texture, and appearance of fruits. The flesh cells enlarge and sugar content increases at the expense of starch, acid, and phenolic compounds as the fruits approach ripening. In addition, certain volatile compounds develop, giving the fruit its characteristic aroma and flavor [54]. Chlorophyll degradation (loss of green color) and synthesis of carotenoids (yellow and orange colors) and anthocyanins (red and blue colors) take place both in the skin and in the flesh. All fruits soften as they ripen due to changes in cell wall composition and structure. The pulp weight increases with the gradual decrease in peel weight upon ripening. Figure 4.5 shows changes in starch, sugars concentrations, and the ratio of starch and sugar as a function of stages of maturity in banana. At the onset of maturity there is little sugar in the fruit, and as maturity increases the fruit sweetness progressively increases due to hydrolysis of starch into sugars, particularly after stage 2, and starch practically disappears at stage 6.

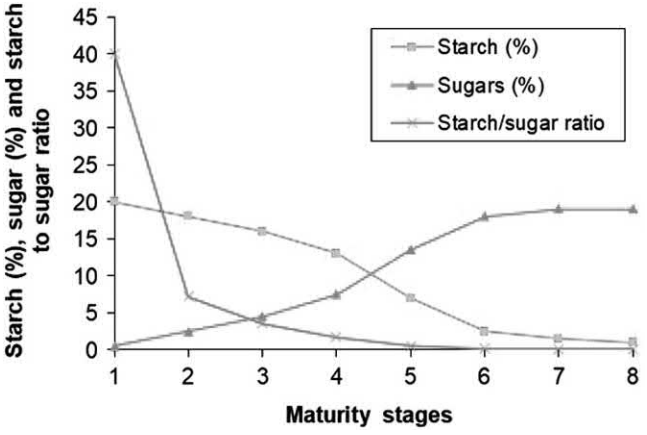

FIGURE 4.5 Relationship between the stages of maturity of banana and starch, sugar and starch–sugar ratio. (Data from Wills et al. [35].)

Every fruit has its unique assemblage of volatile compounds, and an increase in volatiles contributes to the flavor, taste, and aroma of the fruits. The main volatile compounds are acids, alcohols, esters, carbonyls, aldehydes, ketones, and hydrocarbons [12, 19, 35, 54]. These volatiles are present in extremely small quantities (<100 g/g fresh weight), and the total amount of carbon involved in their synthesis is less than 1% of that expelled as carbon dioxide [12]. Although ethylene does not have strong aroma and does not contribute to typical fruit aroma, it does influence the formation of volatiles in climacteric fruits. In both climacteric and non-climacteric fruits, the most important aroma volatiles compounds that increase during ripening are the esters. The characteristic or optimum flavor develops at a specific stage of the ripening process. In the case of tomatoes, while the color changes from the green to the red stage during ripening, the volatile concentration reaches a peak from the pink to red stages of maturity. In mango, the characteristic flavor develops only after the half-ripe stage (climacteric stage), and the extent of flavor generation depends on the temperature conditions during storage [54]. There is also a dramatic increase in aroma volatiles in non-climacteric fruits. Esters, acetals, alcohols, and aldehydes are formed in strawberry. In pineapple, there is a dramatic increase in ester production during ripening, while in citrus there are no changes in volatile production during storage. In grapefruit and pomelo, the changes in volatiles are very minor during storage, except for the important increase in nootkatone, which contributes significantly to pleasant grapefruit flavor.

Non-ethylene, non-respiratory organic volatiles, such as terpenes, carboxylic acids, alcohols, aldehydes, sulfur compounds, ammonia, and jasmonates, impact physiology and/or quality of fresh produce, particularly as antimicrobial or insecticidal agents [55]. Stress and injury, disease, cultivar, and atmospheric composition strongly influence their accumulation.

Fruits become softer upon ripening due to a series of changes at the cellular level. The composition, water content or turgor pressure, and cell wall constituents undergo transformation upon maturity [56–60]. The cellular structure weakens as a result of modification to the polysaccharides, such as cellulose, hemicellulose, and pectins, present in the cell wall and middle lamella by the action of several enzymes, such as polygacturonase and glycosidases. Polyuronide depolymerization, loss of galactan and arabinan, pectin demethylesterification and solubilization, depolymerization of matrix glycan, and cellulose depolymerization are responsible for degradative changes in the cell wall [56, 60]. Considerable variations exist among different fruits as shown in Table 4.9, which lists the extent of changes in arabinan, galactan, pectin solubilization, and depolymerization in the cell wall during

TABLE 4.9
Cell Wall Changes Responsible for Loss of Texture During Ripening

Cell Wall Change	Absent	Low	Moderate	High
Loss of arabinan	Watermelon Apricot Plum	Pepper Tomato	Avocado Peach Kiwifruit	Pear Blueberry
Loss of galactan	Cucumber Plum	Apricot Blueberry	Peach Apple Melon	Muskmelon Pepper Tomato
Solubilization of pectin	Watermelon Apple	Apple	Plum Strawberry Tomato Banana	Avocado Kiwifruit Blackberry
Depolymerization of pectin	Banana Strawberry Apple Pepper	Melon Papaya Watermelon	Peach Tomato	Avocado

TABLE 4.10
Physiological Changes Induced by Phytohormones Other Than Ethylene

Physiological Changes	Phytohormone	Produce Affected
Sprouting	Abscisic acid, gibberellin, cytokinins, auxins	Onion
Senescence	Increased levels of gibberellin and low levels of auxins and cytokinins	Brussels sprouts, lettuce
Elongation of flower peduncle	Gibberellins	Cauliflower
Rooting	High levels of cytokinenins and low levels of gibberellins	Carrot
Pithiness of petiole	Abscisic acid	Celery
Ripening	Abscisic acid stimulates, auxins, gibberellins, and cytokinenins delay ripening	Tomato

Sources: Haard [43]; Salunkhe et al. [13].

ripening for some fruits [60]. These changes have an impact on the gel formation ability required for fruit preserves, juice yield and cloudiness of fruit juices, tissue collapse during thermal processing, etc.

4.5.4 Phytohormones Effects

Phytohormones play an important role in plants by controlling the growth and development processes of plant organs. Physiological processes influenced by hormones are ripening, rest, dormancy, rooting, sprouting, abscission, and floral induction [43, 61, 62]. Besides ethylene, the key hormones responsible for these processes are: auxins, gibberellin, cytokinins, abscisin (Table 4.10). The physiological response to these hormones has been mainly studied in relation to increasing the yield of produce and has been less focused on the postharvest effects [61, 62], since vegetables are harvested from different parts of the plant and stages of development, hence the physiological effects of hormones are, as expected, not limited to ripening and senescence as in the case of fruits.

Ethylene has been studied the most by postharvest physiologists. Ethylene is a natural product of plant metabolism and is produced by all tissues of higher plants and by some microorganisms [12, 32] and is also present in the atmosphere as a pollutant. Ethylene regulates many aspects of growth and development even at concentrations <0.1 ppm. The production of ethylene by fruits and vegetables varies substantially from <0.1 to >100 ml/kg h (Table 4.11). Climacteric fruits, generally, produce higher amounts of ethylene than non-climacteric fruits.

Ethylene is synthesized in plants from methionine, an amino acid, by a series of reactions by a highly regulated pathway (Figure 4.6). The key steps in this pathway are (i) conversion of methionine to S-adenosyl-l-methionine (SAM) by SAM hydrolase, (ii) SAM to 1-aminocycloproane-1-carboxylic acid (ACC) by ACC synthase, and (iii) ACC to ethylene by ACC oxidase [35, 53, 62]. Oxygen is required for ethylene biosynthesis while both O_2 and CO_2 are needed for its bioactivity [61]. ACC can also be converted into two conjugates, malonyl- ACC and -glutamyl-ACC by ACC-N-malonyltransferase and ACC--glutamyltransferase enzymes, respectively. Synthesis of these conjugates reduces availability

TABLE 4.11
Classification of Fruit and Vegetables According to Ethylene Production Rates

Class	Rate (ml/kg h)	Examples
Very low	<0.1	Artichoke, asparagus, cauliflower, cherry, strawberry, pomegranate, leafy vegetables, potatoes
Low	0.1–1.0	Blueberry, cranberry, cucumber, eggplant, okra, olive, pepper, persimmon, pineapple, pumpkin, raspberry, tamarillo, watermelon
Moderate	1.0–10.0	Banana, fig, guava, melon, honeydew, mango, plantain, tomatoes
High	10.0–100.0	Apple, apricot, avocado, cantaloupe, feijoa, kiwi, nectarine, papaya, peach, pear, plum
Very high	>100.0	Cherimoya, passionfruit, sapota

Source: Kader [28].

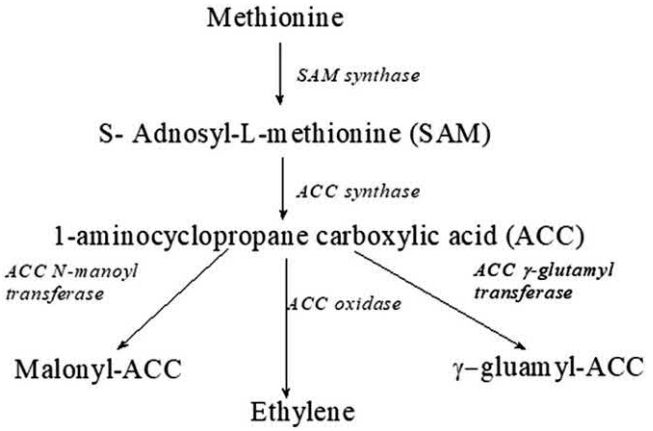

FIGURE 4.6 Biosynthetic pathway of ethylene production. (From King and Donohue [53]; Pech et al. [62].)

of ACC for conversion to ethylene. ACC synthase is the key enzyme in the pathway leading to the production of ethylene in plants. Only one of many genes controlling this enzyme may be responsible for the ripening action of ethylene. It may, therefore, be possible to control ethylene biosynthesis without influencing other physiological processes.

Ethylene stimulates ripening of climacteric and some nonclimacteric fruits, synthesis of anthocyanins, degradation of chlorophyll (degreening), germination of seeds, formation of adventitious roots, abscission and senescence, flower initiation, and respiratory and phenyl propanoid metabolism [63]. It also is known to accelerate its own synthesis in ripening climacteric fruits. Ethylene is used as a "ripening hormone" for climacteric fruits such as banana and mango commercially and as a "degreening hormone" for citrus fruits. The beneficial and adverse effects of ethylene depend on several factors such as the type of produce, cultivar, and the maturity at the time of harvest, temperature, and activity of other hormones, etc. Table 4.12 lists the adverse effects of ethylene on selected fruits and vegetables. Controlling the action of ethylene is of great commercial significance in fruits and vegetables as the adverse effects can lead to serious economic losses. Ethylene production rates by fresh fruits can be reduced by storage at low temperatures, by reduced oxygen (less than 8%, and/or elevated carbon dioxide above 1%), avoiding stressors, such as fruit injury, diseases incidence, and water stress, and cooling to reduce the rate of respiration [12, 32]. Saltveit [63] describes three main ways to control the action of ethylene by: preventing tissue exposure, its perception, and its response to ethylene. Tissue exposure can be avoided by excluding ethylene from the surrounding environment by scrubbing, inhibiting synthesis, and proper ventilation. Methods that work by blocking the perception of ethylene are: use of CO_2, silver, 1-methyl cyclopropene (MCP); reduction in temperature; and using ethylene-insensitive cultivars. MCP is being actively researched and now has been approved for use in some fruits in many countries [20, 64, 65]. The current model of its action suggests that MCP has ten times more affinity to the ethylene receptors than ethylene. This results in the beneficial effects of application of MCP in controlling ripening and senescence of fruits and vegetables.

TABLE 4.12
Adverse Effects of Ethylene on Fruits and Vegetables

Produce	Symptoms
Asparagus	Woodiness
Carrots	Bitterness due to isocoumarine formation
Potatoes	Sprouting
Lettuce	Russet spotting
Broccoli	Yellowing, abscission, off flavors
Eggplant	Browning of flesh and seeds, decay induction
Cucumber	Yellowing, softening
Sweet potatoes	Browning of pulp, off flavor, failure to soften upon cooking

4.5.5 Physiological Disorders and Breakdowns

Physiological disorders result from metabolic disturbances caused by a host of internal (nutritional imbalance) and external (temperature and surrounding atmosphere) factors. Table 4.13 lists some of the common disorders associated with common fruits and vegetables. Besides inducing serious loss of quality in terms of color, flavor, texture, and appearance, physiological disorders can predispose the produce to further deterioration by enzymes and microorganisms. When only superficial tissues are affected by the disorder, fruit may still be able to be processed without seriously impacting the quality of processed products. Maturity at harvest, cultural practices, and climate during growing season, produce size, and harvesting and handling practices can be involved in inducing disorders [25, 66, 67]. Preharvest factors that affect the incidence of postharvest disorders are: type of the produce, variety, nutritional status of produce and soil, level of maturity, temperature, fruit size and color, moisture content of soil, position of fruit on the tree, etc. Crop load and fruiting position are linked with bitter pit [66, 67] in apples and mealiness and browning of stone fruits [68]. Detailed information about the physiological disorders and diseases are covered in Refs. [69–71].

4.5.5.1 Disorders Due to Mineral Deficiencies

Plants require a balanced mineral intake from the soil and a favorable environment for proper development. Bitter pit in apples, characterized by brown lesions in flesh, dark and corky tissue below the skin, and slight bitter taste, develops due to preharvest low fruit Ca and high levels of K and magnesium. Pre- and postharvest application of Ca can control this disorder. Calcium nutrition together with maturity influences early development of water core in apples [72]. Fruit softening in papaya [73] and blossom end rotting of tomato have also been linked to low Ca levels [74]. Ca deficiency in vegetables leads to black-heart in celery, tip burn in chervil and Chinese cabbage, and blossom end rot in tomato and cucumber [75].

TABLE 4.13
Physiological Disorders of Selected Fruits and Vegetables

Fruit	Disorder	Common Symptoms	Cause
Apples	Sunscald or sunburn	White or yellow spots on the fruit facing sun followed by drying out and sunken areas	Heat stress to the tissue
	Storage scald	Irregular brown patches of dead skin developing during warming after cold storage	Chilling injury involving oxidation of α-farnesene to conjugated trienes
	Internal breakdown (brown heart)	Brown discoloration of flesh	CO_2 injury during storage
	Bitter pit	Brown lesion in flesh, dark and corky tissue below the skin	Low levels of calcium and high concentrations of potassium and magnesium, dissolution of middle lamellae by oxalic and succinic acid, changes in proton secretion and potassium permeability
	Water core	Water soaked regions in flesh and core	Inability of fruit to convert sorbitol to fructose and hence accumulation of sorbitol
Pear	Core breakdown	Brown, soft breakdown of core and surrounding tissues	Storing fruits beyond normal storage life
	Flesh spot decay	Partial browning of spots and/or development of cavities	Unknown
	Internal breakdown	Brown to dark brown water-soaked areas in core and/or flesh	Unknown
	Watery breakdown	Soft, watery deterioration	Slow cooling or exposure to warm temperatures
	Senescent scald	Brown to black discoloration of skin, loss of ripening capacity, adverse taste and odor	End of postharvest life and setting of fermentation
Pomegranates	Husk scald	Discoloration of husk	Oxidation of phenolics
	Chilling injury	Brown discoloration of skin, pitting, loss of red color of arils	Oxidation of phenolics in response to exposure to temperature <5°C
Stone fruits (apricots, peach, nectarine, plum, and prune)	Internal breakdown	Flesh browning, lack of juiciness due to mealiness or latheryness, accumulation of red pigmentation, black pit cavity, loss of flavor	Placing fruit at room temperature after cold storage during ripening Mealiness could be genetically controlled
	Inking, black stain	Brown and black spots on the skin	Abrasion damage in association with contamination with metals (iron, copper, aluminum)
	Surface pitting and bruising	Small sunken areas on skin and large flattened areas	Mechanical impact or compression
Tomatoes	Blossom drop	Fruit set failure	Prevalence of extreme temperature during pollination
	Blossom end rot	Brown to black spot on the blossom end	Calcium deficiency, excessive nitrogen fertilization
	Sun scald	Shiny white or yellow spots on the fruit facing sun followed by drying out and sunken areas	Fruit exposure to sun under extreme heat
	Fruit cracks	Radial and concentric cracks at the steam end	Heavy rainfall or irrigation after long dry period
	Catfacing	Puckering and scarring of the blossom end	Cloudy and cool weather during blooming
	Puffiness	Hollow inside and empty seed cavity	Defective pollination due to extremes of temperature, excessive nitrogen fertilization, and heavy rains

TABLE 4.14
Classification of Fruits According to Their Climate Area of Growth

Climate Zone	Examples
Temperate	Pome fruits (apple, pear, quince), stone fruits (apricot, cherry, nectarine, peach, plum), small fruits and berries (grape, strawberry, raspberry, blueberry, blackberry, cranberry)
Subtropical	Citrus fruits (grapefruit, lemon, lime, orange, pummelo, tangerine, and mandarin), non-citrus fruits (avocado, cherimoya, fig, kiwifruit, olive, pomegranate)
Tropical	Banana, mango, papaya, pineapple, carambola, cashew apple, durian, guava, longan, lychee, mangosteen, passion fruit, rambutan, sapota, tamarind

Source: Kader [12].

4.5.5.2 Disorders Due to Environmental Factors

4.5.5.2.1 Low Temperature Injuries or Disorders

Chilling and freezing injuries result from exposure of plant tissues to low temperatures. Both types of defects are prevalent in fruits and vegetables of tropical and subtropical origin, which lack the ability to adapt to low temperature environments. Table 4.14 classifies fruits according to climate area of growth and can indicate fruits susceptible to low temperature injury. The susceptible produce tend to have low storage potential as very low temperatures cannot be used during storage, transport, and handling. The lowest safe storage temperature has to be well above the chilling injury (CI) threshold of susceptible product. The CI manifests as symptoms such as pitting, browning, scalded appearance, darkening of the skin, changes in the flavor and texture, and the loss of ripening ability. The severity of the symptoms depends on the type of the produce, and time and temperature of the exposure. The mechanism of development of chilling injury is complex. Changes in the membrane lipids and dissociation of enzymes and other proteins have been proposed to be the likely causes of development of CI [35, 76, 77]. Most tropical and subtropical produce show CI upon exposure to chilling temperatures below 10–15°C [77]. Table 4.15 shows CI symptoms and the temperature at which injury symptoms appear for selected fruits and vegetables. Internal discoloration, water-soaked appearance, and increased susceptibility to plant pathogens result in the loss of quality for both fresh and processed markets. Besides, avoiding exposures to injury temperatures, CI can be minimized by reducing the exposure time to injury temperatures, precooling produce in stages to build adaptation, selection of resistant varieties, selecting fruits at the appropriate level of ripening, intermittent warming [35, 77, 78] and cooling treatments, controlled atmosphere storage (>2% CO_2 and <5% O_2), maintaining high storage relative humidity, and improving calcium nutrition [35, 39, 69, 76, 77].

Freezing injury (FI) results from exposure of plant tissues to freezing temperatures (<0°C) and formation of ice crystals, which damage the cells, mostly irreversibly. The injury initiates osmotic stress and damage to the cell membrane responsible for water loss and death of cells. The factors that affect FI are type of produce, variety, nature of solutes, field temperature, etc. [35, 69, 77]. Susceptibility of fruits and vegetables to FI varies between the produce (Table 4.16). Light freezing damages the most susceptible crops, while the least susceptible products can be frozen several times before injury occurs. Moderately susceptible produce can recover from one or two episodes or freezing. Susceptibility to FI, however, does not depend on the freezing point, which may vary between –0.1 to –1.8°C [77]. Warm season crops are more highly susceptible to FI than those that are grown in the cold season. The symptoms of the FI include discoloration of the tissue, water-soaking appearance, blistering, and pitting. The damaged tissues are prone to further decay by microorganisms and mechanical injuries, particularly bruising.

4.5.5.2.2 High Temperature Injures/Disorders

Exposure of tissues to high temperature during production or postharvest results in injuries or disorders, which may cause loss of ability to ripening normally, burnt or scorched peal, and darkening of the pulp. Examples of such disorders are scald in apples and tomatoes and blossom drop in tomatoes. Besides avoiding long exposure to sun, superficial scald in apples can be controlled by postharvest spray with ethoxyquin and/or diphenylamine [13]. The latter is more effective.

4.5.5.2.3 Injuries/Disorders Due to Exposure to Adverse Atmospheres

Exposure to low levels of O_2 and/or high levels of CO_2 may lead to tissue injuries such as internal browning in apples and pears when the tissue tolerance is exceeded. The factors that influence the susceptibility are variety, low crop load, exposure to higher concentration of CO_2 at the time of harvest and presence of coatings that restrict the diffusion of gases [68].

4.5.6 Other Biochemical Changes

Chemical and enzymatic changes cause tissue softening, off flavors, pigment loss and off-colors, and overall decline in nutritional value and taste [27]. The enzymes that catalyze biochemical reactions responsible for these changes are given in Table 4.17. Softening of the tissues can be due to hydrolysis of starch and cellulose by amylases and cellulose enzymes, respectively, and degradation of pectin by pectinases. There are three key enzymes involved in the degradation of pectins, endo- and exopectate hydrolases and pectin esterase. Endopectate hydrolase yields methyl galacturonide oligomer, and exopectate hydrolase acts on demethylated pectin produced by pectin esterase to produce galacturonic acid.

TABLE 4.15
Chilling Injury of Fruit and Vegetables Stored above Freezing Temperatures

Class	Produce	T_{inj}[a]°C	Symptoms
A (0–5°C)	Apples (some cultivars)	2–3	Internal browning, brown core, soggy tissues and soft scald
	Asparagus	0–2	Dull, grey-green, limp tips
	Avocados	4.5–13	Grayish brown discoloration of flash
	Lima beans	1–4.5	Rusty brown specks, spots, or areas
	Cranberries	2	Rubbery texture, red flash
	Guavas	4.5	Pulp injury, decay
	Cantaloupes	2–5	Pitting, surface decay
	Watermelon	4.5	Pitting, objectionable flavor
	Oranges	3	Pitting and brown stain
	Pomegranate	4.5	Pitting, external and internal browning
	Potatoes	3	Mahogany browning, sweetening
	Tamarillos	3–4	Surface pitting and discoloration
B (6–10°C)	Snap beans	7	Pitting and russeting
	Cucumber	7	Pitting, water-soaked spots, and decay
	Eggplant	7	Surface scald, Alternaria rot, blackening of seeds
	Limes	7–9	Pitting, turning tan with time
	Honeydew melon	7–10	Reddish tan discoloration, pitting, surface decay, failure to ripen
	Casaba, Crenshaw, and Persian melons	7–10	Pitting, surface decay, failure to ripen
	Okra	7	Discoloration, water-soaked areas, pitting, decay
	Fresh olives	7	Internal browning
	Papaya	7	Pitting, failure to ripen, off flavor, decay
	Sweet peppers	7	Sheet pitting, Alternaria rot on pods and calyxes, darkening of seed
	Pineapple	7–10	Dull green when ripened
	Pumpkin (hardshell and squashes)	10	Decay, especially Alternaria rot
	Tomatoes (ripe)	7–10	Water soaking
C (11–20°C)	Banana (green or ripe)	11.5–13	Dull color when ripened
	Grapefruits	10	Scald, pitting, watery breakdown
	Jicama	13–18	Pitting, membranous staining, red blotch
	Mangoes	10–13	Grayish scald like discoloration of skin, uneven ripening
	Sweet potatoes	13	Decay, pitting, internal discoloration, hard core when cooked
	Tomatoes	13	Poor color when ripe, Alternaria rot

Source: Wang [77].
[a] Approximate lowest safe temperature.

Formation of galacturonide oligomer and galacturonic acid leads to softening of plant tissues. However, formation of calcium pectate as a result of addition of calcium has a firming effect on the tissue. The activity of pectin-degrading enzymes seriously impacts the gel-forming ability of fruits fundamental to the production of fruit preserves.

Fruits and vegetables contain varieties of phenolic compounds that participate in browning reactions catalyzed by enzymes. Cutting or injuring plant tissue results in browning of the cut surface due to enzymatic oxidation of phenolic compounds due to cell de-compartmentation of substrate and enzymes. In the presence of O_2, phenolases oxidize phenols to benzoquinones, which, although colorless, are further converted into brown pigments in fruits and vegetables (potato, mushroom, apple, and banana). While the physiological role of these enzymes in plant cells is not very well understood, these are produced by plants in response to environmental stress. These compounds have strong antioxidant activity. The factors influencing enzymatic browning are type and content of phenolic substances, enzymes, temperature, and presence of

TABLE 4.16
Relative Susceptibility of Fruits and Vegetables to Freezing Injury

Highly Susceptible	Moderately Susceptible	Slightly Susceptible
Vegetables		
Artichoke	Cabbage	Beetroots
Asparagus	Carrot	Brussels sprouts
Beet	Cauliflower	Celeriac
Broccoli	Chives	Collard
Celery	Endive	Horseradish
Cucumber	Leek	Kale
Eggplant	Onion (bulb)	Kohlrabi
Sweetcorn	Onion (green)	Parsnip
Lettuce	Parsley	Rutabagas
Okra	Shelled peas	Salsify roots
Sweet pepper	Peas (pod)	Turnip roots
Potatoes	Radish	
Summer squash	Spinach	
Sweet potatoes	Winter squash	
Tomatoes		
Fruits		
Apricot		
Avocado	Apples	Dates
Banana	Cranberries	
Berries (except cranberries)	Grapes	
Lemon	Oranges	
Limes	Pears	
Peaches		
Plums

TABLE 4.17
Enzymes Responsible for Key Reactions Associated with Ripening and Senescence in Fruits and Vegetables

Enzyme	Reaction	Result
Polyphenoloxidase, catalase, and peroxidase	Oxidation of phenolics	Formation of precursors to colored polymers leading to undesirable browning
Polygalacturonase	Hydrolysis of glycosidic bonds between adjacent polygalacturonic acid residues in pectin	Tissue softening
Pectin esterase	Hydrolysis of ester bonds of galacturonans in pectin	Tissue firming
Lipoxigenase	Oxidation of lipids	Production of off flavor and off odors
Ascorbic acid oxidase	Oxidation of ascorbic acid	Loss of nutrition quality
Chlorophyllase	Cleavage of phytol ring from chlorophyll	Loss of green color
Amylases	Hydrolysis of amylose and amylopectin	Loss of texture and increase in sweetness due to production of sugars
Cellulase and hemicellulases	Hydrolysis of cell wall	Loss of texture
Proteases	Hydrolysis of proteins	Loss of nutritional value and increase or decrease in digestibility
Lipase	Hydrolysis of lipids	Hydrolytic rancidity
Phytase	Hydrolysis of phytic acid	Liberation of phosphates
Glucose oxidase	Oxidation of glucose	Formation of hydrogen peroxide

inhibitors. Chlorogenic acid, a phenol found in potatoes, is also responsible for after-cooking blackening of potatoes. The reaction involves formation of ferric-dichlorogenate from chlorogenic acid and ferrous ions [58]. Conditions leading to a higher ratio of chlorogenic acid to citric acid are conducive to after-cooking blackening. Postharvest sweetening of potatoes is a serious problem in cold-stored potatoes due to conversion of starch to sugars, which can lead to non-enzymatic browning in potato chips and can be avoided by warming the potatoes before use. Injuries can also lead to the formation of stress metabolites through linoleic/linolenic acid cascade producing traumatin and jasmonic acid, which have a role in forming a defense system against insects and microorganisms. Degradation of lipids by lipase and lipoxigenase enzymes can lead to the formation of off flavors in fruits and vegetables (e.g. beans and peas) and can be avoided by inactivating these enzymes or by knocking the genes responsible for their expression.

4.6 CONCLUSION

Fruits and vegetables are live tissues, which have unique postharvest characteristics that influence the postharvest quality of both fresh and processed products. In this chapter, a brief overview of postharvest quality and its relationship to physiological processes is provided. Data on postharvest physiological processes such as respiration, maturity and senescence, and transpiration should be useful to both the fresh and processed food industries in providing the ideal quality required by the modern consumer.

5 Postharvest Handling and Treatments of Fruits and Vegetables

V. K. Mishra and T. V. Gamage

CONTENTS

5.1 INTRODUCTION

The quality of fruits and vegetables deteriorates progressively after harvest within a short time due to a series of physical, physiological, and pathological agents the produce is exposed to before reaching a consumer or a processor. Handling operations vary according to the produce. Figure 5.1 depicts a generic postharvest value chain with common handling operations. Both quantitative (reduction in weight and wastage due to biotic factors) and qualitative (reduction in color, flavor, and texture) losses anywhere along the chain occur in the field, during packaging, storage, distribution, and transportation. Postharvest management practices facilitate the continuous supply of fruits and vegetables to fresh, minimally processed, and processed markets. Given the distance between the sites of production and consumption, these perishable commodities need to travel a long distance, and hence the maintenance of quality over the entire value chain is an onerous task. Generally, fruit and vegetable processing is very seasonal in nature, and the harvested produce must be quickly processed to avoid losses. The processor must assure that all the quality attributes at the time of harvest are maintained before processing. Normally, quality at harvest can only be maintained and not improved down the value chain except for climacteric fruits, which can be ripened after harvest to achieve ideal eating quality.

A good quality processed product can only be possible when good quality raw materials are used in its manufacture. Only those cultivars that are suitable for a particular process application are procured. Cultivars suitable for table-fresh markets are very different from those which are suited for processing. Generally, the produce is harvested at the stage when the eating quality is at its peak as this commands maximum market revenue. Quality specifications vary according to the raw material required for a given processing application and often include optimum color, texture, and flavor; freedom from pathogens and spoilage microorganisms including their metabolic products; freedom from toxic residues such as

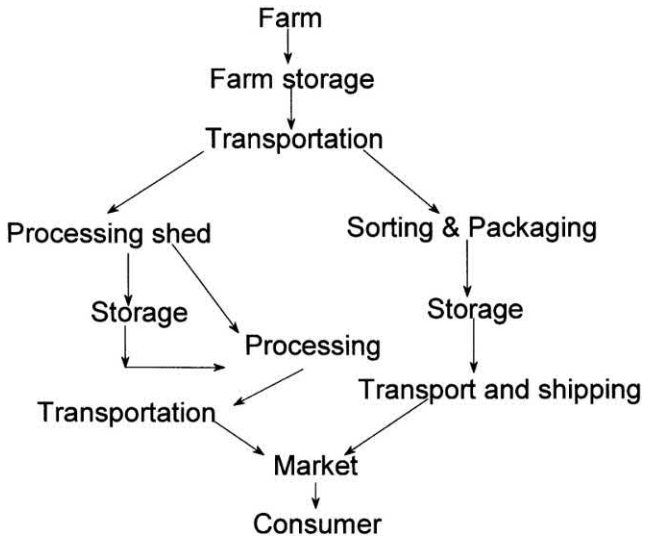

FIGURE 5.1 Postharvest value chain for fruit and vegetables.

pesticides; reasonable storage life, high nutritive value; and extended availability. Table 5.1 lists the quality specifications requirements for various fruit and vegetables processed into various products.

5.2 POSTHARVEST HANDLING OPERATIONS

5.2.1 Sorting and Grading

Most fruits and vegetables are sorted and graded for marketing and these processes have a role in protecting and enhancing product quality. These are generally an important part of field or packinghouse operations and help in reducing cross-contamination of healthy stock destined for storage, transport, distribution, marketing, and processing, in addition to facilitating ease in trade. The produce is sorted according to size, shape, color, and appearance after passing the minimum requirements of quality. The damaged and immature fruits must be removed, as these might become sources of ethylene gas, which will increase the rate of respiration, ripening, and senescence of healthy produce.

Grading determines whether the product meets a specific quality standard prescribed by the local or international market, separates products into different quality grades to determine the price paid to the farmers or to determine the sale value, and enables removal of off-grade products. Grade standards and specifications vary between and within countries, and local authorities should be consulted for updates. Optimal maturity, color, sugar, solids, moisture content, size, and absence of defects are some of the factors considered for various fresh market products. The domestic marketing orders of the USDA specifies mandatory grades for avocados, Irish potatoes, limes, filberts, raisins, onions, table grapes, walnuts, kiwifruit, dates, prunes, canned ripe olives, grapefruits, tomatoes, and oranges [1].

Traditionally sorting and grading are done by hand, which is extremely labor-intensive. Labor shortages and a lack of overall consistency have driven the search for automation of this operation. Color and shape are sorting parameters used in the implementation of many automated vision systems, which involve image acquisition and processing. Optical sorting is currently being used for apples destined for canning in Australia. Magnetic resonance spectroscopy and imaging, near infrared spectroscopy, acoustic response, and impact response are being investigated for their utility in automated sorting and grading of produce. Equipment used in dumping, conveying, and grasping during sorting and grading should have smooth and properly cushioned surfaces to avoid injury.

TABLE 5.1
Raw Material Quality Specifications for Processed Fruit and Vegetables

Processed Products	Raw Materials	Quality Specifications
Fruit juices	Citrus, apple, tomatoes	Acidity, sugar content, flavor
Chips and fries	Potatoes, banana, taro	Texture, starch content, and reducing sugars
Canned products	Apples, peach, pear	Color, texture, flavor
Preserves	Various fruits: apples, peaches	Sugar, pectin content, acidity
Pickles	Cucumber, olive, cabbage	Composition, sugar content, texture
Concentrates: sauce, puree	Tomatoes, apple	Total solids
Alcoholic beverages	Grapes, apples	Fermentable sugar, acidity
Dried products	Mango, apricot	Composition, solid content
Frozen products	Peas, carrots, onions	Composition, color, texture, flavor

5.2.2 Packaging

The packaging contributes greatly to efficient marketing of fruits and vegetables as it (i) serves as an efficient handling unit, (ii) provides a convenient warehouse or home storage unit, (iii) protects quality and reduces waste by avoiding mechanical damage, reducing moisture loss, providing a beneficial modified atmosphere, providing clean or sanitary produce, preventing pilferage, (iv) provides service and sales motivation, (v) reduces cost of transport and marketing, and (vi) facilitates the use of new modes of transportation [2].

Two types of packaging are common in the fresh produce trade. Large-sized containers are used for transport and wholesale, and small-size packagers for retail trade. Properly designed containers for transporting and marketing can maintain product freshness, succulence, and quality by significantly reducing mechanical damage during handling, transport, and storage. The container must be strong enough to withstand stacking and impact of loading and unloading, without bruising or scarring the produce. Thus, containers may require the use of liners, pads, trays, or tissue wraps to

prevent damage from contact with rough surfaces or adjacent produce. The produce can be packed in box (wooden or paper) with absorbent, lining, or padding materials or in bags. The choice of packaging material is based on the requirements of stacking height, duration of storage, pretreatments, cooling, and cost. Lug and pallet boxes are also used. Pallet boxes are used for bulk handling, which saves loading and unloading time, and manual labor [3].

5.2.2.1 Types of Damage

The fresh produce is mechanically or manually handled several times on packing lines before it arrives at the point of consumer purchase. Mechanical damage occurs in the postharvest handling system primarily by impact and compressive forces. The compressive forces act on the product when it is handled in bulk and are normally static loads (in bins, stacks) or dynamic compressive loads (bin handling and transport). The excessive impacts occur during harvesting, grading, handling, and transportation, and excessive compression loads occur during bulk and package handling.

Bruising results from fruit hitting each other during transportation and handling, and from contact with the hard surfaces of machinery, the container, or other handling equipment. Bruising can be caused by intermittent shocks, compressive forces, or prolonged low-level vibrations occurring during transportation of produce from the orchard or field to the packing house, and from the packing house to the retail store [4]. Bruising causes enzymatic browning in apples, pears, peaches, apricots, grapes, and bananas.

Compression damage is the primary cause of damage to fruit while it is handled in bulk. The force on the product is transferred from the vehicle transporting the bin to the produce. The energy is dissipated through movement of the product and absorption by the produce. The severity of the levels of bruising resulting from bulk handling has been reported in various studies. The forces vary considerably within bins according to the load paths due to the produce stacking pattern. This loading pattern is also influenced by the bin design and the transport method [4].

5.2.2.2 Cushioning and Other Protections

Packing line equipment and other harvesting and postharvest handling equipment are traditionally designed and installed using many transfers from one operation to the next. During this handling the produce hits (impacts) hard surfaces or other produce. Cushioning and velocity control devices can avoid bruising in handling systems. A cushioning material must provide effective energy absorption and dissipation and not create the critical stress/strain level in the produce tissue that will initiate bruising. The packing line should be designed with an appropriate drop height or roll velocity. If hard surfaces on the equipment are adequately cushioned, and the roll velocity of each item is controlled to a low enough level, impact bruises can be avoided.

Immobilization and proper cushioning of the produce help in reducing damage due to cuts, punctures, bruises, abrasion, impact, and friction. This is done by the use of various types of trays, or by certain volume fill techniques, such as padding or cushioning [3]. The material used for padding should (i) have the ability to absorb the impact energy without damaging the produce, (ii) not impart a high rebound energy to the produce, (iii) have durability to internal structure fatigue and surface wear (needs lower thickness), (v) cushion cleanup, sanitation, and compatibility with water, fungicides, waxes, and cleaning solutions must be excellent, (vi) cushion physical properties (thickness, stiffness). The materials that can be used are PVC, polyethylene, neoprene, polyurethane, wool carpet, polypropylene, and poron. The materials are usually made with a porous internal structure and specific surface characteristics [4]. Commonly used padding materials are leaves, straw, grass, coconut husk, paper, and plastics.

Plastic films, mesh, or net, plastic-lined paper may also be used to prepackage fresh produce. Individual seal packaging or uni-packaging creates a water-saturated atmosphere around the fruit and reduces water loss and shrinkage. The advantages are that (i) it may be an alternative to expensive traditional refrigeration and sophisticated controlled atmosphere storage, (ii) it doubles and sometimes triples the shelf life, (iii) it also delays physiological deterioration better than when only cooling alone is used, (iv) it may reduce chilling injury in some fruits, such as in citrus. Films used in packages may be used as carriers of fungicides to reduce toxic residue in products and/or ethylene absorbing substances to delay ripening. The use of perforated films allows optimum gas exchange and avoids the accumulation of ethylene in the enclosed micro-atmosphere [6]. Perforated films are more suited to high O_2-demand produce. The limitation of using seal packaging is the possibility of development of off-flavors caused by poor gas exchange and enhancement of decay and spoilage due to the phytotoxic micro-atmosphere (low oxygen, excessive carbon dioxide and ethylene).

5.2.3 Transportation

The harvested produce is transported to the packing and processing sheds inland via road by trucks in pallet boxes. Bulk trucks are used for fruit such as oranges and vegetables. Overseas transportation is normally by sea and rarely by air. The proper management of temperature, humidity, and ventilation is the main requirement. Bruised, decayed, and overripe products are sorted out before transportation to avoid dissemination of diseases, induction of ethylene gas, increase in respiration, and evolution of heat and loss of water. When large-sized products, such as watermelons, muskmelons, pumpkins, yams, and cabbages, are transported in bulk using trucks, trolleys, or lorries, products should be carefully stacked and adequately covered to protect from the environment.

Refrigeration during transportation is the most effective means of reducing losses. Proper insulation and ventilation of trucks help in minimizing loss of quality. The following measures have been suggested to minimize heat accumulation during the transportation of fruit and vegetables [7, 8]: (i) avoiding closed vehicles without refrigeration except for local

deliveries, (ii) fitting open-sided or half-boarded trucks with roofing and siding to protect produce from direct sun and wind exposures; (iii) fitting a second white painted roof 8–10 cm above the main roof to act as radiation shield; (iv) provision for air intake in conjunction with louvers in unrefrigerated vehicles used in long-distance transport to ensure positive airflow through the load; and (iv) equipping transport vehicles such as trucks, rail cars, and sea containers with refrigeration for long journeys. Another important consideration is to make sure that only compatible fruits and vegetables are transported together. Table 5.2 provides the listing of commodities that are compatible during transportation and storage.

5.2.4 Precooling

Good temperature management throughout the postharvest chain is key to avoiding postharvest losses and to the preservation of quality. Rapid cooling of the produce to a safe storage and transportation temperature is imperative in the preservation of quality and to increase the shelf life by arresting the deteriorative changes caused by physiological and pathological agencies. The harvested produce contains a substantial amount of heat associated with the product temperature which is known as field heat, a significant part of cooling load. Precooling is the rapid extraction of heat from the product before transport, storage, and processing. Depending on the temperature and type of fruit or vegetable, the product will lose its quality in a short time unless promptly and appropriately cooled. Precooling assists in reducing the rates of metabolic activity, such as respiration, transpiration, and ethylene production, minimizing growth of decay microorganisms, and easing the load on the cooling system downstream for storage. Improved flexibility in marketing is an additional benefit.

The amount of field heat necessary to be removed depends on the produce and the required storage temperatures. At the time of harvest, the produce temperature is the same as that of the environment; wherever possible, the produce must be harvested when the ambient temperature is low, during night, morning, or evening, to avoid high cooling loads. The amount of heat to be removed can be estimated by methods described in several publications [9–11] or estimated from the compositional data [12].

TABLE 5.2
Compatibility Groups for Transport and Storage of Fresh Fruit and Vegetables

Group	Temperature (°C)	RH (%)	Commodity
1	0–2	90–95	Apples, apricots, beets (topped), berries (except cranberries), cashew apples, cherries, coconuts, figs (not with apples), grapes (without sulfur dioxide), horseradish, kohlrabi, leeks, longan, loquat, lychee, mushrooms, nectarines, oranges,[a] parsnips, peaches, pears, persimmons, plums, pomegranates, prunes, quinces, radishes, rutabagas, turnips
2	0.2	95–100	Amaranth,[b] anise,[b] artichokes,[b] asparagus, bean sprouts, beets,[b] Belgian endive, berries (except cranberries), bok choy, broccoli,[b] Brussels sprouts,[b] cabbage,[b] carrots,[b] cauliflower, celeriac,[b] celery,[b] cherries, corn (sweet),[b] daikon,[b] endive,[b] escarole,[b] grapes (without sulfur dioxide), horseradish, Jerusalem artichoke, kiwi fruit, kohlrabi,[b] leafy greens, leeks[b] (not with figs or grapes), lettuce, lo bok, mushrooms, onions[b] (green not with figs, grapes, mushroom, rhubarb or corn), parsley,[b] parsnip,[b] peas,[b] pomegranate, raddichio, radishes,[b] rhubarb, rutabagas,[b] salsify, scorzonera, snow peas, spinach, turnips,[b] water chestnut, watercress
3	0.2	65–75	Garlic, onions (dry)
4	4.5	90–95	Cactus leaves, cactus pears, caimito, cantaloupes,[b] clementines, cranberries, lemons,[a] lychees, kumquat, mandarin,[a] oranges (California and Arizona), pepino tamarillo, tangelos,[a] tangerines,[a] ugli fruit,[a] yucca root
5	10	85–90	Beans, calamondin, chayote, cucumber, eggplant, haricot vert, kiwano, malanga, okra, olive, peppers, potatoes, pummelo, squash (summer and soft shell), tamarind, taro root
6	13–16	85–95	Atemoya, avocados, babaco, bananas, bitter melon, black sapote, boniato, breadfruit, canistel, carambola, cherimoya, coconuts, feijoa, ginger root, granadilla, grapefruit, guava, jaboticaba, jackfruit, langsat, lemons,[a] limes,[a] mammy, mangoes, mangoseen, melons (except cantaloupes), papaya, passionfruit, pineapple, plantain, potatoes (new), pumpkin, rambutan, santol, soursop, sugar apple, squash (winter, hard shell), tomatillos, tomatoes (ripe)
7	18–21	85–90	Jicama, pears (for ripening) sweet potatoes,[c] tomatoes (mature green), watermelon,[c] white sapote, yams[c]

Source: McGregor [8].

Group 1: Many products produce ethylene.

Group 2: Many products are sensitive to ethylene.

Group 3: Moisture damages these products.

Groups 4 and 5: Many products are sensitive to ethylene and/or chilling injury.

[a] Citrus fruits treated with biphenyl may give odors to other products.

[b] Can be top iced.

[c] Separate from pears and tomatoes due to ethylene sensitivity.

5.2.4.1 Methods of Precooling

Precooling can be accomplished by simply blowing cold ambient air over the produce; however, refrigeration is required for ensuring the short cooling time that is critical in preventing the loss of quality. Cooling rates depend on the type of product, its size, weight, and the surface-area-to-volume ratio. A small-sized product with a large surface-area-to-volume ratio cools at a faster rate. Cooling rates are often expressed as several half-cooling times and can be used for comparing and predicting the effectiveness of different cooling methods for a given cooling time interval irrespective of the temperature of the produce or cooling medium used. Half time is the time required to reduce the temperature difference between the product and the cooling medium by one-half. Figure 5.2 shows a typical cooling curve for a product being cooled from an initial temperature of 30°C by air maintained at 2°C. As depicted in the figure the rate of cooling slows down as cooling progresses. The curve shows three half-cooling periods corresponding to one-half, three-quarters, and seven/eighths cooling, which is generally considered adequate for the transport and storage of most commodities. The essential information required for the design and operation of coolers is available in several publications [9–15]. The most commonly used methods of precooling are described in the following sections.

5.2.4.1.1 Room Cooling

This method involves using cold air as a medium to extract heat from the produce. High relative humidity (90–95%) is maintained in the air to avoid desiccation and weight loss during cooling. The method is not recommended for produce packed in bulk. For efficient heat removal, the produce container should be well-vented and stacked so that the container surface is in contact with cold air and the storage space is utilized to the maximum extent. Since the rate of heat removal by still air is slow it takes longer to cool produce to a safe transit or storage temperature.

5.2.4.1.2 Forced Air or Pressure Cooling

This is a modification of room cooling where cold air is forced through the produce containers and around the produce to speed up cooling to reduce cooling time to 10–25% compared to room cooling. Fans specially positioned in the room create the pressure differential to circulate air. Cooling time depends on the speed of the airflow provided sufficient refrigeration capacity is available for a given duty. The problems of moisture condensation on the produce, package, and the wall are eliminated due to air movement. Forced air cooling is accomplished by using three systems: cold wall, forced air tunnel, and serpentine cooling.

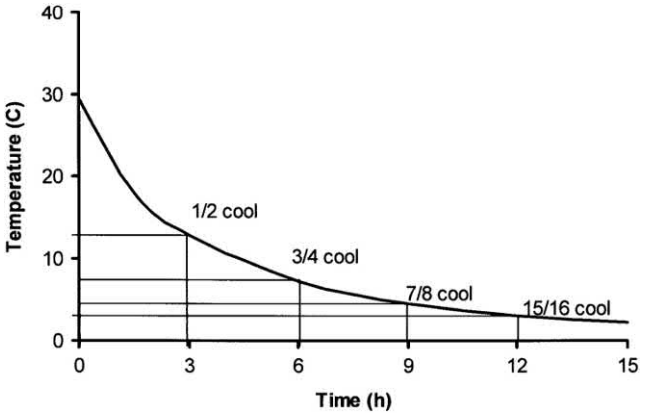

FIGURE 5.2 Typical cooling curve showing half cooling times for fruit and vegetables.

5.2.4.1.3 Package Icing

This method involves keeping finely crushed, flaked ice or an ice–water mixture in direct contact with the produce for cooling and maintaining low temperatures during short-term storage, transit, and display in superstores. The latent heat of melting of ice (334 kJ/kg) provides the cooling effect. The method is limited to products that can tolerate both the weight of the ice and water that wets the product and the package. It is commonly used for cooling spinach and broccoli during transport and retail displays. Use of ice slurry is recommended to avoid mechanical damage due to sharp end ice.

5.2.4.1.4 Hydrocooling

Hydrocooling is a rapid way to cool large batches of product by spraying or flooding the commodity with near-freezing water (~0°C). Near-freezing water cools product about 15 times faster than air, allowing for greater harvesting and marketing flexibility. While there is no desiccation of the product, water can be a source of contamination if soil and debris picked up during cooling are not removed before recycling. Water needs to be appropriately filtered and disinfected. Chlorination is used to disinfect water at 50–200 ppm. Hydrocooling is best suited to medium- to large-scale cooling of product and packages that are both water- and chlorine-tolerant.

5.2.4.1.5 Vacuum Cooling

The cooling effect is generated by partial evaporation of moisture directly from the product, which is placed in a chamber, and a vacuum is drawn to <1 kPa from atmospheric pressure. Evaporation results from a reduction in the vapor pressure of water under vacuum. This method does not require any cooling medium and is relatively faster for compatible produce (leafy vegetables such as Asian greens, silverbeet, broccoli) (www.postharvest.net.au/postharvest-undamentals/cooling-and-storage/cooling-methods/). The reduction in product temperature for a unit percent weight loss can be determined by the ratio of the latent heat of vaporization and heat capacity of the produce. Wang and Sun [16] calculated a reduction of 6.5°C/1% weight loss for leafy vegetables containing 90% moisture with a corresponding shelf life of 2.5 days at 12°C for head lettuce, which were cooled for 20 mins, sealed in polypropylene film and stored for a week at 2°C. This method is suitable for products that have a high surface-to-mass ratio, freely available water, are highly porous, and whose structure will not be damaged by the removal of water. The product may incur a weight loss of about 3–4%; however, adding a

preselected amount of water before or during pre-cooling can prevent weight loss.

5.2.4.1.6 Evaporative Cooling

This is a relatively inexpensive method suitable for precooling produce that requires relatively warmer storage temperatures, such as tomatoes and cucumber. The cooling effect results from the evaporation of water when dry air is blown over wet product. In the process of evaporation, water absorbs energy from dry air to reach its latent heat of vaporization (2260 kJ/kg) and change its phase from liquid to vapor. The method is suited to areas where low ambient humidity (<65% RH) air is readily available.

The choice of an appropriate cooling method is a very important decision that a grower or packinghouse needs to make. The decision is based on (i) the nature of the product to be cooled (e.g. chilling sensitivity), (ii) The temperature of the produce at the time of harvest, (iii) The cooling time required, (iv) The product throughput, (v) the type of packaging used, (vi) The desired storage life, and (vii) the comparative energy efficiency, availability, and associated capital and operating costs. Highly perishable fruits, such as strawberries, bush berries, and apricots, need be cooled to their optimum storage temperature (0°C) in a relatively shorter time (within 6 hours of harvest) than most other fruits (within 12 hours of harvest) [13]. Thompson [9] compared common methods of precooling based on cooling time, moisture loss, water contact with the product, potential for decay contamination, capital cost, energy efficiency, need for water-resistant packaging, portability, and feasibility of in-line cooling. Precooling methods suitable for selected fruit and vegetables are given in Table 5.3.

TABLE 5.3
Recommended Precooling Methods for Selected Fruit and Vegetables

Fruit or Vegetable	Precooling Methods Used
Asparagus	Hydro-cooling, package icing
Apples	Room, forced air, and hydro-cooling
Apricots	Room and hydro-cooling
Beans, snap	Room, forced air, and hydro-cooling
Broccoli	Package icing, forced air, and hydro-cooling
Brussels sprouts	Hydro-cooling, vacuum, and package icing
Cabbage	Room, forced air cooling
Cauliflower	Hydro-cooling and vacuum cooling
Cherries	Forced air and hydro-cooling
Cucumber	Forced air and hydro-cooling
Grapes	Forced air cooling
Lettuce	Hydro-cooling and package icing
Peas	Forced air and hydro-cooling
Potato	Forced air and hydro-cooling
Peaches	Forced air and hydro-cooling
Pears	Room, forced air, and hydro-cooling
Spinach	Hydro-cooling and package icing
Tomato	Room and forced air cooling

5.2.5 Storage and Distribution

Most horticultural produce has a short harvesting season, and short- and/or long-term storage is necessary to not only extend the marketing period for fresh produce but also to regulate the product flow and extend the processing season. The main objectives of storage are (i) to extend the availability of fresh produce in the market, (ii) to ensure the continuous supply of quality raw material to the processors, (iii) to extend the length of the processing season, (iv) to hold raw material obtained during favorable price situations, (v) to condition certain commodities, such as potatoes, onions, and garlic, (vi) to ripen certain fruits, such as mangoes and bananas [15].

Storage requirements vary among fruits and vegetables and can be classified into five groups [10] (Table 5.4) that are based on the rates of respiration and ethylene generation, and perishability. Storage life of <2 weeks to >16 weeks may be observed depending on the commodity. For example, green onions are highly perishable with <2 weeks of storage life compared to 8–10 weeks for dried onions. Variations do exist between and within fruit and vegetable and their cultivars. The storage potential of onions follows the order: yellow > red > white > Spanish and sweet [10]. Most vegetables, except root and tuber crops, are consumed fresh and do not require storage

TABLE 5.4
Storage Potential of Horticultural Produce in Air at Near-Optimum Storage Temperature and Relative Humidity

Class	Storage Life (weeks)	Degree of Perishability	Commodity
I	<2	Very high	Apricot, blackberry, blueberry, cherry, fig, raspberry, strawberry, asparagus, bean sprouts, broccoli, cauliflower, green onion, leaf lettuce, mushroom, muskmelon, pea, spinach, sweetcorn, tomato (ripe)
II	2–4	High	Avocado, banana, grape, guava, loquat, mandarin, mango, melons, nectarine, papaya, peach, plum, artichoke, green beans, Brussels sprouts, cabbage, celery, eggplant, head lettuce, okra, pepper, summer squash, tomato (partially ripe)
III	4–8	Moderate	Apples and pea (some cultivars), grape (sulfur dioxide treated), orange, grapefruits, lime, kiwi, persimmon, pomegranate, table beet, carrot, radish
IV	8–16	Low	Apple and pears (some cultivars), lemon, potato, dry onion, garlic, pumpkin, winter squash, sweet potatoes, taro, yam
V	>16	Very low	Tree nuts and dried fruits

Source: Kader [10].

for a significant length of time unless they will be used as raw materials for processing. For some vegetables the time elapsed from harvesting to consumption or processing is the only time spent in storage. On the other hand, vegetables such as potato, yam, sweet potato, garlic, and ginger can be kept *in situ* for several months after they attain maturity and removed from storage environments before the rainy season to prevent rotting and sprouting. *In situ* storage of these vegetables is easy and economical due to limited expenditure and fabrication for storing. Underground storage in pits and trenches by mounting soil on the surface is most suitable for short-term storage. Hay or straw and then soil are used to protect the surface from water leakage and freezing. Pits are used for storing beet, potato, carrot, turnip, cabbage, parsnip, etc. The disadvantages of underground storage include expensive labor, variable climatic conditions, and adverse weather [18, 19].

Refrigerated or cold storage has established itself as the most accepted storage method all over the world. Its use is determined by the cost and benefit considerations. The storage life of selected fruits and vegetables at given temperature and humidity is given in Table 5.5. In general, commodities store well above the chilling injury threshold temperatures for tropical and subtropical fruits and above the freezing point for temperate fruits. Comprehensive compilation of storage information in terms of optimum temperature, and humidity in normal and modified or controlled atmospheres can be found in several references [2, 7, 9–11, 13, 17–19]. The Optimal Fresh Database, developed by the Sydney Postharvest Lab and Food Science Australia [20], presents information on refrigerated container/cold room recommendations, produce properties (freezing point, humidity, storage time at ambient and at optimal temperature), suitability and conditions for controlled atmosphere storage, respiration and heat transfer, compatibility in mixed storage, and seasonal availability for many fruits and vegetables.

Rooms used for cold storage should provide adequate insulation, working space, vapor barrier, and doors that disallow the ingress of air from outside. Good air circulation is required to assure uniform temperature and humidity in the room. A minimum clearance of 100 mm should be kept from the walls and floors and between pallets while stacking the produce [21]. An efficient operation of storage system involves: acceptance of only high quality produce for storage; rapid cooling of the produce to the storage temperature; storing only compatible mixed load; maintenance of recommended temperature, humidity, and/or gaseous atmospheres; precise monitoring and control of temperature, humidity; and efficient product movement to avoid excessive storage [22].

Often it is necessary to store or transport several types of produce at once. However, the produce should be compatible with one another. The factors that determine the compatibility of products are (i) temperature, (ii) relative humidity, (iii) production of ethylene, (iv) sensitivity to ethylene, (v) production and absorption of objectionable odors or flavors, and (vi) difficulties in loading shipping containers or stores of different

TABLE 5.5
Optimum Storage Temperature and Humidity Conditions for Fresh Fruit and Vegetables

Produce	Optimum Temperature, ˚C	Freezing Temperature	Relative Humidity, %	Storage Life
Apple	–1 to 4.4	–1.7	90–95	1–12 months
Asparagus	2.2	–1.1	95–100	2–3 weeks
Blueberries	0.6–1	–2.2	90–95	2–3 weeks
Broccoli	0	–0.6	95–100	2 weeks
Cabbage	0	–1.1	95	2–3 months

sizes and shapes. Compatibility groups for the storage of fruits and vegetables are given in Table 5.2.

5.3 POSTHARVEST TREATMENTS

Postharvest treatments generally aim at preserving and/or enhancing the quality of fruits and vegetables by controlling the physiological, mechanical, and pathological agents responsible for both postharvest losses and degradation of quality. These may be described as physical and chemical treatments.

5.3.1 Physical Treatments

Physical treatments are mainly considered to be chemical-free, such as cleaning, washing, waxing, heat, and irradiation, and result in an absence of chemical residue in the products. They involve less hazard as compared to the chemicals.

5.3.1.1 Cleaning and Washing

The main goals of cleaning are to (i) eliminate surface dirt and soil particles and contaminants, (ii) remove residues of pesticides, fertilizers, and chemicals used during production, (iii) reduce the microbial load, and (iv) enhance the appearance of the produce. Cleaning can be accomplished using air (dry) or water (washing). Dry brushing with or without air blast may be used to remove loose scales, soil, or dust in products such as onions, garlic, potato, sweet potato, cantaloupes, and melons.

The effectiveness of the washing depends on: the amount of water used, characteristics of water (acidity, hardness, mineral content, temperature, and the initial level of contamination), force applied, use of brushing and rubbing aids, etc. The water used for cleaning should be of acceptable quality and must be filtered and sanitized before reuse. Washing is not an effective method for removing fungi from the infected tissues and may even predispose produce to decay organisms and deplete the protective wax layer. Washing may also lead to water-soaked appearance and moisture penetration, which may aid in pathogen access through the wounds. This is the reason why strawberries, mushrooms, cucumber, and cherries are not generally washed. If fruit is excessively dirty a detergent may be used prior to a sanitizing treatment. The final rinse should be carried out using clean water. Removal of excess surface water by blotting rollers or blowing air over fruits may be necessary to avoid infection and subsequent decay in stone fruits and potatoes [3].

5.3.1.2 Coating and Waxing

The presence of surface wax is a natural defense mechanism in fruits and vegetables against water loss and invasion from pests and disease-causing organisms. Rough handling, approaching senescence, and washing deplete natural waxes. Surface coating using wax or hydrophobic substances has been used since ancient times to improve the appeal and acceptability for the consumer, ease of packing and handling, and to extend the shelf life by reducing weight (water) loss. Retention of color, firmness, flavor, and the prevention of loss of weight result from (i) reduction in the rates of respiration and transpiration, (ii) protection from insects, pests, and fungi causing diseases and deterioration, (iii) generation of local modified atmosphere, (iv) protection from mechanical injuries, and (v) curing of tiny injuries and scratches on the surface [3]. Significant economic benefits accrue by waxing due to resultant water loss reduction to an extent of 30–50% in normal commercial handling and storage conditions [22]. However, coating may not be always favorable as modification of the internal atmosphere can reduce the available oxygen leading to fermentation, which can be precluded by only a thin layer of wax to allow gas exchange through it. The literature related to coatings has been reviewed by Baldwin [23].

Commercial formulations used in coating consist of long-chain fatty alcohols, synthetic resins, chitosans, and other sugar derivatives as active coating agents, and substances to assist in coating, e.g. emulsifying and wetting agents. Commonly used waxes are carnauba, shellac, candelilla, beeswax, paraffin wax, and vegetable oils. Waxing formulations can be used as carriers of chemicals for preventing fungal infestation, senescence, and other physiological disorders. Coating formulations are applied by spraying, fogging, or brushing onto the produce followed by drying using cold or hot air. Examples of fruits and vegetables normally waxed are apples, pears, banana, citrus fruits, cucumber, pepper, and tomato.

5.3.1.3 Heat Treatment

Moderate heating has been used since ancient times as a quarantine measure to control insect pests and pathogens, and to increase the shelf life of plant produce. Deregistration of chemicals used to control physiological disorders, insect pests, and pathogens and consumer demand for produce with no chemical exposures have fueled increased interest in the use of heat in postharvest management of quality. Heat treatment has a positive effect on maintaining fruit quality by preventing and/or controlling incipient fungal and insect infestation, reducing the rate of ripening, increasing sweetness and reducing acidity in fruits, and in reducing impact of storage disorders, such as superficial scald and chilling injury [24–27]. The heating schedules have been specified in terms of temperature and time of heating for each commodity and the purpose for which the treatment is used. Tables 5.6, 5.7, and 5.8 list the conditions of heat treatment used for insect disinfestations, disinfection, and control of physiological disorders and enhancing quality, respectively. The effectiveness of the treatment depends on the nature of the produce and its sensitivity to heat, temperature and time of heating, the heating method used, and any supplemental treatments such as combinations with antioxidants or controlled atmospheres. Exposing the produce to a temperature conditioning treatment before storage by incubating the produce at ambient temperature for a certain length of time may also be beneficial.

Hot air, vapor, and hot water can be used as sources of heat. Hot water treatment has the advantages of low cost and relatively simple application equipment. The vapor heat treatment is relatively expensive due to costs associated with the equipment and process operation. It requires an airtight and moisture-proof treating room equipped with temperature and humidity controls and a boiler for steam generation. In general,

TABLE 5.6
Typical Heat Treatments for Controlling Insects in Selected Fruits and Vegetables

Commodity	Insect	Temperature ˚C/Time	Heating Medium Used
Apples	Codling moth (*Cydia pomonella*)	44/120 mins followed by 0/4 weeks	Hot air or vapor
	Leafroller (*Cnephasia jactatana*)	40/10 h and 45/5 h in reduced O_2	Hot air and CA
	Light brown apple moth (*Epiphyas postvittana*)	40/17–20 h in reduced O_2 and	Hot air and CA
	Obscure mealy bug (*Pseudococcus*	slightly elevated CO_2	Hot air and CA
	longispinus)	40/10 h and 45/5 h in reduced O_2	Hot water and ethanol
	Two spotted spider mite (*Tetranychus urticae*)	45/13 min in 50% ethanol	
Avocado	Mediterranean fruit fly (*Ceratitis capitata*)	40/24 h	Hot air
	Melon fruit fly (*Dacus cucurbitae*)	40/24 h	Hot air
	Queensland fruit fly (*Bactrocera tyroni*)	46/3 min followed by 1/7 days	Hot water and benomyl
Citrus fruits	Mexican fruit fly (*Anastrepha ludens*)	44/2 h with CA	Hot air and 1% O_2
	Caribbean fruit fly (*Anastrepha suspense*)	51.5/125 min	Hot air
	Fuller's rose beetle (*Asynonychus gomani*)	52/8 min	Hot water
Mango	Mediterranean fruit fly (*Ceratitis capitata*)	47/15 min	Vapor heat
	Caribbean fruit fly (*Anastrepha suspense*)	51.5/125 min	Hot air
	Papaya fruit fly (*Bactrocera payapae*)	47/15 min	Vapor heat
	Queensland fruit fly (*Bactrocera tyroni*)	46.5/10 min	Vapor heat
Pear	Codling moth (*Cydia pomonella*)	44/120 mins followed by 0/4 weeks	Hot air and vapor
	Light brown apple moth (*Epiphyas postvittana*)	30/30 h in reduced O_2	Hot air and CA
	Oriental fruit moth (*Grapholita molesta*)	30/30 h in reduced O_2	Hot air and CA

both hot water and vapor heat treatment can cause excessive tissue damage and peel injury compared to forced hot air.

Since surface injuries are sites for infection by decay organisms, heating the surface of fruits to a few degrees below the tissue injury threshold eradicates or delays the development of incipient infections by pathogenic fungi [3]. Typical heat treatments used for controlling pathogens of selected fruits and vegetables are shown in Table 5.7. Curing is a postharvest healing process of the outer tissues of root crops by the development of a wound periderm by the

TABLE 5.7
Typical Heat Treatments for Controlling Pathogens

Commodity	Pathogen	Temperature ˚C/Time	Heating Medium Used
Apples	Grey mold (*Botrytis cinerea*)	38/4 days	Hot air with $CaCl_2$ dip
	Blue mold (*Penicillium expansum*)	38/4 days	Hot air alone or combination with $CaCl_2$ dip
Banana	Crown rot (*Chalara paradoxa*)	45/20 min or 50/10 min	Hot water
Grapefruit	Green mold (*Penicillium digitatum*)	46/6 h or 59–62/15 sec	Hot water
Lemon	Green mold (*Penicillium digitatum*)	45/2.5 min	Hot water with 2% sodium carbonate
		36/3 days	Hot air
Mango	Black spot (*Alternaria alternata*)	60–70/15–20 secs	Hot water
	Antracnose (*Colletotrichum gloeosporrioides*)	46–48/24 sec to 8 min	Hot water, vapor
	Stem end rot (*Diplodia natalensis*)	51.5/2h mins	Air
		51.5/2h mins	Hot air and water
Orange	Green mold (*Penicillium digitatum*)	41–43/1–2 min	Hot water and 6% sodium carbonate
		53/3 min	Hot water
Papaya	Stem and surface rots (*Botryodiplodia theobromae*)	49/20 min or	Hot air
	Stem and surface rots (*Mycospharella* spp.)	32/33 min first and then 49/20 mins	
Cactus pear	Blue mold (*Penicillium italicum)*	38/24 h or 55/5 min	Hot water or air
Pepper	Grey mold (*Botrytis cinerea*)	50/3 min	Hot water
Strawberry	Grey mold (*Botrytis cinerea*)	45/15 min	Hot water
Tomatoes	*Rhizopus stolonifer*	50/2 min	Hot water

application of heat. The periderm acts as an effective barrier against infection and water loss. The purposes of curing are (i) to heal wounds of tubers and bulbs sustained during harvesting, (ii) to strengthen the skin, (iii) to dry superficial leaves, such as onion bulbs, in order to prevent microbial infection during storage and distribution, (iv) to develop desired skin color (onion), (v) to reduce water loss during storage in potatoes, sweet potatoes, cassavas, yams, onions, and garlic [30]. Curing is carried out at the farm level by subjecting produce to high temperatures and humidity for a given duration. If local weather conditions permit, crops can be undercut in the field, windrowed, and left to dry for 5 to 10 days. The dried tops of the plants can be arranged to cover and shade the bulbs during the curing process, protecting the produce from excess heat and sunburn [1]. The optimum curing conditions for different crops are given in Table 5.8. One day or less at 35 to 45°C and 60 to 75% relative humidity is recommended if forced heated air is used for curing onions and other bulbs [1].

Heat treatment can also assist in controlling the postharvest disorders and enhancing the shelf life of fruits and vegetables by the formation of areas of amorphous wax and fewer surface cracks in apples after heat treatment (Table 5.9). Heating apples to 38°C for 3 or 4 days before storage suppressed softening [31], and decreased storage disorders such as superficial scald and bitter pit [32]. Pre-storage heating plus calcium dip has shown a synergistic effect in maintaining fruit firmness [25] and decreasing storage disorders. Prolonged exposure to elevated temperatures must be avoided to reduce weight loss and loss of ripening ability. Heating at 38°C for various holding times has been found to be effective in preventing chilling injury for produce stored at 2˚C for 4 weeks.

TABLE 5.9
Typical Heat Treatments for Controlling Physiological Disorders and Enhancing Quality of Selected Fruits and Vegetables

Commodity	Physiological Disorders/ Injury	Temperature ˚C/Time	Heating Medium Used
Apples	Scald and improving firmness	38/4 days or 42/2 days	Hot air
Asparagus	Inhibition of curvature	47.5/2–5 min	Hot water
Avocado	Browning Pitting	38/3–10 h followed by 40/30 min 38/60 min	Hot air and water Hot water
Cactus pear	Rind pitting	38/24 h or 55/5 min	Hot water or air
Citrus fruits	Rind pitting	34–36/48–72 h 50–54/3 min	Hot air Hot water
Guava	Increased hardness and yellowing	46/35 min	Hot water
Green pepper	Pitting	40/20 h	Hot air
Mango	Pitting	38/2 days or 54/20 min	Hot air
Tomatoes	Pitting	38/2–3 days 48/2 min or 42/1 h	Hot air Hot water

5.3.1.4 Irradiation

Irradiating fruit and vegetables with ionization energy as X-rays, gamma, or electron beam has been investigated to inhibit sprouting in tubers (potato) and bulbs (onion), to delay ripening and senescence in tropical fruits such as mango and papaya, to control infestation by insects such as fruit fly and seed weevils in mangoes, to pasteurize fruit surfaces, and to improve microbial properties of fruits and to improve process efficiency. However, the use of irradiation is limited by people's perception of radiation, the cost of the treatment process, and phytotoxic effects induced in the treated produce that adversely affect quality. Irradiation is very effective in controlling insect disinfestations as a quarantine measure and for sprout inhibition. Table 5.10 lists the principal uses and the doses of irradiation for fruit and vegetable products [33, 35]. Only low- to medium-dose irradiation (0.05 to 3 kGy) is commonly employed. Irradiation is

TABLE 5.10
Application of Irradiation for Fruit and Vegetables

Purpose	Products Subjected to	Dose (kGy)
Sprout inhibition	Potatoes, onion, garlic, ginger, yam	0.05–0.15
Insect disinfestations	Fresh and dried fruits	0.15–0.5
Delaying maturity and senescence	Fresh fruit and vegetables	0.25–1.0
Extending shelf life	Strawberries, mushrooms	1.0–3.0
Improving technological properties	Grapes (juice recovery), dehydrated vegetables (reduced cooking time)	2.0–7.0

Source: Anon [33].

gaining popularity as an alternative to chemical fumigation and is now accepted and approved by about 60 countries as a quarantine treatment [33]. It has been approved by FDA of the US for sprout inhibition of white potatoes, ripening delay in fruits, disinfestations of fruit and vegetables, and as a quarantine measure for mangoes and papaya for the control of fruit fly and stone weevil [33, 35]. Normal doses required for insect disinfestations have been found to produce no phytotoxicity in apple, cantaloupe, cherry, currants, date, guava, honeydew melon, kiwi, litchi, mango, muskmelon, nectarine, papaya, peach, prune, raspberry, strawberry, and tomato (ICGFI task report 13, 1991). Currently, 26 fruits and vegetables are allowed in Australia to be irradiated with a minimum dose of no lower than 150 Gy and no greater than 1 kGy (Food Standards Australia New Zealand Code Standard 1.5.3). The code also specifies mandatory labeling of all irradiated foods.

5.3.2 Chemical Treatments

Chemicals have been used in fruits and vegetables to control microorganisms causing decay and diseases, infestations due to pests, physiological disorders, and to enhance the quality of produce. Chemicals can be applied as spraying and dipping solutions or emulsions, electrostatic spray, dusting, fumigation, thermal fogging, and as adsorbent pads. The choice of a particular chemical treatment and the dose depends on intended use, phytotoxicity, residue, and degradation. These compounds should be selected for both efficacy and minimal interference with the natural color, flavor, and odor of the product along with toxicity, residue in the product, and legal aspects before applying any chemical treatment.

5.3.2.1 Disinfestation and Decay Control

Fruits and vegetables are exposed to deterioration due to insect pests, fungi, and bacteria at any time from production until consumption or processing. Insect pests cause significant losses worldwide [3, 7, 19]. Similarly, pathogens significant to fruits and vegetables have been covered in the literature [19, 22, 28]. The list of chemicals approved for use as insecticides, fungicides, or bactericides is shrinking due to their environmental impact and toxicity. The general trend is to observe strict hygiene in the production and handling of the produce, to use physical methods (heat and modified atmospheres), and to use chemicals that are generally regarded as safe (GRAS) or biological agents.

Chemicals are applied as insecticidal dips or fumigants for postharvest disinfestation of fruits and vegetables. Gaseous sterilants used for quarantine treatments include ethylene dibromide, methyl bromide, acrylonitrile, carbon disulfide, carbon tetrachloride, ethylene dioxide, hydrogen cyanide, phosphine, and sulfuryl fluoride. The use of methyl bromide has been now phased out under the Montreal Protocol and may be permitted only when the importing countries specify it as a quarantine measure for importation (www.postharvest.net.au/postharvest-fundamentals/quarantine-treatments/quarantine-treatments/).

Incipient growth of both fungi and bacteria in fruit and vegetables used as raw material for processed products causes defects in sensory (color, texture, and flavor) and microbiological quality of end product. Increased softening upon canning, pickling, and acidic or alcoholic flavor in fruit juices are some examples of spoilage symptoms. Fungicides are applied to fruits and vegetables both as pre- and/or postharvest treatments depending on the nature of produce, the target pathogen, market life, and cost. Local and international laws strictly control the use of fungicides. Table 5.11 lists chemicals used in the postharvest control of common pathogens. The chemicals that are most effective in controlling fungi are thiabendazole, dichloran, imazalil, sulfur, and its derivatives. However, increased resistance to these fungicides is a problem.

Sulfur and its derivatives are effective in controlling fungi and molds in fruits in the form of fumigation, dipping, and spraying or pads. Fumigation of grapes with sulfur dioxide is standard practice for controlling decay. Salunkhe et al. [3] fumigated grapes with 1% sulfur dioxide (v/v) for 20 min immediately after harvest to sterilize the surface of the berries and any injuries made during harvest. The initial treatment may be followed by periodic fumigation with 0.25% sulfur dioxide at 7- to 10-day intervals during storage. In some cases, the color and texture of fruits are also improved by sulfur dioxide treatment. Two major disadvantages of sulfur dioxide use are corrosion to metal surfaces of the storage and treatment chamber and bleaching the point of attachment of the stem to the berry [3]. Bisulfites can be used as pads in cartons carrying grapes to control molds [1].

Nitrogen trichloride (NCl_3) fumigation treatment has been used extensively to control the sporulation and spread of pathogenic fungi during storage. It is hydrolyzed in a

TABLE 5.11
Chemicals Used in Postharvest Control of Pathogens in Fruits and Vegetables

Chemical	Pathogen Controlled	Host
Inorganic sulfur as SO_2 gas or salts	Monillia, Botrytis	Grapes
Organic sulfur compounds (e.g. thiram)	*Alternaria*	Strawberry, banana
Phenols (sodium o-phenylphenate)	*Penicillium*, bacteria, and fungi	Citrus fruits
Triazoles (imazalil)	*Penicillium, Alternaria*	Citrus fruits
Hydrocarbons (Biphenyl)	*Penicillium, Diplodia*	Citrus fruits
Organic acids (dehydroascorbic acid, sorbic acid, acetic acid, formic acid)	Botrytis and other fungi	Strawberry
Benzimidaxoles (benomyl)	*Penicillium, Collectotrichum, Sclerotinia*, Botrytis	Stone fruits, carrots

Sources: Thompson [19]; Wills and Golding [22].

moist environment to HOCl, which is probably responsible for decay control and for corrosion [3]. In recent years, its use has declined because of its corrosion problems. Biphenyl may be used after impregnation into fruit wraps or onto the paper sheets placed at the bottom and the top of the fruit container to inhibit fungi. It sublimes into the atmosphere surrounding the fruit and inhibits the development of decay. The main problem with using biphenyl is that it leaves a residue on the surface, which gives off a slight hydrocarbon odor [3].

There is a trend to use essential oils and natural substances as fungicides which have low mammalian toxicity. *Trans*-cinnamaldehyde is more effective as an antifungal agent when applied as an aqueous solution than when in the gas phase, since it oxidizes to cinnamic acid when exposed to air [36]. The surface treatment of tomatoes with *trans*-cinnamaldehyde is effective in reducing the number of potential spoilage bacteria and fungi [37] before storage under modified atmosphere. Similarly, Ryu and Holt [38] demonstrated the effectiveness of an aqueous solution of cinnamon oil for the surface disinfection of apples. The effectiveness of treatment can be improved by the addition of Tween 80 (0.05%) and ethanol (3%), which assist in dissolving the wax layer, to apples near fungal spoilage.

In addition to following strict hygiene through good agricultural practices at the farm level and hazard analysis and critical control point (HACCP) protocols through the distribution channel, the potential alternatives of chemical treatments for control of diseases and pests are (i) low and high temperatures treatments (Table 5.7), (ii) atmospheres with very low oxygen and/or very high carbon dioxide, and (iii) atmospheres with natural insecticidal volatiles, and (iv) irradiation (Table 5.10), (v) using radiofrequency for control of insects [39, 40], and (vi) using biological control for wound-invading necrotrophic pathogens [2, 19, 41, 42]. Certain bacteria, e.g. *Bacillus subtilis*, *Bacillus licheniformis*, *Bacillus megaterium*, *Geobacillus stearothermophilus*, are effective in controlling diseases such as anthracnose and stem end rot of mangoes, and *Candida guilliermondii* for molds (*Penicillium* spp. in citrus fruits). These biological agents are very useful in combination with chemicals for disease control [19].

Atmospheres with very low oxygen (≤0.5%), and/or very high carbon dioxide (≥50%) are insecticidal. Insecticidal atmospheres can be used for mango, papaya, and avocado as a quarantine measure. However, not all fresh fruits and vegetables can tolerate such extreme atmospheres. The advantages of using insecticidal atmospheres include (i) absence of toxic residue on the produce, (ii) environmentally safe, and (iii) competitive in cost with chemical fumigants. The disadvantages, however, are that it takes longer to kill insects with insecticidal atmospheres than with fumigants, and may cause anaerobiosis and fermentation in fresh horticultural crops [43].

Water disinfection is required to prevent the introduction and spread of postharvest diseases and food-borne infections of human pathogens. The common disinfectants and sanitizers used and their mechanisms of action are given in Table 5.12. Chlorine compounds are used to sanitize water used in cleaning raw produce, fresh and cut fruit and vegetables, and food processing equipment. Chlorine is very reactive and the most acceptable disinfectant due to its antimicrobial activity against bacterial cells and spores, reduction in the formation of biofilms on the surface of handling equipment, and low residual effect. The use of chlorinated water at 10–200 mg/kg rapidly kills vegetative cells of yeast and bacteria. The recommended levels of chlorine in wash water are 1–3 ppm for rinsing and 50 ppm for sanitizing [6]. Chlorine is used as a gas or sodium or calcium hypochlorite salts. When added to water the following reactions take place:

$$Cl_2 + H_2O \rightarrow HOCl + H^+ + Cl^-$$

$$NaOCl + H_2O \rightarrow HOCl + NaOH$$

$$Ca(OCl)_2 + H_2O \rightarrow HOCl + Ca(OH)_2$$

$$HOCl \Leftrightarrow OCl^- + H^+$$

The disinfectant activity of chlorine compounds depends on several factors, which include the form of the chlorine, pH,

TABLE 5.12
Sanitizers Used in Disinfection of Wash Water

Sanitizer	Activity	Oxidation Capacity (eV)	Concentration	Effectiveness
Peracetic acid	Oxidant	1.81	Up to 80 ppm	pH 1–8, sensitive to organic matter
Hypochlorites	Oxidant	1.36 (for sodium hypochlorite)	1–3 ppm for rinsing 50 ppm for sanitizing	pH 6–7, sensitive to organic matter
Chlorine dioxide	Oxidant	1.57	Up to 5 ppm	pH 6–10, less sensitive to organic matter in comparison to hypochlorites
Hydrogen peroxide	Oxidant		0.5%	Sensitive to organic matter
Ozone	Oxidant	2.07	2 ppm	pH 6–8, sensitive to organic matter, breaks down to O_2 rapidly, corrosive to equipment
UV light	Disruption of genetic material	-	40,000 μw-sec/cm^2	Independent of pH sensitive to organic matter
Iodophore	Oxidant		6–13 ppm of free iodine	pH 2–5, sensitive to organic matter, corrosive

temperature, contact time, and presence of organic matter. Of many forms of chlorine, hypochlorous acid (HOCl) is the most effective as a disinfectant. The pH of the water should be maintained at 6–6.5 to ensure optimum disinfectant activity and to avoid the formation of gaseous chlorine, which causes irritation to workers at <6 pH. It is necessary to maintain the effective concentration of the acid in the wash water especially when water is recycled. In commercial operations, 50 to 100 ppm chlorine at pH 7.5 to 8.5 is frequently employed when the washing water carries a substantial amount of soil and organic matter. Sulfamic acid and other amines can be added to water to form *N*-chloramines which tend to stabilize the concentration of active chlorine. Sodium *o*-phenylphenate (SOPP) is also used occasionally to reduce the number of pathogenic microorganisms in produce treatment water. SOPP is non-corrosive and improves the stability of the solution, and compatibility with chemicals, which react with chlorine. Further stabilization of chlorine solution is possible by adding 2-aminobutane (phosphate) in addition to SOPP [3].

Alternatives to chlorine as a disinfectant are ultraviolet light (UV), ozone, and organic acid formulations such as peracetic acid. The UV light disrupts the DNA and can be used for sanitation of water and surfaces. Most disinfectants are strong oxidizing agents, and their disinfectant power is related to their oxidation capacity. Based on this capacity, ozone is a very effective disinfectant; however, it degrades rapidly to oxygen and loses its activity. Besides wash water, disinfection of storerooms can also be done by spraying with 5% Lysol or 2% formalin, painting of walls with antifungal chemicals, and fumigation with paraformaldehyde [44].

Accurate monitoring, control, and recording of all the factors influencing disinfection are key elements of a sound disinfection program. Oxidation-reduction potential (ORP) is widely accepted as a key indicator of water disinfection potential for real-time monitoring and recording of the disinfection process in postharvest systems. Maintaining an ORP value of 650–700 mV for a few seconds can inactivate most spoilage and food-borne bacteria such as *Escherichia coli* and *Salmonella* spp. [45].

5.3.2.2 Ethylene Removal

Ethylene, a plant hormone, affects the physiological processes of ripening and senescence, which signal cell death. Exposure to ethylene (1 ppm) can reduce the postharvest life of many fruits and vegetables by hastening the onset and increasing the rate of senescence, softening, and loss of green color. Damaged or diseased fruits produce more ethylene and have a catalytic effect in stimulating: softening of tissues, discoloration, bitterness due to production of isocoumarins in carrots, russet spotting in lettuce, browning of tissues in vegetables such as eggplant and sweet potatoes, sprouting of potatoes, development of woodiness in asparagus, shattering of berries, such as blackberries and raspberries, loss of green color in vegetables, and stimulation of growth of fungi (*Penicillium italicum* in oranges, *Botrytis cineria* on strawberries).

The ethylene control strategy includes the prevention of exposure of plants to biologically active levels of ethylene, reducing the perception of atmospheric ethylene, and preventing the tissue response to perceived ethylene [46, 49]. Ethylene damage can be reduced by (i) adequate ventilation, (ii) reduction of O_2 and increase in CO_2 levels, (iii) reducing temperature, (iv) avoiding storage and transportation of ethylene producers and sensitive produce, and (v) reduction of ethylene by forcing air through filters of activated charcoal (brominated), treatment with silver thiosulphate, potassium permanganate ($KMnO_4$) or purafil, 1-methyl cyclopropene (MCP) or EthylBlock, and oxidation by UV light. Potassium permanganate, the most accepted ethylene remover used commercially, oxidizes ethylene into ethylene glycol and is often incorporated into different carrier materials such as activated alumina, silica gel etc. It is applied as sachets, tubes, and blankets in storage and transportation of fresh fruits and vegetables. When used in conjunction with modified atmosphere packaging, the use of $KMnO_4$ increases the shelf life of banana to 21 days from 7 days in air [22]. MCP helps in delaying the rise in respiration and preventing tissue softening and incidence of physiological disorders such as superficial scald in apples. The response of fruit to MCP depends on the type of fruit, cultivar, maturity, the application method, and exposure levels of MCP used [13, 47–49]. MCP has been approved at concentrations up to 1 ppm for use on apples, apricots, avocados, kiwifruit, mangoes, nectarines, papayas, peaches, pears, persimmon, plums, and tomatoes in the United States [13].

5.3.2.3 Controlled Ripening and Color Development

Climacteric fruits, such as banana and mangoes, are harvested well before they are fully ripe to avoid mechanical injury and are ripened during storage or transport under controlled conditions of temperature, relative humidity, and ethylene gas just before consumption or processing. Controlled ripening facilitates uniform development of color, texture, and flavor.

Ethylene is the most active ripening agent. Ethylene is a product of incomplete combustion of fuels such as charcoal and is highly flammable when pure, and hence it is used in relatively low concentrations (<3%). It can be generated by passing ethyl alcohol over a bed of activated column. Ethephon (2-chloroethyl phosphoric acid) may be used as a source of ethylene for ripening of fruits. The amount of ethylene released depends on the fruit pH and relative humidity. Acetylene, generated by mixing water with calcium carbide salt, can also be used as a ripening agent; however, it is 100 times less effective compared to ethylene. Endogenous or exogenous ethylene is used for controlled ripening of fruits (banana, mangoes) and development of a uniform color of the produce (tomatoes and citrus fruits) under controlled conditions. The ripening effect depends on the concentration of ethylene, exposure time, relative humidity, and respiratory behavior of fruits. A batch process for ripening bananas consists of exposing fruits to ethylene concentrations of 20–200 µl/L in a sealed chamber for 24 hours followed by ventilation to avoid buildup of ethylene and carbon dioxide before removing fruits. The chamber temperature is maintained at 15–21°C by controlling the airflow in a forced-air system. Initially, RH

TABLE 5.13
Typical Conditions for Postharvest Ripening and Color Development of Fruits

Fruit	Ethylene Concentration (ppm)	Temperature (°C)	Time (hr)	Application
Avocado	10–100	15–18	12–48	Ripening
Banana	100–150	15–18	24	Ripening
Honeydew melon	100–150	20–25	18–24	Ripening
Kiwi fruit	10–100	0–20	12–24	Ripening
Mango	100–150	20–22	12–24	Ripening
Orange	1–10	20–22	24–72	Degreening
Tomato	100–150	20–25	24–48	Color development

Source: Adapted from Kitinoja and Kader [1].

is maintained first at 85–90% level to preclude water loss, development of blemishes, and poor color formation, and then reduced to 70–75% to avoid skin spotting at later stages of maturity [22]. Table 5.13 lists typical ripening conditions used for some fruits using ethylene as a main ripening agent [1].

5.3.2.4 Delaying Ripening, Senescence, and Sprouting

Ripening is undesired in most vegetables, except in the case of tomatoes, and signals the onset of senescence in fruits. Various plant growth regulators can be used at various stages of production and postharvest handling for delaying ripening, color degradation, and sprouting [3]. These chemicals can be applied as a dip or spray. Table 5.14 lists the chemicals used, their effect, and products for which these are applied.

5.3.2.5 Treatment with Divalent Cations

Calcium and other divalent ions are useful in delaying senescence and maintaining the quality of fruits and vegetables by altering respiration, protein and chlorophyll content, and membrane fluidity [2]. Calcium application also reduces

TABLE 5.14
Chemicals Used for Delaying Ripening, Senescence, and Sprouting

Chemical	Effect	Produce used
Cytokinin	Delays chlorophyll degradation and senescence	Leafy vegetables (spinach), pepper, bean, cucumber
Benzyladenine	Delays chlorophyll degradation and senescence	Cherry
Benzylaminopurine	Delays chlorophyll degradation and senescence	Sweet cherry, cauliflower, endive, parsley, snap beans, lettuce, radish, onions, cabbage, Brussels sprouts, broccoli, mustard greens, radish tops, celery, asparagus
Kinetin	Delays chlorophyll degradation and senescence	Leafy vegetables (spinach), pepper, bean, cucumber
Gibberellin	Retards maturation, ripening, and senescence, delays chlorophyll degradation, increases peel firmness, delays accumulation of carotenoids	Tomato, banana, kiwi fruit, citrus fruits (orange, grapefruit)
Maleic hydrazide and its analogues	Sprout inhibition	Onion, sugar beet, turnip, carrot, potato
	Delays ripening	Mango, tomato, sapota fruit
Alar	Delays deterioration and discoloration	Mushroom
	Preservation of chlorophyll	Leaves of beans
	Inhibition of synthesis of solanine	Potato
Cytocel	Retards senescence and deterioration	Vegetables
IPC	Control sprouting	Root crops
CIPC	Control sprouting	Potato
Tecnazene	Control sprouting and fungi	Root crops
Calcium	Delays chlorophyll degradation and senescence	Vegetables
1-MCP	Delays ripening	Apple, banana, pear, tomato, peach, apricot, nectarine, plum, mango, avocado

TABLE 5.15
Diseases and Disorders Controlled or Prevented by Calcium and Other Divalent Ions

Disease/Disorder	Produce
Blossom end rot	Tomato, pepper
Tip burn	Lettuce
Internal browning	Potatoes
Bacterial and fungal decay	Potatoes, carrots
Bitter pit	Apples
Incidence of molds	Cucumber
Chlorosis	Most vegetables, potatoes

texture loss, ethylene production, browning, development of bitterness, and microbial decay [2, 50, 51] and increases the concentration of ascorbic acid.

Low calcium levels are strongly related to high incidences of bitter pit in apples, blossom end rot in tomatoes, tip burn in lettuce, and hollow heart and brown center in potatoes [6, 50]. Table 5.15 lists the diseases and disorders associated with calcium and other divalent ions. Chlorosis, loss of green color, is induced by a deficiency of magnesium. Since soil fertilization with calcium salts is not effective in raising the level of calcium in fruits, orchard sprays or postharvest dips or vacuum and pressure infiltrations are used to increase the levels of calcium in tissues.

Calcium exists as calcium pectate in the middle lamella of the cell wall cementing the structure of the plant cell. The loss of calcium from calcium pectate leads to the softening of fruits. The addition of calcium improves texture by reacting with pectic acid to form calcium pectate. Sprays and dips of calcium chloride solutions delay softening and senescence of fruits by the formation of cross-links between polygalacturonide chains and calcium in cell walls, thus resulting in an extension of shelf life. Calcium is not used in other fruits except in the case of apples to avoid skin injury due to higher calcium uptake and rot development [22].

5.3.2.6 Treatment with Antioxidants

Superficial scald may develop due to oxidation of α-farnesene during cold storage of apples, as natural antioxidants are lost. This disorder can be controlled by the application of antioxidants. Diphenylamine (0.1–0.25%) or ethoxyquin (6-ethoxy-2, 2,4-thimethyl-1,2-dihydroquinoline) (0.2–0.5%) are two antioxidants used commercially. These may be used as spray or dipping solutions or can be added to the formulation used for the waxing of fruits.

5.4 CONCLUSION

Fruits and vegetables undergo several postharvest handling operations before reaching the consumer in fresh form or a processor as a raw material for further processing. An overview of postharvest handling operations and treatments has been provided in this chapter as this knowledge is essential to extend the shelf life and to maintain the quality of these perishable products.

6 Structure, Composition, and Harvesting of Grains and Pulses

Ajit K. Mahapatra and Yubin Lan

CONTENTS

6.1 STRUCTURE OF CEREAL GRAINS AND LEGUMES

6.1.1 Cereal Grains

Cereals are often considered among the first cultivated crops. They are herbaceous plants belonging to the grass family Graminaceae (the only exception being buckwheat) [1]. Cereal grains such as wheat, rice, corn, barley, oat, rye, sorghum, and millet are used primarily for human consumption and animal feed. These are also used in the manufacture of beverages and industrial products (adhesives, starch). Cereal crops are energy-dense, containing 10,000–15,000 kJ/kg, about 10–20 times more energy than most succulent fruits and vegetables [2]. Nutritionally, they are important sources of dietary protein, carbohydrates, B complex of vitamins, vitamin E, iron, trace minerals, and fiber. Cereal grains contain relatively little protein compared to legume seeds, with an average of about 10–12% dry weight. These provide over 200 MT of protein for the nutrition of humans and livestock, which is about three times the amount derived from the more protein-rich (20–40%) legume seeds [3]. Global cereal consumption directly provides about 50% of protein and energy necessary for the human diet, with cereals providing an additional 25% of protein and energy via livestock intermediaries.

In 2004, world cereal production amounted to 1,985 million tones [4]. Major cereal grains produced worldwide include wheat, rice, corn, and barley. Corn, wheat, and rice together account for three-fourths of the world's grain production [5]. Other globally important cereal crops include sorghum, oats, millet, and rye. Asia, America, and Europe produce more than 80% of the world's cereal grains. Wheat, rice, sorghum,

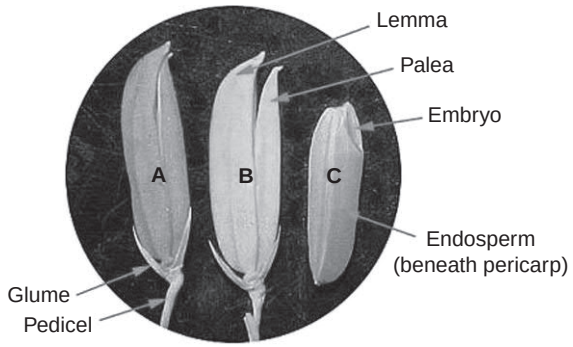

FIGURE 6.1 Rice grain. A: Grain-bearing spikelet showing a pair of slender basal bracts (glumes) and the stalk (pedicel). The inflorescence is composed of numerous spikelets, each bearing a rice grain; B: An empty spikelet with the lemma and palea slightly separated from each other. These two leathery bracts enclosed the grain or caryopsis; C: A grain (caryopsis) removed from spikelet. (From Palomar [66].)

and millet are produced in large quantities in Asia; corn and sorghum are the principal crops in America, whereas barley, oats, and rye are the major crops in the former United Soviet Socialist Republic (USSR) and Europe.

6.1.1.1 Rice (*Oryza sativa* L.)

Rice is a member of the family Poaceae, and it is the major food for about one-third of the earth's population [6, 7]. It has been estimated that 1.7 billion people depend on rice [8]. Cultivated in Asia for thousands of years, rice is also grown in many other parts of the world. Wild rice (*Zizania aquatica*) is native to North America where it was originally harvested from the wild by Native Americans. Another North American wild rice or Indian rice is *Oryzopsis hymenoides*, native to mountains and valleys of Canada and the western United States. Although wild rice is now cultivated, it is expensive and accounts for less than 1% of the American rice market. The rice is first fermented to develop a nutty flavor and to ease hulling.

Rice is harvested with an outer hull or hull intact. This is commonly called rough rice or paddy. The hull, which constitutes about 20% of the weight of rough rice, is made up of the floral envelopes, the *lemma* and *palea*. Brown rice (rice after hulls have been removed) varies from 5 to 8 mm in length. The kernels weigh an average of about 25 mg and are about 2% pericarp, 5% seed coat and aleurone, 2–3% germ, and 89–94% endosperm [9]. The aleurone is the outermost layer of the endosperm. When brown rice is polished to form white rice during milling, the aleurone layer is removed along with the seed coat and pericarp to form the bran. The germ, the pericarp, and the aleurone layer are richer in nutrients as compared to endosperm, and they contain proteins and vitamins. A rice grain is shown in Figure 6.1. Figure 6.2 shows the longitudinal section of a rice grain including the embryo (germ), pericarp (bran), and endosperm.

The embryo or germ is at the upper end. Beneath the brownish outer pericarp and seed coat layers (called the bran) is the endosperm tissue. Most of the vitamin B_1 is found in the germ and bran portions, which are milled off in polished white rice. The detailed structure of rice grain is shown in Figure 6.3, and further details can be found in several publications [5, 8, 10].

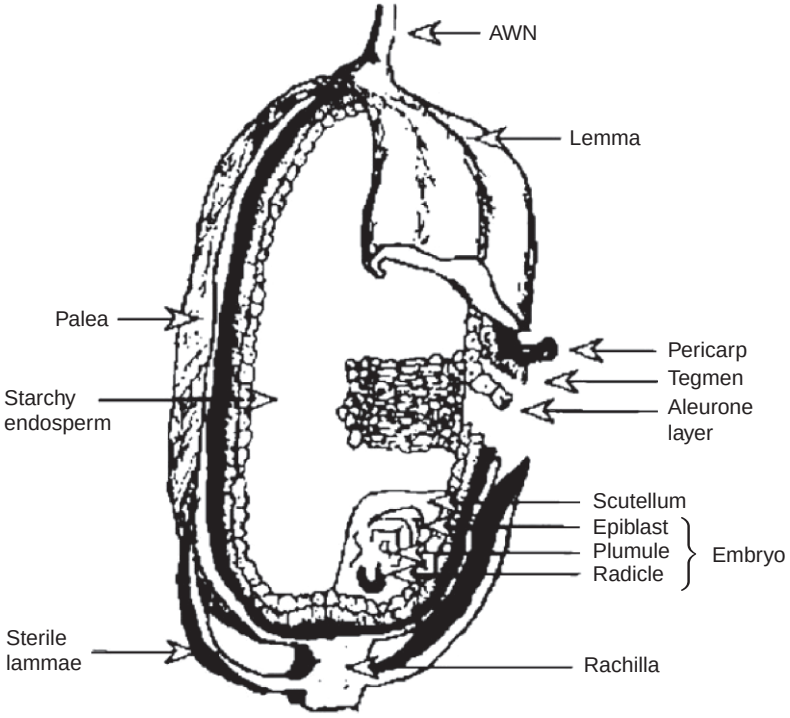

FIGURE 6.2 Longitudinal section of a rice grain. (From Palomar [66].)

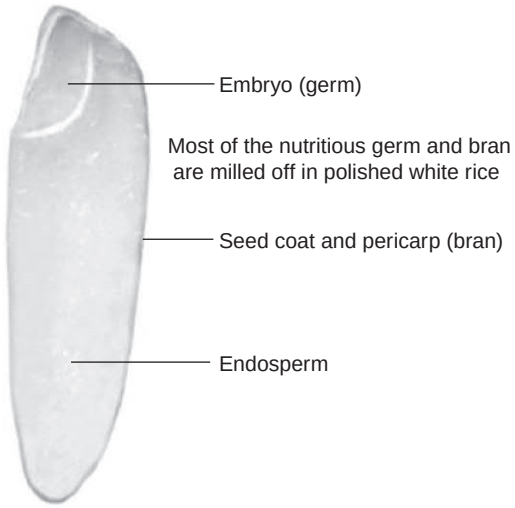

FIGURE 6.3 Structure of a rice grain. (From Haard et al. [2].)

6.1.1.2 Sorghum (*Sorghum bicolor* L. Moench)

Sorghum ranks fourth after rice, corn, and wheat in terms of importance for human nutrition [11]. The plant originates from equatorial Africa and is distributed throughout the tropical, semi-tropical, and arid regions of the world. Today sorghum is an important food crop in Africa [12, 13] and Asia. There are four main types of sorghum-based primarily on how it is used: (i) grain sorghums (including milo), (ii) sweet sorghum or sorgo (used as feed), (iii) Sudan grass (a different but related species), and (iv) broom-corn. The grain is partially covered with glumes, and the most common colors are white, bronze, and brown.

In North America, sorghum is used primarily as livestock feed. Commercial U.S. sorghums are generally 4 mm long, 2 mm wide, and 2.5 mm thick [14]. The kernels are generally spherical, weigh 20–30 mg, and may be white, red, yellow, or brown in color. Hand-dissected kernels are found to be 7.9% pericarp, 9.8% germ, and 82.3% endosperm [15]. The structure of sorghum grain is shown in Figure 6.4, and further details can be found in Hoseney [15]. The outer thick pericarp of a kernel consists of three layers: the epicarp, the mesocarp, and the endocarp. Like corn kernels, sorghum kernels contain both translucent and opaque endosperm.

6.1.1.3 Barley (*Hordeum vulgare* L.)

Barley, like rice and oats, retains its husk (or hull) following harvest. The hull consists of the lemma and palea. Underneath, the 35-mg kernels have the four basic grain components of pericarp, seed coat, germ, and endosperm. The barley kernel is generally spindle-shaped. In commercial varieties grown in the United States, length varies from 7 to 12 mm. A longitudinal section of a barley grain is shown in Figure 6.5.

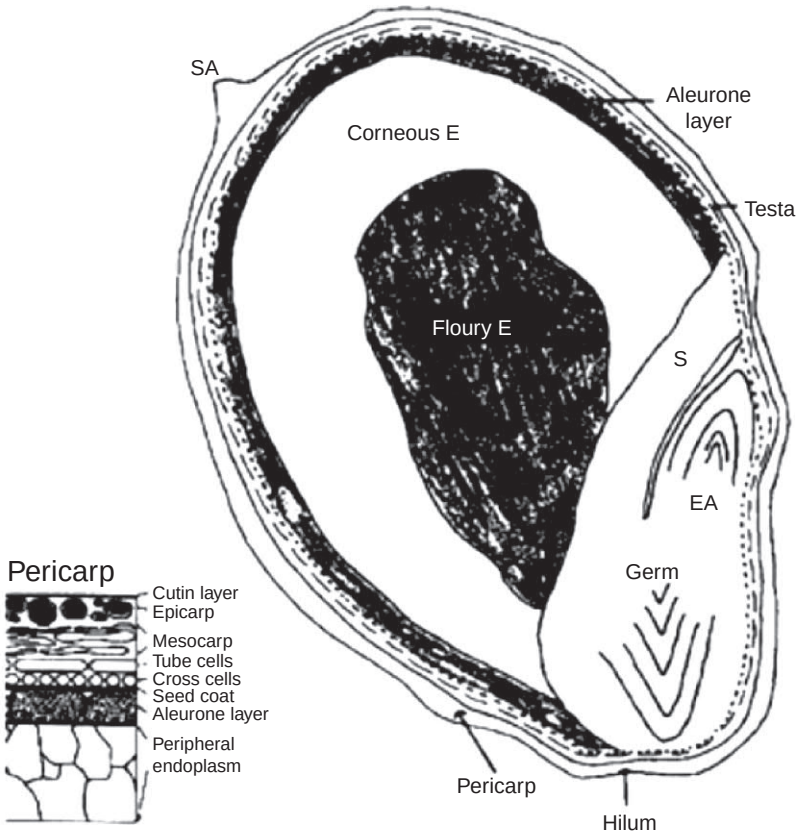

FIGURE 6.4 Diagram of sorghum caryopsis showing the pericarp [cutin, epicarp, mesocarp, tube cells, cross cells, testa, pedicel, and stylar area (SA)], endosperm (E) (aleurone layer, corneous, and floury), and germ [scutellum [4] and embryonic axis (EA) [14].

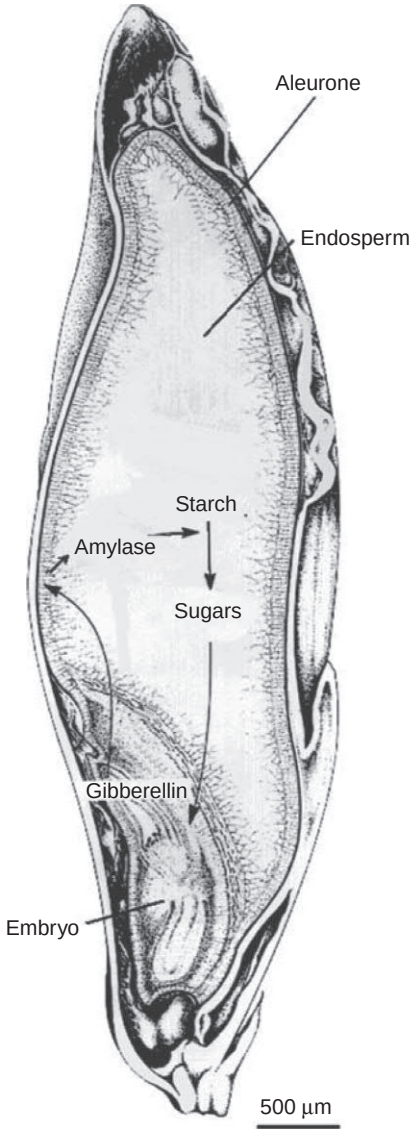

FIGURE 6.5 Longitudinal section of a barley grain. (From Mahapatra and Lan [67].)

The detailed structure of barley grain is shown in Figure 6.6. Further details can be found in MacGregor and Bhatty [16].

6.1.1.4 Wheat (*Triticum aestivum*)

Wheat is native to southwest Asia and the Mediterranean region. Common or bread wheat is widely cultivated in most parts of the world, and is the principal staple food of man. Wheat grains, botanically, are the fruits (caryopsis) of the wheat plant. Mature wheat grain or kernel is roughly ovate- or egg-shaped. The kernels average about 8 mm in length and weigh about 35 mg [15]. The dorsal surface is generally smooth and rounded, but the ventral surface is creased. At the apex, a brush consisting of short hairs is generally present. The color of the kernel varies from dark red through light brown, classed commercially as red wheat, to white; cream or yellow, classed commercially as white, wheat; or amber, in durum wheat.

The wheat kernel structure is shown in Figure 6.7. The kernel consists of three main parts, namely the bran, the endosperm, and the germ or embryo. The outer covering consists of several distinct cell layers in the bran—separated from the flour during most milling processes. It comprises about 12% of the kernel weight. The aleurone, which forms the outer periphery of the endosperm and the innermost layer of the bran, accounts for 3–4% of the weight of the kernel; it is usually removed with the bran during milling. The endosperm consists mainly of starch and makes up about 85 to 86% of the kernel. It is the portion present in white flour. Approximately 2.5–3.5% of a wheat kernel is germ [9], and is separated out in most milling processes. Because it provides nourishment for germination, the germ contains high levels of protein, sugar, and oil. The grain structure of wheat has been documented by Lasztity [17].

6.1.1.5 Corn (*Zea mays* L.)

Corn is the world's most widely grown cereal crop and an essential food source for millions of people in Africa [18], Asia, and Latin America. Corn exists in many varieties and colors, but dent corn is the type used for milling. Corn's flat, broad seeds average around 350 mg, making it the largest of the common cereal seeds. The kernel is made up of three principal parts: hull or bran (pericarp and seed coat), germ, and endosperm. In addition, though, corn kernels frequently have the point of attachment of the cob (tip cap) intact.

Although corn's pericarp and seed coat are collectively called the hull, corn hulls are not the same as the true hulls of rice or barley. Approximately 5–6% of a corn kernel is made up of this outer covering, while 10–14% is germ, with the remainder being endosperm [9]. The outer thin covering is made up of two layers, an outer pericarp and an inner testa or true seed coat. The endosperm consists almost entirely of starch, except in sweet corn. Corn is different from wheat in that both translucent and opaque endosperms are found within a single kernel. Corn kernels or seeds vary in size and shape in different kinds and varieties. The embryo is near one side of the kernel in most kinds rather than in the middle, which contains most of the oil in corn. A longitudinal section of a corn kernel is shown in Figure 6.8, and additional details on the grain structure of corn have been documented by Hoseney [15].

6.1.1.6 Oat

Oats are generally eaten as wholegrain flakes, and the processing contains a heating stage to inactivate enzymes [19]. Most oats are covered in a tough, inedible hull, which must be removed prior to human consumption. The hull contributes to about 30% of the total kernel weight. The oats are called groats after the hulls have been removed [20]. The structure of the oat kernel is shown in Figure 6.9.

Oats, as with barley and rice, retain the hull formed by a floral envelope. Underneath, the oat kernel (called a groat) is similar to wheat or rye. The germ, however, is much larger and narrower than that of wheat, and it extends from 25 to 33% of the length of the groat [9]. The oat groat consists of pericarp, seed coat, hyaline layer, germ, and endosperm. The aleurone makes up the outer layer of the endosperm. Compared with other cereals, oat endosperm contains higher levels of protein and oil. Oat starch is like rice starch in that it exists as

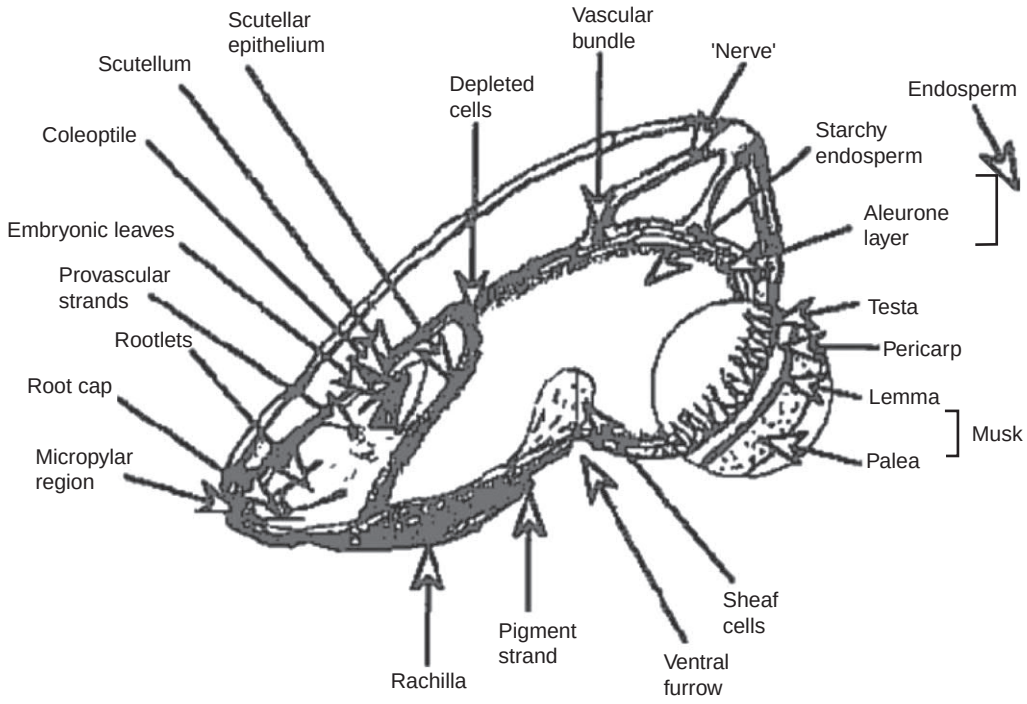

FIGURE 6.6 Structure of barley. (From Haard et al. [2].)

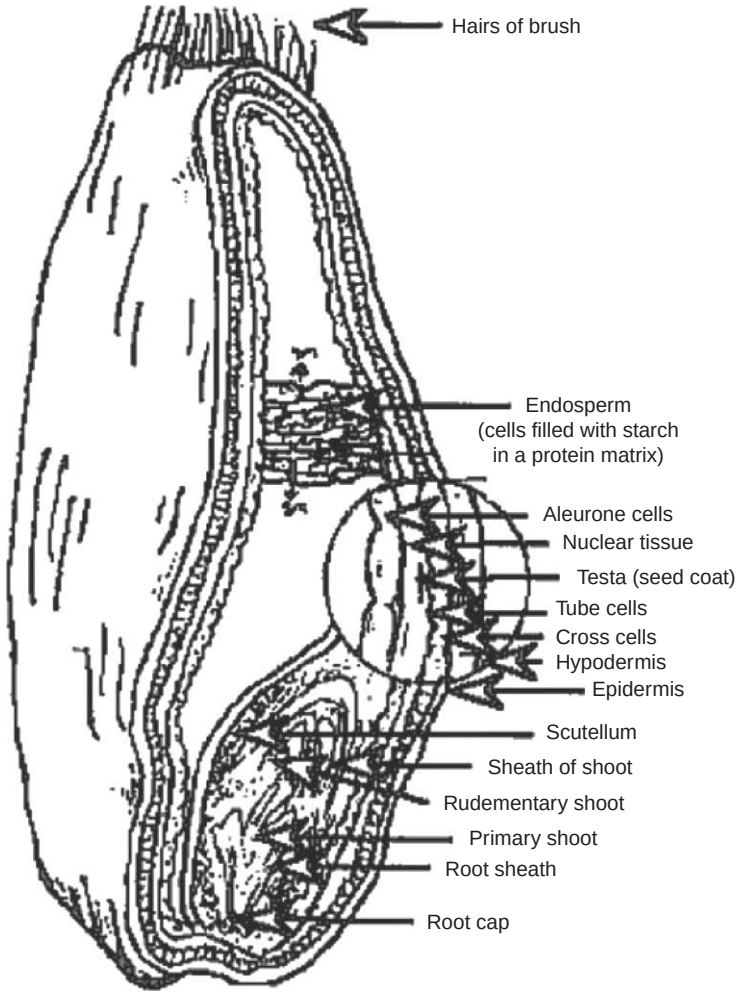

FIGURE 6.7 Structure of wheat kernel. (From Haard et al. [2].)

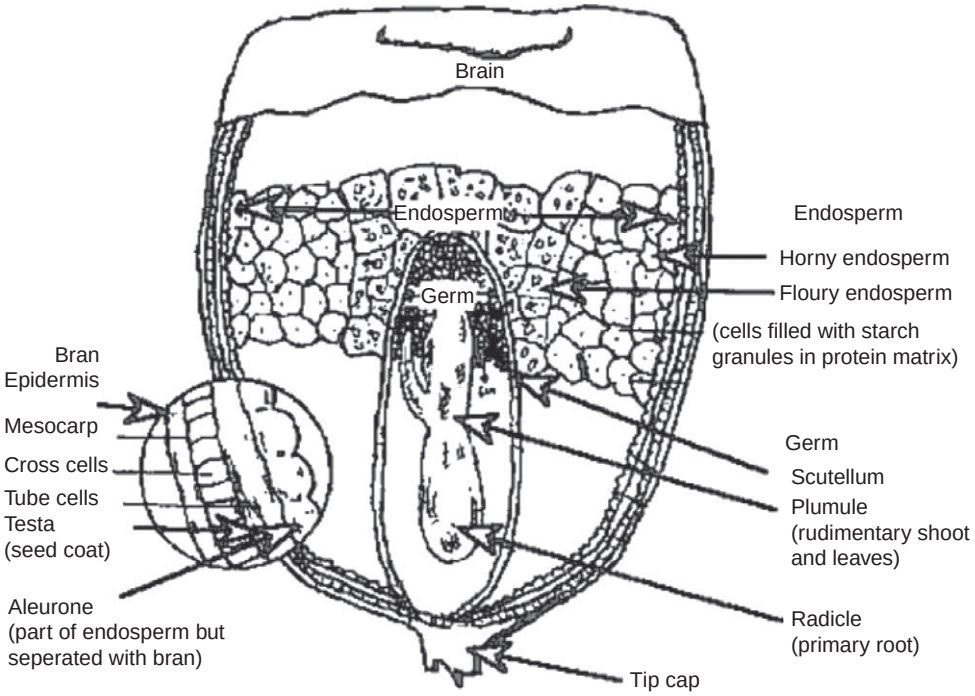

FIGURE 6.8 A longitudinal section of a corn kernel. (From Haard et al. [2].)

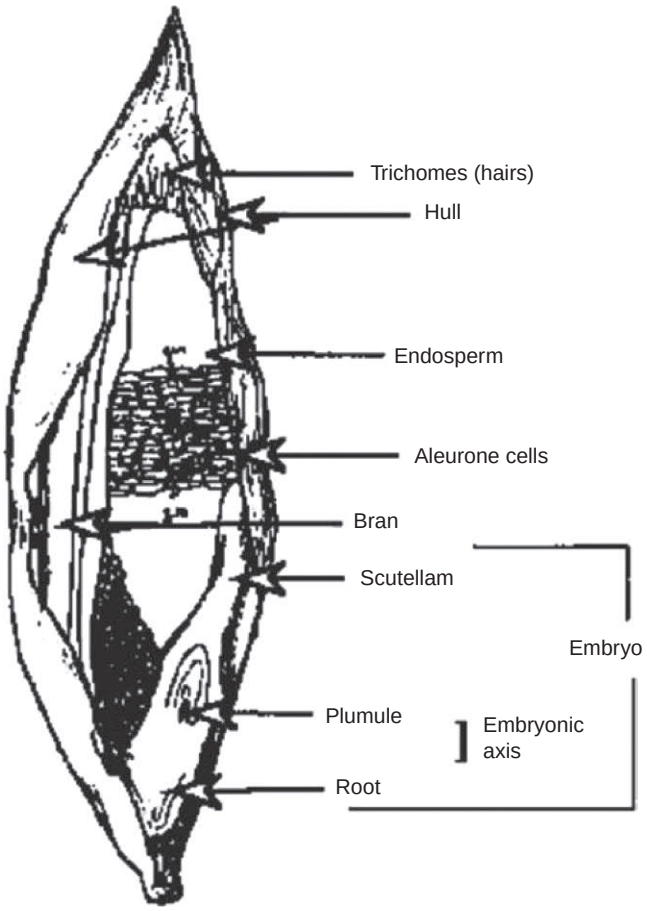

FIGURE 6.9 Structure of an oat kernel. (From Haard et al. [2].)

compound starch granules, which are large granules made up of many smaller individual granules.

6.1.1.7 Rye (*Secale cereale* L.)

Rye is a special European kind of cereal, and more than 90% of the world's production is grown in Europe [21]. Rye kernels are harvested hull-free and have typical grain caryopsis components. The kernels are grayish in color, 6–8 mm in length, and 2–3 mm in width. Like the other cereals, rye consists mainly of pericarp, seed coat, aleurone layer, germ, and endosperm. The endosperm is surrounded by a single layer of aleurone cells. The starch in the endosperm cells has large lenticular and small spherical granules, like wheat and barley. The longitudinal section of a rye grain is shown in Figure 6.10. A microscopic picture of the grain is presented in Figure 6.11.

Before rye grains can be used in food production, the outer part of the grain, the hull, must be removed. After hulling, which generally occurs during threshing, the grains are used whole, cracked, or flaked, or they are ground to make flakes or flour. The starchy endosperm constitutes about 80–85% of the weight of the whole kernel, the germ 2–3%, and the outer layers about 10–15% [22].

6.1.1.8 Pearl Millet (*Pennisetum glaucum*)

Millet and sorghum are often grouped together because their growing conditions, processing, and uses are similar. Pearl millet is one of the two major crops grown in the semi-arid, low-input dryland agriculture regions of Africa and Southeast Asia [23]. Millet was domesticated in Africa, some 3,000 to

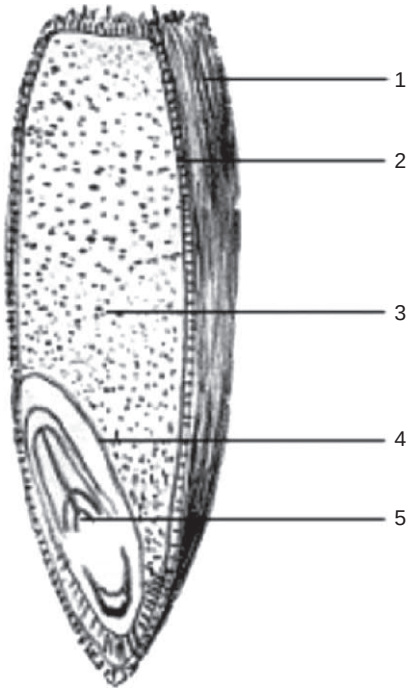

FIGURE 6.10 Longitudinal section through a rye grain [68]. 1: Multilayer husk and seed coat; 2: Aleurone layer; 3: Endosperm; 4: Scutellum; 5: Embryo.

5,000 years ago, and subsequently spread to southern Asia. Pearl millet consists of small (average about 8.9 mg), tear-shaped kernels that are threshed clean of their hulls [15], and, depending on head size, grain number per head ranges from 500 to 3,000 [24]. The caryopsis is very similar to those of other cereal grains. The germ in pearl millet is relatively large (17%) in proportion to the rest of the kernel. Its endosperm has both translucent and opaque endosperm, like those of sorghum and corn. Pearl millet consists of 8.4% pericarp, 75% endosperm, and 6.5% germ [25].

6.1.2 Pulses

Pulses are annual leguminous crops yielding from 1 to 12 grains or seeds of variable size, shape, and color within a pod. Pulses include dry peas, dry beans, vetches, lupins, dry broad beans, lathyrus, lentil, black gram, mung bean, chickpea, pigeon pea, and cowpea, etc. They are used for both food and feed and are important foodstuff in most of the tropical and subtropical countries [26]. The term "pulses" is limited to crops harvested for dry products, excluding, therefore, crops harvested green for forage, used for grazing, or as green manure, and also crops harvested green for food (green beans, green peas, etc.). They also exclude those used mainly for extraction of oil (soybeans and groundnuts), and crops whose

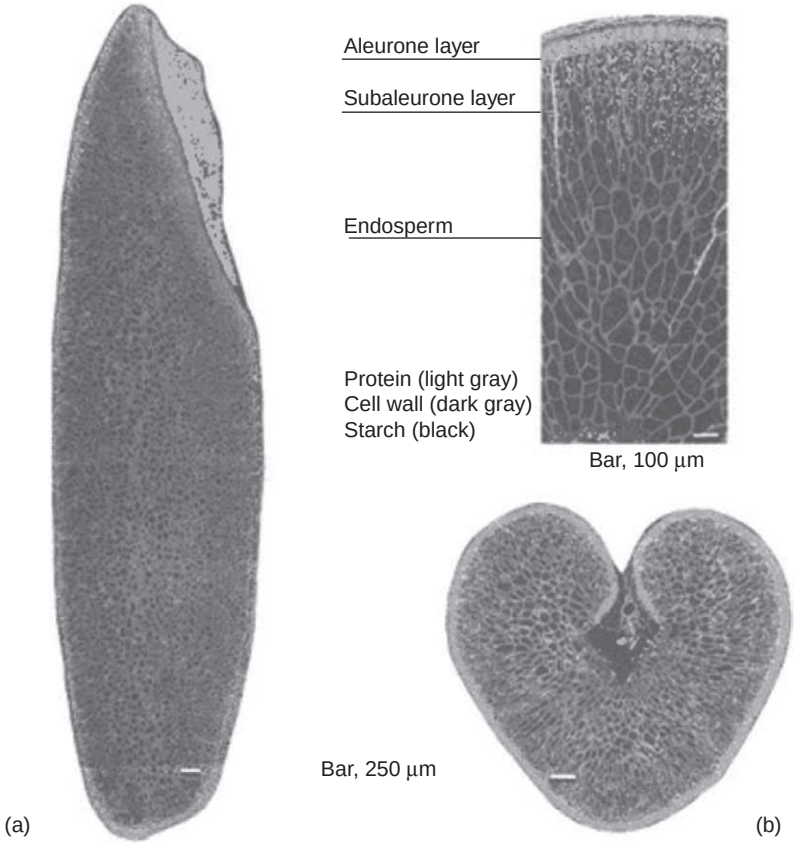

FIGURE 6.11 Microscopic picture of rye grain. (From Nordic Rye Group [22].)

seeds are used exclusively for sowing purposes, such as alfalfa and clover [1].

The structure of food leguminous plants is similar. Mature legume seeds have three major components: the seed coat, the cotyledons, and the embryo axis, which constitute 8, 90, and 2% of the seed, respectively [5]. The structure of a typical legume seed is shown in Figure 6.12. The outer layer of the seed is the testa or seed coat. Usually, legumes have a moderately thick seed coat. In most legumes, the endosperm is short-lived, and, at maturity, it is reduced to a thin layer surrounding the cotyledons or embryo.

6.2 CHEMICAL COMPOSITION

The relative proportions of the main grain components for different grains are presented in Table 6.1. The grain is composed of both organic and inorganic substances, such as carbohydrates, proteins, vitamins, fats, ash, water, mineral salts, and enzymes. Cereal grains are rich in carbohydrates whereas legumes are rich in proteins. The compositions of some of the cereal grains are shown in Table 6.2.

Pulses contain carbohydrates, mainly starches (55–65% of the total weight); proteins, including essential amino acids (18–25%, and much higher than cereals); and fat (1–4%). Pulses are the richest source of vegetarian protein [27–29]. The proportion of seed coat, cotyledon, and embryo in different legumes is presented in Table 6.3. The cotyledons are the major source of nutrients in pulse grains. Legumes contain an appreciable amount of protein and are a good source of minerals. The compositions of some of the Canadian pulses are presented in Table 6.4.

6.3 GRAIN-GRADING SYSTEMS

Grain-grading systems used around the world are similar and depend mainly on visual inspection and comparison of samples [30]. In Canada, grain is graded on five factors, namely test weight, varietal purity, soundness, vitreousness, and maximum limit of foreign material (not including dockage). Of these, the latter four factors are determined visually by trained personnel, and thus can be influenced by experience and human fatigue [31]. In Australia, grain is routinely segregated based on moisture and protein contents determined by near-infrared spectroscopy [32]. Despite training, the grading decisions are inherently subjective and are influenced by the individual experience of a grain inspector [30].

The grading factors in European Union countries include moisture, broken kernels, grain besatz (shrunken kernels, other grains, insect-damaged kernels), sprouted kernels, black besatz (wheat seed, ergot, unsound grain, chaff, impurities), and hectoliter weight. In Russia, color, odor, taste, moisture, foreign kernels, and damaged kernels are listed as grading factors [21].

6.3.1 Recent Progress in Grain-Grading Technology

Research has been carried out to replace the tiresome job of visually inspecting grain samples by a machine vision system (MVS). Such an MVS should be capable of identifying and grading the grain on the basis of size and shape [33], color [34, 35], and texture [36]. Color and size are important grading factors for certain commodities such as peas and chickpeas.

Several systems have been reported in the literature for inspecting grains using machine vision [37, 38]. For classification purposes, shape is the best feature, followed by color and length of the kernels [31]. Visual appeal directly influences consumer acceptance and hence value of the grains. The main visual factor is the color of grain, which is directly related to its market value [39]. Some investigations have been carried out using color features [40] for classifications of different cereal grains and their varieties and for correlating vitreosity and grain hardness. Liu and Paulsen [41] measured the whiteness of corn quantitatively by computer vision. This is a useful application as the prices of corn depend on color [42].

In recent years, optical, mechanical, and electrical techniques have been applied to rapid grain grading and classification [43]. Delwiche et al. [44] using near-infrared spectroscopy with an artificial neural network identified hard red winter and hard red spring wheat classes with accuracies of 95 to 98%. Steenhoek et al. [45] developed a computer vision system to evaluate blue-eye mold and germ damage in corn grading. Sapirstein et al. [46] employed image processing to identify grains such as wheat, oats, barley, and rye. Gunasekaran et al. [47] detected stress cracks and other damage in corn kernels and soybeans from their images. Shatadal et al. [48] used parameters such as area, length, width, and compactness of grain binary images to recognize wheat, oats, barley, and rye. Zayas et al. [49] determined wheat variety by using the texture characteristics of wheat images. The Canadian Grain Commission (CGC) has developed a grading instrument for assessing the color and size distribution of lentils. Modules for grading other pulse grains such as peas, chickpeas, and beans are under development [50].

Stress fissures detection is one of the most important tasks in rice grain quality inspection. A machine vision system has been used successfully to reveal fissure lines in rice [51]. Peck damage is another quality factor affecting the grading and marketing of rice. The rice stink-bug, *Oebalus pugnax*, is a key pest that causes peck damage. An objective method has been developed to classify pecky rice kernels [52].

6.3.2 Grading Systems

Grading systems are used in the marketing of grain. The grade standing systems are not universal and vary significantly between countries. The U.S. grading system for yellow corn is presented in Table 6.5. The grading systems for wheat in Germany and Italy are presented in Tables 6.6 and 6.7, respectively.

TABLE 6.5
U.S. Grade Requirements for Yellow Corn

U.S. Grade	Minimum Test Weight/Bu, lb	Heat Damaged Kernels, Maximum Limit, %	Total Damaged Kernels, Maximum Limit, %	Broken Corn and Foreign Material
No. 1	56.0	0.1	3.0	2.0

6.3.3 Computer Vision Technology

A fast and objective grain-grading and classification system would reduce the inaccuracy caused by inspector subjectivity. Grain quality inspection using computer vision is a nondestructive method. However, the application of computer vision technique for the objective classification of cereal grains and varieties is still at its infant stage. Further development in both software and hardware is necessary for this technology to become more widely used.

6.4 HARVESTING AND THRESHING

Harvesting of cereal grains and pulses refers to the activities performed to obtain the kernels of the plant for grain, or the entire plant for forage and/or silage uses. These activities are accomplished by machines that cut, thresh, screen, clean, bind, pick, and shell the crops in the field. Harvesting also includes loading harvested crops into trucks and transporting crops in the grain field [53].

Cereal kernels are cut as close as possible to the inflorescence. This portion is threshed, screened, and cleaned to separate the kernels. The grain is stored in the harvesting machine while the remainder of the plant is discharged back onto the field. Combines perform all the above activities in one operation. Large amounts of abrasion and breakage may occur as a result of threshing, augering, and impaction when harvested by combines, followed by transfer from combines to grain trucks with subsequent transfer to farm storage [54]. Binder machines only cut the grain plants and tie them into bundles, or leave them in a row in the field, called a windrow. The bundles are allowed to dry for threshing later by a combine with a pickup attachment.

Corn is harvested by mechanical pickers, picker/shellers, and combines with corn head attachments. These machines cut and husk the ears from the standing stalk. The sheller unit also removes the kernels from the ear. After husking, a binder is sometimes used to bundle entire plants into piles (called shocks) to dry [53]. For forage and or/silage, binders, crushers, field choppers, mowers, windrowers, and similar cutting machines are used to harvest grasses, stalks, and cereal grains. These machines cut the plants as close to the ground as possible and leave them in a windrow. The plants are later picked up and tied by a baler. Harvested crops are loaded onto trucks in the field. Grain kernels are loaded through a spout from the combine, and forage and silage bales are manually or mechanically placed in trucks. The harvested crop is then transported from the field to a storage facility [53].

6.4.1 Combine Harvester

Grain harvesting and handling procedures have undergone dramatic changes, particularly with the development of the combine harvester. The combine harvester has become the standard for harvesting grain in the industrialized countries [55] and can perform labor-intensive operations such as harvesting and threshing simultaneously at the field level. Combines are able to fill their grain tanks within 12 minutes and can off-load to a grain cart in as little as 2.5 minutes [56].

6.4.1.1 Function of Combine Harvester

The main process functions of a combine harvester (Figure 6.13) consist of reaping, threshing, separating, and cleaning (Figure 6.14). The threshing function especially is very important because the quality of harvested grain into the tank of the combine harvester depends mainly on the ability of this function [57].

6.4.1.2 Performance of a Combine Harvester

The performance depends on its design, the settings of the individual working elements, the experience of the operator, the harvest conditions, and very strongly on the properties of the harvested materials (Figure 6.15). The technical equipment includes the design of the combine, the threshing and separating system, the dimensions of the individual elements, and engine power. The settings of elements may consist of the speed of the working elements and the concave clearance. Harvest conditions are influenced mostly by the weather, topography, soil conditions, and field size. Though operators are supported by various electronic systems, operators' experience helps in reaching a high field performance. Grain

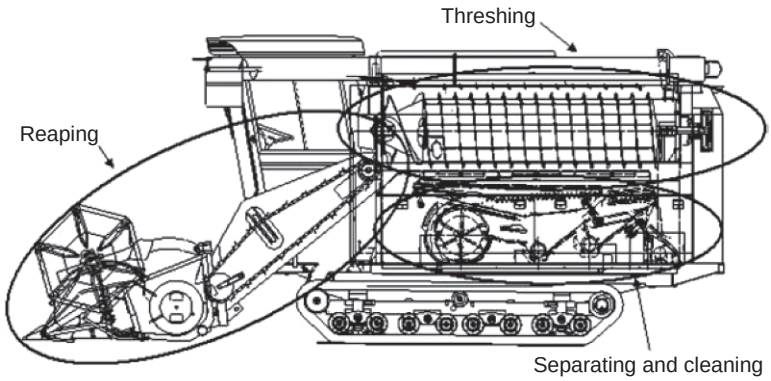

FIGURE 6.14 Main process functions of combine harvester. (From Miyamoto and Murase [57].)

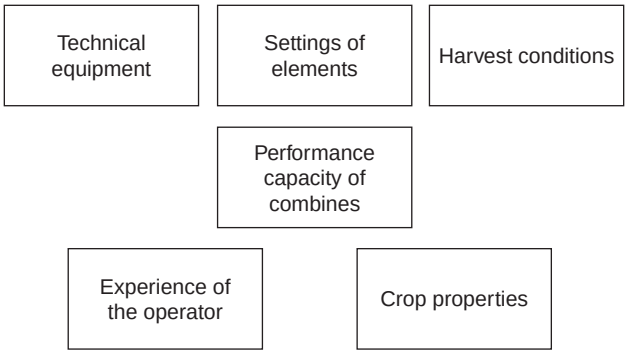

FIGURE 6.15 Influences on the performance capacity of combines. (From Wacker [55].)

properties strongly influence performance capacity and so the field performance [55].

6.4.2 Whole-Crop Harvesting System

Conventional combine harvesting systems harvest only grains and leave the straw and chaffs on the field. If the crop residues are utilized for bioenergy production they have to be harvested with extra cost. Recently, the utilization of crop residues for bioenergy production increased the monetary value of crop residues [58]. Hence, there is a need to harvest both cereal grains as well as crop residues for maximizing profit.

In the case of a whole-crop harvesting system, the whole crop is harvested and transported to a centrally located processing unit where the crops are separated into grains, straws/stover, and chaffs. The cereal grains can be supplied to processing and storage facilities, and straws with high moisture content can be processed into different raw materials based on the requirement of biorefineries.

In the McLeod harvest system, developed by Bob McLeod in western Canada, the harvesting unit cuts the whole crop and threshes to separate the graffs (grains, chaffs, and weed seeds) from the straw [58]. The straws are left on the field for further drying and baling operation. The graff is transported to a central location, where it is further processed to separate grains from chaffs and weed seeds by a milling unit. Figure 6.16 shows the sequential operation of the McLeod harvesting system. It has been reported that the McLeod system is more profitable than the conventional harvesting system.

As new markets begin to emerge for straw and chaff, such as ethanol production and strawboard manufacturing, innovative methods of whole-crop harvesting are being proposed. Five methods of harvesting such as windrow/combine,

straight-cut, stripper header, the McLeod system, and whole-crop baling have been modeled and compared by Ragan [59].

6.4.3 Windrow/Combine

The crop is windrowed (swathed), then harvested with a standard combine with a pick-up header. Straw and chaff are spread behind the combine or dropped in a windrow for baling later. As the system involves separate cutting and threshing operations, additional power is required to pass the entire crop through the combine. Hence, energy consumption is substantially higher than for other systems, and the combine work rate is slow because it is processing nearly all of the available plant material [59]. The conventional swath and combine harvesting method is shown in Figure 6.17.

6.4.4 Straight Cut

The straight-cut system requires one less field operation than the windrow/combine system resulting in less time in the field and lower energy consumption. However, the straight-cut system cannot be used with crops such as pulses and oilseeds. The longer stubble resulting from the higher cut may reduce efficiency in chaff and straw recovery [59]. Figure 6.18 shows the conventional straight-cut harvesting method.

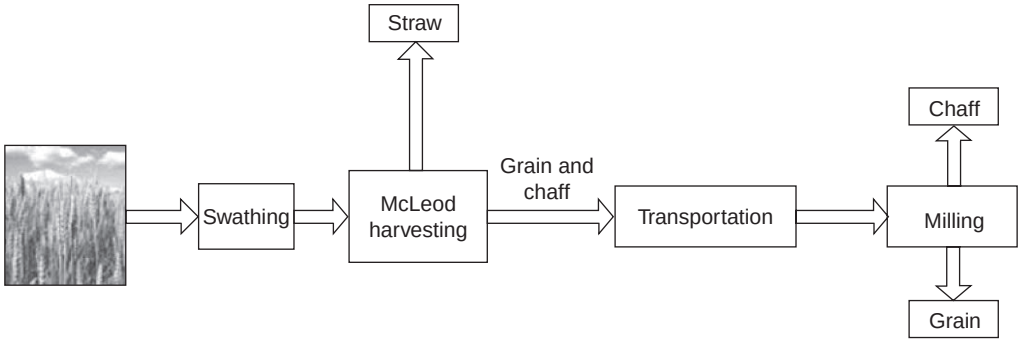

FIGURE 6.16 Sequential operation of McLeod harvesting system. (From Sokhansanj et al. [58].)

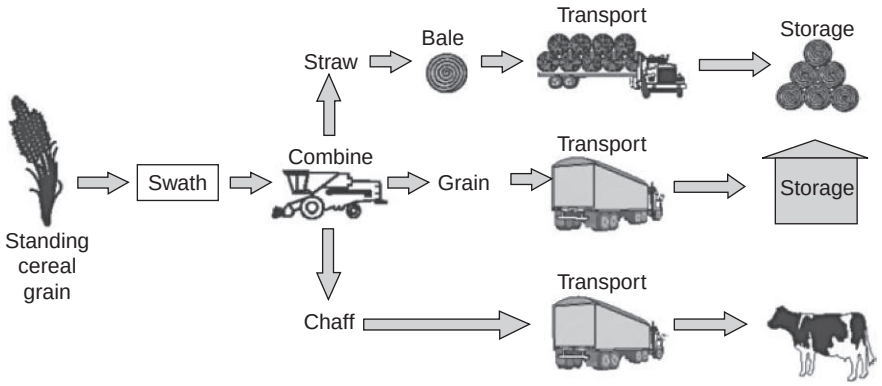

FIGURE 6.17 Conventional swath and combine harvesting method. (From Ragan [59].)

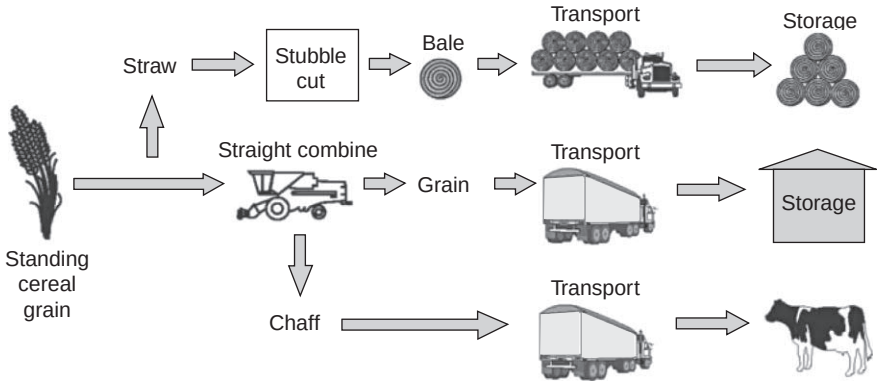

FIGURE 6.18 Conventional straight-cut harvesting method. (From Ragan [59].)

6.4.5 Stripper Header

Currently, stripper headers are being used on conventional combines in place of the straight-cut or pick-up header. Most of the threshing is done by the header, and as a result, much of the capacity of the combine itself is not used. A specifically designed harvesting machine would need to be developed to operate with the stripper header in order to fully capture its inherent advantages.

The stripper header is a very efficient method of collecting grain because of its low energy needs and the short time required for harvesting. In effect, the stripper header removes the heads from the crop and leaves the straw standing. A separate operation is then required to cut the straw so other field operations such as seeding can be conducted with a minimum of problems. Also, some of the straw is flattened in the harvesting operation, making it more difficult to recover later. A limitation is that the stripper header may only be used efficiently with cereal grains [59]. The stripper header harvesting method is shown in Figure 6.19.

6.4.6 The McLeod System

This system is being developed by Bob McLeod of Winnipeg. It consists of a standard combine straight-cut header with a feeder housing and threshing cylinder. The grain and chaff are collected together in a large hopper, and the straw passes over a set of straw walkers to collect any free grain. The unit would be pulled by a large two-wheel drive tractor. The grain/chaff mixture would be transported to the farmyard where it would be processed further by an electric motor driven unit already developed by McLeod [59]. Figure 6.20 shows the McLeod harvesting method, using a straight-cut header.

6.4.7 Whole-Crop Baling

This model does not yet exist as an entire system. It has been based partly on existing machinery—swather and baler—and on assumptions based on previous research done to determine if crops could be baled and then threshed without loss of grain quality or quantity. First, the crop would be swathed to a stubble height of eight inches. Then the entire unthreshed crop would be baled with a medium-sized round baler and transported to the farmyard. In the yard, the bales would be unwrapped and fed through a stationary processor that would perform all the functions of a normal combine [59]. The whole-crop baling method is shown in Figure 6.21.

6.4.8 Stripper Harvester

Stripping involves combing the grain from the panicles without cutting the straw. The simplicity of operation and reduced fuel bills make stripper harvesting an attractive alternative method to conventional harvesting methods [60]. The working part of the header is a rotor of flexible teeth with keyhole access between each pair of teeth. The rotor rotates in the direction opposite to that of a standard reel, and as the crop heads pass through the recesses, the seeds and chaff are stripped from the plant. A conveyor and auger convey the grain and chaff into the combine. It is suitable only for use with grains such as wheat, barley, and oats, and similar types of plants [59].

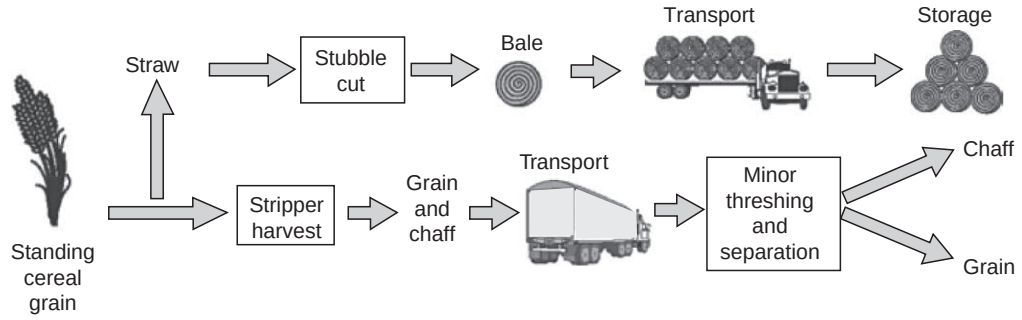

FIGURE 6.19 Stripper header harvesting method. (From Ragan [59].)

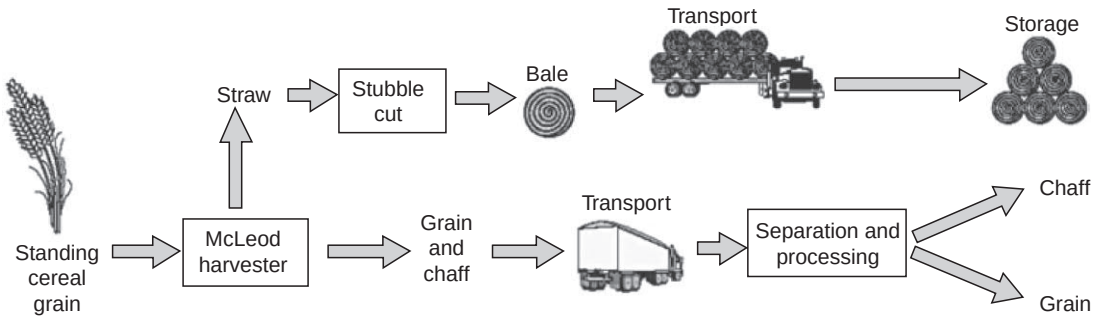

FIGURE 6.20 McLeod harvesting method, using straight-cut header. (From Ragan [59].)

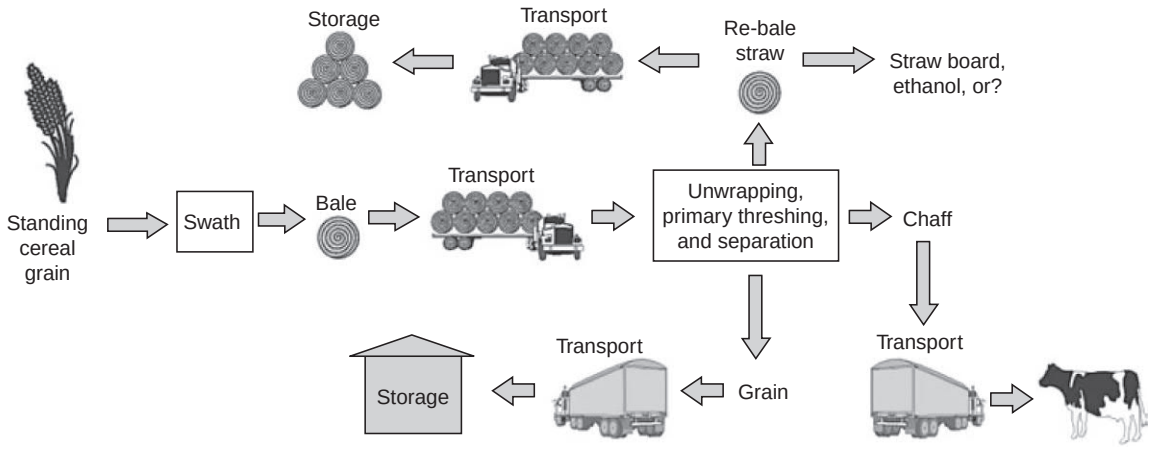

FIGURE 6.21 Whole-crop baling method. (From Ragan [59].)

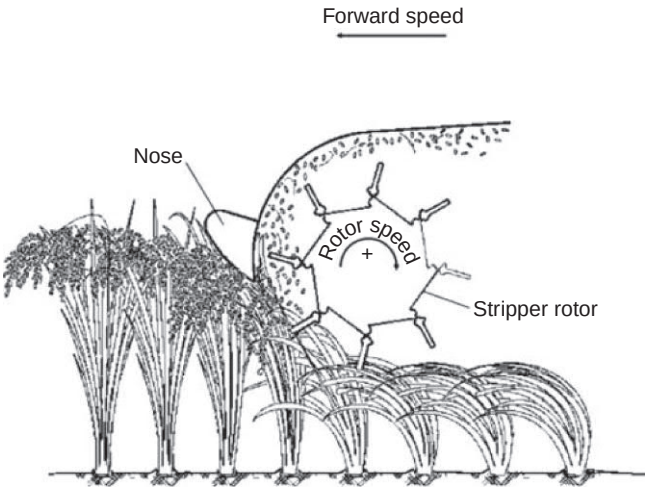

FIGURE 6.22 Principle of operation of the Silsoe stripper rotor. (From Tado and Quick [60].)

With the stripper header in operation, the grain and some leaves are the primary parts of the plant that pass through the thresher. The entire stem of the plant is left standing in the field. The amount of biomass left standing by these headers is greater than that of conventional combine headers. Harvesting speeds could be as high as 2.3 m s^{-1} (5 miles hr^{-1}) with this type of header, but they do not work efficiently in lodged rice [61].

The most promising stripper system header was developed by Silsoe Research Institute, UK. The Silsoe stripper rotor (Figure 6.22) combs up through the crop as the machine moves forward removing the grain from the plant in situ. Flexible V-shaped teeth guide the plant into a keyhole-shaped slot at the base of the teeth where stripping occurs. The upward rotation of the stripper teeth with respect to the crop allows the rotor to pick up fallen plants or lodged crops. The rotor is enclosed on the top by a hood that guides the stripped material back for collection or further processing. A nose protrudes

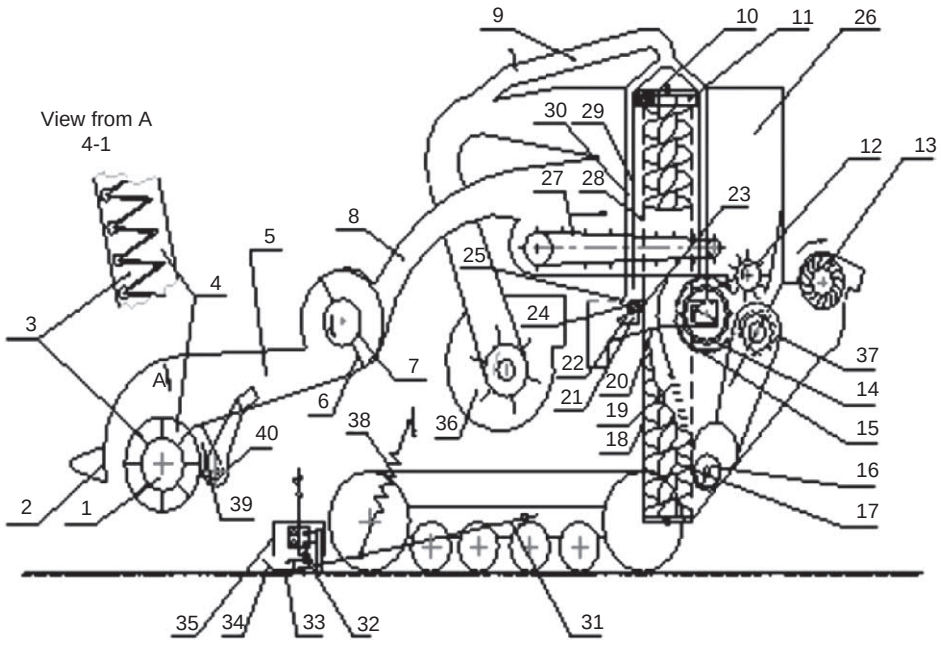

FIGURE 6.23 Schematic arrangement of combine stripper harvester for rice and wheat. (From Jiang et al. [64].)

forward from the inlet edge of the hood to deflect gently the crop prior to stripping. The stripper rotor simultaneously carries out four functions: crop lifting, harvesting, partial threshing, and crop transport that corresponds to the function of the crop reel, cutter bar, threshing drum, and crop conveyor on a conventional combine harvester [62]. Combines fitted with stripper headers are used in the rice fields of Australia and the United States [63]. Specifically designed equipment to complement the stripper header has not yet been developed [59].

A new combine harvester that is capable of cutting and windrowing straw immediately after stripping has been developed for rice and wheat harvesting [64]. Stripper header, grain collection and cleaning mechanism, and straw cutting and windrowing are key components of the combine harvester. The field-testing results show that the free grain loss is low owing to the use of a pneumatic conveying system, and high grain cleaning capacity is achieved by using a vertically cylindrical cleaning system. The schematic diagram of the combine stripper harvester is shown in Figure 6.23. Stripper headers have become more popular for harvesting rice. The shortcomings of existing strippers include high shatter losses caused by crop disturbance, incomplete grain detachment, failure to collect detached grains, blockages of essential crop aligning or stripping components, and inability to harvest tangled and lodged crops satisfactorily [65].

7 Postharvest Handling of Grains and Pulses

Ajit K. Mahapatra and Yubin Lan

CONTENTS

7.1 STORAGE OF GRAINS AND PULSES

7.1.1 Grain Storage: Perspectives and Problems

The primary aim of storage is to prevent deterioration of the quality of the grain. This is achieved through control of moisture and air movement, and by preventing infestation of microorganisms, and attacks of insects and rodents. Foodgrains can be stored for relatively long periods of time under proper storage conditions (low temperature, inert atmosphere, etc.), with little or no detectable loss of quality. The length of time grain can be held in storage depends on the moisture content of the grain, the temperature of the grain, and whether the grain can be kept from heating by means of aeration [1]. Grain spoilage is the result of microorganisms (bacteria, yeast, and fungi) using grain nutrients for growth and reproductive processes. Microorganisms also produce heat during growth that can increase the

temperature of stored grain. Under proper environmental conditions, certain microorganisms can produce toxins or other products that can cause serious illness and even death when consumed by livestock or humans [2].

Safe storage must maintain grain quality and quantity. This means protecting it from weather, molds and other microorganisms, the addition of moisture, destructively high temperatures, insects, rodents, birds, objectionable odors, and contamination. High temperature and high moisture are the most significant factors affecting grain quality in storage. Each can cause rapid decline in germination, malting quality, baking quality, color, and oil composition. Insects and molds impair the quality of grain directly by their feeding and development, and indirectly through the generation of heat and moisture. High temperatures and moistures favor the development of insects and molds. The development of insects is limited by temperatures below 15°C and by moistures below 9% in cereal grains, whereas development of molds is limited by temperatures below 10°C and by moistures below 13% in cereal grains. Spraying with insecticides or fumigating minimizes insect problems but leaves chemical residues in grain [3].

7.1.1.1 Environmental Factors Influencing Grain Quality

To store grain successfully, grain and the atmosphere in which it is stored must be maintained under conditions that discourage or prevent the growth of microorganisms that cause spoilage. Stored-grain ecosystems are complex due to a large number of abiotic and biotic factors and their interrelationships [4]. Computer models have been used to simulate abiotic factors, such as temperatures, moisture contents, and gas concentrations, and biotic factors, such as population dynamics of insects and mites, and fungal growth [5]. Figure 7.1 shows the essential elements of the storage ecosystem, the boundaries of which are the storage container (bag, drum, silo, warehouse, or whatever).

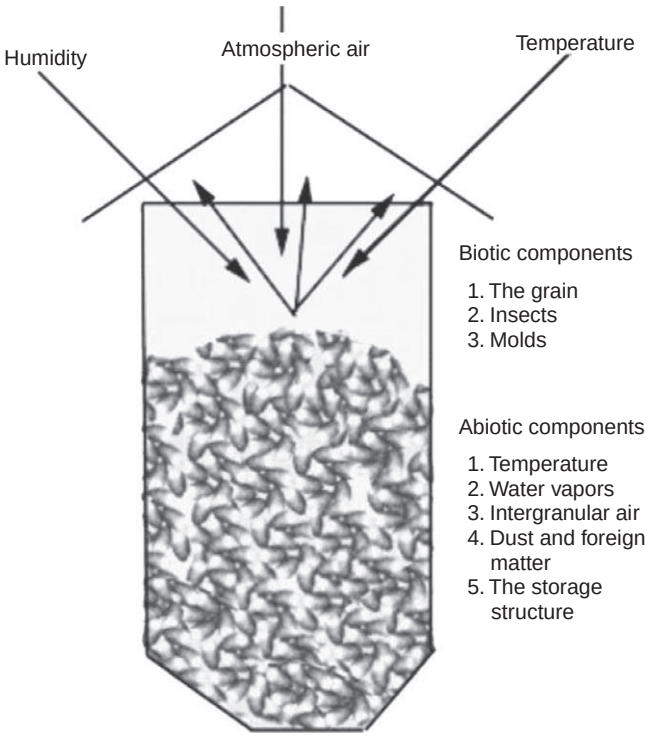

FIGURE 7.1 Essential elements of storage ecosystem. (From Agricultural Research Station of Israel [75].)

7.1.1.2 Types of Storage Facilities

Storage facilities take many forms, ranging from piles of unprotected grain on the ground, underground pits or containers, and piles of bagged grain, to storage in bins of many sizes, shapes, and types of construction. Some of the storage facilities used in the rural areas of Bangladesh are shown in Figure 7.2.

FIGURE 7.2 Rural storage structures in Bangladesh. (From ASB [76].)

7.1.1.2.1 On the Ground

Grain is normally piled on the ground unprotected only between harvest and the availability of transport equipment. Losses are smaller if stored for short periods of time, but the grain is exposed to rodents, birds, insects, and wind so that losses become severe within a week. The angle of repose, pile radius, and bushels for corn, wheat, and sorghum piled from 50 and 60 feet heights for cone-shaped outdoor grain piles are shown in Table 7.1. The amount of ground surface area required for piles that are 15, 20, and 25 feet high for wheat, corn, and grain sorghum are presented in Table 7.2.

If grain must be piled outside on the ground, drainage is a crucial factor. The pile should be on high ground and the earth crowned under the pile. Placing plastic on the ground absolutely is essential to keep soil moisture from migrating into the grain. Piles can be covered with plastic or a tarp to reduce wetting by rain and snow and to minimize damage by wind and birds. Air must flow near the plastic cover to reduce condensation and carry the moisture away. If a rectangular pile is made to store grain, orient the pile north and south to allow the sun to dry condensation off the sloping sides of the cover [1]. The average filling angles of some grains are given in Table 7.3. The quantity of grain in piles can be estimated using Table 7.4. Grain piled outdoors is shown in Figure 7.3.

7.1.1.2.2 Underground

Underground pits (Figure 7.4) are an effective, low-cost method of long-term grain storage, and are most commonly used for storing drought feed reserves on farms. Feed grain

has been recovered in good condition after more than 10 years. The main drawback of underground storage is the difficulty of removing grain. Grain moisture content must be less than 12% to keep the risk of spoilage low. The pit should be located on a well-drained site above the water table, with the immediate surrounds graded to prevent rainfall runoff collecting in the pit area. Water seepage through the sidewalls of the pit is a major concern. Pits should be kept at least 10 m apart to prevent seepage from an empty pit to a full one, and the pit should not be more than 3 m wide. Well-Constructed pit storage is air-tight and oxygen levels gradually reduce over time. The low oxygen levels prevent development of damaging numbers of grain insects. Grain protectants can be applied to the grain when it is placed in storage [6]. Underground storage protects the grain from variations in temperature; the construction is relatively simple; and it protects grain from insects and molds because of the low oxygen and high CO_2 content of the interseed air [7].

7.1.1.2.3 Bagged Storage

Bagged grain can be stored in almost any shelter that protects the bags from weather and predators, and bags can be handled without any equipment. The advantages of a bagged storage system are the lower capital costs without any need for sophisticated aeration and fumigant circulation facilities [8]. However, both bags and bag storage space become expensive, particularly where manpower costs are high. Dunnage should be used to keep grain bags at least 15 cm off the floor. Stack size should not exceed 6 × 9 m, and a stack should be divided into six blocks containing 256 bags, with a row of 6 bags lengthwise adjacent to a row of 10 bags widthwise [9]. Another temporary storage option that holds some promise is the use of large plastic silage bags. Grain going into these bags should be dry and cool (under 15% and 60°F). A system specifically designed for handling dry grain is available from the manufacturer that reportedly greatly reduces grain damage [1]. A bagged storage facility is shown in Figure 7.5.

7.1.1.2.4 Bulk Storage

Bulk storage in beans is the most widely used type of storage for cereal grains. Bins are constructed of steel, aluminum, concrete, and even wood or plywood. Round bins are most common, but large, flat storage buildings are used as well. Figures 7.6 to 7.12 show large-scale grain storage facilities. The capacity of a grain bin per unit depth is presented in Table 7.5.

FIGURE 7.3 Grain piled outdoors. (From Agriculture and Agri-Food Canada [77].)

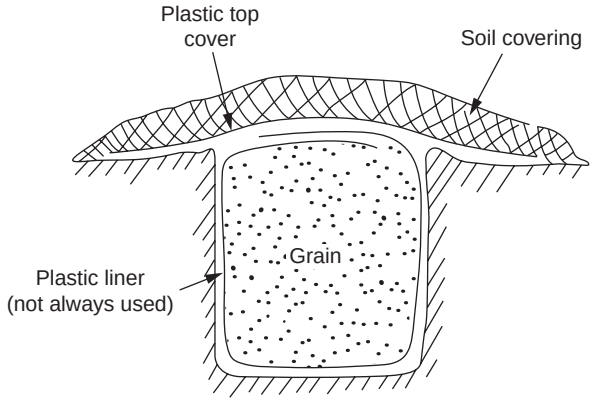

FIGURE 7.4 Underground storage pit. (From DPIF [6].)

FIGURE 7.5 A bagged storage facility. (From Agriculture and Agri-Food Canada [77].)

7.1.1.3 Insects

Insects are a major problem for the storage of grains and seeds. Not only do insects consume some of the grain, but they also contaminate the grain. The U.S. Department of Agriculture (USDA) has estimated that storage losses due to insects exceed $470 million per year [7]. Insects that can live on grain can be divided into those that develop within grain kernels (granary weevils, rice weevils, corn weevils, lesser and larger grain borers, and Angoumois grain moths) and those that develop outside the kernels (red flour and rusty grain beetles, sawtoothed grain beetles, cadelles, khapra beetles, and Indian-meal moths). Some of the insects are shown in Figure 7.13. Grain-damaging insects multiply slowly or not at all below 16°C (60°F), and they cannot survive in temperatures of 42°C (–107°F) or above [10]. Navarro, Noyes, Armitage, and Maier [11] stated that stored-grain insects develop well at 27–34°C (81–93°F) and thrive best at about 29.5°C (85°F).

Moisture is another important factor in controlling grain infestation. Generally, moisture contents of 9% or lower restrict infestation. Even though the grain is stored at a relatively safe storage moisture of 11–14%, in the presence of insects the grain often "heats." The heat is caused by the metabolic heat of the insects. Because of the increased temperature, moisture migration occurs and results in increased moisture in pockets of grain. This leads to microorganisms growing. Air movements in grain and development of hotspots due to insect infestation during storage are shown in Figures 7.14 and 7.15. Table 7.6 lists some common grain-storage insects and their optimal growth conditions.

7.1.1.4 Aeration

Grain stored for long periods of time is generally aerated to maintain the overall quality and reduce the risk of storage losses due to insects and mold growth. Aeration is the process of blowing ambient air through grain masses for the purpose of cooling and conditioning grain [12]. It is a well-known and proven integrated pest management (IPM) tool for controlling insects and other risks in stored grain. Aeration reduces or inhibits biological activity by cooling the grain and preventing moisture migration by maintaining a relatively uniform temperature throughout the grain mass [13].

Aeration can cause changes in temperature and moisture content of the stored grain as "aeration fronts" pass through the grain. In bins over 2000 bushels capacity, the grain bulk or mass is so large that it fails to cool uniformly enough to avoid storage problems as outdoor temperatures change with the seasons [14]. The unequal temperature in the grain mass then causes air current to circulate from warm to cold grain. Since warm air holds more moisture than cold, the air moving up through the warm grain center picks up a full load of moisture, depositing some as it moves through the cold grain in the top layer. This causes moisture buildup, molding, and crusting. These minute "convection currents" in the grain cause moisture migration and accumulation that can only be prevented by reducing temperature difference in the grain bulk. The aeration process is illustrated in Figure 7.16.

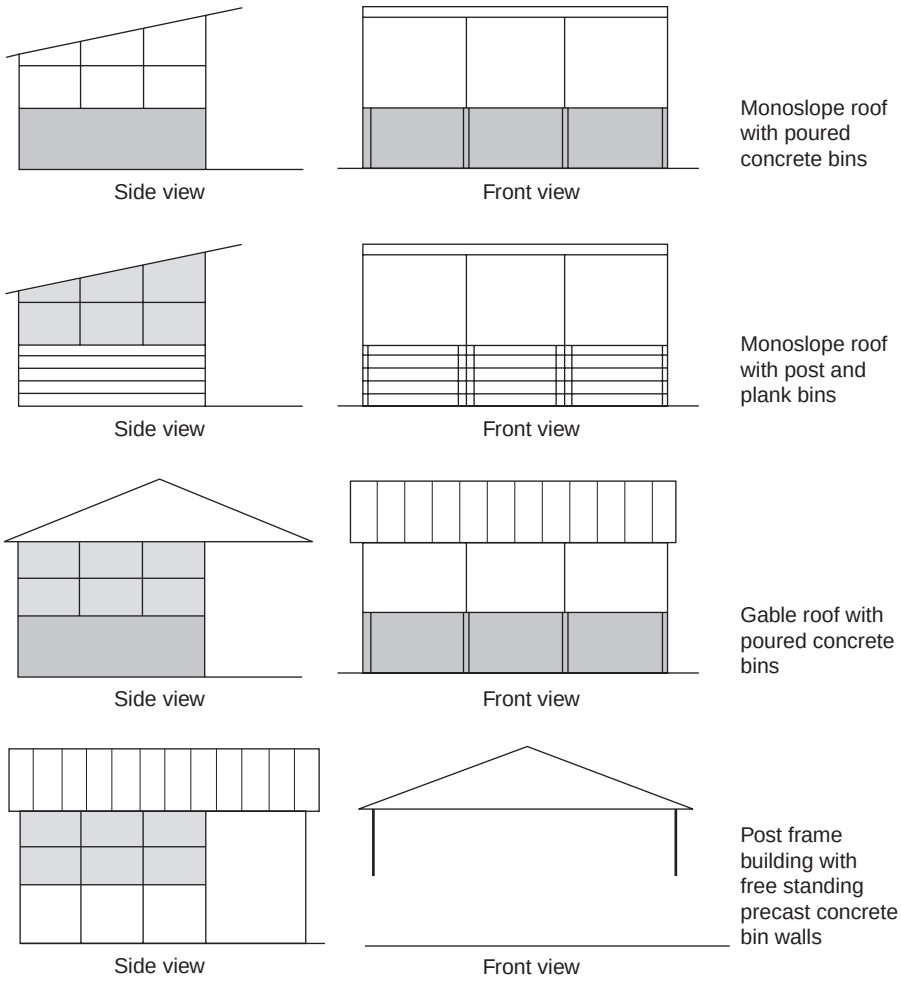

FIGURE 7.6 Typical bulk storage sheds. (From Tyson and Graves [78].)

Typically it is recommended that grain producers maintain the temperature of the stored grain to within +5.5°C (10°F) of the average monthly temperature (depending on location), but not to exceed 15°C (59°F) in the warmer months or less than 0°C (32°F) during the winter [15].

The amount of time required for cooling grain is a function of the airflow rate (fan size), air temperature, and relative humidity of the air. If drying occurs during aeration, evaporative cooling effects will significantly reduce the amount of time required to cool a bin [16]. However, it is not necessary to cool the grain mass below 35 to 40°F because the activity of important storage fungi is very low below these temperatures. The aeration system should not be used to raise the grain temperature above 60°F because mold and insect growth occur at a much faster rate above this temperature [2]. Power requirements for aeration vary with airflow rate, type of grain, and the distance the air must travel through the grain (Table 7.7). The airflow rate should be adequate to cool the entire grain mass before deterioration begins. Normal aeration airflow rates range from 1–2 liters of air per second per cubic meter of grain (1–2 L/s-m^3) (0.08–0.16 cfm/bu). Higher rates should be used (2–6 L/s-m^3) if the grain is stored at higher moisture levels or if a large variance in incoming moisture levels exists [17]. Uniform temperatures through grain mass (Figure 7.17) can be maintained in aerated grain storage if the aeration system has been well designed and is properly operated. Aeration ducts installed in a bin is shown in Figure 7.18. Automatic control of aeration based on ambient temperatures is an inexpensive method to improve the efficiency of aeration systems.

FIGURE 7.9 A bin complex. (From Agriculture and Agri-Food Canada [77].)

FIGURE 7.10 Wooden bins. (From Agriculture and Agri-Food Canada [77].)

7.1.1.5 Grain Inspection

The grain surface should be inspected at least every other week throughout the storage period. Signs of hot spots, insect infestations, or other problems that start in the grain mass soon migrate to the surface. Hot spots will be seen as damp,

FIGURE 7.11 Hopper-bottom bins. (From Agriculture and Agri-Food Canada [77].)

FIGURE 7.12 Farm bins. (From Agriculture and Agri-Food Canada [77].)

warm, and musty areas. Insects and mold growth are more likely to show up where broken corn has accumulated.

7.1.1.6 Chemical Methods

Insect infestation in stored grain and grain products can be controlled effectively by fumigation. Over the past 100 years, fumigation has been the most effective method of pest control in stored rice [18]. Up to nine different chemicals have been used as fumigants, but only chlorpyrifos-methyl (Reldan) and phosphine are currently considered safe. Historically, malathion and methyl bromide were used extensively to protect stored rice from insect damage, but many stored-product insect species have developed resistance to malathion [19]. Many of the chemical pesticides used to protect rice and other grains from insect activity are threatened by environmental legislation. For example, methyl bromide depletes the ozone layer and was ordered to be phased out of use by 2005 in developed countries in response to the Montreal Protocol. Other pesticides may be in danger of losing their registration status due to the Food Quality Protection Act and other Environmental Protection Agency rulings [20]. Chlorpyrifos-methyl is the only insecticide labeled for direct application to stored rice, but recently published reports have stated that

TABLE 7.5
Capacity per Unit Depth for Grain Bins of 4.6 m (15 ft) to 14.6 m (48 ft) Diameter

Diameter (ft)	15	18	21	24	27	30	33	36	39	42	48

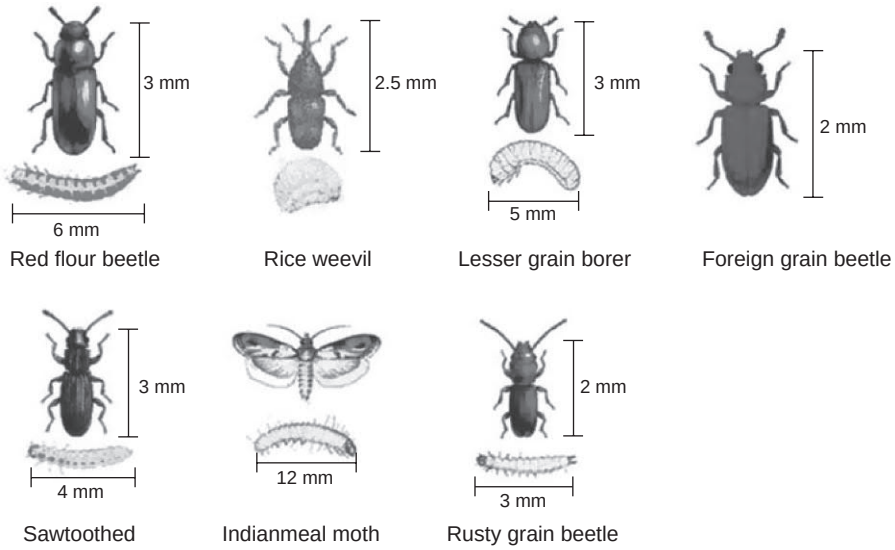

FIGURE 7.13 Some of the grain insects and their dimensions. (From Agriculture and Agri-Food Canada [77].)

lesser grain borers are developing resistance to chlorpyrifos-methyl [21]. Currently, the main chemical option for controlling insects in stored commodities is the fumigant phosphine. The fumigant phosphine has provided an important replacement to methyl bromide in several situations, but phosphine has one important disadvantage: it requires an exposure period of 5 days or longer, which makes it unsuitable for quarantine fumigation [18].

Other possible methods for the protection of stored products from insect infestations would be through the utilization of diatomaceous earth (DE), an inert dust registered to control insects in stored commodities [22], or through the utilization of radiation. Although the newer formulations of DE are more effective than the formulations of the past, they can still affect the physical properties of the stored grain [23]. It may be possible that DE could be an effective method for prevention of infestations, but Arthur [24] demonstrated that extreme conditions, which may not be optimum for grain storage, are needed to allow the DE formulation to be the most effective. Radiation could also supply a direct alternative to the fumigation of rice, but there are few facilities available for this work.

Insects are poikilothermic organisms; therefore, their activity is controlled by their surrounding temperature. The

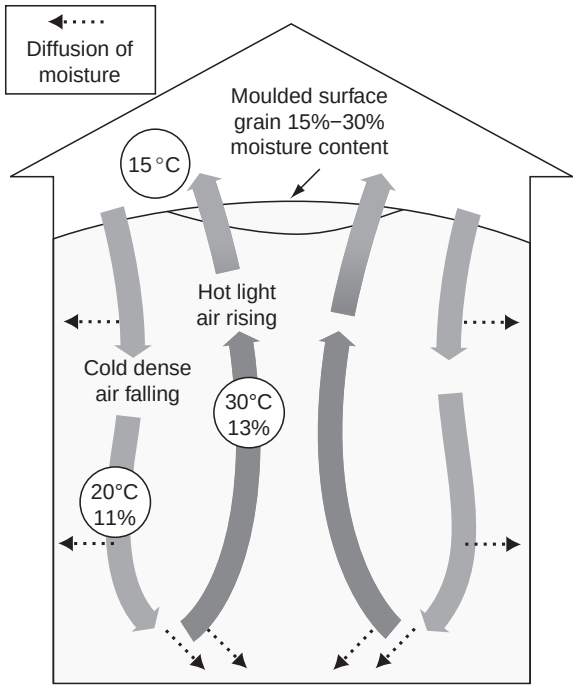

FIGURE 7.14 Air movement in grain. (From Caddick [80].)

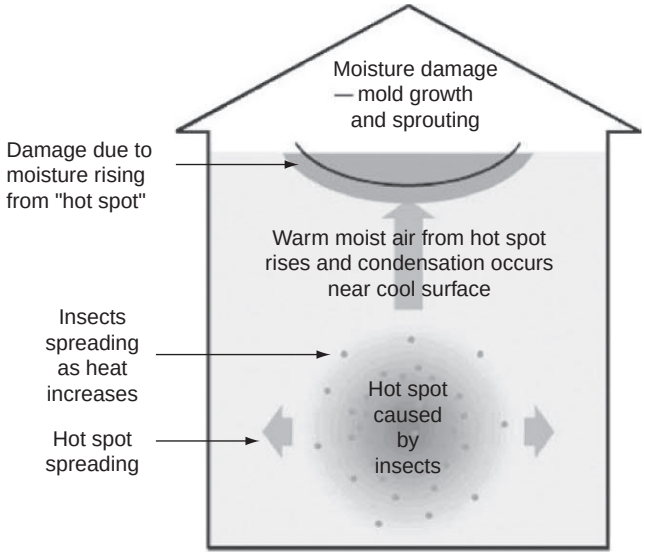

FIGURE 7.15 Development of hotspots due to insect infestation. (From Caddick [80].)

optimal temperatures for their growth and development have been proposed to be between 25°C and 33°C, while 13°C to 25°C and 33°C to 35°C are considered suboptimal [25]. At temperatures below 13°C and above 35°C, most insects will eventually die [26].

7.1.1.7 Rodents

Rodents are among the most important global pests [27]. Three common rodents are the house mouse (*Mus musculus*), the brown rate (*Rattus norvegicus*), and the ship rat (*Rattus rattus*), also known as the roof rat. The brown rat may also be known as the Norway rat, house rat, barn rat, sewer rat, black rat, or wharf rat. Every year, rats in Asia consume food crops that could feed 200 million people for an entire year [28]. Damage due to rodents in Tanzania causes an estimated annual yield loss of 5–15% of corn, corresponding to about $45 million, and food that could feed about 2 million people [29]. In parts of South America, native rodents cause crop damage varying between 5 and 40% of total production [30]. It is estimated that one rat can consume about 10 g of feed per day and destroy ten times this amount during feeding with its droppings and urine [31]. Infestation of feed grains by mites can seriously reduce the nutritional quality the feed grains and acceptance by animals [32]. There is also the possibility of mites causing allergy problems in workers handling contaminated grain and grain products [33].

Rodent killing as a single control measure is expensive and effective for only brief periods of time. It is most effective if carried out during the winter when reproduction is at its lowest level. Two forms of rodent control are normally practiced. Trapping is the most common method of rat killing. Traps may or may not be baited but should always be placed in areas of rodent activity. Bacon, peanut butter, bread, and nutmeats make suitable baits. Mousetraps should be placed at intervals of about 1 m (3 to 4 feet); rat traps should be set 4.5 to 9 m (15 to 30 feet) apart. Traps are an alternative to rodenticides, especially where chemicals cannot be used; however, the use of traps is more labor-intensive than chemicals.

TABLE 7.6
Optimal Development Conditions of Some Common Insect Species Found in Grain Storages

Insect	Temperature (°C)	Relative Humidity (%)
Angoumois grain moth (*Sitotroga cerealella*)	26–30	75
Indian meal moth (*Plodia interpunctella*)	26–29	70
Khapra beetle (*Trogoderma granarium*)	33–37	25
Larger grain borer (*Prostephanus truncates*)	25–32	80
Lesser grain borer (*Rhyzopertha dominica*)	32–34	50–60
Red flour beetle (*Tribolium castaneum*)	32–35	70–75
Rice weevil (*Sitophilus oryzae*)	26–31	70
Rusty flour beetle (*Cryptolestes ferrugineus*)	33	70–80
Sawtoothed grain beetle (*Oryzaephilus surinamensis*)	31–34	90
Maize weevil (*Sitophilus oryzae*)	26–31	70

7.1.2 Structural Considerations: Warehouse and Silo

7.1.2.1 Warehouses

Warehouses are used to store milled rice. Millers normally use bags to store rice, which may vary in size from 50 lb (22.7 kg) to 1 tonne. Warehouses are much less efficient than bins and higher costs associated with storage but are very useful for higher-valued products such as milled and specialty rice [34].

7.1.2.2 Grain Bulk

The design of bins and silos involve bulk materials and geometric and structural considerations. The frictional and cohesive properties of bulk grains vary from one grain to another. In addition, a given bulk grain's flow properties can vary dramatically with changes in numerous parameters, such as particle size, moisture, temperature, and consolidating pressure. Some of the design techniques that are commonly used take into account grain properties such as specific weight (Υ), angle of internal friction (ϕ), and grain-to-wall friction coefficient.

7.1.2.3 Storage Structure Design

While considering the geometric design of a silo, potential problems include arching across an outlet, rat-holing (Figure 7.19) through the material, and the flow pattern during discharge [35]. The arching or rat-holing is primarily related to the grain's cohesiveness, while its flow pattern during discharge depends upon internal friction as well as the friction that

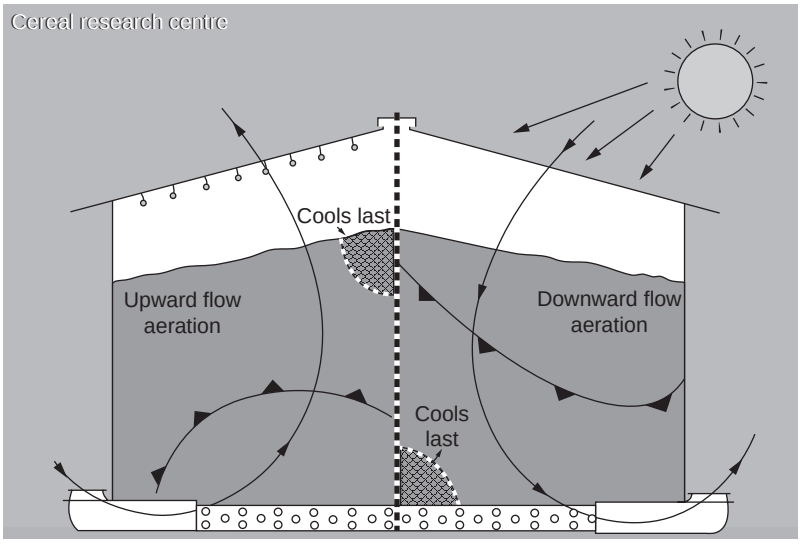

FIGURE 7.16 Aeration process illustrations. (From Agriculture and Agri-Food Canada [77].)

develops between the grains and the hopper walls of the silo. The goal of geometric design is to maximize the usable capacity of a silo while minimizing its capital cost, overall height, etc. [35].

Silo design procedures include the selection of the optimum hopper angles and minimum outlet dimensions. The ideal discharge mode is one where, at steady state, all material flows. The structural design of a silo requires knowledge of the distribution of pressures and shear stresses on its walls (caused by the stored grain) and how that distribution varies during charging, storage at rest, discharging, and recharging [35].

Grain storage bins are generally designed as thin-walled cylindrical shells and typically loaded and unloaded along the line of their central axis. The loads exerted by grain on silo structures can be grouped into two categories: those because of initial fill and those due to flow. When grain is poured into a bin, it forms an angle from the horizontal, called the angle of repose. The outflow hopper at the bottom of a bin must be cone-shaped and have a slope greater than the angle of repose, or the grain will not flow out. Smaller bins require a steeper slope because of the greater friction on the sides of the hopper. The angle of repose of some cereal grains is presented in Table 7.8. The lateral pressure of the grain on bin walls is about 0.3 to 0.6 of the vertical pressure, and the vertical pressure increases very little after a depth of about three times the bin diameter [7]. Grain settles or packs during storage. Lightweight grain such as oats may pack to lose as much as 28% of its volume.

Design values for the coefficient of friction of grains on various materials are important. However, the coefficient of friction varies not only with each type of grain but also with experimental conditions such as moisture content. Hence, the selection of the coefficient of friction will depend on the experience of the individual engineer [36]. Design parameters for some of the grains at different moisture contents are presented in Table 7.9.

Several countries have adopted codes and standards for bin designs to ensure safe and better quality structures. They include the Canadian Farm Building Code [37] and EP433 [38]. In EP433, a maximum of 834 kg/m^3 is recommended for the bulk density of any free-flowing grain, and other material properties depend only on wall material [36]. The properties of some of the wall materials are presented in Table 7.10.

ASAE Standards [38] give design recommendations for axial symmetric states of stress. However, during the

operation of a grain facility, certain loading and/or unloading conditions can create a nonuniform distribution of pressure within a grain bin. The highest asymmetry of bin load is thought to occur during eccentric unloading. Nonsymmetrical bin loads, which occur during eccentric discharge, are considered to be a major cause of bin failure [39].

The design of grain silos requires the designer to understand not only the principles of structural design but also the properties of stored grains. Eurocode for bin design has been published to provide guidelines for silo designers [40]. This design standard predicts bin loads using Janssen's equation.

Recently, numerical methods have been used in grain silo design. It has been possible to better model the behavior of grain inside a bin. However, in order to use these methods, it is necessary to consider additional grain properties, such as elastic modulus (E), Poisson's ratio (ν), and dilatancy angle (ψ). However, very limited information is available on these design parameters [41]. Tables 7.11 and 7.12 present some additional grain properties that can be used in numerical methods of silo design. Storage capacities of grain bins are shown in Table 7.13.

7.2 GRAIN HANDLING

7.2.1 Conveyors

There are various types of grain conveyors, such as en-masse conveyor, U-trough conveyors, and tube augers.

7.2.1.1 En-Masse and Shrouded Conveyors

En-masse conveyors (Figure 7.20) can be designed to move grain in any application, at any operating angle. However, an en-masse conveyor starts to lose capacity with an operating

angle greater than horizontal, and the maximum operating angle is often considered to be 7° [42]. En-masse conveyors do less damage to grain than augers and are often recommended in high-capacity handling situations because of lower power requirements. Once the operating angle exceeds 7°, it is recommended to use a shrouded conveyor. A shrouded conveyor acts more like a drag conveyor, pulling grain along the inside of an enclosed chamber. Shrouded conveyors are typically used with operating angles up to 45° [42].

7.2.1.2 U-Troughs and Tube Augers

U-trough conveyors are often used for horizontal applications for reclaim from bins or across the roofs of bins. Tube augers and U-troughs will both do less damage to grain if run full and at low speeds. Both types of augers lose about 40% of their capacity in wet grain [42]. The capacities and power requirements for horizontal screw conveyors (augers) are presented in Tables 7.14 and 7.15, respectively. The auger capacities will vary with grain type, condition, and loading method. The information presented here is to be used as only a guide and the power requirement will vary with condition and type of grain, loading factor, revolutions per minute (rpm), use of reduction pulleys, and speed reducers. For high moisture grain, the power should be multiplied by a factor of 1.5.

7.2.1.3 Pneumatic Conveyors

Pneumatic conveyors are used for transporting dry grain away from grain dryers to storage bins. Some advantages of pneumatic conveyors are they are self-cleaning, allowing for transport of different products without contamination; dust is totally enclosed, except at discharge; and safe (no moving parts other than blower and airlock). Their disadvantages [42]: power requirements greater than other methods; noisy to operate; grain damage can occur if the system is not operated properly, so grain velocities remain around 762 to 914 m/min (2500–3000 ft/m). Typical pneumatic-conveyor characteristics are presented in Table 7.16.

7.2.1.4 Bucket Elevators

Bucket elevators provide an effective way to distribute and automate handling of grain. Spouts normally come in diameters of 102 mm (4 in.), 152 mm (6 in.), 203 mm (8 in.), 254 mm (10 in.), 305 mm (12 in.), or 356 mm (14 in.) [42]. The power requirement of a bucket elevator depends on the capacity and product-elevating height (Table 7.17).

7.2.2 Controlled Atmospheric Storage of Grain

Controlled atmospheric (CA) storage of grains includes commodity-modified CA storage and artificially modified CA storage [43]. In the case of commodity-modified storage, respiration of the grain and the microorganisms reduce the O_2 and increases the CO_2. The atmosphere in a modified storage is changed by injecting N_2 or CO_2 into the system [9]. Nitrogen-producing exothermic generators are available commercially for altering the intragranular gas composition in a grain storage system. Carbon dioxide (CO_2) is another gas, which can also be used for CA storage of grains.

7.3 MILLING

7.3.1 Grain Milling Operations

The term *milling* refers to the size reduction of granular material, but for cereal grains, the term has different connotations.

Wheat milling means wheat grinding to prepare flour. Rice milling includes operations like dehusking and polishing; whereas pulse milling may involve processing operations such as husk separation, splitting of kernels, and polishing, or just polishing. The dry milling of cereals consists of grain cleaning, tempering and conditioning, and roller milling. It is primarily concerned with separation of the anatomical parts of grain. Roller mills are considered to be the workhorses of the grain milling industry. In flour milling, roller mills perform bran separation as well as size reduction. First-break, or the first roller mill operation in the milling process, performs the first bran separation by opening the wheat kernels with minimum bran breakage. Bran coming out in the form of flakes ensures ease of separation from the endosperm in succeeding stages. Mechanical energy is required to impart compressive and shear forces that break wheat kernels and reduce the size of endosperm particles [44].

FIGURE 7.20 En-masse conveyor. (From GSI Grain Systems [82].)

7.3.2 Specialty Milling

Identity-preserved (IP) grains are referred to as specialty, high value, premium, or niche market grains. They are produced with a specific end-use in mind, perhaps human food, a specific kind of animal feed, cosmetics, pharmaceuticals, or industrial use [45]. An example of an identity-preserved cereal grain is corn: high oil, endosperm/food grade, white, high amylose, waxy, and nutritionally dense (low phytase, high lysine or methionine).

Corn wet milling is a complicated, large-scale, and efficient industrial process designed to separate the chemical components from corn kernels. The success of wet milling, in terms of maximum yields, is largely dependent on the success of the steeping process. Improper steeping, or steeping of corn kernels that have unusual physical or chemical structures, results in lost product and lower profits. Steeping processes, however, are still based largely on an art that was developed more than 100 years ago [46]. As the market increases for specialty corn, corn genetically bred with unique starch characteristics, or corn with altered chemical composition, a thorough scientific understanding of steeping chemistry and the entire wet milling process will become increasingly important.

The wet milling process goes a step further than cleaning, by separating some of those anatomical parts into their chemical constituents, such as starch, protein, oil, and fiber, instead of bran, germ, and endosperm [7]. The steps involved in corn wet milling is shown in Figure 7.21. The different components derived from the corn wet milling operation are shown in Figure 7.22.

The effectiveness of the dry-grind corn process (Figure 7.23) lies in the complete conversion of starch into ethanol. It is important that starch be available for digesting enzymes

such as a-amylase and glucoamylase. This is possible only if starch granules are exposed during grinding and cooking processes. It has been observed that the starch granule structure differs significantly in hard and soft endosperms. The protein and starch matrix also is different in endosperm fractions. It has been observed that hard and soft endosperm in corn significantly differs in their dry milling characteristics, and these differences may be due to structural differences in the protein–starch matrix and nature of endosperm starch granules. Endosperm hardness might have an effect on starch conversion into glucose and the fermentability of glucose into ethanol [47]. Optimization of the dry and wet milling processes require timely knowledge of the distribution of milled products and their by-products. Although the machinery used in various milling operations is important, control and operation of the machines by the operator is even more critical.

7.3.3 Rice Milling and Processing

An ideal rice mill removes the bran layers and germ from brown rice kernels with minimal kernel breakage and preserves each kernel in its original shape [48]. The quality of milled rice is largely determined by the yield of well-milled, whole kernels, referred to in the rice industry as head rice [49]. Broken rice kernels are sold at a much lower price than head rice.

The most common huller used in milling operations is a rubber-roll sheller (Figure 7.24). They are preferred because of their efficiency in removing hull (>90%). In a modern rice mill, a pair of rubber-lined rollers are mounted in an enclosed chamber and driven at a friction ratio. A typical unit using 254 mm nominal width × 254 mm outer diameter rollers run at 1.28:1 friction ratio with the faster roller at 900 rpm. The nip of the rollers is manually adjusted during

dehusking to compensate for the gradual abrasion of the rubber surface and its thermal softening. The paddy passing through the rollers nip is subjected to both compressive and shearing forces. When these forces are correctly predetermined for a particular grade of paddy (by rubber hardness, resilience, rollers nip, speed, and friction ratio), the paddy will remain substantially intact after going through, while the husk is broken off. In practice, dehusking efficiency can be as high as 90% per pass. The products from a rice mill are head rice, brokens, rice bran, rice polish, and the hulls. In general, paddy rice yields 20% hulls and about 2% polish [7]. A schematic diagram of rice milling operation is presented in Figure 7.25.

The pearler or milling machine is the most critical machine in a rice mill, in which barn is removed and also in which most of the breakage occurs [46]. Figure 7.26 shows a mill-top one-pass rice pearler combined with a husker. The degree of milling can be controlled by varying the pressure and thereby regulating the average residence time in the chamber. Figure 7.27 shows a paddy husker.

Parboiling of rice is considered as a means of reducing broken losses during milling. The idea is based on the attributes of the apparent hardness of parboiled rice. Breakage of nonparboiled rice during milling is generally related to various physical properties of the grain and environmental conditions during the growing season, harvesting, handling, and storage of rice [50]. Rice grains with stress fissures break more readily than sound kernels during handling, milling, and transportation, thereby reducing the quality and market value of the grain [51]. The value of the broken rice grain is often one-half the value of the whole grain [52]. The major source of broken rice during milling is fissured grains [53].

7.3.4 Dehulling and Splitting of Pulses

In many countries of the world, pulses are initially processed by removing the hull and splitting into dicotylednous

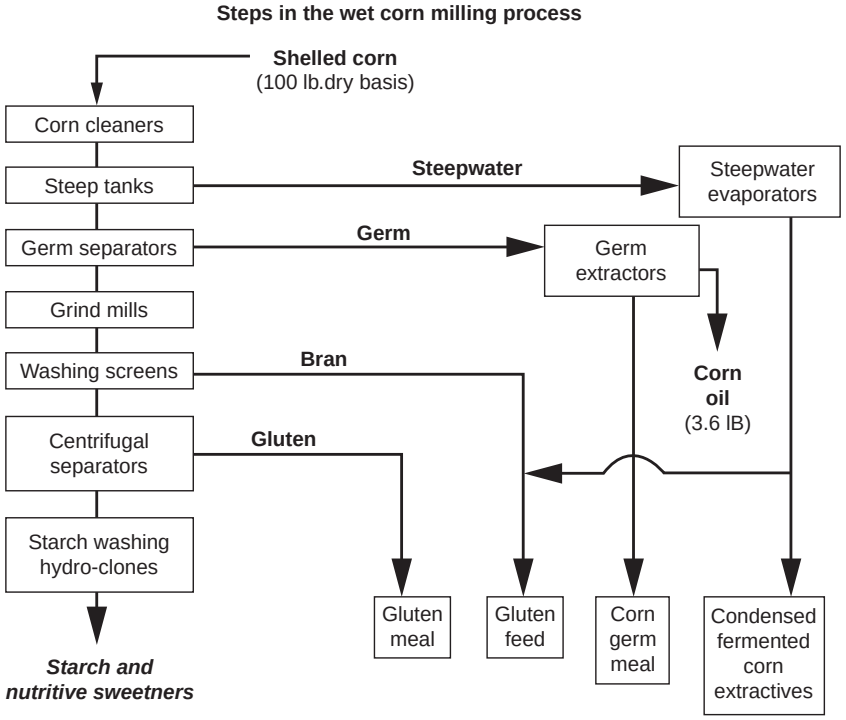

FIGURE 7.21 Overview of a wet corn milling process. (From Schroeder [83].)

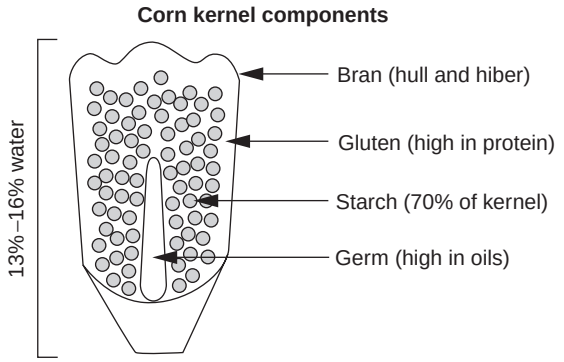

FIGURE 7.22 Component derived from corn in the wet milling process. (From Schroeder [83].)

components. The dehulling operation is usually performed in two steps: the first involves loosening the husk from the cotyledons, and the second removing the husk from cotyledons and splitting them using a roller machine or stone chakki.

Graded grains are made to pass through a roller machine, which causes a mild abrasion (tempering operation). The tempering operation causes slight scratches on the seeds and enhances their oil and water-absorbing efficiency leading to the loosening of the testar. The grain is then treated with oil and water, and then spread on drying yards to dry under the sun. For dehulling of conditioned pulses, emery rollers, called gota machines, are used. In one pass or single operation, about 50% of pulses are dehusked. Dehusked pulses are split into two parts. Dehusked split pulses are separated by sieving and the husk is aspirated off. Unsplit dehusked pulses and tail pulses are again dehusked and milled in a similar way. The whole process is repeated two or three times until all of the pulses are dehusked and split off.

7.3.4.1 Wet Milling of Pulses

There are two types of conventional pulse milling methods in India: wet milling and dry milling. A flow diagram of wet milling is given in Figure 7.28.

7.3.4.2 Dry Milling of Pulses

Hulling of legumes on a commercial scale is generally based on dry-processing techniques. Many of the operations, particularly husking and splitting, are mechanized. For all types of pulses, there is no common processing method. However, some general operations of the dry milling method such as cleaning and grading, rolling or splitting, soiling and moistening, and drying and milling are considered (Figure 7.29). Removal of the loosened husks from the pulses in the dry milling technique is done in small machines. Hand- or power-operated underrunner disc shellers or grinders with emery or stone contact surfaces are normally used. A plate mill with a blunt contact surface is sometimes used both to husk and split soaked and dried pulses. After aspirating or winnowing off the husk, the split cotyledons are separated by sieving. Remaining unsplit whole grains are similarly processed until almost all the grain is husked. In certain parts of India, oil-treated and sun-dried grains are husked in an Engelberg-type rice huller after being mixed with 2–3% stone powder. Sound kernels are removed by sieving, while the husk, powder, and small brokers remain in the stone powder [54]. Figure 7.30 shows the facility for dehulling and splitting of a variety of pulses at the Canadian International Grains Institute [55].

7.3.5 Milling of Pulses

Dry whole seeds of pulses possess a fibrous seed coat or testa (husk, hull, or skin). The seed coat is often indigestible; therefore, pulses are mainly consumed after dehusking to improve their palatability and taste. In most parts of the

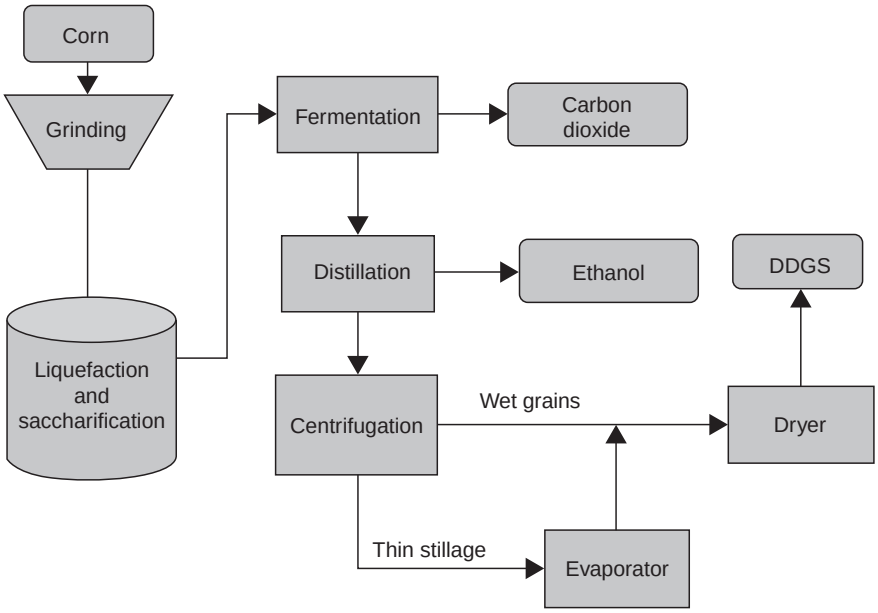

FIGURE 7.23 Dry grind corn process. (From Murthy et al. [47].)

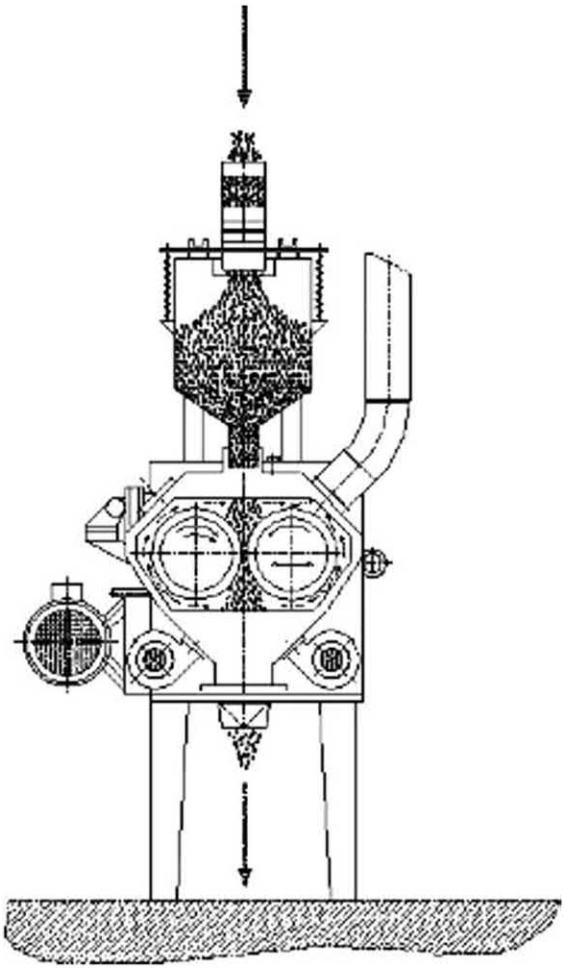

FIGURE 7.24 Rubber-roll sheller. (From Schule [84].)

world, pulses are traditionally consumed either in the whole or in the form of dehusked split pulses. Dehulling, therefore, is an important primary processing activity. Milling provides dehulled cotyledons with better appearance, texture, and cooking qualities [56].

7.3.5.1 Milling Technologies

Milling of pulses involves the removal of the outer husk and splitting the grain into two equal halves. Generally, the husk is much more tightly held by the kernel of some pulses than most cereals, causing dehusking of pulses to be a problem. The method of alternate wetting and drying is used to facilitate dehusking and splitting of pulses. In developing countries, the dehusked pulses are produced by traditional milling methods. In traditional milling, loosening of the husk by conditioning is not sufficient. Therefore, a large amount of abrasive force is applied for the complete dehusking of the grains, which results in high losses in the form of brokens and powder. Consequently, the yield of split pulses in traditional mills is only 65–70% in comparison to 82–85% potential yield [57].

Pulse milling constitutes two major steps: loosening of the husk, followed by removal of the loosened husk by suitable milling machinery. The first step is referred to as premilling, whereas the second is referred to as milling or dehulling. Loosening of the husk is achieved either by a wet or dry method. In the wet method, the grains are soaked in water for a few hours, drained, left in heaps (usually overnight), and dried in the sun. In the dry method, cleaned and size-graded grains are mixed with a small amount of oil, usually after scarification of husk. This scarification of husk is commonly called pitting and is done to facilitate the oil penetration between the husk and the cotyledons. Oil-treated grains are heaped overnight and then dried in the sun for 2–5 days, with intermittent water spraying and mixing. In both of the premilling treatments, adherence of the husk to the cotyledon weakens and, as a result, its removal becomes easy [56].

There is no common processing method for all types of pulses. However, some general operations of dry milling have been described here. General operations of dry milling include cleaning and grading, rolling or pitting, oiling, moistening, drying, and milling [58]. In India, traditional Dhal milling is the most common processing method used for most pulses.

7.3.5.2 Unit Operations

Conventional pulse milling involves many unit operations, such as cleaning the raw material, size-grading, scarification of the husk (pitting), oil mixing, water mixing, drying, dehulling, splitting, aspiration of husk separation of brokens and splits, and, finally, polishing [56].

7.3.5.2.1 Cleaning and Grading

The basic step involved in the processing of pulse products is the cleaning of the raw material. In cleaning, the main aim is to remove any foreign material, adhering soils, dust, chaff, and fungal spores that are attached to or mixed with the product. A simple cleaning unit may consist of a vibratory inclined sieve, hopper, grain collector, waste collector, and motor. The vibratory sieves have different size openings to match the requirements of the type of final product being processed. Grains can be graded according to size by hand-operated or power-operated cleaners and graders.

Cleaning facilities also usually grade the pulse seeds, primarily based on size, color, and absence of visible damage or infection [59]. Color and size are important grading factors for certain pulses. The Canadian Grain Commission (CGC) has developed a grading instrument for assessing the color and size distribution of lentils. Modules for grading other pulses, such as peas, chickpeas, and beans are under development [60].

7.3.5.2.2 Color Sorting

Color sorting is another means of adding value to pulse seeds. The technology uses ultraviolet light to differentiate seed coat color as seeds pass through the machine. However, this advanced technology is very expensive and only a very few pulse processors in some developed countries can possess it.

7.3.5.2.3 Pitting

An emery roller machine is used to achieve cracking and scratching of clean pulses passing through it. This leads to the facilitating of water absorption. The clearance between

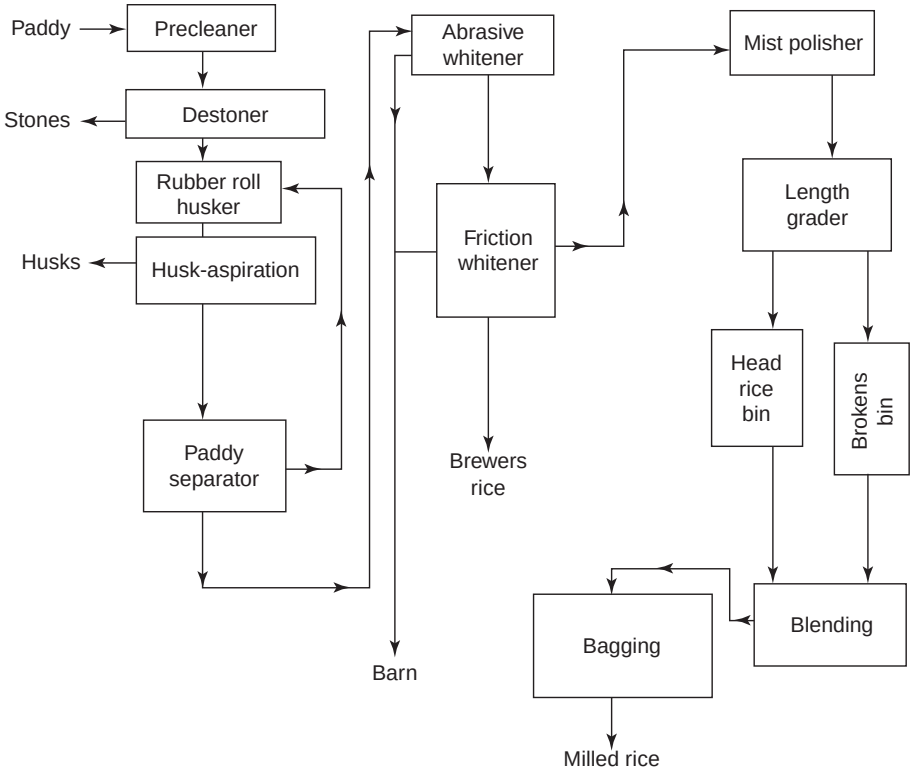

FIGURE 7.25 Schematic representation of rice milling operation.

the emery roller and cage (housing) gradually narrows from inlet to outlet. Cracking and scratching of husks take place mainly by friction between pulses and emery as the material is passed through the narrowing clearance. Some of the pulses are dehusked and split during this operation and are then separated by sieving. Pitting or scratching of grain legumes is done using a roller machine.

7.3.5.2.4 Pretreatment with Oil

A screw conveyor allows passing the scratched or pitted material through it and mixing of some edible oil, such as linseed oil (1.5 to 2.5 kg/tonne of pulses). Then they are placed on floors for about 12 h to diffuse the oil.

7.3.5.2.5 Conditioning

Pulses are conditioned by alternate wetting and drying. Moisture (3–5%) is added to the pulses after sun drying for a certain period and then tempering is done for about 8 h. The grain is dried in the sun again. By allowing water to drop from an overhead tank on the pulses that are passed through a screw conveyor, the addition of moisture to the pulses is achieved. The screw is slowly rotated (50–70 rpm) to achieve proper mixing of oil–water with the grain. The length and width of the conveyors range between 1500–2500 mm and 200–300 mm, respectively [56]. Until all pulses are sufficiently conditioned, the whole process of alternate wetting and drying is continued for 2 to 4 days. Pulses are finally dried to about 10–12% moisture content. Mechanical hot-air-drying systems can also be used for drying of pulses.

7.3.5.2.6 Dehusking and Splitting

Dehusking is a process that reduces the fiber content and improves the appearance, texture, cooking quality, palatability, and digestibility of grains [61]. In one pass or single operation, about 50% of pulses are dehusked. Dehusked pulses are split into two parts. The split pulses are then separated by sieving and the husk is aspirated off. Unsplit dehusked pulses and tail pulses are again dehusked and milled in a similar way. Until the remaining pulses are dehusked and split, the whole process is repeated two or three times. Teckchandani and Mukherjee [62] reported that recovery of dehusked splits is in the range of 68–75% in three passes. A simple box-type aspirator with a suction fan or a cyclone-type separating system can be used. Split pulses are often used by processors in stews and soups because they cook much faster than whole pulses [59].

For splitting, various machines similar to underrunner disc shellers, attrition mills, roller machines or impact machines are used. In India, carborundum emery rollers are used for dehusking, while burr grinders are used for splitting [63]. Dehusking and splitting can also be achieved in a roller machine and can be done as either simultaneous or separate operations. In separate operations, the water-treated and sun-dried seeds are split in sheller machines [64].

7.3.5.2.7 Improved Dehusking Method

A hot air stream of 300°C is passed through the grains to reach a critical point, which makes the seed coat brittle. Then the seeds are allowed to pass through the pulse-dehulling

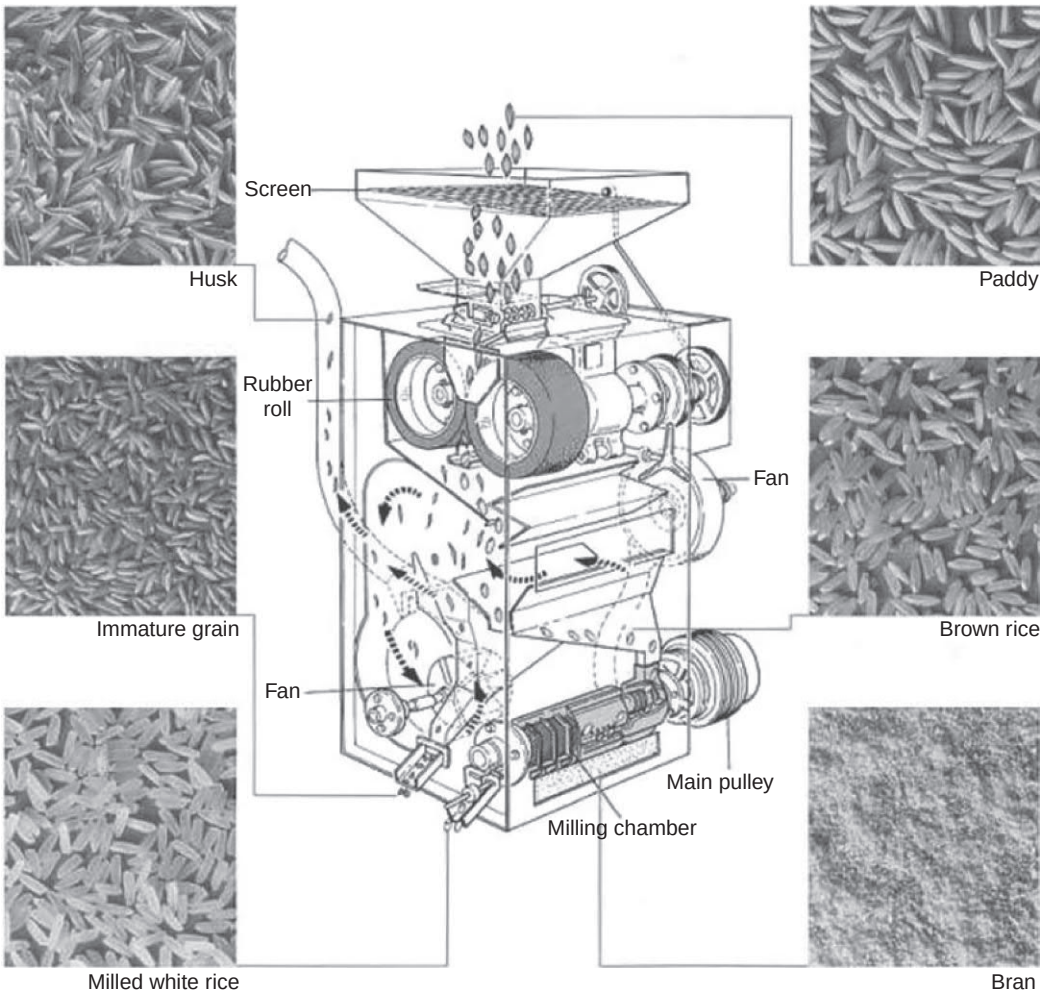

FIGURE 7.26 One-pass rice pearler combined with husker. (From Stake Corporation [85].)

machine to remove the seed coat. This action is achieved by stone-coated rollers [65].

7.3.5.2.8 Polishing

Polishing is done to provide a luster and improve consumer appeal. A screw conveyor is usually used for this operation. Depending on consumer need, different polishing materials, such as water, oil, or soapstone powder are applied to the split surface [56]. Products can then be packaged for consumption.

7.3.5.3 Pulse Flour Milling

Cleaned seed is ground into flour using a hammer, pin, and/or roller mill. Flours can be made from whole seed, dehulled whole seed, or dehulled split seed. Consumers usually prefer dehulled pulse flour, as the bitter flavor, typical of pulses, is minimized [59]. The flour is then packaged and sold to either the retail or ingredient supply market.

7.3.5.4 Fractionation

A relatively new opportunity in pulse processing is specialized wet and dry milling to fractionate pulses. This method generates products that can be sold as ingredients to food processors and other industrial users [59]. With respect to legume utilization, milling of legumes and fractionation of protein and starch have increased in recent years. Milling of whole seed or dehulled seed followed by fractionation of starch-rich and protein-rich fractions will improve the utilization of legumes [66]. The air classification technology is based on the utilization of a spiral air stream to differentiate fine fraction (protein) and coarse fraction (starch). In other words, the particles, which differ in density and mass, are separated in a current spiral airstream [67].

7.3.5.5 Milling Machinery

The loosened seed coats of the pretreated pulses are removed in the milling operation. For this purpose different machines are used, depending upon the type of pulse and scale of operation. The machines work on principles of (i) compression, (ii) shear, (iii) abrasion, and (iv) impact [61].

7.3.5.5.1 Hammer Mill

Hammer mills are composed of hammers mounted on a rotating shaft within a peripheral screen. Grain is subjected to impact forces from the hammers until it is milled fine enough to go through the screen openings. Thus screen opening size primarily controls the fineness of the grind. However,

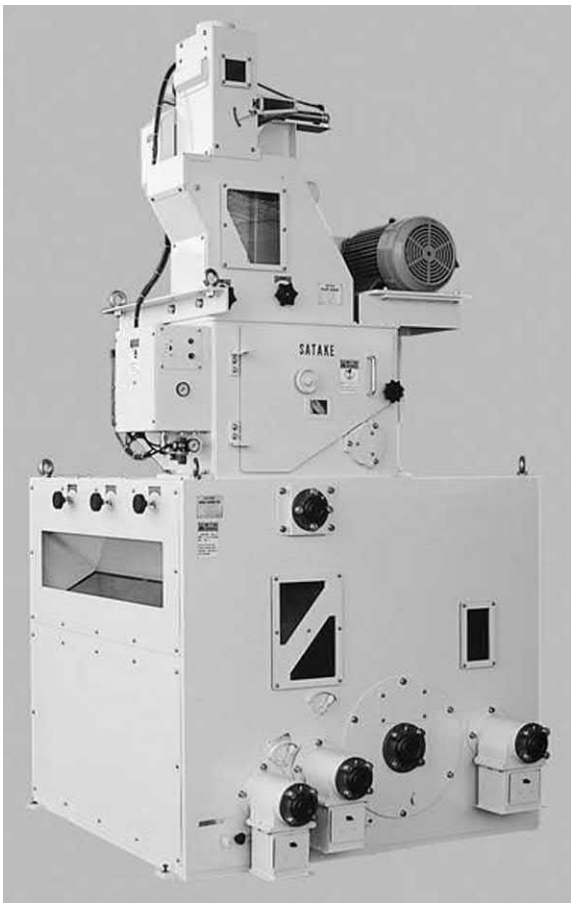

FIGURE 7.27 HR Paddy Husker. (From Stake Corporation [85].)

parameters such as hammer tip speed, rotor volume, type and number of hammers, and feed rate also influence the performance of the hammer mill [68].

7.3.5.5.2 Roller Mill

The roller mill consists of rotating corrugated or smooth paired cylindrical rolls oriented horizontally. Feed grain particles are reduced in size between the metal rolls. The grains are subjected to shear and compressive forces caused by the rolls when particles are pulled toward the nip [69].

7.3.5.5.3 Huller

Dehulling can also be achieved by using an impact huller, where grains are fed down the hollow axle of a rapidly rotating disc. The accelerated grains collide with the wall of the huller, which is typically lined with a polymer that reduces breakage compared with a metal surface.

7.3.5.5.4 Pin Mill

Impact disintegration is a kind of milling that can break up cellular materials selectively, without damaging the starch granules [70]. Traditionally, the pin mill, which is a kind of impact mill, is employed to disintegrate the starch–protein bond and produce fine flour. The pin mill is also categorized as a disc mill. It employs shearing and impact forces to produce fine flour by breaking up the dehulled seed [71]. The pins

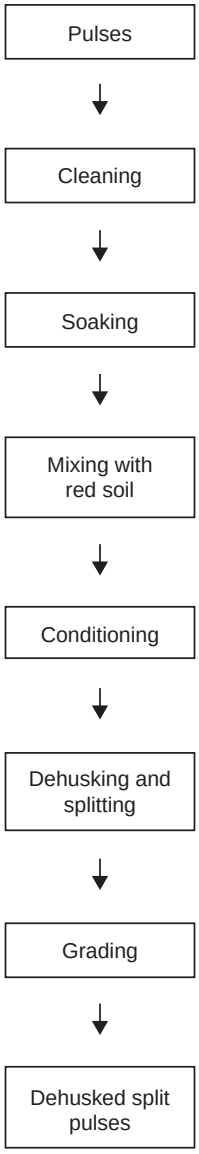

FIGURE 7.28 Flow diagram of pulse wet milling.

in a pin mill are fixed to two discs that rotate opposite of each other at different speeds (Figure 7.31). The radial speed leads to pins pressing the material at high speed through the rows of pins. The resultant impact force grinds the material. The fineness of the final product depends on the distribution and shape of the pins, the circumferential speed of the rotors, the feed rate, and physical properties of the material [72]. Pin mills may be used for dry or wet milling [71, 72]. Moisture content below 10% (w.b.) is optimal for milling of legumes [73].

Some pulses may be subjected to pin milling twice to obtain fine-grade flour [65]. The pin-milled flour is air classified in a spiral air stream and fractioned into light and heavy particles. The fine and light particles contain protein, whereas the coarse and heavier particles mostly contain starch granules [64]. The starch granules remain intact during pin milling and the process must avoid damage to the starch granules. Although dry processing (air classification) does not result in a pure protein fraction as wet processing, it is an effluent-free

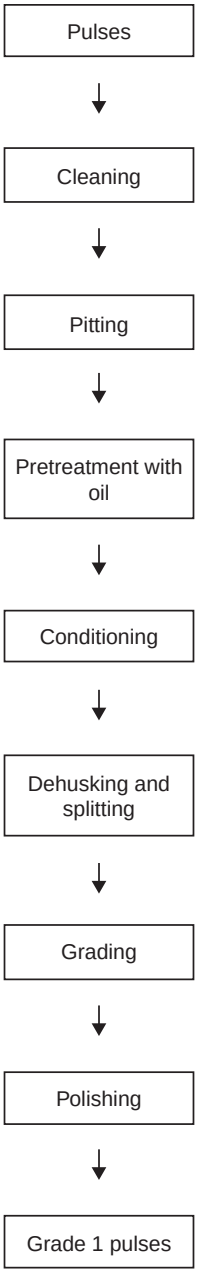

FIGURE 7.29 Flow diagram of pulse dry milling.

process and separated fractions are suitable as food, food ingredients, and other uses [74]. Since some protein bodies still adhere to the starch granules at the end of pin milling, it is necessary to reprocess the coarse fraction by pin milling and air classification for increased protein yield [65].

7.3.5.6 Pulse Milling

Most pulses are consumed in the dehusked, split form. Recovery of dehusked splits from pulses depends on the proportion of the husk to cotyledon and the way it is attached to the cotyledons. Pulse milling, as it is practiced today, is quite tedious, involving elaborate premilling treatments for loosening of the husk and also a long processing time. Traditional

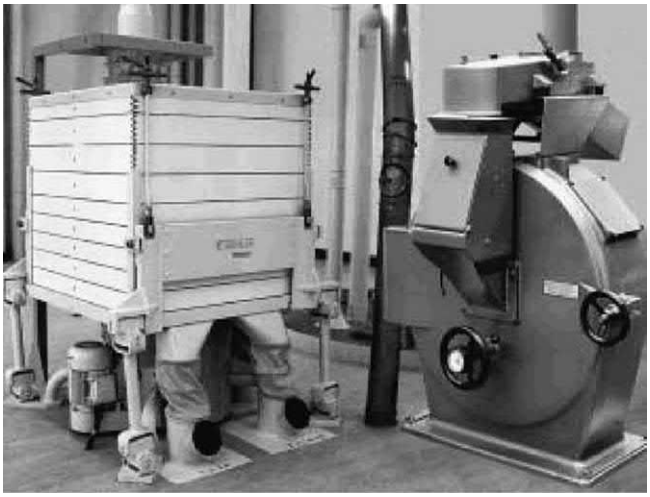

FIGURE 7.30 Equipment for dehulling and splitting pulses. (From Goodman [55].)

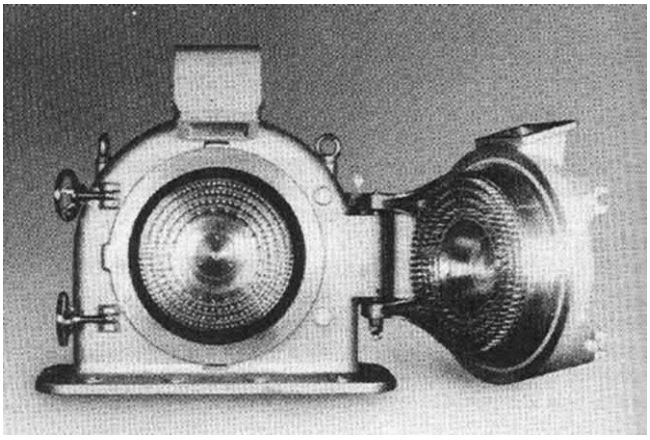

FIGURE 7.31 Pinned disc mill. (From Emami et al. [70]; Fellows [71].

pulse milling methods require more abrasive force due to improper preconditioning. Conservation of pulses can be achieved mainly through the development of superior milling procedures and equipment.

8 Postharvest Handling and Preservation of Fresh Fish and Seafood

Umezuruike Linus Opara, Saud Musallam Al-Jufaili, and Mohammad Shafiur Rahman

CONTENTS

8.1 INTRODUCTION

The fisheries sector plays an important role in food security, food industries development, and poverty alleviation in many parts of the world. The consumption of fish and fishery products has been strongly influenced by improvements in postharvest handling, packaging, storage, transportation, and marketing. These have led to significant improvements in post-production efficiency, lower costs, wider product choice, and safer and improved products. Advances in marine and fisheries science and engineering as well as food product development have resulted in technological innovations for fish capture, postharvest handling, processing, marketing, and distribution. The extent and range of these changes have varied among regions; however, there is increasing recognition of the importance of fish and other seafood in the economies of many regions. The supply of food proteins to many parts of the developing world has raised awareness of the role of fish and other marine foods in enhancing food security and alleviating malnutrition and poverty. In general, there has been a growth in fish and fishery products marketed in fresh

form and in the production of ready-to-cook or ready-to-eat products, particularly in wealthy economies and due partly to increasing understanding of fish functionality in health. The development and application of efficient and cost-effective postharvest technologies for the handling and preservation of fresh fish and other seafood are therefore important to ensure product safety and maintenance of quality throughout the supply chain from sea to plate.

The aim of this chapter is to outline and discuss the techniques and procedures for postharvest handling and preservation of fresh fish and other seafood products. A wide range of marine organisms (fish, crustaceans, and mollusks) are consumed directly by humans as food or utilized as industrial raw materials such as animal feed. Each fish species may respond slightly differently to particular handling procedures and preservation techniques; however, this chapter focuses on the major technologies, which are applicable for the handling and preservation of a wide range of fresh fish and seafood. Where appropriate, specific technological innovations for improved handling, quality maintenance, and preservation are mentioned.

8.1.1 Fish and Fish Products

Processed fish for human consumption (frozen, cured, and canned) remained relatively stable at around 39 million tons. Freezing represents the main method of processing fish for food use, accounting for 53% of total processed fish for human consumption in 2002, followed by canning (27%) and curing (20%). In developed countries, the proportion of fish that is frozen has been constantly increasing, and it accounted for 42% of production in 2002. By comparison, the share of frozen products was 13% of total production in developing countries, where fish is largely marketed in fresh/chilled form. The high demand for fish as fresh produce (Figure 8.1) is partly explained by increasing consumer interest and understanding of fish and fish products as functional food. The high demand for fresh fish also underlines the increasing need to develop and apply appropriate innovative postharvest handling systems for the maintenance of fish freshness and product safety.

In 2002, the average apparent per capita consumption of fish, crustaceans, and mollusks worldwide was estimated to be about 16.2 kg, 21% higher than in 1992 (13.1 kg). This growth is largely attributable to China, whose estimated share of world fish production increased from 16% in 1992 to 33% in 2002. If China is excluded, the per capita fish supply would be 13.2 kg, almost the same as in 1992. Following a peak of 14.6 kg in 1987, world per capita fish supply, excluding China, showed a declining trend from the late 1980s to the early 1990s but has stabilized since then (Figure 8.2). The declining trend was mainly caused by population growth outpacing that of food fish supply during the 1987–2002 period (1.3% per annum compared with 0.6%, respectively). For China, the corresponding annual increase since 1987 was 1.1% for population growth and 8.9% for food fish supply. In 2002, per capita fish supply in China was about 27.7 kg.

8.1.2 Problem of Postharvest Losses in Fish and Seafood

Harvested fish and seafood materials undergo a series of handling operations from catch sites until the product is delivered to the end-user. Fish are highly perishable starting from the point of harvest. Several factors predispose fresh fish to rapid quality degradation once they are harvested, and these include alteration of the surrounding environment due to removal from the marine or aquatic environment, high moisture content of fish, activities of microorganisms inside the gut and intestine, and physical damage resulting from use of improper harvesting tools and procedures and rough handling practices. Apart from being a cosmetic defect, which results in downgrading of fresh fish quality, the presence of physical damage due to rough handling also predisposes fresh fish to accelerated water loss as well as opportunistic microbial infection during subsequent handling operations.

Postharvest losses in fish may occur quantitatively and/or qualitatively. Quantity losses (wastage) occur when fish is removed from the food chain, and this may occur due to spillage or discard when the product is considered completely unacceptable for utilization as food and as an industrial raw

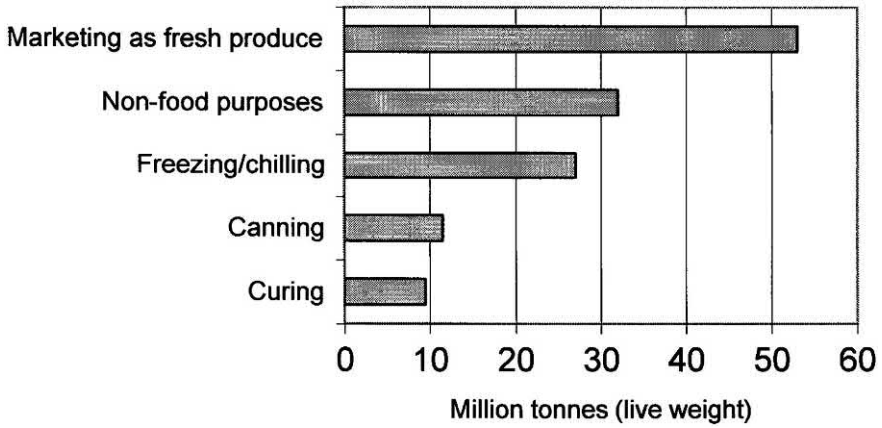

FIGURE 8.1 Utilization of world fisheries production (breakdown by quantity), 2002. (Adapted from Delgado et al. [33].)

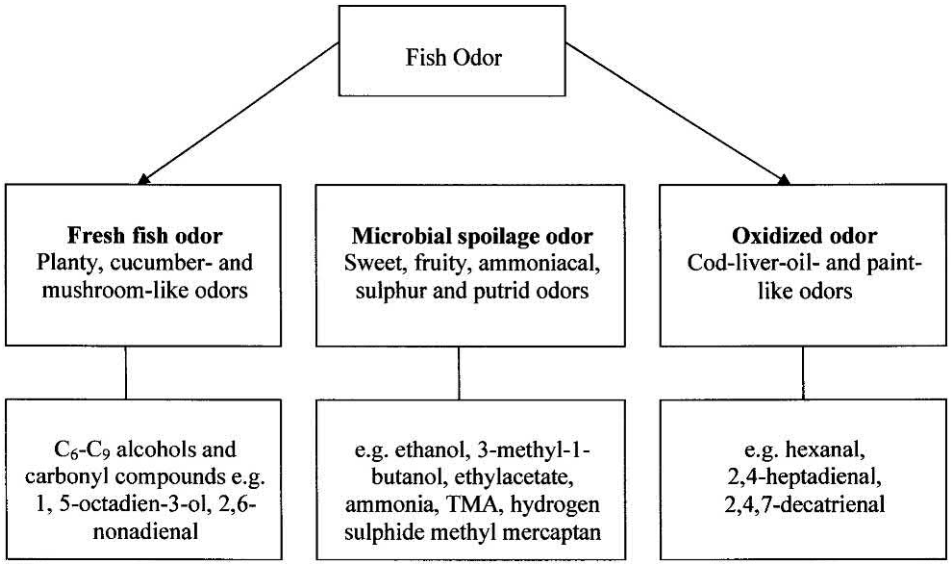

FIGURE 8.2 Categorization of fish odors and the volatile compounds that contribute to the characteristic odor of fresh, spoiled, and oxidized fish. TMA=trimethylamine. (From Olafsdottir et al. [41].)

material. Quantity loss may also be referred to as physical loss. Quality loss in fresh fish occurs when the product value to the end-user is compromised and downgraded due to a reduction in the attributes that are important to the end-user. Quality loss often results in a lower unit market price of fish products and a concomitant reduction in profits to the producer. Given the high volume of globally traded fresh fish produce, quality loss is a major contributor to total economic loss in the fresh fish and seafood industry.

The availability of reliable data on the magnitude and sources of postharvest losses is important in efforts to reduce the incidence of physical and quality losses in the fish and seafood industry. Exact data on losses of fish and other seafood materials are not readily available due to a myriad of factors including variations in species, geographical location, and season, as well as differences in harvesting, postharvest handling, and marketing systems. Nonetheless, several researchers have reported the incidence of fish losses based on surveys at various steps in the handling and marketing chain [1–4]. Others have developed empirical models of postharvest fish losses based on a consideration of the physical and monetary losses associated with various steps in fish handling from landing sites to export [5].

Global levels of fish losses are often estimated to be 20–40%. Published annual estimates of global fish losses include 3 million tons [2], 4.2 million tons [6], and 10–12 million tons [7]; however, most authors do not provide detailed information on the method of data acquisition and the specific type of losses reported. Nevertheless, these figures are expected to be much higher in many producing regions in developing countries where fish harvesting and postharvest handling technologies are not adequate to meet the needs of modern integrated long supply chains and marketing systems. In the Lake Victoria fishing community in Kenya with an annual catch of about 180,143 tons in 2000 and worth over 9 billion Kenyan shillings, it has been estimated that postharvest losses ranged from 20 to 25% [4]. These losses could double to 50% in some seasons or specific locations when large catches are made [8]. Further studies on three major fish species at seven beaches in that area reported quality losses of 13.9% for Clarias fishery, 6.4% for Nile perch, and 6.2% for Protoperus [4]. The authors identified the lack of basic cooling and preservation facilities at landing sites as major causes of quality loss.

Application of the generalized fish postharvest loss model by Cheke and Ward [5] to the Nile Perch fisheries in the Tanzania area of Lake Victoria showed that the total value of losses (US$) per 100 kg ranged from 4.20 to 7.55, depending on the type of fishing gear and method of transportation. The value of physical loss alone ranged from US$3.14 per 100 kg for fish caught by beach seine nets and transported by air to US$4.62 per 100 kg for fish caught by gill nets and transported by rail. According to Cheke and Ward [5], these model predictions supported the common knowledge among fishers and marketers that fish from beach seine nets are usually much fresher and of better quality when landed than those caught by gill nets or long lines.

In the Sultanate of Oman, the high incidence of postharvest losses has been recognized as an economic problem mitigating the economic development of the fisheries sector. The annual loss due to downgrading of fish was estimated at nearly US$62 million [9]. On fish type basis, the loss in quantity ranged between 40 and 70% for demersal fishes, 5% for the pelagic, and 10% for the entire traditional fisheries sector. Recent studies at major fish landing and marketing sites in the Muscat Governorate in the Sultanate of Oman [3, 10] showed that fresh fish losses were a common problem. Fishers and marketers reported a high incidence of losses, resulting in loss of potential revenue ranging from 12.5 to 20%. The authors also found that for the large pelagic, downgrading due to loss

in freshness (value) could reach between 10 and 25% after the first day of landing and 19.0 and 43.8% after the second day at the market.

8.2 MECHANISMS AND MANIFESTATIONS OF SPOILAGE IN FISH AND SEAFOOD

Fresh fish and other seafood undergo many chemical and biological changes immediately after capture, which can ultimately result in spoilage. Several factors contribute to such spoilage in fish, including interactions between the products and handling equipment, interactions between the product and the surrounding environment and atmosphere, and the inherent self-destructive biochemical changes that take place inside the fish once it is harvested. The occurrence of spoilage in fish is manifested and perceived by the end-user through changes in several sensory perceptions, including odor, color, shape, texture, and composition. In this section, we describe the biochemical mechanisms of fish and seafood spoilage, the factors contributing to the incidence of spoilage, and conclude with a synthesis of the various manifestations of spoilage in fresh fish and seafood products.

8.2.1 Biochemical Aspects of Fresh Fish and Seafood Spoilage

Prior to harvest, fish are protected by a skin that secretes antimicrobial compounds, such as lysozyme, and by antibodies in the blood. This self-protecting and self-regulating property is indicative of the biochemical composition of fish. For instance, lean fish contain 20% protein, less than 5% lipid, with little carbohydrate, whereas fatty fish contain 10–30% lipid. The pH of fish flesh is neutral, and the flesh is highly buffered due to the presence of phosphates and creatine in the muscle and has a low oxidation-reduction potential [11].

The harvesting of marine, fresh-water, or aquaculture fish and other seafood is an essential step in the delivery of desired products to the consumer. However, harvesting results in the death of fish with the following consequences [11]: (i) cessation of energy supply for normal body function; (ii) cell membranes are no longer energized, and molecules and ions can freely diffuse; (iii) antimicrobials are no longer produced or distributed; and (iv) microflora penetrates the skin from outside surface and flesh from the intestines and gills.

During this period, the contractile mechanism can still operate, permitting the muscle to contract and relax [12]. In order to remain relaxed, the muscle consumes adenosine triphosphate (ATP); thus, when ATP is no longer sufficient the muscle will contract, resulting in a phenomenon called rigor mortis. In broad terms, rigor mortis is the change that occurs in muscle following death, and its development is influenced by several factors including (i) the prevailing environmental conditions, notably temperature (increasing temperature accelerates it), (ii) the health status of the fish prior to harvest, and (iii) any reduction in muscle glycogen during life. The physical and physiological symptoms of rigor mortis include (i) stiffening, hardening, and shortening of the muscle, (ii) loss of transparency, and (iii) loss of elasticity. In iced fish, this condition usually lasts for one day or more, followed by the resolution of rigor.

All muscle contracts in rigor mortis, either because ATP is exhausted or because the pH has fallen sufficiently below the critical level. Suzuki [13] studied the linewidths of NMR spectra of water in flat fish in pre-rigor, rigor, and post-rigor stages. The results showed that line width in the rigor stage was broader than in the pre-rigor and post-rigor stages, but in the post-rigor stage, it became narrower than in the pre-rigor stage. The same results were also observed in sea bass, but only in the case of starved carp where rigor mortis was obscure and the change in the width of lines was not clear [11]. The state of water in muscles as a function of time after death by spin–lattice relaxation showed that during rigor there was a net transfer of water from the free phase of the region, giving rise to a more rapidly relaxing signal [14].

Marine fish contain trimethylamine oxide (TMAO) as an osmoregulator. Some bacteria or endogenous enzymes can reduce TMAO to trimethylamine (TMA, which has the odor of stale fish) and formaldehyde. The bacteria can obtain energy from this reaction and use reduced TMAO as an electron acceptor in the absence of oxygen. Fresh-water fish containing TMAO usually have a longer shelf life, even if the level of TMAO is low. Thus, the level of TMAO-reducing bacteria is important in order to preserve marine fish. There is little fermentation activity in the microflora due to the low carbohydrate content of most fish [11]. The initial quality of seafood is related to the species, the growing area conditions, the fishing or harvesting techniques, the seasonal biological changes in muscle and other organs, and the postharvest storage and processing conditions [15]. The ultimate quality is linked to the biochemical changes in the major constituents and microbial load and type in the fish or seafood and water from which they are harvested. Bacteria cause organoleptic changes. The active bacteria are psychrotrophic or cold-loving and well-adapted to growth under chill conditions [11].

Stress may occur even at the stunning and killing phases of fishing. A very rapid drop in muscle pH due to stress at killing can affect color parameters (high lightness, hue, and chroma values). This makes fish flesh lighter and more opaque than that of unstressed fish [16]. In addition, increased depletion of muscle energy, anaerobic glycolysis, and lactate accumulation occur due to high muscle activity during slaughter, and these cause a reduction in pH [17]. Electrical stunning (E) and asphyxia in the air (A) are two common stunning/killing methods for fish [18]. The effects of carbon monoxide asphyxia (CO) were compared to E and A on the evolution of post-rigor mortis changes in frozen rainbow trout fillets related to chemical, textural, and sensorial properties during storage time. Fish fillets from the E group showed a higher pH than the A group, with the CO group being intermediate. The CO treatment ensured that the fillets showed the lowest yellowness index while lipid oxidation and texture profile analyses were unaffected, and sensory analysis revealed that

the CO fillets had the lowest odor intensity with the highest juiciness scores [18].

8.2.2 Characterization and Quantification of Fish Spoilage

The most distinct stages of fish spoilage are shown in Table 8.1, based on results obtained from codfish stored in ice over an extended period of time [19]. In summary, a combination of visible signs of degradation and odor production may be used to characterize different phases of spoilage after harvest.

Cooked flavor without added condiments is the most precise objective method of assessing fish spoilage and quality changes. For practical purposes, however, this destructive approach is time-consuming and not suitable for rapid assessment during postharvest handling and marketing operations. For non-destructive measurement, changes in gill color, gill odor, eye color, skin-color, skin-rubberiness, and odor production may be used alone or in combination, to assess the quality status of fresh fish. Among the various non-destructive testing approaches, gill odor has been considered the most reliable and reproducible characteristic [11].

Several biochemical changes have been successfully used to quantify the level of spoilage in fresh fish and seafood. The concentration of TMA is used as an index of spoilage either alone or as a component of the total volatiles containing ammonia and other amines. An alternative chemical index of fish spoilage is hypoxanthine, which is derived from the breakdown of adenosine triphosphate. After the death of a fish, ATP in the meat decomposes to uric acid by a series of catabolic enzymes [20]. Hypoxanthine is an intermediate of these reactions and accumulates as storage time increases. Another more complex measurement is the potassium value, which is based on ATP, adenosine diphosphate (ADP), adenosine monophosphate (AMP), and hypoxanthine [11]. Changes in the dielectric properties of whole fish and skin-on portions occur during spoilage, and these changes can be measured in a non-destructive manner [11].

Drip loss is a quality problem in fish and seafood products. Once the water-holding capacity falls below the water content of the muscle, excess water will be lost, either immediately or later during processing or cooking [12]. Reducing drip loss during postharvest handling and marketing is therefore important in the value-chain management of fish and other fresh foods. The amount of drip loss from muscle depends largely upon changes in the water-holding capacity of the muscle protein after death. The magnitude of drip loss is influenced by a combination of the time and temperature of the immediate postmortem period [12]; therefore, adequate cold-chain management is critical in reducing the incidence of drip loss.

In summary, postharvest fish muscle quality can be maintained and spoilage reduced by a delay in onset of rigor mortis (associated with low stress) or the use of rapid killing methods [20]. In addition, Jerret et al. [20] have noted that a combination of behavioral conditioning, conservative handling practices, and chemical anesthesia can be used to minimize the extent of premortem exercise and thereby provide rested fish. The authors also recommended the importance of reducing preharvest exercise in the production of high-quality fish muscle.

TABLE 8.1
Characteristics of Phase Changes during Spoilage of Cod Fish Stored in Ice

Phase	Storage (Days)	Characteristic Changes
I	0–6	No marked sign of spoilage
II	7–10	No odor production
III	11–14	Production of some odor, slightly sweet to fruity odors
IV	>14	Production of hydrogen sulfite and other sulfide compounds, fecal, and strong ammonia odors

Source: Shewan [19].

8.2.3 Abiotic, Biotic, and Physiological Causes of Fish and Seafood Spoilage

Spoilage of fish and seafood is caused by a myriad of factors, which are related to the harvesting and handling practices and equipment, postharvest handling environmental conditions, the presence of decay-causing microbiological agents, and internal physiological changes or biochemical reactions that are associated with the normal process of aging and death. Like other fresh produce and irrespective of the primary causative agent, the rate of spoilage and quality degradation of fresh fish and seafood products is highly accelerated at elevated temperatures. Conversely, the deleterious effects of spoilage-causing agents can be significantly reduced through a synergistic effect of adequate temperature management in combination with other specific measures.

8.2.3.1 Mechanical Handling Damage

Wholesomeness and freedom from physical damage are important quality attributes in the fish trade, especially for fresh fish destined for the consumer. During harvesting and postharvest handling operations, fish may be subjected to excessive forces, which result in physical injury and blemish. Such damage may occur through several mechanisms including impact, compression, friction/abrasion, and cuts. Impact damage occurs when the fish falls from excessive height to generate sufficient absorbed impact energy that causes damage to the skin alone or in combination with underlying flesh. Compression damage occurs due to excessive stationary forces acting on the produce (such as cartons of produce stacked too high). Mechanical handling of fish affects the degradation of nucleotides in fish. Moreover, handling and mechanical damage to muscle tissue may increase the degradation of inosine monophosphate and inosine by making their substrates more accessible due to enzyme compartmentalization [21]. Furthermore, the presence of physical injuries such as bruises, cuts, and abrasions, provides favorable sites

for opportunistic infection and contamination of produce by decay-causing microorganisms.

8.2.3.2 Environmental Factors

Undesirable environmental conditions around fresh produce, such as the degree of hotness or coldness (temperature), water vapor content in the air (relative humidity), as well as direct exposure to sunlight and airflow, contribute to the onset and rate of quality deterioration and spoilage. By far, temperature is the most influential factor affecting spoilage of fresh produce such as fish and seafood. In addition to its effects in accelerating physiological and biochemical processes associated with tissue degradation and eventual spoilage, temperature also accelerates the action of microbial agents (such as bacteria), which cause spoilage and food safety hazards. The freshness of high-water-content foods such as fish and seafood is maintained better under high relative humidity conditions; thus, storing such produce at low relative humidity contributes to rapid spoilage and development of undesirable attributes. Airflow around fresh fish and seafood must be closely monitored to avoid excessive loss of surface moisture and undesirable changes in skin and flesh quality.

8.2.3.3 Biotic (Bacterial) Factors

The deterioration of fresh fish is primarily due to bacteria action. It is recognized that only some of the bacteria present are responsible for producing the off-odors, off-flavors, appearance, and textural changes that constitute spoiled fish [11]. The composition of the microflora is dependent on different factors, such as environment and season. Spoilage bacteria affect the degradation of nucleotides in fish. In cod fillets, the presence of spoilage bacteria increased the rate of degradation of inosine to hypoxanthine. This indicates that bacterial enzymes play an active role in contributing to the degradative process. The synthesis of proteases depends on the nutrient source, and secretion of proteases increases with the decrease in available nutrients, reaching a maximum concentration by the late log or early stationary phase of the bacterial growth. The level of protease secretion is low during the initial stage of bacterial spoilage, i.e., 106 CFU/g of flesh. Above 106 CFU/g there is high protease secretion [21].

Bacterial spoilage is evident in fish even at 0 to –4°C, but spoilage can be prevented below –10°C [19]. For cod stored in ice, there is a 2- to 3-day lag period with a logarithmic increase by day 10 in the bacterial flora, generally with counts up to 108/cm^2 skin or 108/g muscle. Pseudomonas species dominate up to 90% by day 12. They produce the spoilage odors, such as ammonia, and volatile sulfur compounds, such as mercaptans and hydrogen sulfide [22].

Consumption of contaminated fish and seafood is a potential source of health and safety hazards to humans. The main hazards of fish and seafood are pathogenic bacteria (aquatic environment, from humans or animals, biogenic amine producers, spoilage bacteria), parasites, biotoxins, and viruses [23]. All aquatic environments can harbor spores of *Clostridium botulinum*, which can contaminate fish both in marine and freshwater environments. *Vibrio parahaemolyticus* is the lead cause of food poisoning in Japan, where much fish is eaten raw. It does not grow below 10°C and dies out at chill temperatures, and is heat-labile. As it is halophilic, it survives salting and smoking. Control is therefore achieved by proper chilled storage. There has been a global increase in the presence of algal toxins in shellfish. More toxins are being identified. One of the major concerns in recent years for the fish processing industry has been *Listeria monocytogenes*. This organism can grow at chill temperatures, and it is not inhibited by the levels of salt in smoked products [11].

The bacterial flora of water reflects the flora of fish harvested from the area. The flora of cold-water fish is predominantly gram-negative, while flora in tropical fish are predominantly mesophilic gram-positive microorganisms [21]. The dominant microflora of cold-water fish species are *Pseudomonas*, *Alteromonas*, *Moraxella*, *Acinetobacter*, *Vibrio*, *Flavobacterium*, and *Cytophaga* [24]. Gram-positive organisms found on warm fish species are predominantly *Micrococcus* and *Bacillus* [21]. Psychrotrophic bacteria are found in almost all types of refrigerated and frozen foods. The outgrowth of pseudomonads in spoiling fish is due to their efficient use of free amino acids (especially methionine and cysteine) and peptides in the non-protein fraction during the early stage of spoilage, and their secretion of potent proteases, thus promoting proteolysis after low molecular weight components have been exhausted. The primary use of all nitrogenous compounds is through oxidative deamination, which results in the accumulation of ammonia, volatile fatty acids, and sulfur-containing compounds [24]. Volatile sulfur-containing compounds are believed to produce spoilage odors. These compounds have extremely low thresholds, and their origin is usually traced to non-protein nitrogenous compounds in the skin and flesh.

Changes in *K* value index (ratio of inosine and hypoxanthine to the quantity of ATP), ADP (adenosine diphosphate), AMP (adenosine monophosphate), and IMP (inosine monophosphate) are an objective measure of fish muscle quality during postharvest handling and storage. The *K* value is calculated as [25]:

$$K = \frac{HXR + HX}{ATP + AMP + IMP + HXR + HX} \times 100$$

where *HXR* is hypoxanthine riboside, *HX* is hypoxanthine, and *IMP* is inosine monophosphate. The storage temperature effects on histamine production, for example, fresh yellowfin tuna maintained an acceptable shelf life based on the permitted limit of *K* value for 12, 5, and 1 days at 0, 8, and 20°C, respectively [26]. The fish was rejected by panelists earlier than their *K* value indicated. The fish stored at 8 and 20°C became unsafe for human consumption, reaching unacceptable histamine levels after 4 and 1 days, respectively.

Some volatile compounds that have been isolated from spoiling fish muscle are ethyl mercaptan, methyl mercaptan, dimethyl sulfide, hydrogen sulfide, acetaldehyde, propionaldehyde, diacetyl ethanol, methanol, acetone, acetoin, butanal, methyl butanal, and ethanal [24]. Selected volatile compounds

TABLE 8.2
Selected Volatile Compounds and Their Probable Source in Spoiling Fish

Compound	Probable Source
Hydrogen sulfide	Cysteine
Dimethyl sulfide	Methionine
Methyl mercaptan	Methionine
Acidic, propionic, butyric, and hexanoic acid esters	Glycine, leucine, serine
Trimethylamine	Trimethylamine oxide
Dimethylamine	Triethylamine oxide
Ammonia	Urea, various amino acids

Source: Martin et al. [24].

in spoilage fish and their probable sources are compiled in Table 8.2.

8.2.3.4 Physiological (Internal) Factors: Lipid Oxidation and Hydrolysis

Lipid oxidation is a major cause of quality deterioration in fish and seafood due to lipid content and the extent of poly-unsaturation [24, 27]. Catalysts for lipid oxidation are molecular and singlet oxygen, metals such as iron and copper, and enzymes such as lipoxygenase [15]. The postmortem changes in fish muscle related to lipid oxidation are (i) decrease in ATP, (ii) increase in ATP breakdown products, e.g., hypoxanthine, (iii) changes in xanthine dehydrogenase to xanthine oxidase, (iv) loss of reducing compounds, e.g., ascorbate, glutathione, (v) increase in content of low molecular weight transition metals, (vi) conversion of heme (Fe II) pigments to oxidized form (Fe III), (v) loss of structural integrity membranes, (vi) loss of antioxidants in membranes, e.g., tocopherols, and (vii) inability of muscle cells to maintain calcium gradients [27].

These changes make the tissue more susceptible to oxidation, especially through changes in membranes. In addition, size reduction, such as fillets and minces, can enhance lipid oxidation by exposing more lipid to oxygen. The destruction of antioxidants such as tocopherols by heat, enzymes, and salts also plays an important role in lipid oxidation [15]. The glutathione peroxidase activity is located in various fish muscles and presumably protects muscle from oxidative deterioration of lipid during storage and processing [28]. Nakano et al. [29] reported that glutathione peroxidase increased significantly during storage, which suggested that the increase in enzyme activity could protect fish muscles from oxidative deterioration during storage and processing. Watanabe et al. [28] reported that total glutathione peroxidase activity in Japanese jack mackerel and skipjack tuna fish muscles decreased gradually during storage at 4°C.

Technological approaches to minimizing lipid oxidation that are applicable to fish and seafood include (i) reducing oxygen access to the product through controlled atmosphere storage and modified atmosphere packaging (e.g., vacuum packaging, edible coating), (ii) maintaining natural antioxidants or adding antioxidants, (iii) minimizing increases of pro-oxidants (e.g., iron), (iv) maintaining low temperatures through cool- and cold-chain management, (v) minimizing salt constituents, and (vi) removing unstable lipids (e.g., subcutaneous fats) and dark muscle, which contains more fat [15].

8.2.4 Physicochemical Manifestations of Spoilage in Fish and Seafood

When fresh fish and seafood products undergo improper handling and spoilage, certain changes occur in both the appearance and chemical composition, which can be readily quantified. Proper understanding of these changes is important for the early detection and isolation of affected produce. These manifestations of spoilage are largely sensory in nature.

8.2.4.1 Color Changes

Quality loss of fish muscle after harvest may take the form of color (appearance) changes. Fresh fish has a translucent appearance due to even scattering of incident light. With an increase in spoilage, there is a gradual disintegration of myofibrils, resulting in their wider and more random intracellular distribution. The fish surface then appears opaque because the incident light is unevenly scattered [21, 30].

Changes in fish flesh color occur during low-temperature and freezing storage. The flesh becomes yellow due to oxidation of carotenoid pigments and lipids in tissues. Other factors that may result in yellowing are lipid oxidation and reactions with carbonyl-amines. The red color changes in whole orange roughy during ice storage are shown in Table 8.3 [21].

Factors affecting pigment loss are as follows: (i) myeloperoxidase from fish leukocytes causes rapid discoloration of β-carotene in the presence of hydrogen peroxide and iodide or bromide ions due to the breakage of double bonds, (ii) free radicals addition, free radical abstraction, or singlet oxygen addition to the double bonds of β-carotene, (iii) temperature

TABLE 8.3
Color Changes and Appearance of Gills in Whole Orange Roughy Stored in Ice

Storage (Days)	Color Changes	Appearance of Gills
0	Red/orange	Dark red
4	Red/orange	Dark red
6	Orange on fins, head, and tail	Dark red
9	Slightly blotched, body faded	Dark red, slightly milky slime
11	Blue steel-gray with tinges of orange	Brown/red or bleached, sticky, creamy, slime
13	Bleached pale gray or blue tail with head pale orange	Brown/red or bleached with brown slime on gills
16	Washed-out gray/blue with pale head	Brown or bleached with brown slime

and concentration of storage oxygen, and (iv) progressive increase in pH from 7 to 8 during storage: potassium β–oxyacrolein, the enolic salt of malondialdehyde, formed self-condensation reactions and polymerised at pH 7–8 to form fluorescing compounds [21]. The appearance of surface slime on whole orange roughy as a function of storage duration in ice is shown in Table 8.4.

8.2.4.2 Texture Changes

Fresh fish has characteristic firmness, which can be rapidly assessed subjectively by hand feel, and objectively by instrumental test and sensory panel test. During postharvest handling and storage, the texture of fresh fish changes from "firm" and "moist" to "mushy" and "runny." These textural changes occur due to tissue softening as a result of myofibrillar disintegration and the weakening of connective tissue. During storage, the spoiling intracellular and extracellular proteases degrade myofibrillar proteins [21]. The loss of firmness and resilience and the development of unpleasant odors and flavors are some of the quality changes that occur in fish and seafood after harvest. The changes in texture and odor of orange roughy (i.e., whole) stored in ice for 16 days are shown in Table 8.5. The sensory changes of white fish are presented in Table 8.6. Manifestations of quality degradation and spoilage of stored fish muscle may take the form of excessively soft tissue, loss of liquid-holding capacity, and development of a dry or rough texture upon cooking [31].

Postmortem tenderization of fish muscle is one of the major problems related to fish freshness and its quality [32]. The causes of postmortem tenderization postulated so far are as follows [33]: (i) a weakening of rigor between myosin and actin as seen by the decrease of Mg^{+}-ATPase activity, (ii) breaking down of Z-disc structure of myofibrils, and (iii) degradation of titin [32].

Ando et al. [34] also suggested that postmortem tenderization of fish muscle is closely related to the gradual disintegration of the extracellular matrix structure after death. The weakening of the Z-line depends on a proteolytic mechanism, which removes α-actinin from this structure by action of a calcium-dependent neutral proteinase: calpain [32]. In addition, other myofibrillar proteins such as titin and nebulin

TABLE 8.5
Changes in Odor and Texture of Whole Orange Roughy Stored in Ice

Storage (Days)	Odor Changes in Gills	Texture Changes in Flesh
0	Slightly seaweedy	Firm and resilient
4	Slightly seaweedy	Firm and resilient
6	Mild and sweet	Firm and resilient
9	Fish meal, sweet, salty, briny	Firm and resilient
11	Sweet, salty, mussel, soapy, oily	Retains finger indentation, no gaping, slightly soft
13	Metallic, stale. Seaweedy and slightly rotting odors	Retains finger indentation, soft
16	Strong rotting and putrid	Retains finger indentation, no gaping, soft

are also implicated in postmortem weakening of fish [35] and meat muscle [36]. Papa et al. [32] studied α-actinin release and its degradation from myofibril Z-line in postmortem white dorsal muscle from bass and sea trout stored at 4°C and 10°C. Using α-actinin-specific antibodies, they showed that this protein is rapidly released within the first 24 hours for the two specific species, and reaches a plateau within 4 days. The release and proteolysis of α-actinin are time- and temperature-dependent processes that take place at early

stages of fish storage. The proteolysis of α-actinin seems to be dependent on fish species.

In fish intramuscular connective tissue, type I and V collagens are present. Sato et al. [37] demonstrated that type V collagen was solubilized specifically in softened rainbow trout muscle. Similarly, type V collagen became solubilized in softened sardine muscle after 1 day of chilled storage, whereas tiger puffer muscle did not show significant softening, changes in the structure of connective tissues, or biochemical properties of collagens [37]. This was due to the presence of more type I collagen in tiger puffer muscle than in sardine, carp, and mackerel [37]. Thus, degradation of type V collagen caused disintegration on the tin collagen fibrils in pericellular connective tissue, weakening pericellular connective tissue, and resulting in postharvest softening. Similarly, Tachibana et al. [38] reported that the degradation of Z-discs of ordinary muscle was faster in cultured red sea bream than in its wild counterpart.

This liquid-holding capacity of muscle is highly influenced by fibril swelling/contraction and the distribution of fluid between intra- and extracellular locations [39]. Moreover, changes in muscle structure are an important factor. Changes in muscle structure are strongly influenced by temperature, ionic strength, and chemical composition due to season, and maturation of muscle and pH. Ofstad et al. [31] concluded that the liquid-holding capacity of raw fish seemed to be dependent on two main factors: genetic differences in muscle protein, and the postmortem muscle pH and subsequent time-dependent muscle degradation. They found that salmon muscle possessed much better liquid-holding properties than the cod muscle, as did wild cod compared to fed cod regardless of the storage time. The myofibrils of the salmon muscle were denser and fat, and a granulated amorphous material filled the intra- and extracellular spaces. The denaturation characteristics of myosin, actinin, and a sarcoplasmic protein differed between salmon and cod, indicating the stability of the myosin–actomyosin complex. Postmortem degradation of the endomysial layer and the sarcolemma may further facilitate the release of liquid. Thus, the release was related to species-specific structural features and better stability of the muscle proteins. The severe liquid loss of fed cod was due to a low pH-induced denaturation and shrinkage of the myofibrils [31].

Holes and slits appear between the myotomes (muscle segments) because of breakage of the minute tubes of connective tissue from the myocommata (connective tissue sheets) and run between and around the muscle cells. This phenomenon is known as gaping in the musculature of fish [40]. A low pH leads to gaping and vice versa [40]. At a given temperature, the gaping increases with time, and subsequent freezing increases it further.

8.2.4.3 Odor Changes

As indicated earlier, the release of volatile compounds is one of the important indicators of freshness and spoilage of fish and seafood. Olafsdottir et al. [41] classified the volatile compounds contributing to fish odor into three groups based on origin, as shown in Figure 8.2. There is increasing interest in the importance of rapid measurement of volatile compounds in fresh fish and seafood as objective indicators of freshness. Several authors have reported the traditional methods that rely on classical chemical analysis for the study of total volatile bases and trimethylamine (TMA) in fish [21, 36, 42–45]. Future measurement innovations in this area appear to focus on the development of electronic noses [46, 47].

8.2.4.4 Protein Changes

Proteins in fish and seafood are subjected to significant changes during postharvest handling, storage (both iced and un-iced), and processing. The proteinases are responsible for changes, such as hydrolysis, which can result from animals or from spoilage microflora especially during later stages of spoilage [30]. The types of proteases and their inhibitors are shown in Table 8.7. The solubility of proteins during washing increased when fish were held for a longer time and/or at higher temperatures. This is because the degradation of myosin heavy chain and actin increased rapidly at longer storage times and/or elevated temperatures, resulting in a higher loss of total protein during washing. Lin and Park [48] studied the effect of postharvest storage temperatures and duration on proteolysis of Pacific whiting. Myosin heavy chain degraded rapidly during postharvest storage at low temperatures (0–5°C), and greater degradation occurred at elevated temperatures. Actin degradation was similar to that of myosin heavy chain but to a lesser degree. Degradation of both was highly correlated to protein solubility. Low temperatures reduced but did not completely inhibit proteolysis [48].

It is well-established that the myofibrillar proteins differ in stability depending on the habitat temperature of the species [49]. During iced and frozen storage, the thermal characteristics of myosin subunits deteriorate faster in cold-water than in warm-water fish [50, 51]. Venugopal [51] studied the sites of attack by proteases on protein and found that the points of cleavage for carboxypeptidase, aminopeptidase, endoprotease, and proteinase were carboxyl-terminal, amino-terminal, and internal peptide bonds, respectively.

TABLE 8.7
Types of Proteases and Their Inhibitors

Protease	Inhibitor

	8-Hydroxyquinoline
Acid protease	**Pepstain**
	Diazoacetyl norleucine methyl ester
	Epoxy (*p*-nitrophenoxy) propane

Source: **[51].**

Large amounts of glycogen in mammalian muscle can result in low final pH. The high the postmortem temperature, the quicker is the onset of rigor, the shorter its duration, and the more severe the contraction. However, if meat is chilled below about 13°C soon after death, severe contraction takes place almost immediately, resulting in permanent toughening of the meat. This is cold shortening [12].

8.3 POSTHARVEST TREATMENTS AND PRESERVATION OF FISH AND SEAFOOD

The maximum freshness of harvested fresh produce such as fish and seafood is immediately after harvest [52]. Beyond harvest, the adoption of improved handling systems, maintenance of the cold/cool chain, and application of appropriate physical and biochemical treatments are necessary to reduce the incidence of losses, preserve/maintain quality, and extend storage and shelf life. Warm- and cold-water fish do not always respond in the same way to postharvest handling practices and may often need different treatments to achieve the desired results [12]. Unlike meat, the global fish harvest destined for marketing is still largely hunted traditionally although the contribution of farmed fish (aquaculture) is increasing rapidly, particularly in Asia [33]. This approach gives limited scope for manipulating the immediate pre- and postmortem conditions. In the case of cold-water fish, higher temperatures accelerate the onset and resolution of rigor as in meat, but without resulting in cold-shortening. Another difference between the handling and preservation techniques of fish and animal meat is that fish never seem to attain such low pH values as are sometimes encountered in meat.

8.3.1 Improvement of Harvesting and Postharvest Handling Systems

Fish and seafood quality is affected by harvesting and postharvest handling techniques and equipment used. Improper harvesting and containerization may result in physical injuries such as bruising, cuts, and abrasion. It is also important that steps are taken to land the catch as soon as possible after harvest because the physiological processes that result in spoilage commence immediately. To reduce the incidence of physical damage, harvesting equipment and containers must be checked regularly to avoid the presence of sharp edges. Avoiding excessive loading of fish on top of each other or over-filled boxes of fish, particularly the large fish species such as tuna and kingfish, can reduce compression damage. During transportation from catch to landing sites, fish and seafood products need protection against direct sunlight and heat, particularly in tropical and sub-tropical environments where rapid increases in air temperature can occur in a short time. Throwing fish into containers or onto heaps should be avoided due to increased susceptibility to handling damage and subsequent spoilage.

Hanpongkittikun et al. [53] demonstrated the importance of good harvesting practices in seafood quality. The authors identified *Staphylococcus aureus*, *Salmonella*, and *Vibrio parahaemolyticus* from shrimp samples during ice storage. Using samples taken from controlled harvesting and the open market, the authors found that controlled harvested shrimp had a shelf life of 8 days, while samples from the open market had only 4 days of shelf life.

8.3.2 Pre-Storage Treatments

Pre-treatment of fish and seafood immediately after harvest and/or landing is necessary to improve sanitation and to remove the inedible portions, which would otherwise contribute to accelerated aging and spoilage. Pre-treatments such as washing and cleaning reduce contamination of physical debris and microbial organisms, which pose health and safety hazards to the consumer. Furthermore, gutting and bleeding are typical primary pre-processing treatments that are commonly carried out on fresh fish and some seafood.

Fish may be bled and gutted (i.e., their intestines removed) prior to subsequent handling storage. Depending on the end-use and market requirements, the fish head may also be removed. Gutting is essential for some species, otherwise the digestive enzymes and the bacteria in the gut would soon attack the flesh. In some species, this may not be necessary due to the anatomical location of the gut cavity relative to the edible parts [11]. It is customary to wash fish to remove blood and any remnants of guts. However, washing can remove some natural antimicrobial secretions and may not be advantageous to the storage life [11].

The limited efficacy of heat treatments directly applied to whole fish by hot water immersion or wash is probably due to slow heat penetration and/or changes in microflora interactions [54]. Vaz-Pires et al. [54] took 80 bacterial isolates from sea scad to study their heat stability and found *Shewanella colwellinia* to be more heat resistant. The main target site of damage from heat treatment tested in their experiments was the cell wall. Good hygiene practices are also needed to reduce the possibility of contamination of fish and seafood products. This is achievable on land, but it is difficult on-board fishing vessels [11].

8.3.3 Cold/Cool Chain Technology

Rapid removal of field heat after harvest and maintenance of the cold/cool chain is an effective strategy for fish and seafood preservation and quality maintenance. Chilling can be performed by refrigerated seawater (RS) (i.e., seawater is chilled by a refrigeration system); chilled seawater (CS) is the combination of ice with seawater, and slurry ice (SI) consists of crushed or generated ice of 250–500 μm in diameter. CS is more effective than RS because of the large heat capacity of ice [55–57]. The effectiveness of SI can be due to the following reasons: (i) the large heat capacity of ice is combined with micron-sized ice crystals maintaining a biphasic system for a longer time due to lower buoyancy [59–61]; (ii) the improved heat transfer due to longer contact time with ice as the ice is suspended; (iii) the higher contact surface area

of ice crystals with fish enhances heat transfer; (iv) it reduces fish surface damage due to lower abrasion; and (v) it enables more hygienic handling since slurry can be pumped easily [58]. Keys et al. [58] developed nano-sized ice (NI) slurry with ice crystal size 400–700 nm, which is more like a gel in nature rather than crystalline. The use of NI further enhanced the advantages of the effects of SI as mentioned earlier. In addition, SI is known to separate and form a hard ice crust layer, and it often requires breaking with shovels and results in damage to fish. The gel-like nature of NI and reduced buoyancy combine to prevent ice crusts from forming. However, more rapid melting could be an issue in chilling or achieving temperature threshold. Therefore, a proper ice–fish ratio and best handling practice with the melted water need to be used.

Most fish are chilled with ice soon after harvest unless they are destined only to nearby local markets. Researchers have demonstrated that the importance of rapid chilling cannot be over-emphasized [11]. Chilling reduces the rate of chemical and biochemical changes as well as microbial growth. The temperatures at which fish and seafood materials live are relatively low; thus chilling does not have as great an effect as the chilling of meat from warm-blooded animals [11]. Ice is a very good coolant. It is also cheap, and it must be made from clean, unpolluted, and bacteria-free water. Chilling generally reduces the temperature of fish to 0°C [11]. Chilling to 0°C in ice or refrigerated compartments is an essential requirement for quality retention in most fish and seafood products. For a longer storage period, fish and seafood may also be frozen. From a microbial standpoint, storage at –2 to –4°C is better than at 0°C or 2–5°C; however, this is not necessarily the case from a quality perspective due to toughening and autolytic changes which occur at the lower temperatures such as lipid hydrolysis. Shelf life may be extended further by using sorbate or sulfite [15]. The shelf life of selected types of raw fish as a function of temperature is shown in Table 8.8.

In experiments with fish during ice storage, the penetration of microorganisms occurred primarily from the intestines, the skin flora being found in the flesh only during the later stages of spoilage (8–17 days depending on species) [62, 63]. It was also observed that the quality and keeping time of the trout was reduced when the fish was exposed to physical stress. The infection level in the fish muscle increased with increasing physical stress and was higher for feeding than for starving trout [64]. When gutting the fish, it was observed that the intestines appeared pale and bloodless in the treated samples. This could be the result of a stress condition, which increased the production of adrenalin, thus forcing the blood into muscles and gills. There was good correlation between the log count and the organoleptic score when the bacteria count was higher than 100/g. The lack of correlation at lower bacterial counts may be expected since autolytic spoilage processes are more active in the earlier storage period and it is the dominant factor influencing organoleptic assessment [64].

Black carp fillets could maintain good sensory acceptability for 2, 9, and 15 days during storage at 20°C, 4°C, and 0°C, respectively, while the combined effects of K and TVB-N values showed good quality for 2, 9, and 12 days [65]. *Pseudomonads*, *Aeromonas*, and *Enterobacteriaceae* were the main spoilage bacteria in black carp. Tyramine and putrescine were the main biogenic amines while tryptamine, 2-phenylethylamine, putrescine, cadaverine, and tyramine increased during storage at all storage temperatures. Carp stored at 20°C favored the formation of histamine during storage time and the concentration of histamine was 132.1 mg/kg on the third day, while histamine concentration was 0.62–3.28 mg/kg (during storage period) while stored at 4°C and 0°C. Tyramine, cadaverine, and histamine were highly correlated with the development of tyrosine, lysine, and histidine, respectively, and electrical conductivity (EC) was correlated with sensory, physical, chemical, and microbial parameters. However, EC could be used as a better quality indicator to assess the overall quality of fish stored at 4°C and 0°C as compared to that at 20°C.

TABLE 8.8
Approximate Shelf Life of Selected Types of Raw Fish at Different Temperatures

Fish	Temperature (°C)	Shelf Life (Days)
Cod	0	16
	5	7
	10	4
	16	1
Herring	0	10
	5	4
Salmon	0	2

8.3.4 Chemical Treatments and Use of Bio-Preservatives

A wide range of chemical treatments and living cultures of bacteria have been used in commercial practice or proposed by researchers for mitigating the deleterious effects of abiotic, biotic, and physiological factors, which cause spoilage in fish and seafood. The principal chemical agents used are chlorine and hydrogen peroxide.

8.3.4.1 Chlorine and Chlorine Dioxide

Lin et al. [66] found that a commercial chlorine dioxide killed *Escherichia coli*, *Listeria monocytogenes*, and its streptomycin-resistant strain at 15, 10, and 7.5 ppm. The authors also reported that aqueous chlorine dioxide was more effective than aqueous chlorine in killing *L. monocytogenes* on fish cubes and in washed-off solutions. Fish cubes treated with aqueous chlorine showed no visual changes in color. Treated solutions became lightly milky. A light brown color occurred on fish cubes treated with aqueous chlorine dioxide at 400 ppm. The treated solutions had a light pink (40 and 100 ppm)

to light yellow (200 and 400 ppm) color, with some turbidity. The fish cubes treated with aqueous chlorine or chlorine dioxide contained no detectable chlorine residues, but commercial chlorine dioxide solution showed chlorite and some free and combined chlorine, especially at 200 and 400 ppm.

8.3.4.2 Hydrogen Peroxide

Dipping in a hydrogen peroxide solution can increase the shelf life of fish. Hydrogen peroxide acts as a preservative as well as a bleaching agent, thus yielding a higher quality product with an extended shelf life. A major point of concern had been that hydrogen peroxide treatments could lead to excessive oxidative rancidity, thereby causing a marked decrease in the overall quality of product [67]. Sims et al. [67] reported that hydrogen peroxide was entirely dissipated in the flesh within 0.5 hours when raw herring were immersed in dip solutions containing up to 600 ppm hydrogen peroxide. The color observations carried out on samples from the treatments indicated that the fillets with hydrogen peroxide were considerably whiter than untreated fillets.

8.3.4.3 Lactic Acid Bacteria

The addition of living cultures of lactic acid bacteria is used to control pathogen growth in fish. *Listeria monocytogenes* is difficult to control in lightly salted conditions (<6% NaCl in aqueous phase) with pH above 5, and at storage temperatures around 5°C. Wessels and Huss [68] noted that *L. monocytogenes* in lightly preserved fish products can be controlled using food-grade lactic bacteria. The effect was not due to lactic acid inhibition, but to the production of the natural preservative nisin by the lactic acid bacteria. Sodium chloride solution up to 4% allowed for efficient growth and nisin production, while 5% sodium chloride resulted in very slow growth and no detectable nisin.

8.3.5 Enzyme Inhibitors

The tenderization or flesh softening of seafood has generally been attributed to the activity of endogenous muscle proteases in the postmortem animal. The undesirable postmortem activities of these enzymes have been controlled by low-temperature and chemical treatments [69]. The use of plasma glycoprotein and α2-macroglobulin (the active component in egg white plasma hydrolysates) can be used to inhibit several endogenous proteases [70]. α_2-Macroglobulin noncompetitively inhibited the proteases, in decreasing order: cathepsin D > trypsin > chymotrypsin > collagenase. The inhibitor's activity depended on the size of the substrate molecule, the size of the enzyme, and the relative specificity of the enzyme. Thus, it could control desirable proteolytic activities. In intact fish and other muscle foods, it may be restricted to tissue penetration due to membrane barriers and the relatively large molecular size of the inhibitor. Proteases in surimi and other minced muscle foods should be readily inhibited by it. The activity did not seem to be adversely affected by low temperatures (4–7°C) [69].

Prawns develop blackspot (melanosis) in chilled and frozen storage, and sulfite is a reducing agent used to prevent this discoloration. The presence of sulfite reverses the formation of colored compounds (quinones) and in addition acts as a competitive inhibitor of polyphenol oxidase, the enzyme that causes the production of the pigment melanin [71, 72]. Recently, it was reported that 4-hexylresorcinol binds irreversibly to polyphenol oxidase, inhibiting its action [73]. The likelihood of adverse reactions in humans from the low levels found in prawns was considered slight [74]. Sensory panel assessment found no effect on the taste, texture, visual appearance, and development of normal colors after cooking by treating prawns with 4-hexylresorcinol. Slattery et al. [74] used Everfresh® (which contains 4-hexylresorcinol) to inhibit polyphenol oxidase in trawled and farmed prawns. In comparison with sodium metabisulfite treatment, Everfresh (0.2% 4-hexylresorcinol) provided greater protection against blackspot, particularly on the body of the prawn during storage in ice, in refrigerated seawater, and in ice after frozen storage. When Everfresh was used according to the manufacturer's recommendations, residues of 4-hexylresorcinol were less than 2 μg/g in prawn flesh.

8.3.6 Super Chilling

Super chilling storage incorporated by an ice glazing (SS-IG) approach could minimize fat rancidity, fluid loss, and microstructure disarrangement [75]. The traditional material used as IG layer is water. A thin layer of IG is formed by dipping fish into an icy solution bath to produce a protective barrier on the surface, and it could exclude air and reduce the effects of temperature fluctuations [76]. In addition, extracts (such as essential oil and tangerine peel) from natural plants were shown to be an effective alternative [77–79]. Essential oil of 0.1, 0.2, and 0.3% v/v solutions were used to immerse fresh sea bass samples at ~0°C to form IG layers [75]. Fish was stored at –1°C for 25 days, and a series of freshness assays showed that the treatment was effective in maintaining the storage freshness by retarding the spoilage of preserved fish samples in electric, chemical, microbial, textural, and sensory properties. The SS-IG approach could be promising in the aquaculture industry.

The quality of iced, chilled (+1°C), and super-chilled (–1°C) cod was evaluated by microbial analysis, total volatile base nitrogen (TVB-N), and sensory evaluation [80]. The H_2S-producing bacteria appeared to grow more rapidly in the fish that was iced whole as compared to those that were super-chilled on-board. Total viable counts in fillets were lower during super-chilled storage conditions. The TVB-N level of fish iced on-board and stored chilled rose above the consumption limit on day 11 after catch, while the levels in super-chilled fish remained below the permitted limit. TVB-N levels where fillets were stored super-chilled were still under the limit after 16 days although sensory evaluation rejected both groups. Considering sensory quality, super-chilled storage of fillets showed a much greater impact, resulting in 2–4 days extension of freshness and 3 days longer shelf life. The effects of on-board whole fish super-chilling were less noticeable except for the growth of H_2S-producing bacteria and spoilage attributes (TVB-N, decomposition of proteins, and sensory).

8.3.7 Irradiation Treatment

Gamma radiation is considered an innovative and interesting method to preserve chilled, stored fish and to reduce microbial populations in fresh fish and fish products [81–85]. Several researchers have reported increases in storage times of 1–3 weeks for fresh and cooked product and doubling of storage times for frozen products [86]. Several authors [87, 88] have noted that irradiation doses of 2–7 kGy can reduce important pathogens in food such as *Salmonella*, *Listeria*, and *Vibrio* spp., including many fish-specific pathogens like *Pseudomonadaceae* and *Enterobacteriaseae*, which can be significantly reduced in number.

The application of irradiation treatment in fish and seafood must be viewed as part of integrated quality and safety management, incorporating good manufacturing practice (GMP) and hazard analysis and critical control points (HACCP). Thus, the fish destined for irradiation must be in good quality, free from defects, and handled properly prior to and after irradiation. It is only under these conditions, with good irradiation practices, that most pathogenic microorganisms can be eliminated, and spoilage bacteria can be sufficiently reduced so that significant increases in storage time can be achieved.

Irradiation doses between 0.75 and 1.5 kGy for fresh products and cooked products and between 2 and 5 kGy for frozen foods have been recommended [86]. Marcotte did not consider these doses could be sufficient in controlling spore-forming bacteria such as *C. botulinum* Type E. Furthermore, it was noted that irradiation does not eliminate the toxins produced by *S. aureus* and others, and consequently, the author cautioned that, whether irradiated or not, fish and shellfish must be properly processed and stored cold (<3°C) or in ice, or frozen. Other researchers have reported that fish may be irradiated at doses of 3–4 kGy, without an appreciable increase in temperature during irradiation [85], and without affecting odor and taste, thus increasing the storage life of the product by two- to three-fold [82].

In a recent study to determine the effect of 60 Co gamma irradiation on Atlantic horse mackerel—a highly perishable fish species abundant off the coasts of Portugal and Spain and an important component of the diet in these countries—Mendes et al. [84] applied two levels of irradiation (1 and 3 kGy). Irradiated and uneradicated (control) fish were stored in ice for 23 days after which a series of chemical tests of spoilage were carried out. The authors found that a dose of 1 kGy appeared adequate to extend the shelf life of the fish by 4 days, and increasing the dose to 3 kGy did not give appreciable additional benefits in terms of quality attributes. No detrimental effect on the quality of fish by irradiation was evident.

8.3.8 High-Pressure Treatment

The freshness of fish is caused primarily by endogenous enzymes and microorganisms present in fish flesh [89]. High-pressure processing of fresh fish could be used as one of the thermal treatments [90]. This pretreatment was used in the case of hilsa fillets [91] and sea bass [92] during refrigerated storage; fresh salmon, cod, and mackerel [93], and frozen stored hake [94] and mackerel [95]. Tilapia fillets were treated with high-pressure processing (i.e., 100–400 MPa for 1 or 3 min), and quality attributes during refrigerated storage were evaluated [96]. Color, texture, sensory, and microbiological analysis showed that high pressure of 400 MPa for 3 min was efficient in preserving the fillets in refrigerated storage (5°C) for 1 week. The appearance due to change in color could be an issue for commercialization although fish preservation is achieved.

8.3.9 Edible Coating

Bio-based coating is considered an effective and eco-friendly choice for maintaining the freshness of food products and extending their shelf lives [97]. Chitosan coating combined with glycerol monolaurate was used to extend the shelf life of refrigerated grass carp [97]. Gelatin is widely used in preparing edible coatings and films, but it has poor preservation characteristics, such as antioxidant and antimicrobial abilities [98]. Curcumin possesses potent antioxidant and antibacterial properties and could be used in the coating. Edible coating combining fish gelatin with curcumin-β-cyclodextrin (CUR-βCD) emulsion was effective in maintaining the quality and extending the shelf life of grass carp fillets during storage at 4°C [99]. The coatings containing CUR-βCD emulsions exhibited better preservative effects than gelatin-βCD coating. The quality parameters included were: weight loss, pH, total volatile basic nitrogen (TVB-N), peroxide value (PV), thiobarbituric acid (TBA) value, SDS-PAGE, free amino acids (FAA), microbiological (total viable counts (TVC), *Pseudomonas* counts, yeasts and molds, and H_2S-producing bacteria), color, and sensorial characteristics.

8.3.10 Role of Packaging Technology

Proper packaging plays a crucial role in the preservation of quality and delivery of safe, wholesome fish and seafood products to the end-user. Packaging performs three main functions, namely containment, protection, and information. With regard to fresh fish and seafood, packaging must be carefully selected to cope with the presence of water on fish skin, a condition that could contribute to the breakdown of paper-based packaging as well as rapid microbial contamination. Packaging must also be selected to protect against adverse environmental and atmospheric conditions as well penetration of physical and chemical hazards. To facilitate supply chain management and marketing operations, adequate labeling of the package is essential to inform and educate the end-user about the content and utility. Given the high perishability of fish and seafood, only blemish-free and top-quality produce should be contained in the package.

Innovative packaging technologies based on manipulating the gas exchange characteristics of packaging material to control the redox potential have been developed and applied to preserve and extend the storage stability of fish and seafood products. The application of vacuum packaging, controlled

(CA) or modified atmosphere (MA) packaging around fresh fish is based on the following premise: some spoilage bacteria and lipid oxidation require oxygen—thus, reducing the oxygen around the fish will increase storage and shelf life. Depending on the fish species and intended end-use, specific combinations of O_2, CO_2, and N_2 determine the level of CA or MA. In practice, vacuum packaging, CA storage, and MA packaging are used in combination with refrigerated storage for preservation of fish and seafood products. The combination of methods must be optimized and closely evaluated to match specific requirements.

The use of biodegradable green polymers for packaging from renewable sources is highly desirable for food preservation and packaging. Polylactic acid (PLA) is one of these naturally originated polymers. The polymer composition and addition of nanoparticles (i.e., nano-silica and organomodified montmorillonite) could adjust the release of preservatives from the polymeric material [100]. Active packaging films based on PLA containing 1.5% w/w zinc oxide (ZnO) nanoparticles and varying concentrations (0.5, 1, 1.5% w/w) of essential oil (EO) were used to preserve the refrigerated fish fillets [101]. The effects of the active films on the shelf life extension of fish over 16 days of refrigerated storage (4°C) showed the extension of shelf life from 8 to 16 days. The shelf life was determined considering microbial count (aerobic count, *Enterobacteriaceae count*, *Pseudomonas spp*., lactic acid bacteria, and H_2S-producing bacteria) and chemical levels (TBARS and TVB-N). Carvacrol and menthone were found to be the main antibacterial compounds.

8.4 CONCLUSION

Fish and other marine products are important sources of food throughout the world and in particular for over 1 billion people as their main source of protein. Global consumption of fish is rising steadily and has doubled since 1973 [33]. Current estimates project that the demand for fish will continue due to increasing population growth and increasing purchase because of further realization of the health and nutritional benefits of fish in the diet. However, serious concerns have been raised about the ecological effects of industrialized fishing and the resultant rapid worldwide depletion of predatory fish communities [102]. This scenario has propelled aquaculture (the farming of fish, shellfish, and seaweeds) as the fastest growing sector in global food production.

Despite the growing demand and importance of fish and seafood in the human food system, the incidence of postharvest losses, quantitatively and qualitatively, remains high, especially among many rural fishing communities. Reducing fish losses and preserving fish quality over extended storage periods will contribute towards improved food security and income without the need for additional catches to meet growing demand. Unlike the situation for red meat and poultry, the fact that the majority of food fish and seafood are "hunted" in the oceans and seas presents additional technical challenges to adequately control quality deterioration and preserve the produce. Thus, improved harvesting techniques and procedures are needed which reduce the lag time between catch and landing to avoid unacceptable losses in quality (and quantity) prior to handling and processing.

High consumer preference for fish in fresh form (as opposed to processed product) assures future demand for innovative treatments and preservation techniques that maintain freshness and optimum eating quality over an extended period of time. Continuing research is also needed to develop low-cost, portable, non-destructive devices for rapid measurement of freshness. Such a device will be useful for research as well as use by quality control personnel responsible for enforcing relevant regulations and directives on fish quality standards and marketing.

9 Postharvest Storage and Safety of Meat

Isam T. Kadim, Quazi Mohd. Imranul Haq, Issa S. Al-Amri, Abdulaziz Y. Al-Kindi, and Amera K. Nasser

CONTENTS

9.1 INTRODUCTION

Meat is the edible part of the flesh of an animal's skeletal muscles and is an excellent source of many nutrients for human consumption. The term "postharvest fresh meat" includes meat from recently processed animals as well as vacuum-packed meat or meat packed in controlled-atmospheric conditions to ensure quality and preservation. However, the diverse nutrient composition of meat makes it an ideal environment for the growth and propagation of meat spoilage microorganisms and common foodborne pathogens. It is essential that adequate preservation technologies should be applied to maintain its safety and quality [1]. The postharvest processes used in meat preservation are principally concerned with inhibiting microbial spoilage, although other methods of preservation are sought to minimize quality deteriorative changes such as color and oxidative changes.

The bacterial growth that causes meat spoilage is influenced by several factors, including intrinsic factors (physical and chemical properties, e.g. water activity, structure, content of nutrients), extrinsic factors (e.g. the composition of the atmosphere, storage temperature), processing factors (chemical and physical methods used during processing, e.g. cooking), and implicit factors (reflection of the antagonistic and synergistic effects between bacteria) [2]. A number of interrelated factors influence the shelf life and quality of postharvest meat including temperature, oxygen, endogenous enzymes, moisture, light, and microorganisms [3].

Several articles have reported the dominance of different pathogens in meat; *Campylobacter* (Figure 9.1) and *Salmonella* (Figure 9.2) are highest among them [4]. Meat-contaminating bacterial pathogens from the gastrointestinal tract are *Salmonella enteric* strains, *Campylobacter jejuni*, *Aeromonas hydrophila*, *Yersinia enterocolitica*, *Escherichia coli* (Figure 9.3), and *Listeria monocytogenes* (Figure 9.4) [5]. For meat poisoning outbreaks, poultry meat is highest, and it is an ideal, very well-suited medium for bacterial culture [5].

Although fresh meat quality deterioration can occur due to proteolysis, lipolysis, and oxidation, microbial growth is the most important factor affecting the quality of fresh meat [6]. Poisoning resulting from the ingestion of toxins, exotoxins (secreted by bacteria such as *Clostridium botulinum* (Figure 9.5), and endotoxins (released upon the death of microorganisms) [7]. Postharvest meat preservation can be prolonged

by controlling the atmospheric temperature, moisture, and inhibitory processes of microbial proliferation. New preservation technologies for fresh meat preservation include nonthermal inactivation such as modified atmosphere packaging, active packaging, natural antimicrobial compounds, and biopreservation. The future for fresh meat products will depend mainly on consumer demand and the prices at which they can be profitably produced. Therefore, fresh meat requires proper handling after harvesting. Enhanced meat safety involves the application of measures to delay or prevent microbiological, chemical, and/or physical changes that make meat healthy for human consumption. Bacterial foodborne infections are increasing at a very high rate worldwide [8]. The consumption of raw meat contaminated with multidrug-resistant (MDR) *Salmonella* is a global public health crisis; annually, more than one billion humans are infected, suffering from gastroenteritis, and around five million individuals die [9]. Another

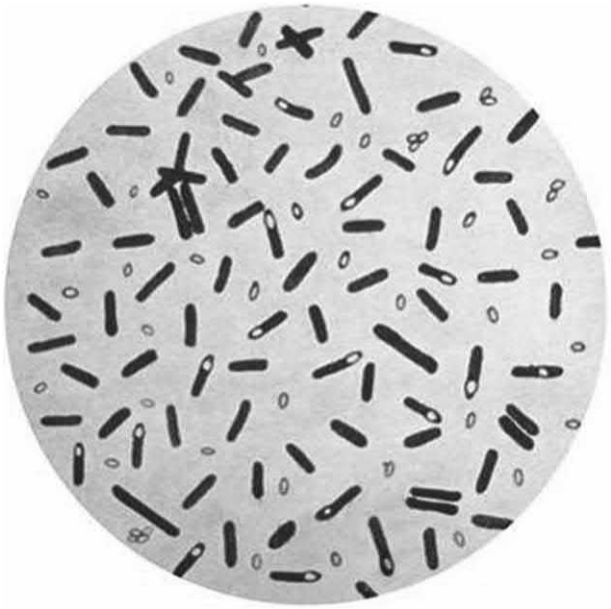

FIGURE 9.5 Morphology of *Clostridium botulinum*. (From CDC. http://phil.cdc.ov/phil/home.asp.)

multidrug-resistant bacteria, *Listeria* spp., is reported in raw meat and meat-related products from Malaysia [10]. Beef meat contamination with *Clostridium difficile*, which is a leading cause of pseudomembranous colitis and nosocomial diarrhea, has been confirmed recently [11]. Resistant bacterial strains that are resistant to many antibiotics are transmitted to humans from animals through uncooked meat and contact with meat surfaces [12]. This chapter aims to review the technologies for the preservation of fresh meat and enhancement of the quality characteristics.

9.2 MUSCLE STRUCTURE

The shelf life of fresh meat depends on the microflora present on the meat, which creates an ecosystem that is affected by many factors, such as the intrinsic properties of the meat, the initial microbial contamination load, temperature, storage time, and the processing method [7]. Fresh meat bacterial contaminants mainly include the genera of *Pseudomonas*, *Acinetobacter*, *Brochothrix*, *Psychrobacter*, *Flavobacterium*, *Micrococcus*, *Staphylococcus* (Figure 9.6), *Moraxella*, various genera of the family Enterobacteriaceae, and lactic acid bacteria [7]. Skeletal muscle is built up of thousands of cylindrical muscle fibers often running all the way from origin to insertion. They are forced together by endomysium connective tissue through which run blood vessels and nerves (Figure 9.7). The conventional instruction for understanding red meat is to start with the muscle structure. Muscle biology is complex due to its various biological functions, such as its role in contraction, accumulation of protein, and protection [13]. Muscle metabolism plays a role in the pathogenesis of metabolic disorders and in the transformation of muscles to meat [14]. Animal physiology also generally plays an important role in controlling the changes that occur in the postmortem conversion of muscle to meat, thereby affecting meat quality [15, 16]. Muscle characteristics are of prime importance since quality is recognized as one of most important social and economic challenges for meat producers and retailers around the world.

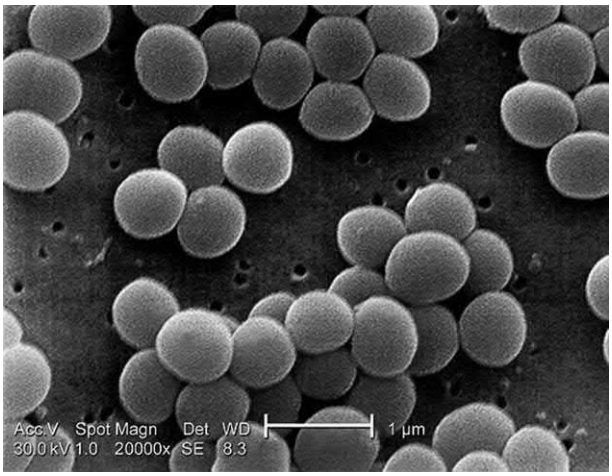

FIGURE 9.6 Morphology of *Staphylococcus aureus*. (From CDC. http://phil.cdc.gov/phil/home.asp.)

Many of the biochemical reactions present retain some degree of activity in animal muscles after death. The biochemical reactions are responsible for quality changes during storage. The rate and extent of muscle postmortem metabolism are dependent on the availability of glycogen at slaughter [17], the temperature of the medium in which the reactions occur [18], and whether or not procedures intended to accelerate metabolic reactions have been applied [19]. Initially, muscles become stiff and hard but gain some softness after hanging and aging.

9.3 CONTAMINATION OF HARVESTED MEAT

There are two approaches to inactivate microorganisms under chilling conditions; the first one is to change the environmental conditions, and the other is to decrease the tolerance of the microorganisms. In the meat sterilization process, the inactivation of dormant bacterial spores is the main objective. These spores are highly resistant to heat, drying, radiation, and chemicals. As germinated spores are not resistant to these agents, it is effective to germinate dormant spores and then inactivate them. Many of the microorganisms that influence meat spoilage require the presence of oxygen to grow. Vacuum-packed meat is also preserved from weight loss and discoloration. Sanitation programs throughout the chilling and storage operations can maximize the shelf life of fresh meat cuts. Reducing the initial microbial contamination of meat significantly decreases the influence of microbes in changing meat odor, appearance, and flavor. Vacuum-wrapped cuts, at the proper temperatures, may be displayed for extended periods during marketing without the occurrence of foodborne pathogens.

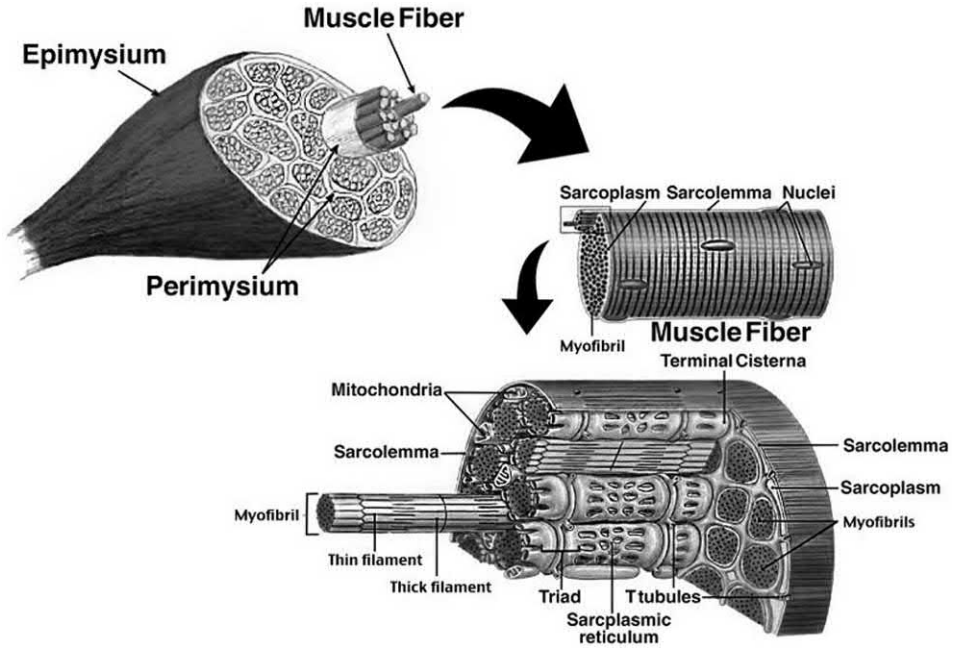

FIGURE 9.7 Microstructure of animal muscle.

9.3.1 Fresh Meat Processing

During meat storage, bacterial metabolic activity may lead to meat spoilage. The methods of operational hygiene for meat handling and packaging are responsible for the composition of the different microflora that develops on meat [2]. Contamination of fresh meat is a direct consequence of processing [20]. By the application of antimicrobial films, the inhibition of surface spoilage bacteria is studied [21]. Many microorganisms from various sources are introduced to nutrient-rich fresh meat surfaces. Although a smaller proportion of microorganisms will predominate and cause spoilage, only 10% is capable of survival and proliferation during storage, distribution, and retail sales of meat at low temperatures. A successful hygiene process extends meat shelf life and allows its delivery from processor to consumption areas. It is generally recognized that the most significant foodborne hazards from fresh meat are bacterial pathogens, which cause many human diseases, such as *Salmonella*, *Campylobacter*, and pathogenic *E. coli* (Figure 9.8) such as *E. coli* O157. Some of these, particularly *E. coli* O157, require only a few bacterial cells to cause food poisoning in humans. The safety of meat and meat products is important to producers, retailers, and consumers. There are mainly two types of microorganisms (i.e. pathogenic and non-pathogenic) able to multiply in meat during chilled storage conditions. The preservation of meat depends on the number of spoilage microorganisms present initially, the temperature history of the meat at all stages of processing, subsequent storage, and handling practices. The problem may be due to several stages in meat processing, in which meat remains in close proximity throughout the operation. Such conditions favor the spread of any pathogens that may gain access to the facilities.

9.3.2 Control Contamination

Fresh meat should be entirely safe from microorganisms; therefore it should be free from all pathogenic organisms. However, practically this is not a realistic goal for fresh meat production. Therefore, some level of product contamination must be tolerated, although this varies widely from one country to another. Control of meat's microorganisms is difficult and subject to cost constraints including implementation of hazard analysis and critical control points (HACCP) in meat-processing plants. However, improved practices in production and processing plants may lead to a steady decline

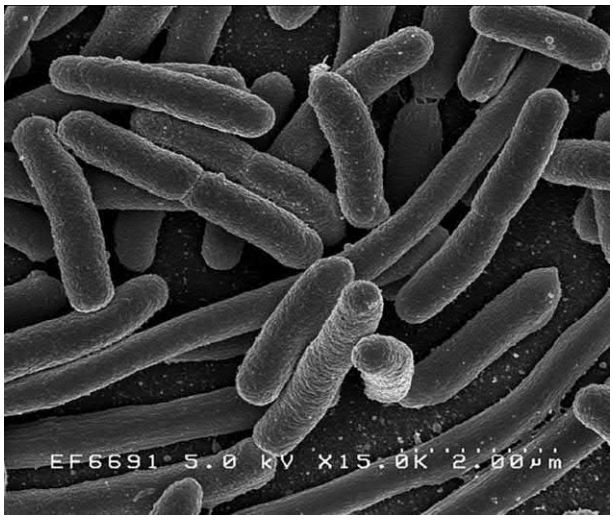

FIGURE 9.8 Morphology of *Escherichia coli*. (From Wikipedia. Credit: Rocky Mountain Laboratories. http://en.wikipedia.org/wiki/Bacteria.)

in the contamination rate [22]. Regular rejection of contaminated fresh meat would be economically unacceptable on the scale required. Instead, there is a growing emphasis on the application of preventative measures within the meat industry, and there is now much reliance on the HACCP system for controlling foodborne pathogens in meat-processing plants. The microbiological hazards in the processing operation are well-known and are difficult to control effectively, because of the technological limitations in the process which can lead to cross-contamination of the meat being processed. Implementation of the HACCP system does not overcome this drawback but has a number of clear benefits, including that the system ensures regular monitoring of the process, hygiene control is optimized, control parameters are an integral part of the system, compliance with hygiene legislation is ensured, and staff awareness of food-safety is necessary. Cross-contamination of fresh meat with pathogens can occur at every stage of the process, and there is little evidence that this problem is significantly reduced by the application of HACCP principles. Moreover, there is no critical control point at which a significant reduction in pathogen contamination can be guaranteed. Without the use of processing aids to improve hygiene, the greatest reductions in fresh meat contamination are likely to come from technological developments in the process that are designed to improve hygiene, as long as these are acceptable to the industry.

9.3.3 Decontamination

The grouping concern about the contamination of fresh meat with enteric pathogens has led to extensive investigation of treatments for reducing the number of bacteria on fresh meat products. Decontamination is very important in reducing meat spoilage and consequently improving meat hygiene. Both psychrotrophic and mesophilic bacteria can grow at temperatures above 20°C [23]. Short-term chilled storage at less than 10°C is the safest procedure for storing meat products. For long-term storage, the temperature should be as near to the freezing point as practicable (1.5°C), and relative humidity should be controlled within 85–95% to prevent drying or condensation on the meat surface. The main spoilage microorganisms present in aerobic conditions in low-temperature storage are *Pseudomonas* species, whereas under vacuum storage, the major spoilage microorganisms are *Lactobacillus* species and yeasts [24]. Reducing fresh meat surface contamination and avoiding or limiting microbial growth would improve safety and external shelf life [25]. Removal of bacteria stuck on the fresh meat surface, followed by spraying antimicrobial hot water, induces the release and inactivation of bacteria, which is necessary for effective decontamination [26]. The possible heat damaging of the appearance of the fresh meat surface reduces the feasibility of such treatment. Steam is one of the more effective and fast methods for reducing the number of pathogenic bacteria on meat. The surface will appear quite rough with many pores. It is difficult to kill bacteria that get into these pores with sanitizing solution because surface tension prevents the liquid from entering the pores. Therefore, steam should be able to enter the pores and kill the bacteria.

9.3.4 Organic Antimicrobial

Surface treatment with organic acids is a more realistic option for eliminating pathogens without adverse effects on the quality of the meat. The use of organic acids reduces bacterial counts in the meat surface layer; lactic acid is often used, as it is a natural meat compound produced during postmortem glycolysis [27]. The combination of physical treatment with hot steam and spraying with a lactic acid solution is another approach for fresh meat surface decontamination [28, 29]. Acid washes have been shown to be effective in reducing the total number of microorganisms present on meat [30]. The antimicrobial effect of the organic acids is due to the reduction of pH below the growth range and metabolic inhibition by the un-dissociated molecules [31]. In this respect, acid and heat inactivation of microorganisms follows the release of microorganisms from the surface. Moreover, the lactate anion slows down the growth of surviving microbes during storage [26]. The antimicrobial action of organic acids depends on three factors: (i) pH, (ii) extent of dissociation, and (iii) specific effects related to acid molecules. The effective growth inhibition by an acid only occurs when an appropriate amount of the un-dissociated molecule is present [32]. This amount may be obtained by either applying more acid or by lowering the pH. Most organic acids are therefore effective only at low pH values, i.e. below ~ pH 5.5. The differences in antimicrobial activities of various organic acids are related to (i) the potency to penetrate a cell, (ii) the part of the cell which is attacked, and (iii) the chemical nature of that attack [32]. The factors influencing the efficacy of acids treatments are (i) nature of meat surface and initial level of contamination, (ii) initial bacterial load, (iii) type of acid used, (iv) concentration and temperature of the acid, (v) types of microorganisms present on the surface [33]. After examining 13 acids, it was recommended that acetic and propionic acids are the most effective agents for microorganisms [34]. Mixtures containing various acids may also be used for their synergistic effects on microorganisms, but synergistic effects may not always be observed. Acetic and lactic acids (1–4% concentration) produce the desired microbial reduction, and their mixture may enhance the effectiveness [33].

Decontamination systems may adversely affect meat quality characteristics that contribute to meat acceptability, such as color, flavor, odor, and drip loss. An efficient decontamination system should reduce bacterial numbers without any detrimental changes to the quality parameters [28]. In general, treatment with lactic acid, acetic acid, and citric acid at low concentrations does not produce much of an adverse effect on color [28]. However, higher concentrations resulted in bleaching of lean meat and fat [33]. When many blood spots are present on the meat surface, the coagulation of blood may cause rusty brown-black spots. This is more particularly evident at higher acid concentrations, but decontamination with acetic or lactic acids at low concentrations of 1 to 2% hardly

affects the sensory quality of meat [33]. The sensory scores are more readily affected by acetic acid than lactic acid; thus mixtures may help to alleviate color problems. Slight visible discoloration forms immediately after application at low concentrations, and usually disappears upon diffusion of the acid. The use of acetic, propionic, lactic, and formic acids for decontamination is considered to be acceptable from a toxicological perspective [35].

Natural compounds including essential oils, chitosan, nisin, and lysozyme, have been replaced by other materials to preserve meat and meat products. The use of natural or lactic acid bacteria and their antimicrobial products including lactic acid and bacteriocins to extend the storage time and safety of meat has been investigated [36]. Bacteriocins are a heterogeneous group of antibacterial proteins that vary in spectrum of activity, mode of action, molecular weight, genetic origin, and biochemical properties, which can be used for meat preservation [37]. Eugenol in cloves and allyl isothiocyanate in mustard seed have preservative properties, and these have been used to extend the storage period of meat products. Nisin is the commercial bacteriocin and has been used to decontaminate artificially contaminated pieces of raw meat [38] and in combination with 2% of sodium chloride as an anti-listerial agent in minced raw meat [39]. The bacteriocins produced by lactic acid bacteria are listed in Table 9.1.

Pentocin produced by *Lactobacillus pentosus* and isolated from fermented meat has been used as a biopreservative in storage-chilled meat. Results showed that pentocin could substantially inhibit the accumulation of volatile basic nitrogen and suppress the growth of microflora, especially *Listeria* and *Pseudomonas* [40].

9.3.5 Inorganic Antimicrobial

Inorganic phosphates, hydrogen peroxide, and ozone can be used for meat decontamination. Trisodium phosphate treatment is officially accepted and widely implemented in the fresh meat process [41], and it does not cause undesirable sensory effects detectable by the consumer [42]. A concentration of 10–12% in alkaline solution could be used [41]. The formation of radicals by hydrogen peroxide damages nucleic acids, proteins, and lipids, thus causing a bactericidal-bacteriostatic effect [83]. Hydrogen peroxide was used as a meat decontaminant at a minimum effective dose of 0.5% (v/v) in water. At this level, a temporary bleaching and bloating of the fresh meat [43] and excessive foaming of chiller water are observed [41], and the application of hydrogen peroxide for decontamination seems to be an effective and safe method to control the spread of pathogens. Ozonated water is also used to eliminate bacteria counts on the fresh meat surface [44]. Ozonated water can be used to decontaminate meat products without visual defects or sensory off-flavors, although bacterial count reduction was poor (>1-log cycle) and there was no increase in shelf life [43]. Spraying beef meat with water followed by spraying with ozonated water is an effective bacteriological sanitation method [45].

Aqueous chlorine is also widely used in food processing to control microbial growth. Its bactericidal activity decreases in alkaline conditions and/or at high levels of organic matter. Furthermore, potentially toxic mutagenic reaction products, including trihalomethanes, are formed during the chlorine treatment of food components [46]. Chlorine dioxide has received much attention due to its advantages over aqueous chlorine: (i) it is seven times more potent than aqueous chlorine in killing bacteria [47], (ii) its bactericidal activity is not affected by alkaline conditions, and/or the presence of high levels of organic matter [48], (iii) it is less reactive than aqueous chlorine in interacting with organic compounds, such as unsaturated fatty acids, their methyl esters, and tryptophan and their derivatives [49].

It is possible to improve the hygiene levels of carcasses by means of antibiotics [50]. The most frequently used and cheap antibiotics are chlorotetracycline and oxytetracycline, and their combination is more effective [51]. However, the application of antibiotics to meat faces wide criticism and protest. Many people do not agree with antibiotic application to meat on legal and hygienic grounds as many antibiotics may cause toxic and allergic reactions as well as bacterial resistance with cumulative effects in the human body. Strict control of antibiotic applications in meat should be maintained [50]. In addition to the treatments, packaging is also used to prevent contamination, controlling the evaporation of water from the surface, and reabsorbing the drip. The absorbent and refrigerant pads benefit by absorbing and retaining unwanted fluids and improve the shelf life and help to maintain humidity levels.

Carbon dioxide and ozone have been used to prevent the growth of surface microorganisms on fresh meat during prolonged storage at chilled temperatures [36]. However, ozone can accelerate the oxidation of fat and is more effective against air-borne microorganisms than against those on meat surfaces [52]. Lactic acid is a frequently effective inhibitory agent used in fresh meat preservation, while other organic acids have been found to be responsible for discoloration and production of strong odors [53]. Sodium lactate has been used in the meat industry due to its ability to enhance meat flavor, prolong shelf life, and improve the microbiological safety of products [54–56]. Nadeem et al. [57] extended the shelf life of meat products stored at 5–7°C for 2–3 days, after spraying the meat with a solution containing potassium sorbate, sodium acetate, sodium citrate, and sodium lactate, each at 2.5%, and sodium chloride at 5%.

9.3.6 High Hydrostatic Pressure

Cheftel and Culioli [58] stated that high-pressure technology (100–1000 MPa, 1000–10,000 bar) is of increasing interest to biological and food systems. High hydrostatic pressure is of interest because it can inactivate meat product-spoiling microorganisms and enzymes at low temperatures without changing the sensory or nutritional properties of the meat. Pressure processing can be carried out in a steel cylinder containing a liquid pressure-transmitting medium (water), with the sample being protected from direct contact by the use of sealed flexible packaging. Maintaining the fresh meat under pressure at the chosen temperature for an extended period does not require any extra energy [58]. High hydrostatic pressure renders meat more stable due to its ability to reduce contamination with pathogenic microorganisms, and to inactivate certain meat enzymes [59, 60]. According to Hugas et al. [61], high hydrostatic pressure is a powerful tool to prevent the growth of *Salmonella* spp. and *Listeria monocytogenes* in raw or marinated meats.

The effectiveness of high hydrostatic pressure for microorganism control depends on the process parameters, pressure level, temperature, and exposure time, as well as on intrinsic factors of the meat itself, such as pH, strain, and growth stage of microorganisms, and meat composition [62]. It has been shown that the combination of high hydrostatic pressure with moderate temperatures can improve the tenderness of the meat [63]. However, high hydrostatic pressure at any temperature may have an undesirable effect on fresh meat color. The color of fresh meat [64] changes with pressure due to the denaturation of globin in myoglobin and heme displacement or release, and ferrous oxidation [65]. Denaturation of myosin and actin creates a greater opacity and therefore minimizes the red appearance.

9.3.7 Ionizing Radiation

Ionizing radiation has been a method of direct microbial inhibition for preserving meat and meat products since 1940 [52]. The radionuclides approved for food irradiation include 137Cs and 60Co, and radioactive cobalt (^{60}Co) decays to non-radioactive nickel by emitting high-energy particles and X-rays [36]. The X-rays kill rapidly growing microorganisms but do not leave the product radioactive because they are highly penetrating; therefore they can be used to treat food [66]. The benefits of using ionizing radiation in food preservation include high efficiency in inactivation of microorganisms, and that the ionized product is essentially chemically unaltered, and can be treated after packing in containers [52]. A maximum dosage of 10 kGy represents a low amount of energy which preserves the freshness and nutritional quality of the meat and meat products when compared with thermal methods [1].

Irradiated fresh meat color changes may be due to the inherent susceptibility of the myoglobin molecule to energy input and alterations in the chemical environment, heme iron being particularly susceptible. Brewer [66] stated that maintenance of a fresh meat color during the process of irradiation could be enriched by combinations of premortem supplementation of antioxidants to livestock, postmortem condition of the fresh meat prior to irradiation (pH, oxymyoglobin vs. metmyoglobin), addition of antioxidants directly to the meat, gas atmosphere, packaging, and temperature control. Radiation treatment resulted in essentially no loss of thiamine [67], therefore suggesting that such radiation has no detrimental effects on meat nutrients. However, capital costs and complicated technology are involved in irradiation.

9.4 PRE-RIGOR CHANGES

Rigor mortis is a temporary process occurring during the course of postmortem anerobic glycolysis and is characterized by progressive stiffening of the muscle and loss of ATP. When ATP is exhausted, the myosin and actin molecules remain locked together and yield the stiffness of muscle in rigor. The development of rigor mortis has been determined by several methods including loss of extensibility, muscle shortening, tension development, resistance to strain, and by a combination of muscle tension and shortening [31, 68]. The rate of postmortem glycolysis and the extent to which it occurs have significant implications in fresh meat quality. As anaerobic glycolysis proceeds from the point of slaughter to rigor mortis, various changes occur in the muscle. The production of H^+ leads to a more acidic condition, which, in turn, is measured as a decrease in meat pH. Fast-glycolyzing muscles yield higher tenderness scores compared with slow-glycolyzing muscle [69]. Pre-slaughter stress causes the depletion of muscle glycogen and therefore limits postmortem glycolysis, resulting in meat with an increased ultimate pH [70].

Interactions between pH and temperature during the onset of rigor directly influence meat quality through effects on proteolysis, protein denaturation, and myofibrillar shrinkage [71]. The calpain system is the most likely cause of myofibril-related tenderization, and proteolytic and/or autolytic activity of μ-calpain is largely a function of the interaction between pH and temperature [72]. Muscle temperature at pH 6.2 has been used as an important threshold in meat science because it could be an indirect indication of cold and heat shortening [73]. At slaughter, the muscle temperature is around ≅38–40°C; once the meat has been processed, it is placed into a cooler at 4°C. Temperature has a significant effect on muscle glycolytic reactions and rigor onset.

Pre-rigor meat has a higher water-holding capacity and better fat-emulsifying properties than post-rigor meat, which makes it more suitable for making processed meat products such as sausages. These properties can be maintained if pre-rigor meat is frozen quickly to temperatures below –20°C. However, when the frozen meat is thawed, it shortens and loses its water-holding capacity. Adding 1.8% salt to pre-rigor meat helps to maintain the pre-rigor attributes for several days when chilled [74]. With pre-rigor salting, the water-holding capacity is maintained due to a strong electrostatic repulsion between adjacent protein molecules caused by an initial combined effect of relatively high ATP concentration, high pH, and ionic strength. Adding salt pre-rigor inhibits ATP turnover but does not affect the rate of glycogen breakdown.

9.4.1 Cold Shortening

Cold shortening is a phenomenon that occurs in pre-rigor muscle and results in less tender meat. "Shortening" refers to the short sarcomere length characteristic of highly contracted muscle with protein denaturation and water loss [68, 75]. Rapid chilling may have a detrimental effect via cold shortening, which results in a drastic decrease in tenderness. The degree of overlap between myosin and actin filaments primarily contributes to meat toughening. Changes in angles of crisscross connective tissue lattice and crimp length are responsible in part for the relationship between sarcomere length and meat tenderness [76]. The toughness of cold shortened meat may also be due to the endogenous enzymatic tenderization mechanism and shortened sarcomere length. The effect of shortening sarcomeres on shear force is significantly detrimental when proteolysis is relatively slow. The "cold" refers to the rapid cooling which must occur in order to observe the effect (Figure 9.9).

If meat is frozen prior to rigor onset and subsequently thawed, it will shorten dramatically and be extremely tough. This phenomenon is referred to as "thaw shortening." The process of pre-rigor freezing can damage the sarcoplasmic reticulum and destroy its ability to regulate calcium concentrations within the myofiber. Both calpains and myosin-ATPase require free calcium ions in the cytoplasm for their activities [77]. It has been shown that calcium-reserving organelles lose their function at abnormal cellular temperature. During thawing, all the components necessary for muscle contraction are still present, but control of the reactions is lost. As a result, anaerobic metabolism processed at a very rapid rate and is concomitant with severe contraction.

9.4.2 Acceleration of Postmortem Glycolysis

Electrical stimulation is the post-slaughter application (pre-rigor) of an electrical current to the carcass to accelerate postmortem glycolysis of the fresh meat [78]. Electrical stimulation causes the muscle to undergo continuous contraction–relaxation cycles. The muscle's content of ATP, the compound needed to produce the energy required for muscle contraction, is being depleted, thus increasing the rate of glycolysis [72]. The variability in overall ATPase postmortem is primarily responsible for the variability in postmortem pH fall in muscle. This causes the muscle to replenish ATP by accelerating postmortem glycolysis. With the acceleration of postmortem glycolysis, a rapid build-up of lactic acid occurs,

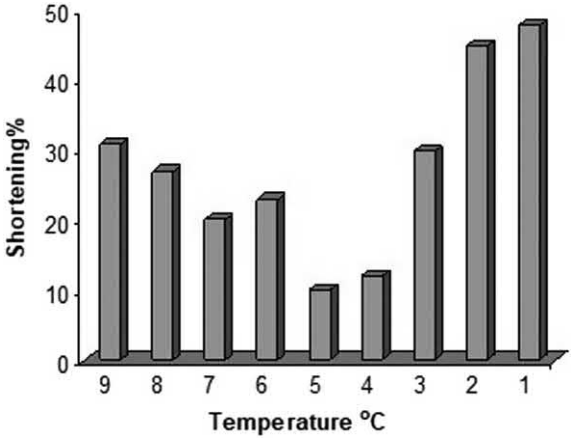

FIGURE 9.9 Changes in biochemical metabolites during the onset of rigor mortis. (From Newbold [160].)

and, in some cases, the pH of electrically stimulated muscle can reach a pH of 6.0 in a few hours instead of the 12 to 16 hr that may be required for non-stimulated muscles. The high energy of activation means that any cooling of the muscles will markedly increase the time for attainment of rigor mortis with a larger effect in stimulated muscle. Additionally, electrical stimulation causes muscular contraction sufficient to cause physical disruption of tissue. Acceleration of proteolysis could be classified as a secondary effect mediated through time/temperature–pH interaction, affecting factors such as enzyme stability and activity [72].

Electrical stimulation has been demonstrated to improve most aspects of meat quality including tenderness, color, and palatability. Chilling for 48 or 72 hr would maximize the quality of beef carcasses. However, most fresh meatpackers do not have the required facilities to hold the meat for this length of time before it is graded or shipped. Therefore, electrical stimulation plays an important role for the packer. There are three theories on the mechanism by which electrical stimulation tenderizes meat. First, because the onset of rigor mortis is hastened by electrical stimulation, muscle fibers do not shorten to the same extent as those from un-stimulated carcasses when exposed to cold-shortening temperatures. Second, because of the rapid drop in pH caused by the accelerated postmortem glycolysis while muscle temperatures are still high, conditions are favorable for the naturally occurring enzymes responsible for tenderization during the degradation of muscle proteins [79]. Third, histological images showed the appearance of contracture bands containing predominantly stretched, ill-defined, and disrupted sarcomere from electrically stimulated muscles [72]. Contractor bands, which may be caused by physical disturbance associated with stimulation-induced contractions, are also observed within some of the electrically stimulated muscle fibers. This structural damage may result in greater fragmentation of the muscle fibers upon chewing or mechanical shearing force, thereby increasing its tenderness [80, 81]. If the time interval between successive stimuli is more than approximately 0.25 s, the muscle titanic shortening is reversible [72]. On the other hand, when a higher frequency of current is applied, the muscle may not have enough time for relaxation between successive twitches, and this forms irreversible contracture bands. However, several researchers have disagreed with respect to the importance of structural damage in increasing the tenderness of electrically stimulated meat. In some studies, electron micrographs of electrically stimulated samples revealed protein precipitation, not structural damage. A number of studies have indirectly indicated that physical disruption had less effect on tenderness than did proteolysis [82]. It is clear that electrical stimulation favors autolysis of calpain rather than proteolytic activity [83]. There is also evidence suggesting that both physical disruption and effects on the calpain system arise as a consequence of stimulation.

There is evidence indicating that flavor is significantly improved by applying electrical stimulation [84]. This is attributed to the concentration of adenine nucleotides and their derivatives. Another advantage of using electrical stimulation is the reduction in aging time. Electrical stimulation resulted in a substantial decrease in the aging time needed to achieve a specified level of tenderness.

Meat retailers benefit from the use of electrically stimulated meat because of the improved appearance of retail cuts. Electrically stimulated fresh meat had a brighter color, less surface discoloration, and a more desirable overall appearance than non-stimulated meat [85]. Meat from electrically stimulated sides had a higher percentage of oxymyoglobin, the pigment responsible for the bright cherry-red color of beef, than meat from their non-stimulated counterparts. There is conflict on the persistence of color of electrically stimulated meat. The color-enhancing effect of high voltage electrical stimulation was reported not to persist beyond 24 h when subjectively scored. Persistent effects of high- and low-voltage electrical stimulation up to 6 days after postmortem treatment were also reported [85]. The improved appearance of the meat from electrically stimulated carcasses does not appear to be significantly related to its effects on bacteria [86].

9.5 POSTMORTEM CHANGES

Although the establishment of rigor mortis is generally accepted to be the point, the exact point at which the conversion of muscle to meat is completed is not easy to determine. The functional role of skeletal muscle is lost and rigor has been established, but the metabolic activity of the tissue would not stop. Many biochemical processes, some of which have significant implications for the meat quality characteristics, may still occur.

9.5.1 Meat Color

Color is the main trait critical to fresh meat purchase decisions [87]. Fresh meat color is governed primarily by myoglobin (Mb) content, its redox state, and interactions with several intrinsic and extrinsic factors [88]. The bright cherry-red color attractive to the consumer has been often associated with freshness of the meat, whereas a brownish discoloration is perceived as indicative of spoilage [89]. In general, the myoglobin concentration within a given fresh muscle will differ according to the species or age and is dependent on muscle fiber distribution [90, 91]. Oxidative muscles (more type I muscle fiber) exhibit greater Mb content [92] and mitochondrial concentration [93] than glycolytic (more type II muscle fiber) muscles. In postmortem oxidative fresh muscles, the mitochondrial metabolism surpasses myoglobin's ability to bind oxygen leading to accelerated metmyoglobin formation and surface discoloration [93]. Psoas major muscle contains a greater proportion of fiber type I (oxidative) than longissimus thoraces muscle [92], which is positively correlated to Mb content [92]. Furthermore, an increased level of Mb in muscles is associated with low color stability. The relative proportions of the three myoglobin forms, deoxymyoglobin (Mb), oxymyoglobin (MbO), and metmyoglobin (MetMb), depend on the oxygen availability and affect the color of fresh meat. The oxygen availability depends on the oxygen partial pressure, penetration, and consumption rate of the muscle

[94]. The penetration depth of light decreases as an effect of increased light scattering due to an increased amount of water outside the myofibrillar space induced by the pH drop during glycolysis [95]. The difference in pH dropping between muscles could be attributed to the difference in muscle fiber type proportion of the muscles [96]. Glycolytic muscles usually exhibit greater glycogen levels favoring increased postmortem accumulation of lactic acid than oxidative muscles [97]. The meat surface may be more or less translucent depending on the rate of postmortem pH drop, ultimate pH, and the extent of protein denaturation [95]. During postmortem glycolysis, the sarcoplasmic proteins denature and precipitate on the myofibrils, resulting in increased light scattering and less light penetration [95]. All these processes occur within the small heme portion of the larger myoglobin protein. When heme iron is in the ferrous form and lacks a sixth position, it is referred to as "deoxymyoglobin." The color of deoxymyoglobin is purplish-red, which is characteristic of fresh meat. Ferrous myoglobin that is exposed to air will bind oxygen at the sixth coordination site and from oxymyoglobin. Oxymyoglobin is cherry red and typical of fresh meat displayed in retail outlets. The process by which deoxymyoglobin binds oxygen and consequently is converted to oxymyoglobin is called "oxygenation." It is important that this should not be confused with "oxidation." The process of oxidation occurs in myoglobin when ferrous (+2) iron (deoxymyoglobin or oxymyoglobin) is converted to ferric (+3) iron and leads to the third form of myoglobin found in fresh meat, metmyoglobin. Metmyoglobin is brownish-red in color and is characterized by ferric iron with a water molecule bound at the sixth position. The oxidation of deoxymyoglobin or oxymyoglobin leads to the formation of metmyoglobin; this process occurs gradually over the surface of meat cuts during storage and/or display.

9.5.2 Lipid Oxidation

Lipid stability of pressure-treated foods of animal origin has been little investigated, and results are contradictory [36]. Rivas-Canedo et al. [98] used high pressure (400 MPa, 10 min at 12°C) to treat minced meat, which was packaged with or without aluminum foil in a multilayer polymeric bag. They found that pressurization produced significant changes in the levels of some volatile compounds presumably originating from microbial activity and the plastic material [98].

Although lipid in meat contributes significantly to flavor, its oxidation will result in the production of free radicals, which lead to the formation of rancid odors and off-flavor. Oxidation might also play a role in controlling the proteolytic activity of enzymes and could be linked to meat quality. The oxidative stability of meat depends upon the balance between anti- and pro-oxidants, including the concentration of polyunsaturated fatty acids [99]. It has been demonstrated that dietary fat and vitamin E supplementation can influence the antioxidant enzyme activities in meat [100]. Fatty acids are chains of carbon atoms with a carboxylic acid group at one end and vary in length according to the number of carbon atoms, which comprise their backbone and may be saturated or unsaturated.

TABLE 9.2
Fatty Acid Content of Muscle Foods

Species	% Saturated	% Monounsaturated	% Polyunsaturated
Beef	55.5	52.0	3.0
Pork	44.0	56.5	10.5
Mutton	55.0	41.5	4.0
Poultry	30.5	45	18.5
Fish	30.0	33.0	37.0
Goats	51.3	43.5	5.09

Source: Hultin [161].

Unsaturated fatty acids may contain one (mono-saturated) or several (polyunsaturated) double bonds between the carbon atoms and are generally liquid at room temperature. It should be noted that the proportions of saturated, monounsaturated, and polyunsaturated fatty acids in meat tissues depend on the species (Table 9.2). In monogastric species, such as pigs and chickens, they may be influenced by diet.

Saturated fatty acids are regarded as harmful to human health in contrast to polyunsaturated fatty acids, which play a favorable role in the prevention of some human artery diseases [99]. Therefore, increasing the proportion of polyunsaturated fatty acids in meat is currently recommended. Meat from monogastric animals contains high levels of unsaturated fatty acids relative to meat from ruminants. Meat fatty acid composition is influenced by a number of factors including muscle type and its oxidation [14]. The factors that make muscle lipids susceptible to oxidation are either intrinsic to the meat products or related to the technological process [101]. Oxidation of muscle lipids produces primary and secondary products such as hydroperoxides, free radicals, endoperoxides, malondialdehyde (MDA), epoxides, alkanes, hydrocarbons, alcohol, thiobarbituric acid reactive substance, and also acids that may be toxic to humans [102]. The oxidation of meat may be reflected in off-odors and flavors detected by sensory panels. It may also result in increased peroxide values or compounds, mainly MDA, giving a red color when reacted with thiobarbituric acid. Increasing aging time from 8 to 15 days increased the levels of MDA due to normal oxidation processes occurring in refrigerated meat. Differences in MDA between meat samples aged for 8 and 15 days were still detected after 4–8 months of frozen storage. Initial storage conditions may affect the subsequent lipid stability of frozen meat regardless of the storage temperature [103]. At –20°C storage temperature, the MDA content increased with increased storage time [104]. The low level of hydroperoxides in fresh meat increases rapidly to reach a maximum after several months of freezing. The threshold value for rancidity is 1–2 mg of MDA per kg of meat [105]. However, consumers are unlikely to detect off-flavor at values below a threshold of about 0.5 mg MDA/kg [106].

The double bonds located within polyunsaturated fatty acids are sites of chemical activity. Oxygen is a key element

for lipid oxidation and may react with these sites to form peroxides, which lead to rancidity. Polyunsaturated fatty acids are susceptible to rancidity as they contain double bonds. Meat with high concentrations of polyunsaturated fatty acids can develop a rancid flavor faster than meat with less polyunsaturated fatty acids. The interaction of oxygen with polyunsaturated fatty acids is a non-enzymatic process. Vacuum packaging of meat products therefore provides a longer shelf life by excluding oxygen from the packaging.

Enzymatic-based lipid oxidation occurs in meat and is also known as microsomal lipid oxidation. This process requires certain biochemical cofactors including reduced forms of nicotine adenine dinucleotide phosphate or nicotine adenine dinucleotide, adenosine diphosphate, and iron ions. The enzymatic nature of the process implies the involvement of membrane-bound proteins. The cooking of meat provides sufficient heat to denature enzymes, and therefore, enzymic/microsomal lipid oxidation will not occur in cooked meats. During normal physiological functioning, the enzymes found in these sub-cellular organelle membranes produce chemically reactive substances known as radicals. These are a necessary part of normal cell functioning, and in the "living state" the cell has a variety of mechanisms for protecting itself against the undesirable actions of radicals. In postmortem, many of these protections are lost; therefore radicals may hasten lipid oxidation and consequently cause rancidity.

Color deterioration and lipid oxidation may be linked, although the precise mechanisms are still unclear [107]. Some control over increased susceptibility to oxidation can be attained by feeding with higher levels of vitamin E, as an antioxidant active in meat [108]. The delaying of myoglobin oxidation is accomplished in a variety of ways. These include storage and display of meat under refrigerated conditions, hygienic preparation of meat cuts, and selective use of lighting. In addition, the application of antioxidants, such as ascorbic acid (vitamin C), citric acid, or γ-tocopherol (vitamin E), may extend the color shelf life.

9.6 MEAT STORAGE AND SAFETY

9.6.1 Refrigeration

The development of refrigeration had more impact on meat preservation than any other technological advancement. Fresh meat refrigeration storage above or below the freezing temperature has been the traditional preservation method. Ultra-chilling technology, which keeps fresh meat just above the freezing temperature, has been used with success [109]. Chilling is critical for fresh meat hygiene, safety, shelf life, and quality characteristics. Chilling air reduces the temperature of fresh meat surfaces and enhances meat drying, which reduces the growth of bacteria [110]. However, it is difficult to remove heat quickly from the deeper tissue of the fresh meat. Proper refrigeration, therefore, not only lowers the temperature of the harvested fresh meat but also slows down the rate of glycolysis as the temperature is decreased. Modern ultra-chilling coolers operate at lower relative humidity than in the past to reduce condensation, which is a source of contamination. The term ultra-chilling is used to describe a process where a minor part of the product's water content is frozen [111]. The lower relative humidity enhances the evaporation of water, which is required for the absorption of heat from the meat surface, speeding up the postmortem fresh meat chilling process and minimizing microbial growth. The use of a blast chilling system and rapid air movement at 1–5 $m.s^{-1}$ for 1–5 h will rapidly cool fresh meat, reducing cooler operation time. Moreover, rapid meat chilling increases meat product yield due to lower surface evaporation, while the rapid drying of the meat surface helps to reduce bacterial growth. Controlling airflow inside industrial meat chillers is of paramount importance because it determines both the efficiency and the homogeneity of meat chilling [112]. Therefore, the use of ultra-rapid chilling results in lower shrink loss that accompanies a reduced chilling period [113]. During ultra-chilling, the temperature of the product is lowered, often 1–2°C, below the initial freezing point of the meat product. The refrigeration technology will maintain the meat temperature between 0°C and the temperature at which ice crystals form in the product (–2°C), and will further extend the shelf life of chilled fresh meats [114]. After initial surface freezing, the ice distribution equilibrates and the product obtains a uniform temperature at which it is maintained during storage and distribution [111]. At ultra-chilling temperatures, most microbial activity is inhibited or terminated and the chemical and physical changes may progress or accelerate. The ice crystals in ultra-chilled meat products protect the fresh meat from temperature rises in poor cold chains; however, some increase in product drip loss may occur during storage [111]. The process involves water chilling of fresh meat and air freezing at –15°C for approximately 30 min and then the packaging of the products. They are again placed in an air freezer to achieve the required meat temperature and then stored and distributed at –1 to –2°C [111]. Ice crystals forming and recrystallization can cause microstructural changes to meat tissue during freezing, resulting in cell dehydration, drip loss, and tissue shrinkage during thawing. Cathepsins B and B+L remained active at the selected storage temperatures, which may lead to softening during subsequent chilled storage. Ultra-chilling of fresh meat at –2.0°C improved the shelf life significantly compared with traditional chilling at +3.5°C [115]. The ultra-chilled fresh meat maintained good sensory quality and low microbiological counts during the whole storage period (16 weeks), while the shelf life of chilled samples was just 14 days.

Ultra-rapid chilling of pre-rigor meat may lead to cold-shortening and toughening [36]. Therefore, James et al. (1992) [116] stated that the ultra-chilling of fresh meat may produce a darker lean color than control meat. The application of blast chilling to fresh meat may result in cold-induced toughening and therefore compromise meat quality. This is due to subtle changes in the rate and extent of pH decline during chilling. An impairment of autolytic enzyme system functions may be responsible for this toughening in addition to the expected effects of cold shortening. At a constant rigor temperature of 35°C, almost 80% of the μ-calpain activity was lost during

rigor development, while only about 20% of the activity was lost when meat was exposed to a constant rigor temperature of 15°C [117]. This inactivation process could be the explanation for the differences in quality between meats with fast and slow pH time courses when exposed to the same chilling regime [118]. However, ultra-rapid chilling of carcasses (–20°C) was reported to produce meat as tender as that from carcasses chilled at 4°C and reduced evaporative weight losses by 0.5–1% [119]. Therefore, blast chilling may be best used in conjunction with electrical stimulation to accelerate the onset of rigor mortis in order to avoid the development of cold shortening.

9.6.2 Aging and Meat Quality

Historically, fresh meat has been aged to improve its quality characteristics. Aging is necessary as meat is often unacceptably tough immediately following rigor onset. The time required for aging varies with the type of muscles. Recently, Colle et al. [120] aged beef strip loin and top sirloin for up to 63 days and concluded that in order to optimize the consumer's perception of tenderness the strip loin does not need to be aged past 14 days, while the top sirloin should be aged for at least 21 days. The ideal storage temperature may be applied in the pre- or post-rigor state and is very effective in improving meat tenderness. The aging processes originate within the myofiber and are responsible for the degradation of cellular constituents.

The analysis of muscle proteins along with meat quality traits during chilled aging is crucial in understanding the biological basis of changes in meat quality. The proteolytic enzymes in meat that have been most studied are the cathepsins and calpains. Aging between 6 and 43°C had significant effects on hunter L*, shear force values, and drip loss [121]. The most relevant consequence of aging is an improvement in meat tenderness [76]. Meat tenderness increased with longer aging for certain muscles, while no difference was observed for other muscles. Fresh biceps femoris muscles and semimembranosus muscles should be aged for at least 14 to 21 days, respectively, to optimize consumer perception of tenderness [122]. They concluded that the tenderness of biceps femoris muscle increased from 53% after 2 days of aging to 63% after 14 days of aging to 75% after 21 days of aging. The improvement in the tenderness of biceps femoris may be due to the breakdown of myofibrillar proteins. The tenderization process involves complex changes in muscle metabolism in the post-slaughter period and is dependent on animal breed, metabolic status, and environmental factors, such as the rearing system and pre-slaughter stress. During aging, the structures of the myofibrillar and other associated proteins undergo some modifications, and collagen is weakened to a lesser extent [122]. The degradation of nine actin and/or actin-relevant peptides out of 20 identified ones is related to meat quality traits during aging [121]. The proteolytic enzymes in meat play a significant role in improving meat tenderness during aging. Enzymes require specific conditions such as temperature and pH for optimal activity, and these can be determined and maximized in meat to improve tenderness. Cathepsins are effective proteolytic agents that have been identified in meat and located within lysosomes and operate best at pH <5.2 values. Myofibrillar proteins are degraded when incubated with various cathepsins *in vitro*. It is believed that catheptic enzymes are able to act on the pH of meat to produce tender meat by degrading myofibrillar proteins.

Calpains are proteases that require calcium ions (Ca2+) for activity. There are two types of calpains found in sarcoplasm: one requires a high concentration of free calcium for activation, and another one requires a low concentration of free calcium. The amount of calcium available in normal muscle cells excludes the high-calcium-requiring calpain as a major contributor to meat tenderization. Both types of calpains require a high pH, <6.6, for optimal activity. This value is substantially higher than the pH 5.6 of normal meat; therefore the maximum activity of calpains would most likely occur during the early postmortem condition.

The degradation of cytoskeletal proteins such as desmin, vinculin, titin, and nebulin was considered to be responsible for changes in the water-holding capacity during aging [123]. The formation of drip is generally considered to be a result of the denaturation of contractile proteins and shrinkage of myofibrils during rigor development [122]. On the other hand, reduced drip loss was related to the "leak-out" effect, and aging itself did not improve water-holding capacity. Higher rigor temperature accelerated drip loss during vacuum-packed storage, and drip loss increased at a high pH (6.2) as aging time lengthened [121]. The effect of early postmortem pH and temperature on meat quality is dependent on aging time. In addition, this affects meat color by influencing the surface reflectance [124]. Injection with calcium/sodium chloride after slaughter accelerated postmortem tenderization and increased the tenderness of the meat sample apparently by enhancing the activity of the endogenous calcium-dependent proteases (m- and μ-calpain) [125].

Flavor intensity increased with aging time [126]. This may be due to postmortem processes such as proteolysis and lipolysis resulting in the development of flavor precursors. Many peptides are produced during aging [104]. They can react with other molecules thus producing new flavor compounds. Another source of volatiles in meat with age is the degradation of lipid. Lipid oxidation can adversely affect fresh meat product flavor [122]. During cooking, these compounds may be oxidized further and react with Maillard products to give many other compounds that may contribute to flavor [127]. Therefore, aging meat for the development of flavor, aside from its tenderizing effect, becomes a questionable practice for meat that is to be held in zero storage for more than six months. The holding period has a direct effect on the storage life because it permits oxygen absorption by the exposed fat.

9.6.3 Packaging

Packaging protects products against deteriorative effects, which may include discoloration, off-flavor and off-odor development, nutrient loss, texture changes, pathogenicity,

and other measurable factors [36]. The factors influencing the shelf life of packaged fresh meat are product type, gas mixture, package, and headspace, packaging equipment, storage temperature, and additives. Modern fresh meat packaging is minimally permeable to air moisture, and so surface desiccation is prevented, while gas permeability varies with the particular film type used. Packaging options for fresh chilled meat are air-permeable packaging, low-O_2 vacuum, low-O_2 MAP with anoxic gases, and high-O_2 MAP. While air-permeable packaging is not MAP, the use of overwrapped packaging materials within the master pack or tray-in-sleeve systems allows for this packaging option to be a component of MAP [128].

Vacuum packaging materials for fresh meat cuts are usually three-layered co-extrusions of ethyl vinyl acetate/polyvinylidene chloride/ethyl vinyl acetate. Vacuum packaging has an O_2 permeability of less than 15.5 ml m^{-2} (24 h) at one atmosphere as a result of the polyvinylidene chloride layer. The absence of O_2 in fresh meat packages may eliminate aerobic microbial growth, which usually causes a brownish color due to the deoxymyoglobin state of myoglobin. Low-O_2 vacuum packages for fresh meat cuts involve placing the retail cut in a barrier polypropylene tray and vacuum sealing barrier films that are heat shrunk to conform to the shape of the product [129]. Vacuum packaging removes the air from the package with gaseous mixtures such as N_2, CO_2, or mixtures of N_2 and CO_2 before heat sealing the film layers [130]. The lidding film of vacuum packaging contains outer and inner air-permeable layers; the outer film layer is usually peeled away from the permeable layer so that O_2 can then contact the meat surface and result in a bloomed color [129, 130]. Mechanisms of intelligent packaging are well-discussed [131].

Modified packaging for display fresh meat requires a barrier of moisture and gas permeation through filming materials to maintain a desirable condition during storage. Although meat vacuum packaging is the most effective packaging, the use of low-O_2 modified packaging is limited [132]. Low-O_2 modified packaging may be used as a barrier package with an anoxic atmosphere of N_2 and CO_2. Nitrogen is not reactive with meat myoglobin; therefore, it maintains the integrity of the fresh meat. The meat pigments become oxygenated when the overwrapped permeable film package is removed from the master pack for retail display [129]. If the air-permeable film does not permit sufficient O_2 for oxymyoglobin formation, microperforated shrink films with additional holes can be used to promote faster meat blooming [133]. Carbon monoxide (CO) has also been used in low-O_2 meat vacuum packaging systems. Small amounts of CO in the packaging system can be sufficient to impart a desired red meat color [129, 134, 135]. The high O_2 (80%) in fresh meat modified packaging is allowed sufficient shelf life for processors and retailers with controlled distribution systems [134].

Active packaging for fresh meat involves the interaction of specific compounds with the contents and atmosphere to maintain or extend meat quality and shelf life [136]. Active meat packaging may also involve the deliberate altering of the atmosphere at a specified time through passive or active monitoring needed with controlled atmosphere packaging [137]. On the other hand, intelligent meat-packaging systems contain components that sense the environment and process the information and then allow action to protect the meat by conducting communication functions. Active and intelligent packaging functions include moisture control, O_2-permeable films, O_2 scavengers, O_2 generators, CO_2 controllers, odor controllers, flavor enhancement, ethylene removal, antimicrobial agents, microwave susceptors, indicators of specific compounds, and temperature control packaging [138, 139].

Antimicrobial packaging is the mixture of antimicrobial substances in meat-packaging materials to control the undesirable growth of microorganisms. The antimicrobial packaging system is an advanced technology to extend shelf life and improve meat safety in both synthetic polymers and edible films [132]. According to [140], antimicrobial packaging films can mix the antimicrobial substances into a sachet connected to the meat package from which the bioactive substance is released during storage, or the antimicrobial can be spread into the packaging film (Table 9.3). The sachets can include O_2 scavengers, CO_2 generators, and chlorine dioxide generators, while bioactive agents dispersed in the packaging may be O_2-scavenging films, silver ions, triclosan, bacteriocins, spices, essential oils, enzymes, and other additives [141]. The active agents can be released onto the meat surface and they will migrate slowly into polymers used for meat packaging. Volatile active substances in the packaging can move into the gaps between the package and the surface of the meat [142].

Potential antimicrobial agents for use in meat-packaging systems are organic acids, acid salts, acid anhydrides, parabenzoic acids, alcohol, bacteriocins, fatty acids, fatty acid esters, chelating agents, enzymes, metals, antioxidants, antibiotics, fungicides, sterilizing gases, sanitizing agents, polysaccharides, phenolics, plant volatiles, plant and spice extracts, and probiotics [143]. Antimicrobial compounds that have been evaluated in film structures are organic acids and their salts, enzymes, bacteriocins, triclosan, silver zeolites,

TABLE 9.3
Natural Active Components Combined Directly into Polymers Used for Meat Packaging

Active Component	Polymer	Substrate	References
Nisin	Polyethylene	Beef meat tissue	[162, 163]
Lactic acid	Alginate	Beef meat tissue	[164]
Vit. E	Low-density polyethylene	Beef meat	[165]
Rosemary extract	Polystyrene	Lamb meat	[166]
Thyme, rosemary, and sag spice	Caseinate and whey protein	Beef minced meat	[167]
Oregano extract	Polystyrene	Lamb meat	[166]
Chitosan	Chitosan	Culture media	[168]
Triclosan	Plastic matrix	Meat surface bacteria	[143]

and fungicides [142]. However, triclosan (500–1000 mg kg^{-1}) in polyethylene films exhibited antimicrobial activity against pathogenic bacteria in agar diffusion assay but did not effectively reduce microorganism growth on meat in vacuum packaging at 7°C [144]. The examination of four polyethylene films coated with three different bacteriocins showed antimicrobial activity against most of the microorganisms [145]. Antimicrobial agents such as nisin and chlorine dioxide have shown effectiveness against bacteria [140]. Fast- and slow-release ClO_2 sachets reduced total plate counts by 1–1.5 logs in packages of meat after 15 days, with no off-odor detected by sensory panelists, but the color of chicken adjacent to the ClO_2 was adversely affected [146]. The combination of rosemary extract and polypropylene film enhanced the stability of myoglobin and meat by the inhibition of metmyoglobin and lipid oxidation [147].

Bioactive edible coatings incorporate an antimicrobial compound in an edible coating, applied by dipping or spraying onto the meat products. Edible coatings of polysaccharides, proteins, and lipids can improve the quality of fresh, frozen, and processed meat products by delaying moisture loss, reducing lipid oxidation and discoloration, enhancing product appearance, and functioning as carriers of food additives [148].

9.6.4 Freezing

The large-scale preservation of meat by freezing commenced about 1880 when there was a surplus of meat and freezing offered a means of preserving meat for a certain period [149]. The advantages of temperatures below the freezing point were in prolonging the useful storage life of meat and in discouraging microbial and chemical changes [52].

Fast freezing produces minute intracellular ice crystals and thus diminishes drip on thawing. The rate of freezing is dependent not only on the bulk of the meat and its thermal properties, but also on the temperature of the refrigerating environment, on the method of applying the refrigeration, and, with smaller cuts of meat, on the nature of the wrapping material used. A temperature of –55°C is ideal for the storage of frozen meat to completely prevent quality changes [150]. The swelling and shrinking of myofibrils are well-studied in the mechanism of the water-holding capacity in meat [151]. Low freezing temperatures will minimize enzymic reactions, oxidative rancidity, and ice recrystallization. Cryogenic freezing technology will significantly reduce freezing times compared with the conventional technique due to the differences in temperatures between the two techniques and the high rate of surface heat transfer resulting from the boiling of the cryogen. The cryogenic freezing technique doesn't need mechanical refrigeration, but a cryogen tank and suitable spray equipment will be enough. However, there may be some distortion of the shape of the meat products caused by the cryogenic process that might impact on the commercial application. Moreover, the cost of the cryogenic liquid is relatively high; therefore, it may limit its commercial use [152]. Steak palatability is slightly affected by thawing methods [153].

Freezing is a common practice in preserving meat quality for an extended time. Although freezing meat will minimize deterioration in meat color, flavor, and texture, the disadvantages of frozen meat are freezer burn, dehydration, rancidity, drip loss, and product bleaching [36]. Many meat products go directly from the freezer to cooking, in which case they are difficult to distinguish from fresh cuts [154] and the consumer is not able to differentiate. The shelf-life extension and the purchasing and inventory flexibility offered by frozen meat items are valuable assets in the meat service industry. Drip loss is one of the most important problems in frozen meat [51]. The loss of fluid generally reduces the eating quality, binding ability, and the weight of meat. The amount of drip loss (85% of the water in muscle) on thawing frozen meat has been related to the size and location of ice crystals in frozen meat, which are generally considered responsible for the changes in meat quality. When the fresh meat is frozen, muscle water associated with muscle protein is replaced with protein [155], which leads to decreased water-holding capacity after thawing. The most critical temperature in thawing meat is between –10 and –2°C; therefore, meat must rapidly pass this range [156]. The rapid chilling of fresh meat compromises the ability of sarcoplasmic reticulum and mitochondria to retain calcium [36].

Although freezing acts as a preservation technique to eliminate the meat enzyme activities and inhibit the growth of spoilage microorganisms, it initiates several physical and chemical changes in meat that lead to the deterioration in quality [157]. The deterioration of frozen meat quality is associated with ice crystal formation. It has been mentioned that at very low temperatures, recrystallization is very slow and equilibrium is approached while the crystals are small, while at temperatures near the melting point, recrystallization is rapid [36]. The rate of crystallization and the size of the crystals formed depend upon the temperature [158]. Slow freezing causes the water to separate into pools that form large crystals, which may cause greater structural damage surrounding tissue associated with larger intercellular ice crystals [159]. However, rapid meat freezing causes little water separation and produces small crystals. At very low-temperature freezing, there is practically no pool crystallization; the drip loss is less than from meats frozen at higher temperatures. Variations in temperature during storage cause recrystallization which may explain the deterioration in meat quality characteristics over frozen storage [77]. Recrystallization involves changes in the number, size, shape, orientation, or perfection of crystals following the completion of initial solidification [36]. The lower the temperature, the greater the inhibitory action and the longer the period of satisfactory storage. Most of the vitamin loss is caused by heat or light or is lost in the juices that escape. Muscle protein denaturation at low temperatures is similar to the denaturation of proteins at higher temperatures, which leads to loss of water. The solubility of myofibrillar proteins is lower in slowly frozen meat compared to fast-frozen meat [159]. Drip loss from thawing meat includes proteins, vitamins, and other nutrients, in addition to moisture, and results in decreased cooked yields and juiciness.

9.7 CONCLUSION

Much has been learned in recent years about the pre- and post-rigor conditions and their role in the determination of meat quality characteristics. This chapter aimed to describe the muscle structure, pre- and post-rigor mortis, and technologies for the preservation of fresh meat. In addition, it also presents important opportunities for ultra-chilling methods to reduce the use of freezing/thawing for the preservation of fresh meat and its capability for prolonging shelf life and improving meat quality and safety. A non-thermal technology can inactivate meat spoilage microorganisms and their enzymes at low temperatures without changing the quality characteristics of the meat and meat products. Further, meat-packaging technology is also reviewed in this chapter, as it incorporates compounds into packing systems to maintain or extend meat quality and shelf life. Natural compounds can replace chemical preservatives to provide the opportunity for "green labeling" to attract more consumers. New technologies are applied to extend the storage life of fresh chilled meat by the control of the hygienic conditions and temperatures of the product to supply high-quality, safe, and wholesome meat and meat products to consumers.

10 Broiler Meat Production and Postharvest Quality Parameters

Isam T. Kadim, Issa S. Al-Amri, Abdulaziz Y. Al-Kindi, Msafiri Mbaga, and Amera K. Nasser

CONTENTS

10.1 INTRODUCTION

Broiler meat production represents one of the largest food industries worldwide. It has experienced larger changes over the past 100 years than over the past two millennia. These have led to an increase in broiler meat consumption and made it very popular all over the world. It is difficult to predict how the industry will develop in the future, but, no doubt, attention will be aimed at improving meat quality, quantity, and the processing of products. Moreover, due to world population growth and increasing income levels, the production of broiler meat has increased over the past few decades. Broiler chickens are reared intensively in most areas of the world to provide a high-quality protein to meet the global animal protein demand. Intensive rearing of broilers is one way of rapidly increasing animal protein supplies for rapidly increasing populations.

Commercially, broilers are housed in environmental-controlled confinement to create optimal conditions in order to manipulate day-length to maximize production. Broiler chicken meat is gaining popularity because of its competitive price, short production period, high rate of productivity, and positive nutritional image. Therefore, worldwide poultry meat production and consumption have increased rapidly, and, in most parts of the world, per capita consumption of poultry meat will continue to grow [1]. Broiler meat has maintained its identity and high value compared to other meats for personal health reasons. It is expected that by 2020 broiler meat production will surpass the production of all other meats [2]. The competitive prices of broiler meat compared to other meats, the absence of cultural or religious taboos, and dietary and nutritional properties are the main factors for poultry meat's attractiveness [3]. Broiler meat also fits the current consumer demand for low-fat meat with high unsaturated fatty acids and low sodium and cholesterol levels. According to Barroeta [4] broiler chicken meat may also be considered a "functional food" via the presence of bioactive substances with favorable effects on human health. These include conjugated linoleic

acid, vitamins and antioxidants, and a balanced omega 6 to omega-3 PUFA ratio.

Changes in the consumer's lifestyle have led to the manufacturing of processed meat products. This has resulted in significant investments in the broiler meat processing industry, increasing the availability of a large variety of processed ready meals [1]. The broiler meat processing industry started to use automatic machines to an even greater degree mainly due to the increasing consistency of raw meat cuts. Nuggets and patties production usually starts with a machine that produces a few hundred identical nuggets/patties every minute (Figure 10.1). Today more automation is seen in the cutting and slicing operations. This chapter highlights the potential development postharvest of the broiler chicken to provide high quality and healthy meat and meat products.

10.2 BROILER CHICKEN PRODUCTION

10.2.1 Populations

Chicken meat is one of the most popular and leading meat products in the world today. This is evidenced by the number of chickens produced globally each year. According to FAO_{STAT} [5], more than 20 billion broiler chickens were raised in 2013. Between 2000 and 2013 for example, a total of approximately 251.3 billion chickens were raised in the world. In economic terms, the production of these billions of chickens has both backward linkages (industries supplying raw materials and inputs to chicken production facilities) and forward linkages (processors, grocery stores, and final consumers). This process generates significant economic activities, tax revenues, and job creation.

Region-wise, Asia leads in terms of chicken production, followed by the Americas, Europe, Africa, and Oceania. In 2013, for example, these regions produced 11.6, 5.3, 2.1, 1.8, and 0.13 billion chickens, respectively. Between 2000 and 2013 a total of 20.7, 68.1, 134.9, 26.1, and 1.6 billion chickens were raised in Africa, the Americas, Asia, Europe, and Oceania respectively. This translates to 8.2, 27.1, 53.6, 10.4, and 0.7% for the five regions, respectively (Figure 10.2).

China was the top chicken producer in the world in 2013; it produced 4.84 billion chickens, followed by the United States (1.92 billion), Indonesia (1.79 billion), Brazil (1.25 billion), and India (0.71 billion). Overall, between 2000 and 2013 these top five chicken producers produced 131.6 billion chickens out of the 251.3 billion chickens produced in the world during that period, which accounted for 52% of global chicken production during that period.

10.2.2 Meat Production

Broiler chicken meat is reported to be a budget-friendly form of protein. Health-wise, chicken meat is naturally low in sodium, and without the skin it is naturally low in fat, providing only 70 milligrams of sodium per 85 g portion. According to the Organization for Economic Co-operation and Development [6], broiler meat is becoming the world's most consumed meat due to its low cost and its being the most accessible type of meat in the world. It is also free of many cultural barriers that affect consumption of other meats such as pork and beef. That is why some of the world's largest chicken-eating countries per capita are those which consume no pork at all. These include Israel and most Muslim countries. Furthermore, chicken production is much more friendly to the environment than most of the other kinds of meat. According to a recent study by the Environmental Working Group, chicken's carbon footprint per kilogram consumed is approximately half that of pork, quarter that of beef, and nearly one-seventh that

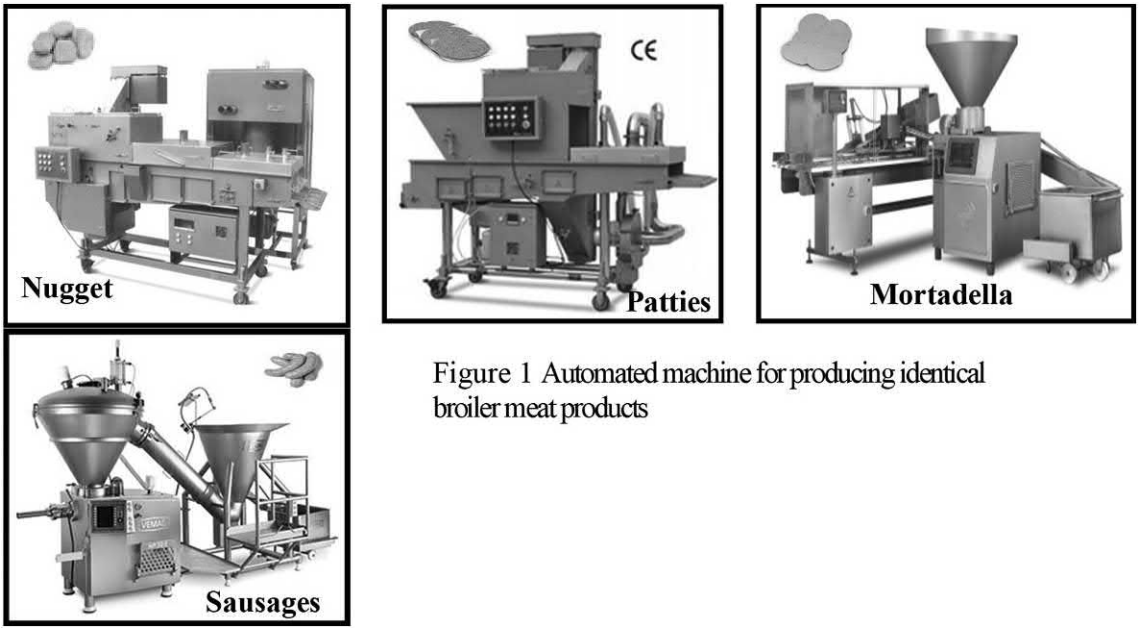

Figure 1 Automated machine for producing identical broiler meat products

FIGURE 10.1 Automated machine for producing identical broiler meat products.

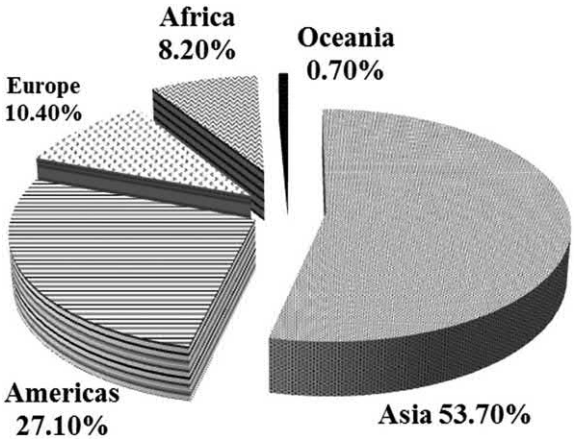

FIGURE 10.2 Regional share of chicken production total for the period from 2000 to 2013. (From FAOSTAT [5].)

of lamb. These qualities and attributes of chicken meat are a reason for the global popularity of chicken in the eyes of consumers, and its increased demand, which has translated to increased chicken meat production globally.

In 2013 approximately 96.3 million tons of indigenous chicken meat and 84.6 million tons of broiler chicken meat were produced globally. In addition, forecasts by USDA and other stakeholders put the expected 2015 global indigenous and broiler chicken meat production at 99 and 87.3 million tons respectively. Between 2000 and 2013, a total of approximately 1,067,109,627 tons of indigenous chicken meat were produced in the world.

Region-wise, the Americas are leading in terms of chicken meat production, followed by Asia, Europe, Africa, and Oceania. In 2013, these regions produced 42.1, 32.21, 16.1, 4.7, and 1.26 million tons, respectively. Furthermore, between 2000 and 2013 a total of 51.68, 483.96, 348.67, 169.14, and 13.64 million tons were produced in Africa, the Americas, Asia, Europe, and Oceania respectively. This translates to 4.8, 45.4, 32.7, 15.9, and 1.3%, respectively, for the five regions.

With respect to the top five chicken meat producers in the world, available statistics indicate that the United States tops the list whereby in 2013 the country produced 17.55 million tons, followed by China (13.35 million tons), Brazil (12.43 million tons), India (2.34 million tons), and Indonesia (1.84 million tons). Overall, between 2000 and 2013 these top five chicken producers produced 543.2 million tons out of the 1.067 billion tons produced in the world during that period. In other words, the top five chicken producers accounted for 51% of global meat production during that period. Trends in broiler chicken meat production indicated a steady increase between 2011 and 2014, while forecasts for the period between 2015 and 2020 also predict a steady increase.

10.2.3 Meat Consumption

Total global broiler meat production has increased by 400% over the past five decades. It is expected that within the next 10 years it will increase by another 25% due to the world's population increasing by 1 billion people, especially in developing countries. Although, poultry meat is generally popular around the world, there are major differences in consumption trends between countries such as Brazil and the United States (which consume 44.4 and 41.0 kg meat/capita/year, respectively) and countries such as China and India (which consume 11.1 and 2.0 kg meat/capita/year, respectively). Differences in broiler meat consumption may be due to differences in income, availability of the products, tradition, and eating habits [7]. The increase in ready-to-cook broiler meat is illustrated in Figures 10.3 and 10.4.

10.2.4 Meat Improvement

The poultry industry has seen major improvements in the genetics, health, husbandry, and processing segments. In 1925 it took, on average, 112 days to grow a broiler chicken to 1.14 kg live body weight. In 2010, it took only 47 days to grow to 2.60 kg market weight and in 2014 it reached 2.8 kg. It should be noted that in the 1920s chickens were grown in small farms and used for egg and meat production. However, when the poultry industry started to grow and specialize, egg and meat production breeds emerged and farmers began to specialize in one or the other. Genetic selection for efficient meat-producing breeds has resulted in an improved feed conversion ratio (kg feed/kg meat) from 4.70 to 1.92. In addition, developments in veterinary medicine and hygiene have helped to reduce mortality rates from 18 to 4%. These improvements over the years along with innovation/modernization in the primary processing sector [8] and in agriculture in general (more corn/soy/acre) have resulted in consumers paying less today for poultry meat than they did 25 years ago. However, it should be noted that the proportion of breast meat in the carcass has also increased.

10.2.5 Changes in Meat Consumption Patterns

In general, there has been a 15% increase in meat consumption. However, the consumption of broiler meat has dramatically increased from 23% in 1965 to 50% in 2015 while the consumption of red meat has decreased from 72% to 50% during the same period. Broiler processed products have increased considerably since 1960, when a limited selection of broiler products such as hot dogs, frankfurters, and luncheon was available on the market [9]. The introduction of chicken nuggets in the 1970s was a tremendous advancement in the poultry industry. Subsequently, the introduction of pre-portioned broiler meat products has helped to increase consumption, in particular of more convenient packages with specific cuts/portions. In the 1960s, 85% of the market consisted of whole broiler chickens, whereas in 2015 they represented less than 10% because consumers today are willing to pay for the convenience of smaller portions with bone and skin already removed. Due to the improvement in automation and mechanization, line speed in broiler plants has increased from 3,000 birds per hour in 1970 to 13,500 in 2015.

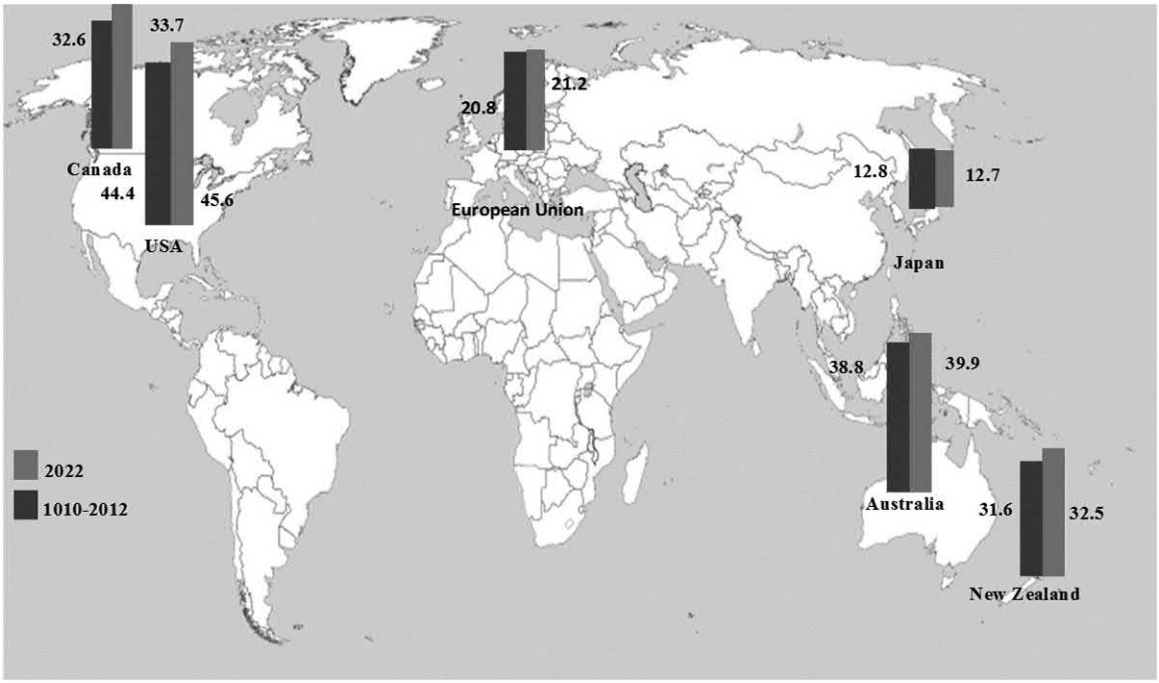

FIGURE 10.3 Demand in the United States, European Union, Japan, Australia, and New Zealand is satiated broiler meat consumption per capita, kg average 2010–2012 (estimate) and 2012 (forecast). (From OECD-FAO [6].)

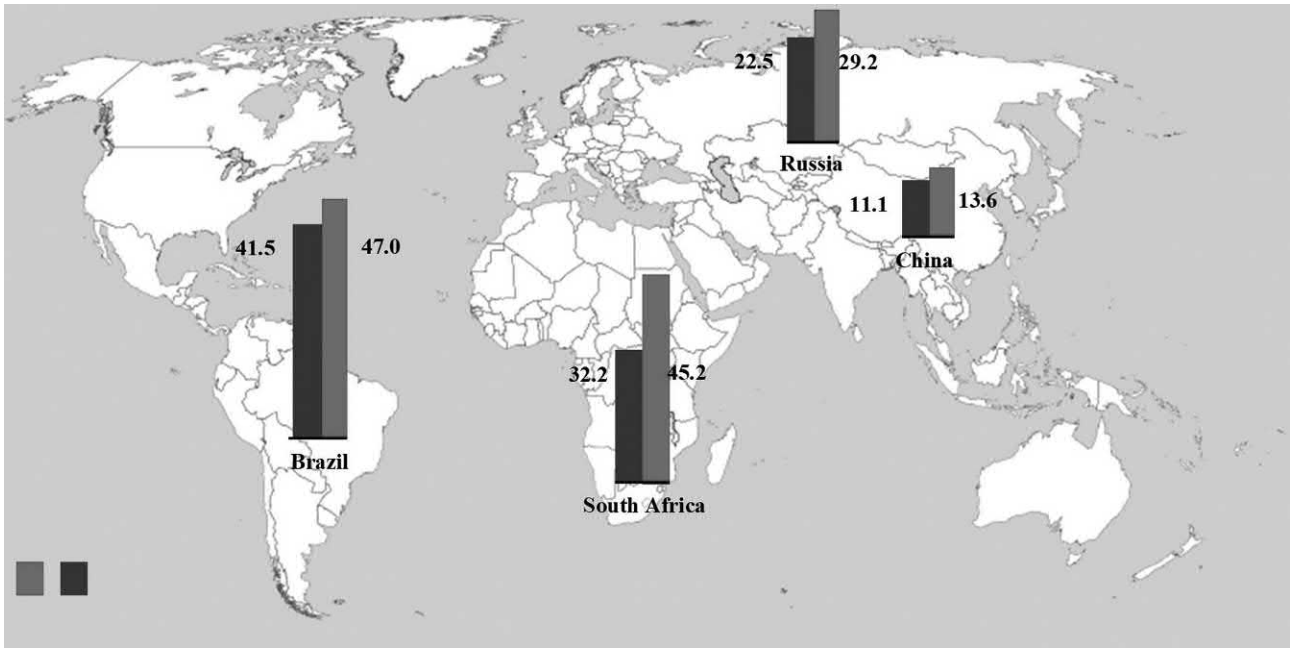

FIGURE 10.4 Demand in Russia, Brazil, China, and South Africa is satiated broiler meat consumption per capita, kg average 2010–2012 (estimate) and 2012 (forecast). (From OECD-FAO [6].)

10.3 BROILERS' SKELETAL MUSCLES

The skeletal muscles of a broiler chicken are shown in Figure 10.5. They range in size from small muscles to large muscles. White and dark meat in broilers represents breast and leg meat, respectively. These muscles comprise 40 to 50% of the average body mass of a broiler chicken. The major muscles in broilers are the leg muscle (biceps femoris) and breast muscle (pectoralis major). Skeletal muscles are also known as striated muscles because of their striated appearance when viewed under a light microscope. Figure 10.5 also shows a schematic diagram of whole muscle that is broken down into its components. A large muscle is composed of numerous muscle bundles covered by epimysium. Each muscle bundle is separated from the others by a connective tissue layer called perimysium. The functions of blood vessels and nerves supply energy to the active muscle and control its movement. The muscle

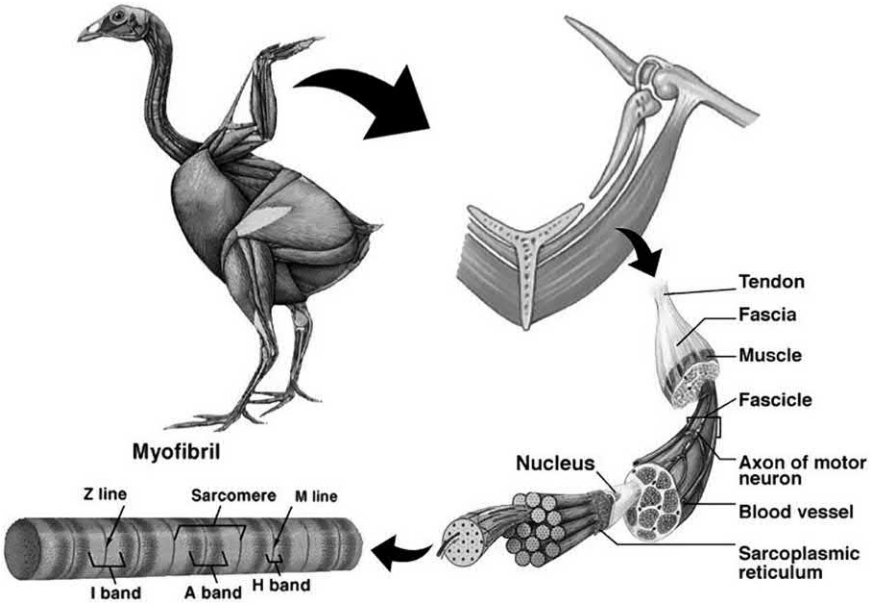

FIGURE 10.5 Broiler chicken skeletal muscle structure.

bundle is composed of small muscle fibers that are covered by a thinner layer of connective tissue called endomysium. Skeletal muscles have elongated fibers that are usually multinucleated, which seems to permit better control over these long cells. Each fiber consists of numerous myofibrils that have myofilaments inside them forming the sarcomeres. The overlapping between actin and myosin is called the A-band, and within the thin filaments is also the I-band. Sarcomeres are the distance between two Z-lines. During muscle contraction, the thick filaments slide toward the Z-line and shorten the sarcomere which the muscle moves.

10.3.1 Muscle Structure

Broiler muscle structure and physiology will be described to enable an understanding of their effect on meat quality characteristics and their effects on post-slaughter changes during rigor mortis, deboning, packaging, and storage. Muscle tissue represents the major edible part of the broiler that is important to both meat processors and consumers. Broiler skeletal muscle is a syncytium that is formed by a single nucleated mesodermal cell that undergoes terminal differentiation to form myoblasts, which then fuse to form multinucleated muscle fibers [10]. A muscle is composed of numerous muscle bundles covered by epimysium and separated from the others by a connective tissue layer called perimysium (Figure 10.5). The connective tissue provides structural organization, anchors the different components, and transmits the power generated by sarcomere contraction. Blood vessels supply energy with the nerves stimulating muscle movement. The muscle bundle is composed of smaller muscle fibers that are covered by a thinner layer of connective tissue called endomysium. Skeletal muscles have elongated fibers that are usually multinucleated, which seems to permit better control over these long cells. Each muscle fiber consists of numerous myofibrils that have myofilaments inside them forming the sarcomeres. The A-band represents the dark area in a stained muscle preparation which is the result of thin and thick filaments overlapping. The light band within the A-band area is called the H-zone (Figure 10.5). The area with only thin filaments is referred to as the I-band. Sarcomeres are the distance between the two Z-lines. Each sarcomere consists of one set of thick (myosin) filaments and two sets of thin (actin) filaments. During muscle contraction, the thin filaments are pulled in over the thick filaments toward the Z-line so that each sarcomere shortens and generates force [11]. The force to produce contraction is generated by the myosin cross-bridge; the head of myosin is the molecular motor. This has a hinged lever arm, to which two smaller proteins, the myosin light chains, are attached. Each cross-bridge is an independent force generator, which interacts with a thin filament and pulls it towards the center of the sarcomere [10]. The cross-bridge then detaches from the thin filament and has to be reprised by adenosine triphosphate before it can go through another cycle of force generation. The intrinsic velocity of contraction of muscle fibers to the specific activity of their myosin ATPasevia, the enzymatic activity of myosin, was discussed by Baranay [12]. The rate of cross-bridge consumption of ATP depends on the type of muscle fiber and the kind of activity for which it is adapted [13, 14].

10.3.2 Muscle Fiber Type

Broiler skeletal muscle fibers, similar to mammalian muscle fibers, can also be divided into white, red, and intermediate muscle fiber types. Broiler white meat refers to breast muscle, white and dark meat refers to the leg muscle. This is based on the color of the muscle, which is related to the proportion of red and white muscle fiber types. Most broiler chicken muscles contain a mixture of red and white fibers. Red, white,

TABLE 10.1
Relative Comparisons between Red and White Muscle Fibers in Poultry

Characteristic	Red Fiber	White Fiber
Myoglobin (conc.)	High	Low
Color	Red	White
Contraction speed	Slow	Fast
Mitochondria (number)	High	Low
Glycogen content	Low	High
Lipid content	High	Low
Oxidative metabolism	High	Low

Source: Barbut [49].

and intermediate muscle fiber types have different physiological functions and therefore have different proportions of certain sub-structures and metabolic rates (Table 10.1). Muscles with a high proportion of red muscle fibers (slow oxidative type 1; high myoglobin) are used for activities such as supporting the skeleton in an upright position due to their unique metabolism (less easily fatigued). A constant oxygen supply is important, and, together with a high proportion of enzymes involved in oxidative metabolism, the fibers can function for extended periods of time. Broiler red muscle fibers contract at a slower rate with the capacity to operate for a longer period of time due to the presence of mitochondria and lipid. The red muscle fiber type has a form of myosin which hydrolyzes ATP slowly resulting in a slow cross-bridge cycle. They are more efficient and more economical for producing slow repetitive movements and sustaining isometric force but not for generating power. The red muscle fibers are particularly numerous in postural muscles, which are activated virtually all the time during standing, walking, and running [15]. In broiler chicken there is another type of slow-twitch fiber, referred to as slow tonic, which is found in muscles such as the anterior latissimus dorsi [10]. This muscle holds the wings back against the body and is, therefore, contracted most of the time with very little expenditure of ATP [16]. Broiler white muscle fibers have less myoglobin with low oxidative activity (Table 10.2).

TABLE 10.2
Total Heme, Myoglobin, and Hemoglobin Content in Chicken Muscles

Muscle	Number	Total Heme	Hemoglobin	Myoglobin
Adductor	8	1.39 ± 0.31^{a}	0.83 ± 0.21^{a}	0.56 ± 0.17^{a}
Pectineus	8	0.10 ± 0.04^{d}	0.09 ± 0.04^{c}	0.01 ± 0.00^{b}
Sartorius	6	0.79 ± 0.12^{b}	0.67 ± 0.11^{a}	0.12 ± 0.02^{c}
Pectoralis	10	0.24 ± 0.04^{c}	0.24 ± 0.04^{c}	ND

Source: Kranen et al. [80].

[a–c] Per parameter, mean with no common superscript differ significantly as analyzed by t test ($P < 0.05$). Values are means ± SD of the numbers (n) of sample indicated. ND= not detectable.

The white muscle fiber type is adapted for high-power output over a short period of time (fast, glycolytic or type II2B), and the intermediate muscle fiber type is adapted for high-power output over a longer period of time (fast, oxidative, glycolytic or type II2A). Glycolytic metabolism, which predominates in white fibers, can occur with or without oxygen. Muscles with a relatively high content of white fibers show lower capillary density. Both types IIB and IIA muscle fiber contain myosin and other contractile proteins that produce a fast cross-bridge cycle time and develop force rapidly [10]. The type IIA fibers contain more mitochondria and have a more oxidative metabolism than the type IIB fibers and are capable of sustaining high-power output over a reasonably long period. White fibers contract more rapidly and in shorter bursts compared to red fibers, and they are more easily fatigued.

10.3.3 Muscle Protein

Broiler muscle proteins represent 18–20% of lean muscle weight with 75% water and 3–5% fat. Broiler muscles contain more than 50 types of different proteins. Table 10.3 shows the three major proteins based on their water and salt solubility [17]. The largest proportion of myofibrillar proteins in broiler muscle is myosin (45%). This is an elongated, rod-shaped

The Major Protein Portions in an Average Muscle Divided into Three Groups According to Their Solubility and % in the Wet Muscle

Group	Protein	%	Description
Sarcoplasmic	Myoglobin	(5.5)	Sarcoplasmic proteins are distributed within the sarcoplasm fluid; it consists of myoglobin and enzymes and comprises about 30% of the muscle's protein.
	Hemoglobin	0.2	
	Cytochromes	0.6	
	Glycolytic enzymes	0.2	
		2.2	
	Creatine kinase	0.5	
Myofibrillar	Myosin	(11.5)	Myofibrillar proteins are the building blocks of muscle (contractile or cytoskeletal proteins), and actin (thin filament) and myosin (thick filament) make up the main portion of protein and comprise about 55% of the muscle proteins.
	Actin	5.5	
	Troptomysin	2.5	
	Troponin	0.6	
	G-protein	0.6	
	A-actinin	0.3	
	B-actinin	0.3	
		0.3	
Stromal	Collagen	(2.0)	Stromal proteins (collagen and elastin) are neither water- nor salt-soluble and represent about 12% of muscle protein and form structural components including membranes that surround cells, muscle bundles.
	Elastin	1.0	
	Mitochondrial	0.05

protein with a very high molecular weight (around 450,000 Daltons). The structure has two heavy chains (heads) and two light chains (tails), which can be separated when myosin is subjected to a specific proteolytic enzyme activity. Actin (thin filament) has a proportion of 2.5%, has a lower molecular weight of 42,000 Daltons, and consists of two chains of F-actin. There is one tropomyosin molecule (5% of total myofibrillar proteins) for every seven actin molecules. There are three troponins (C binds Ca; I inhibits ATP and T binds tropomyosin), which are located around the thin filament and constitute about 5% of the myofibrillar proteins.

10.3.4 Rigor Mortis

At postmortem, oxygen and nutrient supply to the muscles will stop and many homeostatic mechanisms are disrupted including the normal aerobic tricarboxylic acid cycle. Energy metabolism switches to an anaerobic pathway to provide the muscle with ATP [18]. When blood circulation stops, lactic acid accumulates in the muscle until stored glycogen is depleted (ultimate pH). In broiler chicken, the drop in muscle pH occurs quickly as it does in other livestock [18]. In some broilers, glycogen storage has been depleted prior to slaughter due to malnutrition, extended activity, or struggling, which results in low lactic acid production (high ultimate pH: dark, firm, and dry). Muscle pH and meat color have consistently been reported to be highly correlated, especially when wide ranges of meat color are examined [19]. This is especially true when referring to meat as being either pale, soft, and exudative (PSE-like) or dark, firm, and dry (DFD-like) in which case pH is strongly related to these extreme conditions. Higher muscle pH is associated with darker meat while lower muscle pH values are associated with lighter meat color. In the extremes, high-pH meat is often characterized as DFD and the lighter meat as being PSE. Both DFD and PSE meats have been associated with poor functional properties. However, the pH can drop very quickly while the carcass temperature is still high (>35°C). This results in so-called PSE meat [20]. The combination of high temperatures (>35°C) and low pH values causes muscle protein denaturation [21, 22]. The meat color is pale as a result of more light reflected from the loose muscle structure as compared to the tight structure of the high ultimate pH meat. Conditions before and during rigor can have major significant effects on broiler meat quality characteristics. These include maintaining an adequate temperature during the rigor mortis process to prevent shortening and/or toughening of the muscle. In broilers, the meat temperature should be above 15°C (18 ± 2°C) because the rigor process takes 13 hrs. Although a reduction in muscle temperature after slaughter is important to prevent microorganism growth, reducing the temperature too quickly to below 5°C can cause low meat tenderness in broiler meat [23]. Temperature reduction to sub-zero temperatures, prior to the completion of rigor mortis, results in a condition known as thaw rigor due to the release of excess calcium from the sarcoplasmic reticulum into the sarcoplasm [18, 21]. Cold shortening can also cause significant toughening and moisture loss problems. Increasing the muscle temperature above 50°C during the rigor process will also result in excessive shortening known as heat rigor. This is the consequence of rapid ATP and creatine phosphate depletion.

Rigor mortis follows the depletion of glycogen and other energy sources such as creatine phosphate from the muscle, and results in its temporary toughening. When the broiler muscle pH drops to below 6, the sarcoplasmic reticulum calcium cannot store calcium, resulting in more interaction between myosin and actin [23]. In the presence of ATP muscle, myosin and actin start to overlap and consequently become less extensible (onset of rigor mortis). When all the energy sources have been depleted, the actomyosin cross-bridges can no longer be separated and the muscle becomes inextensible. After aging, the muscle becomes flexible again as a result of the action of the proteolytic enzymes (calpains and cathepsins) that slowly break down the sarcomere components including the degradation of the myofibrils, the connective tissue, and degradation of individual proteins such as titin, nebulin, and desmin [22, 24].

10.4 MEAT QUALITY CHARACTERISTICS

The major broiler meat quality attributes are tenderness, juiciness, flavor, color, and functionality [19]. Quality evaluation of raw broiler meat and products is very important to the poultry industry as it helps to control product quality, design, and optimizing of processes. Shear, tension, and torsion can help to optimize formulations and predict the quality characteristics (hardness and chewiness) that will be perceived by the consumer. Sensory evaluations are more time consuming but provide more precise information and can also be used to evaluate flavor, aroma, and overall acceptability of the product.

Evaluating the tenderness parameters of a meat product is important for quality control operations and for optimizing ingredient use/processing conditions to consistently produce an acceptable product. A product that is either too tough or too soft will be unacceptable to the consumer. Texture evaluations are done by several tests including shear, penetration, compression, tension, and torsion. A significant relationship has been observed between ultimate pH (pHu) and dripping loss in broiler chickens [25–27]. However, it is unlikely that a difference in pHu entirely explains the difference in water-holding capacity (WHC), because the magnitude of difference for pHu was quite small.

10.4.1 Meat Tenderness

Tenderness is probably the single most critical quality factor associated with the consumer's ultimate satisfaction with a broiler meat product [19]. Broiler meat tenderness depends upon the maturity of the connective tissues, the contractile state of the myofibrillar proteins, and the chemical and physical changes occurring in the muscle as it becomes meat (rigor mortis). For example, birds that struggle before or during slaughter cause their muscles to deplete glycogen, and rigor

mortis forms much faster than normal. These muscles tend to be tough because energy sources are reduced in the live bird. High pre-slaughter stunning, high scalding temperatures, longer scalding times, and machine picking can also cause poultry meat to be tough. The myofibrillar protein impacts on ultimate meat tenderness are primarily a function of the biochemical predisposition of the muscle at the time of slaughter, the rate and severity of rigor mortis development, and the physical handling of the carcass and muscle during rigor development [19].

The tenderness of portioned or boneless cuts of broiler chicken is influenced by the time postmortem of the processing. Muscles that are deboned during the early postmortem still have energy available for contraction. When these muscles are removed from the carcass, they contract and become tough. To avoid this toughening, meat is usually "aged" for 6 to 24 hours before deboning. However, this is usually costly for the processor. When poultry is deboned early (0 to 2 hours post-mortem), 50 to 80% of the meat will be tough. This means that if the processor waits 6 hours before deboning, 70 to 80% of the poultry meat will be tender. It has been established that broiler meat must be allowed a postmortem aging period prior to cut-up and deboning, cooking, or freezing to avoid adverse toughening, especially in breast meat [28]. Fletcher [19] suggested that a minimum of 4-h aging is required to allow the breast muscles sufficient time to complete rigor development and to allow subsequent removal from the carcass without excessive toughening. The concept of accelerated processing is based on the rapid depletion of muscle glycogen and ATP stores postmortem. Once the muscle loses the ability to generate ATP, rigor contractions cease and the muscle can be released from skeletal restraint with less adverse toughening.

Broiler meat tenderness can be evaluated using a shear force device. It uses a blade/knife to cut the meat sample, whereas penetration tests use a flat/round probe. The values obtained are usually correlated with sensory analysis. A less tender cut of meat will show a higher shear/penetration value. The Warner Bratzler (WB) shear device employs a single blade to shear a core meat sample and provides values for peak force. Shear determination is usually evaluated on intact pieces or cores of sample large enough to ensure a representative sample. The Allo-Kramer shear device (AK) is routinely used by researchers and quality control personnel, and the same considerations regarding the size, muscle, fiber orientation, etc., have been noted for the AK as for the WB. The AK employs a cell consisting of 10 to 13 blades that is guided into a square box to shear a large sample.

Lyon and Lyon [29] showed the effect of broiler breast meat deboning time on meat tenderness using the WB and AK shear methods and correlated the results with a sensory panel (Table 10.4). The results showed that deboning time had a significant effect on the shear values of broiler meat samples using both methods. Both shearing procedures were sensitive enough to discriminate between the three deboning times. The sensory panel showed similar results and tenderness was highly correlated with both shear measurement methods. Juiciness was not significantly related to deboning time but related to tenderness acceptability, with high correlation between values obtained from both shear measurement methods. In the poultry industry WB values of $\leq$4.5 kg are preferred for deboned chicken breast meat sold to the consumer.

Penetration tests are commonly used for restructured products, i.e., those made from small, ground or flaked pieces of meat, and some emulsified meat products such as frankfurters using a small-diameter probe which descends into the product

[a–c] Values within a column with no common superscript differ significantly ($P < 0.05$). For tenderness, mean values are averages of 66 observations (22 birds × 3 replications) for each deboning time. For sensory, 22 panelists × 3 replications. One bench-top Warner-Bratzler device was used to shear a 1.9 cm-wide intact strip. 2 Category scales 1 = very dry, tough, to 6 = very juicy, tender. 4 Category scales: 1 = poor to 5 = excellent.

at a constant rate. The resistance to puncture of the processed product is determined while obtaining a force-deformation curve, and the results are usually used to compare relative toughness.

10.4.2 Electrical Stunning and Electrical Stimulation

Electrical stunning has been shown to improve broiler meat tenderness and alter postmortem rigor and enhance meat quality [61]. Stunned broiler had higher ATP, lower lactate, and higher pH values than non-stunned broiler [30]. Stunning of broiler chicken indirectly delayed postmortem glycolysis (onset of rigor mortis) primarily through a suspension of antimortem struggle than through any direct effects of electrical stunning on muscle metabolism [31, 32]. High-current stunning resulted in a greater effect on early rigor delay than low-voltage stunning [19]. There are differences in muscle glycogen and pH during rigor development but these do not affect ultimate muscle pH, tenderness, or meat quality parameters.

Electrical stimulation is an optional technique to be used within 20 to 30 minutes postmortem on broiler chickens to trigger muscle contraction by stimulating the nerve system to speed up the onset rigor mortis [18, 33, 34]. Electrical stimulation involves passing an electric current through the carcass to overcome some of the problems associated with pre-rigor deboning that might be encountered during rapid chilling. Muscle contractions during electrical stimulation deplete the glycogen within the muscle and cause a rapid onset of the rigor mortis process. Electrical stimulation can rupture muscle fibers and cause physical damage to the sarcomere structure by tearing off some of the sarcomeres, which leads to the improvement of meat tenderness [35]. Electrical stimulation can accelerate ATP depletion of broiler carcasses by falling at 3.5 h post-mortem without the risk of getting tough meat and allowing deboning at an earlier stage. Electrical stimulation can also prevent or minimize cold shortening problems [34]. There are large variations in voltage, frequency, current, method, and time of application used among different researchers [36], which may result in variable and inconclusive results. Generally, a large number of broiler-processing plants are installing electrical stimulation equipment in order to shorten the processing time so that tender breast meat fillets can be harvested immediately after chilling. In countries where deboning is traditionally done 1 h after bleeding, electrical stimulation can help to reduce meat toughening. The carcass is suspended from a moving shackle line and is touched with a metal plate through which a current is passed. Usually the equipment can deliver up to 500 V (AC) and can be set to pulse at 0.2 to 2.0 sec intervals.

A combination of high-temperature conditioning and electrical stimulation could be used to produce early-deboned breast meat. Sams [37] reported that high-temperature conditioning or electrical stimulation had no individual effects on early-deboned broiler breast meat, but when combined they resulted in more tender breast meat. Walker et al. [38] concluded that only high-voltage electrical stimulation with muscle tension had a significant positive effect on muscle tenderness. In this respect, the meat temperature should be above 15°C (18 ± 2°C) because the rigor process takes 13 h when electrical stimulation is applied. If no electrical stimulation is used, the range is longer and can be 38 h; poultry carcass chilling in modern processing plants starts about 30 to 60 min after slaughter and reaches 15°C when rigor is completed or almost completed. It has been shown that electrical stimulation accelerates rigor development while electrical stunning delays rigor development. The electrical stimulation of broiler chicken is most effective following high-current stunning but had little effect following low-voltage stunning.

10.4.3 Meat Flavor

Flavor is one of the most important factors in determining the acceptability of broiler meat. Intramuscular fat and inosinic acid are key factors that influence the flavor of broiler meat [39]. A significant amount of meat flavor develops during cooking via complex reactions between natural compounds present in raw meat [40, 41]. This is evidenced by the aroma of cooked meat, which is completely different from that of raw meat. Many of the compounds produced during cooking have relatively high odor thresholds and present little contribution to the overall aroma and flavor. Gas chromatography and mass spectrometry can be used to identify major compounds of importance for flavor and the lower concentration compounds with which they interact. Meat flavor is a combination of taste and smell, which are perceived by the taste buds and olfactory receptors in the nose, respectively [42]. Meat taste and smell are affected by numerous factors such as the quantity and ratio of different flavor compounds, fat content, and temperature. Taste is perceived by sensors on the tongue that are capable of detecting four major tastes: salty, sweet, sour/acid, and bitter [41].

Cooking meat generates hundreds of volatile compounds. In this respect, Farmer [42] indicated about 500 volatile components in chicken meat. The precursors may include amino acids, reducing and phosphorylated sugars, lipids, and thiamine. Most volatile compounds are present in concentrations below their taste threshold, which suggests that synergistic effects are important in taste perception.

Using diluted aroma extracts (volatile compounds) that can be detected by humans as an assessment method for broiler meat flavor, gas chromatography was used to identify many individual volatile compounds. Discrepancies in the values reported by different researchers may be due to the complexity of sensory perception and the effect of different methods used for extraction, sample preparation, and method of assessment. The effect of the major volatile compounds can be evaluated by entirely removing them from the food or supplementing the food with more of an individual compound [40, 43]. A combination of water-soluble compounds in a cooked broiler chicken extract with amino acids, ATP metabolites, and inorganic ions to simulate the sensory properties of the extract was carried out by Fujimura et al. [43]. They found a glutamic acid (salty tastes), inosine monophosphate (sweetness),

and potassium ions (salty, bitter, or sweet sensation) were the major compounds. During cooking, a change in the concentrations of reducing sugars, amino acids, and nucleotides was observed. This affects the taste and aroma of poultry meat. Ribose appeared to be very important in increasing aroma in roasted broiler chicken and the researchers concluded that the change in odor was probably due to elevated concentrations of compounds such as 2-furanmethanethiol, 2-methyl-3 furanthiol, and 3-methylthiopropanol [40].

The list of the most important volatile compounds in broiler meat is grouped into furanthiols and disulfides, sulfur-containing compounds, aldehydes, ketones, and lactones, heterocyclic (Table 10.5). The latter author concluded that the combination of these compounds can be responsible for providing the typical aroma of a cooked broiler chicken. The important compounds responsible for cooked broiler chicken aroma differ from other meats in that 2-methyl-3-furyl disulfide, methional, and phenylacetaldehyde are less important and certain lipid oxidation byproducts such as trans-2,4-decadienal and trans-undecenal are more important [44]. They concluded that this difference may be related to the higher concentrations of linoleic acid in broiler chicken than meat from other species. It should also be mentioned that cooking methods have a strong effect on flavor and aroma. For instance, fried meat has a different aroma than boiled meat.

The chemical reactions important for flavor and aroma production can be categorized into three main groups: Maillard reactions, lipid oxidation, and degradation of thiamine. A Maillard reaction is the reaction of one or more amino acids with reducing sugar, which can result in many volatile products. Lipid oxidation contributes to a desirable flavor and aroma, but can also cause rancidity in cooked broiler chicken meat. Oxidation occurs at ambient temperature by endogenous enzymes, which result in the production of negative flavor and aroma described as rancid or cardboard-like. The information in Table 10.5 shows ten compounds that result from thermal oxidation, such as 1-Octen-3-one, trans-2-nonenal, trans trans-2,4-nonadienal, and trans trans-2,4-decadienal. The most reactive lipids in broiler meat are the polyunsaturated fats, followed by monounsaturated and saturated lipids, which contribute to the unpleasant odor of reheated cooked broiler meat (warmed-over flavor).

Thiamine (vitamin B1) degradation can produce sulfur- and nitrogen-containing end products that result from the breakdown of the vitamin's bicyclic structure. The 2-methyl-3-furanthiol has a potent aroma, which is responsible for a

TABLE 10.5
List of Some of the Major Compounds Contributing to Odor of Cooked Broiler Meat

Compound	Odor Character	Compound	Odor Character
Furanthiols and disulfides		2-undeccenal	Tallowy, sweet
Bis (2-methyl-3-furyl) disulfide	Meaty, roasted	y-decalactone	Peach-like
2-methyl-3-ifcanthiol	Meaty, sweet	y-dodecalactone	Tallowy, fruity
2,5-dimethyl-furanthiol	Meaty	**Heterocyclic Compounds**	
2-funinmethanethiol	Roasted	2-formyl-5-methyl thiophene	Sulfurous
2-methyl-3-(methylthio) furan	Meaty, sweet	Trimethylthiazole	Earthy
2-methyl-3-(ethylthio) furan	Meaty	2-acetyl-2-thiazoline	Roasted
2-methyl-3-methyldithiofuran	Meaty, sweet	2,5(6)-dimethyl-pyrazine	Coffee, roasted
Sulfur Containing		2,3-dimethyl-pyrazine	Meaty, roasted
3-mercapto-2-pentanone	Sulfurous	2-ethy1-3,5-dimethyl-pyrazine	Roasted
Dimethyltrisulfide	Grassy, metallic	3,5(2)-diethyl-2(6)-methyl-pyrazine	Sweet, roasted
Hydrogen sulfide	Sulfurous, eggy	2-acetyl-pyrroline	Popcorn
Methional	Cooked potatoes	**Other**	Caramel
Aldehydes, Ketones, and Lactones		2,3-butanedione	
1-octen-3-one	Mushrooms	B-ionone	Violets
trans-2-nonenal	Tallowy, fatty	14-methyl-pentadecanal	Fatty, tallowy, train-oil
Nonanal	Tallowy, green	14-methyl-hexadecanal	Fatty, tallowy, orange-like
trans, trans-2,4-nonadienal	Fatty	15-methyl-hexadecanal	Fatty, tallowy
Decanal	Green, aldehyde	4-methylphenol	Phenolic
trans, trans-2,4-decadienal (and an isomer)	Fatty, tallowy		

Source: FAO [42]

"meaty" aroma and flavor in broiler meat [41, 44]. The compound can be formed by thiamine degradation or by a reaction between cysteine and ribose. 2-furanmethanethiol can also be formed by thiamine degradation, and provides a "roasted" aroma in broiler meat. Salama [45] found that conventional heating provides a preferable flavor for leg and breast broiler meat than microwave heating. This may be due to how rapid microwave heating is (rapid change of water molecule polarity throughout the product), which does not allow enough time for odor and flavor development. It has been reported that adding sodium chloride to broiler meat, prior to cooking, will increase the flavor rating under both conventional and microwave heating. The amounts of volatile compounds produced increase as cooking temperature increases from 60 to 80°C [46]. Increasing cooking temperatures from 60 to 70°C can increase the rate of the chemical reactions as well as the release of free amino acids and other precursors and quantities of lipid oxidation byproducts. The amounts of 2-, 3-butanedione, and dimethyl disulfide increased at an almost constant rate between 60 and 80°C [46].

In general, the characteristic flavor of broiler meat is derived from the presence and concentration of various water-soluble and volatile aroma compounds. The concentrations and interactions between these compounds can be affected by age and diet, as well as by processing factors such as evisceration time, chilling rate, storage, and cooking method [41, 42, 47]. Touraille et al. [48] found no flavor differences between sexes until broilers reach sexual maturity. Large dietary changes are required to produce a small change in broiler meat flavor [47]. However, a small amount of feed, such as oxidized fish oil, can induce a fishy aroma in broiler meat [49]. Supplemental vitamin E has been shown to enhance the shelf life of stored poultry meat by retarding lipid oxidation and off-flavor formation during prolonged fresh/frozen storage [50].

10.4.4 Meat Color

Of all the quality attributes, color is the most critical for the selection of broiler products because consumers associate it with the product's freshness, and consequently decide whether or not to buy the product based on their opinion of its attractiveness [19]. Broiler meat is unique because it can be sold with or without skin. Skin color is the most critical characteristic for the marketing of fresh whole broiler or parts [51]. Broiler is also the only species known to have muscles that have extremes in color (white and dark meat). Breast meat is expected to have a pale pink color, while thigh and leg meat are expected to be dark red. The major contributing factors to broiler meat color are myoglobin content, chemical state of the heme structure, and meat pH [19]. Myoglobin content has been shown to be primarily related to species, muscle, and age of the bird. Muscle pH has been shown to be primarily related to the biochemical state of the muscle at the time of slaughter and following rigor mortis development. A significant correlation between L^* of the broiler meat and its pHu has been reported [4, 26]. The redness of chicken breast meat has been shown to positively correlate with myoglobin content [52]. This is lower in glycolytic than in oxidative myofibers [53]. A significant increase in L^*, a^*, and b^* was observed between 4 and 10 days post-slaughter, which could result from myosin degradation [27, 54]. This variation may be related to the chemical changes in muscle myoglobin pigment, which is predominantly converted into purple reduced myoglobin and brown metmyoglobin during the first several days postmortem [55]. This may be due to muscle fiber type; the major muscle of chickens is almost a completely white fast-twitch muscle [56]. Lightness appeared to be highly correlated with pHu.

Variations in raw breast meat color are sufficient to cause variations in cooked product color [57]. Broiler meat color is affected by factors such as bird age, sex, strain, diet, intramuscular fat, moisture content, preslaughter conditions, and the presence of the muscle pigments myoglobin and hemoglobin [58]. Discoloration of broiler meat can be related to the amount of these pigments present in the meat, the chemical state of the pigments, or the way in which light is reflected off of the meat [59]. The discoloration can occur in an entire muscle, or be limited to a specific area, such as a bruise or a broken blood vessel. When an entire muscle is discolored, it is most probably the breast muscle. This occurs because breast muscle accounts for a large portion of the live weight, it is more sensitive to factors that contribute to discoloration, and the already light appearance makes small changes in color more noticeable. Extreme environmental temperatures or stress due to bird handling and before processing can cause broiler breast meat to be discolored. The extent of the discoloration is related to each bird's individual response to the conditions.

Another major cause of poultry meat discoloration is the nature and reactions of the major pigment, myoglobin, as well as the effects of nitrates and nitrites, ovens and gasses, hemachromes, and cytochrome C reactions on final meat color [59, 60]. The poultry industry generally tries to identify where, how, and when the injuries causing discoloration take place, but this is often difficult to determine. The color of the bruise, the amount of "blood" present, and the extent of the "blood clot" formation in the affected area are good indicators of the age of the injury and may give some clues as to its origin. Electrical stunning at high currents (greater than 100 mA) was shown to increase blood spots in broiler breast meat [61]. A bruise will vary in appearance from a fresh, "bloody" red color with no clotting minutes after the injury to a normal flesh color 120 hours later (Table 10.6). The amount of "blood" present and the extent of clot formation are useful in distinguishing if the injury occurred during catching/transportation or during processing. Injuries that occur in the farm are usually magnified by processing plant equipment or handling conditions in the plant. Because bruises are a major source of condemnation and downgrading [62] efforts to reduce their incidence have been identified.

The relationship between muscle type and bird age and its effect on meat myoglobin content and color was studied by Miller [63]. He found that white meat from 8-week-old broiler had the lowest myoglobin content (0.01 mg myoglobin/g meat) compared with 26-week-old broiler white meat (0.10 mg/g),

TABLE 10.6
Broiler Meat Color Changes in a Bruise over Time for Broiler Muscle

Age of Bruise	Color of Bruise
2 minutes	Red
12 hours	Dark red-purple
24 hours	Light green-purple
36 hours	Yellow-green-purple
48 hours	Yellow-green (orange)
72 hours	Yellow-orange
96 hours	Slight yellow
120 hours	Normal, flesh color

Source: Gregory [54].

8-week-old broiler dark meat (0.40 mg/g), and 26-week-old broiler dark meat (1.50 mg/g). In thigh meat, color parameters were affected by genetic strain [64]. Low pH values affect meat protein biochemistry, resulting in higher lightness and redness and lower yellowness. This was confirmed by the relation between pH and color parameters [64]. The effect of genotype on color parameters was reported by several authors [65–67]. This apparent inconsistency may be due to bird movement, as birds reared in free-range systems graze and perform more activity, changing muscle metabolism, with higher development of red muscle fibers [68].

10.4.5 Sensory Analysis

Sensory analysis of broiler meat includes different parameters based on the senses of taste (salty, sweet, sour, and bitter), smell, touch (tenderness, mouthfeel, and moisture level), sight (color, shape), and hearing (crunchy). The field of sensory analysis has scientifically developed over the years to become a recognized discipline in food science for food evaluation. Trained sensory professionals work in areas such as quality control, product development, tenderness and flavor research, and ingredient and process modification. Good sensory evaluation teams can ensure that successful products with desirable sensory attributes reach the market [69]. The sensory evaluation technique is a scientific method used to evoke measure, analyze, and interpret human responses to products via the senses of taste, touch, smell, and sight. There is a set of guidelines that should be followed in preparing and serving the samples under controlled conditions so that bias is minimized. In general, sensory evaluation techniques involve quantitative science in collecting data to establish legitimate and specific relationships between product characteristics and human perception. However, there can be many sources of variation that cannot be completely controlled during the test (previous food eaten, physiological sensitivity to sensory stimulation, mood, past history, and familiarity with similar products). Therefore, some screening should take place to eliminate participants with taste and color vision insensitivity [70].

10.5 MEAT COMPOSITION

Broiler meat has been an important part of the human diet for thousands of years with a significant role in human nutrition due to its high -quality proteins and essential amino acids, lipids and essential fatty acids, vitamins, and minerals [71]. It has also desirable sensory parameters with positive aspects for human health (low fat and high protein) and an acceptable price [72]. Overall, the dietary contribution of broiler meat is dependent on culture, availability, and nutritional value. The presence of skin on a poultry meat cut will increase the fat level of the portion because skin includes subcutaneous fat, and as fat content increases, moisture content decreases (Table 10.7). Overall, broiler meat consumers can obtain a very lean product by removing the skin because most of the fat is deposited subcutaneously rather than intramuscularly. Therefore, the emphasis has been on a better body composition, with higher breast meat yield and lower abdominal fat. This focus responds to the consumer desire for healthier meat, and to the evolution of the market through a rising demand for portioned and processed products [73]. The profitability of broiler production is therefore largely determined by the possibility of increasing the proportion of prime cuts in the carcass, mainly breast meat, and by reducing fat. Based on a 100 g lean fillet portion, lean broiler breast contains relatively higher protein % (>10% compared to beef and lamb), monounsaturated fatty acids (>20% compared to beef and tuna), and polyunsaturated fatty acids (>30% compared to beef, lamb, and pork) [74]. The same author stated that lean breast of chicken also provided relatively more selenium (>25%) than beef, lamb, and pork, and more manganese (>90%) than lamb and relatively more vitamin E (α tocopherol) than lamb and beef (>40%). Differences in nutritional value between broiler chicken and other meat animals may be related to the ability of the chicken digestive system to take up nutrients from feeds and deposit them in the meat. It has been shown that the body composition of broiler chicken varies with age, gender, and bird strain [75]). As a broiler chicken grows the composition of its carcass changes [76] and fat deposits increase [75]. Ultimately the nutrient composition of broiler is a response to the diet that humans consume, particularly in the early stages of life [76, 77]. Knowing the nutritional composition of the product is central to communicating ways in which chicken may form part of a healthy diet.

Table 10.7 shows that the white broiler meat contained more protein than dark meat (20.3% vs. 16.7% with skin and 23.2% vs 21.1% without skin, respectively). When the skin is removed, the fat level in broiler meat drops from about 11.1 to 1.6% in white meat and from 18.3 to 4.3% in the dark portion. The effect of cooking methods on the nutrient composition of raw meat with skin on is presented in Table 10.8. Stewing, frying, and roasting methods result in the highest protein content due to loss of moisture and fat during cooking. Stewing reduces cooking loss (moisture) compared to roasting. This is due to more protein denaturation during the cooking process which results in a lower water-holding capacity. The cholesterol level remains similar to that of the roasting

TABLE 10.7
Composition and Nutritional Value of Broiler Meat

Meat	Skin	Moisture%	Protein%	Fat%	Calcium (mg)	Iron (mg)	Calories (kcal)
White	+	68.6	20.3	11.1	0.86	0.80	186
	–	74.9	23.2	1.60	0.98	0.70	114
Dark	+	65.4	16.7	18.3	0.76	1.00	237
	–	75.9	20.1	4.30	0.94	1.00	125

method because vegetable oil used for frying does not contain cholesterol.

10.5.1 Comparing Broiler Meat with Other Species

The high-value cuts of chicken, lamb, beef, pork, and fish were compared (Table 10.9). Chicken meat appears to be one of the highest protein sources of the "traditional" meats though the equal second when compared with fish. Similarly, the polyunsaturated fatty acid levels in chicken meat are also higher than for all other high-value cuts of meat; however the proportion of each of the fatty acids to the total fat profile should be considered as in Table 10.9, which shows tuna fish clearly having a higher proportion of polyunsaturated fatty acids. Overall, however, chicken meat appears to have the largest amount of monounsaturated fatty acids than all other meats used as a comparison in this report (Table 10.9). These nutrient levels indicated the ability of broilers to utilize the nutrients from their feed more effectively than other animals [78, 82].

Chicken meat appears to have higher values in a number of micronutrients than other raw meats, except fish. The levels of magnesium, calcium, selenium, manganese (Table 10.9), and phosphorus are all greater than those found in the highest-value cuts of beef, lamb, and pork. Values for iron and zinc are not high. Chicken meat also appears to contain greater amounts of vitamin A than beef and pork, more vitamin E than all traditional meat sources (excluding fish), more niacin than lamb and pork, more thiamin than lamb and beef, and more vitamin B_{12} than pork. These reports should be considered with caution as the data are from different sources in Table 10.9 and the animals quite possibly of varying ages, genders, feeds, and living conditions, and differences do not necessarily reflect significance in terms of recommended dietary intakes.

10.6 POSTHARVEST PORTIONS AND DEBONING

Increasing market demand for deboned broiler meat chicken has resulted in the development of mechanical cutting up and deboning operations equipment. Various cutting setups have been developed for the broiler meat processor, ranging from manual deboning to fully automated equipment to cut and debone the whole carcass. Many classification systems for the cutting of broiler carcass are used due to various demands from consumers in different countries. Consumers today have the option of purchasing a whole chicken fresh or frozen or cut up carcass parts including wings, breast fillets, drum sticks, and thighs. Depending on the market, broiler chicken can be sold alive, as an eviscerated whole carcass, the carcass split into halves or quarters, or as separate cuts with or without bones and skin. Although there are many similarities between different systems, each is designed to serve a specific market [49]; standard classification cutting systems are discussed below:

1. Live broiler chicken meat derived from slaughtering and dressing broiler chicken carcasses.
2. Dressed broiler chicken from the carcass after the feathers, head, the feet, and the carcass have been eviscerated.
3. Broiler chicken half carcass from two approximately equal portions of a dressed broiler carcass.
4. Front quarter from the front portion of a broiler half carcass obtained by cutting behind and parallel to the rib cage.
5. Hindquarter: meat from the posterior portion of a broiler chicken carcass which is separated from the front quarter.
6. Wings separated from the shoulder joint.
7. The drumstick is the distal portion of the leg, which is separated from the leg by a straight cut through the knee joint.
8. The thigh is the proximal portion of the leg, which is separated from the whole broiler carcass by cutting at the hip joint and from the drumstick by a straight cut through the knee joint.
9. The full breast is the portion of the whole broiler carcass which is separated from the wing cutting through the shoulder joint, from the back by cutting through the ribs at the junction of the vertebral ribs, and from the hind quarter by cutting behind the rib cage.
10. The half breast is one of the two equal portions of the breast separated by cutting through the breast bone along the median line.

11. The breast fillet is a round, elongated fusiform muscle.
12. The back is the portion of the whole carcass back which is separated from the neck by cutting of the shoulder joint.
13. The neck is the portion of the broiler chicken carcass obtained by cutting near the shoulder joint.
14. Ground broiler meat is a fresh, boneless, with or without skin comminuted meat that has a fat content identified by one of the following terms:
    a. Regular contains approximately 30%.
    b. Medium contains approximately 23%.
    c. Lean contains approximately 17%.
    d. Extra lean contains approximately 10%.

Traditional manual cutting and deboning of broiler chicken has been exercised for thousands of years and can still be observed in small-scale operations in many countries. Manual deboning is usually done on a cutting board. It can be done by cutting the anterior ends of the pectoralis and pulling it away from the bone. This will leave a small portion of meat attached to both sides of the sternum from which they can be manually pulled. The thigh cut is separated by cutting through the femur-pelvis joint. The leg portion can be separated into the drumstick and thigh by cutting through the femora-tibial joint. Boneless thigh meat can be obtained by removing the femur bone as well as the major ligaments.

Automated high-speed cutting and deboning equipment has become very popular with the increased demand for boneless broiler chicken meat. The advanced system can debone 3,600 breast caps/hr. The design of automated deboning

equipment represents a significant challenge to configurations with the same yield. This equipment should be capable of handling birds of different sizes; therefore it should look for flocks with low variation among birds. Recently, new modules have been developed for new end products such as tendon harvesters and cartilage harvesters, which were considered waste a few years ago.

The large demand for deboned broiler meat has resulted in the development of mechanical deboning equipment and the meat obtained is called mechanically deboned meat or mechanically separated meat. The deboning equipment is used for deboning the whole broiler carcass or meat from parts that would not yield a high-priced product which would justify the cost of hand deboning such as neck meat. Salvaging the meat after hand deponing can be of great economic importance, and the resulting minced meat is successfully used for making other further processed products (broiler frankfurters). There are three basic types of broiler chicken deboning on the international market.

1. A belt-drum system: the meat and bone particles are passed between a rubber belt and a perforated steel drum. The meat is squeezed through the holes of the drum while the harder bones and connective tissue

TABLE 10.10
Effect of Deboner Head Pressure on the Chemical Composition and Yield of Mechanically Deboned Whole Roasted Broiler Breasts with Bone and Skin vs. Composition of Broiler Meat Obtained by Hand-Deboned Meat Operation

Pressure (lbr/in²)	Moisture%	Protein%	Fat%	Ash%	Calcium ppm	Iron ppm	Palmedica %	Yield%

stay outside. The pressure on the belts can be adjusted, and sometimes pressure rollers are used to ensure an even distribution of tissue on the belt, which results in higher muscle structure integrity [79].

2. A rotating auger system resembles the inside of a conventional broiler meat grinder. First, bones are pushed through a bone cutter to reduce particle size, then the ground mixture is introduced into a screw-drive boning head where the material is processed. The meat then is squeezed out through holes in the perforated steel cylinder encasing the auger. Hole-size can be adjusted and is usually around 0.5 mm. Bone and connective tissue particles that cannot pass through the perforated cylinder are pushed forward and exit at the end [49].
3. A hydraulic press pushes the meat and bones against a perforated plate in a batch-type system. The bones can also be pre-cut prior to being introduced into a chamber. The material is forced against a stationary, slotted surface/plate by a hydraulic-powered ram piston that squeezes the soft meat tissue through the cylinder openings (1.0 to 1.5 mm). The residual bones and connective tissue are removed, and the meat is separated resulting in a minced/finely chopped product, which is suitable for frankfurters and bologna [49].

Table 10.10 presents the meat composition of deboning broiler meat under different pressures. The presence of skin on a poultry meat cut will increase the fat level of the portion because skin includes subcutaneous fat. Higher fat translates to a higher caloric value, but in general, broiler meat is considered a lean meat when compared to other red meats and has less saturated fat than other red meat species. Cooking methods affect nutrient composition in different ways. Stewing will increase protein content; roasting and frying also elevate protein content as moisture and fat are lost. Stewing reduces cooking losses, resulting in a more-moist product compared to roasting. Battering and breading (22% coating) of fried broiler meat raises the carbohydrate content from 0 to 9.5%, and the total fat content from 11 to 17%. The cholesterol level remains similar to that of the roasting method because vegetable oil used for frying does not contain cholesterol. Yields are also affected by the cooking method due to variations in cooking temperature, time, previous treatment (margination), and processing (freezing, chilling).

10.7 CONCLUSION

The poultry industry has become much more competitive over the past 50 years, and poultry is expected to become the number one meat source around the world. The dramatic changes in the poultry industry over the past 30 years, from a predominantly whole bird commodity to the modern highly diversified industry focused on cut-up, deboned meat and ready-to-eat processed products has also resulted in a change in consumers' quality expectations. Although the basic issues of color and tenderness are still critical quality issues, the specific and relative degree of importance has grown with the changes in market products. The most important aspect of poultry meat is its quality, a function of the combined effects of color, tenderness, and flavor. As the market continues to grow, quality parameters are expected to continue to evolve as well as the identification of new quality products. The market has shifted from traditional concepts of market-based quality, affecting price and preference, to a production-oriented definition of quality based on statistical control and product uniformity. Poultry processing affects meat quality by establishing the chemistry of the muscle constituents and their interactions within the muscle structure. The producer, processor, retailer, and consumer all have specific expectations for the quality attributes (color, water-holding capacity, and tenderness) of broiler chicken meat while the ultimate authority will always be the consumer.

11 Postharvest Handling of Milk

Nejib Guizani and Zaher Al-Attabi

CONTENTS

11.1 INTRODUCTION

Milk is a normal secretion of the mammary glands of female mammals. The US Public Health Service defines milk as "the lacteal secretion, practically free of colostrum, obtained by the complete milking of one or more healthy cows, which contains not less than 8.25% milk-solids-not-fat and not less than 3.25% fat." The term *milk* is understood as referring to cow's milk unless other species are mentioned specifically. For most of the world, particularly the West, milk from cattle accounts for nearly all the milk processed for human consumption [1]. However, other milking animals are very important to some populations because their milk provides an excellent and cheap source of highly valuable animal protein and other constituents. For example, sheep followed by goat make a major contribution to the milk production of the Mediterranean countries and also in large areas of Africa and Asia. Worldwide, the dairy industry produces milk as a fluid product and transformed into a variety of manufactured dairy products using a range of advanced processing technologies. The family of dairy products manufactured from milk is shown in Figure 11.1 [2].

11.2 COMPOSITION AND STRUCTURE

Milk is a polyphasic normal secretion of the mammary glands. Milk consists of (i) an oil-in-water emulsion with the fat in the form of droplets or globules dispersed in the continuous milk serum, known as whey; (ii) a colloidal suspension of proteins of various sizes in milk serum, consisting mostly of casein micelles, globular proteins, and lipoprotein particles; and (iii) a solution of lactose, soluble proteins, minerals, vitamins, and other components [3]. In addition, milk is a very complex food with over 100,000 different molecular species found, but most have not been identified [4]. The main component of milk is water. The remaining compounds are mainly fat (3.9%), protein (3.3%), lactose (5%), and minerals (0.7%) [5]. Milk also contains vitamins (e.g., vitamins A and C), enzymes (e.g., lactoperoxidases and acid phosphatase), and somatic cells [4]. The average composition of milk with respect to the major classes of compounds and a range of average values for milks of western breeds are shown in Table 11.1. There can be considerable compositional differences between species and even between breeds of a single species. The lipid content is the most variable fraction. Lipid is present mainly in the form of triglyceride, which makes up about 98% of milk fat. The remaining 2% consists of diglycerides, monoglycerides, cholesterol, phospholipids, free fatty acids, cerebrosides, and gangliosides [4]. The major fatty acids of milk are C_{14}, C_{16}, C_{18}, and $C_{18:1}$ fatty acids [6]. The fat is present in fresh milk mainly in the form of fat globules surrounded by a phospholipid-rich layer known as the milk fat globule membrane. Milk proteins are fractionated in two main groups: the casein fraction and the whey proteins. Caseins precipitate out of solution upon acidification of milk to pH 4.6 at 20°C, while whey proteins remain soluble under these conditions. Caseins can be fractionated into four main proteins: α_{s1}-, α_{s2}-, β-, and K-caseins [4]. Whey proteins include mainly β-lactoglobulin, α-lactalbumin, serum albumin, lactotransferrin, immunoglobulins, and β_2-microglobulin [6]. Lactose is the predominant sugar in milk; other carbohydrates are present in trace amounts and are mainly galactose and glucose. The most important function of lactose is as a fermentation substrate for lactic acid bacteria.

11.3 QUALITY CRITERIA FOR MILK

Milk is an important raw material for the production of a variety of dairy products. It is therefore important that the

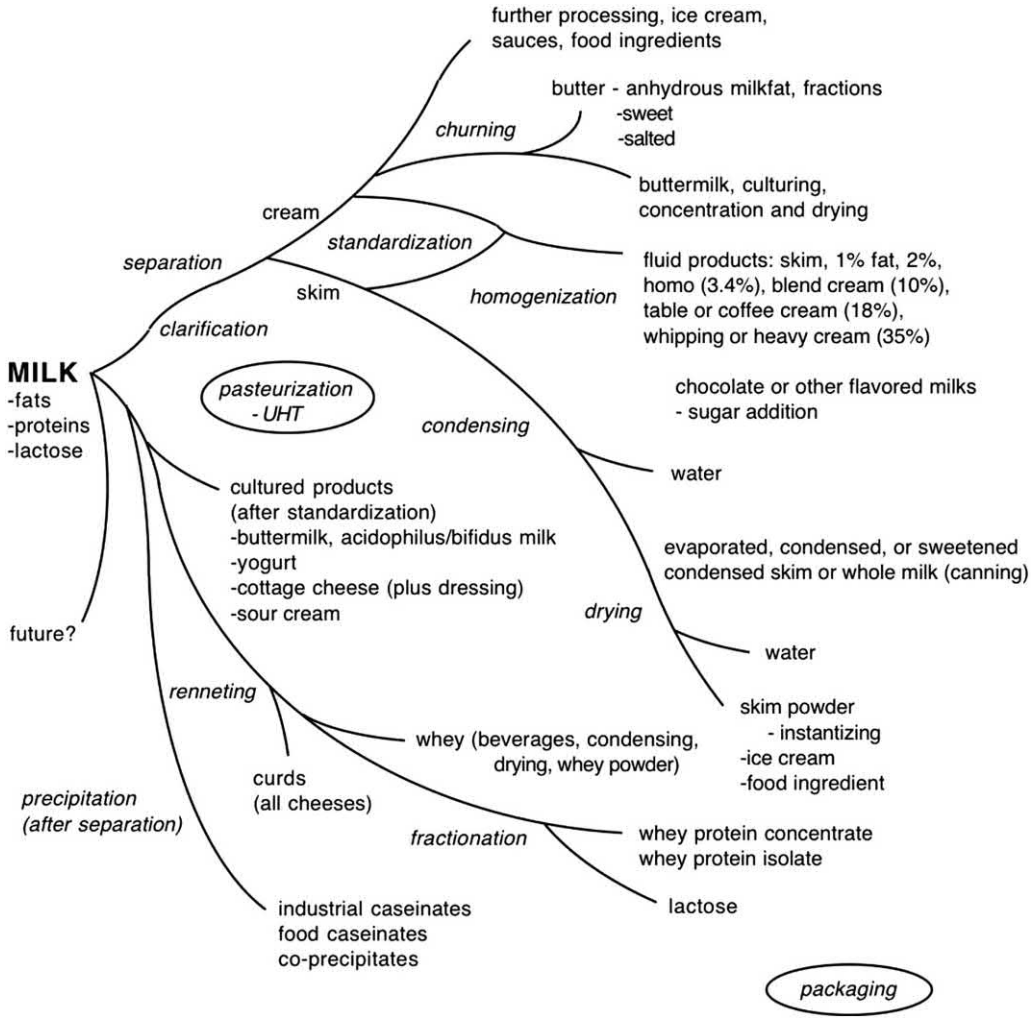

FIGURE 11.1 Family of dairy products manufactured from milk. (From Goff and Sahagian [2].)

milk used for processing has acceptable quality characteristics. Quality characteristics for raw milk include compositional quality, microbial contamination levels, somatic cell count, freedom from inhibitory substances and reception temperature [7].

The most common grades of raw milk in the United States are Grade A and Manufacturing Grade. The dairy farmer must meet state and federal standards to produce Grade A milk. In addition to the state requirements, a few municipal governments also have raw milk regulations. The dairy farmer must have healthy cows, have adequate facilities (barn, milk house, and equipment), and must maintain satisfactory sanitation of these facilities. The Food and Drug Administration's Pasteurized Milk Ordinance (PMO 2001) [8] requires that Grade A milk not exceed 100,000 CFU/ml standard plate count (SPC) for an individual milk producer, 300,000 CFU/ml SPC as commingled milk, and 750,000 cells/ml somatic cell count (SCC). In addition, good quality milk must not contain pesticides, antibiotics, sanitizers, drug residues, and other abnormalities. The storage temperature should not exceed 7°C within 2 hours of milking. It is also important that the milk used for processing has acceptable flavor characteristics. Various weed, feed, and cowy flavors can be transmitted to milk by the cow's respiratory or digestive system. These are considered normal and acceptable up to certain level, although excessive amounts can cause off-flavors that are difficult to remove by processing. A salty flavor can arise from cows in late lactation and infected with mastitis. Milk diluted with water can taste flat and be lacking in typical flavor [9].

11.4 MICROFLORA OF RAW MILK

Milk is an excellent medium for the growth of a variety of microorganisms owing to its high water content, neutral pH (6.4–6.6), and ample supply of nutrients. Aseptically collected milk from clean, healthy cows typically has an SPC less than 1000. Higher SPCs indicate that milk was subject to contamination. Microbial contamination generally occurs from three main sources: from within the udder, from the exterior of the udder, and from the surface of milk handling and storage equipment [10]. The contribution of some sources of contamination on the colony count of raw milk is shown in Table 11.2. Bacterial contamination from within the udder is frequently a result of mastitis, an inflammatory disease

TABLE 11.1
Composition of Milk from Different Sources

Component	Average Percentage (%)	Range for Western Breeds* (Average percentage, %)
Total solids	13.23	12.16–14.42
Fat	4.22	3.54–5.13
Protein	3.58	3.29–3.98
Lactose	4.78	4.68–4.94
Ash	0.74	0.72–0.77

Source: Webb et al. [43]

* Western breeds include Holstein, Brown Swiss, Ayrshire, Guernsey, Jersey, and Shorthorn.

TABLE 11.2
Contribution of Some Sources of Contamination on the Colony Count of Raw Milk[1]

Source of Contamination	Estimate of the Contribution to the Count (ml^{-1})
Udder of a healthy cow	Up to several thousand
Water for cleaning, rinsing	Up to several thousand
Udder of a mastitic cow	Up to several million
Dirty cows	A hundred up to several thousand
Dirty equipment	A thousand up to several million

Sources: Tetra Pak Processing Systems AB [32]; Murphy and Boor [44].

[1] Approximate examples.

of the mammary tissue. Many microorganisms can cause mastitis, the most important being *Staphylococcus aureus*, *Escherichia coli*, *Streptococcus agalactiae*, *Streptococcus uberis*, *Pseudomonas aeruginosa*, and *Corynebacterium pyogenes*. The first three of these are all potential human pathogens [11]. Sources of contamination from the exterior of the udder include water, soil, vegetation, and bedding material. In general, contamination with psychrotrophic bacteria has been associated with bedding material, untreated water, soil, and vegetation; coliform contamination with soil; and spore formers with bedding material [12, 13]. Therefore, milk is susceptible to contamination by two types of microorganisms: the pathogenic bacteria and the spoilage bacteria. The presence of pathogenic microorganisms in milk may result in infection and threat to the consumer's health. The growth of the spoilage bacteria is more determinant to the shelf life of milk than that of the pathogenic flora. The spoilage bacteria degrade the milk through the production of enzymes. Four types of enzyme activity are encountered [14]: (i) lactose may be fermented to lactic acid resulting in a soured product; (ii) lipids are hydrolyzed by lipase—both microbial and the native milk enzyme—and, as a result, rancidity develops; (iii) proteinase activity results in breakdown of milk proteins with both physical and organoleptic effects, principally gelation and the development of intense bitter flavors; and (iv) phospholipases can attack the milk fat globule membrane, which stabilizes the native emulsion of milk fat.

Raw milk contains a diverse and complex microbial population [15, 16]. Raw milk contains a high number of lactic acid bacteria (LAB) populations that include *Lactococcus* (8.2×10^1 to 1.4×10^4 CFU ml^{-1}), *Lactobacillus* (1.41×10^1 to 1.5×10^4 CFU ml^{-1}), *Leconostoc* (9.8×10^1 to 2.5×10^3 CFU ml^{-1}), and *Enterococcus* spp. (2.57×10^1 to 1.58×10^4 CFU ml^{-1}). Other microorganisms are also present in significant proportions; these include psychrotrophs such as *Pseudomonas*, *Acinetobacter*, and *Aeromonas* spp., which flourish during cold storage [17]. Milk contains a more diverse microflora than that originally reported owing to new developments in DNA sequencing technologies. A recent study using high-throughput DNA sequencing detected 256 bacterial species in raw cow's milk that was to be used for cheese production [18]. Among these bacteria, *Streptococcus thermophilus* and *Lactococcus lactis* dominated in the milk, representing 43.7% and 19% of the total, respectively. Other microorganisms previously associated with raw milk have also been detected. These include *Acinetobacter*, *Aeromonas*, *Brevibacterium*, *Corynebacterium*, *Lactobacillus*, *Pseudoalteromonas*, *Pseudomonas*, and *Staphylococcus*, representing between 1.3% and 3.7% of the total [18].

Once milk leaves the cow, the retention or preservation of milk quality requires cleanliness, sanitation, and careful handling. Undesirable changes in raw milk are initiated by microbiological growth and metabolism or by chemical or enzymatic reactions. Temperature is critical for dairy food quality and shelf life. Cold temperatures are used to minimize microbial growth in raw milk until it can be processed and to extend the shelf life of nonsterile dairy foods. A reduction in temperature below the minimum necessary for microbial growth extends the generation time of microorganisms and in effect prevents or retards reproduction. This is clearly shown in Figure 11.2, which illustrates the likely effect of

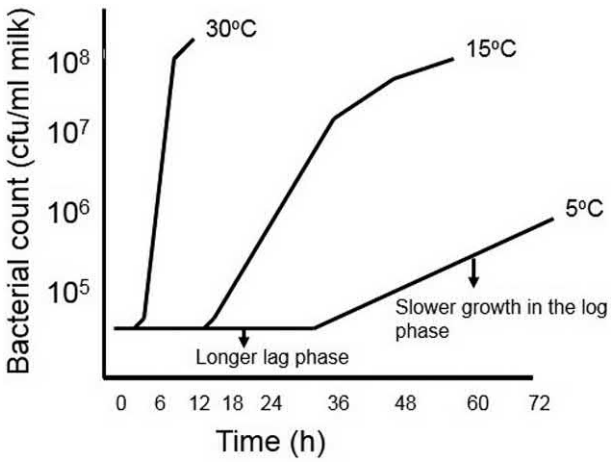

FIGURE 11.2 The effect of storage temperature on the bacterial count of raw milk having an initial SPC of 50,000 CFU/ml. (From Singh and Bennett [4].)

temperature on milk having an initial SPC of 50,000 CFU/ml. The microorganisms in raw milk just prior to pasteurization may include heat-susceptible pathogens as well as spoilage types [9]. Psychrotrophs became an escalating problem for the dairy industry during the introduction of refrigerated storage of raw milk. Psychrotrophs are of primary concern to the dairy industry since they can grow and cause spoilage in raw and processed dairy products commonly held under refrigeration. Psychrotrophic microorganisms capable of growing in milk at temperatures close to 0°C are represented by both Gram-negative and Gram-positive bacteria. For example, the gram-negative bacteria are *Pseudomonas*, *Achromobacter*, *Serratia*, *Alcaligenes*, *Chromobacterium*, and *Flavobacterium*; and gram-positive bacteria are *Bacillus*, *Clostridium*, *Corynebacterium*, *Streptococcus*, *Lactobacillus*, and *Microbacterium* [19, 20]. In aerated milk at 4°C, many strains of *Pseudomonas* spp. can produce sufficient proteinases to hydrolyze all of the available casein into soluble peptides [21, 22]. The enzyme activity from psychrotrophs stimulates the growth of starter lactic acid bacteria in milk [19]. Most psychrotrophs normally would not be a serious problem in milk because they are eliminated by pasteurization or ultrahigh temperature (UHT) treatment. However, psychrotrophs produce thermostable proteolytic enzymes, most of which attack κ-CN, resulting in a destabilization of the casein micelles and coagulation of the milk in a manner that is analogous to chymosin [23]. The quality of milk may be affected by heat-resistant enzymes secreted by psychrotrophs in raw milk before heat treatment, or other enzymes and metabolites that are produced by microflora during cold storage. Some of these enzymes are not inactivated by pasteurization or by other heat treatments and these may degrade milk products, even when the bacterium is destroyed. The shelf life of various dairy products is given in Table 11.3.

The spoilage of milk and dairy products is characterized by taste and odor changes, such as sour, putrid, bitter, malty, fruity, rancid, and unclean. The type of spoilage may also cause undesirable body, texture, and functional changes [9]. In milk about 40% of the milk solids are lactose, a major substrate for microbial fermentation in milk. Microorganisms use one of the two following methods to start fermentation: by the lactase enzyme (β-D-galactosidase) or by hydrolyzing the phosphorylated lactose by β-D-phosphogalactoside galactohydrolase. Microorganisms containing the lactase enzyme include *E. coli*, *S. thermophilus*, *L. lactis*, *Lactobacillus bulgaricus*, *Lactobacillus plantarum*, and *Bacillus subtilis*. Lactic acid bacteria convert lactose to lactic acid and other by-products. Milk with a detectable acid/sour flavor is considered unacceptable commercially. Cold storage temperatures and sanitary storage and processing conditions for raw milk and cream can prevent the development of high acid/sour flavors [9].

A malty flavor or odor can occur in milk if *Streptococcus lactis* var. *maltigenes* grows and metabolizes amino acids in milk to aldehyde and alcohols. The fruity flavors in dairy foods can be caused by the metabolic activity of lactic acid and psychrotrophic bacteria with the formation of esters. Flavor defects in milk described as putrid, bitter, and unclean may be caused by the growth and metabolism of psychrotrophic bacteria. The lipase enzyme is often active at low temperatures, causing a lipolyzed flavor. Gram-negative psychrotrophic bacteria have lipolytic activity [9]. Table 11.4 summarizes the most important types of spoilage and the microorganisms responsible.

11.5 CONTROL OF MICROORGANISMS IN RAW MILK

Raw milk has been associated with several pathogenic bacteria such as *Campylobacter jejuni*, Shiga toxin-producing

TABLE 11.3
Shelf Life of Dairy Products

Product	Temperature (°C)	Shelf Life (Days)
Marketed milk	<4	12–14
Cottage cheese	2–4	15–30
Yogurt, sour cream, and dairy dip	<4	30–60
Curd cheese	<4	Several months

Source: LaGrange and Hammond [9].

TABLE 11.4
Some Types of Spoilage of Milk

Type of Spoilage	Microflora
Souring	Lactic acid bacteria
Casein precipitation	Lactic acid bacteria producing enough acid to drop the pH below 4.6
Gas production	*Clostridium*, *Bacillus*, yeasts, coliform bacteria, heterofermentative lactics, and propionics
Proteolysis	*Psychrotrophic bacteria: Streptococcus faecalis* var. *liquefaciens, Bacillus cereus, Micrococcus, Pseudomonas, Flavobacterium, Acinetobacter, Aeromonas* Thermophilic organisms: *Streptococcus* and *Lactobacillus* Spore-forming organisms: *Bacillus*
Lipolysis	Psychrotrophs: *Pseudomonas* spp., *Achromobacter* spp., *Alcaligenes* spp., *Acinetobacter* spp. Thermoduric organisms: *Streptococcus* and *Lactobacillus* Spore-forming bacteria: *Bacillus*
Ropiness	*Alcaligenes viscolactics*, *Enterobacter*, lactics
Changes in butterfat	*Pseudomonas*, *Proteus*, *Alcaligenes*, *Bacillus*, *Micrococcus*
Numerous off-flavors	*Pseudomonas*, *Actinomyces*, *Flavobacterium*, *Alcaligenes*, *Acinetobacter Proteus*, *Lactococcus lactis* var. matigenes, molds, yeasts, coliforms, and mastitis-causing organisms
Color changes	*Pseudomonas syncyanera*, *Pseudomonas synxantha*, *Serratia marcescens*, *Pseudomonas fluorescens*

Sources: Banwart [45]; Fields [46]; Hayes and Boor [47].

E. coli, *L. monocytogenes*, *Salmonella* spp., and *Yersinia enterocolitica* [15], and the risk of infection increases if milk is consumed raw [16]. Outbreaks linked to the consumption of cow's milk and cheese were estimated to cause on average 761 illnesses and 22 hospitalizations per year in the United States, mostly from *Salmonella* spp. and *Campylobacter* spp. Unpasteurized products are consumed by a small percentage of US dairy consumers but cause 95% of illnesses; the risk for illness was found to be 840 times higher for consumers of unpasteurized milk or cheese than for consumers of pasteurized dairy products [24].

Microbial growth and contamination can be prevented, slowed, or reduced by many means: (i) cleaning and sanitizing of the milk-handling equipment and the environment, (ii) holding the milk at low temperature, (iii) use of antimicrobial systems, (iv) thermization, and (v) clarification.

11.5.1 Cleaning and Sanitizing

Hygienic processing of food requires that the equipment is cleaned frequently and thoroughly to restore the equipment to the desired degree of cleanliness. The degree of cleanliness of the milking system probably influences the total bulk milk bacterial count as much, if not more, than any other factor [25]. Since proper cleaning and sanitizing of dairy equipment are important for the production of milk with acceptable microbial quality, control of psychrotrophs should begin at the farm level [12]. Psychrotrophic bacteria tend to be present in higher counts in milk and are often associated with occasional neglect of proper cleaning and sanitizing procedures [25]. Cleaning of dairy facilities involves removing soil from all surfaces that come into contact with milk and using a sanitizer after each processing period. Soil in the dairy industry is mainly minerals, lipids, carbohydrates, proteins, and water. Soil may also contain dust, lubricants, microorganisms, cleaning compounds, and sanitizers [26]. Microbial cleaning, also known as sanitizing or disinfection, is used to reduce the load of microbial contaminants that may be present on milk contact surfaces. Most chemical sanitizers used in the dairy industry kill off a broad spectrum of microorganisms, provided that they are used properly. Sanitizers commonly used in the dairy industry include chlorine compounds, iodophors, quaternary ammonium compounds (QUATs), acid anionic surfactants, and peroxyacetic acid. All disinfectants are deactivated to some extent by organic matter. This is why they are best used after thorough cleaning has removed most of the soil [11]. Many dairy plants use hot water as a common method of sanitation. This can be achieved by circulating water of 76°C to 85°C for at least 5 minutes, followed by a cooling chemical sanitizer rinse. Hot-water sanitation requires careful control to ensure that the required temperature is maintained long enough for it to be effective. This can be achieved by the use of thermostat-controlled tanks, which will circulate the water and maintain the desired temperature [27–29]. Hot water will often provide greater kill and longer milk shelf life than can be achieved with chemical sanitizer alone.

11.5.2 Cooling of Milk

Milk leaves the udder at a temperature of about 37°C, which is favorable for the growth of a large number of microorganisms, mainly mesophiles. Milk should therefore be quickly cooled on the farm after leaving the udder and stored in refrigerated bulk tanks at <7°C prior to collection. Collection by an insulated tanker is often done on alternate days and therefore some of the milk in the tank could be 48 hours old at the time of collection. Temperature control at the time of collection is thus critical to minimize microbial growth. Bacterial numbers in the milk may increase during transport as a result of contamination from surfaces of inadequately cleaned tankers or from the growth of psychrotrophic bacteria. Milk temperature and duration of transport are therefore important factors. On arrival at the processing site, the milk is usually transferred to bulk storage tanks prior to processing and cooled rapidly. Cooling is the main means of slowing the growth of bacteria in milk. The maximum storage time of milk is closely related to the storage temperature. Milk is typically stored at refrigeration temperatures that reduce the growth of most bacteria, with the exception of psychrotolerant microorganisms that can proliferate under these conditions and become a major cause of milk spoilage [30, 31]. This is primarily a result of the production of extracellular enzymes, mainly lipases and proteases. These lipases degrade milk fat causing rancidity, while proteases degrade casein producing a gray color and bitter off-flavors [31].

Low-temperature storage can reduce the frequency of raw milk collection from dairy farms to just two or three times a week, and enable further storage of milk in the dairy plant over weekends [19]. Spray and immersion coolers are commonly used on farms, which deliver milk to the dairy in tanks. In spray cooling, circulating chilled water is sprayed onto the outsides of the cans to keep the milk cool. The immersion cooler consists of a coil, which is lowered into the tank. Chilled water is circulated through the coil to keep the milk at the required temperature [32].

Where milking machines are available, bulk milk tanks, usually ranging from 0.8 to 19 m^3, are used to receive, cool, and hold the milk. As the cows are mechanically milked, the milk flows through sanitary pipelines to an insulated stainless steel bulk tank. An electric agitator stirs the milk, and mechanical refrigeration begins to cool it even during milking, from 32.2°C to 10°C within the first hour, and from 10°C to 4.4°C within the next hour. Some large dairy farms and collecting centers may use a plate or tubular heat exchanger to rapidly cool the milk. In these cases, the tank is mainly to maintain the required storage temperature. The temperature of the blended milk must be below 7.2°C during the second and subsequent milkings [33].

Since the milk is picked up from the farm tank daily or every other day, cooled milk may be stored in an insulated silo tank. Milk in the farm tank is pumped into a stainless steel tank on a truck for delivery to the plant or receiving station. The tanks are well insulated and the temperature rise should not be more than 1.1°C in 18 hours when testing the

tank full of water and the average gradient between the water and the atmosphere surrounding the tank is 16.7°C [33].

Most dairy processing plants either receive raw milk in bulk from a producer or arrange for pick up directly from the dairy farms. Storage tanks, from 4 to 230 m^3 made of stainless steel lining and well insulated, may be required for nonprocessing days and emergencies. The average 18-hour temperature change should be no more than 1.6°C in the tank filled with water, and the gradient to the surrounding air 16.7°C. For horizontal storage tanks, the allowable temperature change under the same conditions is 1.1°C. The tank may need cooling depending on the initial milk temperature and holding time. A plate heat exchanger may be connected or the tank surface, around the lining, may be cooled by passing a refrigerant or by circulation of chilled water or glycol solution. Agitation is essential to maintain uniform milk fat distribution. Milk held in large tanks, such as the silo type, is continuously agitated with a slow-speed propeller driven by a gearhead electric motor or with filtered compressed air [33].

11.5.3 Antimicrobial Constituents

11.5.3.1 The Lactoperoxidase System

There are some naturally occurring antimicrobial systems present in raw milk that might improve its shelf life. The main representative of these systems is lactoperoxidase. The milk enzyme lactoperoxidase catalyzes the oxidation of thiocyanate by hydrogen peroxide to produce antimicrobial substances. The inhibitory substances are claimed to be short-lived intermediary compounds, such as hypothiocyanate, cyanosulfurous acid, and cyanosulfuric acid [34]. Hypothiocyanate can kill gram-negative bacteria and inhibit gram positives, possibly by damaging the bacterial cytoplasmic membrane [11].

The lactoperoxidase system (LP) consists of three components: lactoperoxidase, thiocyanate, and hydrogen peroxide. All three components are required for antimicrobial activity. The enzyme is available in milk in abundance, however, the availability of thiocyanate in milk for the proper LP preservation is not sufficient. Certain bacteria in milk produce small quantities of hydrogen peroxide, but the quantity of oxygen that can be provided is too small for the oxidation process in the LP system. Stimulation of lactoperoxidase activity through the addition of exogenous thiocyanate and hydrogen peroxide has been investigated as a means of preserving raw milk in developing countries where ambient temperatures are high and refrigeration is not often available. For proper LP preservation, very small quantities of thiocyanate (0.00015%) and hydrogen peroxide (0.00085%) must be added to milk [35]. These quantities are sufficient to preserve milk at tropical temperatures for about 8 hours, whilst the preserved milk can be easily kept overnight at temperatures of 15°C to 20°C; at temperatures of 4°C, the milk can be kept for a few days without spoilage. Similarly, Bjorck et al. [36] studied the effect of this system on the quality of raw milk in developing countries. Their results showed that the quality of treated milk was significantly improved over that of the untreated control. Furthermore, they demonstrated that the length of bacteriostasis is temperature-dependent: 7 to 8 h at 30°C, 11 to 12 h at 25°C, 15 to 16 h at 20°C, and 24 to 26 h at 15°C. The International Dairy Federation (IDF) [37] recommended the addition of hydrogen peroxide and thiocyanate at about concentrations of 10 to 15 ppm in order to activate the LP system and extend the shelf life of raw milk.

11.5.3.2 Hydrogen Peroxide

Hydrogen peroxide is a preservative that has been used for a long time to preserve raw milk, under conditions where it may be difficult to cool the milk quickly. The concentrations required (300–800 ppm) are much higher than those required to activate the lactoperoxidase system [38]. For milk of reasonably good quality, 0.03% to 0.05% of pure hydrogen peroxide may be used to extend the keeping quality by at least 5 hours, depending on a number of conditions, such as temperature, catalase content of the milk, presence of heavy metals, and type of contaminating microorganisms [35]. In one trial in Africa, the addition of hydrogen peroxide increased the proportion of samples passing the 10-minute resazurin quality test from 26% to 88% [11]. Treatment levels of 0.115% completely inactivated *Mycobacterium tuberculosis*. Hydrogen peroxide is more effective at increased temperatures. A level of 0.8% by weight combined with a temperature of 49°C to 55°C for 30 minutes has been suggested as a substitute for pasteurization [38]. Anaerobic and coliform bacteria are more resistant than lactic acid and anaerobic bacteria [35]. Gram-positive bacteria are not inactivated by hydrogen peroxide to the same extent as gram-negative bacteria [39].

11.5.4 Thermization (Thermalization)

Often, a dairy is unable to process all milk supplies within 4 days of milking. Consequently, measures must be taken to keep the raw milk for a longer time. Dairy processors in European countries use a process called thermization to prevent psychrotrophs from growing in milk [28, 40]. Thermization is a mild thermal process applied to milk that may need to be stored over a long period prior to use. Thermization has now been defined as a heat treatment that uses temperatures between 57°C and 68°C for 15 seconds [38]. The purpose of this treatment is to protect against microorganisms that may grow during the storage of raw milk, especially gram-negative psychrotrophic bacteria. These bacteria produce heat-resistant lipases and proteinases that may eventually cause deterioration of milk products [41]. Thermization should be applied as soon after milk treatment as possible and it is only effective if thermized milk is kept cool (4°C) [38]. Thermization is a far better method of controlling the quality of dairy products than merely cooling the raw milk, but it also is more expensive. Except for the killing of many vegetative microorganisms, thermization causes almost no irreversible changes in milk [41]. However, some problems associated with thermization were reported by Muir [14]. One problem is associated with the contamination of thermized milk with gram-positive cocci such as *S. thermophilus* as a result of a buildup in the regeneration section of a commercial thermization unit.

Thermization may also slightly affect the flavor and texture of cheese but not the yield.

11.5.5 Clarification

Clarification is a commonly employed pretreatment of milk prior to its storage/manufacture into other products. The shelf life of milk can be extended by clarification. Clarification may be as simple as filtration or may include high-speed centrifugation to remove microbial cells and spores. Filtration is usually carried out by pumping milk through specially woven cloth. This results in the removal of debris and all extraneous matter.

Bactofugation refers to a high-speed centrifugation process carried out in a specifically designed separator, called a clarifier. The purpose of bactofugation is to separate bacterial cells and spores. The process is particularly important in Europe where it has been used in the cheese industry to remove spores from cheese milk that could cause latent fermentation in some types of cheeses. Bactofugation has also been adapted to processing drinking milks, where it succeeds in prolonging the shelf life of fresh, pasteurized milk by 3–5 days as a result of a reduction in the microbial population [42]. In addition, a reduction in the microbial population induces a reduction in the pasteurization temperature and consequently the manufacture of a product with improved flavor.

12 Quality Assessment Methods and Postharvest Handling of Fresh Poultry Eggs

Mohammad Aboonajmi and Hamideh Faridi

CONTENTS

12.1 INTRODUCTION

One of the main objectives of food processing is to achieve uniform quality of raw materials and the final products. The demand for reliable, fast, and non-destructive quality assessment methods and postharvest handling of poultry egg has resulted in the development of many principles. The quality of poultry eggs is evaluated based on the physical, chemical, biological, and functional properties of eggs. The quality of eggshell is largely influenced by storage conditions, such as temperature and relative humidity, and stress conditions, such as impacts and vibration caused during transport and handling. In this chapter, the postharvest handling of eggs and quality assessment methods are described.

12.2 QUALITY ASSESSMENT METHODS FOR FRESH POULTRY EGGS

12.2.1 Overview

The quality of egg and the healthy conditions of layer flock can be carried out to correct problems before they create large economic losses or hygienic problems. The contaminations of eggs with bacteria like *Salmonellae* are common. The presence of a fragile eggshell requires a sophisticated gentle way of handling in the automated grading systems. Quality consists of the interior and external characteristics of eggs. Most of the exterior quality aspects are related to the eggshell and include shell integrity, color, thickness, porosity, and strength. Other external quality aspects are the presence of dirt on the shell and cuticles. Except for the shell color, these external quality characteristics are related to the protection of interior contents by avoiding physical damage and bacterial invasions.

In general, internal egg quality relates to the characteristics of the albumen. The albumen quality decreases with the storage time due to biochemical reactions, which are governed by complex internal and external factors, such as temperature and relative humidity as well as the presence of bacteria. The albumen transforms into a watery substance from a highly viscous component over several weeks. Therefore, albumen quality is often taken as a yardstick to evaluate albumen (i.e. egg) freshness. Historically, albumen quality is estimated by Haugh units [1], which measure the albumen height after breakage and are empirically corrected by egg mass. This technique has some important disadvantages although it is an easy method. Albumen can include dissolved blood, bloodspots, and meat spots (i.e. inclusions other than blood).

Ovomucin, one of the major egg white proteins, has wide potential applications in the food, functional food, and nutraceutical industries due to its unique physicochemical properties and bioactivities [2–7]. Although ovomucin can be easily precipitated from diluted egg white at acidified pH, the method for preparing high-purity ovomucin is challenging due to the co-precipitation of lysozyme and ovalbumin [8–10]. In literature, the purity of ovomucin prepared by the precipitation

method was less than 70%. For research purposes, pure ovomucin can be prepared by the gel filtration method; however, this method is not suitable for large-scale production [11]. A new two-step method was recently reported that was able to prepare ovomucin with over 90% purity [12]. The storage of eggs is known to lead to quality deterioration or egg white thinning [13]. The storage of eggs was also reported to affect the physicochemical properties of egg white [14]. Schafer et al. [15] reported that storage did not affect the content of lysozyme and ovotransferrin, while ovalbumin decreased after 6 weeks of storage. Since shell eggs inevitably have to be stored before processing, it is not known if storage of the egg might affect the extractability of ovomucin.

A new two-step method was recently developed to prepare high-purity ovomucin by Wang et al. [16]. In this study, the effect of shell egg storage on ovomucin extraction was investigated. The composition of ovomucin extracts from egg white was determined by gel filtration chromatography. Both storage temperature and time could significantly ($p < 0.05$) affect the purity and yield of the ovomucin. After nine weeks of storage at 4°C, the content of the ovomucin in the extract decreased from 92.5 to 82.4%, and the yield of ovomucin decreased from 214 to 120 mg/100 g of egg albumen (egg white). After 5 weeks of storage at 22°C, the content of ovomucin extract decreased from 92.5 to 73.0%, and the yield of ovomucin decreased from 214 to 112 mg/100 g of egg albumen. The increase in egg white pH during prolonged storage leading to degradation of ovomucin is very likely responsible for the decreased extractability of ovomucin.

The rate at which eggs are graded today is up to 180,000 eggs/hour; thus this task cannot be controlled individually by a trained human eye. Therefore, the egg-grading equipment is equipped with specially developed sensor devices to estimate one or more quality aspects. The devices need to be non-destructive and fast. These novel devices are commonly compared to the classic tests for quality assessment, which are usually destructive and time-consuming.

Visual inspection is commonly performed to evaluate the quality of egg. However, the required grading rate makes visual inspection impractical since huge numbers of eggs need to be assessed within a very short time. Therefore, the development of new non-invasive and non-destructive apparatus to measure the quality of eggs is needed. Three main types of quality-sensing devices are commercially available. The first type is based on mechanical techniques, which measure eggshell properties, such as the presence of cracks and the eggshell strength. Spectroscopic principles are the basis of the second type of sensors used to assess the interior egg quality. At the beginning, the spectroscopic details were used on the basis of one or a limited number of wavelengths (e.g. to discover blood or other inclusions). Later, advanced spectroscopic facilities used hyperspectral data to determine albumen properties like Haugh units, pH, and viscosity. Finally, computer vision techniques are used to acquire information on the external quality of eggs (e.g. eggshell color and dirty shell detection). They can detect quickly the cracks which could be a major problem in the hygiene and cleanliness of the egg. Recently, researchers are paying attention to modern sensors, which are based on ultrasonic, magnetic resonance and electronic nose techniques. In addition, the combination of two different measurement methods (e.g. eggshell conductance) could be assembled.

12.2.2 Mechanical Techniques

A lot of mechanical techniques have been used to evaluate the physical qualities, like the strength and the integrity, of the shell. A whole set of mostly destructive and time-consuming protocols is reviewed by Hamilton [17]. These techniques are often used as reference techniques to evaluate the development of fast and non-invasive techniques. For the non-invasive evaluation of eggshell strength and integrity, a mechanical technique is used to detect hair cracks in commercial egg-grading machines. In these devices, the local integrity of an eggshell is assessed by measuring the number of rebounds of a small impactor on it.

Several elastic rebounds of this impactor denoted a locally intact eggshell. Close to a crack in the eggshell, the elasticity of the eggshell impairs the rebounds of the impactor (i.e. heavily damped). This is reflected in a serious reduction of the rebounds number of the impactor. Utilizing these measurements on several locations, cracks all over the egg can be discovered. In one case, a small ball moving an electromagnetic probe has the roll of an impactor [18]. In another commercially available application, the impactor is the egg itself and the rebounds are counted by a piezoelectric element [19]. In these methods, the crack detection rate varies from 70 to 85%.

Coucke [20] and later De Ketelaere et al. [21] evaluated the dynamic response of eggs after an excitation. After excitation, the egg exhibits a complex damped harmonic vibration. For an unbroken eggshell, this vibration is identical wherever measured on the equator of the eggshell. Therefore, it is possible to judge the integrity of the eggshell by comparing the frequency spectrum measured at various places on the equator of the vibrating egg. Broken shells show a different response at different places on the equator. Up to 90% of the cracked eggs are detected using this fast technique since it works at about 7 m/s. By applying discriminant analysis and a multiple regression technique, Cho et al. [22] increased the detection rate by up to 94%. Jindal and Sritham [23] detected almost 99% of the cracked eggs using neural networks to compare the recorded spectra. The possibility of detecting cracked eggshells by comparing the vibrational behavior at the blunt end and at the equator after excitation was shown by Wang and Jiang [24]. Further, the dynamic stiffness from the measured frequency spectrum was measured for intact eggshells [25, 26]. This dynamic stiffness was correlated with other parameters of the eggshell strength, such as static stiffness and eggshell thickness. An acoustic technique for measuring the dynamic stiffness could be used to predict the cracks in eggs during handling and transport [27]. Micro-organisms, such as *S. enteritidis*, can easily penetrate into eggs which have low dynamic stiffness [28].

The eggshell is fragile, and cracked eggs are more vulnerable to bacterial infections, which can lead to health hazards. Hence, detection and removal of cracked eggs continue to be very important for quality assurance in the production and marketing of eggs [29, 30]. There are two main methods prepared to detect eggshell cracks including vibration-based response analysis and machine vision inspection [30]. Many studies have shown that the vibration-based response analysis is a more effective detection method than the machine vision inspection method, especially for the detection of hairline cracks and invisible cracks [7, 31]. In the vibration-based detections, Fourier analysis is broadly used to find crack-sensitive indicators by comparison of the feature difference between cracked and intact eggs. For instance, De Ketelaere et al. [31] found that for intact eggs, the impulse responses are nearly identical at every point on the eggshell equator, whereas eggs with a damaged shell show different responses at different locations of the equator. A crack detection algorithm based on the correlations between the repeated measurements obtained from the same egg (four repetitions) was suggested by the authors [31]. The magnitudes of the peak frequencies (peak frequencies indicate the frequency of the highest peak, the frequency of the second peak, and so on) were found to be similar for the cracked eggs and showed that the first dominant resonance frequency values of the cracked eggs were lower than those of the intact eggs [24]. Jindal and Sritham [23] classified eggs using artificial neural network techniques based on the vibration after impact and reported 99% crack detection and 10% false rejection. The physical properties of eggshells were also analyzed using vibration-based methods. Coucke et al. [25] measured the mechanical stiffness of an eggshell through resonance frequency analysis and stated a correlation of 0.71 between the static and dynamic stiffness of an eggshell. Wang et al. [24] explained the relationship between the dynamic resonance frequency and the eggs' physical properties. They found that the dominant frequency rises while the shell stiffness or egg density increases, and decreases when the egg mass increases. Kemps et al. [32] investigated the incubation of eggs and its relation to embryonic development using the vibration analysis method. They found that the time at which the damping of the vibration suddenly changed, the diameter of the eggs, and their interaction were significant explanatory variables in predicting hatching time. Bamelis et al. [33] measured the conductance of eggshells using the acoustic resonance technique, based on the optical transmission spectra. The authors found that the dynamic stiffness of an egg and the optical transmission at 611 nm are the parameters with the highest predictive power when estimating eggshell conductance. It is also worthwhile to point out that vibration-based analysis techniques have been broadly applied in the quality detection and control of agricultural products [34–39].

It is well-known that cracks in table eggs increase the risk of bacterial contamination, and the removal of cracked eggs has been a USDA grade standard for many years [40, 41]. Cracks still frequently occur throughout various points of egg collection and processing, and there are numerous high-speed online commercial crack detectors in use. The accuracy of crack detectors is validated by USDA human graders to ensure that they are in compliance with voluntary grade standards (USDA, 2005). However, to validate the high-speed systems, human graders still rely on hand-candling techniques with somewhat antiquated candling lights. In recent years, especially at integrated egg processors with fresh eggs, USDA graders have been having difficulty in detecting small hairline cracks and micro-cracks [42]. Lawrence et al. [43–45] have developed and patented an imaging system to assist the graders in detecting these fresh cracks in table eggs. The system was designed for white table eggs and took about 60 seconds to process a set of 15 eggs. In a 1000-egg study with approximately 350 fresh hairline-cracked eggs, the system was 99.6% accurate with only a 0.2% false rejection rate (intact eggs incorrectly classified as cracked). The system had a higher accuracy than any other crack detector currently in use [29, 46]. The imaging-based system used a high-resolution digital camera to capture an image of 15 eggs in a transparent enclosure. Then a small, quick negative pressure was applied to the enclosure, which opens any eggshell cracks, while a second image was taken. The comparison of the two images was then used to detect any change in the image intensity, which was associated with a crack. Jones et al. [47] showed that the system did not affect egg quality, including Haugh units, albumen height, egg weight, shell strength, vitelline membrane strength and elasticity, and whole-egg total solids, during cold storage [47]. Recently, additional modifications to the system have been made, including enlarging the enclosure to hold 20 eggs, automating the rollers, adding a case light for external shell quality, and implementing a touch screen with data management software. Previous measurements on intact eggs had shown that the system did not cause cracks in intact eggs [44, 45]. However, in discussions with industry representatives, there was a concern about the system causing cracks in poor-shell-quality eggs. There are many factors that affect eggshell quality including adequate nutrition, flock health, management practices, environmental conditions, and breeding. However, it is well-known that consistently poor shell quality occurs in eggs laid from hens just prior to melt in the heat of the summer [48]. Lawrence et al. [49] reported the improvements to the system and the system's effect on poor-shell-quality eggs. To aid graders, a modified-pressure imaging system was developed to detect cracks in table eggs [49]. The original system was modified to grade 20 eggs at a time in batch mode. The eggs are positioned on rollers and held in a sealed clear acrylic chamber (Figure 12.1). The system utilizes high-intensity white LED lights for illumination, and a stepper motor is now used to automate the rotation of the eggs. It also uses a high-resolution monochromatic camera to take images of the eggs. The first image is taken at atmospheric pressure, and the second is taken while the chamber undergoes a short, rapid, negative change in pressure. If there is no crack, then there is effectively no difference in the two images. However, if a crack is present, it causes an increase in the intensity of the crack pixels in the negative-pressure image, resulting in a significant difference between the two

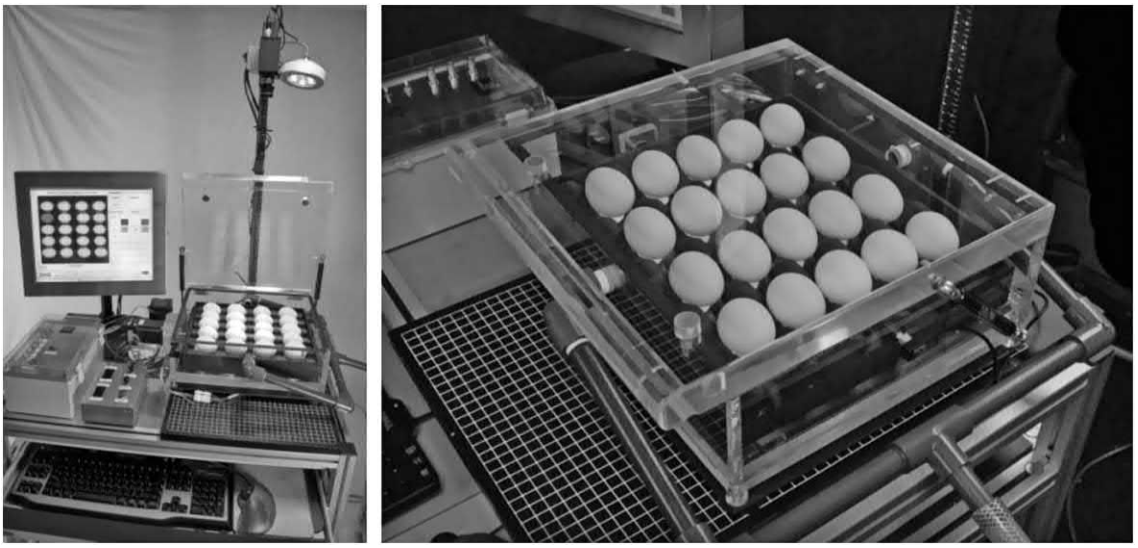

FIGURE 12.1 (Left) Crack detection system as shown: acrylic egg chamber with hinged lid, CCD camera, case light, control box, and touch-screen monitor. (Right) Close-up of the vacuum chamber holding 20 white table eggs. Note the two cylindrical magnets mounted in the lid to hold it closed. (From Lawrence et al. [49].)

images. This difference (in the form of a ratio) is the basis for identifying a crack. The software then displays the egg images and each egg is color-coded either green (intact) or red (cracked), and any cracks are highlighted with a contrasting color. Typically, the system uses four sets of images to cover practically all the eggs' surface and completes the crack detection in about 40 seconds. The modified system was tested with poor-shell-quality eggs from multiple strains of hens to see if it would induce cracks in these eggs. The analysis of 3279 poor-shell-quality eggs (both white and brown), from six strains of hens, laid in the heat of the summer, resulted in only one crack caused by the system (0.03%). Thus, it is highly unusual for the system to cause cracks in intact eggs, even eggs with poor shell quality.

The most useful information could be obtained from the inside of the egg, where the embryo is developing. Acoustic Resonance Analysis (ARA) has the ability to detect the embryo after 96 hours of incubation. By measuring the blood value retrieved from optical transmission spectra, embryonic presence is even found after about 72 hours of incubation [50]. Moreover, the dynamic stiffness can be determined by ARA to state the effect of heat stress on a layer flock [51] and to determine the risk of shell breakage at different stages of production.

Eggshell quality is important in selecting the program to choose new breeder flocks both for layers and broilers. The fast and non-invasive measurement of the dynamical stiffness might be a useful tool in breeding as it demonstrates a high heritability [50] and seems to be a good estimator for the risk indicator to determine cracks during handling and transport. Lin et al. [52] evaluated eggshell stiffness using an acoustic resonance system. The evaluation was achieved by analyzing the measured frequency response of eggshell excited with light mechanical equipment. Partial least squares (PLS), synergy interval PLS (si-PLS), genetic algorithm PLS (GA-PLS), and GA-siPLS algorithms were used to calibrate the regression model. The GA-PLS model can help to build a compact and robust model serving for on-line measurement of the stiffness of eggs.

For decades, breeding companies have used laboratory-based measurements, such as shell breaking strength, non-destructive deformation, and specific gravity [53]. While these measurements have generally helped in making a selection, it has been notoriously difficult to prove that they directly relate to the incidence of breakage based on the shell strength. This is due to the number of possible physiological responses to choose from for shell strength, including rate of shell deposition, uterine environment, changes in acid–base balance, and efficiency in metabolizing calcium [54, 55]. Eggshell strength is generally measured using either direct tests, such as non-destructive deformation [56, 57] or destructive fracture force [58–60] of an egg under quasi-static compression between two parallel plates, or indirect tests, such as the measurement of eggshell thickness [61–65] or specific gravity [66]. Many of these methods, however, are destructive, slow, or subject to environmental influences; hence these are regarded as impractical. Coucke [25] constructed a fast, objective, and non-destructive technology for the determination of eggshell strength based on acoustic resonance analysis. This method measured the egg resonant frequency (RF) and damping ratio. Based on the RF and egg weight, the dynamic shell stiffness (K_{dyn}) was defined. This technique can also be used to detect cracks in the eggshell [25, 26, 30, 67]. Many studies show the K_{dyn} to be a useful eggshell quality measurement. De Ketelaere et al. [31], for instance, investigated the variation of this strength parameter in relation to certain production parameters. A small-scale experiment also indicated a decline in K_{dyn} to be a result of heat stress [35]. Coucke et al. [30], De Ketelaere et al. [31], and Wang et al. [67] also found an acceptable correlation between the measurement of K_{dyn}

and other measures of eggshell quality. Eventually, K_{dyn} provided a good approximation of eggshell strength in relation to the likelihood of breakage in practice as shown by Bain et al. [32]. This created the opportunity to treat K_{dyn} as a new eggshell quality parameter in breeding programs. As most deformations that cause the eggshell to break in practice are dynamic, this might lead to an increased selection response as compared with the classic static techniques, but it needs to be proved. Researchers investigated the relationship between some measures of shell quality (specific gravity, breaking strength, shell thickness, percentage of shell, and shell weight per unit of surface area) and egg breakage in practice [68–71]. The mechanics and mechanisms of failure of eggs have been examined through punch tests, and these show the importance of establishing damage over a critical area before the macroscopic failure of the eggshell at the maximum load (i.e. one or more of the micro-cracks become unstable) [72]. Structural strength, on the other hand, is related to the interactions among the building units and depends on several variables, namely size, shape, thickness, and distribution of the shell components. Most techniques used to quantify eggshell strength measure the eggs as a whole and thereby make no distinction between properties of structural strength and mechanisms of failure of hens' eggs. For example, static stiffness (K_{stat}; 22) and dynamic stiffness (K_{dyn}; 5) are measured for total shell strength. The practical loads on the eggshell have a dynamic nature, and so the dynamic strength of an eggshell could be related better to conditions experienced during the handling and transportation of the eggs. Thus, there is apparently no ideal variable for the stability of eggshell strength. As a new non-destructive method for the stability of eggshell strength based on the different strains of laying hens with different ages in terms of their eggshell quality, the compression cone hardness was tested [73]. Seven measurements were used in the classical method, such as egg mass, shape index, static stiffness, breaking strength, shell thickness, and shell mass. Furthermore, the dynamic stiffness as mentioned by Coucke [25] was compared with the compression cone hardness. The results from multiple regressions revealed stronger influences on breaking force strength than static stiffness (deformation) due to the compression cone hardness and dynamic stiffness. It is necessary to develop other measurement methods to estimate eggshell quality without destroying the eggshell. Compression cone hardness (CCH), shell deformation, shell breakage strength, shell thickness, static stiffness, dynamic stiffness, and shell mass showed high coefficients of correlation. Intact eggs produced sound signals at a single dominant peak in the frequency range of 3000–8000 Hz with a duration of about 20 ms. The cracked eggs showed frequency spectra in a relatively wider frequency range of 2000–10,000 Hz and a shorter signal duration of about 15 ms. Finally, it was concluded that the influence of strength (i.e. breaking force) upon total eggshell strength (i.e. crack detector) is limited.

In the albumen, one of the most obvious changes is the physical deterioration of the thick white [74]. The gelatinous structure of the thick white gradually deteriorates to thin white during storage [75]. The "thinning" phenomenon was widely described by Raymond Haugh [76] as a good indicator of egg quality [77]. During storage, the vitelline membrane surrounding the yolk loses its structural integrity and stretches [78, 79]. The European Union legislation provides the measure of the air cell height for the commercial classification of eggs (EEC, 1991). The air cell height increases in volume for the loss of carbon dioxide with age. These changes are influenced by storage conditions, like relative humidity and temperature [80]. Wavelet analysis was introduced in the early 1990s to mathematically analyze signals from the time domain into different layers of frequency levels. The wavelet transform is described in a fashion similar to the short-time Fourier transform. It uses a waveform function called the wavelet instead of using periodic functions. Therefore, the wavelet transform is more suitable for the analysis of non-stationary signals by effectively extracting the time-frequency features of the signals; it has been developed as an alternative to Fourier transform in order to overcome problems related to the frequency resolution. More details of the wavelet function and its applications can be found elsewhere [81–87]. Fourier analysis is performed to find an effective crack feature for eggshell crack detection, and the wavelet analysis has not yet been utilized. For binary classification, a support vector machine (SVM) was initially designed, and its aim was to find a decision from the closed training points that has the maximum distance (margin) from the closest training points [88]. Many studies showed the SVM to be a powerful classification method in different applications [89]. Denga et al. [90] proposed a new detection methodology for eggshell cracks using a continuous wavelet transform and a support vector machine (SVM) technique (Figure 12.1). The proposed methodology included an experimental system and a data processing system, which was used to generate the impact force and to measure the acoustic signal, whereas the data processing system extracted timely signal features and classified the signals based on an SVM algorithm. This method led to achieving the highest crack detection rate of 98.9%, and the smallest false rejection rate of 0.8%.

Aboonajmi et al. [91] demonstrated the possibility of the non-destructive prediction of the main quality indices of commercial eggs by processing a short ultrasound burst passing through the egg material and calculating the ultrasound phase velocity. For this purpose, a set of 300 samples of commercial eggs (Boris Brown, 33 weeks of age) from the first day (i.e. egg lying) were purchased from a farm and classified in two groups. The first group was kept at room temperature (22–25°C) while the second group was kept in a refrigerator (4–5°C). Twenty-five eggs were picked every week from each group (room and refrigerator) and then subjected to the non-destructive ultrasound test at room temperature. Each day, the ultrasound signal was recorded from the eggs. Then the air cell, thick albumen heights, Haugh unit, and yolk index of the eggs were also determined by a destructive method for comparison. Both the Haugh unit and yolk index decreased with time over 5 weeks in storage at room and refrigerator temperatures, while the air cell height increased. The lower the Haugh unit for the eggs in the refrigerator, the lower the phase velocity (1573 m/s on the first day compared to 1540

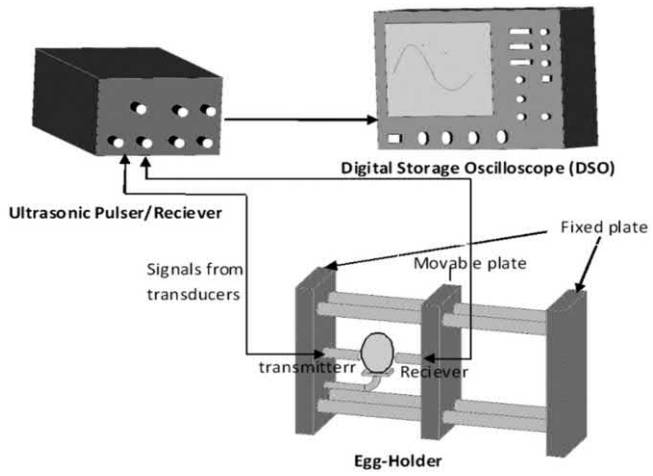

FIGURE 12.2 The experimental setup for ultrasonic testing of poultry eggs. (From Aboonajmi et al. [92].)

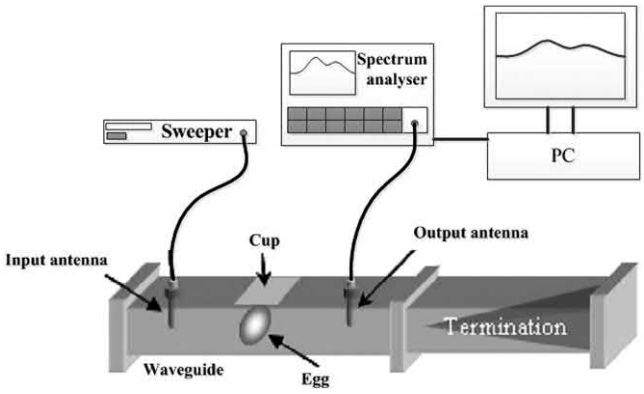

FIGURE 12.3 Layout of the used instrumental chain. (From Ragni et al. [93].)

m/s after 3 weeks). Similar changes of the phase velocity were found for the eggs at room temperature (1571 m/s on the first day compared to 1514 m/s after 3 weeks).

Another study was done by Aboonajmi et al. [92] using a non-destructive ultrasound method to develop a model for poultry egg freshness assessment (Figure 12.2). The proposed model can predict the Haugh unit, albumen thickness, air-cell height, and a number of other egg quality parameters by computing the ultrasound phase velocity within the egg material. For this purpose, the effect of the storage time on the ultrasound phase velocity within the poultry eggs and the peak values of the transmitted ultrasound signals in the time and frequency domains were considered to be indicators of egg freshness. Tests were conducted on eggs stored for 5 weeks in different storage conditions. The computed parameters were used to develop different models to predict the number of storage days for the egg samples. The results showed that the amplitude of the main peaks of the ultrasound signal in the time domain increased with the days of storage. Moreover, there was a significant difference between the mean values of the phase velocities obtained at different times during the storage period. Comparing the results obtained for the eggs kept at room temperature as compared to refrigerated showed that variations were more significant for the eggs kept at room temperature.

A waveguide technique for the non-destructive determination of egg quality parameters was carried out by Ragni et al. [93]. By applying a waveguide probe as an input for shell eggs to a sinewave sweeper oscillator, the signal at the output was captured by a spectrum analyzer (Figure 12.3). The correlations between the quality parameters and tests carried out on albumen, yolk, and plastic eggs for simulating the air cell showed how one index can be indirectly predicted through another one.

12.2.3 Spectroscopic Techniques

In general, light is composed of electromagnetic waves of a broad spectrum of wavelengths; the visible range (VIS) is within wavelengths between 300 and 750 nm and the near-infrared range (NIR) is between 700 and 2500 nm. This spectrum is changed due to physical and chemical interactions when it is passed through a material. Thus, the original spectrum can be compared with the changed spectrum, and optical information details of the object could be linked with the chemical and physical quality. Several authors have found reliable methods to link this optical information with the quality of eggs. The optical measurements have the advantage due to their non-destructive and fast measurement; hence the risk for cross-contamination can be avoided due to their non-contact with eggs.

Bamelis [94] demonstrated an inter-egg variation in optical transmission spectra on white-shelled eggs using visible light. The size of an egg and thickness of the eggshell varied during the storage time of eggs. From these optical spectra, the transmission ratio of two wavelengths, 674 and 663 nm, was calculated, and this ratio varied logarithmically towards a constant value; however, the time to reach this constant differed from egg to egg. The use of a time-dependent evolution of the optical spectra in the NIR range was also reported by Norris [95]. Kemps et al. [96] investigated the possibility of estimating albumen quality parameters, such as pH and Haugh units (HU), from the optically measured VIS/NIR transmission spectra. A correlation of 0.82 between predicted and measured parameters was reported. Schmilovitch et al. [97] predicted the pH from NIR transmission spectra as measured through whole eggs. Kemps et al. [98] reached the same results for pH and HU.

The optical spectrum can be influenced by optical active pigments and two pigment detection devices are available to detect hemoglobin and protoporphyrin. The blood and color of eggshell are measured by detecting their important pigments. First Brant et al. [98] suggested a technique to discover blood in a non-invasive way by selecting the absorption peaks of hemoglobin at 577 nm. Gielen et al. [99] showed that the range between 585 and 610 nm could be useful as a reference value to calculate the blood value. The presence of protoporphyrin in the shell of brown eggs was a big problem in the detection of blood, but protoporphyrin can be detected from the color of eggshells [100]. Besides protoporphyrin, biliverdin is an important eggshell pigment for the eggshell color [101]. Using the light reflected by an eggshell, Wei and Bitgood [102] developed a device to measure the eggshell color.

Another non-destructive assessment of the egg's internal quality and freshness is mainly performed by spectroscopic techniques, when the interaction of an electromagnetic wave with the product represents the common principle [103]. Similar studies have been carried out for other agricultural products during the last few years [94, 104–107]. The main results showed significant correlations of the visible near-infrared transmission spectra with the storage time [94] and the albumen quality in terms of Haugh unit, an expression relating to the thick albumen height and the egg mass [1]; for this last parameter in particular, coefficient of correlation (R) values of 0.883 [95] and 0.890 [94] were observed. By using FT-near infrared reflectance spectra, coefficient of determination (R^2) values up to 0.819 for the thick albumen height [104] and 0.722 for the air cell height [104] were obtained.

Narushin et al. [108] reported the comparison between infrared spectroscopy (IRS) and egg size measurements for the non-destructive evaluation of eggshell strength. Infrared and egg size parameters were correlated with eggshell quality parameters as obtained using invasive techniques. A correlation coefficient of 0.72 demonstrated the ability of IRS to predict shell weight with reasonable accuracy. Another study was done by Aboonajmi et al. [109] to evaluate poultry egg freshness using VIS/NIR spectroscopy. In this study, a new method for egg freshness prediction using transmission visible near-infrared spectroscopy was investigated. The non-destructive VIS/NIR spectral measurements from 300 to 1100 nm (832 wavelength) were used as well as Haugh units and air cell height for each egg, and a database was created for both environments. Finally, a maximum likelihood latent root regression algorithm was developed to predict Haugh unit and air cell height by the observed spectrum. The results showed that this method was better in comparison with partial least square regression (R^2 up to 0.79 and 0.72 for air cell height and Haugh unit).

Aboonajmi et al. [110] carried out a quality assessment of poultry eggs using VIS/NIR spectroscopy and radial basis function networks. The developed models yielded a good prediction accuracy of Haugh unit for intact egg (R^2 values 0.745 and 0.76) as well as air cell height (R^2 values 0.835 and 0.844) for room and refrigerator conditions, respectively [110]. The results of the experiment showed that the developed model can be used to predict egg freshness indices satisfactorily.

The potential of the ultraviolet and visible (UV/VIS 200–800 nm) transmittance method to inspect the internal quality (freshness) of intact chicken egg was investigated by Liu et al. [111]. It was concluded that the non-destructive inspection of egg freshness by transmittance properties is feasible in the range of 400–600 nm, while it is impossible to inspect egg freshness in the range of 200–400 nm due to the low transmittance.

Giunchi et al. [112] evaluated the freshness assessment of shell eggs using FT-NIR spectroscopy non-destructively. Diffuse reflectance spectra were acquired in the spectral range 833–2500 nm on the samples of eggs collected from three different farms and characterized by different methods. Models were performed, and the prediction showed R^2 values up to 0.722, 0.789, and 0.676 for air cell height, thick albumen heights, and Haugh unit, respectively (test set validations). The specimens were correctly classified (100%) according to the days of storage. Hierarchical cluster analysis showed a low level of heterogeneity for the three previous methods within the days of storage.

Another study was carried out by Abdel-Nour et al. [113] to predict the egg freshness and albumen quality by means of visible/near-infrared spectroscopy as a rapid and non-destructive technique for egg quality assessment (Figure 12.4). The

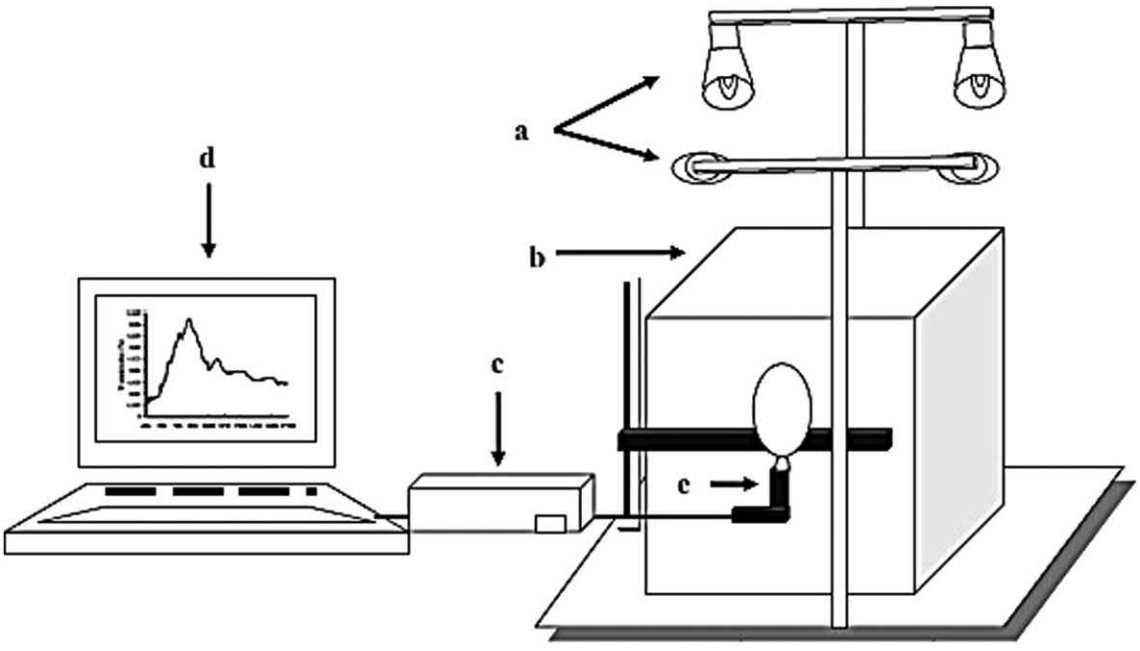

FIGURE 12.4 System setup: (a) halogen lighting source, (b) white frame, (c) spectroradiometer, (d) personal computer, and (e) sensor. (From Abdel-Nour et al. [113].)

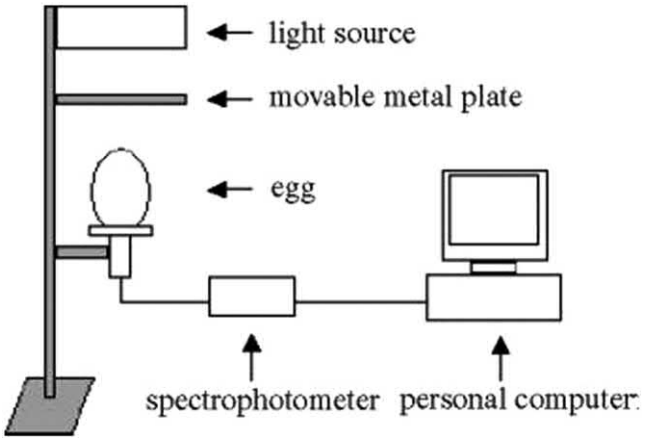

FIGURE 12.5 Experimental set-up for the measurements of transmission spectra. (From Kemps et al. [114].)

results showed that VIS/NIR transmission spectroscopy acts as a useful tool in assessing egg freshness and albumen pH and can be suitable for use as a non-destructive method to predict HU, albumen pH, and length of storage.

Kemps et al. [114] investigated the feasibility of visible transmission spectroscopy for freshness assessment of an individual egg (Figure 12.5). The non-destructive spectral measurements were compared with the two most widely used destructive freshness parameters, namely Haugh units and albumen pH. A model of partial least squares (PLS1) was performed to predict Haugh units and pH of the albumen. These results showed that the light transmission spectrum of an egg provides quantitative information about egg freshness [114].

Another property used to predict physical features is dielectric properties. Materials' dielectric properties are influenced by the electric conduction, dipoles, electronic, and ionic properties. Maxwell–Wagner mechanisms are closely dependent on electromagnetic wave frequency [115]. This is useful in studying and developing heating processes or grading techniques based on electromagnetic energy.

Several studies have been performed to characterize the dielectric properties of foods over the past 50 years [116–119]. Dielectric properties are related to temperature and frequencies, and these properties have been reported for different agricultural commodities, including grains and seeds [120], fruits and vegetables [121–129]. Studies also reported the possibility of non-destructively predicting selected physical characteristics of foodstuffs, like fruits and eggs [2, 130, 131]. No similar studies have been reported that relate dielectric properties of egg ingredients to storage quality. Changes in the dielectric parameters of fresh eggs during storage were investigated for the development of a method to assess the main quality indices by Ragni et al. [132]. The dielectric constant and loss factor of yolk generally increased with the storage time.

A simple resonant radio frequency circuit equipped with a parallel plate capacitor probe was used to predict the qualitative indices of shell eggs in other studies [133]. For hatching eggs, shells have to be thick and strong for the preservation of the embryo as well as thin for gas exchange and weak enough to allow the chick to crack the shell when hatching [134]. For maximum efficiency, it is important to detect eggs with unfit shells and remove them from further incubation, processing, and/or transportation. Shell-breaking force and/or shell stiffness, calculated as a ratio of force and shell deformation at failure, can adequately determine shell strength characteristics directly [58, 59, 135–137]. It was shown that such shell thickness, the ratio of shell weight to surface area, and the percentage shell are in close relationship to the shell-breaking force and shell stiffness [58, 59, 138–143]. Therefore, it is possible to predict the strength characteristics of eggshells indirectly. However, as all these parameters are destructive, there are no values for practical application. The following non-destructive parameters are used to indirectly predict shell characteristics: egg specific gravity [54, 58, 70, 139, 143, 144], egg mass [145–147], and shell non-destructive elastic deformation [17, 59, 97, 144, 148]. However, none of the above variables can accurately predict the strength characteristics of the shells [149, 150]. The correlation of shell-breaking force with egg weight was found to give a value for the correlation coefficient (R) of 0.27; 0.04 value for specific gravity of egg [150]; and with non-destructive elastic deformation, the value for R was 0.47 [150].

The relationship between shell compressive stress and the non-destructive elastic deformation was improved by considering additionally the values of egg length and maximum breadth [151]. Several studies reported the possibility of using infrared spectroscopy (IRS) to define the quality of foodstuffs like meat [152], food [153], and animal feeds [154, 155]. The infrared spectra absorption is proposed for the relation of the shell and its density, inner structure, and/or chemical composition, and so correlated with the shell strength. Guo et al. [156] surveyed the dielectric properties of the albumen and yolk of eggs at 24°C over the frequency range from 10 to 1800 MHz to monitor quality changes during a 5-week storage period at 15°C (Figure 12.6). Quality factors including Haugh unit, yolk index, moisture content, and egg weight were also measured during the same period [157]. On average, the

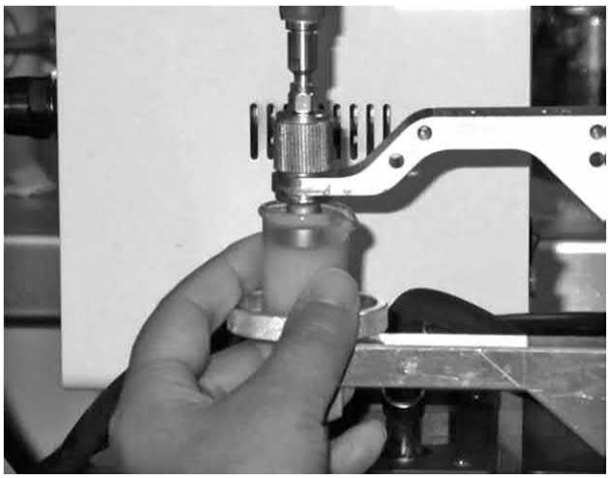

FIGURE 12.6 Dielectric properties measurement arrangement. (From Guo et al. [156].)

Haugh unit, yolk index, and egg weight decreased with time, indicating its quality deterioration. Albumen moisture content increased at first and then decreased after the third week of storage. The opposite trend was observed for the yolk moisture content. Correlations between these quality changes and corresponding measured dielectric properties over the storage period show potential for the use of dielectric measurement techniques for the rapid assessment of egg quality.

As mentioned above, by correlating measured dielectric properties to physical properties of interest, a line of metrology was developed with a wide spectrum of applications including pharmaceuticals, mining, construction materials, food, and agriculture [158–160]. The most popular and well-known applications are moisture sensing [161], microwave heating [162], and remote sensing [163, 164].

Recent developments in electronic nose (EN) technology and modern statistical methods including chemometrics and artificial intelligence provide opportunities to extend the scope of odor measurement. This new technology, the electronic nose, is an instrument including an air sampling apparatus and an array of gas sensors interfaced to a personal computer (PC) or an embedded system. The most important feature that distinguishes an electronic nose from other instruments is the ability of its sensor array to respond differently to various odors. Each odor may contain hundreds, sometimes thousands, of different volatile organic compounds (VOCs). Classical spectrometry analytical methods such as gas chromatography–mass spectrometry (GC–MS) are able to identify and measure individual odorous chemical compounds in an odor sample. On the other hand, the electronic nose can react to the "total odor sample" as does a human nose. In the human olfactory sensing system, it is not necessary to separate individual chemicals in the sample as part of an assessment process; the odor is assessed as a whole, and the odor is identified using our brain (i.e. the odor pattern is recognized from the memory bank).

Researchers have identified that the electronic nose is capable of quantifying odors and discriminating between odors from different sources [165]. Developments in the statistical techniques required to analyze outputs from electronic nose devices have broadened the scope of electronic nose applications. Bicego et al. [166] identified how an apparent lack of reproducibility of the sensors could be compensated for by using a flexible calibration and recognition tool based on neural networks. Boccorh et al. [167] postulated that the predictions made with artificial neural networks (ANN) arose from the ability of neural networks to simulate the non-linear relationships observed in human perceptions such as taste and odor. Improved statistical methods were used by Guadarrama et al. [168] to discriminate between various VOCs derived from car components. More recently, Sohn et al. [169–171] and Qu et al. [172] were able to determine significant relationships between electronic nose output and odor concentration determined by dynamic olfactometry. The former researchers were then able to accurately determine the odor concentration of samples to train the electronic nose using an ANN approach. Although errors associated with olfactometry were identified as a constraint to improve the accuracy of electronic nose odor prediction model, it was shown that ANN algorithms significantly improved the model's ability to predict new samples when compared to alternative linear and non-linear multivariate modeling techniques. Sohn et al. [170] also showed that an electronic nose with a reduced number of sensors could quantify odor concentrations from a specific source. In these approaches, reliable olfactometry data are important because ANNs are trained using not only the sensor outputs of an electronic nose but also the odor concentration results from olfactometry. The air quality research group in the Department of Primary Industries and Fisheries, Queensland (QDPI&F) has developed and evaluated an electronic nose system. This system includes an array of metal oxide semiconductor (MOS) sensors, which are appropriate for the assessment of odor emissions from intensive livestock industries. This was due to their sensitivity to volatile chemicals found in such odors. The electronic nose is able to provide qualitative information (i.e. discriminate between samples from different sources) and predict odor concentrations using a model based on results from olfactometry. This device and associated models were applied to odors derived from a broiler shed.

A sample study performed by Dutta et al. [173] on egg freshness considered an electronic nose-based approach (Figure 12.7). Principal component analysis, fuzzy C means, self-organizing maps, and 3D scatter plots were used to define regions of clustering in multi-sensor space according to the state of freshness of the eggs. These were correlated with the "use-by date" of the eggs. Then four supervised classifiers, namely multilayer perceptron, learning vector quantization, probabilistic neural network, and radial basis function network, were used to classify the samples into the three observed states of freshness. A comparative evaluation of the classifiers was conducted for this application. The results showed that this method was able to predict egg freshness into one of three states up to 95% accuracy with good potential for commercial exploitation. Sohna et al. [174] implemented an electronic nose for continuous odor monitoring in a poultry shed. The results demonstrated that it was possible to develop a model to allow an electronic nose to provide a semi-continuous measurement of odor concentrations. The electronic nose

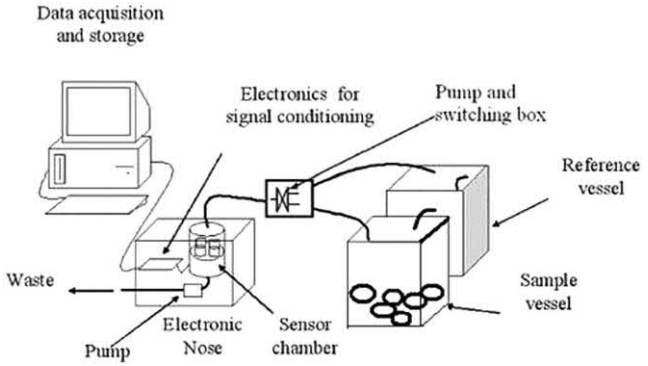

FIGURE 12.7 Experimental set-up for egg quality monitoring experiments. (From Dutta et al. [173].)

was also able to demonstrate the influence of shed conditions on odor emissions.

12.2.4 Imaging Techniques

Computer vision techniques are carried out in three main applications for egg grading purposes. First, a computer vision system needs to be developed to detect open cracks and hair cracks in eggs. The first application was reported by Elster and Goodrum [175]. Based on their work, Patel et al. [176] increased the detection rate to nearly 90% using a decision algorithm based on neural network development. Instead of neural network analysis, Han and Feng [177] used a two-dimensional fast Fourier transformation to extract relevant information from the images, but their detection rate was not more than 88%. Bloodspot detection was also performed using computer vision. Using a color image analysis combined with a neural network detection technique, 92.8% of the bloodspots in eggs could be detected.

Dirt stains can be detected in different ways, as reported by Patel et al. [178], Garcia-Alegre et al. [179–182], and Ribeiro et al. [183]. Recently, new research has shown the possibility of differentiating between the different types of dirt that can be found on the egg (feces, uric acid, yolk, and blood). This was done with high accuracy and a rather low computing time, making on-line implementation possible [184]. A blood spot detection neural network was trained, tested, and evaluated entirely on eggs with blood spots and fresh (grade A) eggs [185]. The neural network could accurately distinguish between fresh and blood spot eggs. However, when eggs with other defects were included in the sample, the accuracy of the neural network was reduced. The accuracy was also reduced when evaluating eggs from other poultry houses. To minimize these sensitivities, eggs with cracks and dirt stains were included in the training data, for example, eggs without blood spots. The training data were also combined with eggs from different sources. Similar inaccuracies were observed in neural networks for crack detection and dirt stain detection. New neural networks were developed for these defects using the method applied for the blood spot neural network development. The neural network model for blood spot- and dirt-stained egg detection had an average accuracy of 92.8 and 85.0% respectively. The average accuracy of the crack detection neural network was 87.8%. These accuracy levels were sufficient to produce graded samples that would exceed the USDA requirements (Figure 12.8).

Gittins [186] studied alternative methods to grade eggs and developed an electronic system for measuring various characteristics of an egg, such as weight, color, albumen quality, yolk color, and shell density. Elster and Goodrum [187] developed a program to analyze grayscale images of stationery eggs for cracks. The egg was isolated from background noise and enhanced using image processing algorithms. A 96% success rate was achieved. However, the average time required to process one egg was 25.3 seconds. Goodrum and Elster [188] extended their work to detect cracks at any point on the surface of rotating eggs. The identification of cracks

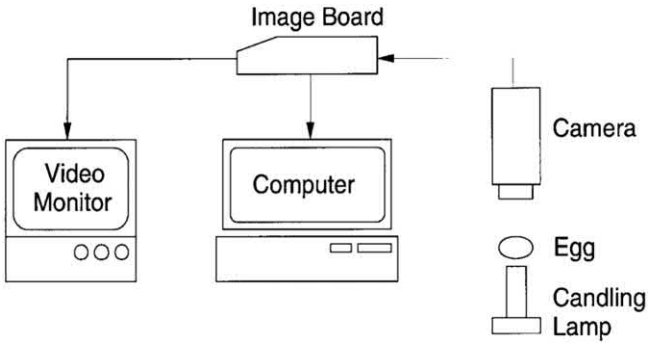

FIGURE 12.8 A schematic diagram of the imaging system. (From Patel et al. [185].)

was dependent on the egg size and required software calibration constants. Bullock et al. [189] provided a brief tutorial on artificial neural networks and discussed two applications—the inspection of cookies for damage, and inspection of apples for bruises. The use of artificial neural networks and color computer vision systems in agriculture were discussed by Davidson and Lee [190]. However, various application areas and potential uses, such as planning, harvesting, sorting and inspection, image analysis, and the control of processing plants, were outlined [190–192].

Patel et al. [185] used image acquisition routines to capture grayscale images of cracked and fresh (grade A) eggs. Histograms of the images were generated and used to train a neural network for the detection of cracked eggs. The model was 90% accurate and provided significant improvement in speed over the method of Elster and Goodrum [186]. The work was extended to the detection of blood spots and dirt stains. The neural network model for blood spot detection was 85.6% accurate. An accuracy of 80% was achieved on dirt stain detection.

Grading and quality inspection of defective eggs using machine vision were performed by Dehrouyeh et al. [193]. They showed that the algorithms were based on image processing to detect internal blood spots and eggshell dirt by processing acquired images from eggs under different illuminations. The algorithm can also detect the severity of dirt on an eggshell. In order to carry out image processing and extract useful features of captured images of eggs by machine vision, an algorithm in HSI color space was developed. The results of the experiments indicated that the accuracy of differentiation of the blood spots algorithm was 90.66% of defective eggs and 91.33% of intact eggs, while the total average of this algorithm was 91%. Accuracy of differentiation of the dirt-detect algorithm was 86% of clean eggs, 83% of low-dirt eggs, and 88% of high-dirt eggs. The total average of this algorithm was 85.66%.

12.3 POSTHARVEST HANDLING OF FRESH POULTRY EGGS

12.3.1 Transport and Shipment

Several stress conditions can produce deterioration in the internal characteristics of eggs, such as vibrations and impacts due to shipment. From the research carried out by

Adam and Skinner [194], the Haugh unit measurements were significantly influenced by the container position, as they were probably subjected to different temperatures, air movement, and vibrations on the truck. A significant decay in the albumen and yolk quality of eggs following journey hazard tests, such as vibration, impact, and drop, was reported [195, 196]. The road roughness, distance, and traveling speed, load, some characteristics of the truck such as the suspension and the number of axles influence the vibrations due to transportation [197, 198]. The effects of the transportation on foodstuffs depend on the type of packaging [199]. Some types of packaging, such as bulk bins, can remarkably amplify vibrations during transportation from the bottom to the top of the shipment column [200–202]. In order to assess the effects of transport strains on foodstuffs, several studies were performed by reproducing conditions in the laboratory, and power spectral density (PSD) curves were calculated from the vibrations measured during transportation. For this purpose, a shipping column containing the produce was attached to the vibrating table of an electro-hydraulic or electro-dynamic shaker, which could simulate the transport conditions [203, 204]. The effects of transport on foodstuffs were also assessed by vibration tests according to the ASTM standards [ASTM, 1979, ASTM, 1987, 205, 206]. Berardinelli et al. [207] reviewed the effects of transport vibrations on the parameters describing the egg quality: Haugh unit, vitelline membrane strength, and air cell height (Figure 12.9). Measurements of mechanical vibrations were carried out on the floors of three vehicles during the transportation of eggs from the packing house to the market. These transport vibrations were used to stress a typical packaging column for egg distribution by means of an electro-dynamic shaker. Haugh unit (28%) in the sample with vibration showed the highest level as compared to a non-vibrated sample when analyzed by PSD. Variations in the resistance of the vitelline membrane (18%) were also observed among the samples which were vibrated with different PSD profiles.

12.3.2 Coating

Over recent decades, a number of studies have been performed on the use of edible films and coatings. They have taken the form of moisture, gas, or solute barriers in food packaging to extend the shelf life and to improve overall quality. Edible films and coatings from biopolymers have received attention. Potential sources and applications of edible films and coatings have been reviewed by Guilbert et al. [208], Debeaufort et al. [209], and Morillon et al. [210]. The most plentiful organic renewable resource is cellulose, a polysaccharide composed of linear chains of (1–4)-b-D-glucopyranosyl units; its derivatives have unique physical, chemical, and colloidal properties, and an ability to form films. They have been used as edible films and coatings since the 1980s [211].

Cellulose-based materials are very efficient oxygen and hydrocarbon barriers, and their water vapor barrier properties can be enhanced by the addition of a lipid [212–214]. Fresh eggs are an excellent protein source. Nevertheless, several problems, such as weight loss and interior quality deterioration

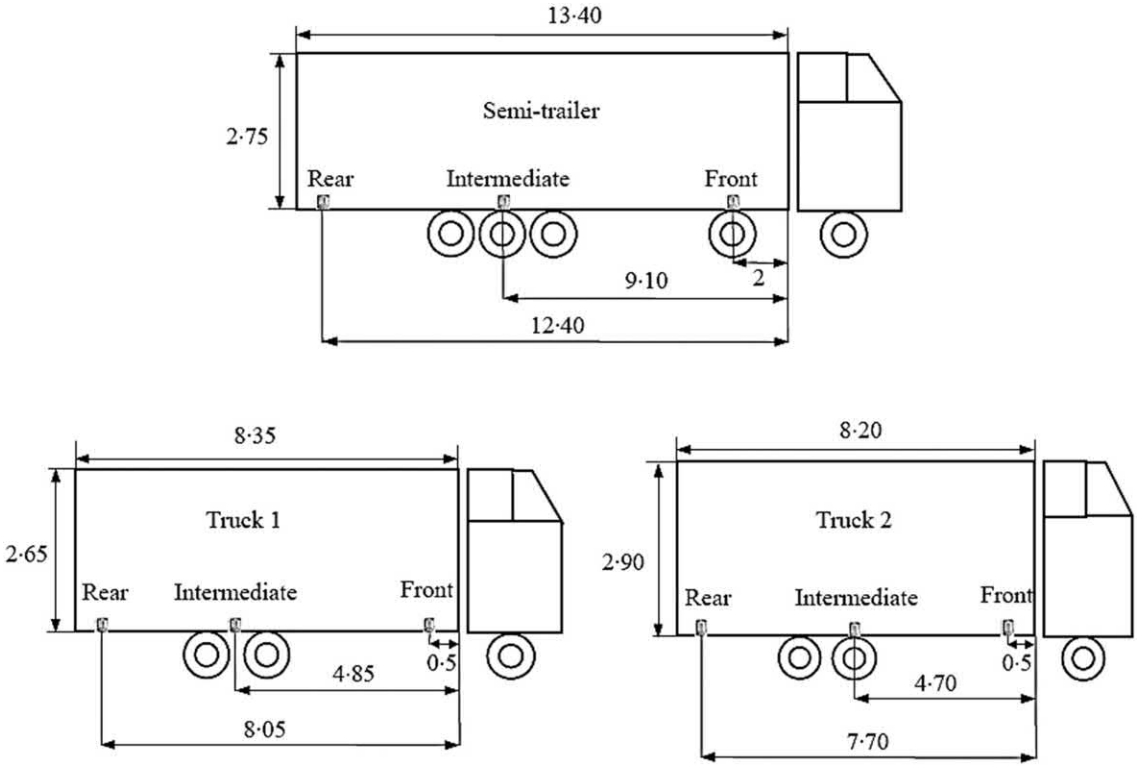

FIGURE 12.9 Geometrical characteristics of the vehicles and positions of the transducers on the floor (all measurements are in m). (From Berardinellu et al. [207].)

encountered during egg storage, have caused major economic losses to the poultry industry [215]. During the storage of eggs, quality deterioration is directly associated with changes in egg white (albumen), yolk, weight, and pH. Meyer and Spencer [216] reported the effects of various coatings, including polyvinyl alcohol, acrylic resin, and zein, on shell strength and egg quality. Herald et al. [217] studied the quality of eggs coated with wheat gluten solution. In a study by Bhale et al. [218], the efficacy of chitosan coating in improving the shelf life of eggs was reported. In addition, Xie et al. [219] stated that eggshells coated with soy protein isolate (SPI), whey protein isolate (WPI), carboxy methyl cellulose (CMC), or wheat gluten (WG) showed greater puncture strength than those of non-coated eggshells. The results showed that edible coatings enhance eggshell breakage minimization. In terms of the bacterial barrier property, it was found that all treatments with these four different coatings significantly reduced post-wash dye penetration into eggs (water, NaOCl, or Na_2CO_3 washed only).

Suppakul et al. [220] reported a methylcellulose (2.00% w/v) and hydroxypropyl methylcellulose (1.00% w/v) based coating was formulated to study the effects of polyethylene glycol-400 (PEG-400). They used a stearic and palmitic acid blend (SPB) on water vapor permeability (WVP) and tensile properties. The efficacy of cellulose-based coating on fresh egg quality during 28-day storage at ambient temperature was investigated in terms of weight loss, pH, and albumen quality. An edible cellulose-based solution was prepared for eggshell coating. A batch of fresh, grade AA 1-day eggs was coated with the cellulose-based coating solution. The other batch consisted of uncoated eggs, which served as the control. This study highlighted the promising use of a cellulose-based coating to enhance the shelf life of fresh eggs.

Another attempt at coating was assessed by Kim et al. [221]. They evaluated the chitosan–lysozyme composite coating on hard-boiled eggs, which exhibited antimicrobial control against *S*. Enteritidis on shell-on eggs. They proposed that chitosan–lysozyme-based coatings may be used to increase microbial safety and extend the shelf life of hard-boiled eggs by reducing post-processing contamination.

12.3.3 Storage Temperature

Chung and Lee [222] sampled eggs from two flocks of different ages (40- and 60-week-old laying hens) in a commercial layer operation immediately after laying and used them for egg quality testing after periods of storage of 7, 14, 21, and 28 days *at* room and refrigerator conditions [222]. Freshly laid eggs from the two age groups did not differ in egg weight, Haugh unit, albumen pH, albumen and yolk weights, or eggshell thickness. Upon incubation at different temperatures and durations of storage, the age of hen did not affect egg weight loss or Haugh unit, but affected yolk and albumen weights. The increase in storage temperature accelerated egg weight loss and reduction in albumen weight but decreased Haugh unit and the pH of albumen. As the storage duration increased, egg weight loss, albumen pH, and yolk weight were increased, but the Haugh unit was lowered. Interaction between temperature and storage duration was noticed in egg weight loss, Haugh unit, and albumen pH. It is concluded that egg quality is more affected by temperature or storage duration, but not by hen age. As the age of hens is an important contributing factor to egg quality, further study is needed to clarify the lack of clear effect of hen age on egg quality which emerged from this study.

12.3.4 Washing Process

Egg washing is currently not permitted within the European Union, with few exceptions. This is mainly because there are concerns that cuticle damage could occur during or after the washing process, as a result of a suboptimal operation. Leleu et al. [223] compared the cuticle coverage levels of 400 washed and unwashed eggs, derived from either a brown or a white egg-laying flock at the end of lay. The eggs from older hens inherently have poorer cuticle coverage and as a result constitute a greater risk to safety when eggs are washed. Thus, the effects of the washing procedure used in this study on cuticle quality were tested under the worst-case scenario. A standard Swedish egg-washing process was used. The cuticle coverage of the eggs was assessed by a colorimeter by quantifying the color difference before and after staining with Tartrazine and Green S. The cuticles of an additional 30 eggs from each of the four groups were then visually assessed by scanning electron microscopy. The staining characteristics of the cuticle varied greatly within each group of eggs and showed that the washing process did not lead to cuticle damage. Scanning electron microscopy confirmed that there was no irreversible damage to the cuticle of the washed eggs and that it was not possible to correctly assign the treatment (washed or not) based on a visual assessment. In conclusion, no evidence could be found to suggest that the washing procedure used in this investigation irreversibly changed the quality of the cuticle.

Chemical washing also affects the microstructural changes of the eggshell [224]. Cetylpyridinium chloride (CPC) solution at 10, 50, or 100 ppm, and trisodium phosphate (TSP) at 0.5, 1.0, or 5.0% were evaluated and eggshell surfaces were examined using scanning electron microscopy (SEM). As the concentration of CPC increased, the eggshell surface became pitted and the cuticle layer became thinner. TSP caused the cuticle layer to fissure and flake, and even cuticle-free areas were observed at 5.0%. When the porosity of eggs was measured using the blue lake staining method, there were significant differences between control and TSP- or CPC-washed eggs as observed by SEM. These results suggest that depending on the types of chemicals used in the wash water, different microstructural changes occur in eggshell surfaces, and the more damaged eggshell surfaces allow more bacterial penetration.

12.3.5 Packaging

Zabaniotou and Kassidi [225] presented the application of life cycle assessment (LCA) for the comparison of two egg

packages, from polystyrene and recycled paper. The input and output streams of mass and energy were examined, and the environmental impacts associated with the two systems were analyzed. The application of LCA using Eco-Indicator 95 has made possible the comparison of the environmental impacts of two egg packages. The results of this LCA study are discussed and it is revealed that the PS packages contribute more to acidification potential, and winter and summer smog, while recycled paper egg packages contribute more to heavy metal and carcinogenic substances impact. Nevertheless, it seems that paper egg packages have less environmental impact than polystyrene ones with the assumption that the accuracy of the results is limited by the credibility of the European databases used for primary data [225].

12.4 CONCLUSION

The demand for fast, non-destructive, and reliable egg quality assessment techniques motivated the development of the acoustic or optical method. However, promising results are available from the lab-scale experiments, but commercial applications did not emerge significantly [18, 19]. The classic approaches like measuring Haugh units or shell breaking force are destructive tests and not suitable for large-scale application. The dynamic stiffness of an egg or optical absorption at a given wavelength is still not in use. However, it might not be good practice to always mimic the older destructive methods such as breaking strength with a new technique and report results in terms of the older standard units. This is certainly the case if the old technique measures something that is only moderately correlated with the desired characteristic (e.g. non-destructive deformation as related to the number of broken eggs in practice). If, however, the old reference is in principle a good measure of the desired characteristic but is time-consuming and/or destructive, then mimicking those older reference methods with new, fast, and non-destructive methodology can still be of interest.

A fast and non-destructive quality assessment tool together with modern information technology has multiple advantages that reach far beyond the classical grading step in the total egg production chain. In the packing plant, such fast technologies allow for measuring the quality of an individual egg instead of estimating the quality by sampling some eggs out of a large batch. This allows for a very concise and rapid tracking of batch quality. Moreover, these techniques allow for measuring more quality attributes and thus can guarantee a better overall quality of each individual egg. The data that are gathered from such packing plants about several quality attributes can be fed back to egg producers by means of modern information technologies. This allows the producer to track the quality of the delivered eggs, and eventually to trace anomalies within hours. As an example, it is proven that the dynamic stiffness of an egg is impaired by heat stress.

It has been shown that a long list exists of techniques that can be used to grade eggs. Some of them are used already on commercial grading machines. The possibilities of other techniques have to be explored more in detail before they become of real commercial value. The price to implement other techniques is too high or the computer time needed for the measurements is too long, and hence more development is needed to solve these problems. An interesting idea for the scientists involved in the development of these techniques is to use combinations of different non-invasive techniques to define the risk that an egg can be dangerous for the consumer's health. Before this will be possible, we have to be able to make more links between the inner content of the egg and the bacterial defense mechanisms present in the egg. Another challenging concern which leads to economic losses of poultry eggs is damage caused by vibrations and impacts during shipment. The road roughness, distance, and traveling speed, load, and some characteristics of the truck influence the vibrations due to transportation.

Part II

Preservation of Minimally Processed Foods

13 Minimal Processing of Fruit and Vegetables

Conrad O. Perera

CONTENTS

13.1 INTRODUCTION

In recent years, the demand for high-quality fruit and vegetables has increased considerably around the world due to the health consciousness of consumers. Minimally processed fruit and vegetables (MPFV) possess fresh-like quality characteristics of flavor, texture, color, and aroma, and these are convenient to use [1]. Other terms used for the minimally processed produce are fresh-cut, lightly processed, partially processed, fresh processed, and pre-prepared. MPFVs are also important to the foodservice industry, such as restaurants and catering companies, as they offer many advantages (i.e. convenience, low cost, savings in labor, and high hygiene levels) over traditional products. Despite its popularity, the production of minimally processed products is limited due to their rapid deterioration and senescence (natural aging leading to death of the tissues). Hence minimally processed produce is more perishable than its unprocessed raw materials [2], since nutrients are easily available to the microorganisms, and reactants are more prone to interact with each other.

The minimal processing of fruit and vegetables generally involves washing, peeling, slicing, or shredding before packaging and storage at low temperatures. All these steps have an effect on the nutrients, shelf life, and quality of the prepared products [2, 3]. Examples of these products already on the market include packaged shredded lettuce/cabbage/carrots, cut fruit and vegetable salads, and peeled/sliced potatoes/carrots, and broccoli and cauliflower florets. More recently, tropical fruits such as peeled, cut, and sliced mango, pineapple, papaya, watermelon, jackfruit, and durian segments have appeared on the market as minimally processed products [4, 5].

Minimal processing of raw fruit and vegetables should serve two purposes. The first purpose is the importance of freshness of the products with nutrition quality and convenience of use. Second, the product should have a shelf life sufficient to make distribution feasible within the region of consumption. The shelf life of minimally processed fruit or vegetables, in terms of microbiological, sensory, and nutritional quality, should be at least 4–7 days, but preferably even longer. The producers and distributors demand increased

product safety. MPFV products are highly perishable, thus preservation actions are important in making the products safe. Technologies that allow for a two- or three-fold extension of the shelf life are important to reduce the food losses. In order to produce minimally processed fruit and vegetables with a longer shelf life, good safety considerations, cleaning, peeling, cutting, and packing are usually carried out in centralized locations.

Minimally processed produce is often less stable due to the enzymatic activity of the cut cell walls and also to bacteriological contamination from handling during treatment. Various postharvest treatment methods are employed to increase the biological stability and to extend the shelf life of products. In all these treatments, low temperatures and good hygiene practices are essential to maintain food safety and to achieve the desired shelf life.

Contamination of fruit and vegetables in the field and unhygienic handling practices are sources of human infection and illness. Irrigation water must not be contaminated, raw manure should not be used as fertilizer, and sanitation facilities should be provided for field workers. The trucks used for transportation should be cleaned especially if animals are also shipped in them. The use of clean ice and refrigerated trucks is recommended. Once produce is harvested, the dirt should be cleaned off with water maintained at the proper temperature to prevent contamination [6]. The use of chlorinated water (200 ppm chlorine) in the packing line is recommended. For MPFVs that are usually eaten raw, there is no treatment that can be relied on for the total elimination of the contaminating microorganism. However, the risks of contamination could be minimized by adhering to Good Manufacturing Practices (GMP) and food safety plans based on hazard analysis critical control points (HACCP) [6].

13.2 PHYSIOLOGICAL RESPONSES AND BIOCHEMICAL CHANGES

Fruit and vegetables are living organs of plants that continue to respire after harvest. Plant tissues incur damage during minimal processing but remain raw and still living after processing. The physiology of MPFVs is essentially the physiology of wounded tissue. This type of processing, involving abrasion, peeling, slicing, chopping, or shredding, differs from traditional thermal processing. In the case of MPFVs, the tissue remains viable during subsequent handling. Thus, the behavior of the tissue is generally similar to that of plant tissues that have been wounded or exposed to stress conditions [7].

The rate of respiration and ethylene production markedly increases within minutes of undergoing minimal processing of fresh produce, and essentially a "wound response" is initiated [7]. Both respiration and ethylene production can result in a shorter shelf life for the product. The ethylene can accelerate ripening, softening, and senescence [8], which leads to membrane damage, while the respiration uses energy reserves. Other consequences of wounding are chemical and physical in nature, such as oxidative browning reactions and lipid oxidation or enhanced water loss [7].

Injury-stresses caused by minimal processing result in mechanical rupture of tissues, and cellular decompartmentalization leading to delocalization and intermixing of enzymes and substrates. One such enzyme system is the ascorbic acid oxidase, which oxidizes ascorbic acid to dehydroascorbic acid, which can then further degrade to other compounds leading to browning. Thus nutritional quality such as vitamin C is lost [9]. Therefore, wound-induced physiological and biochemical changes take place more rapidly than in intact raw commodities, and microbial proliferation may be accelerated.

There is little information about the physiology and chemistry affecting minimal processing of tropical fruit and vegetable products. Such information is vital for the extension of the marketing of both fresh and minimally processed products. Pineapple, which because of its morphology is difficult to consume directly, stands out among the tropical fruits that have the potential to be commercialized as ready-to-eat products [10–12]. Recently, ethylene receptor inhibitors such as 1-methylcyclopropene (1-MCP) that retard C_2H_4 biosynthesis have been tested on guavas [13], mangoes [14], and other tropical fruits to extend the shelf life with success [15].

Tropical fruits such as jackfruit, durian, and pineapple are ideal for minimal processing because of their large size and difficulty in peeling. Minimal processing can also ease export by reducing air-freight cost and quarantine barriers, which are related to the compliance with regulations related to fruit pests, particularly fruit flies. Recently it was reported in the International Tropical Fruit Network, about Malaysian exports of minimally processed tropical fruits to various European countries [ ].

13.2.1 Ethylene

Ethylene is a naturally occurring plant hormone that has numerous effects at very low concentrations ($\mu l L^{-1}$) on the growth, development, and storage life of many fruit and vegetables, and ornamental crops [16]. It is produced virtually by all parts of the higher plants, including leaves, roots, flowers, fruits, tubers, and seedlings. The pathway of ethylene biosynthesis elucidated by Adam and Young [17] is now well-documented, and in both wounding and ripening, the pathway is the same. Methionine is first converted to S-adenosyl methionine (SAM) that then gives rise to 1-aminocyclopropene 1 carboxylate (ACC), catalyzed by ACC synthase. The final step is catalyzation by ACC oxidase (also known as the ethylene-forming enzyme), in which ACC is converted to ethylene. In most plant tissues, the level of active ACC synthase determines the rate of ethylene production; however, the mechanism(s) underlying the regulation of ACC synthase gene(s) during plant development is unknown. Both ACC synthase and ACC oxidase transcript levels greatly increase due to ripening and wounding [16]. The biosynthesis pathway is illustrated in Figure 13.1.

Harvested fruits and vegetables may be intentionally or unintentionally exposed to biologically active levels of ethylene, and both endogenous and exogenous sources of ethylene contribute to its biological activity [16]. Figure 13.2 is a

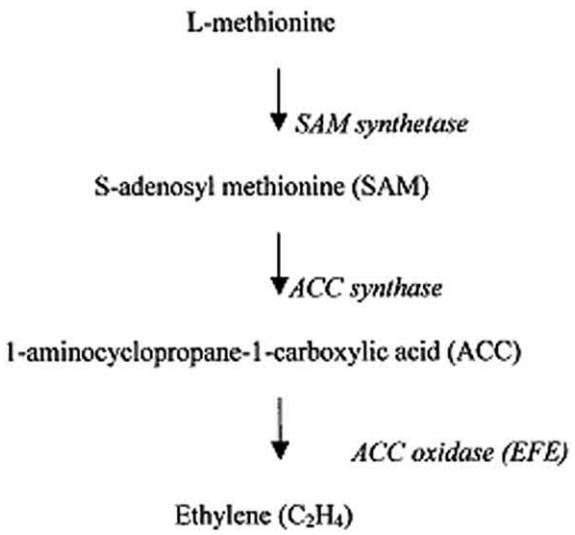

FIGURE 13.1 Simplified diagram of ethylene production in higher plants. (Adapted from Adams and Young [17].)

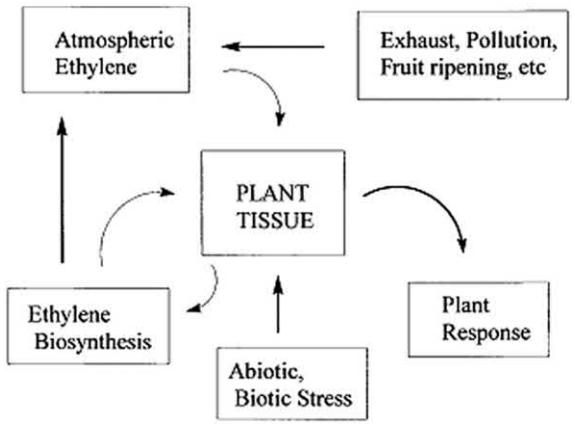

FIGURE 13.2 Ethylene interactions with the plant and its environment. (Adapted from Saltveit [16].)

schematic diagram showing the ethylene interactions between plants and their environment. Endogenous sources of ethylene originate from internal synthesis within plants and fruits, and exogenous sources are from external sources such as engine exhaust, heaters, or ripening fruits. Ethylene production is promoted by stresses such as chilling injury [18] and wounding [19], and this stress-induced C_2H_4 can enhance fruit ripening. Cell wall enzymes, such as exo- and endo-polygalacturonase, β-galactosidase, and pectinmethylesterase, induced by ethylene can digest cell walls, resulting in texture changes [20], and lipoxygenase can degrade membrane lipids [21].

Wounding plant tissues induces elevated ethylene production rates, sometimes within a few minutes, but usually within 1 hour, with peaks usually within 6 to 12 hours [19]. Ethylene produced by the physical action of minimal processing was found sufficient to accelerate softening of banana and kiwifruit and chlorophyll loss in spinach [22]. The ethylene level increases in proportion to the amount of wounding in several fruits and vegetables [7]. Levels of ACC and ACC synthase activity increase the ethylene in tomato, winter squash, and cantaloupe muskmelon [19].

There are various detrimental effects of ethylene on fruits and vegetables. C_2H_4 can cause yellowing of green stem and leafy vegetables [16]. Ethylene from either endogenous production or exogenous applications stimulates chlorophyll loss and the yellowing of harvested broccoli florets [23]. Russet spotting is a postharvest disorder of lettuce in which small brown sunken lesions appear on the leaf. It is caused by the exposure to hormonal levels of C_2H_4 at storage temperatures of around 5°C [24]. Many biotic and abiotic stresses stimulate phenylpropanoid metabolism and the accumulation of phenolic compounds in lettuce [25]. However, even though the level of phenolic compounds is elevated in stressed lettuce, ethylene is still essential for the browning reaction, which is characteristic of the occurrence of russet spotting [26]. The firmness of many ripening fruits and vegetables decreases with C_2H_4 treatment. This is usually beneficial when associated with ripening (e.g. bananas, tomatoes), but if applied for too long, ripening can progress into senescence and the flesh can become too soft. The crisp texture of cucumbers and peppers is lost upon exposure to C_2H_4 [16]. The beneficial effects of C_2H_4 are realized by its application to growing plants in the field and orchards, greenhouses, and harvested commodities [16]. Table 13.1 illustrates some of the beneficial effects of ethylene on the quality of fresh fruits and vegetables.

13.2.2 Respiration

As mentioned earlier, fruit and vegetables are living organs of plants that undergo biological and biochemical activity even after they are separated from their plants. The process known as respiration is a sequence of reactions whereby sugars and other substrates, for example organic acids, are oxidized to carbon dioxide, and water vapor and energy are released [27]. The released energy is utilized to synthesize compounds such as proteins and carbohydrates, which together constitute the tissues of the plant. In general, respiration converts the stored energy into usable energy to sustain life. However, harvested or fresh-cut products detached from the plants have a limited energy supply. Basically, the rate of deterioration of harvested products is proportional to their rate of respiration. Hence, the higher the rate of respiration, the shorter the shelf life [28].

The respiration rate of peeled and sliced ripe kiwifruit is doubled compared to the whole fruits, but ripe bananas were unaffected by peeling and slicing [29]. Wound respiration

TABLE 13.1
Beneficial Effects of Ethylene

Benefit	Ethylene Response
Degreening of citrus	Accelerates chlorophyll loss
Ripening of climacteric fruits	*De novo* synthesis of enzymes that promotes ripening
Defense against pathogens	Induces phenylpropanoid metabolism in wounded tissue

in some plant tissues may be related to alpha-oxidation of fatty acids, which oxidizes fatty acids to CO_2, and is responsible for the CO_2 released after slicing of potato tubers [30]. Respiration in plants is an oxidative degradation of sugars, organic acids, and lipids to produce carbon dioxide and water with the release of energy. Modifying the atmosphere around the product by lowering the amount of oxygen with an increase in the amount of carbon dioxide may lower the metabolism with a decrease in CO_2 production and O_2 consumption. The effects of low O_2 and high CO_2 are additive, but the optimal concentrations of the two gases in the storage atmosphere of fruit and vegetables and even between cultivars of the same species may vary [31]. Due to the high affinity for O_2 of the terminal oxidase enzymes in the electron transport chain located in the mitochondria, the amount of O_2 in the surrounding air must be reduced to below 10%. On the other hand, a change to anaerobic respiration will take place if the O_2 concentration approaches 2% [32]. Although high CO_2 and low O_2 levels in the micro-atmosphere of fresh products may extend their shelf life, off-flavor and off-odor developments may be caused by anaerobic respiration, if the oxygen level falls below the 2% critical level [33].

13.2.3 Oxidative Browning

Discoloration occurs at the cut surface of fruits and vegetables as a result of the disruption of compartmentation that occurs when cells are broken, allowing substrates and oxidase enzymes to come in contact with each other [7]. Wounding also induces the synthesis of some enzymes involved in browning reactions or biosynthesis of their substrates [34]. Thus, browning intensity in diverse tissues and crops can be affected by polyphenol oxidase activities and substrate concentrations [33]. Oxidative browning at the cut surface is the limiting factor in storage of many minimally processed fruits and vegetables [7].

Phenylalanineammonialyase (PAL) is a key enzyme in the synthesis of phenolic compounds. The activity of PAL is increased in lettuce midrib tissue with wounding and storage in the presence or absence of ethylene [34]. PAL catalyzes the first reaction in the biosynthesis of plant phenylpropanoid products. The phenolic compounds can then be oxidized by polyphenoloxidase (PPO), thus brown polymers can be produced that can contribute to tissue browning in lettuce [35].

When fruits such as apples and bananas are cut, the cut surfaces usually turn brown within an hour. On the other hand, it takes several hours for the section of cut or shredded vegetables such as lettuce to turn brown. This time lag is considered to be due to the *de novo* biosynthesis of polyphenols [36]. The lettuce tissues with the highest susceptibility to enzymatic browning are the "white" tissue, or the so-called "midribs." This browning is a major problem, which arises during minimal processing and further storage of lettuce midribs [37]. Russet spotting of lettuce is characterized by the appearance of small, reddish-brown spots or lesions on the midribs of the leaves [25].

Ethylene increases the activities of PAL, peroxidase (POD), and PPO. Hence, there is a correlation between PAL activity and development of russet spotting (RS) in ethylene-treated lettuce midribs. Hyodo et al. [38] found a significant increase in some phenolic compounds such as chlorogenic and isochlorogenic acids in the RS-affected tissue. Increased PAL activity promotes the synthesis of cinnamic acid and their derivatives via the shikimic acid pathway. These compounds are then available for lignin synthesis. Ethylene-induced POD activity is correlated with increased lignin formation and cell wall thickening, one of the characteristics of RS. Flavonoids and chlorogenic acid, the other products of the shikimic acid pathway, are oxidized by PPO to form brown compounds [39].

13.2.4 Nutrient Losses: Ascorbic Acid Oxidation

Fruit and vegetables, either processed or "fresh," are major sources of dietary vitamin C for humans. Before consuming, they have to undergo various handling, storage, and processing steps. The vitamin C content of sliced, cut, or bruised fruits and vegetables may diminish rapidly depending on the handling, processing, and storage conditions used [40]. Ascorbic acid is an organic acid found in fruits and vegetables. It is very soluble in water and is sensitive to alkali, oxygen, and the presence of copper, iron, and heat. Ascorbic acid is often considered to be equivalent to vitamin C content, and dehydroascorbic acid (DHAA), the oxidized form of ascorbic acid, also has vitamin C activity [41]. Further oxidation of DHAA converts it to 2,3-diketogulonic acid, which is devoid of biological activity [42]. Figure 13.3 illustrates the oxidation process of ascorbic acid. The loss of ascorbic acid provides a useful index of oxidative deterioration in minimally processed fruits and vegetables [3].

There are two aspects of ascorbic acids degradation. First, ascorbic acid can be oxidized due to mechanical damage as a result of cutting. When the cells of a fresh product are ruptured as occurs during cutting, chemical reactions are initiated that shorten the storage life of the cut product. The enzyme, ascorbic acid oxidase (AAO), released when the cell walls are damaged, will oxidize the ascorbic acid to DHAA, which can undergo further degradation to produce products that no longer possess vitamin C activity [43]. Ascorbic acid can be oxidized due to the physiological activity of AAO that shortens storage life. The auto-oxidation rate of ascorbic acid to DHAA by air is influenced by metal ion concentration and pH. The rate becomes high in alkaline medium, while acetic acid restrains the influence of Fe^{3+} [44]. Albrecht [45] reported that the whole lettuce lost ascorbic acid during storage. Ku and Wills [46] reported that 1-MCP can delay senescence of broccoli. Agar et al. [47] also reported that removal of C_2H_4 from the storage atmosphere increased retention of total ascorbic acid in kiwi fruit. Tay and Perera [48] found that 1-MCP was effective in reducing the loss of ascorbic acid in lettuce.

13.2.5 Water Loss

Plant tissues are in equilibrium with an atmosphere at the same temperature and relative humidity of 99 to 99.5% [7]. Water loss can occur when there is a reduction of water vapor

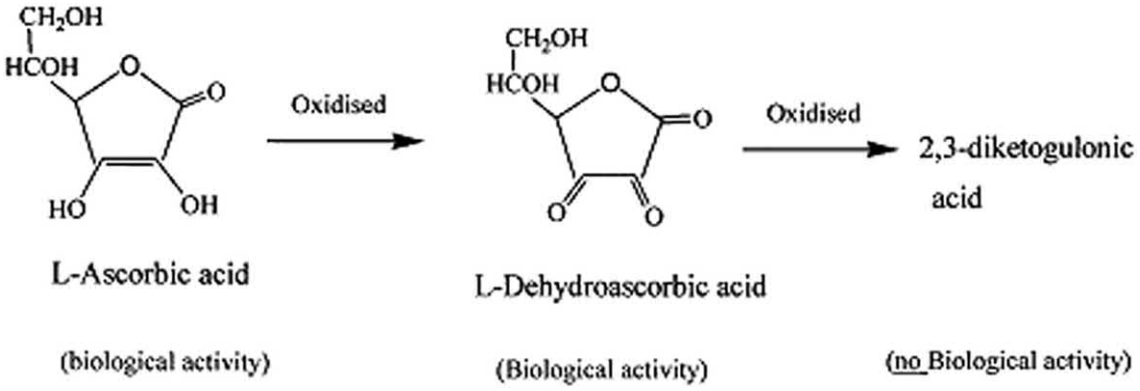

FIGURE 13.3 Oxidation of ascorbic acid.

pressure in the atmosphere surrounding the tissue. In whole fruit or vegetables, water in intercellular spaces is not directly exposed to the outside atmosphere. However, cutting or peeling a fruit or vegetable exposes interior tissues and drastically increases the water evaporation rate [7]. To subsequently maintain the lowest possible water vapor pressure deficit, minimally processed products are routinely handled in packages with a semi-permeable film that has low water vapor transmission rates. Condensation within the package is most severe when the product is at a higher temperature than the storage atmosphere, which is often the case when the product is first placed in the cold-storage room or transport vehicle [7].

13.2.6 Leaf Yellowing in Vegetables

Leaf yellowing is a particularly important quality problem during the transport and storage of fresh or minimally processed green leafy vegetable products. Over the storage period, the leaves could be wrinkled, yellowed, and softened. The decrease in green pigmentation would probably result from the loss of chlorophyll during storage [49]. Tay and Perera [48] found that 1-MCP was effective in retarding storage-induced leaf yellowing in lettuce.

13.3 TECHNIQUES TO EXTEND THE SHELF LIFE

Various approaches are being used to control the undesirable physiological changes that adversely affect the quality of minimally processed products. Refrigeration, humidity control, and dipping in chemical solutions, such as ascorbic acid and calcium, have been used successfully to preserve product quality and enhanced shelf life. Exogenous treatments with calcium chloride ($CaCl_2$) dips were reported to reduce browning and retard flesh softening of vegetables [50]. However, $CaCl_2$ may also cause detectable off-flavors when used at levels higher than 0.5% [51].

Minimally processed products should be refrigerated (0–5°C) to prolong their quality and safety [52]. The removal of C_2H_4 from the storage environment of minimally processed fruits and vegetables can retard tissue softening [52]. Desirable modified atmospheres can be predicted and created within and around commodities by selecting appropriate packaging. Controlled atmospheres can reduce the effects of C_2H_4 on fruit tissues and retard senescence, delay softening, and help to extend the postharvest life [52]. Edible coatings and films are being used successfully with some commodities to provide useful barriers to moisture, O_2, and CO_2 while improving package recyclability [53].

13.3.1 Sanitation

Sanitation is an integral part of minimal processing. Minimally processed fruits and vegetables are essentially damaged tissues. The chances of food pathogens or spoilage organisms' growth in the products are very high. There are three factors that are necessary for foodborne illnesses, namely, the host, pathogen, and exposure [54]. There are no absolute guarantees of the absence of all pathogens in minimally processed products by the current processing methods and technologies. However, a reduction in one or more of the three factors will have a substantial effect in reducing the chances of foodborne illnesses [54]. Considering the growing increase in the consumption of minimally processed and fresh fruit and vegetables in the United States, the FDA sets out clear guidelines to minimize microbial food safety hazards for fresh fruit and vegetables [6]. These guidelines span from "farm to fork" and include Good Agricultural Practices (GAP), Good Manufacturing Practices (GMP), and Hazard Analysis Critical Control Points (HACCP).

Sanitization is unlikely to eliminate completely all pathogens on the produce. Therefore, it is important to use sanitizing protocols that are efficient. The efficacy of the sanitizers used to reduce microbial populations is usually dependent upon the type of treatment, type and physiology of the target microorganisms, characteristics of produce surfaces (cracks, crevices, texture, and hydrophobic tendency), exposure time and concentration of sanitizer, pH, and temperature [55]. Numerous studies have been conducted to evaluate the efficacy and effectiveness of sanitizing treatments on different produce. Researchers have looked into treatments with the use of different sanitizers such as chlorine [55, 56], chlorine dioxide [55–57], hydrogen peroxide [55, 58], and heat [55, 59] as ways to sanitize whole and minimally processed fruits. Most of the research was conducted using fruits such

as apples, oranges, strawberries, and tomatoes, and very little information is available on tropical fruits. Working with tropical fruits, Kiang and Perera [55] showed that the efficacy of sanitization treatments depends on the type of produce and characteristics of produce surfaces. The efficacy of sanitizer treatments on guava, star fruit, and pineapple is shown in Figures 13.4, 13.5, and 13.6. Research has demonstrated that an increase in microbial populations on minimally processed products can have an adverse impact on shelf life: the higher the initial microbial load, the shorter the storage life [56]. While psychotropic Gram-negative rods are the predominant microorganisms on minimally processed products, the primary spoilage organism on prepackaged salads appears to be the fluorescent pectolytic pseudomonads [60].

Washing of fresh fruits and vegetables before cutting is important to control initial microbial load, including mesophilic microflora, lactic acid bacteria, coliform, fecal coliforms, yeasts, molds, and pectolytic microflora [61]. Minimally processed products are generally rinsed in 50–200 ppm chlorine or 5 ppm of chlorine dioxide, which may also aid in reducing the browning reactions [56, 62]. However, product safety, not shelf life, is the critical sanitation issue in minimally processed fruits and vegetables [62].

13.3.1.1 Chlorine

Chlorine is one of the most widely used sanitizers for the cleaning and washing of minimally processed products. Most processors use a concentrated form of liquid bleach (sodium hypochlorite), although solid calcium hypochlorite or chlorine gas may also be used. However, chlorine gas is difficult to handle, and solid granules of calcium hypochlorite need to be dissolved, which requires additional labor. Free chlorine is an excellent disinfectant; as little as 1 ppm free residual chlorine will sanitize cold process water at a pH of 6.5 to 7.0 [63]. However, it is not effective against *Cryptosporidium* and *Giardia* [64]. Water pH has a significant impact on chlorine activity. At pH values below 5, chlorine gas may be formed and higher levels of free chlorine may cause irritation in workers' lungs and skin. pH values below 6 may cause product discolorations, increase equipment corrosion, and promote the formation of volatile chloramines that may account for health hazards [65]. Also, the chlorination of some organics such as phenols not only results in toxic end products such as chlorophenols but also can impart undesirable tastes and odors to the product treated. However, to date there are no known human health hazards associated with chlorine or chlorine dioxide at the recommended use levels of the two sanitizers [66].

13.3.1.2 Ozone

Ozone has strong oxidizing power and is capable of inactivating microorganisms effectively. To date, there are no indications of adverse human health or environment effects of water ozonization [60, 65]. However, at moderate concentrations, browning reactions may be enhanced in minimally processed products. Ozone finds applications in natural disinfection, water, air purification systems, and fresh fruit and vegetable storage. Recent findings show that ozonized water maintains the quality and flavor of fruits [66]. The off-smell of chlorinated water is absent in ozonized water. (Cl can be detected by humans down to 0.5 ppm, and by some even at 0.25 ppm.)

Ozone is unsurpassed in natural control and killing of common bacteria like *Escherichia coli*, fecal coliforms, molds, and viruses and deactivation of cysts and parasites. It attaches and destroys by oxidation any offending molecule that gets in its path. It rapidly decomposes, leaving no traces of oxidation and does not produce any toxic halogenated compounds.

Chlorine can take minutes or even hours to penetrate the cell walls of bacteria or virus, while activated ozone oxidation occurs within seconds. Unlike chlorine, it does not produce trihalomethanes or chloramines and is non-carcinogenic. There is no evidence of any deaths to humans from over exposure to ozone. Ozone oxidizes organic chemicals into safer elements. During the ozonization process, some compounds like cyanide [67] and ammonia [68] are broken down into nitrogen and water or other safe compounds.

In all reactions, the main by-product after oxidation is O_2. Ozone does not change the pH. Ozonated water is free of algae, bacteria, cysts, mold, viruses, yeast, and parasites. It does not cause an after-taste, and ozonated water is softer with less scale build-up in appliances and plumbing lines. It does not stain plumbing fixtures or cause tub rings. It oxidizes organics, iron, heavy metals, and other contaminates. Water without chemicals or offensive chlorine and sulfur odors is possible with ozone.

13.3.1.3 Electrolyzed Water

Electrolyzed water (EW) has gained popularity as an effective broad-spectrum sanitizer over the last few decades. It has been tested for its bactericidal, fungicidal, and viricidal potential. It is produced by electrolysis of water containing a dissolved electrolyte such as sodium chloride (NaCl). In a water electrolysis plant, the typical cell voltage of 1.8–2.0 V at an operating current density of 100–300 mA cm^{-2} is considerably higher than the equilibrium voltage of 1.23 V [69]. Upon the onset of the electrolysis process, NaCl dissociates into positively and negatively charged ions (Na^+ and Cl^-, respectively). Meanwhile, hydroxide (OH^-) and hydrogen (H^+) ions are also formed in the solution. The negatively charged ions (OH^- and Cl^-) move toward the anode where electrons are released, and hypochlorous acid (HOCl), hypochlorite ion (−OCl), hydrochloric acid (HCl), oxygen gas (O_2), and chlorine gas (Cl_2) are generated. However, positively charged ions (Na^+ and H^+) move toward the cathode where they gain electrons to produce sodium hydroxide (NaOH) and hydrogen gas (H_2) [70]. Two types of EW are generated simultaneously. At the anode, an acidic solution with a pH of 2–3 and oxidation–reduction potential (ORP) >1100 mV and available chlorine concentration (ACC) of 10–90 ppm is produced. This solution is referred to as acidic electrolyzed water (AEW) or electrolyzed oxidizing water (EOW). Meanwhile, at the cathode, a basic solution with a pH 10 to 13 and ORP of –800 to –900 mV is produced, and this solution is termed basic electrolyzed water (BEW). Neutral electrolyzed water (NEW) is produced by mixing the anodic solution with OH− ions or by using a single-cell unit (without diaphragm) from NaCl or HCl [70], whereas slightly acidic electrolyzed water (SAEW) is produced by electrolysis of HCl alone or in combination with NaCl in a single-cell unit without a diaphragm [71].

The main reason for the popularity of EW is the simplicity of its production and application. The acceptance of EW as a sanitizer is evident from its use in a number of applications in various fields including agriculture, medical sterilization, food sanitation, livestock management, and other fields that employ antimicrobial techniques [72]. EW has been used in Japan for several years as an antimicrobial agent. It exhibits antimicrobial activity against a variety of microorganisms. It is active against most common types of viruses, bacteria, fungi, and spores within 5 to 20 sec in food products, food processing surfaces, and non-food surfaces [73, 74]. Various studies have been conducted on the antimicrobial activity of EW on the surfaces of different products including food-handling gloves [74], cutting boards [75], shrimp [76], fish [77], beef [78], pork [79], poultry carcasses [77], fruits [80], and vegetables [81]. Acidic electrolyzed water (AEW) is effective against Listeria even at refrigerated temperatures. AEW and Cl exhibit the same bactericidal effect against Listeria with a 1.2 and 1.6 $\log_{10}$ CFU/g reduction after 5 seconds as compared to the number recovered from unwashed peaches [80]. Recently Rahman and others [82] reviewed the current trends and future prospects of electrolyzed water as a novel sanitizer in the food industry. They concluded that EW is a sustainable green concept and has several advantages over traditional cleaning systems, including cost-effectiveness, ease of application, on-the-spot production, and safety to human beings and the environment.

13.3.1.4 Chlorine Dioxide

Chlorine dioxide-based sanitizer has strong oxidizing properties and is efficient at killing microorganisms. Due to its true oxidizing characteristics, there is no residue to affect the quality of the food. It is non-toxic, low-corrosive, and pH-independent. Unlike chlorine, it does not combine with organic compounds to form toxic chlorinated compounds and does not react with ammonia. The product formulation is comprised of biodegradable compounds, which break down after use to form natural substances. It is approved for food use, by the US FDA, USDA, and Environmental Protection Agency (EPA) [64]. The killing power of a sanitizer is expressed as the product of the concentration C (mg/L) and time t (min) of exposure of the sanitizer to the microorganisms concerned. Table 13.2 illustrates the relative killing power (Ct) of chlorine dioxide, chlorine, and ozone on the common water-borne microorganisms, *Giardia*, *Cryptosporidium*, and viruses [64].

13.3.2 1-Methylcyclopropene (1-MCP)

The chemical 1-methylcyclopropene (1-MCP) is currently formulated as SmartFresh™, a powder having 3.8% of the active ingredient for postharvest use in fruits and vegetables and EthylBloc™ for the use in flowers. SmartFresh™ liberates the active 1-MCP when added to water and is stable in its powder form. The chemical structure of 1-MCP is shown in Figure 13.7. Acute toxicity, mutagenicity, and product chemistry studies conducted on the SmartFresh™ formulation indicate that the toxicology profile is acceptable. In addition, 1-MCP has a

TABLE 13.2
Required Ct Values (mg min/L) for Inactivation of Pathogenic Microorganism in Water

	Inactivation Level (Log)	ClO_2	Cl_2	O_3

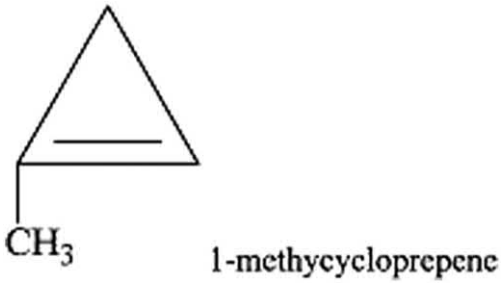

FIGURE 13.7 Structure of 1-MCP.

non-toxic mode of action, is applied at extremely low parts per billion dose levels, and has no exception of measurable residues in food commodities. The EPA has classified 1-MCP as a plant regulator structurally related to plant-containing materials. Watkins [83] recently reviewed the status of 1-MCP and stated that EPA registration was granted for flowers in April 1999, and in 2002 it was approved for use in apples. It is currently approved for use in over 42 countries, and according to Agrofresh, the manufacturers of SmartFresh™, it also provides better firmness maintenance for highly ethylene-sensitive fruits like plums and persimmons [84]. In 2015, EPA [85] approved a new 1-MCP technology for use in fruits.

1-MCP is a cyclic olefin, analogous to the photodecomposition product of diazocyclopentadiene (DACP), and, to date, is the most useful compound among recently developed inhibitors of ethylene response. 1-MCP is a gas at room temperature, has no obvious odor at required concentration levels, and is non-toxic. It is relatively stable in dilute gas phase for several months [86], but is unstable in the liquid phase, polymerizing even at low refrigerator temperatures [87].

Autocatalytic ethylene production requires up-regulation, by ethylene, of ACC synthase and ACC oxidase activity [88]. Lelievre et al. [89] demonstrated that treatment with 1-MCP resulted in reduced accumulation of ACC synthase/oxidase transcripts and ethylene production in pears, during chilling. Presumably, 1-MCP competitively binds to a metal in the ethylene receptors involved in feedback regulation and consequently blocks the ability of ethylene to up-regulate. However, in the case of wounding whereby ethylene production is not autocatalytic, another mechanism must operate in order for 1-MCP to reduce ethylene synthesis. 1-MCP is capable of allene-type arrangement, which probably is a crucial factor when binding occurs [90]. The affinity of 1-MCP to the receptor is about ten times that of ethylene [91]. Once 1-MCP is bound to the ethylene receptor, ethylene binding is impossible and therefore fails to elicit its subsequent actions on the tissue.

1-MCP provides protection for a longer period of time than other potential ethylene inhibitor compounds [92]. It acts at concentrations of 0.5 nLL^{-1}, and the effect is prolonged. 1-MCP has been reported to delay or reduce ethylene-induced effects on senescence in a variety of potted flowering plants and cut flowers [93–95]. The effects of 1-MCP on fruits and vegetables include inhibiting the ripening of tomatoes [96], delaying senescence of eggplant [97] and broccoli [98], inhibiting the yellowing of cut lettuce [48], extending the firmness and shelf life of minimally processed apples [99], and degreening of mandarin oranges, while not suppressing other ethylene-induced effects such as chilling injury [100]. Also, after treatment, tomatoes, bananas, and other plant materials were found to have no response even to very high amounts of ethylene [87].

1-MCP reduces ethylene synthesis and respiration rate and thus decreases the activities of phenylalanineammonialyase (PAL) [101]. PAL is a key enzyme in phenolic synthesis. The phenolic compounds can then be oxidized by polyphenoloxidase (PPO), producing brown polymers that can contribute to tissue browning in lettuce [26]. Fan and Mattheis [102] reported that short-term 1-MCP treatment prevents the development of RS and isocoumarin accumulation in iceberg lettuce. The russet spotting (RS) level was also lowered in 1-MCP-treated lettuce [48]. This indicates that ethylene is important for the development of RS in lettuce.

13.3.3 Edible Coating

Coatings of fruits and vegetables have been known for many years [103]. Edible coatings are generally made from one or more of four major types of materials: lipids, resins, polysaccharides, and proteins [104]. Coatings made from polysaccharides (cellulose, pectin, starch, alginates, chitosan, carrageenan, gums) are generally good barriers and adhere well to cut surfaces of fruits or vegetables, but their hydrophilic nature makes them poor barriers to moisture [48, 105].

Almost all minimally processed fruits have all or part of the peel or outer protective coating removed. This allows the entrance of spoilage organisms and dehydration of the fruit's tissues. Dehydration may be partially responsible for some of the softening that is observed in minimally processed fruit products. The use of edible coating or plastic packaging is necessary to retard moisture loss by providing a barrier to water vapor resulting in a high relative humidity environment, as well as to minimize microbial contamination [105].

Attempts have been made to control leakage from minimally processed (peeled) grapefruit segments with an edible coating of calcium alginate, with varying levels of coating firmness. The coatings effectively enhanced the firmness

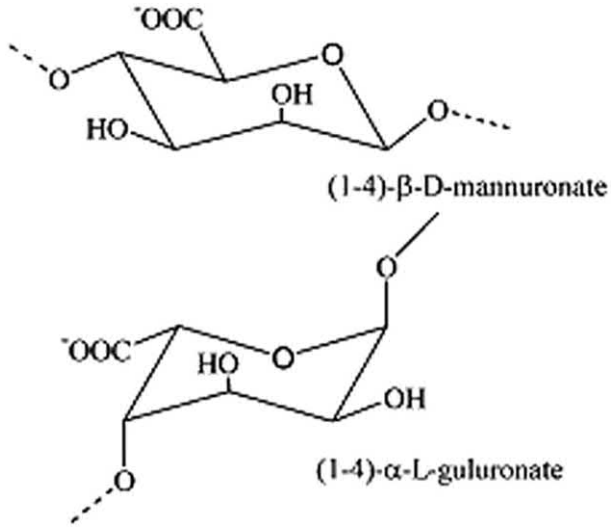

FIGURE 13.8 The alginate monomer units.

of segments, but the effects on fluid loss were negligible. An 89% increase in tissue firmness was accompanied by only a 16% decrease in fluid loss [106]. Alginate is a group of naturally occurring polysaccharide (MW ~240,000) isolated from brown seaweed composed of D-mannuronic acid and L-guluronic acid subunits [107]. Figure 13.8 shows the alginate monomer unit. It is a non-toxic and biodegradable polymer that can be used in food [108]. Sodium alginate and polypropylene glycol alginate are commonly used as thickeners in foods such as ice cream and fruit-filled snacks [109]. Alginates form gels with a number of divalent cations [110]. For food purposes, calcium is particularly suitable because of its non-toxicity. Figure 13.9 illustrates water-soluble sodium alginate polymer cross-linked with Ca^{2+} (long chains are interconnected) to form flexible, translucent gels. The longer the calcium alginate polymer is in contact with the calcium chloride solution, the more rigid the gel will become [107].

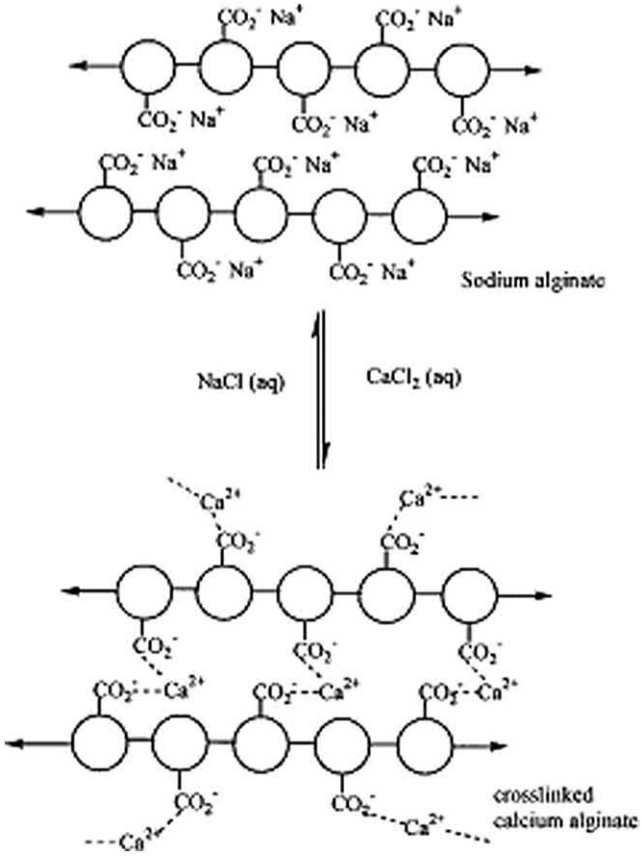

FIGURE 13.9 Alginate polymer in NaCl or $CaCl_2$ solution. (From Perera et al. [112].)

13.3.4 Firming Agents

Treatments with $CaCl_2$ dip have been reported to reduced browning and flesh softening of vegetables [50]. Tay and Perera [48] found that the calcium alginate-coated lettuce had pronounced improvement in crispiness. The thin calcium alginate edible coating retards moisture loss and prevents dehydration that may be partially responsible for some of the crispiness. However, the calcium alginate-coated lettuces were more likely to suffer bruises during the coating process. Hence this may be the reason why the reduction in browning was not so significant. Izumi and Watada [50] reported that exogenous treatments with calcium chloride ($CaCl_2$) dip reduced browning and retarded flesh softening of vegetables. The alginate-coated lettuces were dipped in $CaCl_2$ solution for a cross-linking reaction. Hence the $CaCl_2$ could also be responsible for the crispness. Dipping times ranging from 1 to 5 min have been used in most of the published work [111]. Different calcium salts have been studied for decay prevention, sanitation, and enhancement of the texture of minimally processed fruits and vegetables. Calcium lactate, calcium chloride, calcium phosphate, calcium propionate, and calcium gluconate are often used when the objective is the preservation and/or the enhancement of the product firmness. The selection of the appropriate source depends on several factors. Solubility, flavor change, and interaction with food ingredients are the most significant ones. The concentrations of the calcium salts used usually ranged from 0.5 to 3%, and dipping time ranged from 1 to 5 minutes as mentioned in most of the published work [111].

13.3.5 Intelligent and Active Packaging

Minimally processed fruit and vegetables are commonly packed in perforated plastic boxes or plastic bags. In addition, active packaging technologies can also be incorporated. Active packaging technologies include some physical, chemical, or biological action, which changes the interactions between the package, product, and headspace of the package in order to achieve the desired outcome [113]. The most common active packaging systems act to scavenge oxygen from the package, and they may even be activated by an outside source such as UV light [114]. Active packaging is typically found in two types of systems: sachets and pads which are placed inside the packages, and active ingredients that are

incorporated directly into the packaging materials. Sachets were developed in Japan in the late 1970s for scavenging oxygen from the headspace of packages. The principle is essentially the process of rusting, where ferrous oxide is oxidized to ferric oxide in the presence of KCl used as a catalyst. Similarly, a carbon dioxide absorber was made from hydrated lime [$Ca(OH)_2$]. When carbon dioxide comes in contact with this material, it forms a precipitate of calcium carbonate, and the CO_2 in the headspace is reduced.

Small amounts of ethylene can trigger many chemical reactions and impart ripening and senescence in fruit and vegetables. A number of catalytic oxidizers have been combined with adsorbents to remove ethylene from air. Examples include potassium dichromate, $KMnO_4$, iodine pentoxide, and silver nitrate, each respectively on silica gel. A novel palladium-promoted material with a significant ethylene adsorption capacity at room temperature has recently been patented [115]. Catalytic oxidation of ethylene by $KMnO_4$ is one of the most commonly used ethylene-scavenging processes. In one system known as "BioSwitch" [116], an antimicrobial agent is released on command when bacterial growth occurs. The basic concept is that when a change in the environment such as pH, temperature, or UV light occurs, the antimicrobial responds accordingly.

13.4 HARVESTING AND HANDLING OPERATIONS

Harvesting and handling are important operations in extending the shelf life of minimally processed fruit and vegetables. Major factors involved include (i) careful harvesting so as not to injure the product, (ii) harvesting at optimal horticultural maturity for intended use, (ii) rapid removal of "field heat," (iv) sharp cutting methods to cause minimal cell disruption, (v) maintenance of low temperature throughout, and (vi) good sanitation practices. When these are practiced, the implementation of optimum storage conditions through modified atmospheres can be quite effective at maximizing the shelf life and quality of the product.

Harvesting should be done in such a way as to minimize any bruising or injuring of the tissues of fruits and vegetables, which might raise the respiration rate and, thus, reduce the shelf life. A number of studies have shown that a drop as small as 10 cm could cause bruising injuries in some fruits [117–119]. The maturity of the fruit or the vegetable at harvest is very important. As a general rule of thumb, vegetables are harvested when they are tender, that is, in their early growth period when lignification of the fibers has not occurred, e.g. carrots, beans, peas, and asparagus. At this stage of maturity, most of the common vegetables contain the highest amount of soluble sugars, and these are tender, sweet, and flavorful and contain the maximum amount of nutrients, such as vitamins and minerals.

On the other hand, fruits are harvested when they are fully mature, but unripe. At this stage of maturity, they carry the maximum amount of nutrients and develop the flavor, color, and texture when they undergo ripening with which all of us are familiar. If harvested at the ripe stage, the fruits will be soft and will be difficult to handle and transport. Therefore, the optimum stage of maturity of harvest is required for each fruit and vegetable. Once harvested, the produce needs to be cooled as rapidly as possible to remove the "field heat." Otherwise, the temperature within the stack of fruit or vegetables can increase the rate of respiration and cause the produce to deteriorate rapidly. Field heat can be removed by one of several methods. Hydro-cooling by immersion in cold water is one method of cooling rapidly, but it may not be suitable for certain types of fruits and vegetables. Certain fruits (e.g. golden delicious apple) that have tiny passages opened to the interior of the fruit from the calyx end provide a pathway from outside to the interior of the seed cavity. Fruits washed by the immersion method could get infected when contaminated water gets inside the fruit through these passageways [120]. In order to avoid such undesirable happenings, the wash water should be at a higher temperature than the fruit. Thus, good sanitary practices are important when handling fresh fruit and vegetables for minimal processing.

Air cooling is probably the ideal, as it does not lend itself to possible contamination as discussed above. In air cooling, it is important to maintain a high level of relative humidity of the cooling air. Otherwise, it may lead to desiccation of the product and a possible economic loss to the producer. Another important aspect is to choose the right varieties of produce for minimal processing. For example, certain apple varieties have a higher tendency to brown (browning potential) than others [121, 122]. Therefore, those varieties that have lower browning potential are used to minimize browning changes during processing and storage.

The sharpness of cutting blades significantly affects the shelf life of minimally processed products. Dull knives could damage and bruise several layers into the product tissues and could cause extensive cell damage. Consequent physiological and chemical changes could result in loss of texture, color, and susceptibility to the growth of microorganisms [52]. The maintenance of low temperatures is another critical factor in extending the shelf life of minimally processed products. The fruit and vegetable tissues that have been peeled, cut, sliced, or grated essentially contain damaged cells, which cause elevated respiration rates. Therefore, it is most essential that the cut products are chilled at temperatures as low as possible to reduce the rate of respiration and control biochemical and microbial activity.

It is well-known that the shelf-life of some tropical and sub-tropical fruits and vegetables can be limited by chilling injury, a disorder induced by low (0–4°C) but non-freezing temperatures. The extent of chilling injury is influenced by temperature, duration of exposure to a given temperature, and chilling sensitivity of the particular fruit or vegetable. The symptoms of chilling injury may not be evident while produce is held at chilling temperatures, but they become apparent after transfer to higher temperatures [123]. The susceptibility to chilling injury in tropical fruits may only manifest in whole or unprocessed products as has been observed during the storage of pineapple at 8°C [124], papaya at 10°C [125], durian at 15°C [5, 126], and jack fruit at 10°C [127]. However, there was

no chilling injury reported in minimally processed pineapple [128] and durian [126] during storage at 2°C and papaya and melon stored at 4°C [129].

13.5 FOOD SAFETY REGULATIONS

The natural protection offered by the peel/skin of the fruit is generally lost due to peeling, cutting, and slicing operations on minimally processed products. Hence, the product becomes highly susceptible to microbial spoilage [130]. If the sanitation of the whole fruit is not properly carried out, cross-contamination may occur during the minimal processing operations. Leakage of cell sap from the damaged tissues allows the growth of some species of yeasts such as *Saccharomyces cerevisiae* and *Saccharomyces exiguous* [131]. The damaged plant tissues increase their susceptibility to contamination with human pathogens.

Regulatory initiatives specific to minimally processed products are still under development in many countries, although the United States and most European countries already have relevant regulations. Most of them limit the counts of aerobic microorganisms to 10^6 CFU/g at the expiry date of the product. In addition, pathogenic microorganisms are not permitted or are greatly restricted (*E. coli*, *Listeria monocytogenes*) in ready-to-eat meals prepared from raw vegetable products [130].

13.5.1 Regulatory Requirements

The current regulatory requirements for minimally processed produce and Current Good Manufacturing Practice requirements for foods (CGMPs) are stipulated under Code of Federal Regulations Title 21 Part 110 [132]. These regulations establish CGMPs in manufacturing, packing, and holding human food. However, "raw agricultural commodities (RACs), as defined in section 201(r) of the Federal Food, Drug, and Cosmetic Act (the Act), are not subject to the CGMP requirements by virtue of the exclusion in 21 CFR 110.19. Section 201(r) defines a raw agricultural commodity as any food "in its raw or natural state." Fresh-cut fruits and vegetables are not RACs because they are no longer "in [their] raw or natural state" and instead have become "processed food" as that term is defined in the Act. Section 201(gg) of the Act defines a "processed food" as "any food other than a raw agricultural commodity and includes any raw agricultural commodity that has been subject to processing, such as canning, cooking, freezing, dehydrating, or milling." Under 21 CFR 110.3, the definitions in section 201 of the Act apply to Part 110. Thus, fresh-cut fruits and vegetables are appropriately considered "processed foods" and are subject to the CGMPs in Part 110. The conclusion that fresh-cut produce are not RACs is consistent with the preamble to the proposed revisions to the CGMP regulation (44 FR 33238 at 33239, June 8, 1979), which states, when discussing the exclusion for RACs, that such products may be excluded because "food from those commodities is … brought into compliance with the Act at the later stages of manufacturing, processing, packing, or holding." The CGMPs establish food safety practices applicable to processors who manufacture, process, pack, or hold processed food. The FDA believes that the recommendations in this guidance complement the CGMPs by suggesting "more specific food safety practices for processors of fresh-cut produce" [133].

Guidelines for microbial examination of ready-to-eat foods are given by Food Standards Australia and New Zealand [134]. The standard plate count (SPC), also referred to as the aerobic plate count or the total viable count, is one of the most common tests applied to indicate the microbiological quality of food. The significance of SPC, however, varies markedly according to the type of food product and the processing it has received. SPC is not applicable to foods such as fresh fruits and vegetables (including salad vegetables), fermented foods, and foods incorporating these (such as sandwiches and filled rolls). It would be expected that these foods would have an inherent high plate count because of the normal microbial flora present. For minimally processed products *Escherichia coli* should be less than 3 CFU/g and pathogenic strains of *E. coli* should be absent. In addition, the limits for the following pathogens are: Coagulase +ve staphylococci should be less than 10^2 CFU/g, *Clostridium perfringens* less than 10^2 CFU/g, *Bacillus cereus* and other pathogenic *Bacillus* spp. less than 10^2 CFU/g, *Vibrio parahaemolyticus* less than 3 CFU/g, *Campylobacter* spp. not detected in 25g, *Salmonella* spp. not detected in 25g, and *L. monocytogenes* not detected in 25g [134].

In New Zealand, the latest Food Act has been passed to cover minimally processed food products. From 1 March 2016, there is a mandatory requirement for processors of minimally processed products to implement a Food Control Plan (FCP) and a National Program 1 [135]. If it is a new business, then they need to implement these requirements now, but if it is a continuing business, then they have until 31 March 2017 to implement them.

13.6 CONCLUSION

Minimal processing is a growing processing trend, which offers consumer convenience, "freshness" of quality, nutrition, and safety. Because it involves removing or reducing the natural barriers to respiration and deterioration, it offers scientists an enormous challenge in trying to extend the shelf life of minimally processed fresh produce. However, the consumer demand for minimally processed products and changes in the perceptions of consumers of the "freshness" of quality of fresh produce and the convenience of such products warrant further research and developments in this area. In order to do this, a deeper understanding of the physiology and biochemistry of the plant materials used for minimal processing is essential. An outcome of such understanding is the development of 1-MCP as an ethylene block. While this may offer some hope of extending the shelf life of minimally processed fresh produce, more research is needed for its application to different fruits and vegetables and their diverse cultivars. In addition to technological methods for extending the shelf life of minimally processed products, there are regulatory

requirements that cover the safety of these products in many countries, which offer safeguards for the safety of these products to the consumer.

14 Preservation of Part-Baked Products

Mehmet Murat Karaoglu

CONTENTS

14.1 INTRODUCTION

Bakery products are the most widely consumed foods in the world and are gaining popularity as processed foods because of their availability, convenience (i.e. they are ready to eat with a simple process after purchase), comparatively good shelf life, and sensory acceptance [1, 2]. Baked products are generally consumed as fresh and have a short shelf life since undesired changes begin just after the baking process. The major undesirable changes are (i) a decrease in humidity, (ii) moisture redistribution, (iii) starch retrogradation, (iv) increased firmness, and (v) loss of aroma and flavor. Moreover, these changes cause bakery products to go stale, which is the main reason for consumer rejection of bakery goods [2, 3].

Bakery products, especially those with high moisture content, are mostly cellular solid food systems, which consist primarily of gluten and starch fractions [4]. During and after baking, structural changes occur particularly in starch and protein and cause a significant effect in the consumption quality of the product. Starch is the main component of most bakery products, and its gelatinization induces major structural changes during baking, especially in bakery products of high moisture content. The swollen starch granules and partially solubilized starch act as important structural elements of baked products. The other important components are gliadins and glutenins, which are transformed into a cohesive viscoelastic gluten protein network. The viscoelastic protein network in the fermenting dough plays a major role

in retaining the carbon dioxide produced during the process. These gas retention properties in turn determine the volume and crumb structure of the resulting products. On heating, the gluten transforms from a gel to a coagel by polymerization. Consequently, the change from dough to final product involves changes in both the starch and protein fractions. At the macroscopic level, baking induces the solidification of dough and a change from a very viscous liquid (foam structure) system with gas cells to a semi-rigid elastic solid (elastic crumb sponge) with an open pore system [5–8]. On cooling and aging of the product, staling comes into effect, which significantly affects the quality of bakery products [9].

Water activity (a_w) can be used as an indicator of the stability of foods because it influences the microbial growth, spoilage rates, and physical/chemical properties. As the water activity increases, the ability of water to act as a solvent, medium, and reactant increases. The water activity also plays a role in the textural properties of food, because the physical state of water in a food system significantly affects its structure, physical, and chemical properties. Foods with high water activity generally have a texture defined as moist, juicy, tender, and chewy. However, when foods' water activity is lowered, their texture changes and is normally described as hard, stale, dry, and crunchy. When looking at low moisture-content foods, they have a texture described as crispy and crunchy. Thus, when their water activities are increased, the texture generally changes to soggy [10].

The pH and water activity of bakery products can be classified into different groups for a better approach to understanding storage stability (Table 14.1). These groups are high-acidic (pH < 4.6), low-acidic (pH > 4.6 and pH < 7), and non-acidic bakery products (pH > 7), and low-moisture (a_w < 0.6), intermediate-moisture (a_w between 0.6 and 0.85), and high-moisture bakery products (a_w > 0.85 and generally between 0.95 and 0.99). The classification of products according to their pH and a_w is helpful in recognizing the spoilage potential and safety risk of bakery products [2, 11].

The rate of spoilage in baked products depends on the water activity of the product. Water activity is the most important factor influencing microbiological activity in bakery products [12]. The minimum a_w values for the growth of spoilage microorganisms in some baked products are shown in Figure 14.1. For low-moisture baked products (a_w < 0.6), microbiological spoilage is not a challenge. Osmophilic yeasts and molds are the predominant spoilage microorganisms in intermediate moisture products (a_w 0.6–0.85). In bakery products with high moisture (a_w 0.94–0.99), almost all bacteria, yeasts, and molds are capable of growing [2, 13].

Storage temperature, relative humidity, packaging material and the gaseous environment surrounding the product, level of preservatives, pH, and especially the moisture content and a_w significantly affect the spoilage problems in baked products. Food spoilage is a change in a food that makes it unacceptable or undesirable for consumption. The spoilage problems of bakery products can be subdivided into three main groups: (i) physical spoilage (moisture loss, staling), (ii) chemical spoilage (rancidity), and (iii) microbiological spoilage (yeast, mold, bacterial growth). The shelf life of low- and intermediate-moisture bakery products is limited by physical

TABLE 14.1
pH and Water Activity (a_w) Range of Bakery Products

Product	pH Range	Product	a_w
High acidic		Low moisture content	
Sourdough bread	4.2–4.6	Cookies	0.2–0.3
Low acidic		Intermediate moisture content	
Cake, angel food	5.2–5.6	Fruit cake	0.73–0.83
White bread	5.3–5.8	Cream-filled cake	0.78–0.81
Whole wheat bread	5.6	Danish pastries	0.82–0.83
Date nut bread	6.1–6.7	Chocolate-coated doughnuts	0.82–0.83
Nonacidic		High moisture content	
Crumpets	6–8	Baked cake	0.90–0.94
Cake, pound	6.6–7.1	Fruit pies	0.95–0.98
Cake chocolate	7.2–7.6	Bread	0.95–0.98
Carrot muffin	8.7	Pizza	0.99

and chemical spoilage processes, while microbiological spoilage is the main concern for intermediate- and high-moisture products. The vast majority of partially baked (i.e. part-baked) products are high-moisture and low-acid bakery products, thus ideal substrates for microbial development [2, 11].

14.2 STALING AND SPOILAGE IN BAKED PRODUCTS

14.2.1 Microbial Spoilage

Soft bakery products are dynamic systems that undergo physical, chemical, and microbiological changes during processing and storage, and this limits their shelf life. Physical and chemical changes result in the loss of freshness, in terms of desired texture and taste, and lead to the progressive firming of the crumb. Microbiological spoilage by bacteria, yeasts, and molds consists of visible mold growth, invisible production of mycotoxins, and formation of off-flavors [14]. From these factors, the most important one limiting the shelf life of the product is microbial spoilage [15].

Besides going stale, microbial spoilage by bacteria, and especially molds, remains responsible for enormous economic losses in the bakery industries [14, 16]. It is considered that about 60% of the spoilage problems are caused by molds, resulting in losses of 1 to 5% of the total bread production. Furthermore, there is evidence that molds produce mycotoxins, which can have an adverse effect on human health. Viable vegetative molds and mold spores are normally inactivated by the heat during the baking process due to thermal shock. However, post-baking contamination occurs during the cooling and packaging stages. In addition, mold, bacterial, and yeast spoilage can also occur in bakery products. In particular, ropiness caused by *Bacillus subtilis* is the most common bacterial spoilage in bakery products such as bread [15, 17]. Heat-resistant spores of *Bacillus* species are not inactivated during baking and can then germinate and grow within 36–48 h inside the loaf to form a characteristic soft, stringy, brown mass with an odor of ripe pineapple or melon due to the release of volatile compounds, such as diacetyl, acetoin, acetaldehyde, and isovaler-aldehyde. Their growth can cause undesirable texture or flavor changes and can spoil the product. The crucial step during the part-baking process with regard to the propagation of bacilli spores is the re-baking or final baking process [18]. Yeast spoilage is the least common of all types of microbial spoilage since yeasts do not survive in the baking conditions. Contamination rather occurs during the cooling stage of products, and, in the case of industrial bread, it happens especially during the slicing step [14, 19].

The prevention of post-baking contamination can be achieved by (i) placing under aseptic conditions immediately after baking, (ii) destruction of post-baking contaminants on the surface of products after packaging, and (iii) controlling the growth of post-baking contaminants in the packaged products. These preventions of contaminations are the basic strategies to extend the microbiological shelf life of bakery products. The mold-free shelf life of many bakery products could be increased if post-cooking contamination can be prevented by packaging as soon as possible after baking. However, the success of preventing post-baking contamination of bakery products has achieved limited success. For this reason, attention has focused on the other methods, such as ultraviolet light, infrared irradiation, microwave heating, low-dose γ-irradiation, pulsed light, and high pressure to control any post-processing contamination of mold spores [11, 14, 15, 20]. However, the most practical, efficient approach to extend the microbiological shelf life of bakery products is to control the growth of any post-baking contamination in the packaged products. Post-baking contamination can be controlled by reducing a_w of reformulated product, chemical preservatives (such as sorbates or propionates), and modified-atmosphere packaging [2].

14.2.2 Staling

In spite of all this, the most important factor affecting the consumption quality of bakery products is staling [21]. The undesirable changes occur in bakery products, especially soft products, such as bread, cake, and doughnuts. The decrease of crust crispiness or toughening of the crust, firming of the crumb, and loss of flavor over storage time are known as staling. The staling phenomenon can be explained by two basic mechanisms: (i) the moisture migration from the crumb to the crust during storage leaving the crust soft and leathery and the crumb hard and dry, and (ii) recrystallization of starch that starts when the baked product is being cooled down after baking [10, 22, 23]. However, crumb hardening is a complicated process resulting from events that happen at the same time.

Since starch is the major constituent in the bakery product, the physical changes accompanying the retrogradation of starch have been suggested as the main reason for staling. Starch retrogradation is a complex process in which gelatinized starch molecules re-associate to form double-helical crystalline structures. Therefore, structural changes in starch occurring during baking and storage have an extremely important effect on the structure, texture, and quality of the baked products [10, 24]. Depending on the source, starch consists of 20–30% amylose, an unbranched α-1-4 polymer of D-glucose, and 70–80% amylopectin, which consists of α-1-4 links with α-1-6 links every 25–30 glucose residues. The recrystallization tendencies of amylose and amylopectin differ from each other [25]. Amylose recrystallizes rapidly upon cooling, and recrystallized amylose can be partially responsible for the initial crumb firmness and in the early stages of aging [26]. On the other hand, the recrystallization of the amylopectin fraction within and between the swollen and deformed gelatinized starch granules occurs over a longer period (i.e. several days after baking), probably because of the branched structure of amylopectin. For this reason, it determines the long-term development of structure and crystallinity in starch systems like bakery products. It is more often referred to as retrogradation [27–29]. Amylopectin retrogradation, in particular the formation of double-helical structures and crystalline regions, is mainly responsible for crumb firming. The optimum

temperature for the retrogradation of amylopectin occurs between glass transition and ice-melting temperatures [30].

At present, many reports have shown that starch retrogradation is not the only factor in the staling of bakery products. Water also plays a critical role in bread staling. When the recrystallization of starch occurs, water molecules are incorporated into the crystallites and the distribution of water is shifted from gluten to starch, thereby changing the nature of the gluten network. Besides the molecular arrangement of starch, water has also an important role in crumb firmness due to its plasticizing effect [22]. Other factors affecting crumb firmness are amylose recrystallization, moisture loss, interactions between starch and gluten, and moisture redistribution [9]. In the latter case, gluten, a continuous phase in the bread, is cross-linked by the gelatinized starch resulting in increased crumb firmness [23].

14.3 RETARDING STALING OF BAKED PRODUCTS

The aging of baked products has attracted research interest for many years. Researchers and the baking industry have attempted to retard staling by applying different methods. Many efforts have been focused on the development of different additives such as emulsifiers, hydrocolloids, and enzymes such as α-amylases, hemicelluloses, lipases, and reformulation with these additives. These could extend the shelf life of the soft bakery products by retarding the staling process during storage. In addition to these additives, other different approaches, such as fermentation, baking, and chilling conditions, freezing, and appropriate storage conditions have been studied [31–33]. Recently, part-baking has been used to extend the shelf life of bakery products and to offer fresh-like baked products after final baking before consumption.

There are three important methods used to extend the shelf life of bakery products. These are (i) frozen dough technology, (ii) freezing of bakery products, and (iii) production of partially baked (i.e. part-bread) products. Although freezing is appropriate for extending the shelf life of bakery products, the quality of frozen products can be affected in terms of texture and aroma as compared to fresh ones [33, 34]. The freezing process can be applied to dough in order to interrupt the fermentation process for bakery products before proofing. The frozen dough led to bakery products of reduced volume, mainly due to the physical damage caused to the protein network structure and the deterioration of yeast during frozen storage. Thus, the market is moving from frozen dough to part-baked products [35, 36]. These difficulties can be minimized by using strong wheat flour and freeze-tolerant yeasts. However, the baking process of frozen dough still needs specific flour quality, freezing and thawing conditions, and dough handling. In the part baking process, the product is ready for consumption after a simple cooking process [31]. In view of certain difficulties related to the preservation of yeast activity in frozen dough, a better way of maintaining freshness could consist of freezing part-baked products [37]. The freezing process can also be applied to part-baked products, and successful results could be obtained. The freezing of part-baked fermented bakery product is an easy way to prolong the shelf life and keep its freshness [31].

14.4 PART-BAKING PROCESS

14.4.1 Understanding Part-Baked Products

Changing consumer habits and new social lifestyles have had an important impact on the bakery industry. In recent years, there has been a growing demand for high-quality foods based on convenience with minimum requirements for preparation time. Part-baked products have an advantage in relation to fully baked ones since they need very little preparation time in the oven [38]. Another advantage of the part-baking process is its limited microbial activity and chemical reactions due to pre-baking; thus it enables a longer shelf life [39]. In addition, recent consumer trends have promoted an increase in the consumption of partially baked bakery products due to the availability of fresh products at any time of the day [9].

The baking of bakery products is a complex heating process that causes a series of physical, chemical, and biochemical changes, such as volume expansion, evaporation of water, denaturation of protein, gelatinization of starch, crust formation, formation of a porous structure, browning reaction, and development of flavors. Starch gelatinization is one of the critical factors that determine the baking time and extent of gelatinization in the crumb of soft bakery products, and surface color is another important characteristic of baked products. Therefore, these could be taken as a minimum or critical baking index [40, 41]. However, partial baking is a gradual baking process. The part-baked product is a semi-finished product with an adequately rigid structure so that its preparation for consumption, handling, and storage is easy. Part-baking or partial baking is a method of bakery product manufacture consisting of two stages of baking with an intermediate storage stage (Figure 14.2).

The partial baking method is economical and time-saving as there is no need for skilled labor or baking instruments except for an oven for re-baking, and it takes a short time to obtain a fresh final product. It is very suitable for places such as restaurants, hot points in supermarkets, schools, or by domestic users, where consumers do not want to spend time and effort to perform the whole process of dough making and processing. The part-baking method, or the two-step baking procedure, can also be used successfully for bakery products such as bread, cake, and pizza (Figure 14.3). Cake and pizza are not products for daily consumption, such as bread, so long-term storage of the partially baked cake and pizza is necessary and frozen storage could be preferred over room-temperature storage [42]. In addition, the part-baking method in the bakery market could also be very advantageous, especially in special bakery products such as gluten-free bread, rich-fiber bread, and other products for different purposes. These types of products are addressed to a certain consumer group, and most of the time it is very difficult to find these products in conventional and industrial bakeries. For this

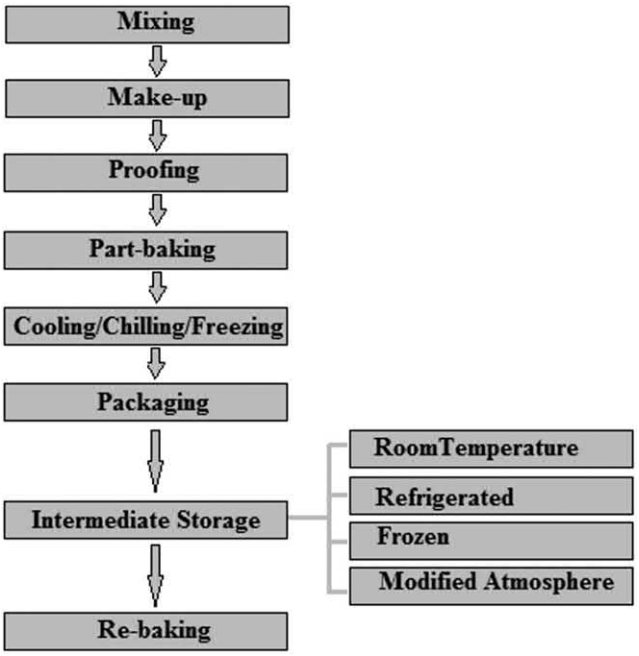

FIGURE 14.2 Flow chart of part-baked products.

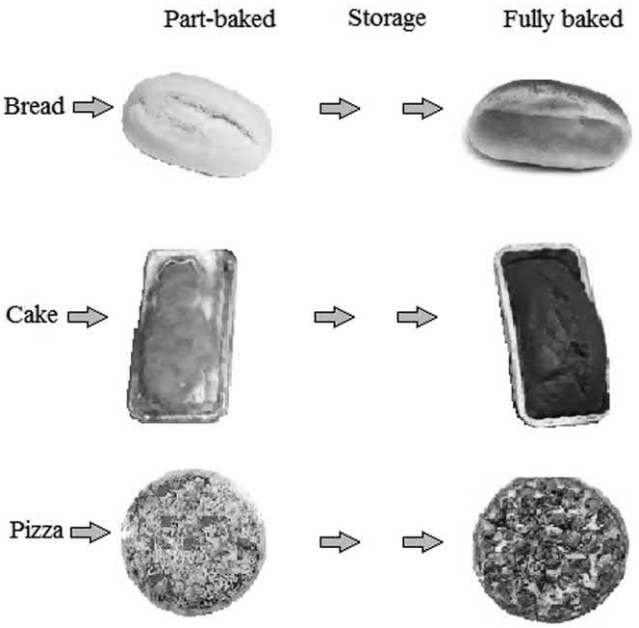

FIGURE 14.3 Part-baked and fully baked bread, cake, and pizza.

reason, the use of the part-baking process could overcome those problems and could provide a wide range of products for consumers [35, 43].

14.4.2 Part-Baked, Pre-Baking, and Post-Baking Processes

Terms such as "part-baked," "part-baking," "partially baked," and "par-bake" are used to describe a production method that involves two stages of baking (Figure 14.2). First, dough pieces with yeast are baked under the defined oven conditions into partially baked products with the minimum crust coloration, proper crumb texture, and the maximum moisture retention [33]. An increase in volume in the initial stages of prebaking is mainly caused by the expansion of the gas enclosed in the porous dough structure. The pore size in the crust may be different from the crumb, the crust having a more dense structure than the crumb [6]. In the first stage, the proper crumb texture is obtained by gelatinizing the starch and coagulating the proteins [44]. The part-baked products are cooled to a suitable temperature for packaging within the range of about 20–30°C. If the product is to be stored for a prolonged period, it is refrigerated or frozen immediately. Then, cooled and packaged part-baked products are stored up to the final re-baking at the point of sale or consumption. Finally, these part-baked products are re-baked to create an appropriate flavor and crust color similar to fresh product [23, 45]. In the household, the soft bakery products can be kept frozen, and then thawed and reheated just before consumption. Although reheating generally inverts the staling process, this is not enough to recover all the quality characteristics, like the smoothness of a freshly baked product. On the contrary, when a product is partially baked until the crumb is formed and rapidly frozen, it is possible to obtain a final product with similar characteristics to the fresh product after appropriately re-baking.

The part-baking conditions such as temperature and time have a great effect on the quality characteristics and shelf life of part-baked product [46]. Generally, a lower initial baking temperature is required to avoid excess crust coloring. However, a lower baking time efficiently extends the period of yeast activity at the beginning of the first baking. For this reason, a compensatory reduction in proof time is required. Steam may be applied during both of the baking stages [42]. Karaoglu and Kotancilar [47] stated that in relation to crumb softness, a short part-baking time was recommended for white pan bread baked in two stages (re-baking after part-baking and storage). However, Fik and Surowka [37] stated that the optimum par-baking time was between 74 and 86% of the time necessary for complete baking. The effect of baking conditions on the quality and shelf life of part-baked products is explained in detail in Section E.

14.4.3 Cooling of Part-Baked Products

Post-baking chilling or cooling of partial-baked product is an important part of the production process. Before packing, partially baked products are cooled down to storage temperature to avoid moisture condensation [48]. Physical and chemical changes occur during the cooling stage after baking [49]. When the baked products are chilled after cooking, the matrix of product that transformed from dough into crumb during baking undergoes a solidification phase due to the decrease in temperature. The heat transfer related to the cooling kinetic is highly influenced by evaporative cooling, especially at the beginning of the cooling process. This evaporative cooling corresponds to significant water loss from the product [50].

After leaving the oven, hot part-baked products must be cooled to a certain temperature to improve storage stability.

The cooling stage itself presents a spoilage risk. An appropriate cooling method should be selected at this stage because physical and chemical changes also occur during the cooling stage after baking, and these changes significantly affect the end-product quality. Therefore, a rapid technique such as vacuum cooling may provide some advantages in cooling partial-baked products. The porous structure of many bakery products is poorly conductive and causes difficulties in terms of heat removal. Vacuum cooling can be successfully used in a wide range of products, in particular with a porous water-rich matrix such as bread and cake [51]. The main advantages of this method are increased productivity, and reduced energy consumption, as well as a possible contribution to longer shelf life. Novotni et al. [48] studied the impact of barley sourdough fermentation and vacuum cooling on the shelf life and quality of composite partially baked bread during 30 days of ambient storage in modified atmosphere. They showed that vacuum cooling improved bread shape and porosity, and reduced sour taste, crust coloring, and crumbliness. Although vacuum cooling is a rapid cooling technology, it is more expensive and causes noticeable moisture loss from the products. Le Bail et al. [51] stated that vacuum chilled breads exhibited a higher moisture loss than conventionally chilled bread and that vacuum chilling had a negative effect on the texture of the bread.

14.4.4 Packaging of Part-Baked Products

The basic function of food packaging is to minimize reactions that affect the stability of packed products. In general, naturally occurring gaseous reactants (water vapor and oxygen) can seriously restrict stability under the usual food storage and distribution conditions [52]. Food packaging must protect the product from external environmental effects, such as water, water vapor, gasses, odors, microorganisms, dust, shock, vibration, compressive forces, and temperature. It should also provide compressive strength to withstand stresses and perform satisfactorily during storage and transport [53]. Each food requires different packaging characteristics due to its nature and processing steps. Therefore, packaging material must be selected by considering the balance between the barrier properties of the materials. In addition, the suitability of the form of packaging, method of preservation, and handling after purchase needs to be considered [12].

The packaging material for part-baked products must be kept in such a condition as to avoid moisture loss at a minimum. It needs to have good oxygen-barrier characteristics, physical strength against breakage at low temperature, good heat-seal ability, and low cost [54]. The most popular packaging materials applied to part-baked products are polyethylene films that are soft and flexible. Petroleum-based low-density polyethylene (LDPE) bags are a common packaging material for frozen food including frozen bread. LDPE film has characteristics of clarity, easy processing by extrusion, and low permeability to water vapor, but it is not good as a barrier for gasses, oils, or volatiles. LDPE with a density around 910 kg/m^3 has physical characteristics of softness and stretchability, and it can withstand freezing temperatures up to –70°C. However, high-density polyethylene is a good water vapor barrier, and it is an alternative approach to controlling water loss in fresh product [12, 55]. In recent years, antimicrobial packaging materials have been developed, leading to the extension of the shelf life of foods, and increased reliability is provided. In this method, antimicrobial compounds have been incorporated into packaging materials to inhibit microbial growth without compromising food quality. Antibacterial food packaging changes the atmosphere inside the package, reducing the proliferation of bacteria and thereby increasing the shelf life of the food. For this reason, antibacterial packaging materials can be used effectively for part-baked products [56–58].

14.4.5 Important Factors Affecting Quality in the Part-Baking Process

There are many factors that significantly affect the quality of part-baked products during the partial baking process, such as initial baking time and temperature, chilling, freezing, storage, and final baking (re-baking) conditions. The initial baking time of part-baked products has a significant effect on the quality of the final product. Short initial baking times at high temperatures lead to a more open structure of the crumb. The optimum prebaking time is approximately two-thirds of the time required for full baking, and at the initial baking stage, high steam is recommended for improving the crust [35]. In general, the 71% fraction of baking time for bread made it possible to obtain a product with sensory and textural qualities close to those of fresh product [37].

Chilling conditions of part-baked products, especially part-baked bread, are the most determinant parameter on the crust flaking followed by the proofing conditions. High air humidity during the chilling process generally tends to give a better crust structure and to reduce crust flaking. Also, freezing and frozen storage conditions have generally negative effects on the quality of final baked products. For this reason, different studies have been done both to optimize the processing conditions and to modify the formula to improve the quality of part-baked products [42].

The re-baking stage is compulsory to make part-baked products ready for consumption. The final baking of part-baked products is done for two main purposes; these are the coloration of the crust and the "refreshing" of the firm crumb. The second purpose corresponds to the melting of the amylopectin crystallites (at around 40–60°C) that form during storage and that result in staling. In general, partially baked products are frozen after the initial baking process and stored frozen. During the re-baking of frozen products, the heat does not penetrate to the inner parts of the crumb, and partial refreshment occurs after the second baking. For this reason, frozen part-baked products must be either partially or completely thawed by an appropriate method before the second baking. This thawing provides a uniform matrix in the second baking and a better warm-up of the inside of the crumb. In addition, the thawing process has a positive effect on crust flaking.

14.4.6 Quality Improvement Efforts in Part-Baked Products

The quality of the re-baked products after part-baking and storage is influenced by formulation and processing parameters. Bakery shortenings are a mixture of oil and solid fat at dough temperatures, and these provide specific functional properties (softness, texture, mouthfeel, structural integrity, air incorporation, heat transfer, and increase in shelf life) to bakery products [59]. Carr and Tadini [60] investigated the effect of vegetable shortening and yeast on the physical and textural properties of frozen part-baked French bread stored for 28 days. They found that higher yeast content formulations produced bread with a higher specific volume due to higher yeast activity, and the firmness and chewiness values of breads were lower in formulations containing shortening due to the softening effect, with respect to control formulations. Ferreira and Watanabe [61] showed that the use of vegetable shortening and ascorbic acid in the production of frozen part-baked French bread results in a higher specific volume.

Hydrocolloids are widely used as additives in the food industry due to their high water retention capacity. The presence of hydrocolloids retards the staling process during storage by influencing the melting, gelatinization, fragmentation, and retrogradation processes of starch, and increases water absorption. Therefore, these confer stability to products that undergo successive freeze–thaw cycles and provide multiple quality improvements in many frozen foods [62, 63]. Hydrocolloids could be also used in part-baked products that are frozen stored, and influence in a different way the characteristics of the final products according to their type. Mandala et al. [34] reported that the influence of hydrocolloid stabilizers, such as hydroxypropyl methylcellulose, xanthan, guar, and locust bean gum, on final bread characteristics was more pronounced in part-baked frozen bread than in control samples. Barcenas et al. [64] studied the influence of hydroxypropyl methylcellulose and k-carrageenan on the quality and staling of part-baked bread after frozen storage and re-baking. They concluded that the addition of hydroxypropyl methylcellulose improved the overall quality of the product during extended frozen storage and the k-carrageenan was not a good improver for the partially baked frozen bread. Hejrani et al. [65] reported that the addition of gums and enzymes to the bread recipe improves the crumb texture of the Barbari bread obtained from part-baking, frozen storage, and re-baking. In addition, the guar, amylase, and lipase interacted and increased the specific volume and the overall qualitative characteristics of the product during long frozen storage by reducing the adverse effects of that process. Conversely, they concluded that xanthan is not an appropriate improver for the part-baking process in the frozen storage of Barbari bread.

The increase in water content and in water retention of a product delays the staling of soft bakery products. Dietary fibers, such as cereal bran, have been shown to increase the water absorption of dough and the initial water content of bread and showed an enhanced effect on staling parameters, like firmness [66]. The effects of different fermentation times (90–120–420 min) and fiber contents (6% wheat bran and 6% wheat bran with 2% inulin) on the staling of bread from frozen part-baked bread were studied by Ronda et al. [66]. They reported that wheat bran had a positive effect on bread staling while inulin had the opposite effect. On the other hand, the increase in fermentation time showed a positive effect in delaying bread staling. Bignea et al. [67] have investigated the applicability of mesquite (*Prosopis alba*) flour to part-baking bread technology. They reported that breads with mesquite flour were less affected by the freezing process and frozen storage (8 weeks) in comparison with wheat breads. This would suggest the possibility of a protective effect of mesquite flour components, like fiber, against damage by freezing.

14.5 PRESERVATION OF PART-BAKED PRODUCTS

Product formulation, processing form, packaging, and storage conditions are major factors affecting the storage life of part-baked products. The desired storage life of part-baked products depends mainly on the change in their quality parameters. The chemical and physical properties of these products are the most important quality parameters as perceived by consumers [23]. Storage of partially baked product is a very important stage as its duration significantly affects the quality of the final (re-baked) product [23, 49]. Part-baked products are commercially stored at room temperature or in a freezer or refrigerator. Some undesirable changes occur during the storage of part-baked products. However, the second baking phase eliminates these undesirable changes, and the product regains its fresh textural properties [68, 69].

Partially baked products generally have very short shelf lives due to their lack of crust, light baking, and high moisture content, which increase the susceptibility to microbial growth. However, it is estimated that the storage life of part-baked products can be extended up to 6 to 12 months using various methods. Different applications, such as the use of antimicrobial preservatives, modified atmosphere packaging, infrared and ultraviolet irradiation [15], storage at refrigerator temperatures, and freezing storage, have been suggested for prolonging the shelf life of partially baked products. Packaging in a modified atmosphere containing different levels of carbon dioxide and nitrogen considerably prolongs the shelf life of a part-baked product. Storage at low temperatures (2–6°C) successfully extends the shelf life of the partially baked product up to 10 days. However, the most effective application to extend shelf life is to freeze the part-baked product and to keep the frozen product in the freezer during the storage period up to its final baking [35].

14.5.1 Room Temperature Storage

The shelf life of part-baked products stored at room temperature is limited (Table 14.2). The microbial count increases significantly during the storage of bread at room temperature if anti-microbial agents are not used [70]. After 5 and 7 days of storage, molds are visible on the crust, marking the end of the shelf life. After approximately 1 week of storage, while

TABLE 14.2
Shelf Life of Some Part-Baked Products Stored in Different Conditions

Part-Baked Product	Storage Method	Storage Temperature (°C)	Shelf Life	Reference
Sangak bread	MAP (100% CO_2)	25	21 days	Khoshakhlagh et al. [86]
Brown soda bread	40% CO_2 and 60% N_2	4	13 weeks	Leuschner et al. [69]
Gluten-free breads	Refrigerator	4	7 days	Sciarini et al. [107]
Tubers	Refrigerated storage	4	21 days	Singh et al. [111]
Bread	Freezing at –30°C	–18	12 and 20 weeks	Vulicevic et al. [23]
Bread	Refrigerator	1	28 days	Lainez et al. [72]
		7	7 days	
Flat bread	Incubator	25	3 days	Majzoobi et al. [32]
(Barbari)	Freezer	–18	60 days	
White pan bread	Incubator	20	7 days	Karaoglu et al. [70]
White pan bread	Refrigerator	4	21 days	Karaoglu et al. [70]

the crust becomes softer, the crumb becomes more crumbly and firm, and the fresh product aroma mostly disappears. Leuschner et al. [18] studied the effects of the re-baking process in part-baked soda breads on *Bacillus* spores and determined D values of *Bacillus* spores. Rope formation was observed at the end of 2 days at room temperature. The D values of spores of *Bacillus subtilis*, *Bacillus pumilus*, and *Bacillus licheniformis* isolated from breads were 14, 10, and 56 min at 100°C, respectively. However, the second baking process after storage at room temperature causes a reduction in the microbial count and promotes product freshness again [70].

Storage at room temperature is not the preferred method for the storage of partially baked products. Because the product is not fully baked, it may quickly deteriorate during storage at room temperature. Therefore, room-temperature storage can be used together with modified atmosphere packaging techniques to extend the shelf life of part-baked products. In addition, the use of antimicrobial additives causes a decrease in the numbers of total aerobic mesophilic bacteria (TAMB), coliform bacteria, *Bacillus* spores, and mold in the part-baked breads stored at room temperature [70]. Karaoglu et al. [70] studied the shelf life, microbiological, and sensory qualities of part-baked breads (i.e. white pan breads) stored at room temperature for 7 days. They reported that the numbers of TAMB, yeast, mold, and *Bacillus* spores increased before the second baking as the storage period was increased. The use of antimicrobial compounds caused a decrease in the numbers of TAMB, coliform bacteria, yeast, mold, and *Bacillus* spores in the breads. The TAMB counts of the breads without added antimicrobial were about 8-log CFU/g at the end of storage for 7 days; however, in the breads with Ca-propinate, these were 2-log CFU/g with a decrease of 6-log CFU/g. In addition, reductions of 5- and 3-log CFU/g in the numbers of *Bacillus* spores and yeast and mold counts of the breads were observed.

14.5.2 Refrigerated Storage

Refrigerated storage is a suitable alternative to preserve part-baked products since it extends the shelf life with a lower energy requirement as compared to frozen storage [46]. Therefore, partial baking and further storage at refrigerator temperatures is an effective way to delay the staling process of baked goods [71]. In fact, starch retrogradation is more rapid at refrigerator temperatures than at room temperature and is responsible for the hardening of soft bakery products. The crystallization of amylopectin can only take place when the temperature is between the glass transition temperature and the polymer melting point. Crystallization takes place in three stages, namely: nucleation, growth, and annealing of crystals. The nucleation stage is an important step because it controls crystallization. As the temperature is decreased until glass transition is achieved, the nucleation rate increases, while the growth rate of crystals increases as the temperature increases until melting temperature is reached. Recent studies show that par-baked bread stored at 1°C has a higher rate of nucleation compared with bread stored at 7°C, and a higher rate of amylopectin re-crystallization results in a faster hardening of the crumb. However, this is not a problem in the storage of partially cooked products because re-baking of the part-baked products after storage, before consumption, allows them to regain their first freshness. Therefore, the final product has the characteristics of a freshly baked product. That is, when part-baked product is re-heated to 50°C and above, the cross-linkages between starch and gluten are also easily broken and the product can return to its original freshness [9, 10].

Figure 14.4 shows the amylopectin retrogradation index produced in par-baked bread during its storage at 2°C, and in full-baked bread during its staling at 25°C. The retrogradation index of part-baked bread increases during storage at low temperatures (2°C) due to the retrogradation of amylopectin. When full (second) baking is applied, the amylopectin crystallization produced during staling was reversed due to heat, leading to a reduction of the retrogradation index. Finally, the retrogradation index increases again during the storage of full-baked bread at 25°C. This increase is not as much as in part-baked bread. Moreover, it is stated that the storage time of part-baked bread at low temperatures did not affect the

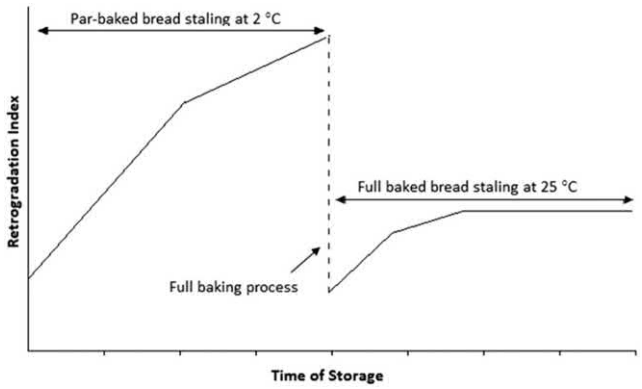

FIGURE 14.4 The retrogradation index of amylopectin during the interrupted bread-making process and storage. (From Barcenas and Roswell [9].)

crumb hardness of the full-baked counterpart, nor its further behavior during staling at 25°C [9].

The storage temperature of part-baked products significantly influences the rate of microbiological spoilage and the type of microorganism present. Refrigeration storage significantly extends the microbial shelf life of part-baked products as compared to storage at room temperature. It is stated that the microbial count of par-baked bread stored at refrigerator temperature (4°C) was lower than that of bread stored at room temperature [70]. In addition, Lainez et al. [72] noted that part-baked bread stored at 7°C presented mold growth on the 9th day, while there was no mold growth in the product stored at 1°C for 28 days.

The refrigerated storage time of part-baked bakery products generally affects baking loss, specific volume, and textural properties of the final (re-baked) product. Recent studies show that an increase in storage time of the par-baked bread under refrigeration (4°C) results in a reduction in the quality of the re-baked bread, which is related to losses in moisture content and softness and an increased baking loss [47].

Refrigerated storage leads to a lower rate of moisture diffusion from crumb to crust as compared to storage at room temperature. During the storage of a packaged product at ambient temperature, the crust becomes soft after 1 day of storage. However, with storage at refrigerator temperature, the crust keeps a certain crunchiness for more than 2 days. These crusts re-form more rapidly during re-baking than the soft crust. The re-baked crust from refrigerated product gives a better impression of freshness than the crust from a product stored at room temperature. The crust of a re-baked product stored at refrigerator temperature gives a better impression of freshness than the crust from storage at room temperature. In addition, when compared to freezing storage, it seems that storage at refrigerator temperature has some advantages. The crumb microstructure of bread stored under refrigeration is better protected as compared to that of bread stored frozen. Positive temperature storage leads to bread with better specific volume, low crumb hardness, and a slower hardening rate during staling than the bread stored as frozen [46]. However, microbial spoilage may occur in the refrigerator storage. Therefore, refrigeration in combination with modified atmosphere packaging (MAP) would generally be useful in extending the shelf life of part-baked bread [69]. In general, the use of low temperatures (2–6°C) can be successfully used for extending the shelf life of the partially baked products for up to 10 days [35].

14.5.3 Frozen Storage

Frozen storage is a process that is mostly used to preserve part-baked bakery products. To retard staling and to extend shelf life safely, the part-baked products are very often frozen and frozen stored [44, 73]. As part-baked products are baked at high temperatures, rapidly frozen at low temperatures, and then re-baked, the possibility of microbial survival is significantly reduced (Figure 14.5) [23, 74, 75]. Freezing is an excellent process for preserving food quality for prolonged shelf life because deterioration due to microorganisms and selected biochemical processes are decreased during the frozen storage. The shelf life of frozen part-baked products is much longer than that of ordinary products [43]. Gujral et al. [75] stated that the partial baking process and further frozen storage could extend the shelf life and improve the eating quality of chapati bread. However, structural changes in frozen foods occur during freezing, storage, and subsequent thawing. Although part-baked products can be frozen stored up to 12 months without microbial spoilage, the quality of the product begins to reduce after 6 weeks of frozen storage. Rapid freezing creates small ice crystals and reduces structural changes of frozen foods during storage and thawing. For this reason, controlling the freezing conditions to achieve small ice crystals is essential for frozen foods [43, 76].

The extensibility, peak force, and rupture energy of the partially baked chapati increased during prolonged frozen storage. Since soft and easily chewable chapatis with pleasing color and flavor are desirable, frozen partially baked chapati breads are considered a better option than conventionally

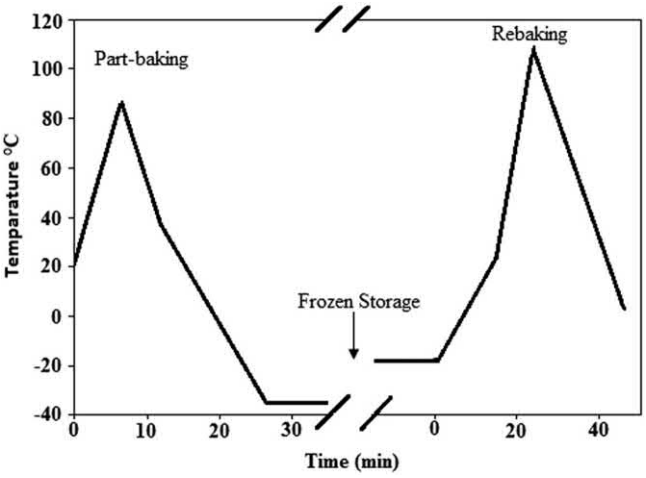

FIGURE 14.5 Temperature profile reached in the center of the crumb during a part-baking and re-baking process including frozen (intermediate) storage. (From Barcenas et al. [31].)

baked chapatis. Frozen storage is expensive due to the high maintenance costs of the cold chain as compared to storage at room and refrigerator temperatures. Under industrial conditions, the frozen part-baked bread process generally requires about 2.2 times more electrical energy than the conventional process although it may vary depending on the storage period [46, 77].

The loss of freshness in bakery products affects product quality and consumer acceptance and shortens the shelf life. Although fresh bakery products currently dominate the food market, it should be expected that in the future their importance could grow together with the consumers' increasing demands. Frozen storage is one of the most convenient and easiest of food preservation methods as compared to other commercial preservation techniques [78]. The freezing process, which can be applied before proofing or after part baking to the frozen dough or partially baked products, can increase the shelf life of product up to 12 months [35]. However, the frozen storage of part-baked products does not eliminate changes that could occur after final baking, such as interactions among the various components, which develop during the aging or storage of the re-baked product [31].

The freezing process and frozen storage temperature significantly affect the quality of fully baked and part-baked breads during storage [33]. The greater part of staling occurs in passing from 0 to 5°C with the maximum rate occurring around 4°C. A poorly performed freezing–thawing cycle can significantly increase the degree of staling undergone by the bakery product, since it passes through the optimum staling temperature twice. For this reason, during cooling of the part-baked bakery product, it must pass through this temperature range as quickly as possible, so that its quality during frozen storage is preserved. In addition, the temperature, speed, and relative humidity in the freezing process are the air parameters with greater influence on weight loss, ice concentration at the crust–crumb interface, and freezing time. The freezing time and weight loss generally decrease with the reduction in temperature and increase in air speed, whereas the ice concentration below the crust decreases with reductions in both temperature and air speed. Hence, quick freezing should be used when the objective is to minimize weight loss and freezing time, and slow freezing should be used when the objective is to minimize the ice concentration at the crust–crumb interface during the freezing process of par-baked bread [46].

The freezing treatment at temperatures above the glass transition enhances the nucleation-growth process of amylopectin crystals. Thawing and storage at higher temperatures can cause the growth and maturation of crystals and therefore an increase in the recrystallization rate as compared to unfrozen systems. The storage of fully baked and part-baked bakery products at refrigerator temperature increases the shelf life with respect to the risk of mold growth but accelerates the staling in storage at room temperature because it is in the optimum temperature range (between glass transition and melting temperature). Part-baked products at temperatures from –10 to 5°C experience maximum retrogradation of starch molecules, which in turn contributes to crumb firmness. It is, therefore, necessary to cool the part-baked product between these temperatures as quickly as possible to preserve their quality during prolonged storage [23, 33].

For all these reasons, part-baked bakery products should be stored frozen below –10°C if they need to be kept for a long time before re-baking. Immediate freezing of bakery products after baking prevents crystallization of both amylose and amylopectin and consequently slows product staling. Najafabadi et al. [33] reported that there was no significant difference among firmness of re-baked bread samples after they were part-baked and stored at –18°C compared with fresh (control) bread. However, the differences among re-baked bread samples after being part-baked and stored at 4 and 20°C are significant as compared to the fresh (control) samples. Storage at 4°C resulted in an increasing melting enthalpy of amylopectin crystallite as compared to storage at 20°C. They consequently reported that immediate freezing after baking and storage at –18°C prevented bread staling as compared to other storage temperatures.

The storage period of part-baked products under controlled freezing conditions could change the desired quality characteristics of product, such as moisture loss, starch retrogradation, loss of flavor/aroma, and increased firmness. If the part-baked products are baked adequately at the appropriate high temperature, rapidly frozen at low temperatures, and then sufficiently re-baked, the possibility of microbial survival is significantly reduced. For this reason, the desired storage life of these products generally depends on the change in their quality characteristics as mentioned above. The factors such as product formulation, processing, baking time, packaging, and storage conditions significantly affect the storage life of part-baked products [23, 79].

The freezing process and frozen storage time cause significant physicochemical changes in part-baked products, such as starch retrogradation and redistribution of the water, which have a great influence on the consumption quality of the re-baked (final) product. The freezing process itself and frozen storage can have different effects on the textural properties of re-baked (final) product compared to part-baked goods. In some studies, it was reported that the freezing process affected the quality of re-baked products more than frozen storage. However, contrasting results have also been reported by some researchers. Fik and Surowka [37] reported that the freezing process itself produces the greatest changes in sensory and textural properties of fresh bread produced from part-baked bread, while the frozen storage did not have any effect on the aging behavior. On the contrary, Barcenas et al. [31] found that the freezing process itself did not have an impact on the bread aging, whereas the time of frozen storage influenced the rate of hardening during aging, especially when prolonged frozen storage was applied.

Factors affecting the consumption quality of the part-baked products such as a reduction in specific volume, a loss of moisture content, an increase in crumb hardness, and loss of aroma can change with the increase in frozen storage time. Frozen par-baked products have generally a reduced specific volume and weight compared to fresh ones [32, 43, 80]. In

addition, long periods of frozen storage appear to be associated with a greater rate of staling [46]. Barcenas et al. [31] found a significant increase in the crumb hardness of the bread with the frozen storage time (Figure 14.6). In general, the use of baking improvers is an effective means of extending the freshness of bakery products. The baking improvers used in the full baking processes can also be directly applied to the interrupted baking process to retard staling. Barcenas et al. [81] stated that the presence of improvers such as α-amylase, k-carrageenan, and hydroxypropyl methylcellulose minimized the negative effect of the frozen storage period on staling, because these contribute to the redistribution of water and avoid interactions between starch and gluten. Therefore, baking improvers would also be useful in part-baking processes with frozen storage.

Wheat-based cereals contain both fat-soluble antioxidants, such as tocols, ferulic and caffeic acid esters and carotenoids, and water-soluble antioxidants, such as phenol acids and glycated flavonoids. Moreover, bread oxidative stability is strongly affected by temperature, presence of air or oxygen, light, and lipolytic enzymes [82]. Novotni et al. [54] stated that during frozen storage of part-baked and fully baked bread, the total phenolic content and oxidative stability decreased, but part-baked bread had longer oxidative stability than fully baked frozen bread. The researchers also noted that the oxidative stability of bread in blue-colored high-density polyethylene pouches was better than in transparent polyester-polyethylene-ethylene-vinyl alcohol copolymer pouches. This is probably due to their blue color and lower light transparency.

The freezing of bakery products is generally carried out in a single-stage process. However, a two-stage freezing process can also be used. Recently, the effects of two-stage freezing on crust flaking, total weight loss, and ice concentration in the crumb–crust interface of part-baked bread as compared to single-stage freezing were studied. It was observed that the temperature, velocity, and relative humidity of cold air are the most influential cold air parameters on the weight loss, ice concentration in the crumb–crust interface, and freezing time [83]. Moreover, it was also reported that the ice content in the interface can be considerably decreased by using slow freezing in the first stage and fast freezing in the second stage in comparison to a single-stage regime.

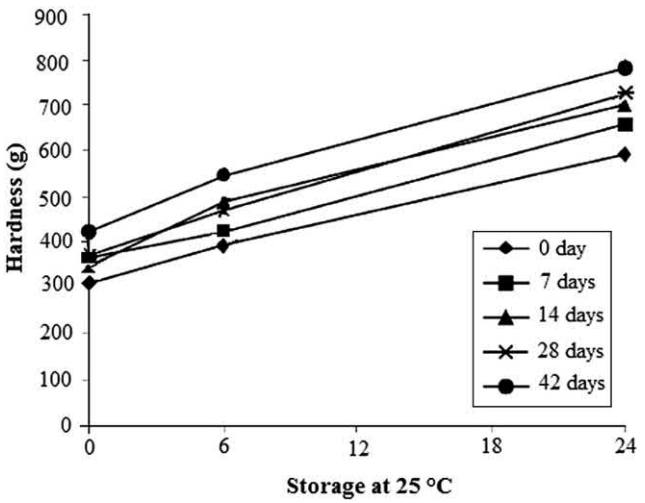

FIGURE 14.6 Effect of part-baking, freezing, frozen storage at different times, thawing, and re-baking on the crumb hardness during aging at 25°C. The different series correspond to the time of frozen storage. (From Barcenas et al. [31].)

The recrystallization of ice is observed in frozen part-baked products. It is a physical phenomenon whereby ice crystals in frozen foods increase in size but diminish numerically during frozen storage. The formation of large ice crystals through redistribution of water from small to large crystals can reduce product quality [84]. Results for microstructure observed by low-temperature scanning electron microscopy showed the physical damage suffered by the crumb constituents of par-baked bread during frozen storage. This was caused by the progressive growth of ice crystals, and this damage appears to be the main factor responsible for the loss in quality and the greater rate of staling [46].

The freezing of a non-packaged product is a faster process compared with the freezing of a packaged product. The moisture loss from non-packaged bread during freezing is negligible. Because the fast freezing process is important for the protection of product quality, it is recommended that part-baked bakery products be frozen in the non-packaged form in order to minimize the loss of quality during freezing [46]. Freezing is an expensive method of preserving, transporting, marketing, and storing foods. Moreover, cellular destruction of food could occur when foods are frozen. If freezing and frozen storage are not done correctly, the product quality can be adversely affected. The main purposes of the use of frozen partially baked products are to limit the weight loss and ice crystallization under the crust during freezing while keeping the freezing time short. To ensure that freezing is effective, it is necessary to optimize process conditions, such as air velocity, air temperature, and relative humidity [83].

14.5.4 Modified Atmosphere Packaging

Modified atmosphere packaging (MAP) is an effective method to increase the mold-free shelf life of bakery products [85]. MAP is a procedure in which the composition of air in a package of known permeability is changed after the food is filled. Several methods can be used to modify the atmosphere within the packaged product, including (i) vacuum packaging, (ii) gas packaging, and (iii) active packaging.

14.5.4.1 Vacuum Packaging

Vacuum packaging involves evacuating most of the oxygen present in the package (i.e. to a level of less than 1%). This low oxygen concentration will help to prevent the growth of aerobic organisms and to reduce the rate of oxidative rancidity. However, in the part-baking industry, vacuum packaging is not widely used because of its crushing effect on the products.

14.5.4.2 Gas Packaging

Generally, gas packaging consists of two stages. It begins with a vacuum on the product in order to remove oxygen as much

as possible from the system. Then the pack is flushed with a gas or gas mixture. Generally, gas types and concentrations in MAP systems are determined by internal factors, such as types of products, permeability of packaging material, microbial load, and product ingredients, and external factors such as temperature and storage time [86]. The common gases used are oxygen, nitrogen, and carbon dioxide. Minimum oxygen levels are used to pack food under a modified atmosphere because oxygen reacts with the foodstuff resulting in oxidative breakdown. Nitrogen is an inert gas and is used as a sterile filler gas to dilute the concentration of oxygen and carbon dioxide in the package. It acts as a cushion, thereby preventing pack collapse. Although carbon dioxide is not lethal to microorganisms, it showed both bacteriostatic and fungistatic properties and hinders the growth of certain aerobic organisms. For this reason, there is an increasing demand for the storage of bakery products in modified atmospheres, which are most often composed of carbon dioxide alone or mixtures of carbon dioxide and nitrogen [86–88].

Storage temperature fluctuations should be avoided during the storage of MAP products because changes in storage temperature had a significant effect on the characteristics of the system such as the gas composition, relative humidity, and volume of package headspace. The gas solubility, permeability of packaging, and microbial respiration can also affect headspace gas composition [86].

The possible effect of modified atmosphere packaging, ethanol content, and UV radiation dose on the mold-free shelf life of wrapped part-baked baguettes with/without chemical preservative was studied by Doulia et al. [15]. The use of modified atmosphere with 70% CO_2/30% N_2 had a very positive effect, raising the microbial shelf life of part-baked baguettes to very high levels (>70 days), as compared to the control bread which showed a shelf life of 4.6 days (i.e. 14 times) [52].

14.5.4.3 Active Packaging

Active packaging is an innovative approach to maintain or to extend the shelf life of food products while ensuring their quality, safety, and integrity. It is a good alternative to the use of chemical preservatives and MAP [89, 90]. Active packaging applications consist of two systems, namely active-scavenging (absorbers) and active-releasing (emitters). Absorbers remove undesired compounds such as moisture, carbon dioxide, oxygen, ethylene, and odor from the package environment, while emitters release desired compounds such as antimicrobial compounds, carbon dioxide, antioxidants, flavors, ethylene, and ethanol to the packaged food or into the package headspace [90].

The application of oxygen scavengers (OS) is one of the main active packaging systems in bakery products. An oxygen absorber can remove oxygen from the package headspace to a level of less than 0.01% and therefore reduce the growth of aerobic bacteria, molds, and insects, and it may prevent undesirable oxidative changes that could deteriorate the sensory quality of the bakery product [10]. For packaged part-baked bakery products, mold growth is the key factor limiting shelf life. Oxygen absorbents are three times more effective than gas packaging in improving the mold-free shelf life of bread rolls [52]. In a study, in which the palladium-based OS film in modified atmosphere (MA) packages were applied to partially baked buns, toast bread, and gluten-free bread slices, it was shown that at normal and MA conditions without OS film, visible mold growth was detected in all samples after 2 d with a simultaneous reduction in oxygen concentration in the headspace. In contrast, in MA packages with OS film, mold growth was retarded up to 8 and 10 days, resulting in a three- to four-fold longer shelf life for all types of bread tested [90].

The most commonly used absorbent to reduce the O_2 concentration in the package is Atco or Ageless. The majority of commercially available O_2 scavengers react on the basis of iron, and they actively modify the headspace and reduce the O_2 levels to less than 0.01% within 1 to 4 day(s) at room temperature. It is stated that Atco O_2 absorbers considerably extended the microbial shelf life of sliced bread, decreased O_2 concentration to below 0.1% within a few days of packaging, and did not seem to have any effect on the sensory quality of bread during storage [52].

Another example of an antimicrobial, active packaging concept is an ethanol emitter, like Ethicap. Ethicap is a sachet containing microencapsulated food-grade ethanol in a free-flowing powdery form, and it consists of 55% ethanol, 35% silicon dioxide, 10% water (all w/w), and a trace of flavors to mask the ethanol. The antimicrobial effect of ethanol as a preservative is based on ethanol's ability to lower the water activity, and it is effective in suppressing the growth of a number of bacteria, yeasts, and molds [91]. Franke et al. [91] stated that pre-baked buns, with a water activity of 0.95, packaged with different amounts of Ethicap, into gamma-sterile low-density polyethylene bags and stored at room temperatures, can be stored up to 13 days without mold growth. Typical examples of active packaging methods are presented in Table 14.3 [52].

Nanotechnologies can also be applied in order to design active packaging and are opening up new possibilities for both the food industry and consumers. Nanotechnology has been applied in the production of nanocomposites and in the nanoencapsulation of active compounds (Figure 14.7). Nanocomposites are multiphase materials characterized by a polymer (continuous phase) merged to nano-dimensional material (discontinuous phase) that can come in the form of inorganic or organic fibers, flakes, spheres, or particulates, commonly referred to as "fillers." Therefore, nanocomposites are a fusion of traditional packaging polymers with nanoparticles. Generally, the inclusion of fillers in nanoscale improves the mechanical strength of food package materials and the barrier ability against oxygen, carbon dioxide, ultraviolet radiation, moisture, and volatiles. In addition, they may allow air and other enzymes, but degrade ripening gas, such as ethylene, and have antimicrobial activity. Hence, nanocomposites may be used to extend food shelf life; thus these reduce the addition of chemical preservatives in foods. Several materials, such as metal, metal oxides, silica, clay, polysaccharide nanocrystals, chitosan, and cellulose, have been explored as fillers. Nanoencapsulation is also used to obtain antimicrobial

TABLE 14.3
Examples of Active Packaging Techniques for Bakery Products

Technique	Reagent	Packaging Form	Desirable Effect
O_2 absorber	Ferrous compounds	Sachet	Prevent mold growth
	Metallic salts	Label	Oils and fats oxidation inhibition
	Organometallic compounds	Plastic film	Elimination of insect pests
	Catechol		Flavor retention

packaging systems. This technology has been applied by using essential oils that can act as potent antimicrobials, may present antifungal activity, and/or have antioxidant properties. It consists of coating essential oils within another material in the nanoscale [14].

14.5.5 Irradiation

The ionizing radiation source could be high-energy electrons, X-rays, or gamma rays, while non-ionizing radiation is electromagnetic radiation mainly from ultraviolet (UV) rays, visible light, microwaves, and infrared [92]. In particular, ionizing radiation and UV can be used to extend the microbial shelf life of part-baked products [11]. Ionizing radiation does not cause any significant rise in the temperature of the product. Therefore, the flavor, texture, and other important technological or sensory properties of most ingredients are not influenced at low doses [93]. Ionizing radiation can be used to extend the shelf life of foods by destroying yeasts and molds. The destruction of viable spoilage microorganisms can be achieved using a dose of 0.4–10 kGy, the reduction of viable non-spore forming food-borne pathogens using a dose of 0.1–8 kGy, or the sterilization of products by killing both vegetative bacteria and spores using dose levels of 10–50 kGy [20].

UV light is used in bakery products to prevent the growth of mold on the surface of fresh products. The lethal effect of UV radiation on microorganisms occurs at about 260 nm with a quantum energy of 4.9 electron volts [94]. In UV light

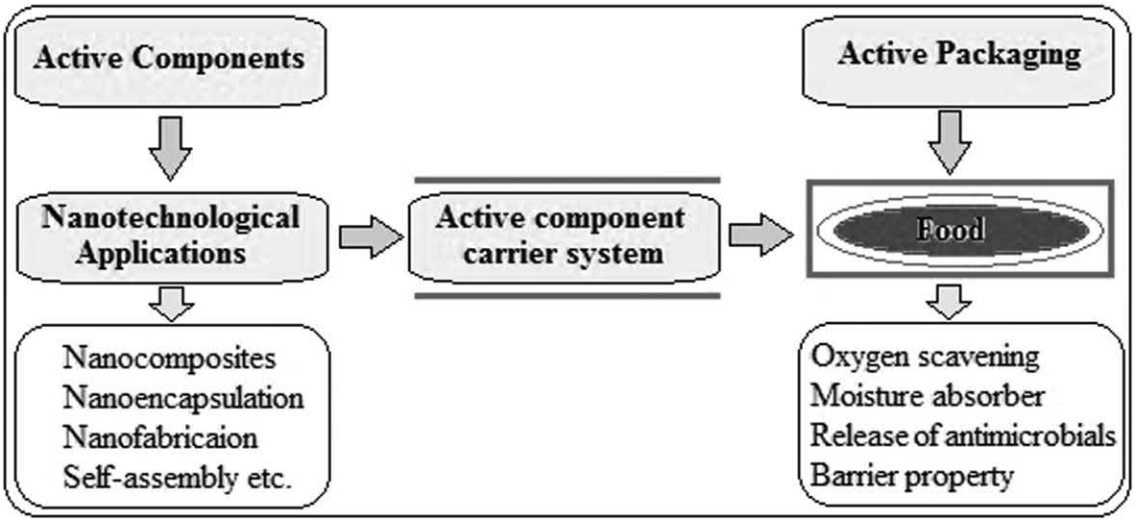

FIGURE 14.7 Active packaging and its association with nanotechnology.

processing, radiation is obtained from the UV region of the electromagnetic spectrum and classified into four wavelength ranges: UV-A (315–400 nm), UV-B (280–315 nm), UV-C (200–280 nm), and vacuum-UV (100–200 nm) [11]. UV-C has the capability of causing damage to the nucleic acid of microorganisms such as bacteria, viruses, and fungi. At a dose rate of 1000 J/m^2 or more, bacteria, yeasts, and viruses undergo as much as 4-log reductions. UV light has very low penetration depth. For this reason, it is only used for surface treatments [53]. There is direct UV irradiation of the surfaces of wrapped bakery products, which allows an extension of shelf life [11]. UV treatment can also be used to prolong the shelf life of wrapped partially baked products to minimize postbaking contamination. Doulia et al. [15] mentioned that ultraviolet treatment increased the shelf life of part-baked bread by 100%, as compared to the control, and there was no significant difference in bread shelf life among the absorbed doses of UV of 32, 81, and 162 kGy. UV light has poor penetration capacity, and therefore, a treatment of 32 kGy seems to be sufficient to decontaminate the surface of the bread, but the highest doses are not able to decontaminate the cracks and crevices.

Microwave energy is a form of electromagnetic (wave) radiation between 300 MHz and 300 GHz delivered in an enclosed cavity. Microwave heating allows the rapid and even heating of a product without major temperature gradients between the surface and the interior. Generally, a 30–60 s treatment makes wrapped bread mold-free. However, the use of this treatment is limited by the fact that it can cause condensation problems, which can adversely affect the appearance of the product [14].

14.5.6 Chemical Preservatives

Another common method to extend the microbial shelf life of part-baked products is to use chemical preservatives (antimicrobial agents) (Table 14.4). Chemical preservatives used in bakery products are calcium and sodium propionate, sorbic acid, potassium sorbate, sodium diacetate, methylparaben, propylparaben, sodium benzoate, and acetic acid at levels of 0.005 to 0.5% w/w. However, the most used chemical preservatives are propionic acid, sorbic acid, and their salts [95]. Propionic acid and calcium propionate are usually used at concentrations of 0.1 and 0.2% respectively. At these levels, they retard the growth of filamentous fungi and germination of *Bacillus* spores but do not inhibit yeast development. Sorbic acid is effective at controlling mold growth in bakery products at levels of 0.125 to 0.3% [1, 3, 96].

The storage of part-baked products at positive temperatures can cause deteriorations such as microbial and fungi growth or enzymatic reactions during storage. Therefore, it can be concluded that the use of an antimicrobial agent in part-baked bakery products is very important and, if one is not used, the part-baked breads must be stored at refrigerator temperature or in frozen storage [42]. Karaoglu et al. [70] stated that the addition of calcium propionate in the bread formulation significantly decreased TAMB, coliform bacteria, *Bacillus* spore, and yeast and mold counts, due to a decrease in the pH levels.

Adding ethanol to the complete surface of the part-baked products before wrapping, or inside the pouches before being filled with a loaf is another way to extend the shelf life of part-baked products (Table 14.5). The absorption of ethanol by the product can have a water activity-lowering effect. In addition, the great microbial inhibitory action of ethanol arises principally from the vapor phase in the headspace. Ethanol has a major effect on the structure and function of membranes, and it can disrupt cellular metabolism in diverse ways. Due to its high vapor-phase activity, ethanol has the advantage that all parts of the wrapped product are protected. It is reported that the presence of ethanol has a beneficial effect, greatly

TABLE 14.4
Common Chemical Preservatives Used in Bakery Products

Active Ingredient	Commercially Available Forms	Applications	Recommended Level (ppm)	Remarks
Propionic acid CH_3CH_2COOH	Propionic acid	Bread	2000	It is effective against molds and bacteria
	Calcium propionate	Bread (part-baked)	2000	Most effective below pH 5.5
		Soft flour tortillas	4000	Not suitable for chemical-leavened products
	Sodium propionate	Cakes, pie fillings, tortillas	2000	Compatible with baking powder Preferred in chemically leavened bakery products
Sorbic acid CH_3-CH=CH-CH=CH-COOOH	Potassium sorbate	Breads, cakes, pies	1000	Typically utilized in chemically leavened products Surface spraying for bread
Acetic acid CH_3COOH	Sodium diacetate	Yeast-leavened bakery products	3000	A synergistic anti-microbial effect with calcium propionate
Benzoic acid C_6H_5COOH	Sodium benzoate	Pie fillings	1000	Used in systems with high water activity Below pH 4.5

TABLE 14.5
Effect of Ethanol on Microbial Shelf Life of Bakery Products

Product	Treatment	Ethanol Content (%)	Storage Temperature	Mold-Free Shelf Life (Days)	Reference
White bread	Added inside the bag	0	Room temp.	4.4	Doulia et al. [15]
	Added inside the bag	1.5	Room temp.	50.7	
	Surface treatment	1.5	Room temp.	45.6	
Apple turnover	Added inside the bag	0	Room temp.	14	Smith [115]
	Added inside the bag	1.1	Room temp.	21	
Bakery product	Surface treatment	0.5	Optimal	Double increase	
	Surface treatment	1.0	Optimal	Triple increase	
Cake	Surface treatment	3	21	90	Kalathenos and Russell [116]
Muffin	Surface treatment	0.5	Room temp.	>50	Doulia et al. [117]
	Surface treatment	1.5	Room temp.	>70	

increasing the microbial shelf life of part-baked baguettes up to 50 days [15]. It is reported that ethanol also prevents or delays staling by plasticizing the protein network in the bread crumb. The anti-staling effect of ethanol has been observed in bread and flour-based confectionery products [97–99].

In a sense, the addition of an antimicrobial agent may be a waste of resources since microbial contamination of many baked products takes place primarily at the surface during the post-processing stage. Consumers mostly demand preservative-free food as well as more natural, disposable, biodegradable, and recyclable food packaging materials. Furthermore, these synthetic additives need to be declared on a product label, and this can conflict with the current consumer desire for clean labeling [79].

14.6 QUALITY DEFECTS OF PART-BAKED PRODUCTS

Some undesirable changes may occur in part-baked products stored under different conditions. These defects are crumb shrinkage, reduction/contraction in specific volume, weight loss, discoloration (dull color of the crust), separation of the crust from the crumb, and microstructure problems.

14.6.1 Crust Flaking

One of the most important quality problems in stored part-baked products is crust flaking [83], which generally occurs during the final baking stage [49]. Crust structures that are generally high in gelatinized starch content and low in evenly distributed gluten are more susceptible to cracking after the final baking, and freezing [100]. Crust flaking can be generally explained by a synergic effect of three factors: thermo-mechanical shock, drying out of the crust, and an accumulation of ice under the crust [46]. Industrial investigations show that the chilling conditions and the freezing step after partial baking are the most influential parameters in crust flaking. Generally, higher air humidity during the chilling process tends to minimize crust flaking. In addition, a higher temperature of the partially baked product on entry into the freezer seems to enhance the crust-flaking phenomenon [101].

Crust flaking in part-baked bakery products can be especially related to mechanical damage due to the intense thermomechanical shock during chilling-freezing and final baking. Depending on the hydration of the crust at the end of partial baking, the crust is affected differently by the thermomechanical strain and stresses imposed during the freezing process. Flaking does not occur after the final baking step if the part-baked products are not frozen. However, crust flakes can form even in the absence of cold storage [49, 83, 102].

The relative humidity during proving and pre-chilling is the key factor in controlling the amount of crust flaking [103]. Higher air humidity during the chilling process tends to minimize crust flaking [44]. There are two mechanisms used to explain flaking in part-baked bread. The first is the condensation of water vapor under the bread crust during the cooling phase. The mechanism by which a layer of condensed water might lead parts of the structure to become separated from the crumb has not been well explained. However, the mechanism has been based on properties or behaviors of the subsurface layer, which differ from those of the rest of the product matrix. Water crystallization between the different layers such as crust, water, and crumb might give rise to local stresses, which might be responsible for the separation of the upper crust after sudden evaporation during the final baking. The same hypothesis has been advanced to explain the formation of cracks within the crumb several millimeters or even centimeters under the crust. Considerable instantaneous evaporation of more mobile water under the upper crust during final baking might also be responsible for the detachment of the upper crust [103]. The second hypothesis is the tensile forces. The tensile forces within the bread matrix cannot relax in response to the contraction of the crumb phase during the

cooling process. It could make the bread matrix more sensitive to mechanical shocks or high hydrothermal stresses on final baking and so, in turn, would finally result in a detachment of parts of the crust and flaking phenomena [44].

Baking and storage conditions can also affect crust flaking [101]. In the production of fermented part-baked products, relative air humidity during proving and pre-chilling is the key factor in controlling the amount of flaking. In general, it is emphasized that low levels of surface hydration in these stages could favor the appearance of crust flakes [103]. However, high relative air humidity at the proving and cooling stages minimizes flaking. In other words, it can be supposed that the state of hydration of the material partly or primarily determines its capacity to deform, and the greater its level of hydration is, the more deformation it allows.

14.6.2 Shrinkage of Structure

Another problem is the crumb shrinkage developed during the chilling and freezing of part-baked products. In general, the thermo-mechanical properties of par-baked products change with freezing [46]. During freezing, the frozen superficial crust is exposed to a negative tangential stress that could explain the crust-flaking phenomena because of this crumb shrinkage. Actually, these tensions and stresses act in the crust–crumb interface in which extreme gradients in terms of temperature, moisture, and frozen water occur [44]. Crystallization of the amylose during cooling and partial recrystallization of the amylopectin during freezing and frozen storage could clarify the crumb shrinkage [46]. Reduction of the crumb shrinkage is an important issue as it causes crust flaking. Specific enzymes and additives combined with appropriate processing conditions such as a specific cooling and freezing rate should be permitted to reach this goal [44]. Almeida and Chang [104] reported that the structural problem of pre-baked bread could be overcome through joint adoption of the following parameters: (i) carrying out a more open modeling, (ii) ending the proofing stage when the dough is resistant to touch, (iii) establishing a good par-baking stage (only a few seconds of water steam at the beginning of baking), (iv) appropriate baking time and temperature, (v) last moments realized at dry conditions (steam elimination), and (vi) ending only when the center of the bread reaches 93–96°C.

14.6.3 Reduction in Specific Volume

Although some studies revealed that the storage period negatively affects the part-baked product volume [32, 80, 105, 106, 107], some others showed no significant relationship between storage period and volume [64, 108]. Karaoglu et al. [80] showed that the increase in the frozen storage time of par-baked cake leads to a decrease in the quality of the re-baked cake, namely an increase of baking loss and cake crumb firmness, and a loss in the moisture content and specific volume. Majzoobi et al. [32] studied the influence of storage (at ambient, 25°C and freezing, –18°C temperatures) on the quality and staling of part-baked flat bread (Barbari). They reported that the volume of full-baked breads, after part-baking and storage, decreased over the storage time at both ambient and freezing temperature (Figure 14.8). However, Almeida and Chang [108] stated that specific volume, springiness, and sensory evaluation of re-baked rolls practically did not change with the frozen storage period.

14.6.4 Weight Loss

If the bakery products are frozen without packaging, weight losses occur due to water evaporation during pre-chilling. Water loss of frozen part-baked products is higher than in the case of a conventional process. The evaporation amount is related to the difference in partial vapor pressure between the surface of the product and the ambient air. The lower the freezing rate is, the slower reduction is in surface temperature, and this causes the difference in vapor pressure between food and

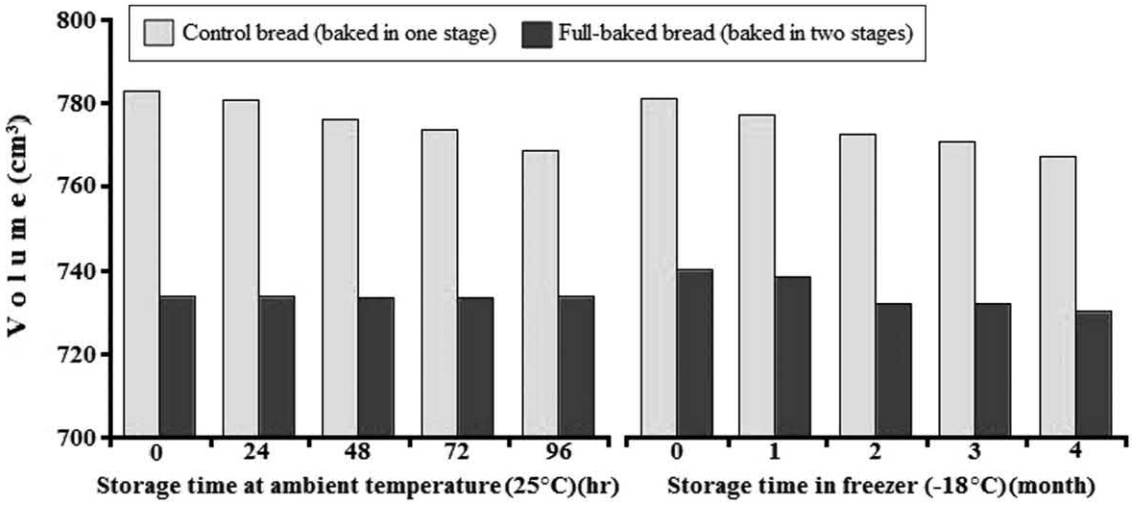

FIGURE 14.8 Volume of control and full-baked bread samples stored at ambient temperature and in freezer. (Revised from Majzoobi et al. [32].)

air to remain large for a longer time. At the same time, a low freezing rate would cause the prolongation of freezing process duration. Eventually, both factors increase the weight loss of frozen products. The weight loss by dehydration in products frozen in this way is approximately 2–3% [83]. Figure 14.9 shows the baking weight loss of the re-baked breads obtained from part-baked breads and part-baked brown soda bread during freezing storage and re-baking at in-oven temperatures of 180 and 200°C. The nonfrozen samples have lower baking weight loss compared with the frozen samples. In addition, a linear relationship between baking loss and length of the second baking phase was observed. The moisture loss for the higher oven temperature increases as compared to the lower re-baking temperature [43, 69].

Weight loss can be overcome by reducing the post-baking–chilling time and by starting the freezing earlier or by increasing the air humidity during chilling. In addition, a higher temperature of the partially baked product upon entrance to the freezer can enhance the crust-flaking phenomenon. Therefore, the temperature of the pre-baked product at the start of freezing should not be too high. The final baking is generally combined with thawing. The lower baking temperature results in higher water loss and longer baking time. For this reason, a fast final baking time at a high temperature is usually used for these products to decrease weight loss [101].

14.6.5 Discoloration

Another problem caused by frozen storage is the appearance of snow-white discoloration of the crumb. The appearance of discoloration generally occurs after a relatively long time in the freezer. After thawing the product, the white rings become weaker but do not disappear. The formation of this white ring or freezing ring is due to the drying of the crumb just under the crust during frozen storage. Researchers have reported that this discoloration (white rings) of the crust is caused by the transference of moisture by sublimation and diffusion from the highly moist center of the crumb to the low moisture-content region of the crust [46].

14.6.6 Separation of the Crust from the Crumb

During baking of bakery products, there is a small empty space that separates the crust from the crumb. This separation has the following effects: (i) during baking, the heat transfer from the crust to the crumb is slower, (ii) the crust can be baked more thoroughly than the crumb, and (iii) after baking, diffusion of the moisture from the crumb to the crust is slower. Freezing of bakery products can make more obvious the problem of the separation of the crust from the rest of the product. This is especially true for crisp bread like baguettes in which the most obvious manifestation of the quality problem is the separation of the crust from the crumb. Because, in crispy bread, there is a considerable difference in moisture content between the crust and the crumb, expansion and contraction occur at different rates during the freezing and thawing processes. This creates remarkable pressure on the structure of the product, and the crust is separated from the crumb due to various stresses and deformations. This problem could be solved by the migration of moisture from the crumb to the crust, which would subsequently leave it softer and more flexible, but this could be unacceptable for a crisp product [46].

14.6.7 Microstructure Problems

The internal microstructure of bakery products plays an important role in maintaining quality, since the physicochemical,

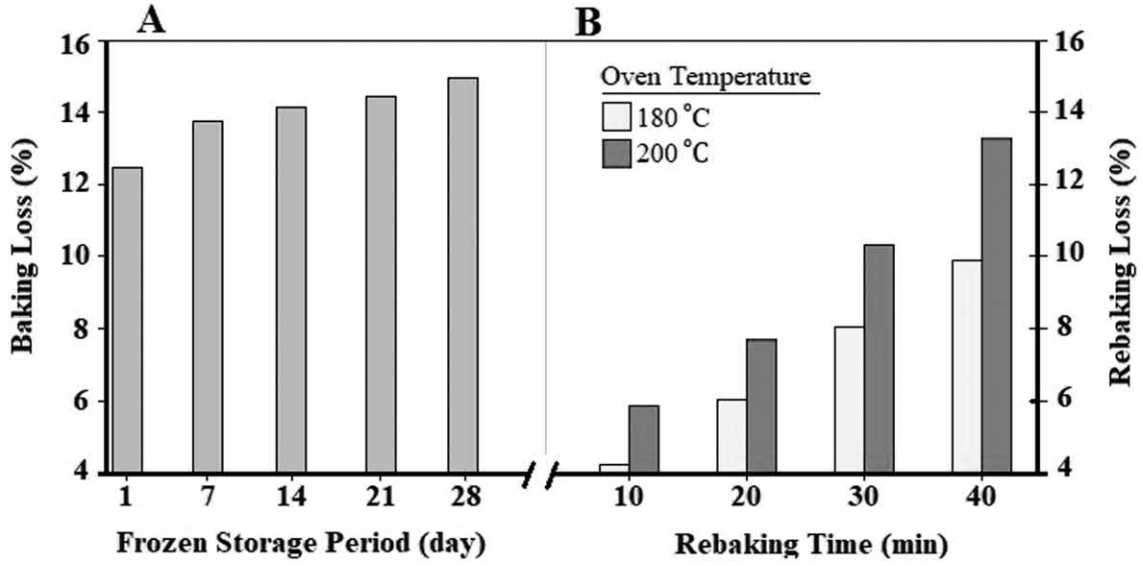

FIGURE 14.9 Baking loss of the re-baked breads obtained from part-baked breads during frozen storage (A) and baking loss of re-baked breads obtained from part-baked brown soda bread during re-baking at different oven temperature (B). (Adapted from Majzoobi et al. [43]; Leuscher et al. [69].)

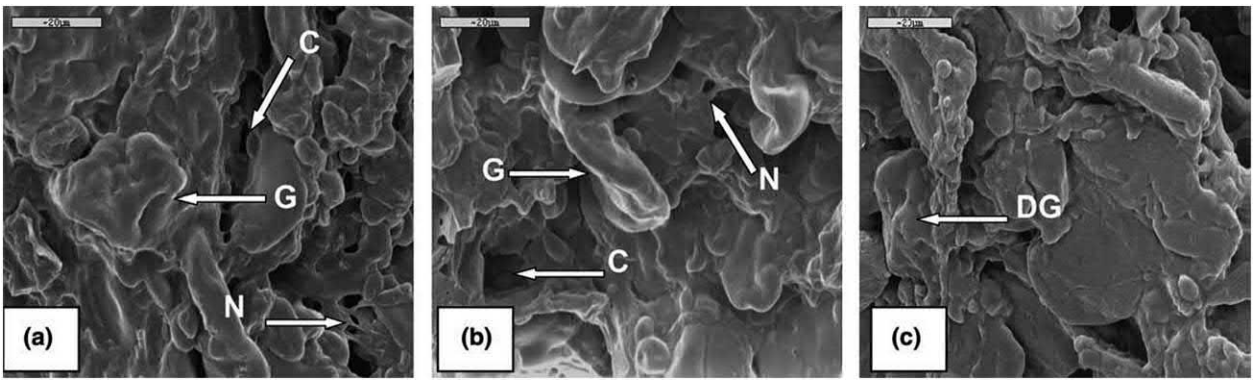

FIGURE 14.10 Cryo-SEM micrographs of gas cell walls (1500X) of bread from conventional breadmaking process (a), bread crumb from par-baked bread after freezing, thawing, and baking (b), and crumb bread from par-baked frozen bread after 42 days of frozen storage (c). The arrows show starch granules (G), cavities (C), protein network (N), and damaged granules (DG). (From Barcenas and Rossell [74].)

sensory, and transport properties of these foods are largely dependent on crumb structure, and crumb construction affects textural properties of bakery products [109]. Freezing results in the disrupted microstructure of crumb, mainly the protein matrix, bringing about the rupture of the denatured gluten network and the subsequent release of the bound water, and some damage and deformed starch granules. The faster the freezing rate is, the less damage the microstructure of the food undergoes. The effect of frozen storage time on the microstructure of the par-baked bread crumb has been studied by Barcenas and Rosell [74]. Cryo-SEM micrographs of gas cell walls of bread crumb are shown in Figure 14.10. The microstructure results from cryo-SEM might indicate that the physical damage undergone by the crumb constituents of the part-baked bread during frozen storage is caused by the progressive growth of the ice crystals. This damage seems to be the main cause of quality loss and the greater rate of aging.

14.7 CONCLUSION

Bakery products are the most widely consumed foods in the world and consumers generally desire to eat them fresh. However, most of them have a short shelf life, resulting from undesired changes that begin just after the baking process. Soft bakery products are dynamic systems that undergo physical, chemical, and microbiological changes during processing and storage, which limit their shelf life. Storage temperature, relative humidity, packaging material and the gaseous environment surrounding the product, level of preservatives, pH, and especially the moisture content and a_w significantly affect the spoilage problems in baked products. Basically, there are three important methods to extend the shelf life of bakery products. These are frozen dough technology, freezing of bakery products, and the production of partially baked products. The partial baking process allows fresh products to be available at any time of the day. This method is economical and time-saving as there is no need for skilled labor or baking instruments except for an oven for re-baking, and it takes a short amount of time to obtain a fresh final product at any time. Part-baking or partial baking is a method of producing baked products involving two stages of baking with an intermediate storage stage. Storage conditions are the major factors affecting the storage life of part-baked products. The desired storage life of part-baked products depends mainly on the change in their quality parameters such as chemical, physical, and microbiological. Partially baked bakery products generally have a very short shelf life due to their lack of crust, light baking, and high moisture content, which increase the susceptibility to microbial growth. However, it is estimated that the storage life of part-baked products can be extended up to 6 to 12 months by using various methods. Different applications such as the use of antimicrobial preservatives, modified atmosphere packaging, infrared and ultraviolet irradiation, storage at refrigerator temperature, and freezing storage have been suggested for prolonging the shelf life of partially baked products.

15 Hurdle Technology (Combined Methods) for Food Preservation: Theory and Basic Aspects

Lothar Leistner and Mohammad Shafiur Rahman

CONTENTS

15.1 INTRODUCTION

The microbial stability and safety of most traditional and novel foods depend on a combination of several preservative factors (called hurdles), which the microorganisms present in the food are unable to overcome. This is the so-called hurdle effect, first introduced by Leistner [1]. Figures 15.1 and 15.2 show the visualized concept of hurdle technology, and these indicate when the microbe passed over the hurdles or stairs, and when it was exhausted and unable to perform its physiological process or died. The hurdle effect is of fundamental importance for the preservation of foods, since the hurdles in a stable product control microbial spoilage and food poisoning as well as desired fermentation processes [1, 2]. Leistner and co-workers acknowledged that the hurdle concept illustrates only the well-known fact that complex interactions of temperature, water activity, pH, redox potential, etc., are significant for the microbial stability of foods. From an understanding of the hurdle effect, the hurdle technology [3] is derived, and it allows improvements in the safety and quality of foods, by deliberate and intelligent combinations of hurdles. Over the years, the insight into the hurdle effect has been broadened and the application of hurdle technology extended. In industrialized countries, hurdle technology is currently of particular interest for minimally processed foods, whereas in developing countries it is of interest for foods storable without refrigeration, due to stabilization by hurdle technology; thus at present hurdle technology has paramount importance. The application of deliberate and intelligent hurdle technology is now advancing rapidly worldwide. This concept is synonymously called food preservation by combined methods, combined processes, combination preservation, or combination techniques. Special expressions for this concept have been coined in different languages, for example Hürden-Technologie in German, hurdle technology in English, technology des barrières in French, tecnologia degli ostacoli in Italian, tecnologia de obstaculos in Spanish, zanglangishu in Chinese. Recently, the term hurdle technology has been most often used.

In Europe, a three-year research project on "Food Preservation by Combined Processes," supported by the European Commission, to which scientists from 11 European countries have contributed, fostered the application of hurdle technology [4, 5]. The hurdle technology concept proved successful, since an intelligent combination of hurdles secures microbial stability and safety as well as the sensory quality of foods [6–8]. It provides convenience and freshness of foods to consumers and is cost-efficient for the producers since it demands less energy during production and storage.

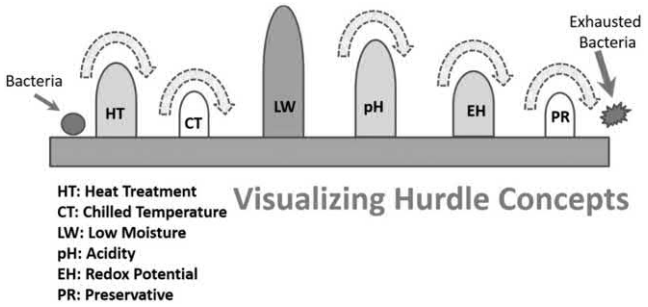

FIGURE 15.1 Visualization of hurdles on microorganism considering each preservation effect is a hurdle.

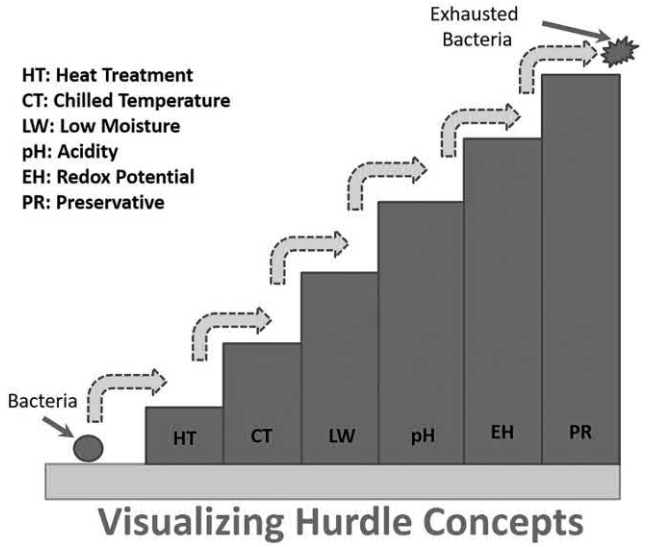

FIGURE 15.2 Visualization of hurdles on microorganism considering each preservation effect is a stair.

15.2 PRINCIPLES OF COMBINED PRESERVATION METHODS

There are many preservation methods used for making foods stable and safe, e.g. heating, chilling, freezing, freeze-drying, drying, curing, salting, sugar-addition, acidification, fermentation, smoking, and oxygen removal. However, these processes are based on relatively few parameters or hurdles, i.e. high temperature (F value), low temperature (t value), water activity (a_w), acidification (pH), redox potential (E_h), preservatives, and competitive flora. In some of the preservation methods mentioned, these parameters are of major importance; in others they are only secondary hurdles [1, 6, 9, 10].

The critical values of these parameters for the death, survival, or growth of microorganisms occurring in foods have been determined in recent decades, and are now the basis of food preservation. However, the critical value of a particular parameter changes if other preservative factors are present in the food. For instance, the heat resistance of bacteria increases at low a_w and decreases in the presence of some preservatives, or a low E_h increases the inhibition of microorganisms caused by a reduced a_w. The simultaneous effect of different preservative factors could be additive or even synergistic. Furthermore, as mentioned before, the microbial stability and safety of many foods are based on the combined effects of hurdles. For instance, mildly heated canned foods ("half-preserved" or "three-quarter-preserved") need refrigeration during storage, or fermented sausages are only stable and safe if both the a_w and the pH are in an appropriate range. Therefore, in food preservation the combined effect of preservative factors must be taken into account, which is illustrated by the so-called hurdle effect.

15.2.1 Hurdle Effects

For each stable and safe food, a certain set of hurdles is inherent, which differ in quality and intensity depending on the particular product; however, the hurdles must keep the "normal" population of microorganisms in this food under control. The microorganisms present ("at the start") in a food should not be able to overcome ("leap over") the hurdles present, otherwise the food spoils or even causes food poisoning. In previous publications [6, 7], some examples were given to illustrate the hurdle effect, which are quite helpful for an understanding of the hurdle effect, as well as for the applications of combined methods in food preservation.

Figure 15.3 gives eight examples of the hurdle effect. Example 1 represents a food that contains six hurdles: high

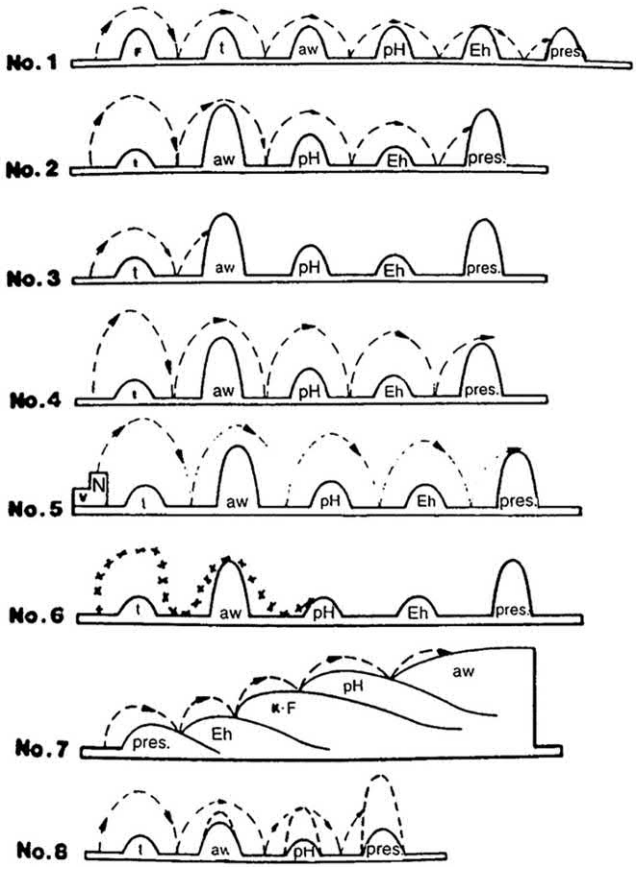

FIGURE 15.3 Illustration of the hurdle effect, using eight examples. Symbols have the following meanings: F, heating; t, chilling; a_w, water activity; pH, acidification; E_h, redox potential; pres., preservatives; K-F, competitive flora; V, vitamins; N, nutrients. (From Leistner [6, 8].)

temperature during processing (F value), low temperature during storage (t value), water activity (a_w), acidity (pH), redox potential (E_h), and preservatives (pres.). The microorganisms present cannot overcome these hurdles, and thus the food is microbiologically stable and safe. However, example 1 is only a theoretical case, because all hurdles are of the same height, i.e. have the same intensity, and this rarely occurs. A more likely situation is presented in example 2, since the microbial stability of this product is based on hurdles of different intensity. In this particular product the main hurdles are a_w and preservatives, whereas other less important hurdles are storage temperature, pH, and redox potential. These five hurdles are sufficient to inhibit the usual types and numbers of microorganisms associated with such a product. If there are only a few microorganisms present at the start (example 3), then a few or only low hurdles are sufficient for the microbial stability of the product. The ultra-clean or aseptic processing of perishable foods is based on this principle. The same proves true if the initial microbial load of a food (e.g. high-moisture fruits or carcass meat) is substantially reduced (e.g. by application of steam), because after such a reduction fewer microorganisms are present at the start, which are easier to inhibit using few or low hurdles. On the other hand, as in example 4, if due to bad hygiene conditions too many undesirable microorganisms are initially present, even the usual inherent hurdles in a product may be unable to prevent spoilage or food poisoning. Example 5 is a food rich in nutrients and vitamins, which foster the growth of microorganisms (this is called the "booster" or "trampoline effect"), and thus the hurdles in such a product must be enhanced, otherwise they will be overcome. Example 6 illustrates the behavior of sublethally damaged microorganisms in food. If, for instance, bacterial spores in meat products are damaged sub-lethally by heat, then the vegetative cells derived from such spores lack "vitality," and therefore are inhibited by fewer or lower hurdles. In some foods, stability is achieved during processing by a sequence of hurdles, which are important in different stages of the ripening process and lead to a stable final product. Example 7 illustrates a sequence of hurdles in fermented sausages. Finally, example 8 illustrates the possible synergistic effect of hurdles, which probably relates to a multi-target disturbance of the homeostasis of microorganisms in foods.

15.2.2 Hurdle Technology

The better understanding of the occurrence and interaction of different preservative factors (hurdles) in foods is the basis for improvements in food preservation. If the hurdles in a food are known, the microbial stability and safety of this food might be optimized by changing the intensity or quality of these hurdles. Therefore, from an understanding of the hurdle effect, hurdle technology has been derived [3], which means that hurdles are deliberately combined in the preservation of traditional and novel foods. By an intelligent mix of hurdles, it is possible to improve not only the microbial stability and safety but also the sensory and nutritive quality as well as the economic properties of a food. For example, it is important how much water in the product is compatible with its microbial stability, and if an increased a_w is compensated by other hurdles (pH, E_h, etc.) this food becomes more economical. Even the pet food industry now employs this principle. A stable pet food was formerly produced with a_w of 0.85, and this needed the addition of excessive amounts of propylene glycol, which might have caused health implications for cats. With the application of hurdle technology, pet foods are microbiologically stable at ambient temperatures with a_w of 0.94, and these are healthy, tasty, and economic [6]. Hurdle technology is increasingly used for food design in industrialized and developing countries for optimizing traditional foods and for making new products according to needs. For instance, if energy preservation is the goal, then energy-consuming hurdles such as refrigeration are replaced by other hurdles (a_w, pH, or E_h) which do not demand energy and still ensure a stable and safe food [1]. Furthermore, if we want to reduce or replace preservatives, such as nitrite in meats, we could emphasize other hurdles in the food, e.g. a_w, pH, refrigeration, or competitive flora, which would stabilize the product [11].

15.2.3 Total Quality

Stanley [12] proposed that the hurdle technology approach might be applicable to a wider concept of food preservation than just microbial stability, but in order for it to work, a precise knowledge of the effectiveness of each hurdle for a given commodity is required. Furthermore, he suggested distinguishing between positive and negative hurdles for the quality of foods. Certainly, hurdle technology is applicable not only to safety, but also to quality aspects of foods, although this area of knowledge has been much less explored than the safety aspect. McKenna [13] emphasized that while hurdle technology is appropriate for securing the microbial stability and safety of foods, the total quality of foods is a much broader field and encompasses a wide range of physical, biological, and chemical attributes. The concept of combined processes should work towards the total quality of foods rather than the narrow but important aspects of microbial stability and safety. At present, the tools for applying hurdle technology to total food quality are still not adequate, and this is equally true for predicting food quality by modeling. However, researchers should appreciate the wider power of the hurdle technology concept, and the food industry should use the available tools of combined processes for as many quality enhancements as possible [13].

Some hurdles, e.g. Maillard reaction products, influence the safety as well as the quality of foods, because they have antimicrobial properties and at the same time improve the flavor of the products, and this also applies to nitrite used in the curing of meat. The possible hurdles in foods might influence the stability and safety, as well as the sensory, nutritive, technological, and economic properties of a product, and the hurdles present might be negative or positive for securing the desired total quality of a food. Moreover, the same hurdle could have a positive or a negative effect on foods, depending on its intensity. For instance, chilling to an unsuitable

low temperature will be detrimental to fruit quality ("chilling injury"), whereas moderate chilling is beneficial. Another example is the pH of fermented sausages, which should be low enough to inhibit pathogenic bacteria, but not so low as to impair taste. If the intensity of a particular hurdle in a food is too small, it should be strengthened; on the other hand, if it is detrimental to the total food quality it should be lowered. By this adjustment, the hurdles in foods should be kept in the optimal range, considering safety as well as quality [7, 14].

15.2.4 Potential Hurdles

For the advanced application of hurdle technology, a continually increasing number of preservative factors (hurdles) become available (Table 15.1). The most important hurdles in common use for the preservation of foods, either applied as "process" or "additive" hurdles, are temperature (high or low), decreased water activity (a_w), acidity (pH), low redox potential (E_h), preservatives (e.g. nitrite, sorbate, sulfite), and competitive microorganisms (e.g. lactic acid bacteria). However, in addition, more than 50 hurdles of potential use for foods of animal or plant origin, which improve the stability and/or the quality of these products, have hitherto been identified and described [14, 15], and the list of possible hurdles for food preservation is by no means complete. At present especially physical, non-thermal processes (e.g. high hydrostatic pressure, mano-thermo-sonication, oscillating magnetic fields, pulsed electric fields, light pulses) receive considerable attention, since in combination with conventional hurdles they are of potential use for the microbial stabilization of fresh-like food products with little induced degradation of sensory and nutritional properties. With these novel processes, often only a reduction of the microbial load is intended (i.e. not complete sterility), and the growth of the remaining microorganisms is inhibited by additional, conventional hurdles. Another group of hurdles which is at present of special interest in industrialized as well as in developing countries are "natural preservatives" (e.g. spice extracts, lysozyme, chitosan, pectin hydrolysate, protamine, paprika glycoprotein, hop extracts). Moreover, the microstructure of some foods (e.g. emulsions, fermented sausages, ripened cheese) might be a considerable hurdle in relation to microbial growth. However, not all of the potential hurdles for food preservation are commonly applied, and certainly not all of them to the same food product.

TABLE 15.1
Incomplete List of Potential Hurdles for Foods of Animal or Plant Origin, Which Improve the Stability and/or the Quality of These Products

Hurdle	Possible Options
Temperature	Low or high
pH	Low or high
a_w	Low or high
E_h	Low or high
Modified atmosphere	Nitrogen, carbon dioxide, oxygen
Packaging	Aseptic packaging, vacuum or modified atmosphere or active packaging, edible coatings
Pressure	High
Radiation	Microwave, ultraviolet light (UV), irradiation
Other energy	Nano-thermo-sonication, high electric field pulses, oscillating magnetic field pulses, radiofrequency energy, photodynamic
Microstructure	Emulsions, fermented sausage, ripened cheese
Competitive flora	Lactic acid bacteria
Preservatives	Organic acids, lactate, acetate, sorbate, ascorbate, glucono-delta-lactone, phosphates, propylene glycol, diphenyl, parabens, free fatty acids and their esters, phenols, monolaurin, chelators, Maillard reaction products, ethanol, spices and their extracts, nitrite, nitrate, sulfite, carbon dioxide, oxygen, ozone, chlorine, smoke, antioxidants, pimaricin and other antibiotics, lysozyme, chitosan, lactoperoxidase, nisin and other bacteriocins, pectine hydrolysate, protamin, hop extracts

15.3 BASIC ASPECTS

Food preservation implies putting microorganisms in a hostile environment, in order to inhibit their growth, shorten their survival, or cause their death. The feasible responses of the microorganisms to such a hostile environment determine whether they may grow or die. Related to these responses more basic research is needed, because a better understanding of the physiological basis for the growth, survival, and death of microorganisms in food products might open new dimensions for food preservation [7]. Furthermore, such an understanding would be the scientific basis for an efficient application of hurdle technology in the preservation of foods. Recent advances in these respects have been made by considering the homeostasis, metabolic exhaustion, and stress reactions of microorganisms, as well as by introducing the concept of multi-target preservation for a gentle but effective preservation of foods [3, 11].

15.3.1 Homeostasis

A key phenomenon, which deserves more attention in food preservation, is the interference by the food with the homeostasis of microorganisms [16]. Homeostasis is the tendency to uniformity or stability in the normal status (internal environment) of organisms. For instance, the maintenance of a defined pH within narrow limits is a feature and prerequisite of living organisms [17], and this applies to higher organisms as well as to microorganisms. The homeostasis in higher organisms at the molecular, subcellular, cellular, and systematic levels are known in the fields of molecular biology, biochemistry, physiology, pharmacology, and medicine [17]. This knowledge should be transferred to microorganisms important in the poisoning and spoilage of foods. If the homeostasis of microorganisms, i.e. their internal

equilibrium, is disturbed by preservative factors (hurdles) in foods, they will not multiply, i.e. they will remain in the lag-phase or even die, before their homeostasis is re-established ("repaired"). Thus, food preservation is achieved by disturbing the homeostasis of microorganisms in a food temporarily or permanently [7].

Gould [16] has pointed out that during evolution a wide range of more or less rapidly acting mechanisms (e.g. osmoregulation to counter-balance a hostile water activity in food) have developed in microorganisms that act to keep important physiological systems operating, in balance, and unperturbed even when the environment around them is greatly perturbed [18]. In most foods the microorganisms operate homeostatically, in order to react to environmental stresses imposed by the preservation procedures applied, and the most useful procedures employed to preserve foods are effective in overcoming the various homeostatic mechanisms that the microorganisms have evolved in order to survive extreme environmental stresses [18]. The repair of a disturbed homeostasis demands much energy, and thus the restriction of energy supply inhibits the repair mechanisms of the microbial cells and leads to a synergistic effect of preservative factors (hurdles). Energy restrictions for microorganisms are caused by anaerobic conditions, such as in "vacuum" or in "modified atmosphere" packaging of foods. Therefore, a low a_w (and/or a low pH) and low redox potential of foods act synergistically [18]. The interference with the homeostasis of microorganisms or entire microbial populations forms an attractive and logical focus for improvements in food preservation techniques [18].

15.3.2 Metabolic Exhaustion

Another phenomenon of certainly practical importance is the metabolic exhaustion of microorganisms, which could lead to an "autosterilization" of foods (i.e. decrease of bacteria with storage time instead of their growth) (Figure 15.4). This was first observed by us and initially not believed, many years ago [19], with mildly heated (95°C core temperature) liver sausage adjusted to different water activities by the addition of salt and fat; the product was inoculated with *Clostridium sporogenes* PA 3679 and stored at 37°C. Clostridial spores, which survived during the heat treatment, vanished in the product during storage, if the products were stable. Later this behavior of *Clostridium* and *Bacillus* spores was regularly observed during the storage of shelf-stable meat products (SSP), especially F-SSP [20]. The most likely explanation is that bacterial spores, which survive the heat treatment, are able to germinate in these foods under less favorable conditions than those under which vegetative bacteria are able to multiply [6]. Therefore, during storage of these products some viable spores germinate, but the germinated spores or vegetative cells derived from these spores die. Thus, the spore counts in stable hurdle technology foods actually decrease during storage, especially in unrefrigerated foods. During studies in our laboratory with Chinese dried meat products, we observed the same behavior of microorganisms [21]. If these meats were contaminated after processing with staphylococci, salmonellae, or yeasts, the counts of these microorganisms in stable products decreased quite quickly during unrefrigerated storage, especially in meats with a water activity close to the threshold for microbial growth. The same phenomenon was observed by Latin American researchers [22–25] in their studies with high-moisture fruit products (HMFP). A variety of bacteria, yeasts, and molds, which survived the mild heat treatment, decreased quite quickly in the products during unrefrigerated storage, because the hurdles applied (pH, a_w, sorbate, sulfite) did not allow growth.

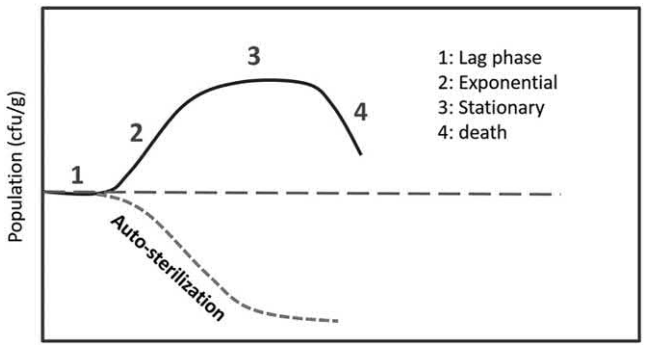

FIGURE 15.4 Microbial population decreasing during storage as a result of auto-sterilization.

A general explanation for this behavior might be that vegetative microorganisms which cannot grow will die, and they die more quickly if the stability is close to the threshold for growth, the storage temperature is elevated, antimicrobial substances are present, and the organisms are sub-lethally injured (e.g. by heat) [7]. Apparently, microorganisms in stable hurdle technology foods strain every possible repair mechanism for their homeostasis in order to overcome the hostile environment; by doing this they completely use up their energy and die, if they become metabolically exhausted. This leads eventually to an autosterilization of such foods [26]. Thus, due to autosterilization, hurdle technology foods, which are microbiologically stable, become even safer during storage, especially at ambient temperatures. For example, salmonellae, which survive the ripening process in fermented sausages, vanish more quickly if the products are stored at ambient temperature, and they will survive longer and might then cause food poisoning if the products are stored under refrigeration [7]. Salmonellae survive in mayonnaise at chill temperatures much better than at ambient temperature. Unilever laboratories in Vlaardingen have confirmed metabolic exhaustion in water-in-oil-emulsions (resembling margarine), which were inoculated with *Listeria innocua*. In these products, listeria vanished faster at ambient (25°C) temperature than at chill (7°C), at pH 4.25 > pH 4.3 > pH 6.0, in fine emulsions > in coarse emulsions, and under anaerobic conditions > at aerobic conditions. From these experiments it was concluded that metabolic exhaustion is accelerated if more hurdles are present, and this might be caused by increasing energy demands to maintain internal homeostasis under stress conditions.

15.3.3 Stress Reactions

In relation to the preservation methods, the adaptation of pathogens to environmental and processing stresses constitutes a serious challenge for the food industry [27]. A limitation to the success of hurdle technology foods could be stress reactions of microorganisms. Some bacteria become more resistant (e.g. toward heat) or even more virulent under stress, since they generate stress shock proteins. The synthesis of protective stress shock proteins is induced by heat, pH, a_w, ethanol, etc., as well as by starvation. These responses of microorganisms under stress might hamper food preservation and could turn out to be problematic for the application of hurdle technology. On the other hand, the switching on of genes for the synthesis of stress shock proteins, which helps organisms to cope with stress situations, should become more difficult if different stresses are received at the same time. In order to counter different stresses simultaneously, the cell needs energy synthesis of several or at least much more protective stress shock proteins, which the microorganisms cannot deliver since they become metabolically exhausted [8]. Therefore, a multi-target preservation of foods could be the answer to avoid the synthesis of such stress shock proteins, which otherwise might jeopardize the microbial stability and safety of hurdle technology foods [26]. Nevertheless, further research in stress shock proteins, and the different mechanisms which cause their switch on or by which they could be avoided, seems warranted also in relation to hurdle technology foods.

In many instances, microorganisms are likely to be stressed or injured rather than killed in food processed by preservation technologies. The adaptation of microorganisms to stress during processing constitutes a potential hazard. Sub-lethal stress induces the expression of cell repair systems (Figure 15.5). For instance, nucleic acids are the primary target of ionizing radiations and UV light. When cells are exposed to UV, enzymatic photo repair and expression of excision-repair genes could restore DNA integrity. *E. coli* that survive UV exposure have an activated gene, i.e. a transcriptional regulator involved in multiple stress resistance [28]. Strains which survive high pressure have a similar type of enhanced gene-regulated resistance to both high pressure, light heat and cold shocks, and other stresses [27, 29, 30]. It was also observed that reversible DNA supercoiling protects cells against osmotic pressure [31]. However, microbial lethality by high pressure and pulsed electric fields is mainly attributed to changes in the membrane structure and functionality [32]. In addition, repetitive exposure of bacterial contaminants to the preservation process can transform highly resistant mutants [33]. Slow replication (i.e. under sub-optimal growth conditions) increases the time allowed for cell repair activity, and thus favors the recovery of sub-lethally injured microorganisms [34].

Kang et al. [35] studied the heat resistance of *Salmonella Enteritidis* in the presence of a salt and/or acid medium. *Salmonella* adapted to a single stress (acid or salt stress) and increased the heat resistance, whereas the combination of acid and salt stresses reduced heat tolerance; acid stress played a more critical role in mediating this effect as compared to salt concentration. Therefore, acid–salt combined preservation techniques and subsequent refrigeration may prevent *S. enteritidis* survival in heat-pasteurized food products caused by cross-protection of acid- or salt-adapted cells. Tola and Ramaswamy [36] measured the D and z values of *Bacillus licheniformis* as affected by different heating methods (conventional vs. ohmic), types of acidifying agent (citric vs malic acid), and pH levels (pH 4.5, 5.5, and 6.2) (Table 15.2). Temperature and pH showed a highly significant effect in destruction, while ohmic heating showed a marginally better rate as compared to conventional heating. The lowest D_{97} was 1.1 min at pH 4.5, when citric acid was used as an acidifying agent in ohmic heating. Types of acidifying agents did not show any effects on destruction.

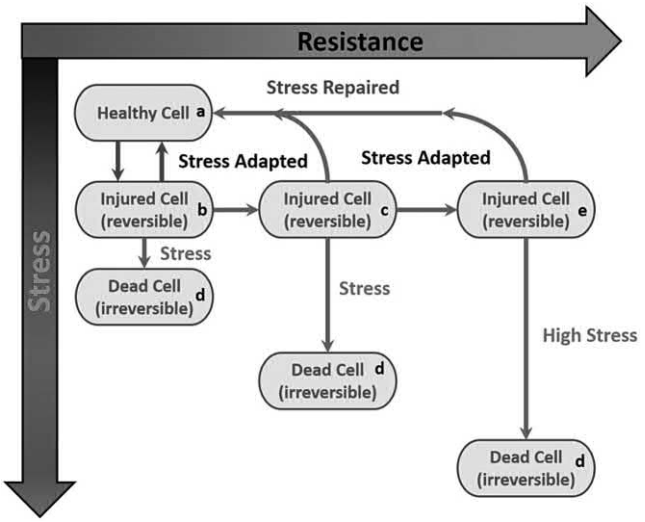

FIGURE 15.5 Microbial stress, injury, adaptation, and resistance to processing. (From Lado and Yousef [32].)

15.3.4 Multi-Target Preservation

The multi-target preservation of foods should be the ultimate goal for a gentle but most effective preservation of foods [8]. For foods preserved by hurdle technology, it has been suspected for some time that different hurdles in a food could not just have an additive effect on microbial stability, but act may synergistically [1]. Example 8 in Figure 15.3 illustrates this. A synergistic effect could occur if the hurdles in a food hit, at the same time, different targets (e.g. cell membrane, DNA, enzyme systems, pH, a_w, E_h) within the microbial cell, and thus disturb the homeostasis of the microorganisms present in several respects; then the repair of homeostasis as well as the switch on of stress shock proteins become more difficult [7]. Therefore, employing different hurdles simultaneously in the preservation of a particular food should have advantages, because optimal microbial stability could be achieved with an intelligent mix of gentle hurdles. In practical terms, this could mean that it is e.g. more effective to use different preservatives in small amounts in a food than only one preservative in larger amounts, because

TABLE 15.2
D and z Values of *Bacillus licheniformis* Spores in Carrot Juice Extract as Influenced by pH, Types of Acidifying Agent and Heating Methods

different preservatives might hit different targets within the microbial cell, and thus act synergistically [14].

It is anticipated that the targets in microorganisms of different preservative factors (hurdles) for foods will be elucidated, and then the hurdles could be grouped in classes according to their targets within the microbial cells. A mild and effective preservation of foods, i.e. a synergistic effect of hurdles, is likely if the preservation measures include an intelligent selection and combination of hurdles taken from different "target classes" [7]. This approach seems not only valid for traditional food preservation procedures, but for modern processes (such as food irradiation, ultra-high pressure, mano-thermo-sonication, etc.) too. An example for a multi-target novel process is the application of nisin (which damages the cell membrane) in combination with lysozyme and citrate, which are then able to penetrate easily into the cell and disturb the homeostasis with different targets [26].

Food microbiologists could learn in this respect from pharmacologists because the mechanisms of action of biocides have been studied extensively in the medical field. At least 12 classes of biocides are already distinguished which often have more than one target within the microbial cell and multiple lesions in microorganisms are known. Often, the cell membrane is the primary target, becomes leaky, and unzips the organism, but biocides also impair the synthesis of enzymes, proteins, and DNA [37]. The "multi-drug attack" has proved successful in the medical field in fighting bacterial infections (e.g. tuberculosis) as well as viral infections (e.g. AIDS), and thus a "multi-target attack" on microorganisms should be a promising approach in food microbiology too [26].

Khan et al. [38] explored the potential of hurdle technology using combinations of novel technologies such as pulsed electric field, food irradiation, radiofrequency and microwave heating, Ohmic heating and high pressure, ozone and electrolyzed water treatment, and chemical preservatives and strategies for the food industry. However, they pointed out that further work is required to establish the proper combinations of different treatments in order to reduce the severities of unit processes and improve the overall properties and quality of food.

15.4 PREDICTION MODELS

Predictive microbiology attempts to describe the effects of environmental conditions on the growth, survival, and death of microorganisms. Hurdle technology needs both boundary and kinetic models. The boundary models provide the growth/no growth regions within a time-frame, while kinetic models provide the growth rate with time in the growth region [10]. Table 15.3 shows an example with four hurdles and four

TABLE 15.3
Examples of Growth/No-Growth Modeling and Prediction

a_w	pH	T_s (°C)	C_s	Growth/No-Growth	Rate
0.80	6.5	10	0.5	Growth	Needed
0.75	5.0	5	0.1	No-growth	0
0.95	4.1	25	1.1	No-growth	0
0.90	6.0	15	1.6	Growth	Needed

Note: These are arbitrary examples (not from experiments).
Specific type of bacteria or deteriorative reaction considered for a specific timeframe
a_w: water activity
pH: acidity
T_s: storage temperature (°C)
C_s: salt concentration (g/100 g sample)

possible scenarios indicating that the boundary is required first and then growth rates are needed.

15.4.1 Kinetic Model (Growth or Death Rate)

Bigelow [39] developed a mathematical model (i.e. kinetic model) to describe the logarithm nature of thermal death. Nevertheless, it was not until the 1980s that mathematical models predicting the behavior of microorganisms experienced a great development. A new field emerged in the food microbiology area: predictive microbiology. Most models used in the past in predictive microbiology have been inactivation models, to predict the death of microorganisms, in particular bacterial spores, caused by different treatments, such as heat, disinfectants, and radiation. It is only in the last two decades that kinetic models have been developed to predict the growth of food poisoning and recently also of spoilage microorganisms in foods. Different types of empirical growth models for microorganism are widely used. Kreyenschmidt and Ibald [40] reviewed different types of growth models. These are specific to the types of microorganism, physicochemical properties of food, and the hurdles used. Cornu et al. [41] developed a model for *Listeria monocytogenes* growth rates on cold-smoked salmon as a function of temperature, water-phase salt, and phenolic contents.

Davey et al. [42] developed the thermal inactivation rate (i.e. ln k) of *C. botulinum* as a linear function of 1/T, pH, and pH^2. Similarly, Cerf et al. [43] also developed the regression correlations of ln k as a function of 1/T, pH, pH^2, and a_w. The non-monotonous changes of pH and a_w make it more difficult to predict the effect of hurdles in combination. Velugoti et al. [44] generated growth data of *Salmonella* in sterile pork at various isothermal conditions, and dynamic (i.e. kinetic) models were developed within storage temperature (10–45°C).

Pujol et al. [45] developed a gamma-type model for the factors of storage temperature, pH, a_w, and acetic, lactic, and sorbic acids. It allowed the use of different combinations of hurdles to be quantified and compared to each other in terms of their inhibitory effect (i.e. iso-hurdle). They collected and analyzed existing data from industry, a public database, and the literature, after which a total of 650 growth rates were retained. Three steps were used to (i) build a predictive model based on existing literature data, (ii) build an experimental design focused on the iso-hurdle using the model output, and (iii) validate the model and the iso-hurdle rules with new data. The methodology used in the model allowed an assessment of the equivalence of inhibitory effects without intensive data generation; it could be applied to develop milder formulations which guarantee microbial safety and stability.

15.4.2 Boundary Models (Growth/No-Growth)

Increasing attention has been given to the development of models that allow the prediction of the probabilities of growth under different conditions and therefore allow predictions of growth/no growth boundaries or the growth/no growth interface [46]. In the 1970s the "probability model" (i.e. boundary model) for the prediction of germination of spores, population growth, survival, and toxin production within a specified period of time under defined conditions of storage and product composition emerged [47]. "Growth/no-growth" or "interface" modeling has progressed. Such boundary or probability models are of particular significance for ambient stable hurdle technology foods, and these should be applied to food-poisoning as well as to spoilage microorganisms. One of the first attempts at growth/no-growth (G/NG) modeling was developed by Pitt [48]. He related the boundary with the temperature and water activity limits for *Aspergillus* spp. growth by an empirical equation. McKellar and Lu [49] developed a probability-of-growth model for *Escherichia coli* 0157:H7 as a function of temperature, pH, sodium chloride, and acetic acid. The model predicted 99% correctly the growth/no growth of 1820 treatment combinations. Spoilage yeasts are often tolerant microorganisms in low-pH, low-a_w foods, and Lopez-Malo [50] developed a probability and boundary model. Carrasco et al. [47] reviewed the methodology of development of a probability or growth/no-growth (G/NG) model. The logistic regression approach has been widely adopted for probability and G/NG modeling. In general, probability models are devoted to data, which can be measured as "positive" or "negative." For example, if we consider the variable "detection of toxin," only two responses are possible: "detectable" or "not detectable." The responses can be coded as 1 (positive response) or 0 (negative response), or even better, if response replicates are obtained, a number between 0 and 1 can be given to the response, calculated as the average of the scores (0 or 1) of the replicates. The number obtained can be considered as the probability of occurrence of the phenomenon studied. This probability can be related to independent variables such as temperature or pH by some mathematical function using regression techniques. In logistic regression, the probability (P) is expressed as "logit":

$$logit\, P = \log\left(\frac{P}{1-P}\right) \tag{15.1}$$

Mertens et al. [51] developed a G/NG model by linear logistic regression, and *logit* was correlated as a function of a_w, pH, sodium chloride, and acetic acid. A simplified G/NG model was conceptually derived from the gamma model. Logit was related to the variables or factors in order to determine the boundary. Polese et al. [52] developed a G/NG boundary using the gamma function, and he suggested that limited number of fail dangerous predictions; thus he suggested that a simplified G/NG model could be used as a first estimate method when experimental data are missing or insufficient. In addition, a practical time-frame is usually used to generate the boundary data; thus the model ignores stability for longer periods. In general, extrapolation in prediction, especially in foods, is not straightforward because of the complexity of the food matrix [53].

In addition to gaining a fundamental understanding of the hurdles and their interactions, prediction models need to be available to apply hurdles in real food systems, and they are

key to determine the shelf life and safety. McMeekin et al. [54] reviewed the predictive microbiology and its applications. They revisited traditional predictive microbiology with an emphasis on temperature dependence and interpreted the temperature vs growth rate curve as comprising 11 regions, some already recognized. Their review envisioned a future of predictive microbiology in which models morph from empirical to mechanistic underpinned by microbial physiology and bioinformatics to grow into systems biology. They started by considering enzymes, which, being proteins, must be folded correctly to function, and considered what drives the folding process (i.e. is it thermodynamic or kinetic?) [55, 56]. The rate of protein folding is accelerated by molecular chaperonins, and it is essentially a spontaneous process [56]. In turn, this confirms the view of the 1972 Nobel Prize winner Anfinsen that the most probable conformation of a folded protein in any given environment is determined solely by its amino acid composition [57]. The work of Rothman and Shekman [58] highlighted the role of molecular chaperonins in accelerating rates of protein folding. The protein folding can be described by a mechanistic, thermodynamically based, and temperature-dependent model [59, 60]. The effect of other constraints on microbial growth, such as water activity and pH, can be modeled thermodynamically and can be extended to temperature dependence. These thermodynamic models could be applied not only in microbiology but also in protein stability, thermal biology, ecological theory, biogeochemistry, and extremophile biology and climate science. Finally, McMeekin et al. [54] envisioned that "the transition from empirical to mechanistic predictive models has its genesis, in part, in food microbiology."

15.5 CONCLUSION

The concept of single- and multi-hurdle effects in food preservation is now established through experimental evidence. Research is being conducted to improve the fundamental understanding, in areas such as homeostasis, metabolic exhaust, stress reactions, and microbial prediction models. It is important to develop both empirical and fundamental prediction models including wide ranges of multi-hurdles. Models could be an important tool for the food industry to develop safe food products with desired sensory and nutritional properties. Davidson et al. [61] stated "more research is needed on the effectiveness of antimicrobial combinations and antimicrobials in combination with physical methods (e.g. hurdle technology) that are effective against different groups of microorganisms. Combinations could well be the ideal antimicrobial for which everyone is searching."

16 Hurdle Technology (Combined Methods) for Food Preservation: Applications

Lothar Leistner and Mohammad Shafiur Rahman

CONTENTS

16.1 INTRODUCTION

Foods based on combined preservation methods (hurdle technology) are prevalent in industrialized as well as in developing countries. Often hurdle technology is applied empirically without knowing much about the governing principles of the preservation of a particular food. However, with a better understanding of these principles and improved monitoring devices, the deliberate application of hurdle technology has advanced. Recently, Singh and Shalini [1] reviewed products developed using hurdle technology. Subsequently, examples of the application of combined preservation methods in industrialized and in developing countries were given.

16.2 ANALYZING THREE CATEGORIES OF FOODS

With regard to the application of hurdle technology, one might differentiate between intermediate-moisture foods, high-moisture foods, and integer foods, since they differ somewhat in the types of hurdles used or the mode of hurdle application. Therefore, these three groups are discussed separately.

16.2.1 Intermediate-Moisture Foods

Intermediate-moisture foods (IMFs) are in the water activity (a_w) range of 0.90–0.60, and thus water activity is their primary hurdle for securing microbial stability and safety. However, IMFs are often stabilized by additional hurdles, such as heating, preservatives, pH, redox potential, and competitive microflora [2]. These foods are easy to prepare and storable without refrigeration, thus they are cost and energy-efficient. Traditional IMFs based on meat, fish, fruits, and vegetables are common and much liked in different parts of the world because they are tasty, nutritious, and in general safe. On the other hand, newly developed, tailor-made IMFs (except for certain candy bars) have not achieved the expected breakthrough in human nutrition. Some reasons for this disappointing performance are the poor palatability of

most novel IMF due to the high concentration of humectants, and the need to introduce often high amounts of antimicrobial additives ("chemical overloading of foods"), which may cause health concerns and pose legal problems [3].

Traditional IMFs are today the prevalent food items in developing countries, even though practically none of the food manufacturers have the ability to measure water activity, and few recognize the relevance and significance of water activity for the preservation of their foods. Thus, the application of hurdle technology in the processing of IMF in developing countries is done empirically. Only recently have changes occurred. An outstanding example of these recent developments is the CYTED-D program (Science and Technology for Development) of Latin America, which was sponsored by Spain and to which Argentina, Brazil, Chile, Costa Rica, Cuba, Mexico, Nicaragua, Puerto Rico, Uruguay, and Venezuela have contributed. A project in this program, titled "Development of Intermediate Moisture Foods (IMF) Important to Ibero-America," had the objective to identify and evaluate foods of Latin America that are storable without refrigeration. This study comprised fruits, vegetables, and bakery products as well as foods derived from fish, milk, meat, and miscellaneous products. About 260 food items were approved to be microbiologically stable and safe at ambient temperatures. The properties (such as a_w, pH, preservatives, food composition) and the production technology for these products were measured and described [4, 5], and it was concluded that most of the approved products were intermediate-moisture foods. However, some had higher a_w values, sometimes as high as 0.97–0.98, and nevertheless were stable and safe without refrigeration, and it turned out that the stability of these high-moisture foods was caused by a combination of several, empirically applied hurdles. This observation was the starting point for Latin America to apply intentional hurdle technology [6] to high-moisture foods, especially to tropical and subtropical fruits, storable without refrigeration. In the opinion of Latin American scientists, the technological achievements of their region deserve a closer look, in particular by developing countries where refrigeration is scarce. Since IMFs are often not satisfactory from the sensory point of view and contain high levels of additives, the application of hurdle technology to stabilize high-moisture foods, which also need no refrigeration, seems to have great potential [5].

The Latin American CYTED-D study demonstrated a promising approach for improving the stability of foods in developing countries, which could be applied in other regions. Following this concept, first, the properties of already available, microbiological stable and safe food items should be thoroughly studied and described. Second, the preservative factors (hurdles) effective in these foods and thus the principles behind their microbial stability and safety must be elucidated. Third, if feasible, the preservation and quality of these foods should be improved by the intentional application of hurdle technology [3]. Using this concept, Tapia de Daza et al. [7] have identified the hurdles in food items studied within the CYTED-D program, and by critical evaluation of the hurdles that have been traditionally applied to certain foods, they assessed the microbial stability and safety of these products. It was demonstrated that similar hurdles are active in the same type of foods in different countries of Latin America. However, there were also surprising differences, which pointed to an over- or underprocessing of the same food in different countries of the same region [7]. This insight could lead to the avoidance of some nonessential preservatives or, on the other hand, to the improved stability, safety, and quality of some food items by fortification of certain hurdles.

Latin American researchers [5, 7] pointed out that reduced water activity was the main hurdle in IMFs as they have described within the CYTED-D project. However, in practically all of these products, additional hurdles were present that contributed considerably to stability and safety. This observation has confirmed the opinion expressed by Leistner and Rodel [2] that in most intermediate-moisture foods several hurdles are inherent. Tapia de Daza et al. [7] listed many traditional IMF of Latin America, derived from fruits, vegetables, meat, milk, fish, etc., in which several identified hurdles contributed to microbial stability and safety. Very often the reduced a_w was combined with a reduced pH. However, in some salted fish and shrimp the pH was more than 8.0, and thus in these foods, the elevated pH might contribute to the preservation. Many meat, fish, fruit, and dairy products contained additional preservatives (e.g., nitrite, smoke, benzoate, sorbate, sulfites, spices, Maillard products) and sometimes competitive microorganisms.

Maillard reaction products, which are generated during the caramelization of sweet condensed milk (dulce de leche), are probably an important hurdle for this Latin American food item. A special case concerns candied fruits common in this region. Their heavy sugar coating acts as a physical barrier (hurdle) against microbial contamination after the heat process, so that these foods are stable during storage in spite of the absence of preservatives and sometimes a rather high pH. Often a thermal treatment was used to inactivate heat-sensitive microorganisms during the manufacturing process and improve microbial stability, and a vacuum in sealed containers was achieved by hot filling of the products. Once the container is opened, the redox potential increases and then the microbial stability of these IMF against molds and yeasts must be secured by the presence of preservatives. Additional hurdles were employed in particular in those IMF, which had rather high a_w and/or pH values. In the IMF studied, it was exceptional if the a_w was apparently the only hurdle present, but in most IMF products three to five hurdles have been identified [7]. How many hurdles, besides a_w, are active in intermediate-moisture foods depends on the type of the product, however, it may be concluded that the microbial stability and safety of IMFs in general is based on a combination of several preservative factors.

It is obvious that a thorough study of traditional IMF using up-to-date methodology would be of benefit to developing countries. However, for industrialized countries such studies are rewarding because traditional products are an abundant source of innovative ideas that could be used in food design. For instance, we learned from traditional Chinese sausage (la chang) that a sausage could be preserved in the raw state even

without fermentation, or we realized that in traditional charqui of Brazil a fermentation takes place even at an a_w <0.90 if halophilic pediococci are involved. Heat inactivation of most pathogenic bacteria, including *Staphylococci*, is achieved in some Chinese IMF meats by just applying 50°C for several hours. Another interesting aspect of traditional IMF meats is the bactericidal effect of Maillard products toward food poisoning bacteria, because if these recontaminate the product after heating and drying they do not survive long, probably due to metabolic exhaustion. Apparently, the growth inhibition of xerotolerant molds on unpackaged Chinese IMF meats with a_w <0.69 is also supported by Maillard reaction products, which, therefore, are important hurdles for traditional IMF [8].

16.2.2 High-Moisture Foods

Intermediate-moisture foods are prevalent in developing countries, whereas in industrialized countries high-moisture foods (HMFs) are common, because they are often only minimally processed and due to their fresh-like properties and convenience are appealing to the consumer. However, since in HMFs the water activity is above 0.90, this hurdle is less prominent, and other hurdles have to secure microbial stability and safety of foods during storage. Therefore, HMFs are often chilled or frozen, and low-temperature storage is widely used. However, refrigeration is energy consuming and thus costly, and in case of temperature abuse, the stability and safety of the foods might be jeopardized. Therefore, besides the low-temperature hurdle for HMFs, additional hurdles (such as heating, pH, E_h, a_w, preservatives, and competitive flora), often applied in combination by means of hurdle technology, are significant. The hurdles are employed in HMF either empirically or now more often intentionally.

An example of the empirical use of hurdles in HMFs is Italian mortadella. This meat product is an emulsion-type sausage, which is traditional and very common in Italy, and might be even stored without refrigeration, as long as the sausage is uncut. Italian mortadella contains, due to a mild heat process (78°C core temperature), viable spores of bacteria. However, the growth of bacilli and clostridia is inhibited in genuine mortadella by a slightly decreased a_w (below 0.95), and this adjustment (by salt, sugar, milk powder, and drying) was done in the past without understanding the reasons. However, applying traditional recipes, the water activity has been surprisingly adjusted to the desired level <0.95, by hand-down experience [9–11]. In Germany, meat products preserved by a similar principle (pasteurization and a_w adjustment to <0.95 by drying of the sausage) are popular. These a_w shelf-stable products (SSP) are stable at ambient temperature.

Another example of a shelf-stable emulsion-type sausage of Europe is the Gelderse rookworst, in which intentional hurdle technology has been used for a number of years. A major hurdle of this product is the reduced pH, which is adjusted to 5.4–5.6 by the addition of 0.5% glucono-delta-lactone, and thus rookworst belongs to the group of pH-SSP. This sausage is stable for several weeks at ambient temperature, if vacuum packaged and reheated at 80°C for about one hour in the pouch. The heat treatment eliminates vegetative organisms, and bacterial spores are apparently not of much concern, as their numbers decrease during the heat process and surviving spores are inhibited by the pH and other hurdles present (e.g., nitrite). Gelderse rookworst is exported from the Netherlands in large quantities to Britain, and a pH >5.4 is acceptable from the sensory point of view. The binding of water and fat in rookworst is not problematic, in spite of the relatively low pH, if pork rinds and/or phosphates are added to the product [6, 9].

As mentioned before, IMFs are prevalent in developing countries. However, there is a trend also in developing countries to move gradually away from IMFs toward HMFs [12]. Because IMFs contain high amounts of humectants (such as sugar and/or salt) as well as many fungistatic preservatives (such as sorbate, benzoate, sulfite), they are undesirable from the sensory or nutritional point of view, and in addition they have a less appealing texture and appearance than HMFs. Therefore, efforts are being made to improve the quality of IMFs by decreasing sugar and salt addition, as well as by increasing the moisture content and a_w, without sacrificing the microbial stability and safety of the products if stored without refrigeration [9]. It might be expected that high-moisture, fresh-like foods that nevertheless are storable at ambient temperature, since they have been stabilized by intentional hurdle technology, will be on the increase in developing countries as soon as the application of advanced hurdle technology has been mastered [12].

16.2.3 Integer Foods

Whole or integer foods are not comminute and consist of large pieces of plant or animal tissue, nevertheless, their microbial stability and safety could be improved by the application of hurdle technology. Two approaches are common: (i) either the use of coatings that contain and maintain inhibitory substances in order to protect the surface of the foods against microbial deterioration or (ii) the dewatering and impregnation process, which consists of soaking foods in highly concentrated solutions of humectants or other food additions [9, 13].

An example of an application of a surface layer is pastirma, a traditional beef product of Muslim countries is storable for several months at ambient temperatures and is eaten in the raw state [14]. The stability and safety of pastirma are based on a reduced a_w (0.90–0.85), in combination with several additional preservative factors [12, 15]. The interior of this product is stabilized by dry curing of meat stripes (~5 cm thick) with salt and nitrate (which is reduced by bacteria to nitrite) and the removal of water by drying and pressing of the meat, as well as by the growth of lactic acid bacteria, which decrease the pH to about 5.5. These hurdles secure the inhibition of spoilage and pathogenic bacteria, including salmonellae, within the meat. The surface of pastirma is covered with an edible paste (3–5 mm thick) containing 35% freshly ground garlic and other spices (paprika, cumin, and mustard, as well as fenugreek as a binder). This surface coating prevents the growth of molds on the product during storage,

even at elevated humidity and temperature. Thus, at least five hurdles (a_w, nitrite, pH, competitive flora, garlic) are relevant to the preservation of pastirma.

Torres [16] studied the surface microbial stability of model foods by using coatings, which maintain preservatives and the desired low pH, and he confirmed that a low pH in the surface layer greatly improved the effectiveness of sorbic acid in this coating. Guilbert [17] used superficial edible layers for easily perishable tropical fruits and achieved preservation without affecting the integrity of food pieces. He pointed out that the formulation of edible films and coatings must include a component that can form an adequately cohesive and continuous matrix as well as the addition of a plasticizing agent to overcome brittleness. Specific agents (such as antimicrobials, antioxidants, organic acids, nutritional additives, flavors, and coloring) can be incorporated into edible films to obtain functional effects localized on the surface [18].

Edible coatings and osmotic dehydration represent two ways to apply hurdle technology to solid foods without affecting their structural integrity [18]. Osmotic dehydration is a dewatering and impregnation process that consists of soaking foods (such as fruits, vegetables, meat, cheese, and fish) in concentrated solutions of humectants (such as sucrose and sodium chloride) and is employed for solute transfer from a solution into the product [19]. With this process, also called "direct formulation," not only water-activity-lowering agents may be inserted into the food, but also preservatives and nutrients, as well as substances that control the pH, texture, and flavor, and this would build up positive hurdles that improve the stability as well as the quality of food products [18, 20]. As opposed to traditional soaking techniques (e.g., salting as used in cheese making, fish or meat curing, candying, and semi-candying), osmotic dehydration generally involves significant water removal (40–70 g of water is lost per 100 g of initial product) with limited and controlled solute incorporation (5–25 g of solute is gained per 100 g of initial product). Under typical operating conditions used for fruit and vegetables, mass transfer mainly occurs during the first two hours; thereafter, mass transfer rates become progressively slower until water loss stops, whereas solute gain continues to increase steadily. A soaking process does not generally produce stable products, but soaking has to be used as a preprocessing step before complementary processing steps, such as drying, freezing, pasteurization, canning, frying, and/or the addition of preservative agents [21].

16.3 APPLICATIONS IN INDUSTRIALIZED COUNTRIES

The deliberate and intelligent application of hurdle technology started in the mid-1970s in Germany [15] and was first used for the preservation of meat products [6]. Soon this concept was applied to a variety of food items in industrialized as well as in developing countries. In this review, some examples of advanced hurdle technology employed in industrialized countries for fermented, heated, or chilled foods, and for the design of healthful foods as well as in relation to the trend to less packaging of foods will be discussed.

16.3.1 Fermented Foods

In fermented foods—such as fermented sausages, raw hams, ripened cheeses, and pickled vegetables—a sequence of hurdles leads to a stable and safe product. For instance, in fermented sausages (salami) by the sequence of hurdles (i.e., preservative, E_h, pH, and a_w), food poisoning and the spoilage organisms are inhibited, and the desired competitive flora (lactic acid bacteria) is selected [9, 22–24] (Figure 16.1).

Important hurdles in the early stages of the ripening process of salami are nitrite and salt (preservative), which inhibit many of the bacteria in the batter. However, other bacteria are able to multiply, use up the oxygen, and thus cause the redox potential of the product to decrease. This in turn enhances the E_h hurdle, which inhibits aerobic organisms and favors the selection of lactic acid bacteria. They are the competitive flora and flourish by metabolizing the added sugars, which causes a decrease in pH value, i.e., an increase of the pH hurdle. In long-ripened salami, the nitrite is depleted and the lactic acid bacteria vanish, while the E_h and pH increase again, i.e., all these hurdles become weak during a longer ripening of salami. Only the water activity hurdle is strengthened with time and is then mainly responsible for the stability of long-ripened raw sausage [8, 22]. Since this sequence of hurdles and their effects has been revealed, the production of fermented sausages has become less empiric and more advanced, and this knowledge is used to achieve the required inhibition of *Clostridium botulinum*, *Listeria monocytogenes*, and *Staphylococcus aureus* as well as the inactivation of *Salmonella* spp. and verotoxins producing *Escherichia coli* in salami during fermentation and ripening. The sequence of hurdles that secures the microbial stability and safety of raw hams is also well known [25]. Probably in other fermented foods, such as ripened cheeses and pickled vegetables, a sequence of hurdles should be important for the proper fermentation process, and it would be challenging to elucidate them.

In Germany, fermented sausages are into two groups, i.e., quick-ripened products and slow-ripened products (Table 16.1). Quick-ripened products amount to about 80% of the production and the slow-ripened products to only 20%. In quick-ripened products, a_w is rather high, because these still contain much water and therefore are less expensive. However, to compensate for this high a_w, a low pH in such products is essential for microbial stability. On the other hand,

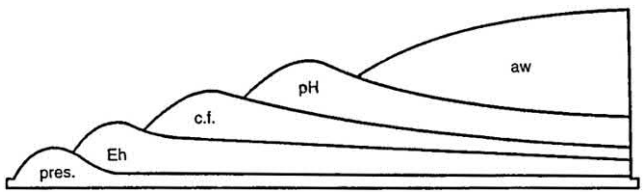

FIGURE 16.1 Sequence of hurdles occurring during the ripening and drying of fermented sausages (salami). Symbols have the following meaning: pres., addition of nitrite-curing-salt; E_h, decrease of redox potential; c.f., growth of competitive flora; pH, acidification; a_w, decrease of water activity during the drying process. (From Leistner [22].)

TABLE 16.1
Criteria of the Quick and Slow Ripened Fermented Sausages of Germany

Criterion	Quick-Ripened Products	Slow-Ripened Products
a_w	0.95–0.90	0.90–65
pH	4.8–5.2	5.4–6.0
Weeks	1–2	4–8
Production	8%	20%

slow-ripened products, which are more expensive due to the long drying period, have a low a_w, and therefore these products can afford a rather high pH, which makes them tastier. These differences between quick- and slow-ripened salami are mentioned here because they nicely illustrate that the hurdles in food are possibly interchangeable. Therefore, emphasis could be given to different hurdles to achieve microbial stability, with the consequences that the products have different features related to their sensory properties and price. Most of these sausages are air-dried or smoked, not ripened by growing molds. Lucke and Vogeley [26] developed slow-ripened traditional sausage by mincing meat, mixed with spices and minimal amounts of sugars, salt, and nitrate. It was stuffed and then allowed to ripen for a minimum of 6–8 weeks at temperatures below 15°C. In addition, surface mold growth during ripening was regularly removed or suppressed. This process required a minimum of investment and labor with a clean hygienic standard.

A feature peculiar to fermented sausages (and probably for ripened cheeses too) is their microstructure, which influences the desired ripening process as well as the survival of pathogenic bacteria in the product. Thus, the microstructure is an important hurdle for the stability of salami [3, 9]. Electron microscopy studies [27] revealed that the natural flora as well as added starter cultures were unevenly distributed in fermented sausages, but are arrested in little cavities of the product, i.e., the ripening flora can only grow in nests. These nests are 100–5000 µm apart, and thus large areas of the sausage must be influenced by metabolites (e.g., nitrate reductase, catalase, organic acids, and bacteriocins) accumulated in such nests or cavities. Thus, the entire fermentation of the product must be accomplished from small nests of desirable bacteria, and from these nests the pathogenic bacteria (e.g., salmonellae or listeria) must be inactivated and even their nests might be located in distant areas of the food matrix. Within each nest, the bacteria, either in pure or mixed cultures, are in keen competition for nutrients and impair each other with their metabolic products. In nests of mixed cultures, generally the lactic acid bacteria prevail due to their tolerance of low E_h, pH, and a_w. At the beginning of the sausage fermentation in these nests, the lactobacilli appear vigorous and metabolically active, whereas at the end of the ripening process the lactobacilli in their nests have degenerated and may have died [9, 27]. Small and equal distances between nests of desirable bacteria in the sausage matrix should be advantageous since this would foster the proper ripening process and the inactivation of pathogenic bacteria. The thorough mixing of the meat and fat particles of the sausage batter, before stuffing the sausage mix into casings, would bring about the desired more even distribution of bacteria in the sausage matrix. Moreover, if starter cultures are used, they should be added in a fashion that favors an even distribution, and this could be better achieved by using starter cultures not in a powdery state but in a liquid state [3, 9].

The microstructure is not only important for salami (and cheese) but for other foods too. In concentrated oil-in-water emulsions, the bacteria form small colonies, and in water-in-oil emulsions, the bacterial growths are confined to the water droplets, which might lose their integrity due to coalescence [28]. The impact of microstructure on microbial growth, survival, and death in foods has theoretical and practical implications. Certainly, under these circumstances predictive modeling of the behavior of microorganisms is difficult. On the other hand, it is possible to influence the number, size, and distance of microbial nests in such foods, and thus their safety, stability and quality, by the recipes of the product and the technology applied [3, 9]. The microstructure of foods is definitely an important hurdle for certain foods. Further studies on the behavior of submerged bacterial colonies in food matrices seem warranted [29].

16.3.2 Heated Foods

Heat-processed high-moisture foods based on hurdle technology, which are stable at ambient temperature, have been named shelf-stable products (SSPs) [6], and these offer the following advantages: the mild heat treatment (70°C–110°C) improves the sensory and nutritional properties of the food, and the lack of refrigeration simplifies distribution and saves energy during storage. SSPs are heated in sealed containers (casings, pouches, or cans), which avoid recontamination after processing. However, because of the mild heat treatment, these foods still contain viable spores of bacilli and clostridia, which are inhibited by an adjustment of a_w, pH, E_h, and, in the case of autoclaved sausages, by sublethal injury of the spores. At present four different types of SSP foods are distinguished (F-SSP, a_w-SSP, pH-SSP, and Combi-SSP), depending on their primary hurdles (Table 16.2), though additional hurdles foster the safety and stability of these products [3, 8, 9].

16.3.2.1 F-SSP

In one type, F-SSP [6, 8, 22], the sublethal damage of the spores is the primary hurdle, which is achieved by mild heat treatment. Examples are sausages with an adjusted a_w (Bologna-type sausage <0.97, liver and blood sausages <0.96) in polyvinylidene chloride (PVDC) casings, which are heated in counterpressure autoclaves to F_o >0.4. Such products are in large quantities and considerable variety since the mid-1980s in German supermarkets. These are stored unrefrigerated for several weeks and have caused no problems with regard to food poisoning or spoilage because guidelines for their processing have been suggested and followed [30]. F-SSPs, due to

TABLE 16.2
Different Shelf Stable Products (SSP) and Their Primary Hurdles*

F-SSP	Sublethal damage of bacterial spores
a_w-SSP	Slightly reduced water activity
pH-SSP	Slightly increased acidity
Combi-SSP	Combination of equal hurdles

* All are mildly heated foods, stable at ambient temperature, and nevertheless have fresh-product characteristics.

metabolic exhaustion of the microorganisms, even autosterilize during storage. For F-SSPs, casings are more advisable than cans, because during chilling of the cans after autoclaving, some water condensation may occur inside the lid, and if drops of water fall back on the surface of the sausage mix, locally the critical a_w increases and thus growth of clostridia may start in this portion of the product. If autoclaved sausages fill the casings tightly, water condensation inside the container cannot occur, and therefore F-SSP in casings are more stable than in cans with headspace [31].

16.3.2.2 a_w-SSP

The stability of another type, a_w-SSP [6, 8, 9, 11, 22], is primarily caused by the reduction of water activity below 0.95, and guidelines for their processing have been suggested [22]. Examples of traditional a_w-SSP meats are Italian mortadella and German brühdauerwurst, however, a large variety of such meat products is now on the market, and most of them are snack items. The shelf life of a_w-SSP at ambient temperature is even better than with fermented sausages since in a_w-SSP, due to the heat treatment (internal temperature >75°C), lipases are inactivated and thus these products are less prone to become rancid.

16.3.2.3 pH-SSP

In the third type, pH-SSP [6, 8, 22], increased acidity is the primary hurdle. This principle is applied in Gelderse rookworst, a shelf-stable meat product. Another traditional meat product of the pH-SSP type is brawn, and these jelly sausages are adjusted to an appropriate pH by the addition of acetic acid. Such products are, for example, composed of a brine (pH <4.8) made of water, gelatine, salt, sugar, agar-agar (2%), and spice, and a solid phase, made of bologna-type sausage in cubes with a_w of <0.98. Both components are mixed (two parts brine and three parts meat), filled in casings and heated to an internal temperature of >72°C but not higher than 80°C. If the product is in equilibrium, it should have a final pH <5.2, and then it is storable for several days at ambient temperatures. Outside the meat field, pH-SSPs are common as heat pasteurized fruit and vegetable preserves with pH <4.5, which are bacteriologically stable and safe, in spite of mild heat treatment. In such products, vegetative microorganisms are inactivated by heat, and the multiplication of surviving bacilli and clostridia is inhibited by the low pH. Since bacterial spores are able to germinate at lower pH levels than vegetative bacilli and clostridia are able to multiply, in pH-SSPs, as in F-SSPs and a_w-SSPs, the number of spores tends to decrease during storage due to metabolic exhaustion of microorganisms. On the other hand, while the heat resistance of bacteria and their spores is enhanced with decreasing a_w, it is diminished with decreasing pH. Thus, pH-SSPs need less heat treatment for inactivation of microorganisms than do a_w-SSP.

16.3.2.4 Combi-SSP

In the fourth type, Combi-SSP [8, 9, 32], a combination of rather equal hurdles is applied, each of which adds a little on an imaginary balance [8], which should swing from the unstable to the stable state of the product. Even small enhancements of the individual hurdles in a food in summation have a definite effect on the microbial stability of a product. For instance, for the stability and safety of a food it is of significance whether the F_o is 0.3 or 0.4, the a_w is 0.975 or 0.970, the pH is 6.5 or 6.3, and the E_h value is somewhat higher or lower. Every small improvement or reinforcement of a hurdle brings some weight to the balance, and the sum of these weights determines whether a food is microbiologically unstable, uncertain, or stable (Figure 16.2). In other words, all little steps in the direction of stability decide whether the balance swings from an unstable into a stable state of the product [8]. It is followed in designing of Bologna-type sausages as Combi-SSP. Different types of brühwurst (wieners, bockwurst, fleischwurst, fleischkäse, etc.) were developed, which proved microbiologically stable and safe at least for one week at 30°C. The initial spore load of the sausage mix is low because spice extracts instead of natural spices are used, nitrite (100 ppm) with curing salt must be added, and these products are heated to a core temperature >72°C, and are adjusted to an a_w and pH of <0.965 and <5.7, respectively. These products are repasteurized after vacuum packaging for 45–60 min (depending on the diameter of the products) at 82–85°C [33]. Combi-SSPs offer opportunities for many food items, however, they require strict rules for food design and process control. The Combi-SSP concept is not only applicable to meat products but to other foods too.

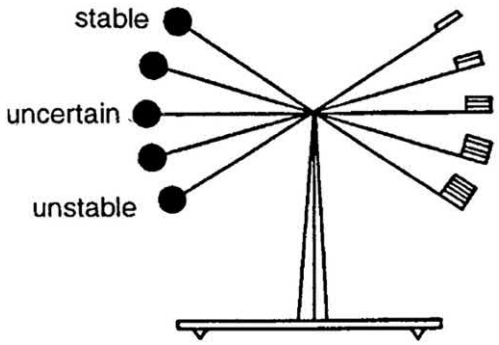

FIGURE 16.2 The balance should illustrate that even small enhancements of different hurdles could in summation bring about a substantial improvement of the microbial stability of a food. (From Leistner [8, 48].)

For instance, an Italian pasta product (tortellini) was stabilized by using as hurdles a water activity reduction and a mild heat treatment, as well as modified atmosphere or ethanol vapor during storage, combined with moderate chilling temperatures [34, 35]. Another example is paneer, a dairy product of India, which was developed as a Combi-SSP [36, 37].

The Federal Centre for Meat Research in Germany demonstrated the efficiency of the application of hurdle technology in an extensive study (supported by the Medical Corps of the German Army) on 75 meat products with fresh-product characteristics, which nevertheless were storable without refrigeration [9, 32, 33]. In this study eight categories of meat products were selected and optimized, one represented fermented sausages and most of the others were F-SSPs, a_w-SSPs, and Combi-SSPs (Table 16.3). Since these meats must be suitable for army rations during military exercises, they had to be stable and safe at least for 6 days at 30°C, and they should be tasty and nutritious. In this situation, a linkage between hurdle technology and HACCP are introduced [9, 38]. In the manufacturing plants processing the recommended meats for the army, no microbiological tests must be carried out, however, time, temperature, pH, and a_w must be strictly controlled. These measurements should be done on-line, or at least close to the line. Fortunately, a precise instrument for this purpose became available [39], which allows a_w determinations of meat products within 10–20 minutes. This army study might be used for other occasions, in which hurdle technology and HACCP should be linked [32].

16.3.3 Chilled Foods

The results of hurdle technology are most obvious in high-moisture foods, which become shelf-stable at ambient temperature due to an intelligent application of combined methods for preservation. However, the use of hurdle technology is appropriate for chilled foods too, because in case of temperature abuse, which easily might happen during food distribution, the stability and safety of chilled foods could break down, especially if low-temperature storage is the only hurdle. Therefore, it is reasonable to incorporate into chilled foods (e.g., sous vide dishes) some additional hurdles, which would act as a backup in case of temperature abuse. This type of safety precaution for chilled foods might be called "invisible technology" [9, 40], and this implies additional hurdles act as safeguards in chilled foods and ensure that they remain microbiologically stable and safe during storage in retail outlets as well as in the home.

However, for many chilled foods, additional hurdles are already routinely used. This is particularly true for refrigerated foods for which modified atmosphere packaging (MAP) is employed. Raw and minimally processed vegetables are amongst the most popular ready-to-eat foods that are stored chilled in MAP [41, 42]. In Europe, MAP is mainly applied to salads, potatoes, carrots, and cabbage, whereas in the United States the fresh-cut produce market is stocked mainly with salads, paprika, onions, cabbage, mushrooms, endive, and spinach. MAP is intended to suppress microbial growth, retard respiration, ripening and aging of vegetables, and to inhibit oxidative reactions requiring oxygen. In combination with appropriate chilling, shelf life of foods under MAP can be up to 5–7 days. Immediately before sealing, a gas of defined composition is introduced in the packages that are generally stored at 4–7°C. Typically, the gas composition in MAP for fresh and minimally processed vegetables is 2–5% oxygen and 5–10% carbon dioxide. The modified composition of the gas atmosphere in MAP systems has a marked impact on the growth of spoilage microorganisms as well as on pathogens [43–45]. Minimally processed vegetables are not sterile and numerous genera of spoilage bacteria, yeasts, and molds are frequently encountered, and some cold-tolerant pathogens (*E. coli* 0157:H7, *Bacillus cereus*, *Yersinia enterocolitica*, *Aeromonas hydrophila*, *L. monocytogenes*) are hazards for MAP produce and all have been reported to occur on vegetables [46]. Even the CO_2 in MAP does not inhibit the pathogens directly; the competitive flora that grows in MAP at reduced oxygen and increased carbon dioxide might act as a hurdle and thus suppress the pathogens mentioned [43]. However, occasionally *L. monocytogenes* might under certain conditions in MAP systems proliferate to hazardous levels. Additional preservative factors (hurdles), e.g., *Enterococcus mundtii* as protective culture, may be integrated into the MAP system to ensure a safety better than what is possible with current standards [47].

16.3.4 Healthful Foods

Consumers demand healthy foods, which shall contain less fat, salt (sodium), and cholesterol. Because of this trend, muscle foods, derived from red meat, poultry, or fish are modified. However, less salt or fat as well as their substitutes and replacers might diminish the microbial stability and safety of foods, since important hurdles change. Compensation of these deficits can be achieved by the application of intelligent hurdle technology [48, 49].

Several substitutes and/or enhancers for sodium chloride (i.e., various other salts and hydrolysates) and >100 fat replacers (i.e., fat mimetic systems or synthetic fat replacers) are available today and of potential use for modified muscle foods. However, the microbial consequences of their use are generally unknown. Increased water activity is probably of major importance for the stability and safety of low-fat and/or low-salt muscle, and acidity might be unfavorable too since low-salt muscle foods have a slightly higher pH compared with the normal products. If fat is replaced by proteins, the pH and/or the buffering capacity might increase, and thus the microbial stability and safety of these products would decrease. Added preservatives might be diluted, and thus render them less effective. This is due to the increased water-holding capacity caused by fat replacers. Furthermore, the redox potential (E_h) might change, because proteinaceous fat replacers might increase the E_h-buffering capacity of a food, whereas foods with a high water content should have a low E_h-capacity. The microstructure of some foods (e.g., emulsions, fermented products) is significant for their microbial stability and safety. This microstructure could change by the addition of some fat replacers, however, this effect has not yet been investigated. More data are needed on the impact of different replacers for fat and substitutes for salt (sodium), as well as of relevant combinations and on the important preservative factors (hurdles) of modified foods. The obtained quantitative data should be the basis for the microbial stability management of novel low-fat and/or low-salt muscle foods and would make the design by intelligent hurdle technology feasible.

To keep low-fat and/or low-salt muscle foods microbiologically stable and safe, the refrigeration during storage of these products must be perfect. Since this cannot always be guaranteed, the weak hurdles in modified products should be compensated by alternative preservative factors. In the design, processing, and marketing of low-fat and/or low-salt muscle foods, microbiologists should take an active part and close cooperation with technologists will prove fruitful. Hitherto in the design and production of low-fat and/or low-salt muscle foods, the nutritional aspects have been more emphasized than the microbial aspects. However, microbiology must not be neglected, because these foods will only be continuously accepted by the consumer if they cause no food poisoning and do not spoil easily [49, 50].

16.3.5 Packaging of Foods

Packaging is an important hurdle for most foods since it supports microbial stability and safety as well as the sensory quality of the products. Because of the various types of hurdle technology foods known, the appropriate packaging materials and procedures must be selected and applied with respect to the individual properties of the food items [40, 48].

Industrialized countries have the tendency to overpackage their foods, whereas in developing countries there is a lack of knowledge and of simple packaging materials for foods. Therefore, further exploration into the application of easy-to-\use, cheap, environmentally friendly, and efficient packaging for hurdle technology foods of developing countries should be a challenging and even a lucrative approach [48].

Packaging in industrialized countries is sophisticated, because absorbers, scavengers, scrubbers, and getters or emitters for gas components as well as desiccants, antimicrobial packaging material, tuned infrared films, edible food coatings and films, time–temperature integrator tags, microwave doneness indicators, etc. are employed for food items [51, 52]. These procedures and devices might be summarized under the term "active packaging." Japan was in many respects and for several decades the world champion in food packaging, and recent developments in active or smart packaging frequently originated in this country. However, since the mid-1980s several Japanese packaging experts have cast doubt on these developments and questioned whether such strategies in food packaging should be pursued in the future. According to the opinions of Japanese packaging experts, which were conveyed by Ono [53], five generations of food packaging are distinguishable. First came the function of "containing," i.e., since prehistorical times people have used vessels, pots, baskets, etc. as containers for foods. The second generation of packaging had the function of "transporting," i.e., wrappings, bottles, barrels, etc., which were used for food transport and distribution. The third generation provided an extended shelf life to foods by hermetically "sealing" the packages, and this made canning, vacuum, and modified atmosphere as well as aseptic packaging possible. In the fourth generation the packaging would "create quality" during distribution of the food, i.e., the packaging itself has a processing function, in addition to the common processing of foods. Therefore, such systems are called smart or active or functional packaging, and they are sophisticated but costly and wasteful too. In addition they create environmental problems, which in a densely populated country like Japan have already had severe consequences. Therefore, recycling and/or reduced packaging have become necessary goals. Japan is taken aim with the fifth generation of packaging at "less packaging" of foods, and this generation might be called the "climax of packaging or its despair" [53]. In the fifth generation, the shelf life and quality of foods should not be provided by the packaging but by the food itself or by the mode of distribution (Table 16.4).

TABLE 16.4
Generations of Food Packaging Suggested in Japan

First: Containing	People used packaging (i.e., pots, baskets) since pre-historical days for containing foodstuffs
Second: Transporting	Packaging is used to transport foods in bottles, barrels, containers, cartons, etc.
Third: Sealing	Possible canning of foods, vacuum, modified atmosphere, and aseptic packaging possible
Fourth: Create quality	Active packaging improves the food through scavengers, absorbers, getters, emitters, etc.
Fifth: Less packaging	Just-in-time distribution of foods or advanced hurdle technology foods provide the shelf life

Sources: Ono [53, 54].

In the opinion of Japanese experts, future packaging should provide only information (name and picture of product, nutritional and shelf life data, etc.), and some convenience to the consumer. The required shelf life of the food shall not come from the packaging, but shall be secured either by (i) aseptic packaging combined with just-in-time delivery systems, or by (ii) development of stable and safe hurdle technology foods.

Aseptic (ultraclean) packaging of food is perfectly executed in Japan because factory workers carry out orders with discipline and diligence. If due to ultraclean packaging only few microorganisms are "at the start" in the food, only a few hurdles of low intensity are needed to inhibit microbial growth, and thus ultraclean packaging is an important component of hurdle technology [3, 8]. Ultraclean packaged foods need only simple packaging if a quick delivery at low temperature is guaranteed. In Japan, such foods are transported close to freezing point, and just-in-time distribution systems have been widely introduced because they provide the needed shelf life at low costs due to reduced inventory at the point of sale [53]. Delivery is often done three times a day, and this just-in-time delivery proved successful and is expected to increase rapidly. However, the frequency of the transportation needed could also be a burden on the environment.

Another method to avoid elaborate packaging is to design foods that are stable, safe, and of a superior sensory quality in spite of minimal packaging. In this respect, Japanese authors discussed initially the promotion of intermediate-moisture foods [53]. However, after getting acquainted with hurdle technology applied to high-moisture foods, the latter concept became a promising option for achieving the fifth generation of food packaging [54].

16.4 APPLICATIONS IN DEVELOPING COUNTRIES

There exists an abundant variety of preserved foods in developing countries, because the gap between harvest peaks has to be bridged, and the taste as well as the nutritional properties of foods might improve due to preservation. Most of the preserved foods in developing countries, which preferably must be storable without refrigeration, are based on empiric use of hurdle technology. However, several foods have already been optimized by the intentional application of hurdles. The state-of-the-art in the use of hurdle technology in some countries of Latin America, Asia, and Africa has been presented in a comprehensive review [12].

16.4.1 Fruits of Latin America

During the last decade a novel process for the preservation of high-moisture fruit products (HMFP: $a_w > 0.93$) has been developed in seven Latin American countries (Argentina, Costa Rica, Cuba, Mexico, Nicaragua, Puerto Rico, and Venezuela), and has been applied to peach halves, pineapple slices, mango slices and purée, papaya slices, chicozapote slices, banana puree, plum, passion fruit, and tamarind, as well as whole figs, strawberries, and pomalaca [55, 56]. The new technologies were based on the combination of a mild heat treatment (blanching for 1–3 min with saturated steam), slight reduction in water activity (to 0.98–0.93, by addition of glucose or sucrose), lowering of pH (to 4.1–3.0, by addition of citric or phosphoric acids), and the addition of antimicrobials (potassium sorbate or sodium benzoate, and sodium sulfite or sodium bisulfite) in moderate amounts to the syrup of the products (Table 16.5). During storage of HMFP the sorbate and in particular the sulfite levels decreased, whereas the a_w fell (the a_w hurdle increased) due to the hydrolysis of sucrose [55]. Thus, "combined methods technology" (hurdle technology) was applied in these novel processes [55–59]. The minimal processes proved inexpensive, energy-efficient, simple to carry out (little capital investment), and were satisfactory to preserve fruits *in situ*. The resulting fresh-like products were still scored highly by a 30–50 member consumer panel after 3 months of storage at 35°C for taste, flavor, color, and especially for texture, which is often problematic for canned fruits. Thus, according to Latin American researchers [55, 56, 58, 60, 61], the combined methods applied allow storage of fruits, without losses between seasonal harvest peaks; for direct domestic consumption; or for further processing to confectionery, bakery goods, and dairy products; or for preserves, jams, and jellies. Fruit pieces can also be utilized as ingredients in salads, barbecues, pizzas, yogurt, and fruit drink formulations [56, 61]. Moreover, these novel HMFPs could open new possibilities for export markets.

The high-moisture fruit products stabilized by hurdle technology proved shelf stable and safe for at least 3–8 months storage at 25–35°C. Due to the blanching process, the initial microbial counts were substantially reduced, and during the storage of the stabilized HMFPs, the number of surviving bacteria, yeasts, and molds further decreased, often below detection limits [55, 56, 58–62]. Banana puree challenged with yeasts, molds, clostridia, and bacilli, known to spoil fruits, and stored at ambient temperatures for 120 days remained stable if proper hurdles were applied (mild heat treatment,

TABLE 16.5
Typical Process Used for the Preservation of High-Moisture Fruit Products (HMFP), as Developed in Latin America

Hurdle	Intensity
1. Heat treatment[a]	Saturated steam for 1–3 min
2. Water activity[b]	a_w, reduction to 0.98–0.93
3. Acidification[c]	pH, adjustment to 4.1–3.0
4. Preservative (I)	1000 ppm sorbate or benzoate
5. Preservative (II)	150 ppm sulfite or bisulfite

[c] Adjusted, if necessary, with phosphoric or citric acid

adjustment of a_w to 0.97 and pH to 3.4, addition of 100 ppm potassium sorbate, 400 ppm sodium bisulfite, and 250 ppm ascorbic acid). The inoculated microorganisms declined and often vanished below the detection limit [57]. These favorable microbiological results obtained with HMFP are probably due to "metabolic exhaustion" of the microorganisms present in the stabilized products. Since HMFP during storage at ambient temperatures become apparently sterile, pathogenic and toxigenic microorganisms are not likely to be a hazard for these foods [12].

Alzamora et al. [56] expressed the opinion that HMFP technologies as developed in Latin America could attract much attention in many developing countries because they are easy to implement and considerably improve the quality of stored fruits. They even believe that the usefulness of combined methods preservation (hurdle technology) for HMFP may give rise to an "explosion" of research on minimally processed fruits, and the application of this innovative process by the food industry [55]. Latin American advances in fruit preservation are impressive and have recently been confirmed by Indian researchers, who concluded that "hurdle technology is seen as a promising technique for the preservation of fresh fruits and vegetables" [63]. However, the preservation of HMFP must certainly be based on guidelines for good manufacturing practice (GMP) in order to be successful under industrial or even artisan conditions [64]. For instance, the reuse of syrup may become a risk in relation to a build-up of the spoilage flora (e.g., *Zygosaccharomyces bailii*, which could be sorbate-resistant), and therefore the reuse of syrup in HMFP processes should only be recommended after pasteurization.

Preciado-Iniga et al. [65] developed a stable tamarillo sweet product by applying hurdle technology. The hurdles were blanching (boiling water 93°C for 12 min), low pH, reduction of water activity, sodium benzoate and potassium sorbate (1:1) addition, and stored at 4°C, with oxygen and light protection. The product was stable up to 56 days considering permitted limits of aerobic mesophilic bacteria (<50 CFU/g) and molds and yeasts (<10 CFU/g), without changes in anthocyanin, phenolic, antioxidant capacity, and color. However, the unblanched tamarillo was microbial stable up to 42 days.

16.4.2 Fruits and Vegetables in India

Sinha et al. [66] developed microbial and sensory stability of fresh cauliflower for 180 days using hurdle technology. They followed five steps: (i) optimize the blanching process (temperature: 98–100°C, 30–60 s), (ii) potassium metabisulfite dipping treatment (0.25% for 10 min), (iii) steep in preservatives solution (i.e., six treatments with a combination of salt, potassium metabisulfite, sodium benzoate, and citric acid), (iv) aseptic packaging, and (v) chilled storage (temperature: 30–37°C and 5–7°C). The following treatments showed microbiologically safe products until 180 days with the highest sensory qualities. These are (i) steeping 8% salt, 0.3% citric acid, 300 ppm potassium metabisulfite, 300 ppm sodium sorbate, storage 30–37°C; (ii) steeping 10% salt, 400 ppm citric acid, 500 ppm metabisulfite, 100 ppm sodium benzoate, storage 5–7°C; and (ii) steeping 8% salt, 0.3% citric acid, 300 ppm potassium metabisulfite, 300 ppm sodium sorbate, storage 5–7°C.

16.4.3 Meats of China

Even though the per capita consumption of meat, compared to Western countries, is rather low in China, due to the huge number of people living in China this country has the largest meat consumption worldwide. Pork is the preferred meat in China, however, beef, water buffalo, sheep, poultry, and rabbit are also used as raw materials [67]. Only about 15% of the available meat of China is processed [68]; however, this is still a large amount and meat products are an important and precious part of the diet. Two categories of meat products exist in China side by side: Chinese meats and Western meats. Of the Western meat products, recently autoclaved emulsion-type sausages have gained ground in China. Their technology has been derived from the German F-SSP. However, the a_w of the Chinese products is not adjusted, and therefore they must receive a severe heat treatment (F_o >5.0), which is not beneficial for the taste but results in shelf-stable products. On the other hand, the recipes of traditional Chinese meat products date back centuries, and their microbial stability and safety are based on combined preservative factors empirically applied. Studies are in progress to identify the hurdles inherent to these traditional meats [69]. The concept of hurdle technology was introduced to China and work related to the application of hurdle technology to meat products is being carried out in several Chinese research institutes [70–74].

Traditional Chinese meat products are quite simple to prepare without expensive equipment, have a typical flavor, are ready-to-eat, and storable for an extended time without refrigeration. The traditional meats of China listed in Table 16.6 are all intermediate-moisture foods, and this implies that they might be too salty or too sweet, too tough, and too dark due to the formation of such Maillard reaction products. The water

* All these meat products are intermediate-moisture foods and are storable without refrigeration.

activity is the primary hurdle in these meats, but if additional hurdles are strengthened, then the a_w might be raised and this often improves the sensory quality of the products. However, the microbial stability and safety of the meats must not be jeopardized by an increased a_w. Therefore, intentional and intelligent hurdle technology is increasingly applied.

Rou gan is a typical dried meat product of China, prepared mainly from beef, using a technology that has not been changed for hundreds of years, but improvements are possible and desirable. Consumers now prefer products with a softer texture, lighter color, and less sugar. Shafu is a modified dried meat that fulfills these expectations. The a_w of rou gan is in the range of 0.60–0.69, whereas shafu has an a_w of 0.74–0.76, because its moisture is higher and the sugar content lower. Additional hurdles in shafu are nitrite and ascorbic acid, which improve the color and delay rancidity, whereas rou gan is cured with nitrate only. Furthermore, the microbial stability of shafu is improved by the selection of raw material with low microbial load, low temperature during curing but relative high temperature and shorter times during heating, minimizing of recontamination after the heat process as well as vacuum packaging of the final product in order to inhibit mold growth and to delay rancidity. Therefore, shafu is microbiologically stable and safe for several months at ambient temperatures, and thus has the same shelf life as the traditional rou gan [68]. Both products have low residual levels of nitrite and nitrate, contain few microorganisms including in general no pathogenic or toxigenic bacteria, and thus are safe meats.

A similar approach was chosen to improve the quality of Islamic dried beef, which is also storable for several months without refrigeration. The traditional product is just salted and dried, and therefore is very salty and becomes easily rancid. The modified product contains less salt, is cured with nitrate to improve color, and some ascorbic acid is added to delay rancidity. Furthermore, vacuum packaging is applied to reduce oxidation and to avoid mold growth [75]. More examples of the application of hurdle technology to Chinese meat products are available in a review article [12].

Finally, the stabilization of the Chinese sausage, which was achieved in cooperation with Taiwan [76], will be mentioned. Chinese sausage is highly esteemed by oriental consumers and differs from the fermented sausages common in Western countries. It is processed raw, with little fermentation. Several types of la chang (also called lup cheong) are known, e.g., the Sichuan type is spicier and the sweeter Cantonese, whereas the Taiwanese la chang is softer. In mainland China, finished products of la chang have the following properties: a_w 0.85–0.70, pH 5.9–5.7, NaCl 3–5%, sugar 4–20%, total count $<10^6$ /g, shelf life 2–3 months without refrigeration and if vacuum packaged 4–5 months (Table 16.7). To the coarsely ground meat and pork fat, sugar, salt, soya sauce, liquor, spices, nitrate (or nitrite), and sometimes sodium ascorbate, are added. The mix is stuffed into casings with small diameter, and the sausages are dried fast over charcoal at 45–60°C to a_w <0.92, and then further at ambient temperature to a_w <0.80, in order to avoid an increase of lactic acid bacteria counts, since most Chinese dislike sour meats. Thus, la chang is a typical meat product preserved by combined factors. In general, before consumption la chang is sliced and heated in rice or vegetable dishes [5, 22, 72, 76].

TABLE 16.7
Examples of Meat and Paneer Based on Hurdle Technology

Product	Hurdles	Shelf Life
La chang (meat) (China)	a_w: 0.85–0.70 pH: 5.9–5.7 NaCl: 3–5% Sugar: 4–20% Refrigeration: no Total count < 10^6/g	2–3 months

Paneer (India)	a_w: 0.97 pH: 5.0 F_o: 0.8 min Storage: 35°C	Several weeks
Paneer in gravy (India)	a_w: 0.95 pH: 5.0 F_o: 0.8 min Potassium sorbate: 0.1%	2 weeks (storage: 45°C) 1 month (storage: 30°C) 3 months (storage: 15°C)

Sources: Kuo et al. [76]; Rao [36]; Rao et al. [37]; Rao and Patil [85].

The Taiwanese variety of Chinese sausage contains more moisture and therefore can have a_w as high as 0.94. This improves the sensory properties since the products are softer, but decreases their microbial stability and safety, because in such products lactic acid bacteria still grow and lead to a sour taste, and *S. aureus* might cause food poisoning. After the addition of 3.5% sodium lactate and 1.0% sodium acetate, the Taiwanese sausage remains tasty but is rendered microbiologically stable and safe, even if stored for several weeks without refrigeration. These additives reduce a_w of the product but also have some antimicrobial effects [76]. Challenge tests using inoculum of *S. aureus*, *L. monocytogenes*, or *Salmonella* spp. confirmed that Taiwanese sausage, which was modified by intentional hurdle technology, was stable and safe [76]. Furthermore, they demonstrated that in this product the number of pathogens decreased faster during storage at 25°C than at 10°C. This was probably due to a faster metabolic exhaustion of the pathogens at the higher storage temperature.

16.4.4 Dairy Products of India

The application of hurdle technology to traditional and modified Indian food products has been applied [37, 63, 77, 78].

Paneer is a traditional, cottage-cheese type product fried in cubes with oil and onions, to which a sauce containing salt, spices, and often tomatoes is added. This food is frequently consumed and much liked in the northern provinces of India, because of its nutritive value and characteristic taste. However, paneer spoils bacteriologically within 1–2 days at room temperature (which in India can reach 35°C), and this is a strong drawback for its industrial production. Sterilized paneer in cans has severe sensory limitations with regard to flavor, texture, and color. A mildly heated paneer in hermetically sealed containers, with the desired flavor (like prepared fresh), color (little browning), and texture (not too hard) was developed [37]. This product was stabilized by hurdle technology and thus is stable and safe for several weeks without refrigeration. The following combinations of hurdles proved effective with this product: a_w = 0.97, heating to F_o of 0.8, pH = 5.0, or alternatively a_w = 0.96, F_o = 0.4, pH = 5.0 [37]. Fried paneer in cubes made from buffalo milk with gravy was packed either in tins or flexible retort pouches, and a set of hurdles, i.e., a_w = 0.95, F_o = 0.8, pH 5.0, and 0.1% potassium sorbate, was chosen, which had maximum lethal and inhibitory effects on microorganisms and minimum effects on textural and chemical characteristics (Table 16.7) [36]. The water activity of paneer and gravy was lowered using humectants, such as dahi, skim milk powder, salt, and glycerol. The pH was adjusted by changing the dahi:skim milk powder ratio. The resulting product had a keeping quality of 2 weeks at 45°C, 1 month at 30°C, or over 3 months at 15°C, which was limited by textural changes (hardness, cohesiveness, gumminess, springiness, and chewiness) as well as by chemical changes (browning, oxidation, lipolysis, and loss of available lysine), but not by microbial spoilage. The stabilized product was compared with fresh samples from restaurants and was found to be equally acceptable. This method of paneer preservation has a large scope for alterations in product formulations depending on regional taste preferences, without affecting the keeping quality of the product [36]. Via paneer, the hurdle technology has been introduced into food science of India, and its application to other indigenous foods is now anticipated. Further examples of the products with their hurdles and shelf life are presented in Table 16.8.

A recent example is dudh churpi. This is a popular dairy product of the Himalaya region of India (i.e., Bhutan, Sikkim, Darjeeling) made of milk from yaks or cows, and it is stable for several months without refrigeration. Most important for dudh churpi is the texture (elasticity), since people living in high altitudes chew it as an "energy tablet." The sensory quality and microbial stability of dudh churpi were optimized by Hossain [78] using combined methods (hurdle technology), that is, heating, acid coagulation, addition of sugar and sorbate, smoking, drying, and packaging in closed containers. In this detailed and diligent study, dudh churpi was scientifically explored and then a feasible optimization of the product was suggested. Thus, hurdle technology was applied to improve the quality of a traditional food of the remote Himalaya region, and at the same time the scientific basis of this study opened new avenues for food science and industrial food production in India.

16.4.5 New Technologies as Hurdles

Pulsed electric field and microfiltration as cold hurdles were used effectively instead of conventional thermal processing [79]. Milk processed with hurdles as pulsed electric field and microfiltration could produce greater microbial inactivation and overall similar shelf stability at lower processing temperatures as compared to thermal processing. This could retain better sensory properties. Although novel technologies are being used to develop hurdle products, one of the main purposes of the hurdle technologies is to use simple, easy, cheap, and low-cost methods. However, all new technologies need huge capital investments (i.e., costs), systems are complex and not readily available, and safety and design aspects are not well documented.

16.5 DESIGN OF HURDLE TECHNOLOGY FOODS

The application of hurdle technology is useful for the optimization of traditional foods as well as in the development of novel products. There are similarities to the concepts of predictive microbiology and hazard analysis critical control point (HACCP). The three concepts have related but different goals: hurdle technology is primarily used in food design, the predictive microbiology for process refinement, and the HACCP concept for process control. In product development, these three concepts should be combined. Therefore, we have suggested for the design of foods a ten-step procedure, which comprises all three concepts (Table 16.9), and this approach proved suitable when solving real product development tasks in the food industry [9, 32, 80]. However, these 10 steps should still be considered tentative until further practical experience with the application of the suggested user guide for food design has accumulated in the food industry.

In food design, different disciplines, including microbiologists and technologists, must work together. The microbiologist should determine which types and intensity of hurdles are needed for the necessary safety and stability of a particular food product, and the technologist should determine which ingredients or processes are proper for establishing these hurdles in a food (i.e., taking the legal, technological, sensory, and nutritive limitations). Because the engineering, economic, and marketing aspects have to be taken into consideration too, food design is indeed a multidisciplinary endeavor [3, 9].

Predictive microbiology [81, 82] is a promising concept that allows computer-based and quantitative predictions of microbial growth, survival, and death in foods, and thus should be an integral part of advanced food design (see Table 16.9, steps 4 and 7). However, the predictive models constructed so far handle only up to four different factors (hurdles) simultaneously. But there are numerous hurdles to be considered that are important for the stability, safety, and quality of a particular food, and need to be included in the model. It is unlikely that all or even a majority of these hurdles could be covered by predictive modeling. Thus, predictive microbiology cannot be a quantitative approach to the totality of hurdle technology.

TABLE 16.8
Examples of Hurdle Products

Food or Media	Hurdle	Shelf Life	Reference
Cane juice	Pasteurized at 80ºC for 10 min PMS (150 ppm) Citric acid (0.05%) Sterilization 80°C for 20 min Irradiation: 1.0 kGy Packed glass/PET/LDPE bottle Quality good in glass bottle Microflora: indigenous	RT: 60 days LT: 90 days	Sankhla et al. [86]
Shrimp (ready-to-eat)	a_w: 0.85 Marinated and cooked Irradiation: 2.5 kGy Storage 25°C Packaging	15 days	Kannatt et al. [27]
Assai fruit	pH 3.5 (0.5% w/w citric acid) Pasteurized at 82.5°C for 1 min Low a_w with 40% sucrose and 0.15% potassium sorbate *or* Low a_w with 25% sucrose and 0.075% potassium sorbate Storage: 25°C Light protected	150 days	Alexandre et al. [87]
Sausage	a_w: 0.95 Pasteurized 75°C or 80°C at center Storage RT	150 days	Santos et al. [88]
Pineapple or mango	Blanched 85°C for 5 min Dipped in syrup (340 ppm PMS and 413 ppm SB) 8 h Sulfur dioxide 65–85 ppm and benzoic acid 150–200 ppm Packed in polypropylene (150 gauge)	30 days (27°C) 60 days (2°C)	Vijayanand et al. [89]
Papaya	Blanched 85°C for 5 min Dipped in syrup (680 ppm PMS and 826 ppm SB) 8 h Packed in polypropylene (150 gauge) Storage 2°C or 27°C	90 days	Vijayanand et al. [89]

Notes: PMS (potassium metabisulfite); SB (sodium benzoate)

However, it does allow quite reliable predictions of the fate of microorganisms in food systems, while considering few but the most important hurdles. Because several hurdles are not taken into account, the predicted results are fortunately often on the safe side, i.e., the limits indicated for growth of pathogens in foods by the models available are in general more prudent (“fail-safe”) than the limits in real foods. Nevertheless, predictive microbiology will be an important tool for advanced food design, because it can considerably narrow the range over which challenge tests with relevant microorganisms need to be performed. Although predictive microbiology will never render challenge testing obsolete, it may greatly reduce both time and costs spent in product development [3, 9, 13].

HACCP could be a reasonable supplement to hurdle technology because after the food has been properly designed, its manufacturing process must be effectively controlled, and for this purpose, the application of HACCP might be suitable. However, in a strict sense, the HACCP concept only controls the hazards of foods and not at the same time their stability and quality [83]. Even in commercial practice, safety and quality issues will often overlap if HACCP is applied [9]. Since for hurdle technology foods the microbial safety and stability as well as the sensory quality, i.e., the total quality of the food (see Section 16.2.3), are essential, the HACCP concept might be too narrow for this purpose if it relates only to biological, chemical, and physical hazards. Therefore, the HACCP concept should be broadened in order to cover the microbial safety (food poisoning) and stability (spoilage) of foods as well as their sensory quality. If this is not acceptable, instead with HACCP the production process should be controlled by GMP, and for this purpose GMP rules or guidelines for the production of each food item must be defined [22]. For hurdle technology foods of developing countries, GMP guidelines are often more acceptable, because the application of HACCP faces practical difficulties where many small producers prevail.

TABLE 16.9
Steps for Food Design Using an Integrated Concept Comprising Hurdle Technology, Predictive Microbiology, and HACCP or GMP

Step 1	For the modified or novel food product, the desired sensor properties and the desired shelf life are tentatively defined.
Step 2	A feasible technology for the production of this food has to be outlined.
Step 3	The food is manufactured according to this technology, and the resulting product is analyzed for pH, a_w, preservatives, or other inhibitory factors. Temperatures for heating (if intended) and storage, as well as the expected shelf life are defined.
Step 4	For preliminary microbial stability testing of the food product, predictive microbiology might be employed.
Step 5	The product is challenged with food poisoning and spoilage microorganisms, using somewhat higher inocula and storage temperatures than would be "normal" for this food.
Step 6	If necessary, the hurdles in the product are modified, taking "multitarget preservation" and the sensory quality of the food (i.e., "total quality") into consideration.
Step 7	The food is again challenged with relevant microorganisms, and if necessary, the hurdles in the food are modified again. Predictive microbiology for assessing the safety of the food might be helpful at this stage.
Step 8	After the established hurdles of the modified or novel foods are exactly defined, including tolerances, the methods for monitoring the process are agreed on. Preferably, physical methods for monitoring should be used.
Step 9	The designed food should now be produced under industrial conditions, because the possibilities for a scale-up of the proposed manufacturing process must be validated.
Step 10	For the industrial process, the critical control points (CCPs) and their monitoring have to be established, and therefore the manufacturing process should be controlled by HACCP. If HACCP is not appropriate, guidelines for the application of manufacturing control by GMP must be defined.

16.6 CONCLUSION

The stability, safety, and quality of most preserved foods are based on the empirical application of combined methods for preservation and more recently on knowingly employed hurdle technology. The deliberate and intelligent application of hurdle technology allows a gentle, but efficient preservation of safe, stable, nutritious, and tasty foods, and is advancing worldwide. Moreover, knowledge of the physiological basis of growth, survival, and death of pathogenic and spoilage microorganisms in foods is increasing, since the homeostasis, metabolic exhaustion, and stress reactions of microorganisms in relation to the hurdle effect are now better understood. Therefore, the future achievement of multitarget preservation, the ultimate goal for gentle but effective preservation of foods, is becoming more likely.

In industrialized countries, the hurdle technology approach is at present of most interest for minimally processed, fresh-like foods, which are mildly heated or fermented, and for underpinning the microbial stability and safety of foods coming from future lines, such as healthful foods with less fat and/or salt or advanced hurdle technology foods that require less packaging. For refrigerated foods, chill temperatures are the major and sometimes the only hurdle. However, in the case of temperature abuse during distribution, this hurdle breaks down, thus spoilage or food poisoning could happen. Therefore, additional hurdles should be incorporated as safeguards into chilled foods, and this approach might be called "invisible technology."

In developing countries, the intentional application of hurdle technology for foods, which remain stable, safe, and tasty even if stored without refrigeration, has made impressive strides, especially in Latin America with the development of novel high-moisture fruit products. However, much interest in intentional hurdle technology is also emerging for meat products in China as well as for dairy products of India. There is a general trend in developing countries to gradually move away from intermediate-moisture foods, because they are often too salty or too sweet, and have a less appealing texture and appearance than high-moisture foods. However, deliberate hurdle technology should be applied to high-moisture foods without sacrificing the microbial stability and safety, especially of those foods, which are stored without refrigeration. Therefore, if hurdle technology foods become more sophisticated, they will require a thorough understanding of the principles involved as well as more backup of their production by guidelines based on GMP and, where appropriate, by application of the HACCP concept.

Hurdle technology foods are in general less robust than traditional food products, which are often overprocessed and thus have a large margin of safety. Therefore, if modified hurdle technology foods are produced the applied processes must be exactly defined and controlled. For the design of hurdle technology foods a ten-step procedure has been suggested that comprises hurdle technology, predictive microbiology, and HACCP or GMP guidelines. This procedure proved suitable for solving real product development tasks in the food industry but is open to further improvements. Hurdle technology should not lead to the addition of too many additives but should instead reduce the number of additives used even if their number might increase. It is of paramount importance that additional hurdles are introduced into a food product only after careful consideration of the essential amounts, otherwise an undesirable chemical overloading of the food might result.

Combined methods used for tissue preservation are by no means a new process, as has been pointed out by Chirife et al. [84] in their study on the mummification in Ancient Egypt. In the opinion of these authors the embalmed mummies contained >3000 years ago (at least) three hurdles, namely, reduced a_w (0.72), increased pH (10.6), and preservatives (spices, aromatic plants). However, recently, the action of combined preservative factors is being understood and their intentional and intelligent application is progressing, and further applications of hurdle technology for optimization of traditional as well as in the design of novel foods are anticipated.

Part III

Preservation Using Chemicals and Microbes

17 Fermentation as a Food Biopreservation Technique

Nejib Guizani, Ismail M. Al Bulushi, and Ann Mothershaw

CONTENTS

17.1 INTRODUCTION

17.1.1 Fermentation Definition

Fermentation could be described as a process in which microorganisms change the sensory (flavor, odor, texture etc.) and/or functional properties (i.e., microbial health benefits) of a food to produce a desired product to the consumer. In this chapter, particular emphasis is placed on how these changes are beneficial to extend the shelf life and influence the safety of the product.

17.1.2 History

The rapidly increasing world population necessitates that the amount of food wasted needs to be kept a minimum. Food production is only one part of the process to ensure continuous,

diverse, and safe food supplies to meet consumer demand. Food must also be stored and preserved to achieve this objective. The requirement to store and preserve foods has long been recognized, even before any knowledge of microbiology. Fermentation along with cooking, smoking, and sun drying is one of the earliest ancient traditions developed by cultures all around the world to extend the possible storage time of foods. Before the initiation of preservation technology, man frequently had to choose between starvation and eating spoilt foods and then suffering the possible consequences of this. For thousands of years, raw animal and plant ingredients have been fermented. Fermented fruits were probably among the first fermented foods eaten 1, 2]. The methods for fermentations were developed by trial and error, and from the experiences of many generations.

17.1.3 Common Fermented Foods

A selection of the most common fermented foods, which has wide geographical distributions, is shown in Table 17.1. The key types of microorganisms associated with these foods are also included. Yeasts and lactic acid bacteria (LAB) are the most important groups of microorganisms. These types of microorganisms are widely used to process and preserve foods, and to produce certain types of flavors. LAB are of great industrial importance since they play an important role in the process of maturation, processing, and preserving foods. They are commonly used as starter cultures for vegetal, cereal, dairy, or meat-based products to carry out fermentations under controlled conditions. Molds, on the other hand, have limited uses in fermentation and their role is to produce desired flavor and color in certain dairy products and fermented Asian foods.

TABLE 17.1
Examples of the More Common Fermented Foods

Food	Principal Ingredient	Key Microorganisms
Wine	Grapes	Yeasts
Beer	Barley	Yeasts
Cider	Apples	Yeasts
Sake	Rice	Molds
Bread	Wheat	Yeasts
Yogurt	Milk	LAB
Cheese	Milk	LAB
Buttermilk	Milk	LAB
Kefir	Milk	LAB + yeasts
Vinegar	Grapes	Yeasts followed by *Acetobacter* + *Gluconobacter*
Tempeh	Soya beans	Molds
Soy sauce	Soya beans	Molds + LAB + yeasts
Pickled cucumbers	Cucumbers	LAB + yeasts
Sauerkraut	Cabbage	LAB
Pickled olives	Olives	LAB + yeasts
Fermented sausages	Meat	LAB + molds

Note: LAB, lactic acid bacteria.

17.2 MECHANISMS OF FOOD PRESERVATION BY FERMENTATION

In many instances, the importance of fermentation processes for food preservation has declined as new preservation techniques have been developed. Yet fermentation can be effective at extending the shelf life of foods and can often be carried out with relatively inexpensive and basic equipment. Therefore, it remains a very appropriate method for developing countries and rural communities with limited facilities. In addition, the nondependence of fermentation on the use of chemical additives to the food appeals to the "more aware" consumer market. The chemical composition of most foods is relatively stable; therefore, generally, preservation is based on eliminating microorganisms, or controlling their growth and the overall composition of the microflora. To reduce or prevent microbial spoilage of food, four basic principles can be applied:

1. Minimize the level of microbial contamination onto the food, particularly from "high-risk" sources.
2. Inhibit the growth of the contaminating microflora.
3. Kill the contaminating microorganisms.
4. Remove the contaminating microorganisms.

Fermentations use a combination of the first three principles. Fermentations should not be expected to sterilize substandard raw products, but rather should use high-quality substrates. Microorganisms can improve their own competitiveness by changing the environment so that it becomes inhibitory or even lethal to other organisms whilst stimulating their own growth, and this selection is the basis for preservation by fermentation. A number of different bactericidal and bacteriostatic factors that can be produced by LAB are shown in Table 17.2.

Fermentation can also prevent or reduce food spoilage by chemical agents. For instance, certain LAB such as

TABLE 17.2
Factors Produced by the Metabolic Activity of Microorganisms That Can Contribute to the Increased Stability and Safety of Fermented Foods

Low pH
- Organic acids, e.g., lactic acid, acetic acid, and formic acid
- Low redox potential
- Nutrient depletion (16)
- Accumulation of inhibitors, e.g., toxins, bacteriocins (183), antibiotics, lantibiotics, lactococcins, nisin, natamycin, hydrogen peroxide
- Ethanol
- Diacetyl
- Carbon dioxide

Source: Adams and Moss [30].

Lactobacillus plantarum, Lactobacillus casei subs casei, and *Pediococcus pentosaceus* were found to suppress the production of thiobarbituric acid reactive substances (TBARS), total volatile base nitrogen (TVB-N), and trimethylamine (TMA) levels [3–5]. Inhibition of the production of TBARS by LAB was explained by their capacity to scavenge oxygen (O_2), whereas their ability to suppress the increase of TVB-N and TMA was attributed to the preservative effects of LAB metabolic products and LAB antimicrobial activity [3, 6, 7].

Fermentation improves the safety of foods by reducing the risk of pathogens growing, thus limiting the chances of pathogens achieving their minimum infective dose in addition to preventing the consequential production of their metabolic products including toxins. This growth inhibition is, in part, achieved by the activity of the metabolic end-products and bacteriocins produced by the LAB. In general, bacteriocin modes of actions include inhibition of proteins synthesis and stopping synthesis of DNA and RNA in the target/pathogen bacteria [8, 9]. Different LAB have highly effective antimicrobial activities against many pathogens. For instance, *Lactococcus lactis* and *Enterococcus faecium* isolated from some fermented milk products demonstrated inhibitory action against different strains of *Listeria monocytogenes*, *Pseudomonas aeruginosa*, and *Bacillus cereus* [10, 11]. In this respect, Enterocin R69 was found to have a specificity of action against *Listeria* spp., whereas Enterocin R18 had a broad spectrum of activity. *Lactococcus lactis* R9/2 and *E. faecalis* R18 induced a 2 log reduction in *L. monocytogenes* ATCC 15313 population [10]. In terms of preventing health risks from harmful microbial metabolites, certain types of LAB such as *Tetragenococcus halophilus* were found to impede the formation of histamine [7].

17.2.1 Microbial Contamination of Foods

Foods are derived from other living organisms and during their development and preparation, and these are continuously exposed to microbial contamination. The resultant contaminating microflora can have different effects on the food. These include negative effects such as spoilage, where the food becomes unfit for human consumption or health risks when infectious or toxigenic microorganisms are present. Negligible effects on the food occur when the microflora does not cause disease or any detectable changes in the food. However, benefits can also be reaped from the action of the microorganisms when their activity brings about improvements in the appeal (i.e., desired or preferred sensory attributes) of the food. In developed countries, the improved appeal is the major reason for microbial fermentation of foods continuing today.

The nutrient content and intrinsic properties of many raw foods make them ideal environments for microbial replication. The rate at which the microorganisms grow depends not only on the intrinsic properties of the food (pH, redox potential, water activity, etc.) but also on the conditions under which it is being stored, the extrinsic factors, e.g., temperature. Therefore, many raw foods need to be consumed soon after production to retain their nutritional value. The delays in preservation measures lead to degradation of the nutrients and utilization by the contaminating microflora.

A major consideration needs to be given to ideal conditions, since microorganisms can grow very rapidly, being able to double in number in a short period. It must also be noted that there is a variation in the optimum environmental conditions for different types and species of microorganisms, e.g., microorganisms can be categorized into broad groups such as aerobes and anaerobes depending on their tolerance and use of oxygen, and psychrophiles, mesophiles, and thermophiles based on temperature growth requirements. In addition, the biochemical activity of different microorganisms varies and may change in response to fluctuations in environmental factors, leading to a range of metabolic end products (Table 17.3). By manipulating the environmental conditions, it is possible to select specific kinds of microorganisms that impart a particular taste, odor, texture, or appearance to the food. This is one of the important bases of fermentation.

17.2.2 Benefits of Fermented Foods

Microbial applications in food industry are of major interest. The acceptability of a food to the consumer is based mainly on its sensory properties when food safety is achieved. The sensory properties of fermented foods are brought by the biochemical activity of microorganisms. Fermented foods were developed simultaneously by many cultures for two main reasons: (i) to preserve harvested or slaughtered products, which were abundant at certain times and scarce at others, and (ii) to improve the sensory properties of an abundant or unappealing product [1, 12].

The range of benefits that can be obtained from fermentation of foods can be extended to include preservation through formation of inhibitory metabolites such as organic acids (lactic acid, acetic acid, formic acid, and propionic acid), ethanol, bacteriocins. This activity is frequently enhanced by combining with (i) decreased water activity (by drying or salting) [13, 14], (ii) improving food safety through inhibition of pathogens [15] or removal of toxic compounds [16], (iii) improving the nutritional value [17, 18], (iv) improving organoleptic quality of food [1, 12, 19, 20], and (v) consumer acceptance due to its natural process without the addition of synthetic chemicals.

TABLE 17.3
Examples of Microbial Metabolic End Products Used in Fermented Foods

Metabolic End Product	Example of Uses
Carbon dioxide	Leavening bread
Ethanol	Alcoholic beverages
Acids	Vinegar
Acetic	Fermented vegetables
Lactic	
Flavor compounds	Dairy products
Acetaldehyde	Yoghurt

Fermentation has low energy demands and can often be carried out without sophisticated technology and designated plants. The simple techniques mean that the procedures can often be carried out in the home [21]. Fermented foods and drinks retain an important role in the human diet. A number of studies have shown that consumers regard fermented food products as healthy and natural, and increasing consumer demand makes profitability [22]. Consumer interest in probiotic foods, which include live LAB, has increased due to their health benefits. Potential health benefits from the activity of probiotic foods include hydrolysis of lactose, reduced serum cholesterol levels, reduced colon cancer, improved immune response and reduced allergic diseases [23].

In fermentation of food wastes, a number of useful chemicals have been produced. For instance, volatile fatty acids yield of 30.22 g/L and improve acetic acid production to 25.88 g/L were produced by yeasts and acetic acid bacteria fermentation of food wastes (24). Using *Rhodobacter sphaeroides* as a fermenter, average yields of hydrogen was approximately 199 ml hydrogen/g cassava and 220 ml hydrogen/g food waste were produced by a two-step process of dark fermentation and photofermentation, respectively [25].

17.3 MICROORGANISMS USED IN FOOD FERMENTATIONS

Various groups of microorganisms are frequently used in fermented foods and the principal groups are shown in Table 17.4.

17.3.1 Lactic Acid Bacteria

Lactic acid bacteria perform an essential role in the preservation and production of wholesome foods. Examples of lactic acid fermentations include (i) fermented vegetables, such as sauerkraut, pickled cucumbers, radishes, carrots, and olives; (ii) fermented milks, such as yogurt, kefir, and cheeses; (iii) fermented/leavened breads, such as sourdough breads; and (iv) fermented sausages (Table 17.1). LAB have been grouped together as they possess a range of common properties (Table 17.5) and all produce lactic acid, which can kill or inhibit many other microorganisms [26]. The primary use of lactic acid in the food industry is as a preservative, an acidulant, or a dough conditioner and raiser. The principal genera of lactic acid bacteria are shown in Table 17.6. In general, excluding some streptococci, they are harmless to humans. This makes lactic acid bacteria ideal agents for food preservation. LAB are subdivided based on their products from glucose fermentation. Homofermenters produce lactic acid as the major or sole product from glucose, whereas heterofermenters produce equimolar amounts of lactate, carbon dioxide, and ethanol. Heterofermenters have an important role in producing aroma components, such as acetaldehydes and diacetyl. LAB have a range of methods for outcompeting other microorganisms (Table 17.2). Their most effective mechanism is to grow readily in most foods, producing acid, which rapidly lowers the pH to a point where other competing organisms can no longer grow [12]. Lactobacilli also have the ability to produce hydrogen peroxide [27], which is inhibitory to spoilage organisms [12], whilst lactobacilli are relatively resistant to hydrogen peroxide [28]. The role of hydrogen peroxide as a preservative is likely to be minor, especially when compared to acid production. Carbon dioxide produced by heterofermenters also has a preservative effect resulting partially from its contribution to anaerobiosis [12].

Consumers are taking a greater interest in the quality of foods and are creating a demand for chemical-free, "natural health" foods. This has stimulated extensive research into the applications of lactic acid bacteria for both the control of pathogenic and spoilage microorganisms and also for health promotion. A range of potential health benefits has been associated with the consumption of LAB. Some benefits due to a consequence of their growth and activity during food fermentations and some from the resultant colonization of the gastrointestinal tract (Table 17.7). Many of these health claims are still controversial [23]) and are the subject of research to identify and substantiate specific roles [16, 23, 29].

TABLE 17.4
Principal Groups of Microorganisms Used for Food Fermentation

Microbial Group	Product
Lactic acid bacteria (LAB)	Lactic acid
Acetic acid bacteria	Acetic acid
Yeasts	Alcohol and carbon dioxide
Molds	Enzymes

TABLE 17.5
Characteristics Common to Lactic Acid Bacteria (LAB)

Gram-positive
Catalase negative
Oxidase negative
Non-spore forming
Fermentative anaerobes that are aerotolerant
Produce most of their cellular energy from the fermentation of sugars
Produce lactic acid from hexoses

17.3.2 Acetic Acid Bacteria

A second group of bacteria with importance in food fermentations is the acetic acid producers. Acetic acid is one of the oldest chemicals known; it is named after the Latin word for "vinegar," *acetum.* The acetic acid bacteria are acid-tolerant; grow well at pH levels below pH 5.0; are gram-negative, motile rods; and are obligate aerobes. They derive energy from the oxidation of ethanol to acetic acid following the reaction

TABLE 17.6
Genera of Lactic Acid Bacteria Commonly Used in Food Fermentations

Genus	Cell Shape and Grouping	Homofermenter	Heterofermenter
Lactobacillus	Rods, single or chains	+	+
Lactococcus	Oval cocci, pairs or chains	+	–
Leuconostoc	Oval cocci, pairs or chains	–	+
Pediococcus	Cocci, pairs and tetrads	+	–
Streptococcus	Cocci, pairs and chains	+	–
Weissella	Coccoid/short rods; single, pairs, or short chains	–	+
Enterococcus	Cocci; single, pairs, or short chains	+	–

Sources: Modified from Axellson [26] and Adams and Moss [30].

$$C_2H_5OH + O_2 \rightarrow CH_3COOH + H_2O$$

They are found in nature where ethanol is being produced from the fermentation of carbohydrates by yeasts, such as in plant nectars and damaged fruits. Other good sources are alcoholic beverages like fresh cider and unpasteurized beer. In liquids, these grow as a surface film due to their demand for oxygen.

Acetic acid bacteria consist of two genera: *Acetobacter* and *Gluconobacter*. *Acetobacter* can eventually oxidize acetic acid to carbon dioxide and water using Kreb cycle enzymes, referred to as overoxidation. This is not the case with *Gluconobacter*. The most desirable action of acetic acid bacteria is in the production of vinegar. The same reaction can also occur in wines, when oxygen is available, and here the oxidation of alcohol to acetic acid is an undesirable change, giving the wine a vinegary off-taste.

17.3.3 Yeasts

Yeasts are widely distributed in natural habitats that are nutritionally rich and high in carbohydrates, such as fruits and plant nectars [30]. Yeasts are rarely toxic or pathogenic, and are generally acceptable to consumers [31]. After extensive study, yeasts have been classified into about 500 species [32]. However, only a small number are regularly used to make alcoholic beverages [30]. *Saccharomyces cerevisiae* is the most frequently used and many variants are available. *S. cerevisiae* ferments glucose but does not ferment lactose or starch directly. Yeasts are used to produce ethanol, carbon dioxide, flavor, and aroma. The reaction can be represented by the following equation:

$$C_6H_{12}O_6 \rightarrow 2C_2H_5OH + 2CO_2$$

$$\text{yeast} + \text{glucose} \rightarrow \text{ethyl alcohol and carbon dioxide}$$

Other metabolic products include minor amounts of ethyl acetate, fusel alcohols (pentanol, isopentanol, and isobutanol), sulfur compounds, and leakage of amino acids and nucleotides can all contribute to the sensory changes induced by yeasts [31].

TABLE 17.7
Potential Health Benefits from Lactic Acid Bacteria

Benefits
From Foods
Improved nutritional value, e.g., production of vitamins or essential amino acids
Reduced toxicity, e.g., by degradation of noxious compounds
Increased digestibility and assimilability of nutrients (23)
From Colonization
Control of intestinal infections
Improved digestion of lactose
Inhibition of tumor growth
Lowering of serum cholesterol levels
Immune stimulation (184)

Source: Drouault and Corthier [185].

17.3.4 Molds

The majority of fungal species has filamentous hyphae and it is referred to as molds. They are grouped into four main classes based upon the physiology and production methods of their spores. Molds are aerobic and have the greatest array of enzymes. Some molds are used in the food industry to produce specific enzymes, such as amylases for use in bread making. They are relatively tolerant to extreme environments and are able to colonize and grow on most foods. Molds are important to the food industry, both as spoilers and preservers of foods and in particular in fermentations for flavor development. Certain molds produce antibiotics [33, 34], whereas mycotoxin production by others is an emerging cause of concern in the food industry.

The *Aspergillus* species are often responsible for undesirable changes in foods, although some species such as *Aspergillus oryzae* are used in fermentations of soybeans to make miso and soy sauce. *Mucor* and *Rhizopus* are also used in some traditional food fermentations. *Rhizopus oligosporus* is considered essential in the production of tempeh from soybeans. Molds from the genus *Penicillium* are associated

with the ripening and distinctive flavor of cheeses. For example, during ripening of Roqueforte and blue cheeses, *Penicillium roqueforti* is grown in air veins throughout the curd and the distinctive flavors develop as the milk lipids are broken down into methyl ethyl ketone and proteins are structurally altered.

17.3.5 Starter Cultures

Fermented foods may be produced by the action of fermentative microorganisms naturally found on the raw materials or in the production environment. However, "starter cultures" are frequently used to improve reliability. Starter cultures may be pure or mixed cultures. Mixed starter cultures can reduce the risks of bacteriophage infection [35] and improve the quality of the foods when the organisms are mutually beneficial. Food fermentations frequently involve a complex succession of microorganisms induced by dynamic environmental conditions. Fermentative microorganisms must be safe to eat even in high numbers and must produce substantial amounts of the desired end product(s).

To ensure food safety, starter cultures must be carefully selected to avoid incorporation of LAB metabolic products that could pose health risks following consumption of the food products. For example, organisms that can produce biogenic amines by possessing amino acid decarboxylase activity should be avoided [36]. Other criteria that could be considered in selection of the starter culture may include acid and bile tolerance; intestinal epithelial adhesion properties (for efficacy as probiotics); production of antimicrobial substances that can kill or inhibit pathogens and spoilage microorganisms; antibiotic resistance patterns; and immunogenicity [37].

For practical reasons, the organisms should be easy to handle and grow well, enabling them to outcompete undesirable microorganisms. The organism also needs to be genetically stable with consistent performance both during and between food batches. In many traditional fermentations the natural microflora were used for the fermentation. Even so, some form of inoculation was frequently performed using simple techniques like the use of one batch of food to inoculate the next batch or the repeated use of the same container [38]. Natural fermentations have a degree of unpredictability, which may be unsatisfactory when a process is industrialized. Starter cultures are increasingly used to improve not only the reliability, but also the reproducibility and the rate at which the fermentation is initiated. Failed, poor quality, or unsafe products lead to loss of customers and revenue, therefore their incidence must be minimized.

The composition of starter cultures is based on the knowledge of food-grade microbial genetics [39, 40], metabolism, and physiology as well as their interactions with foods [40]. Starter cultures are now developed mainly by design rather than by screening [41, 42]. The overall objective is to exploit the properties of the starter cultures to ensure reproducible standards of safety and quality [43].

17.4 CLASSIFICATION OF FERMENTED PRODUCTS

Fermented foods are classified in a number of different ways. They may be grouped based on the microorganisms, the biochemistry, or on the product type [44]. Campbell-Platt identified seven groups for classification, namely, (i) beverages, (ii) cereal products, (iii) dairy products, (iv) fish products, (v) fruit and vegetable products, (vi) legumes, and (vii) meat products [45]. Steinkraus classified fermentations according to the methods of fermentation, e.g., alcoholic (wines and beers) and alkaline (Nigerian dawadawa) [46]. In this chapter, the fermentations are grouped in terms of the biochemical products used to transform the food, i.e., production of lactic acid, acetic acid, ethanol, and/or carbon dioxide.

17.5 FERMENTED PRODUCTS

17.5.1 Alcoholic Beverages

Throughout history, alcoholic beverages have had a place in most cultures. They require the alcoholic fermentation of fruits or other high-sugar materials by yeasts. The alcohol content of the beverage acts as a preservative and many of these products have long shelf lives. Over the years, brewing yeasts have evolved by selection and mutations, and have been developed by genetic engineering. Major advances have been made in improving the characteristics of the fermentation strains driven by the high revenue associated with the alcoholic beverage industry.

17.5.1.1 Beer

Beer is produced by the fermentation of partially germinated cereal grains, referred to as malt, by yeasts. Beers have a final ethanol content of about 3–8%. A huge variety of beers exists, and these include ales, lagers, and stouts. Both lagers and ales can be either light or dark in appearance. Ale is produced using *Saccharomyces cerevisiae,* a top fermenter yeast, whereas lagers are produced using pure cultures of *Saccharomyces carlsbergensi*, a bottom fermenter yeast. Ales are produced using warm fermentation temperatures (12–18°C), and lager fermentation temperature is generally cold (8–12°C) [30]. Most beer produced is of the lager variety.

Several steps are needed to make beer. First, the barley is soaked in water for 5 to 7 days in order to make malt [47, 48]. During this step, the grains partially germinate and produce enzymes, mainly amylase and protease, that are essential to the brewing process. Amylases degrade starch to glucose, a sugar needed for the yeast fermentation, and proteases solubilize compounds in the grain and hops, which is important for the quality of beer. Following germination, heat is applied to stop further sprouting and to dry the grain. To develop color and aroma, the malt is roasted for 4–5 hours at a temperature of 80–105°C. Maillard reactions are responsible for the color and aroma formation during kilning. The dried and crushed malt is suspended in water and mixed with boiled malt adjuncts, such as ground rice and corn. Amylase is

generally added at this stage to ensure complete hydrolysis of starch. The mash is then incubated at 65–70°C for a short time to allow the amylase to degrade the starch to glucose. The temperature is subsequently raised to 75°C to inactivate the enzymes, and the medium is allowed to settle. Insoluble matter sinks to the bottom and serves as a filter as the liquid, called wort, is taken from the container. Hops or hop extracts are then added to the wort. Hops are an indispensable ingredient, as they act as a clarifier causing protein to precipitate; they give a specific aroma and bitter taste. Hops also possess antibiotic properties and together with ethanol and carbon dioxide contribute to the stability of beer [49–51]. In addition, the protein content of hops enhances the foam-building ability of beer. The mixture is boiled for 1.5–2.5 h to obtain the correct delicate hop flavor [52]. The wort/hops mixture is then boiled in order to concentrate the wort, kill many spoilage microorganisms, inactivate enzymes in the mash, and solubilize important compounds in the hops and mash. The wort is then separated, cooled, and fermented.

Fermentation is initiated by adding the appropriate yeast to the wort. Ale fermentation is completed when the pH is lowered to around 3.8, generally in 7–12 days; lager has pH values of 4.1–4.2 and the process is completed in 5–7 days [53]. During fermentation, the glucose in wort is converted to ethanol and carbon dioxide. The fermented wort is then aged at 0°C for a period of weeks or months. During this period, the yeast settles to the bottom of the vessel, bitter flavors are mellowed, and other compounds are formed that enhance flavor. The beer is then filtered or centrifuged to remove yeast cells before packing and pasteurization. The beer is finished by the addition of carbon dioxide to a final content of 0.45% to 0.52%. Finally, pasteurization of the beer at 60°C or higher, may be carried out to destroy spoilage microorganisms [54].

There are a number of factors that protect beer from the growth of contaminating microorganisms. These include low pH, redox potential and levels of readily available carbon sources, the isohumulones of hops that inhibit gram-positive bacteria, and the alcohol produced by the yeast [55]. The spoilage of beer is caused mainly by acetic acid bacteria, lactic acid bacteria, and wild yeasts. The industrial spoilage of beers is commonly referred to as beer infection [54]).

17.5.1.2 Wine

Wines can be produced from any fruit juice with sufficient levels of fermentable sugars. In most cases, wine is a beverage obtained by full or partial alcoholic fermentation of fresh, crushed grapes or grape juice (must), with an aging process. Wine-type grapes from cultivars of *Vitis vinifera* vines are the most used to produce wines [49]. Winemaking involves a series of steps. First, grape clusters are cleaned of rotten and dried berries and then separated from the stems. The grapes are subsequently crushed and pressed to release juice, the must. The remaining grape skins and seeds, called pomace, are then removed after a second press. In red winemaking, the must is fermented together with the skin in order to extract the red pigments from the skin, which are released only during fermentation. The extraction of the red pigments is sometimes facilitated by raising the temperature to 50°C prior to fermentation of the mash, or to 30°C after the main fermentation, followed by a short additional fermentation.

The fresh sweet must is treated with sulfur dioxide to suppress the growth of undesirable microorganisms and to prevent enzymatic browning and oxidation, thus stabilizing the wine color. The must is then inoculated with *Saccharomyces cerevisiae* var. *ellipsoides* or *pastorianus*, and allowed to ferment for 3–5 days at temperatures between 21°C and 32°C. During this period, ethanol production may reach 14% to 18%. Fermentation of red wine is longer than that of white wine, until the correct amount of color is extracted from the skin. The wine is racked in order to get rid of the sediments. The wine is drawn-off or decanted into barrels, vats, or tanks for aging, the length of which could vary between 3 and 9 months. During this stage, the wine clears and develops flavors. The wine is then removed from vats and poured into bottles in which aging continues [56]. Following the alcoholic fermentation, a malolactic fermentation can be initiated to reduce the acidity and mellow the wine. During the malolactic fermentation, malic acid is degraded to lactic acid by many lactic acid bacteria, mainly of the genera *Lactobacillus*, *Leuconostoc* (*L. oenos*), and *Pediococcus* (*P. cerevisiae)* [55]. Lactic acid is not as acidic as malic acid, hence the acidity of the wine is reduced. Wine can be subjected to some microbial and chemical defects. Microbial spoilage can be caused by the complex natural microbial flora of grapes and wine, which comprises molds [57], lactic acid bacteria [58], and acetic acid bacteria [59, 60].

The presence of acetic acid bacteria is less desirable than lactic acid bacteria and yeasts. Wines are subject to spoilage by acetic acid bacteria at many stages during the winemaking process. Spoilage by acetic acid bacteria gives wine a characteristic volatility; a vinegar-like sourness on the palate; and a range of acetic, nutty, sherry-like, solvent, or bruised apple aromas and often a reduction in fruity characters [61]. Such wines have low commercial value but can in some cases be improved by blending or treatment by a reverse-osmosis process to lower the acetic acid content [62]. Chemical defects lead mainly to the browning of wine as a result of oxidative reactions of phenolic compounds, which in red wines, may result in complete flocculation of the color pigments. [63])

17.5.2 Distilled Spirits

The aforementioned fermentations can only produce a maximum alcohol content of about 17%. Concentrations in excess of this inhibit the metabolism of the yeasts. To obtain higher alcohol concentrations, the fermented product must be subsequently distilled. Whiskeys, gin, vodka, rum, and liqueurs are examples of distilled spirits. Although the process for producing most products of these types is quite similar to that for beers, the content of alcohol in the final products is considerably higher.

17.5.3 Lactic Acid Products

17.5.3.1 Dairy Products

17.5.3.1.1 Yogurt

Yogurt is a coagulated milk product obtained by lactic acid fermentation through the action of *Streptococcus thermophilus* and *L. delbrueckii* subsp. *bulgaricus*. Several other microbial species might be added to yogurt such as *Lactobacillus. acidophilus*, *Bifidobacterium lactis*, *L. casei* [64], *L. reuteri*, and *L. rhamnosus* [65]. These microorganisms make yogurt rich in probiotics, which is one of its beneficial characteristics, and the presence of probiotics does not negatively affect yogurt flavor or consumer acceptance [66].

The main quality characteristics of yogurt include texture, taste, aroma, and flavor [67–69]. Typically, yogurt is a smooth, viscous gel with a characteristic taste of sharp acid and a green apple flavor [70]. Yogurt can be made available in different forms such as drinking yogurt, lactose-hydrolyzed yogurt, strained yogurt, frozen yogurt (with categories soft, hard, or mousse), dried yogurt, bio-yogurt (yogurt made with different live cultures other than the two most widely used), vegetable oil yogurt, soy yogurt, and chemically acidified yogurt [71].

Yogurt is prepared using either whole or skim milk, where the nonfat milk solids are increased to 12–15% by concentrating the milk or adding powdered skim milk or condensed milk. The concentrated milk is pasteurized to 82–93°C for 30–60 min and cooled to the starter incubation temperature of 40–45°C. Yogurt starter is then added at a level of around 2% by volume and incubated for 3–5 h, or until the titratable acidity of the final product reaches 0.85–0.90% or a pH of 4.4–4.6 [54]. The yogurt is then cooled to 5°C to inhibit further acid production. The symbiotic growth of the two organisms of the yogurt starter culture has been reviewed by many authors [72–74]. The symbiotic growth of the two organisms is better observed when they exist in a 1:1 ratio and results in lactic acid production and acetaldehyde at a rate greater than that produced by either when growing alone [72]. Streptococci produce lactic acid, formic acid. and carbon dioxide. Formic acid stimulates the growth of lactobacilli. The lactobacilli liberate some amino acids needed for the growth of the streptococci, and produce acetaldehyde and more lactic acid to bring the pH to 4.4–4.6. Most flavor compounds in yogurt are produced from lipolysis of milk fat and microbiological transformations of lactose and citrate. More than 100 volatiles, including carbonyl compounds, alcohols, acids, esters, hydrocarbons, aromatic compounds, sulfur-containing compounds, and heterocyclic compounds, are found in yogurt at low to trace concentrations. Besides lactic acid, most of the typical aroma and flavor of yogurt are mainly due to acetaldehyde and to a lesser degree to diacetyl, acetoin, acetone, and 2-butanone, which are produced in lower concentrations [75, 76]. Yogurt flavor continuously changes during manufacture and storage. Flavor changes may vary depending on the cultures, mix formulation, and incubation and storage conditions [77]. *Lactobacillus acidophilus* may be added with yogurt culture to reduce excessive aldehyde in addition to its health benefits. The type of yogurt starter used can change the physical characteristics of the final yogurt product. For example, ropy cultures, used to enhance the viscosity of "stirred" types of yogurt, comprise *Streptococcus salivarius* ssp. *thermophilus* and *Lactobacillus* strains [78]. "Non-ropy" starters are used for the manufacture of "set" types of yogurt. Other ways to increase the viscosity of yogurt and subsequently to decrease the syneresis of the whey include the addition of stabilizers, increasing nonfat milk solids, and extending the time and/or increasing the temperature of pasteurization.

The effect of the addition of fruits to the yogurt formula on lactic acid bacteria was found to depend on the type of fruits and lactic acid bacterial strains. Adding mixed berry, strawberry, mango, and passion fruit in yogurt formula and using starter culture consisting of *Lactobacillus acidophilus* LAFTIs L10 and *Bifidobacterium animalis* ssp. *lactis* LAFTIs B94, Kailasapathy et al. [79] found that the addition of either 5 or 10 g/100 g fruit preparations had no significant effect on the viability of the two probiotic strains except on *L. acidophilus* LAFTI L10 yogurt with 10 g/100 g passion fruit or mixed berry.

17.5.3.1.2 Cheese

Cheese is a concentrated milk product obtained after coagulation and whey separation of milk, cream or partially skimmed milk, buttermilk, or a mixture of these products. Cheese may be consumed fresh or after ripening. Cheese is commonly made from cow, ewe, goat, or buffalo milk. The majority of cheeses are made from pasteurized milk. The use of subpasteurization heat treatment of milk, or thermization, is also practiced in order to limit heat-induced changes in milk without compromising microbiological safety. There are over 400 varieties of cheeses representing fewer than 20 distinct types, and these are grouped or classified according to texture or moisture content, whether ripened or unripened, and if ripened, whether by bacteria or molds [54]. Table 17.8 shows the classification of cheeses according to moisture on fat-free basis, with subdivisions depending on the role of microorganisms in cheese ripening. The majority of cheeses, with the exception of whey cheeses, are made using variations of the same basic process, as illustrated in Figure 17.1. Slight variations of these processes and the use of different types of milks generate the huge range of cheeses available today.

In general, the process of manufacture starts with the preparation of milk. Milk receives generally a treatment equivalent to pasteurization at the start of the processing. The milk is then cooled to the fermentation temperature, which depends on the type of cheese to be manufactured: 29–31°C for cheddar, Stilton, Gouda, Camembert, and Leicester; higher temperatures are employed in the manufacture of high scalded cheeses such as Emmental, Gruyere, and Italian cheeses. Milk is inoculated with an appropriate lactic starter. The starter culture produces lactic acid, which, with added rennin, gives rise to curd formation. In addition, lactic acid is also responsible for the fresh acidic flavor of unripened cheeses and plays a major role in the suppression of pathogenic and some spoilage microorganisms, and in the production of volatile flavor

TABLE 17.8
Cheese Varieties and Their Classification

MFFB*	
> 67%	Soft Cheeses
	Unripened
	Cottage, Quark, Cream, Mozzarella
	Salt-cured or pickled

compounds, and the synthesis of lipolytic and proteolytic enzymes involved in the ripening process of cheese. The starter organisms most used for cheese production are mesophilic starters, strains of *Lactococcus lactis* and its subspecies. Thermophilic starters such as *Lactobacillus helveticus*, *Lactobacillus casei*, *Lactobacillus lactis*, *Lactobacillus delbrueckii* subsp. *bulgaricus*, and *Streptococcus thermophilus* are used in the production of cheeses where a higher incubation temperature is employed. Propionic bacteria, molds, such as *Penicillium camemberti*, *P. candidum*, and *P. roqueforti*; red- or yellow-smearing cultures, such as *Bacterium linens* are also added, depending on the type of cheese to be manufactured. The time of renneting and the amount added differ with cheese type. After coagulation of the milk, the curd is cut into small cubes for whey expulsion. The curd is further shrunk by heating it and then pressed to expel more whey, followed by salting. Finally, the cheese is ripened under conditions appropriate to the cheese in question.

Cheese ripening involves a complex series of chemical and biochemical reactions. Proteolysis and lipolysis are two primary processes in cheese ripening with a variety of chemical, physical, and microbiological changes occurring under controlled environmental conditions [80, 81]. These reactions are of importance to the flavor and texture development in cheeses [82–84]. Flavor compounds include peptides and amino acids, free fatty acids, methyl ketones, alkanes,

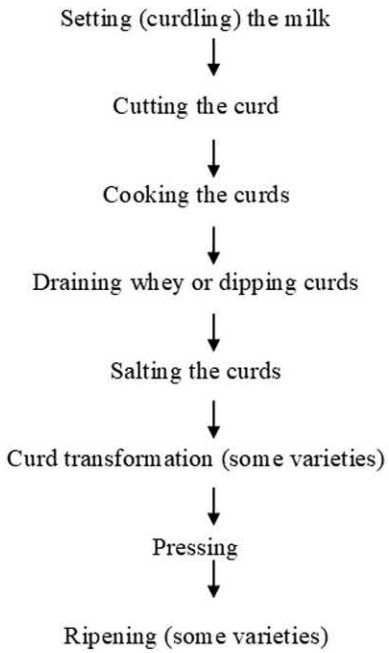

FIGURE 17.1 Basic steps in cheese making.

lactones, and aliphatic and aromatic esters. Figures 17.2 and 17.3 briefly summarize, respectively, the proteolytic and lipolytic products obtained during ripening.

Although most ripened cheeses are the products of metabolic activities of the lactic acid bacteria, several known cheeses owe their particular character to other related organisms. In the case of Swiss cheese, *Propionibacterium shermanii* is added to the lactic bacteria organisms *L. bulgaricus* and *S. thermophilus*. Propionibacteria contribute to the typical flavor and texture of Swiss-type cheeses [85]. The lipolytic and proteolytic activities of molds play an important role in the maturation of some cheeses. In blue cheese, such as Roquefort and Stilton, *Penicillium roqueforti* grows throughout the cheese and imparts the blue-veined appearance characteristic of this type of cheese. *Penicillium camemberti* is associated with surface-ripened soft cheeses such as Camembert and Brie.

17.5.3.2 Fermented Vegetables

A large number of vegetables are preserved by lactic acid fermentation around the world. The most important commercially fermented vegetables in the West are cabbage (sauerkraut), cucumbers, and olives. Others include carrots, cauliflower, celery, okra, onions, and peppers. Typically, these fermentations do not involve the use of starter cultures and rely on their natural flora. Brine solutions are prepared in the fermentation of sauerkraut, pickles, and olives. The concentration of salt in the brine ranges from 2.25% for sauerkraut to 10% for olives. The fermentation yields lactic acid as the major product. The salt extracts liquid from the vegetable, which serves as a substrate for growth of lactic acid bacteria. Growth of undesirable spoilage microorganisms is restricted by the salt. Aerobic conditions should be maintained during fermentation to allow naturally occurring microorganisms

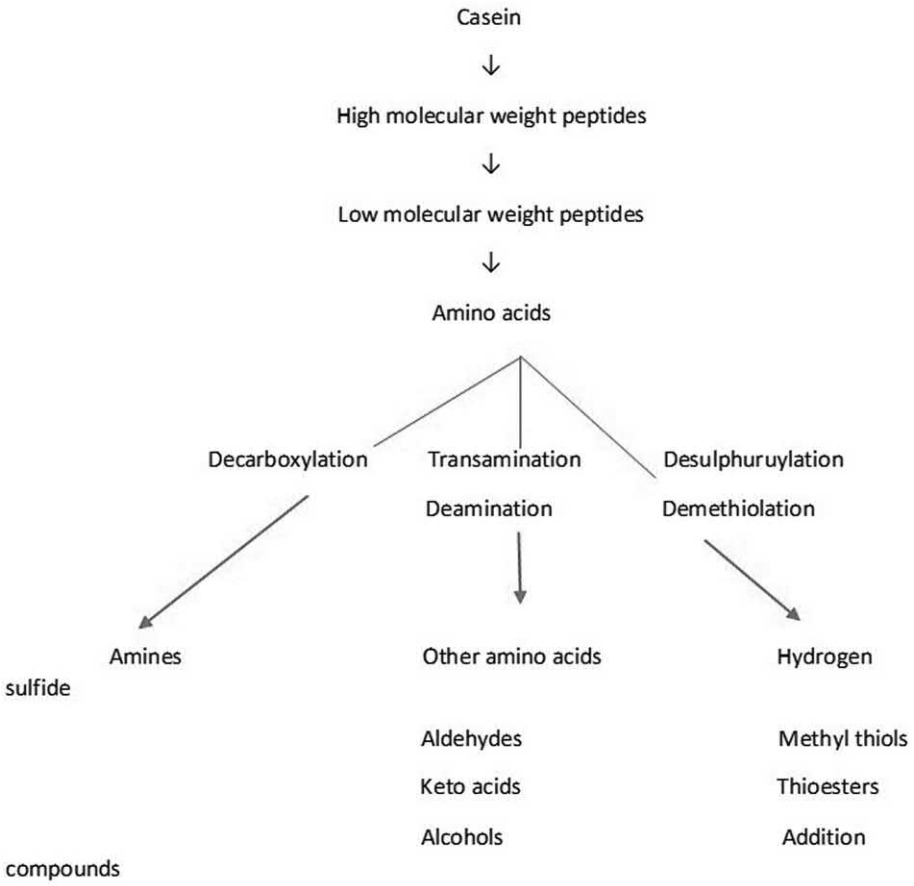

FIGURE 17. 2 Protein degradation during ripening of cheese. (Adapted from various sources.)

to grow and produce enough lactic acid, and to prevent growth of spoilage microorganisms. Olives receive a special treatment before brining, and green olives are treated with a 1.25% to 2% lye solution (sodium hydroxide), usually at 21°C to 25°C for 4 to 7 hours. This treatment is necessary to remove some of the oleuropein, a bitter compound in the olives. In some countries, the fermentation of cucumbers is controlled by the addition of acetic acid to prevent growth of spoilage microorganisms, buffered with sodium acetate or sodium hydroxide, and inoculated with *L. plantarum* alone or in association with *P. cerevisiae*. The controlled fermentation

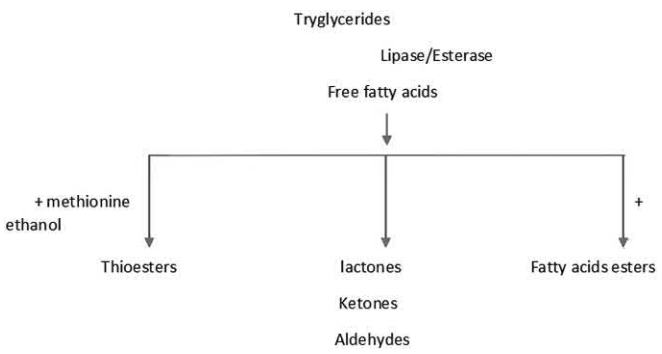

FIGURE 17.3 Lipid degradation during ripening of cheese. (Adapted from various sources.)

reduces economic losses and leads to a uniform product over a shorter period. Many researches have shown a sequential involvement for different species of lactic acid bacteria [1, 86–88]. For sauerkraut production *Leuconostoc mesenteroides* grows first, producing lactic acid, acetic acid, and CO_2; followed by *Lactobacillus brevis*; and finally *Lactobacillus plantarum* grows, producing more acid and lowering the pH to below 4.0, allowing the cabbage to be preserved for long periods of time under anaerobic conditions. The lactic acid bacteria chiefly responsible for production of high-salt pickles are initially *Pediococcus cerevisiae* followed by the more acid-tolerant *Lactobacillus plantarum* and *Lactobacillus brevis. Leuconostoc mesenteroides* makes little contribution in high-salt pickles but is active in low-salt pickles [89]. The microbiology of olive lactic acid fermentation is complex with a number of microbial strains being involved. Vaughn et al. [90] have divided the normal olive fermentation into three stages. The initial stage is the most important from the standpoint of potential spoilage if the brines are not acidified. Acidification eliminates the original contaminating population of dangerous gram-negative and gram-positive spoilage bacteria and, at the same time provides an optimum pH for activity of the lactic acid bacteria [91]. Currently, in olive fermentations starter cultures are not used, although a proportion of brine from a previous fermentation may be used to supplement the new brine. The natural flora of green olives,

consisting of a variety of bacteria, yeasts, and molds carries out the fermentation with the lactic acid bacteria becoming prominent during the intermediate stage. *Leuconostoc mesenteroides* and *Pediococcus cerevisiae* are the first lactics to predominate, followed by lactobacilli, mainly *Lactobacillus plantarum* and *Lactobacillus brevis* [92].

To enhance control of the fermentation process and to improve the quality of the final product, the use of starter cultures has been investigated. A possible role for yeasts as starters has recently been proposed for production of table olives [93, 94]. A new protocol for the production of black table olives belonging to two Italian (Cellina di Nardò and Leccino) and two Greek (Kalamàta and Conservolea) cultivars has been developed: for each table olive cultivar, starter-driven fermentations were performed inoculating, firstly, one selected autochthonous yeast starter and, subsequently, one selected autochthonous LAB starter [95].

A range of potential health benefits has been associated with the consumption of lactic acid bacteria.Fermented vegetables can be used as a potential source of probiotics, as they harbor several lactic acid bacteria such as *Lactobacillus plantarum*, *L. pentosus*, *L. brevis*, *L. acidophilus*, *L. fermentum*, *Leuconostoc fallax*, and *L. mesenteroides* [96, 97].

The consumer demand for nondairy beverages with high functional value is increasing. It is driven in part by the ongoing trend of vegetarianism and the increasing prevalence of lactose intolerance. The use of vegetable matrices as potential nondairy vehicles for delivering probiotic strains has been assessed [98, 99]. Tomato, carrot, cabbage, artichokes, and red beet juices were proven to be particularly suitable for probiotic fermentation, allowing a rapid growth of the strains and viable cell populations above ca. 8 log cfu/mL [99]. Nutrients essential for microbial growth and survival are also added to vegetable juices. *L. plantarum* and *L. acidophilus* strains showed optimal growth and acidification in beetroot juice when yeast extract was added. The careful selection of the vegetable matrix, probiotic strains and the addition of other ingredients are all biotechnology options to optimize the manufacture of probiotic, non-dairy beverages [100].

17.5.3.3 Fermented Animal Products

The primary reason for developing methods to ferment meats and fish was to extend the shelf life of these highly prized, perishable foods. Gram-positive micrococci have an important role in these fermentations [101]. Several products became popular including fermented sausages, fish sauces, and fish pastes. Many of the traditional fermentation methods are still used, although the primary reason for their use is no longer preservation but because the products are popular for their enhanced flavors.

17.5.3.3.1 Fermented Sausages

A variety of procedures for producing stable, fermented meat sausages have developed around the world. In general, preservation of the meat is achieved by adding salts and the generation of lactic acid by bacteria, which leads to a rapid fall in the pH. Micrococci, staphylococci, and yeasts are responsible for the development of color, taste, and flavor during the fermentation. In addition to fermentation, sausage processing may also include curing, smoking, drying, and aging to both improve the flavor and shelf life. In addition to the major inhibitory factors of low water activity achieved by the addition of salt and in some cases drying and the accumulation of lactic acid, a "hurdle effect" is created by a combination of other inhibitors (Table 17.9), contributing to the preservation of sausages [102].

TABLE 17.9
Factors Contributing to the Stability of Fermented Sausages

Low pH
High acidity
Accumulation of lactic acid
Various antimicrobial compounds
Hydrogen peroxide from LAB
Phenolic compounds from smoking
Low water activity
Drying
Salting
Spices
Potentially stimulate LAB, inhibit normal spoilage microflora
Low availability of oxygen
The oxygen is reduced by growth of LAB

Sausages can be split into groups based upon the extent of drying (Table 17.10). A weight loss of up to 50% can occur in shelf-stable salamis during drying [103]. Bacteria responsible for the fermentation need to be tolerant of both low water activity and salt. These environmental conditions inhibit proteolytic spoilage by gram-negative bacteria and encourage the generation of LAB, resulting in an increase in the proportions of LAB, which may even become dominant [102, 104]. Growth of LAB results in a decrease in pH and the amount of available oxygen. These inhibitory factors also contribute to the hurdle effect and in combination with other factors control the growth of the gram-negative and gram-positive pathogens commonly associated with raw meats.

Pediococcus cerevisiae, *Staphylococcus carnosus*, and *Lactobacillus plantarum* are among the most common bacteria involved in meat fermentations [101]. Natural fermentations

TABLE 17.10
Examples of Different Sausage Types

Dry Products (Moisture Content up to 35%)	SemiDry Products (Moisture Content about 50%)
Salamis	Cervelats
Pepperoni	Mettwursts
	Lebanon bologna (in US)
	Thuringer

are still used, but fermentations are increasingly initiated with starter cultures because of their greater dependability. LAB and nitrate-reducing bacteria are important members of starter cultures. Commonly used LAB include *Pediococcus cerevisiae* and *Lactobacillus plantarum*. High-salt tolerant yeasts, such as *Debaryomyces hansenii* and molds of the *Penicillium* spp. may also be included [30, 105]. Species such as *Micrococcus varians* and *Staphylococcus carnosus* are important when nitrate salts are added instead of nitrites, as they convert nitrates to nitrites, which react faster and less is required for compound stabilization [30, 49, 106].

Fermented sausages are prepared by mixing ground meat with various combinations of spices, flavorings, salt, sugar, additives, and frequently starter cultures. Common additives include acidulant, ascorbic acid, and colorings [30]. Pork, beef, mutton, or turkey meat can be used, but to achieve good sensory properties and safety, the meat must be fresh and of high quality. The meat is generally used raw, with no heat processing, as this can damage the texture of the sausage product [30]. Frequently, fermented sausages are eaten without any cooking [1]. The physical properties of the meat, especially the fat content, can affect the efficiency of the drying. To encourage efficient moisture loss, the meat particles must not be too large and the cut edges should not be effectively sealed by being covered in fat. The spices and flavoring agents modify the flavor and odor of the sausages [82]. Spices can also inhibit spoilage agents whilst stimulating lactic fermentation.

A range of times and temperatures (commonly 15–42°C) are used for the fermentation. Generally, the fermentation lasts for several days and the ripening for several weeks. During the fermentation and ripening periods, the pH falls, usually into the range pH 4–5. Investigators have demonstrated that the final pH is lower when higher fermentation temperatures are used [107].

Following fermentation, the flavor and odor of the product may be further developed by smoking and/or drying. Smoking sausages provides distinctive flavors, e.g., those of salami and hot dogs, which are developed by the accumulation of phenolic compounds from wood smoke [30]. Different wood types can be used to impart different flavors. The phenolic compounds also have antimicrobial activity and contribute to the safety and stability of the sausages.

Following fermentation, the meat is forced into casings to obtain the typical sausage shape and to provide some form of packaging. A range of properties is required for the casing materials and these are shown in Table 17.11. The casings are firmly packed to force out the air, which can cause discoloration of the meat and reduce the shelf life of the sausage.

In addition to microbial growth and the activity of endogenous meat enzymes, lipid autoxidation reactions and the breakdown of proteins to peptides and amino acids by microbial and chemical reactions are also important in generating many flavor compounds [82]. At the end of the ripening period, the flavor of unsmoked sausages can be improved by surface growth of molds, which alter the levels of amino and free fatty acids, and volatile compounds [108]. These fungi should not be toxigenic and should have proteolytic, lipolytic, and antioxidative activity [108].

TABLE 17.11
Characteristics of Appropriate Sausage Casing Material

Permeable to moisture and smoke
Acceptable to the consumer
Shrink as the meat is dried
Retain the sausage mixture
Form the required sausage shape
Edible
No detrimental effects on the sensory attributes of the products

Source: Adams and Moss [30].

The primary safety concern during sausage-making is to prevent growth of *Clostridium botulinum*. Nitrites can be used to assist the concern of *Clostridium botulinum* growth. Outbreaks of disease caused by *Staphylococcus aureus, Salmonella,* and verotoxigenic *Escherichia coli* have also been associated with fermented sausages [30]. Although counts of *Salmonella* and other Enterobacteriaceae species decline during fermentation and drying, they may not be eliminated [30, 109]; indeed, they have been shown to survive during the production of pepperoni [110].

17.5.3.3.2 Fermented Fish

Fermentation of fish is most common in Southeast Asia where fish is a major component of the human diet. Traditional and naturally produced fermented fish products such as suan yu, chouguiyu, narezushi, and plaa-som are common fermented products in countries such as China, Japan, and Thailand [111–114]. The carbohydrate content of fish is low; usually less than 1%, therefore, an additional source of carbohydrate is required for lactic fermentation. Ingredients such as rice and garlic may be added as carbohydrate sources; the carbohydrate reserve in garlic is inulin [115, 116]. The higher the level of supplemented carbohydrate, the faster the fermentation. The product is often ready after only a few weeks, making the process much more efficient. The supplementation of carbohydrates enables the fish to ferment and an acidic, stable product to be made [30].

The most common products from fish are produced by microbial fermentation and by the degrading activity of autolytic fish enzymes. These products are known as fish sauces and fish pastes. The annual production of these commodities is around 250,000 tonnes [101]. Good-quality fish sauces and pastes provide distinct aromas and flavors. They are used like condiments and are important flavoring ingredients of the diet; they are used to flavor soups, curries, salads, rice, etc.

Sauces and pastes are prepared using whole, eviscerated, or mashed fish. Low value, abundant small fish are most commonly used, often anchovies or related species. Shrimp may also be used. The fish variety, fermentation conditions, cure duration, and technique all affect the texture, amino acid content, and volatile flavor profile of the finished product. To get a product with a pleasing, fragrant aroma and taste, very fresh fish must be used.

Fish batches are washed and salted using approximately three parts fish to one part salt [54]. The salting takes the water activity below 0.75, which prevents normal fish spoilage [30]. Higher concentrations of salt slow the production rate, but extend the shelf life of the final product [105, 117]. The fish are sealed into vessels for up to 18 months or more [30]. To shorten the production time, the temperature can be increased; this can be simply achieved by placing the vessels in direct sunshine.

The proteins of the fish are broken down by autolytic enzymes producing free amino acids and volatile flavor compounds. The fish become liquefied; the liquid is harvested and any sediment is removed by filtration. The filtrate is ripened in the sun for a couple of months removing the strong fish odors. Good fish sauce is brown, clear, without sediment, has a pleasant aroma (not too fishy), and is not too salty. Fish sauce is high in protein (up to 10%), and contains all the essential amino acids. Fish sauces are also a rich source of B vitamins, especially B_{12}, pantothenic acid, riboflavin, and niacin. Other beneficial nutrients include calcium, phosphorous, iodine, and iron. Low numbers of streptococci, micrococci, staphylococci, and *Bacillus* spp. have been isolated from fish sauces and are associated with the development of flavor and aroma [54, 118]. LAB play an important role in the organoleptic properties and shelf life of these products, especially those with a lower salt content.

Fermented fish paste is prepared from salted fish with or without flavoring ingredients. It has a smoother consistency and lower moisture content than sauces. Fat is often added to the final product so that it is spreadable and can be used, for example, as a sandwich spread. The combined effects of salt, acidity, spices, and perhaps fatty acids from the fish oil of fish sauces and pastes usually guarantees microbial safety. However, these products have been implicated in outbreaks of botulism [119, 120]. A diverse collection of LAB species were found in fermented fish products including *Lactobacillus plantarum*, *Lactobacillus brevis*, *Lactobacillus reuteri*, *Pediococcus pentosaceus*, *Leuconostoc* sp., *Lactobacillus paralimentarius*, *Lactococcus garvieae*, *Lactococcus lactis*, *Lactococcus raffinolactis*, *Vagococcus* sp., *Enterococcus hermanniensis*, *Macrococcus caseolyticus*, and *Streptococcus parauberis* [111, 112, 121].

17.6 COMBINED FERMENTATIONS

The release of carbon dioxide by microorganisms has two major roles in food fermentations: (i) it can act as a leavening agent, and (ii) it can be used for carbonation of beverages. One of the most common uses of carbon dioxide is to leaven dough during bread making.

17.6.1 Bread

The use of yeasts to produce bread dates back thousands of years [122]. Breads have relatively short shelf lives, therefore the primary reason for their production was not preservation, but to improve the digestibility and eating appeal of grains. To make leavened bread, flour produced from grains, such as wheat, that contain gluten proteins is used. When the bread is kneaded, the gluten forms a matrix that makes the dough elastic and extensible [122, 124]. These properties enable the dough to stretch and retain sufficient amounts of gas to produce loaves with good volume and a fine, soft open structure [125, 126]. The gas is a combination of air incorporated during mixing and kneading and CO_2 produced from the fermentation of sugars by yeasts. The yeasts used are normally strains of *Saccharomyces cerevisiae*, commonly known as baker's yeast as they are well adapted for leavening bakery products [126]. The metabolic activity of the yeasts helps to chemically ripen the gluten enabling the dough to expand evenly and retain the gases during baking. The yeasts contribute to the flavor and provide an appealing aroma. When the loaves are baked the proteins are denatured fixing the structure and the low levels of ethanol produced by the yeasts evaporate.

To extend the shelf life of bread calcium propionate, up to a level of about 3000 ppm or ascorbic acid are added [127]. Due to the low water activity of bread the main spoilage agents are molds, particularly *Rhizopus stolonifer* and *Nerospora sitophila* [128, 129], and yeasts, which can cause the defect known as "chalky bread" [130]. In general, baked goods have a good safety record. *Bacillus subtilis* spores may naturally contaminate flour and survive baking, and subsequently germinate and grow, degrading the loaf's internal structure producing a sticky slime; this is described as "ropy bread" [131–133]. The sensory of ropy bread is not always sufficiently extreme to prevent people eating the bread and a number of *B. subtilis* outbreaks have been associated with bread [44].

Extension of the shelf life of products is one of the biggest challenges facing the baking industry today. The shelf life of bread and other baking products is short, mainly as a result of staling, which involves a number of physicochemical alterations that occur after baking and during product storage. Staling is characterized by crumb firming mainly due to retrogradation of the starch polymers and interactions between starch and proteins, crust softening due to transfer of moisture from the crumb to the crust, and finally flavor changes. These changes are responsible for the disposal of large quantities of bread (8–10%), resulting in high economic losses [134–136]. The main techniques for delaying staling and extending the shelf life are the use of hydrocolloids, emulsifiers, exogenous enzymes, etc. [134–136]. Recently, it has been proposed that a return to more traditional processes like sourdough bread making, employing pure cultures of LAB, could significantly improve bread quality in terms of delaying staling; improving taste, texture, and aroma; and generally increasing shelf life [137–139].

17.6.2 Sourdough

The use of sourdough has been established as a very important process for modern baking technology, due to the superior quality and prolonged shelf life of the sourdough baking products [140–142]. The advantages of sourdough over yeasted breads can be highlighted by its enhancement of the following features: (i) technological properties including

improved dough machinability; (ii) nutritional properties, like phytate hydrolysis; (iii) organoleptic properties such as improved bread volume, crumb texture, and unique flavor; and (iv) extended shelf life [143].

The fermentation combines the metabolic activity of LAB for souring and yeasts for leavening. Methods for their fermentation date back thousands of years [144]. The sourness of the product depends on many factors including fermentation temperature and time, type of grain, and the strains of yeast and LAB [145]. The complexity of the bread flavor is based on the lactic and acetic acids produced by LAB and flavor compounds formed by the activity of endogenous cereal enzymes, microbial metabolism, and the baking process. [146–148]. The metabolism of the LAB and yeasts also provide a range of desirable aroma products.

Traditionally, a natural starter culture that was continuously propagated from one fermentation to the next was used in sourdough fermentations [149]. The dominant yeast strain in sourdough starter cultures was classified as *Saccharomyces exiguous* [150] and later reclassified as *Candida milleri*. In San Francisco sourdough cultures the ratio of yeasts to bacteria is about 1:100. The most common LAB are members of the genus *Lactobacillus* including strains of *L. sanfranciscensis* (also referred to as *L. sanfrancisco*) [151], *L. reuteri*, *L. brevis*, and *L. pontis*. To obtain a stable symbiotic relationship the fermentation conditions must encourage metabolic activity by both the yeasts and LAB. The acid produced by the LAB lowers the pH of sourdoughs into the range pH 3.8–4.5 [54]. *Candida milleri* can tolerate this acid environment [152]. Amylases in the dough provide maltose from starch, which is utilized by the lactobacilli [153]. *Candida milleri* does not metabolize maltose but catabolizes the other sugars present, including glucose released by the lactobacilli [154]. Dead yeast cells can provide a source of fatty acids and amino acids required by the lactobacilli [155, 156]. LAB produce various compounds including organic acids that inhibit a range of mold genera, such as *Fusarium, Penicillium*, and *Aspergillus*, that are associated with bread spoilage [157]. The lactobacilli also secrete cycloheximide, which kills many organisms in the dough, but not *Candida milleri*. These act to preserve the bread.

Baked goods can be protected from fungal and yeast spoilage by destroying contaminating spores by using LAB with high and wide antimicrobial activities as starters in sourdough fermentations [158]. The microorganisms in sourdoughs that are responsible for the inhibition of the growth of certain molds are believed to be species of the *Lactobacillus* genus such as *L. plantarum, L. sanfranciscus*, *L. rhamnosus*, and *L. paracasei* [159, 160]. The antimicrobial effect of LAB is mainly related to the production of lactic and acetic acids, as well as propionic, sorbic and benzoic acids, hydrogen peroxide, diacetyl, ethanol, and phenolic and proteinaceous compounds. In addition, some strains are able to synthesize bacteriocins [161].

17.6.3 Vinegar

Vinegar is one of the oldest known culinary products [162]. It is thought that it was discovered by accident from spoilt wine; in fact it is named after the French term *vin aigre* meaning "sour wine." Vinegar is classified as a condiment that contains a minimum of 4% w/v (40g/l) acetic acid and has a pH value between pH 2.0 and pH 3.5 [30, 163]. The strength of vinegars may also be quoted in grains, with ten grains being equivalent to a concentration of 1% acetic acid [55]. Higher strength vinegars may be used for pickling; spirit vinegar is made from an alcoholic solution that has been distilled [44]. Although vinegar has been produced for thousands of years, it remains very popular. It is estimated that the annual worldwide production of vinegars is around 2000 million liters [101].

Vinegar is one of the great successes of the preservation industry, although acetic acid has numerous applications in the food industry. The shelf life of a wide range of foods is extended by storing the product submerged in vinegar; this includes pickled vegetables, such as gherkins, olives, and onions. Vinegar is also incorporated into a range of sauces and relishes such as tomato ketchup, Worcester sauce, and a variety of salad dressings and mayonnaise to improve their shelf stability. New applications of vinegars continue to be sought. One such study investigated the feasibility of incorporating acetic acid into a chitosan matrix to prepare a film that could be applied onto processed meat samples so that the acetic acid was slowly released and enhanced bacterial inhibition during vacuum packaging. Inhibition of some bacterial species was observed [164]. In addition, as new foodborne pathogens emerge, research studies focus on the tolerance of these organisms to acetic acid challenges [165, 166].

Vinegars are produced from a variety of fermentable substrates [30, 167]; fruits, honey, coconut, malt, and cereal grains are among the most common [55], but they may also be produced from alcoholic drinks such as wine or cider. Frequently the substrate used reflects the common local crops, e.g., grapes are used in France, rice in Japan, and malt vinegar is common in the UK. Vinegars are also important flavoring agents and their potential as "functional foods" is being investigated [44, 162, 167].

Vinegars are produced from a two-stage fermentation, initially an anaerobic, alcoholic fermentation of sugars by yeasts, followed by oxidation of the ethanol to acetic acid by bacteria; this second reaction is known as acetification. Acetification is also a common cause of spoilage of alcoholic beverages. Acetification can be described by the equation:

$$C_2H_5OH + O_2 = CH_3COOH + H_2O$$

Traditionally, vinegar was produced without the use of selected starter cultures (SSC), both in small as well as in large scale [168]. The process in this case relies on the indigenous yeasts strains of the sugar-rich substrates. Now, specific vinegar-making yeasts strains, usually *Saccharomyces cerevisiae* var. *ellipsoideus* [101], are often used. The alcoholic fermentation used in the production of malt vinegar essentially follows the same procedures as those used in beer making. In addition to ethanol, the fermentation also yields carbon dioxide, some higher acids, and small amounts of glycerol and acetic acid.

In contrast to alcoholic fermentation, acetification is a highly aerobic process, where bacteria oxidize ethanol to acetic acid. Small quantities of acetaldehyde, ethyl acetate, and acetoin are also produced during this reaction [101]. Commercial acetic acid bacteria are members of the genera *Acetobacter* and *Gluconobacter*. These bacteria are strict aerobes that are often found naturally in association with yeasts on plants. They are gram-negative rods and high tolerance to acid. Some acetic acid bacteria such as *A. aceti* and *A. pasteurianum* can oxidize acetic acid to carbon dioxide and water, a process known as overoxidation [101], and obviously an undesirable reaction in the production of vinegars. Overoxidation is not a problem when *Gluconobacter* species are used [162]. Also, acetic acid concentrations above 6% repress this reaction, therefore maintaining a minimum level of acetic acid during acetification reduces the risk of the acetic acid being further metabolized [30, 163, 169].

The methodology used to convert the alcoholic vinegar stock to vinegar is based on effectively combining the alcoholic stock with air and acetic acid bacteria. The rate of vinegar production is dependent on the efficiency of the aeration. Modern techniques have increased the availability of oxygen to the bacteria and enhanced the rate of vinegar production. Oxygen is not only desirable to stimulate the metabolism of the bacteria, but it is also essential for their survival. The bacteria utilize oxygen during energy production. Consequently, to avoid product failure, the equipment design must ensure a continuous, uninterrupted supply of oxygen [30]. Industrially, three main methodologies are used: (i) traditional surface methods, (ii) the trickle generator process, and (iii) the submerged method [30, 162, 169].

17.6.3.1 Traditional Surface Methods

The static surface method is the oldest production method and relies on a layer of acetic acid bacteria forming a bacterial "mat" on the surface of the vinegar stock. When the production time is long and aeration is inadequate, the product can be unpredictable, making this method less suitable for mass production. However, small quantities of traditional vinegars are still produced using these techniques for their enhanced aroma and flavor. The technique is simple and requires only basic equipment. The Orleans method, which was developed in France at the end of the 14th century [101], attempted to improve the efficiency of the surface technique by making it run semi-continuously. In the Orleans process a large wooden barrel or vat is partially filled with vinegar stock. Air holes are made just above the surface of the stock. This provides a draft of air across the bacterial film. Inlets to the barrels are covered to prevent insects and debris entering using only material that does not inhibit airflow. The barrel is left undisturbed until the required acidity is achieved. One acidification cycle usually takes about 14 days [30]. The same barrel may be used continuously for extended periods by removing volumes of the vinegar slowly from the base of the barrel and then replacing this volume with new stock, requiring acetification, into the bottom of the barrel via a tube that passes through the bacteria. Using this technique the bacterial mat remains intact and functioning, thus improves the efficiency of subsequent batches. A schematic diagram of the Orleans process for acetification is shown in Figure 17.4.

17.6.3.2 The Trickling Methods

The trickling methods are a further development of the surface technique. These processes have enhanced rates of vinegar production. This is achieved by larger areas of bacterial film in conjunction with improved aeration. The surface of the bacterial film is greatly increased by including packaging material in the process vat onto which the acetic acid bacteria form a biofilm. The material is usually inert lignocellulosic in nature, e.g., birch, vine, rattan, beechwood shavings, or corncobs, and is loosely packed. The stock is sprayed into the vat, then slowly trickles down through the packing material across the bacterial film, and at the same time air is forced up through the system from below [30]. The distance that the stock travels through the packaging and the time of contact between the bacteria and the vinegar stock can be further increased by using larger sized vats. The process is operated semicontinuously; vinegar collects at the bottom and is recirculated back through the vat until these reach the required level of acidity. This usually takes about 3–5 days, much quicker than the surface method [30, 169]. Between batches, the bacterial film remains more or less intact within the packaging material. As the oxidation of ethanol is exothermic, a cooling system is often incorporated into the vat. A schematic diagram of the quick method for acetification is shown in Figure 17.5.

17.6.3.3 Submerged Fermentation

In the 1950s, submerged culture technology began and subsequently developed to produce the most rapid rates of vinegar production. Using these systems, the time to convert alcoholic vinegar stock to vinegar is reduced to around 24–48 h [30, 162, 163]. The commercially successful processes are frequently based upon the Frings acetator [30, 162, 163]

Tiny bubbles of air are continuously sparged through the culture volume to improve the efficiency of the aeration to enable the bacteria to grow and metabolize effectively suspended throughout the culture volume. Specific strains of acetic acid bacteria have been selected for their suitability

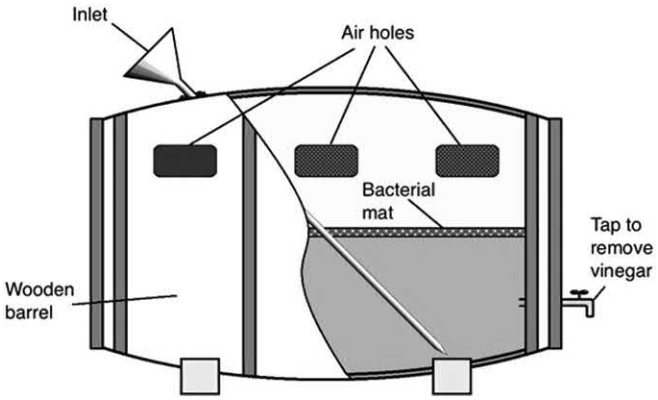

FIGURE 17.4 Schematic diagram of the Orleans process for acetification.

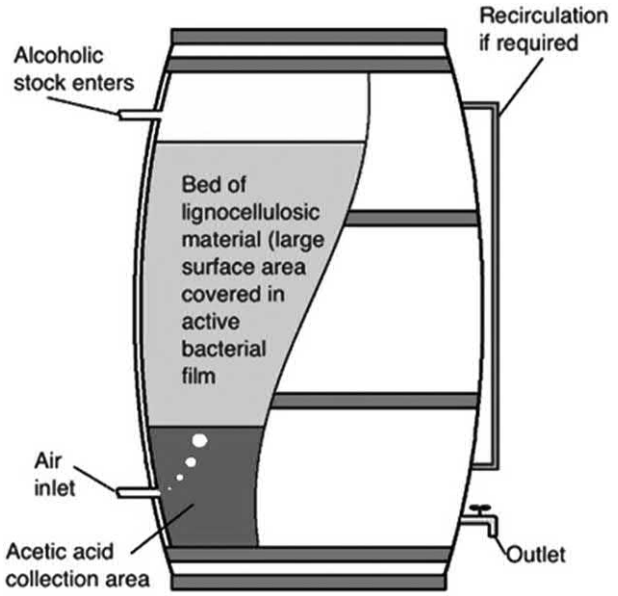

FIGURE 17.5 Schematic diagram of the quick method for acetification.

to growth in suspension. The temperature is controlled and the system is stirred continuously to maintain homogeneity throughout the culture volume. Submerged cultures are generally run automated to ensure accurate control and monitoring of the environmental parameters to prevent product loss. The systems are run semi-continuously by withdrawing only proportions of product and replacing them with equivalent volumes of fresh stock. A schematic diagram of the submerged process for acetification in vinegar production is shown in Figure 17.6. The produced flavors of vinegars using these more rapid techniques are improved by allowing a period of maturation. Before bottling, vinegars are pasteurized at 75–80°C for 30–40 seconds [101]. Defects of vinegars include cloudiness resulting from the precipitation of certain metal ions and sliminess following infection with lactic acid bacteria. Entire fermentation batches can fail if the culture becomes infected with bacteriophages.

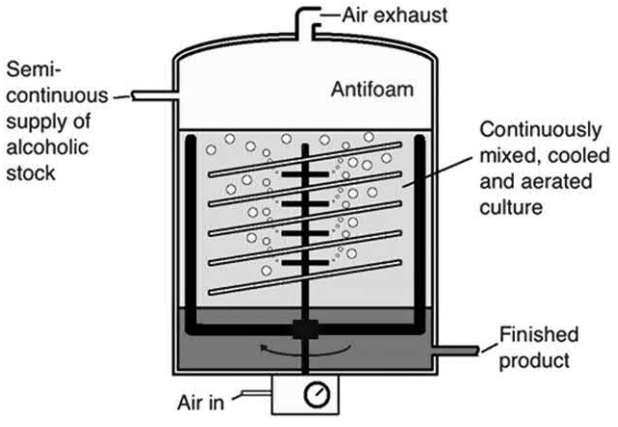

FIGURE 17.6 Schematic diagram of the submerged process for acetification in vinegar production.

17.6.4 Kefir

Kefir is produced by an acid/alcohol fermentation of pasteurized milk with a mixture of lactic acid bacteria, yeasts, and other bacteria. The final product is acidic, slightly alcoholic, liquid to semiliquid and effervescent, and is consumed as a beverage [170, 171]. Kefir grains are used to inoculate the milk. Kefir grains are comprised of proteins, polysaccharides, and a mixture of microorganisms mainly lactose-fermenting yeasts and lactic acid bacteria [172, 173]. Kefir is produced by the diverse spectrum of microbial species present. Lactobacilli are present as the largest portion (65–80%) of the microbial population [174], with *Lactococci* and yeasts making up the remaining portion of the microbes present in the Kefir grains. The yeasts consist mainly of *Candida kefir* and *Saccharomyces kefir,* while the lactic acid bacteria are comprised mainly of *Lactobacillus kefir, Leuconostoc* species, and *Lactococcus lactis.* The yeasts are responsible for the production of ethanol and carbon dioxide from lactose, the *Lactococci* produce lactate from lactose, and the lactobacilli and *Leuconostoc* species are responsible for the production of lactate, acetate/ethanol, and carbon dioxide [175, 176]. Kefir fermentation requires a moderate room temperature (17–23°C). The final composition of kefir includes 0.8% lactic acid, 1–3% alcohol, diacetyl, and acetaldehyde.

17.6.5 Oriental Fermented Products

The production of soy sauce, miso, and saki involves koji fermentation. Koji comprise soya beans or grains on which molds grow to produce enzymes such as protease, lipases, and amylases. The fungal enzymes produced digest proteins, carbohydrates, and lipids into nutrients that are used by microorganisms in subsequent fermentations. Koji is produced in many varieties depending on the products to be manufactured. Koji differ in terms of the molds, the substrate, method of preparation, and the stage of harvest.

17.6.5.1 Soy Sauce

Soy sauce is a dark brown liquid made by the fermentation of soya beans and wheat in a salt brine. The manufacture of soy sauce starts with the treatment of raw material. Soya beans, or defatted soya bean flakes, are moistened and cooked. The cooked beans are then mixed with roasted, cracked wheat in varying ratios for each type of soy sauce. The mixture is inoculated with pure culture of *Aspergillus oryzae* (*A. soyae*). After 3 days of fermentation, 17–19% of salt solution is added to the koji to produce a mash called moroni. Lactic acid bacteria such as *Pediococcus soyae* or *Lactobacillus delbrueckii* are allowed to grow on the moroni to make it acidic enough to prevent spoilage and acidic in taste. Yeasts such as S*accharomyces rouxii* and *Torulopsis* sp. grow on the moroni to produce alcohol and help the formation of flavor [177]. The moroni is aged, pressed to produce a liquid, soy sauce, which is then pasteurized.

17.6.5.2 Tempeh

Tempeh is a protein-rich food that is considered one of the world's first meat analogs. It is made by growing the mold

Rhizopus oligosporus or related species on soaked, dehulled, partially cooked soya beans, then knitting them into a firm cake, which can be sliced and deep-fried, or cut into cubes and used in place of meat in soups [12]. The processing steps of tempeh fermentation are shown in Figure 17.7. Tempeh production is not a means of improving shelf-life but it does however improve the acceptability and the nutritional quality of its raw material (soybeans).

17.7 MICROBIAL PRODUCTS AND THEIR USE AS FOOD PRESERVATIVES

As a whole, microorganisms naturally produce an arsenal of antimicrobial agents to improve their competitiveness. A common example is lactic acid, and its use as a food preservative been discussed extensively in this chapter. The major concern when substances are added to foods as preservatives is any potential risks to the consumer. Consequently, the use of antibiotics as food preservatives has not been pursued due to the health risks posed by bacteria acquiring resistance to antibiotics that are used clinically for controlling infections in humans.

The efficacy of bacteriocins produced by LAB as food additives to inhibit foodborne pathogens is of particular interest, as they are produced by food-grade organisms and could therefore be classed as "natural," and they are considered to be safe for consumers, as they have been consumed in fermented foods for generations. Bacteriocins are bactericidal peptides or proteins that are usually inhibitory to species closely related to the producer. Nisin, lactococcin, and pediocin are bacteriocins that are produced by LAB.

Nisin, which is produced by some strains of *Lactococcus lactis,* has been accepted for use as a preservative in the food industry. It is a class I bacteriocin which is active against most gram-positive bacteria including spore-formers such as *Clostridium botulinum,* which is a major concern in the food industry. Nisin is especially useful for controlling spoilage of heat-processed foods, as it inhibits the outgrowth of spores including those from *Clostridium* and *Bacillus* spp., the major spoilage agents in these foods. Nisin acts on the outside of the cell, and it destroys the integrity of the cell by creating minute holes in the cell membrane. This allows cellular components to leak from the cell and disrupts the potential across the membrane [178, 179]. Nisin is not active against gram-negative organisms, yeasts, or fungi.

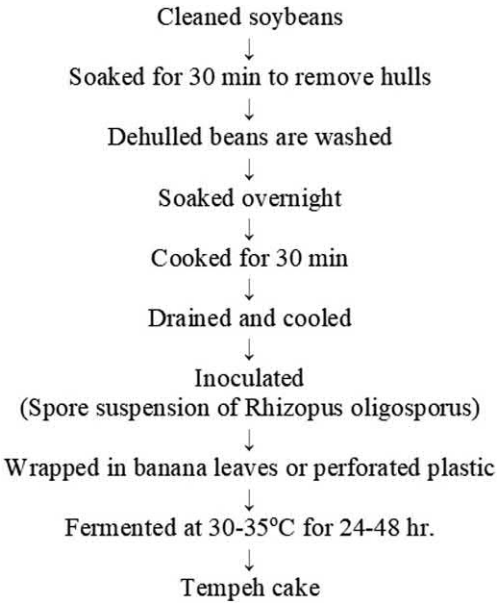

FIGURE 17.7 Flow chart of tempeh fermentation.

Nisin has been widely applied in foods as a biopreservative and pathogen inhibitory agent. Initially, nisin was used in processed cheese [180, 181]. Its application in cheese was extended to control total plate and anaerobic *Bacillus stearothermophilus*, *Bacillus cereus*, and *Bacillus subtilis* [178]

In the meat industry, nisin at 75 ppm (75 ug/g) was found superior to 150 ppm of nitrite in inhibiting outgrowth of *Clostridium sporogenes* PA3679 spores in meat slurries (182). After a 1 h exposure to 50 μg of nisin per ml and 20 mM disodium EDTA at 37°C, Stevens et al. [186] observed a 3.2 to 6.9 log-cycle reduction in population of most common species of pathogens such as *Salmonella enteritidis*, *S. typhimurium*, and *Escherichia coli* 0157:H7.

18 Natural Antimicrobials for Food Preservation

Eddy J. Smid and Leon G. M. Gorris

CONTENTS

18.1 INTRODUCTION

The spoilage and poisoning of foods by microorganisms is a problem that is not yet under adequate control despite the range of robust preservation techniques available (e.g., freezing, sterilization, drying, preservatives). In fact, food manufacturers increasingly rely on more mild preservation techniques to comply with consumer demand for foods with a more natural appearance and nutritious quality than can be achieved by the robust techniques. In addition, consumers increasingly refuse foods prepared with preservatives of chemical origin, which still is everyday practice to achieve sufficiently long shelf life for foods and a high degree of safety with respect to foodborne pathogenic microorganisms. To meet consumer criteria, food manufacturers are searching for new, more natural alternatives that sufficiently ensure the safety of their products in the retail chain.

The search for natural alternatives to chemicals is a logical one, because nature has long been a very generous source of antimicrobial compounds, many of which play an important role in the natural defense or competition systems of living organisms (ranging from microorganisms to insects, animals, and plants). Many plants contain compounds that have some antimicrobial activity, collectively referred to here as *green chemicals*. Spices and herbs, for instance, are well known to inhibit bacteria, yeasts, and molds, and have traditionally found wide use in food preservation as well as for medicinal purposes. The use of spices and herbs or their extracts is often less effective than the use of their active ingredients, for which a number of attractive applications have been identified, as will be discussed. With respect to natural antimicrobial activity associated with microorganisms, referred to as *biopreservatives*, a mainstream field of study currently is the use of lactic acid bacteria. These bacteria have a long and safe tradition in food fermentation, and many potent applications as food preservatives have been established. The bacteriocins produced by lactic acid bacteria are especially promising, which will be discussed in detail. The use of natural antimicrobials in practice is subject to legislative requirements, which can be quite different in various parts of the world, and

this needs to be considered when discussing new development in this area of food preservation.

18.2 RATIONALE FOR THE USE OF NATURAL ANTIMICROBIAL COMPOUNDS

In many countries worldwide, there is a rapidly growing demand for environmentally friendly, safe preservatives to be used for mild food preservation. Traditional food preservation techniques have undesirable effects on the appeal of fresh food products and artificial preservatives are increasingly being banned. As a consequence, a variety of fresh or minimally processed, highly perishable vegetables have emerged on the marketplace having undergone milder preservation techniques, such as a combination of refrigeration and modified-atmosphere packaging (see Chapter 22). Mild preservation techniques can control product spoilage caused by microorganisms to some extent, mainly because they are used in adherence with the "hurdle technology" (combined processes) concept [1], as discussed in Chapter 15. However, it is now becoming more evident that potential safety hazards may occur with mild preservation systems due to the survival and growth of certain foodborne pathogens. Of special concern are cold-tolerant (psychrotrophic) pathogens, like *Listeria monocytogenes*, *Yersinia enterocolitica*, and *Aeromonas hydrophila*, which may grow to concerning levels during the long shelf life these perishable foods may have. Mesophyllic pathogens (i.e., *Salmonella* spp., *Staphylococcus aureus*, enteropathogenic *Escherichia coli*, and *Bacillus cereus)* pose a health hazard when temperature abuse occurs. Thus, there is an urgent need for the introduction of additional safety factors with these mild preservation techniques.

Chemical preservatives, such as sorbate and benzoate, have for long been used as reliable preservative factors to control a number of microbial hazards. However, such compounds do not satisfy the concept of "natural" and "healthy" food that consumers prefer and that the food industry, consequently, needs to manufacture. The negative reaction to chemical preservatives in our society is strongly increasing, despite the fact that such compounds are as yet indispensable in food processing. As a result, replacement of chemicals by more natural alternatives can only be relevant when necessary (i.e., when the chemical alternatives are no longer acceptable) and possible (i.e., when natural substitutes are indeed [eco-]toxicologically safe to use and effective in practice). The necessity is underlined by many in agro-industry, legislatures, and consumer organizations. The possibility is supported by many studies performed by academics and food industrialists. It is clear that natural alternatives are not always as potent as existing chemicals and that the clever use of combined processes may be a prerequisite for optimal functionality. Also, it is evident that even natural alternatives will have to pass legislative scrutiny and that the label "natural" should not be confused with inherent safety.

Nature is well known to contain many different types of antimicrobial compounds, which play an important role in the natural defense or competition systems of all kinds of living organisms, ranging from microorganisms to insects, animals, and plants. In this chapter, only natural antimicrobials from plants and microorganisms will be discussed, since these may be the most feasible substitutes for chemical food preservatives considering practical, legislative, and ethical aspects.

Regarding the development of natural antimicrobial compounds from plants (collectively called green chemicals) for food preservation, research is now focused on the potential use of phytoalexins, organic acids, and phenols. In addition, promising results have been obtained with essential oils from herbs and aromatic plants. Such essential oils consist of mixtures of esters, aldehydes, ketones, and terpenes with broad-spectrum antimicrobial activity. The toxicological basis of many herbs and spices as well as of their active components has been studied [2], and often they are known to be food-grade or even GRAS (generally recognized as safe).

With respect to the natural antimicrobial activity derived from microorganisms (referred to as biopreservatives), the most promising ongoing development in food preservation is the use of lactic acid bacteria (LAB). LAB are GRAS organisms and have a long and safe tradition in food-fermentation practices. Use of these organisms or of the antimicrobial compounds they produce has been successfully achieved in many different types of foods. Most prominently, bacteriocins produced by LAB have been under investigation worldwide for food-preservation purposes. Bacteriocins are proteins with a rather narrow antimicrobial spectrum, as compared to traditional preservatives. This apparent disadvantage is compensated for by the possibility to use these compounds for targeted control and by the fact that they are not persistent in the environment and are destroyed in the human stomach.

In the rest of this chapter, basic knowledge about the occurrence and antimicrobial properties of those natural antimicrobials of plant and microbial origin will be presented that is relevant and feasible in modern food preservation. In fact, a wealth of knowledge on the topic is available in scientific literature and elsewhere, but only a small sample will be discussed here to illustrate the ongoing quest for useful natural antimicrobials [3, 4].

18.3 NATURAL ANTIMICROBIALS OF PLANT ORIGIN

Plants have for centuries been appreciated for their antimicrobial or medicinal activity. Certain of these plants would be suitable to cultivate instead of lower value crops, thus improving cultivation revenues, which are currently under economic pressure. In many instances, antimicrobials in plants (green chemicals) function in the resistance or defense systems against microbial diseases or pests. Often, they have a particular taste or smell, which has led to them being used in the perfume and fragrance industry. Herbs and spices have been used since ancient times not only as "tastemakers," but also as preservatives or antioxidants [5–7]. A wide selection of literature exists describing the favorable properties and identifying the active components of plants.

The majority of antimicrobial plant compounds are identified as secondary metabolites, mainly being of terpenoid or phenolic biosynthetic origin. The rest are hydrolytic enzymes (glucanases, chitinases) and proteins acting specifically on membranes of invading microorganisms with antimicrobial activity [8, 9]. In general, no sharp chemical division can be made between constitutive and induced antimicrobials [10]. Based on the accumulating data on various plant compounds involved in disease resistance, Ingham [11] proposed categorizing the chemical defense systems of plants into preinfectional and postinfectional factors. Preinfectional factors are constitutive antibiotics, also called *prohibitins,* which are synthesized and stored in specialized tissues where they slow or arrest in situ microbial growth instantly upon infection. Examples of prohibitins are essential oil components with antimicrobial activity. Preinfectional factors that require a postinfectional increase in concentration for an adequate effect are called *inhibitins.* In addition, two types of postinfectional factors can be distinguished: postinhibitins and phytoalexins. Compounds belonging to the first class are toxic metabolites formed after infection by hydrolysis or oxidation of preformed compounds. The second class includes antimicrobial compounds, which are synthesized upon invasion of the host plant [12]. In this chapter, a brief overview will be given of natural antimicrobial compounds in plants that belong to one of four categories: phytoalexins, phenols, organic acids, or essential oil components.

In general, herbs and spices and several of their antimicrobial constituents are GRAS, either because of their traditional use without any documented detrimental impact or because of dedicated toxicological studies. Their application in crop protection and food preservation should be facilitated by this feature, but to date plants still are a poorly exploited source of alternative antimicrobial agents. The enormous potential of plants as a source of antimicrobial compounds is well illustrated by a review of Wilkins and Board [13], who report over 1389 plants as potential green chemical sources, and more specifically by the identification of over 250 new antifungal metabolites in plants between 1982 and 1993 [10]. Obviously, not all of the potential plant sources would qualify to be introduced in our agriculture practices, simply because they would only grow in specific environments. Also, whenever a plant is considered to be exploited as a green chemical source, a thorough evaluation will have to be carried out of its value with respect to the net economy of its cultivation and actual production of the green chemical (be it the whole crop, an extract, or a purified compound), the market value of this antimicrobial preparation, and the costs for going through legislative procedures. Many of the potential sources may not pass this evaluation.

18.3.1 Phytoalexins

Phytoalexins are defined as host-synthesized, low molecular weight, broad-spectrum antimicrobial compounds whose synthesis from distant precursors is induced in plants in response to microbial infection or treatment of plant tissues with a range of naturally occurring or synthetic, artificial compounds (biotic or abiotic elicitors) [14]. More than 200 different phytoalexins have by now been identified in more than 20 plant families. Phytoalexins are broad-spectrum antibiotics, generally active against phytopathogenic fungi. In contrast to the preformed prohibitins, disease resistance due to phytoalexins is a dynamic process, requiring de novo synthesis of secondary metabolites. In addition, the enzymes responsible for the synthesis of phytoalexins are themselves synthesized in response to exposure to microbes or other effective stimuli [15]. Elicitors, the compounds triggering the synthesis of phytoalexins, range in nature from bacterial proteins [16–18] to fungal fatty acids [19] to host-plant-derived oligosaccharides [20].

The antimicrobial activity of phytoalexins is often directed against fungi [21], although activity has also been reported toward bacteria [22]. Gram-positive bacteria have been found to be more sensitive than gram-negative bacteria. Isoflavonoids, characterized by a C_6–C_3–C_6 basic skeleton structure, are among the most important chemical classes of phytoalexins [23], and studies on their application outside the natural sources have been undertaken [24]. The Leguminosae are known for the production of isoflavonoid phytoalexins, for example, pisatin (Figure 18.1a) from *Pisum sativum,* phaseollin from *Phaseolus vulgaris,* and glyceollin from *Glycine max* [25]. The production of isoflavonoid phytoalexins in plant cell and tissue cultures has aroused much interest [26, 27], and this could be a method for larger-scale artificial production when a plant itself has no sound commercial potential.

For structurally related compounds in the group of isoflavonoid phytoalexins, it was found that an increase in lipophilicity correlates positively with increased antifungal activity [28]. Terpenoid phytoalexins such as rishitin (Figure 18.1b) are mainly found in the family of *Solanaceae,* e.g., in potato tubers. The *in vitro* activity of rishitin against bacteria was found to be inhibited by low levels of the divalent cations Ca^{2+} and Mg^{2+} [29], indicating that these compounds act on the cytoplasmic membrane of the target microorganisms.

Another major group of phytoalexins, also referred to as disease- or pathogenesis-related proteins, comprises chitinases, thionins, zeamatins, thaumatins, etc. [8, 30, 31]. Some of these proteins are involved in the synthesis of other phytoalexins or phenolic compounds as constitutive or inducible enzymes. Others reportedly have a direct antimicrobial effect. Because they are proteins, they would be completely digested in the stomach and thus would have no impact on the health of a consumer. Chitinases target chitin, a major component of the cell wall of most phytopathogenic fungi and also of

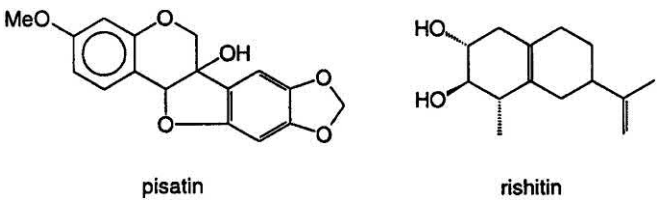

FIGURE 18.1 Phytoalexins from *Pisum sativum* (left) and *Solanum tuberosum* (right).

the skeletal structure of most invertebrates, e.g., insects and mites. Healthy plants normally contain low levels of chitinase, but their production is induced following pathogen attack. The induced chitinase accumulates either intracellularly or in the intercellular space, where their activity is required. Because vertebrates and higher plants do not contain chitin, no adverse impact is known, reinforcing the appeal of chitinases for fungal control. The use of chitinases as antifungal agents has been studied successfully in the laboratory for almost 10 years [32, 33], but practical application has not yet been realized. The same holds true for thionins, a group of small polypeptides with antifungal and antibacterial activity that occur in cereal endosperm, e.g., in barley, oat, and maize [30]. A closely related compound is viscotoxin from mistletoe. Extracts from this plant have been used against a variety of diseases and are still part of many herbal remedies.

Although the use of phytoalexins in food preservation has been suggested in many reviews [3, 34–36], there are still very few examples of the actual use of these compounds in food preservation. This is possibly due to the fact that phytoalexins in general show adequate antimicrobial effects at relatively high concentrations. In plants, this may not be a problem since these compounds accumulate locally to high concentrations, specifically in wounded plant tissue. The high concentrations necessary in food matrices when applied from an exogenous source and their occasional cytotoxicity [37] hamper the application of these compounds as food-preservative agents. The development of analogs with higher specific activity and reduced toxicity could facilitate the application of these types of compounds.

18.3.2 Organic Acids

Citric, succinic, malic, and tartaric acids are commonly found in fruits (e.g., citrus, rhubarb, grapes, pineapples) and vegetables (e.g., broccoli, carrots). Through their use as acidulants or antioxidants in foods, benefit is taken as well from their antimicrobial properties. Lactic and propionic acids do not occur naturally in foods other than in trace amounts, although they are readily formed during natural fermentation. The antimicrobial activity of the various acids is extensively documented [38]. They target cell walls, cell membranes, metabolic enzymes, protein synthesis systems, and genetic material. Thus, they are active against a wide range of microorganisms. The organic acids contained in crops may well contribute to the natural crop resistance. Many organic acids or their derivatives are already applied as food preservatives.

18.3.3 Phenolic Compounds

At the beginning of the 20th century, it was believed that plants contained compounds that were toxic toward invading fungi [39]. Initially, the abundant presence of phenolic compounds combined with their apparent *in vitro* activity toward many microorganisms was taken as an indication that these compounds could fulfill the primary role of the chemical defense system of plants. However, the role of plant phenolics in the chemical defense of plants against invading microorganisms is still unclear. Nevertheless, it has been appreciated that a vast range of phenolic compounds contribute to the defense mechanisms of plant tissues as well as to the sensory (taste, odor, appearance) and nutritional qualities of fresh or processed plants. Phenolics are characterized by an aromatic ring bearing one or, more frequently, several hydroxy substituents, including functional derivatives. Phenolic compounds usually occur conjugated, e.g., to sugars as β-D-glucopyranosides. The phenolic compounds are classified into three groups: simple phenols and phenolic acids (e.g., p-cresol, 3-ethylphenol, hydroquinone, protocatechuic, vanillic, gallic, syringic, ellagic acids), hydroxycinnamic acid derivatives (e.g., p-coumaric, caffeic, ferulic, sinapic acids), and flavonoids [36]. The latter group is the most important single group of phenolics in food, comprising catechins, proanthocyanins, anthocyanidins, and flavons, flavonols, and their glycosides. Finally, tannins, a polymeric form of phenolics, are an important group of plant phenolics, unified by the common ability to precipitate protein from aqueous solution. The antimicrobial activities of the naturally occurring phenolics from olives, tea, and coffee have been studied in more detail than those from other sources, which may in part be due to the high value of the products being processed [36]. Phenolics from spices, such as gingerol, zingerone, and capsaicin, have been found to inhibit the germination of bacterial spores. Native plant phenolics are important food-preservative factors and have, as a group, an impressive antimicrobial spectrum, although their deliberate use as food preservatives is rarely exploited.

18.3.4 Essential Oils and Their Components

Essential oils are mostly derived from spices and herbs but can also be isolated from fruits, roots, and stems of plants. Some oils and isolated plant compounds are used in food as flavoring agents. Derived from their functionality in plants, these compounds show a wide range of interesting biological activities [7]. Some compounds have been shown to attract flies for pollination, whereas others show a distinct insect-repelling activity. Others attract herbivores for seed distribution or show fungicidal or bactericidal activity to suppress infection by plant pathogenic microorganisms. Compounds that are approved for use in food and combine antimicrobial activity with low mammalian toxicity have great potential for application as natural food preservatives.

The antimicrobial activities of extracts obtained from spices, herbs, and other aromatic plants or parts thereof using organic solvents or steam distillation have been recognized for many years. Plants and plant extracts have been used since antiquity in folk medicine and food preservation, providing a range of compounds possessing pharmacological activities [40]. Most commonly, the active antimicrobial compounds are found in the essential oil fraction. With many herbs and spices, these compounds contribute to the characteristic aroma and flavor. Essential oils are mostly soluble in alcohol and to a limited extent in water. They consist of mixtures of esters, aldehydes, ketones, and terpenes [41]. Essential oil

components with a wide spectrum of antimicrobial effects include thymol from thyme and oregano, cinnamaldehyde from cinnamon, and eugenol from clove.

The impact of essential oils on bacteria, especially on pathogens, has been extensively studied in the laboratory, and significant variations have been noted. For example, *Escherichia coli* was found to be more vulnerable than *Pseudomonas fluorescens* or *Serratia marcescens* to the essential oils of sage, rosemary, cumin, caraway, clove, and thyme [42], whereas *Salmonella* Typhimurium was more sensitive to oregano and thyme oils than *Pseudomonas aeruginosa* [43]. Deans and Ritchie [44] studied the effect of 50 plant essential oils on 25 genera of bacteria and concluded that both gram-positive and gram-negative bacteria are susceptible, but the levels of impact were highly variable. Tassou and Nychas [45] have shown that the essential oil of *Pistacia lentiscus* var. *chia* (mastic gum) inhibits the growth of the food pathogen *Salmonella enteritidis* in skimmed milk. Mold growth on black table olives was found to be suppressed by methyl eugenol and the essential oil from *Echinophora sibthorpiana* [46]. The use of mustard oil in homogenized, canned beef was investigated by Drdak et al. [47]. Concentrations of 0.1% allylisothiocyanate, the active antimicrobial compound in mustard oil, did not cause unacceptable sensory effects, allowed sufficient thermosterilization, and resulted in a microbially safe product. A recent detailed review by Nychas [36] summarizes findings that essential oil compounds from many different plant sources inhibit many foodborne pathogens (Table 18.1). *Staphylococcus aureus*, *Listeria monocytogenes*, *Aeromonas hydrophila*, *S. typhimurium*, and *Clostridium botulinum* are to some degree sensitive to extracts from linden flower, orange, lemon, grapefruit, mandarin, sage, rosemary, oregano, thyme, cinnamon, cumin, caraway, clove, thyme, allspice, mastic gum, and onion. However, most researchers inevitably came to conclude that the effectiveness of essential oils decreased when experiments were conducted in vivo. This could well be due to specific components of the food matrix, such as proteins and fats, which immobilize and inactivate the essential oil components.

The antifungal effects of essential oil components from several herbs, spices, and other plant materials have been investigated against important food spoilage or mycotoxigenic species of *Penicillium* and *Aspergillus,* but contradictory results were obtained [43, 48–51]. While some found inhibitory activity, other researchers actually noted stimulating effects. Again, the food matrix may have had a decisive influence here, and it is recommended to standardize the experimental setup accordingly.

Because essential oils contain a variety of compounds from different chemical classes, it is not possible to isolate a single mechanism by which these compounds act on microorganisms. An important common feature of essential oil components is their high degree of hydrophobicity. Therefore, these compounds partition preferentially into biological lipid bilayers as a function of their own lipophilicity and the fluidity of the membrane [52]. The accumulation of lipophilic compounds into biological membranes enhances their availability to the cell and therefore may inhibit cell vitality [53, 54]. Despite the high degree of ordering of solutes in a lipid bilayer compared with bulk liquid phase [55], a good correlation between the partitioning coefficient of various lipophilic compounds in membrane buffer systems and octanol/water two-phase systems has been observed [53, 56]. Therefore the octanol/water partitioning coefficients, which are known for many different compounds present in essential oils, can be used to assess the potential antimicrobial effect of these compounds [53]. However, the presence of specific reactive groups in compounds, the variability in membrane composition, and the metabolic capacities of the target organisms make a reliable

prediction of the toxicity of compounds based solely on their hydrophobicity difficult, if not impossible. This is exemplified by carvone and cinnamaldehyde, two compounds with comparable hydrophobicities but different antifungal mechanisms. Both compounds inhibit growth of *Penicillium hirsutum* when administered via the gas phase [57]. Full suppression of growth by carvone was observed only as long as the compound was present in the atmosphere. On the other hand, fungal growth inhibition by trans-cinnamaldehyde was found to be strictly irreversible. In conclusion, carvone acts as a fungistatic agent, whereas trans-cinnamaldehyde acts as a fungicide. The mechanism behind this difference in antifungal activity was investigated using *Saccharomyces cerevisiae* as a model organism [58]. Cinnamaldehyde was found to cause a (partial) collapse of the integrity of the cytoplasmic membrane, which leads to excessive leakage of metabolites and enzymes from the cell and finally loss of viability. In agreement with its fungistatic rather than fungicidal effect, loss of membrane integrity was not observed with carvone [58].

Considering any exploitation of essential oils, it should be stressed that large variations may occur in the yield of active compounds or total oil with the plant genotype and with different extraction methodologies, and also that variations are to be expected in the essential oil composition of the same species according to geographical location and environmental and agronomical conditions, as well as differences in essential oil content with diurnal rhythm. It is clear that essential oils or their active components are by no means a ready-to-use source from a production point of view, and many parameters need to be carefully standardized in detail in that respect.

18.3.5 Example of Application of Antimicrobials from Plants

Among the essential oil components, the volatile monoterpenes and aldehydes have attracted the recent interest of research and food industries because they can be used as food preservatives that leave a negligible amount of residues. Regarding application in practice, however, the volatile nature of the very potent compounds requires the development of suitable slow-release formulations or tailored packaging systems to maintain their functional activity for a sufficient time. For instance, with carvone, the prime monoterpene in the essential oil of caraway (*Carum carvi* L.) seeds (Figure 18.2),

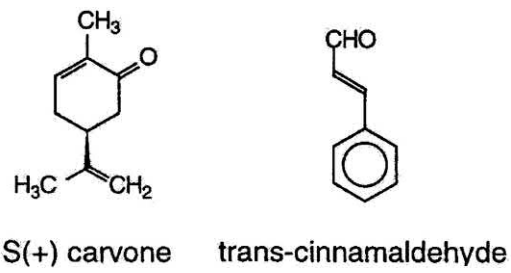

FIGURE 18.2 Structures of carvone (left) and trans-cinnamaldehyde (right), two secondary plant metabolites with antifungal activity.

a powerful antifungal effect has been found, which is already exploited for the protection of potato tubers under storage conditions [59]. However, carvone is gradually lost from the storage environment and has to be administered regularly.

Cinnamaldehyde, the major compound in cassia oil (Figure 18.2), shows potent antifungal activity against several food-associated fungi like *Penicillium* sp., *Fusarium* sp., and *Aspergillus* sp. [60]. Cinnamaldehyde also has been shown to possess antiaflatoxigenic properties [61]. When exposed to air, cinnamaldehyde is readily oxidized to cinnamic acid. Therefore, gas-phase application of this compound is less effective [57]. However, its very potent fungicidal activity and low mammalian toxicity [2] make this natural compound an interesting candidate for application as a surface disinfectant for foods. An example of the use of cinnamaldehyde in food preservation is its potential use as a surface disinfectant for tomatoes [54]. Tomatoes are particularly vulnerable to microbial spoilage at calyces and wound sites on the fruit surface. The major pathogens affecting the postharvest life of tomato fruit are *Alternaria alternata*, *Botrytis cinerea*, and *Rhizopus stolonifer.* Calyces are usually the first part of the tomato on which fungi appears. It has been shown that disinfection of tomatoes with sodium hypochlorite before packaging greatly reduced subsequent microbial spoilage. However, several countries have abandoned the use of hypochlorite for disinfection of foods, and natural plant-derived compounds with sufficient antimicrobial activity and low mammalian toxicity such as cinnamaldehyde could be good alternatives. Smid et al. [54] investigated the reduction of spoilage-associated fungi and bacteria on whole tomatoes packaged under modified-atmosphere conditions. Tomatoes were treated for 30 minutes with a solution containing 13 mM cinnamaldehyde and stored at 18°C in sealed plastic bags. Under these conditions the development of the microbial population was recorded on treated and untreated (control) tomatoes. On day 4, visible fungal growth was observed on calyces of untreated fruits. *Penicillium* sp. was found to be the dominant fungal species on the calyx. The calyx of cinnamaldehyde-treated tomatoes remained free from visible fungal growth for at least 9 days. These observations agree with the microbial analysis of the tomatoes (Figure 18.3). After 2 days of storage, pronounced growth of the bacterial population was observed on control tissues treated with 0.85% NaCl. After 4 days of storage, a significant increase in the size of the bacterial population was detected on untreated tomatoes. In contrast hardly any development of the bacterial population was detectable on cinnamaldehyde-treated tomatoes (Figure 18.3a). As expected, visible fungal growth on calyces of both untreated and NaCl-treated tomatoes appearing at day 4 corresponded with a rapid increase in size of the fungal population. The size of the fungal population on cinnamaldehyde-treated tomatoes remained small under day 11 (Figure 18.3b).

Fungicidal and bactericidal compounds from natural sources, such as cinnamaldehyde, may offer attractive possibilities for the disinfection of fresh and minimally processed fruits and vegetables. A bottleneck for practical use of these compounds may be not the efficacy, but rather specific odors

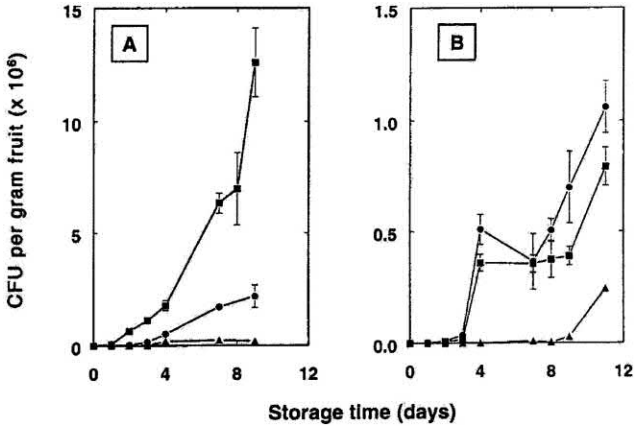

FIGURE 18.3 Development of the microbial spoilage organisms on tomatoes stored for 11 days at 18°C in sealed plastic bags. The microbial population on cinnamaldehyde-treated fruits (▲), NaCl-treated fruits (■), and untreated fruits (●) was monitored for 9 (bacteria; panel A) or 11 days (fungi; panel B). The data represent mean values of triplicate measurements, and each data point is calculated from a sample of five tomato fruits. Standard errors of the mean are indicated by error bars. (Modified from Breidt et al. [94].)

associated with such compounds at higher dosages. To overcome this problem, antifungal plant metabolites should be selected for both efficacy and minimal interference with the natural odor of the product.

18.4 NATURAL ANTIMICROBIALS OF MICROBIAL ORIGIN

Microorganisms produce a wide range of components that influence the growth of other microorganisms present in their environment. Often these components increase the competitive edge of the producing organism and as such are an important feature of their survival and proliferation. Regarding food preservation, the most important single group of organisms to be considered as a source of biopreservatives are lactic acid bacteria (LAB). These have been used in food fermentation for centuries to produce stable food products, including dairy (cheese), meat (sausages), and vegetable (sauerkraut) products. The fact that fermented products, which naturally contain these microorganisms and the antimicrobials they may produce, have been consumed traditionally without a negative health effect, has given LAB GRAS status [62]. Lactic acid bacteria may produce both antimicrobial compounds with a relatively broad inhibition spectrum (i.e., organic acids and hydrogen peroxide) as well as compounds with a rather narrow antimicrobial spectrum (i.e., bacteriocins). The use of LAB as biopreservatives is possible via the application of the producing organism as a "protective culture" to the food product and relying on its proliferation and consequent competition with the microorganisms to be suppressed. Alternatively, preparations of the active antimicrobial compounds may be utilized, with the advantage of an instant and more controllable effect. While the use of protective cultures in most countries needs only to be declared on the product, the use of antimicrobial metabolites such as the bacteriocins is subject to specific rules and regulations in food legislation. Several reviews give more detail on bacteriocins and LAB in relation to their potential for food preservation [63–70].

18.4.1 Lactic Acid Bacteria as Protective Cultures

The use of lactic acid bacteria as starter cultures in the production of fermented meats, dairy products, and vegetables is one of the oldest food-processing practices utilized and meant to stabilize food products while obtaining specific, desired sensory and organoleptic properties. The success of the fermentation process depends on the competitiveness of starter cultures, and it is exactly for this reason that LAB have been so widely used. The many different antimicrobials they produce are able to counteract a wide range of competitors that would cause problems in the fermentation process. In recent years, there has been some research into the use of LAB in food-processing applications where the outgrowth of specific problem microorganisms is to be controlled. In this case, the selected LAB are referred to as *protective cultures* and should affect pathogens or spoilage microorganisms without any negative impact on the sensory or organoleptic characteristics of the food product. Production of acids as the main antimicrobial agents is often detrimental to food quality and is not a suitable mechanism of action for protective cultures. LAB that produce a minimum amount of acids but expel bacteriocins in their environment offer good options as protective cultures.

Whereas LAB as starter cultures have become widely used and accepted, their use as protective cultures is still under development. Exploitation depends partly on legislative hurdles that relate to the consideration that protective cultures that rely for their activity on bacteriocins are intended for use as preservative agents and function by use of compounds not yet generally recognized as safe in many countries, as discussed elsewhere in this chapter. This is in sharp contrast to the legal status of starter cultures, which are considered to be processing aids or ingredients and not preservatives, and for which the mode of action seems not to be a decisive issue from the legislative point of view. Recently, it has been advocated to employ molecular biology tools to improve the performance of starter and protective cultures with regard to their production or preservation capacity [71]. Whereas, within current food legislations, natural strains already have limited access to practice, it is expected that the use of genetically modified strains will not be more easily approved.

The effort to develop protective cultures has been increasing over recent years but up to now has been confined to laboratory studies. Some review papers on the topic are available [35, 66, 69, 72–76], although several are published in sources that may not be readily accessible. A number of interesting developments with respect to the use of LAB as protective cultures for several different food categories are discussed next.

18.4.1.1 Meat Products

In a screening exercise involving 221 strains of *Lactobacillus* species evaluated for their ability to inhibit the growth of

microorganisms commonly occurring in meat products [77], a wide range of bacteria was found to be affected by individual strains, e.g., *Serratia marcescens* (by 47% of the strains), *Citrobacterfreundii* (47%), *Proteus vulgaris* (67%), *S. typhimurium* (9%), and *Brochothrix thermosphacta* (87%). In most cases, the inhibitory activity of the protective culture was attributed to lactic acid formation, although 6 of the 221 LAB isolates (all isolates of *Lactobacillus sake*) formed a bacteriocin contributing to the inhibition of *L. monocytogenes*. Experiments performed by the same researchers on comminuted cured pork (German-type fresh Mettwurst) with pH 5.7 were aimed at control of *L. monocytogenes* and showed that a strain of *L. sake* producing a suitable antilisterial bacteriocin was able to reduce the growth potential of the pathogen by about 1 log cycle [78]. A mutant of *L. sake* that did not produce the bacteriocin did not affect the number of *Listeria* inoculated into this product. In another study using *L. sake* as the protective culture, the control of *L. monocytogenes* in vacuum-packaged sliced Brühwurst (cooked sausages) was emphasized [79]. Sliced sausage samples were inoculated with a mixture of four *L. monocytogenes* serovars, fortified with either one of two bacteriocin-producing strains of *L. sake,* isolate Lb706, which produced sakacin A, and isolate Lb674, which produced sakacin 674, or of a non-bacteriocin-producing strain of *L. sake* and stored for up to 28 days at 7°C. Whereas the non-bacteriocin-producing LAB reduced counts of *L. monocytogenes* but not to an acceptable extent, both bacteriocin-producing strains of *L. sake* were able to control growth of *L. monocytogenes* adequately at the high initial counts tested.

Using bacteriocin-producing and non-bacteriocin-producing strains of *Pediococcus acidilactici* for protection of turkey summer sausages against *L. monocytogenes*, Luchansky [80] found that the pathogen could be reduced by the bacteriocin-producer by 3.4 log cycles, but by only 0.9 log cycle when the non-bacteriocin-producing strain was used. In vacuum-packaged wiener and frankfurter sausages, proliferation of *L. monocytogenes* inoculated in the products was suppressed for over 60 days by the addition of *P. acidilactici* JD1-23 at 10^7 CFU/g product, whereas the viable count of the pathogen increased from 10^4 to 10^6 in the control [81]. Degnan et al. [82] observed a clear antilisterial effect of yet another bacteriocin-producing strain of *P. acidilactici* in vacuum-packaged wieners stored at abuse temperature (25°C), where the addition of the protective culture resulted in a reduction of *L. monocytogenes* counts by 2.7 log cycles within 8 days while pathogen counts increased by 3.2 log cycles in sausages without added pediococci. In bacon, a pediocin-producing strain of *P. acidilactici* has been used in combination with reduced levels of nitrite to prevent toxin production by outgrowth of *C. botulinum* spores. Here, the protective culture would grow during conditions of temperature abuse, producing lactic acid and inhibitory pediocins. Strain *P. acidilactici* H, isolated from fermented sausage, and exhibited a broader range of bactericidal activity than any other pediococcal bacteriocin due to the production of a bacteriocin termed pediocin AcH.

Pediocin producers have also been used as protective cultures relying on their lactic acid production, rather than on the production of a bacteriocin. Hutton et al. [83] used the "Wisconsin process" (a combination of lactic acid starter culture and sucrose) to prevent toxigenesis by *C. botulinum* in reduced nitrite bacon. In chicken salads these authors found that a combination of *P. acidilactici* and glucose prevented botulinum toxigenesis. When the chicken salad was temperature abused, the protective culture catabolized available glucose to lactic acid, which caused a decrease in the pH of the product. Pathogen challenge tests verified that the rate and extent of lactic acid accumulation in the chicken salad during temperature abuse was sufficient to preclude botulinum toxigenesis.

Kotzekidou and Bloukas [84] studied the effect of protective cultures on the shelf life of sliced vacuum-packed cooked ham. They found that cooked ham produced with *Lactobacillus alimentarius* and *Staphylococcus xylosus* as protective cultures was acceptable up to 28 days, while control ham has a shelf life of 21 days. The activity of the protective cultures was directed to micrococci, staphylococci, and *B. thermosphacta*. Meat salads with relatively high pH values (pH 6.0–6.5) were studied by Hennlich and Cerny [85] for potential application of LAB as protective cultures in limiting the hygienic risks caused by food salmonellae, staphylococci, or clostridiae. The risk of pathogen growth in these foods is most apparent under temperature-abuse conditions, and the research showed that distinct cultures of lactic acid bacteria are indeed able to decrease microbial risks due to foodborne pathogens at elevated temperature. Whereas they do not reduce spoilage by bacilli, yeasts or fungi, the protective cultures used could reduce the growth of pathogens and actually spoiled the food before the pathogens could grow to hazardous levels.

Andersen [86] recently reported on a commercial protective culture developed for fresh sausages (called "FloraCarn L2"), where contamination during or after processing is a possible hazard and the protective culture can be used as an additional safety and quality factor. FloraCarn L2 was tested in fresh British sausage mince and was shown to suppress the indigenous microflora and *B. thermosphacta*. In fresh coarse-chopped sausages, the protective culture inhibited the possible development of indigenous coliform bacteria during storage.

Research on protective cultures has not always found potential positive applications for bacteriocin-producing LAB. Targeting control of *L. monocytogenes* in meats during long-term storage, Buncic et al. [87] tested *L. sake* 265 (Lb 265) and *Lactobacillus casei* 52 (Lb 52) isolated from chilled meat products as protective cultures. Although both starter cultures produced bacteriocin at 4°C, they were not able to suppress growth of *L. monocytogenes* inoculated at 10^3 CFU/g on vacuum-packaged, raw beef (pH 5.3–5.4) during 23 days storage at 4°C when they were inoculated at the same low level. The protective cultures were equally ineffective when applied to vacuum-packaged emulsion-type sausages (pH 6.4) inoculated with *L. monocytogenes* and stored at 4°C for 23 days. Apparently, the amounts of bacteriocin produced in situ

by the low initial numbers of protective cultures employed were not sufficient to inhibit or reduce *L. monocytogenes* on chilled meats to any significant extent, whereas higher initial numbers of lactic acid bacteria are not desirable in chilled meats for product quality reasons.

18.4.1.2 Fish and Seafood

Wessels and Huss [88] studied the use of protective cultures as inhibitors of *L. monocytogenes* in lightly preserved fish products. Co-culture of the pathogen with a nisin-producing strain of *Lactococcus lactis* subsp. *lactis* at 30°C resulted in a decline of the pathogen from 5×10^5 to <5 CFU/ml within 31 hours. However, when the protective culture was inoculated on slices of commercial cold-smoked salmon stored at 10°C for 21 days, no net growth was detectable. Despite this lack of evidence for in situ proliferation of the protective culture, on cold-smoked salmon slices co-inoculated with *L. monocytogenes* (10^4 CFU/g) and the protective culture (3×10^6 CFU/g), the population of the pathogen declined by a half log cycle during the first 15 days, then increased at a rate slightly lower than that of the control not inoculated with the lactococcus. Although a complete reduction of the pathogen was not achieved, the experiments proved the point that control of proliferation was feasible under practical conditions.

The use of bacteriocins from LAB for the preservation of brined shrimps, which are usually protected from microbial deterioration by addition of sorbic or benzoic acid, was tested by Einarsson and Lauzon [89]. Three different bacteriocins were evaluated (nisin Z, carnocin U149, and bavaricin A) for their biopreservative potency. With nisin Z, the most effective bacteriocin, a delay in bacterial growth was observed that resulted in an extension of the shelf life by 21 days (from 10 to 31 days). The strongest preservative effect was found with sodium benzoate and potassium sorbate, which completely inhibited microbial growth for 59 days when added to the brined shrimps at levels of 0.05–0.1% (w/w). In a recent overview paper, Huss et al. [35] presented an update on biopreservation used with fish products as they discussed a range of relevant topics: biopreservation as a full or partial alternative to salt or chemical additives, protective cultures and their characteristics, selection of protective cultures, and limitations to the application of protective cultures.

18.4.1.3 Dairy Products

To control the growth of clostridia in cheese spreads, which cause the "late blowing" of the product (a combination of gas formation and butyric acid production), Zottola et al. [90] proposed adding nisin-producing lactococci. Many clostridia are sensitive to nisin, and the use of the protective culture resulted in a significant extension of the shelf life of the product. Specifically, spoilage by *Clostridium sporogenes* was reduced in the nisin-containing cheese spreads.

Contamination by *L. monocytogenes* can also cause problems in the production of cheeses, especially in products such as the Italian cheeses Taleggio, Gorgonzola, and mozzarella, in which the pH rises during ripening and maturation. Giraffa et al. [91] showed that *Enterococcus faecium* added during the manufacture of Taleggio cheese releases a stable, antilisterial bacteriocin. An advantage of the rather narrow activity spectrum of bacteriocins from LAB is apparent from this study: the pathogen was suppressed by the added protective culture, whereas the activity of the thermophilic starter used in the cheese-making process was not affected.

Stecchini et al. [92] investigated the control of postprocess contamination of mozzarella cheeses by bacteriocin-producing strains of *Lactococcus lactis*. They observed that heat-treated cultures of such strains added to mozzarella cheese inoculated with *L. monocytogenes* and packaged in small bags resulted in a decrease in the initial counts of *Listeria*. *Listeria* counts remained significantly below those of the samples prepared without the addition of biopreservatives during a storage period of 2–3 weeks at 5°C.

Giraffa [72] presented a concise state-of-the-art review of the use of biological preservation with dairy products. In this overview, practical applications of protective cultures of LAB to increase the hygienic level of dairy products were reported as well as sensitivity of pathogens during the cheese-making process, survival of pathogens (i.e., *Listeria*) in cheese, cheese made with raw milk, and antimicrobial metabolites of LAB with emphasis on bacteriocins. The author concludes that biological preservation cannot replace good manufacturing practice (GMP) but offers an additional tool for improving food quality.

18.4.1.4 Vegetable Products

Bacteriocin-producing LAB also show potential for the biopreservation of foods of plant origin, especially minimally processed foods such as prepackaged mixed salads and fermented vegetables. Vescovo et al. [93] observed a reduction of the high initial bacterial loads of ready-to-use mixed salads when bacteriocin-producing LAB were added to the salad mixtures. Furthermore, bacteriocin-producing starter cultures may be useful in the fermentation of sauerkraut [94, 95] or olives to prevent the growth of spoilage organisms. In the fermentation of Spanish-style green olives, a bacteriocin-producing strain of *Lactobacillus plantarum* dominated the indigenous LAB without adversely affecting the organoleptic properties of the product [96]. In contrast, a non-bacteriocin-producing variant of this strain was outnumbered by the natural *Lactobacillus* population.

From studies of Cerny and Hennlich [97] on the use of LAB as protective cultures in potato salad to control food poisoning by salmonellae and toxin-producing staphylococci or clostridia, several prospects became evident. In mayonnaise-based potato salads with pH values of 5.5–6.0 that were exposed to ambient temperatures for up to one week, the protective cultures greatly reduced the hygienic risks, although they did not increase the shelf life of those products.

Hennlich [98] reported on the selection and evaluation of LAB isolated from potato salads as protective cultures for chilled delicatessen salads, assuming that they were well adapted ecologically. Important criteria for selection were minimum growth temperature, rate of acidification at refrigeration temperature, and rapid growth and acid formation at

abuse temperature (mimicking interruption of the cold chain). These criteria were adequately met by *L. casei* ILV 110 and *L. plantarum* ILV 3. When used as protective cultures (10^4 CFU/g minimum), these strains inhibited the normal spoilage flora of delicatessen salads and also suppressed growth of *E. coli* and *C. sporogenes* inoculated into meat salads during storage at chill temperature. One of the isolates, *L. plantarum* ILV 3, was found to be suitable as a protective culture for weakly acidic delicatessen salads (pH 5.0–6.0) as well.

Cerny [99] studied the inhibitory effect of a range of lactic LAB (*Leuconostoc cremoris*, *L. lactis* var. *diacetylis*, *L. lactis* subsp. *lactis*, *L. lactis* subsp. *cremoris*, and *Lactobacillus casei*) on the growth of several indicator microorganisms (*E. coli, Staphylococcus saprophyticus,* and *C. sporogenes*) in mayonnaise-based meat and potato salads (pH 5.5–6.5; prepared using pasteurized ingredients to eliminate endogenous LAB). It was found that addition of *L. cremoris* as a protective culture to potato salad completely controlled *E. coli* and *C. sporogenes* growth at room temp. *L. lactis* subsp. *lactis* (inoculation level 10^3–10^6 CFU/g) suppressed *E. coli* (10^2–10^4 CFU/g) in meat salad stored at room temperature. Importantly, it was concluded that the best protective effects were observed when the ratio of *L. lactis* subsp. *lactis* to *E. coli* was greater than 10:1.

18.4.2 Bacteriocins Produced by Lactic Acid Bacteria

Bacteriocins are small proteins produced by many bacterial genera, including lactic acid bacteria. Most of the bacteriocins produced by LAB inhibit the growth of other lactic acid bacteria, but some are bactericidal to a number of food pathogens and food-spoilage bacteria. In all cases, these other bacteria are gram-positive. Thus, the bacteriocins or their producers can probably not be used as a general safety hurdle, but could still be used to form a specific hurdle to suppress the growth of notorious gram-positive pathogens such as *L. monocytogenes, C. botulinum,* and *B. cereus.*

Although many different bacteriocins have currently been identified and their potential use as food preservatives is apparent, the exploitation in current practice is limited to two bacteriocins: nisin and pediocin. The limited exploitation of bacteriocins is mainly due to the rather small bactericidal range of most bacteriocins, their low efficiency of production, their limited stability in the food matrix, and, overall, their disputed regulatory status. In fact, considering the limitations to practical application, only a few of the new bacteriocins have sufficiently favorable assets in comparison to nisin and pediocin that would warrant the effort of pursuing implementation in practice. Nevertheless, despite the increasing doubt about the safety of traditional chemical preservatives such as nitrite and propionate fuels, the revival of interest seen in applied research today is aimed at the introduction of natural preservative factors such as the bacteriocins.

Ever since the identification of the inhibitory activity of a strain of *Lactococcus lactis* subsp. *lactis* in 1928, LAB have been increasingly scrutinized by bacteriocin production.

TABLE 18.2
Foods and Beverages in Which Bacteriocin Nisin Has Been Used

Food Product	Function or Use
Swiss-type cheese	Prevention of blowing faults caused by clostridia
Milk	Extension of shelf life
Tomato juice	Allows lower heat-processing requirements
Canned foods	Control of flat sour caused by thermophilic spoilage bacteria
Sauerkraut	Optimizing starter function by improving competitiveness
Beer	Inhibition of spoilage by lactic acid bacteria
Wine	Control of spoilage by lactic acid bacteria

Source: Farag et al. [42].

The inhibitory agent was later termed nisin, the first known and most extensively studied bacteriocin of LAB. Table 18.2 lists some of the potential applications of nisin. Today, more than 30 different bacteriocins produced by some 17 species of lactic acid bacteria have been identified, and much information has been obtained on the biochemistry and range of bactericidal activity. For food preservation, advantageous features of several bacteriocins are their relatively high heat resistance and inhibition of gram-positive food-borne pathogens and spoilage organisms. Much attention has been given to the inhibition of *L. monocytogenes.* This cold-tolerant bacterium, which can result in a high mortality rate, occurs in many different foods, causing problems specifically in dairy (soft cheeses) and meat (pate, sausages) products. Also, the bactericidal impact of several bacteriocins on spore-forming bacteria, such as *Bacillus* and *Clostridium* species, has been the subject of research for many decades and indicates the greater potential these bacteriocins could have in food preservation. In the following, a brief overview of the research on three interesting bacteriocins is presented with data taken from a variety of sources [65–67, 70, 77, 100–103].

18.4.2.1 Nisin

Nisin is a protein consisting of 34 amino acids, which is stable to autoclaving and effectively inhibits growth of important gram-positive foodborne pathogens like *L. monocytogenes* and *S. aureus,* and prevents outgrowth of spores of many species of *Clostridium* and *Bacillus.* It is especially active in acidic food matrices. The bacteriocin is produced by some strains of *Lactococcus lactis* subsp. *lactis*, although different strains may produce structural variants deviating slightly in exact amino acid composition. Originally nisin was considered for use as an antibiotic, but because its range of inhibition is limited, it was not judged suitable for therapeutic use. However, nisin is completely degraded in the alimentary tract and it therefore can be used safely as a food additive. Its potential use as a food preservative was first demonstrated through the successful employment of nisin-producing cultures in the

manufacture of Swiss-type cheeses. Due to their inhibition of gas-producing clostridia, blowing of the cheeses is prevented. Although vegetative cells of these organisms are killed or reduced in number by normal processing conditions, the heat-resistant spores require an excessive "botulinum cook" or the use of chemical additives to prevent their outgrowth. Nisin may be used as a natural additive to inhibit spore outgrowth or reduce their heat resistance.

Nisin has been used in conjunction with other preservative measures to enhance product safety or quality. In canned foods such as vegetables, soups, and puddings, nisin has been applied in conjunction with heating to successfully counteract heat-resistant spores of flat-sour thermophilic bacteria. Normal heating and nisin may be combined for milk production in countries where pasteurization, refrigeration, and transportation facilities are not adequate and where it is difficult to ensure the supply of good quality milk to the public. When nisin is used with acetic, lactic, or citric acid, the effectiveness of blanching and pasteurization treatments may be better than with nisin or the organic acids alone. The use of nisin in combination with nitrite in meat products has been frequently reported. Although the combined application may allow for less nitrite to exert an identical degree of inhibition of clostridia compared to nitrite alone, the meat systems seem to strongly influence the effectiveness of nisin. Inhibition of *L. monocytogenes* in raw meat, for instance, may continue for 2 weeks at 5°C, but both the inhibitory effect and the nisin-related activity rapidly diminish at room temperature. Comparable findings hold for clostridia suppression in bacon and sausages. Conceivably, binding of nisin to meat particles and high salt concentration may reduce the amount of nisin in solution where it may be active.

18.4.2.2 Pediocin

Pediocins are bacteriocins produced by LAB of the genus *Pediococcus.* The first report on pediocin production dates back to 1975, when it was found that *Pediococcus pentosaceus* inhibited growth and acid production of *Lactobacillus plantarum,* an undesirable competitor in mixed-brine cucumber fermentation. The active agent, designated as pediocin A, inhibited a broad range of LAB as well as several clostridia, *S. aureus*, and *B. cereus.* The finding implied that pediocin production might be a favorable asset of starter cultures in the fermentation of sausages and vegetables, where reported staphylococci and naturally competing LAB are the major concern, respectively.

Several applications of pediocins have been assessed with regard to food safety. Pediocin PA-1, produced by a strain of *Pediococcus acidilactici,* has been shown to inhibit growth of *L. monocytogenes* inoculated into cottage cheese, half-and-half cream, and cheese sauce for 1 week at 4°C, whereas rapid growth to high cell densities was observed in the control samples (no bacteriocin added). The activity of pediocin PA-l was not affected by fat or proteins present in the foods, while a synergistic action was noted between the effect of the bacteriocin and lactic acid. Extensive tests have shown that this pediocin is nontoxic, nonimmunogenic, and readily hydrolyzed by gastric enzymes. The potent antilisterial activity and the effectiveness of pediocin AcH and other pediocins as biopreservatives has by now been well established experimentally in beef wieners, semidry sausage, frankfurters, and fresh meat.

18.4.2.3 Sakacin

Sakacins, a group of bacteriocins produced by *Lactobacillus sake*, owe their discovery to the intensive search for natural antimicrobial compounds capable of increasing the shelf life of raw meat by inhibiting growth of meat-spoilage microorganisms and controlling *L. monocytogenes.* Several different antimicrobials are known to be produced by strains of *L. sake,* which normally reside on meat products. These strains are well adapted to the conditions in meats and conceivably are the best competitors in this food environment.

Lactocin S, produced by strain *L. sake* 45 isolated from naturally fermented sausage, is inhibitory against a range of LAB, including organisms from the same sausages. A similar bacteriocin is produced by a strain of *L. sake* isolated from Spanish thy sausages. However, the bactericidal range of this compound is much wider, including LAB and several gram-positive foodborne pathogens, e.g., *L. monocytogenes*, *S. aureus*, *C. botulinum*, or *C. sporogenes.*

18.4.2.4 Other Bacteriocins and Combined Treatments

Most other bacteriocins identified are interesting mainly from a food-quality point of view, since their bactericidal activity is directed toward closely related LAB only. The impact of this in the quality of starter cultures has been mentioned before. Bacteriocin-producing strains of *Lactobacillus helveticus* (producing helveticins and lactocins), *Lactobacillus acidophilus* (lactacins, acidophilucin), and *Lactobacillus plantarum* (plantaricins, plantacin) have been most extensively studied in this respect. With regard to food safety, the reported inhibition of *C. botulinum* and even the gram-negative *A. hydrophila* by plantacin BN-producing strains of *L. plantarum* is very noteworthy.

Several members of the genus *Carnobacterium,* a group of LAB that have been found in large numbers in chilled meat products, have been found to produce bacteriocins (carnocins) or bacteriocin-like compounds in relatively high amounts at chill temperatures, which would give them a favorable competitive edge over psychrotrophic foodborne pathogens and spoilage organisms. Again, the bactericidal range is restricted mainly to the closely related LAB, but inhibition of *L. monocytogenes* and *A. hydrophila* has been reported too.

Although gram-negative bacteria, yeasts, and molds are in general not sensitive to the action of bacteriocins from LAB, the presence of chelating agents, surfactants, or osmotic shock (high salt) may sensitize them. A combined preservation scheme would be advantageous here, as shown by Stevens et al. [104] for several combination treatments with nisin that inactivate *Salmonella* and other gram-negative species. Other reports highlighted the specific benefits of combining nisin with EDTA [105], citrate [106], lysozyme and citric acid [107], pediocin [108], and siderophores [109] in improving the

inhibitory activity of nisin toward gram-negatives or even in extending its inhibitory spectrum to cover gram-negatives.

18.4.3 Natural Occurrence of Bacteriocin Producers

Lactic acid bacteria naturally occur on many different foods (e.g., fruits and vegetables) or are used often in their production. Much research in the recent past has been devoted to tracing bacteriocin-producing LAB in fresh and fermented food products. Although the methods used were not always standardized, it is generally accepted that only a very small number of isolates obtained from food products are able to produce bacteriocins and that the spectrum of inhibition is highly variable. Vaughan et al. [110], for instance, evaluated LAB isolated from cheese, milk, meat, fruits, and vegetables for bacteriocin production targeted at a number of spoilage and pathogenic bacteria. Approximately 1000 isolates from each of the food categories were tested to inhibit *Staphylococcus aureus*, *Listeria innocua*, and *Pseudomonas fragi*. LAB isolated from cheese, milk, and meat samples inhibited *L. innocua* rather than the other target strains. LAB isolated from vegetable material generally inhibited S. *aureus*. The majority of active strains were effective against only one of the indicators, but a few were inhibitory to two or three of the target microorganisms. In our own laboratory, only 9 out of 890 isolates taken from fresh and modified-atmosphere-stored vegetables were found to be bacteriocinogenic [111, 112]. This indicates that indeed only a small part of the total population of LAB has this ability. Investigations into the capacity of different strains of *L. lactis* subsp. *lactis* present in different culture collections throughout the world to produce nisin have shown that there is drastic difference in this respect even between isolates of the same subspecies.

18.4.4 Application of Bacteriocins and Bacteriocin-Producing Cultures

Bacteriocins can be applied to food systems by three basic methods [62]. First, a pure culture of the viable bacteriocin-producing LAB can be applied, which offers an indirect way to incorporate bacteriocins in a food product. The success of this type of application depends on the ability of the bacteriocin-producing LAB to grow and produce the bacteriocin to the required extent in the food under the prevailing environmental conditions (temperature, pH, etc.). Second, a (semi-) purified preparation of the bacteriocin can be employed. In this way, the dosage of the bacteriocin can be most accurate and thus its effect most predictable. However, application of (semi-)purified preparations is limited by national regulations concerning food additives. Finally, a crude bacteriocin preparation is obtained by growing the bacteriocin-producing LAB on a complex, natural substrate (e.g., milk). This mode avoids the use of a purified compound while still being able to use a preparation of known and constant activity. This latter method is now employed for the industrial-scale production of nisin preparations. A nisin-producing LAB is grown in milk whey at optimal temperature. During the course of incubation, nisin is expelled into the substrate. At a sufficiently high level, the substrate is pasteurized, which kills the bacteria but does not affect the heat-stable nisin.

A suitable application system for natural antimicrobials of microbial origin was recently developed for the control of *L. monocytogenes* on minimally processed vegetables [111, 112]. This study set out with the concept that a suitable protective culture, in order to grow well and produce sufficient amounts of the bacteriocin, should be well adapted to the ecosystem it is used in and therefore might best be obtained from the food product considered. LAB occur on most if not all minimally processed vegetables, although they generally account for only about 1% of the natural microflora. To identify bacteriocin-producing LAB, 890 LAB isolates were obtained from different fresh and modified-atmosphere-stored vegetables and screened for their ability to produce bacteriocins [111, 112]. Only nine isolates were found that could adequately control *L. monocytogenes* on artificial growth media. Three isolates were found to have the required characteristics: one strain of *Enterococcus mundtii* and two strains of *Pediococcus parvulus*. Both types produced a bacteriocin that effectively controlled growth of *L. monocytogenes* in *in vitro* studies [111, 112]. Both pediococci, however, only produced significant amounts of bacteriocin at temperatures over 15°C and were not really suited for any application at lower temperature. The bacteriocin produced by both strains was fully identified and characterized, and appeared to be identical to pediocin PA-1, formerly only known to be produced by *Pediococcus acidilactici* [111]. *E. mundtii* produced significant amounts of a bacteriocin even at 4–10°C [113]. Thus, although it is not a LAB and does not have GRAS status, the organism is very suitable to test whether biopreservation can be the required safety hurdle for certain psychrotrophic pathogens. On laboratory media (sterile vegetable extract in agar) the application of the mundticin producer as a protective culture at 8°C was very promising (Figure 18.4a). However, on fresh, nonsterile produce, no activity was found. Either the production of mundticin on produce at low temperature is not sufficient or the mundticin is inactivated after production (enzymatic inactivation, adsorption to produce). Since the application of partially purified bacteriocin was found to significantly delay the growth of *L. monocytogenes,* the inactivation may not be the most prominent problem. Although the direct application of *E. mundtii* on mung bean sprouts was not effective in reducing the initial viable count of *L. monocytogenes* or its growth potential, a decline of 2 log units in the initial numbers was achieved when the produce was dipped in a solution of mundticin prior to contamination with the pathogen (Figure 18.4b). Identical results were obtained when the product was treated with a mundticin-containing alginate film. The increase of the viable count of the pathogen after 5 days may, again, be attributed to proteolytic degradation and growth of part of the *Listeria* population that was not affected by the intact mundticin. Noteworthy is that the counts of the pathogen did not exceed the initial inoculation level for approximately 8 days. Thus, the use of food-approved bacteriocins in a dipping

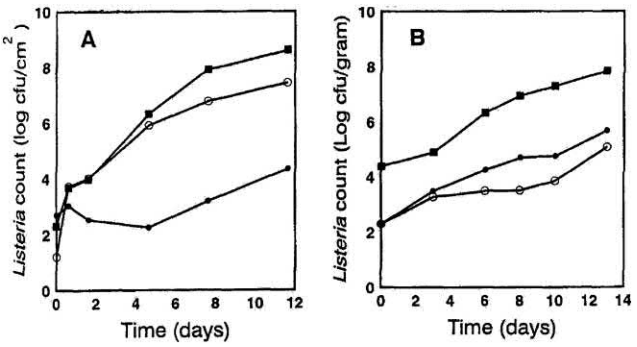

FIGURE 18.4 (A) Growth of *L. monocytogenes* (1:1 mix of strain LDCD681 and strain LDCD1087) on vegetable agar medium in the absence of *E. mundtii* (■), co-cultured with the bacteriocinogenic *E. mundtii* (●), or co-cultured with the bacteriocinogenic *E. mundtii* DSM3848 (o), using initial *E. mundtii* levels of 10^6 cfu/cm^2. Incubations were performed at 8°C under a constant flow of 1.5% O_2 and 20% CO_2, balanced with N_2. (B) Growth of *L. monocytogenes* on mung bean spouts after treatment with purified bacteriocin of *E. mundtii*. The product was dipped in sterile water (■), dipped in sterile water containing 200 BU/ml of mundticin (o), or coated with an alginate film containing 200 BU/ml mundticin (●). Again, incubations were performed under 1.5% O_2/20% CO_2/78.5% N_2 at 8°C. (Modified from Grayer and Harborne [10].)

solution or as part of an edible coating may have good potential as a biopreservative treatment for minimally processed vegetables.

18.5 LEGISLATIVE ASPECTS

Existing food legislation in most countries would not favor the use of natural compounds purified from their natural source, unless these compounds have genuinely acquired GRAS status. The purification process would bring green chemicals into the same category as synthetic chemical compounds, thus significantly lengthening the procedure for marketing approval and hampering economic implementation in practice. In fact, in most cases the legislative viewpoint on green chemicals or biopreservatives may be that they are new food additives or are applied for new purposes and consequently would require a nontoxicity record, despite their possible GRAS status. A more favorable form of application would thus be the inclusion of the spice or herb that contains the desired active ingredient or of the bacteriocin-producing strain in the food preparation because this still may be regarded as the most natural type of source.

The current regulatory status of bacteriocins and bacteriocin-producing organisms is a clear example of the current controversy between the use of the active compound or the natural source as a whole. In 1969, a joint FAO/WHO expert committee accepted nisin as a legal food additive, although it was not until 1988 that it was approved by the U.S. Food and Drug Administration (FDA) for use in certain pasteurized cheese spreads. Presently nisin is permitted in at least 50 countries for the inhibition of clostridia in cheese and canned foods. None of the other bacteriocins known to date has a fully approved legal status as a food additive, although also the application of a pediocin-producing strain of *P. acidilactici* has been approved by the U.S. Department of Agriculture (USDA) for use in reduced-nitrite bacon to aid in the prevention of botulinum toxin production by outgrowth of *C. botulinum* spores. The regulation of bacteriocin preparations from LAB stands in sharp contrast to the common use of these organisms as starter cultures. Moreover, LAB are commonly consumed in high numbers in fermented or cultured products, and are often present as indigenous contaminants in many retail products. The general conception would be that the introduction of bacteriocins in foods at levels analogous to those capable of being produced by starter cultures should be as safe as the consumption of the cultured products themselves.

18.6 FUTURE OUTLOOK

Food preservation by natural means has become a major challenge for food-manufacturing industries of all sizes and is dictated by the changes in consumers' attitudes in recent years toward chemical preservatives. All foods can be processed to extremes using physical methods that render them sterile and thus microbiologically safe. However, such foods would be unmarketable because consumers favor foods that are "natural" and "as good as fresh" because they associate such products with a healthy diet. Current research trends in food microbiology and food technology focus on mild physical preservation techniques and the use of natural antimicrobial compounds.

Food preservatives of natural origin are generally considered as potential, safe sources of antimicrobials, but their effective use in practice has been established in only a few cases. Any antimicrobial extract or purified compound from a natural source will have to undergo tough toxicological scrutiny whenever its safe use is not guaranteed by well-documented data. Toxicological data for natural antimicrobials are often lacking and are as expensive to assemble as data for chemical compounds. The economy of changing from the range of still available synthetic chemicals to green chemicals will dictate whether commercialization is feasible at all. In many countries legislation has been passed to achieve significant reductions—in some cases even a total elimination—of chemical preservatives within the next decade. As may follow from the data briefly reviewed in this chapter, research and technological development (RTD) institutions and food industries have identified a good number of possibilities for natural antimicrobials for future food preservation. However, successful marketing relies heavily on proper communication between industries, governments, and consumers. Negotiating marketing with legislative bodies up to now has been mainly on a national level, which poses a major stumbling block to the introduction of natural alternatives. The cost for industries of obtaining legislative approval for marketing are relatively high and to date have not specifically encouraged the search for natural alternatives. This increase in legislative pressure toward nonchemical strategies may favor their economic odds, but it could be even more helpful if the procedures of

approval were accelerated on a worldwide scale in favor of natural antimicrobial compounds.

19 Antioxidants in Food Preservation

Afaf Kamal-Eldin and Jan Pokorny

CONTENTS

19.1 INTRODUCTION

Many chemical reactions proceed in foods during storage and affect their sensory quality and/or nutritional value. The main chemical reactions of interest from this point of view include fermentation, Maillard, and lipid oxidation reactions. Rancidity is used as a collective term to describe objectionable sensory attributes in foods resulting from lipid oxidation reactions [1]. In the preindustrial period, food materials were used for immediate food consumption, and food products were usually consumed within a few hours or days. The rancidity of durable products, such as nuts, flour, lard, or olive oil, was considered normal and was dealt with variably in households. With industrialization and storage of food products for days or months before consumption, processes leading to food deterioration become substantially more important. Rancidity is observed in different foods as discussed in the book *Rancidity in Foods* [1].

Rancidity is observed as objectionable flavor in, for example, stored nuts [2, 3] and biscuits [4, 5], as oxidized off-flavor in milk and milk products [6, 7], and warmed off-flavor in meat products [8, 9]. It results from the free radical oxidation of the polyunsaturated fatty acids and their interactions with proteins and amino acids in the foods [10]. Most susceptible to rancidity are essential fatty acids that do not only lose their physiological activity by autoxidation but may turn into non-nutritive agents when highly oxidized (e.g., in frying oils). Rancidity may lead to reduced levels of vitamins, such as vitamin E, vitamin C, and vitamin A or its carotene provitamins [11]. Lipid oxidation and rancidity may be inhibited by a wide range of antioxidants and synergists, as will be discussed in detail later in this chapter. Certain lipid oxidation products, such as cyclic dimers/polymers and aldehydes, may pose direct toxicity. In addition, hydroperoxides and ketones may react with primary amine groups of amino acids/proteins, and some B vitamins decreasing their biological value [2].

Research in the 20th century established the chemical basis for lipid oxidation reactions and their inhibitory mechanisms, but many details related to antioxidant protection remained paradoxical. After a breakthrough review of the problems by William Porter in 1993 [12], realization of the important role of the physical state of the oxidation reaction environment and the negative effects of increased antioxidant concentrations started to emerge. Porter observed that polar antioxidants are more active in oily environments, whereas non-polar antioxidants are more active in watery emulsions. In the same year, Ulla Brimberg performed kinetic analysis of lipid oxidation data in different media and concluded that lipid oxidation is catalyzed by hydroperoxide-loaded micelles [12–15]. Unfortunately, her papers were not noticed, possibly because her work was presented in a non-conventional way. In 1994, Edwin Frankel and coworkers suggested the interfacial phenomenon as an explanation of the polar paradox, but considered the interface as that between oil and air [16, 17]. Becker, Ntouma, and Skibsted [18] and the group of Eric Dekker [19–24] further refined the interfacial concept, considered the involvement of association colloids, and highlighted the importance of colloidal interfaces. Berton-Carabin et al. [25] reviewed the involvement of the interfacial layer in the oxidation of oil-in-water emulsions. Thus, lipid oxidation follows the roles of supramolecular chemistry where molecular organization is a decisive factor for stabilization by antioxidants [26]. With this paradigm shift in our understanding [27], new possibilities for food preservation technologies are emerging.

19.2 TYPES OF RANCIDITY IN FOODS

Rancidity describes the objectionable defects in food quality manifested as changes in odor or flavor leading to a significant deterioration of the sensory quality that might lead to rejection of the food [1]. Rancidity may include several types of reactions, but the degradation due to changes in lipid components is considered the main feature of rancidification [1]. The most important types of rancidity are summarized in Table 19.1.

Lipolytic rancidity is mainly caused by the cleaving action of lipases (triacylglycerol-acyl hydrolases, EC 3.1.1.3) on triacylglycerols to yield free fatty acids and partial glycerol esters, i.e., mono- and diacylglycerols. The release of small amounts of free fatty acids is often not perceptible by human senses as flavor deterioration, but release of higher amounts may be perceived as sourness, e.g., in crude vegetable oils. Milk fat is one exception because small amounts of free butyric acid impart a typical disagreeable off-flavor such as that encountered in rancid butter [28]. Similarly, caproic, caprylic, and capric acids released by the lipolysis of seed oils of palms (Palmaceae, such as coconut or palm kernel oils) result in a soapy off-flavor. The soapy flavor, frequently observed in stored food products containing coconut, is not only due to soap but to all derivatives (free fatty acids, methyl or ethyl esters) having a hydrocarbon chain of 6–10 carbon atoms. There is a link between lipolytic and oxidative rancidity because free fatty acids have higher oxidation rates than esterified fatty acids [29, 30].

Oxidative rancidity, resulting from the oxidation of unsaturated fatty acids, is the most important type of food rancidity that is inhibited by antioxidants. The primary oxidation products are typically lipid hydroperoxides, which degrade to low and high molecular weight secondary oxidation products. Volatile oxidation products possessing 3–12 carbon atoms, including aldehydes, ketones, alcohols, short-chain acids, and hydrocarbons, are responsible for the sensory perception of rancidity. A very low level of rancidity is not perceived by most consumers and it might sometimes make the flavor richer and more acceptable. Virgin olive oil or frying oils are typical examples of products where minute amounts of oxidation products are desirable but higher amounts are objectionable. Rancidity is a very complex phenomenon, and rancid foods may be described as, for example, old, warmed-over, cardboard, wet dog, or dumpy. Small amounts of oxidation products of polyunsaturated fatty acids impart a fried flavor to food [31]. Higher amounts of the same compounds may cause the perception of burned flavor. Rancidity may be controlled by decreasing the storage temperature, the access of oxygen, and the degree of unsaturation of the lipid fraction. When application of the aforementioned methods is not possible or satisfactory, the best way to control rancidity is with the addition of antioxidants. The oxidative rancidity is the central topic of this chapter, which discusses its mechanisms, implications, and inhibition by antioxidants.

Flavor reversion, typical for soybean oil, is a type of rancidity that appears during storage of fully refined, bland soybean oils and imparts a "beany" off-flavor to the product. It results after minute absorption of singlet oxygen by the oil leading to the formation of specific oxidation products containing furan groups. Ketonic rancidity, with a characteristic floral off-flavor, is sometimes observed during the storage of foods containing short- or medium-chain (4–10 carbon atoms) fatty acids, such as those containing milk fat or coconut oil [32]. Ketonic rancidity is caused by microbial oxidation of medium-chain fatty acids into the respective alkan-2-ones or methyl ketones [33]. This flavor in objectionable in butter, but it is characteristic of blue cheese aroma.

19.3 KINETICS AND MECHANISMS OF OXIDATIVE RANCIDITY

Lipid oxidation involves the deteriorative change of polyunsaturated fatty acids and other unsaturated lipid substrates (e.g., sterols, carotenoids) into hydroperoxides and the subsequent decomposition of these hydroperoxides into a wide range of secondary oxidation products [34, 35].

$$LH + O_2 \rightarrow LOOH \tag{19.1}$$

$$LOOH \rightarrow \text{Secondary oxidation products} \tag{19.2}$$

The oxidation of LH by oxygen, called autoxidation, is a free radical chain reaction consisting of three main phases,

TABLE 19.1
Types of Rancidity Occurring in Fats, Oils, and Fatty Acids

Types of Rancidity	Main Substances Producing Rancidity	Types of Chemical Reaction	Foods Subject to This Type of Rancidity
Lipolytic	Low fatty acids, medium-chain fatty acids	Enzymic hydrolysis	Milk fat, palm seed oils
Oxidative	Lower aldehydes and ketones	Autoxidation, enzymic oxidation	Foods containing polyunsaturated fatty acids
Flavor reversion	Oxygen-substituted cleavage and rearrangement products	Oxidation, cleavage, and rearrangement	Soybean oil
Ketonic	2-Alkanones (methyl ketones)	β-Oxidation and enzymic decarboxylation	Milk fat, palm seed oils

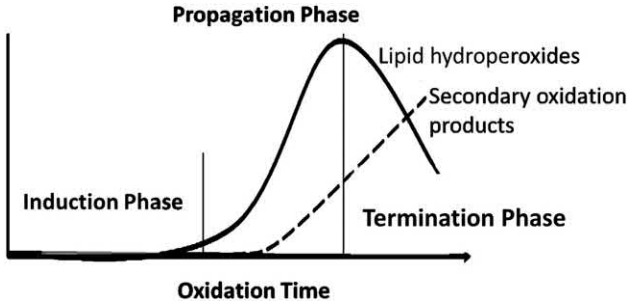

FIGURE 19.1 Typical lipid oxidation scheme for the evolution of hydroperoxides and secondary oxidation products consisting of three phases: initiation, propagation, and termination. The x-axis is the oxidation time and the y-axis is any indicator of change related to a concerned product.

namely, initiation, propagation, and termination [36, 37]. A typical kinetic curve describing the lipid oxidation cascade is shown in Figure 19.1.

19.3.1 The Initiation Phase or Induction Period

The initiation of the lipid oxidation reaction is not yet exactly understood, but depending on the catalyst(s) involved, oxidation is slow during an induction period (or a lag phase). During this stage, the reaction rate follows a first or pseudo-first order with respect to lipid hydroperoxides. It is assumed that lipid oxidation is initiated by a *discrete reaction* between an unsaturated lipid and an oxidant ($X^{\bullet}$) leading to the formation of the first alkyl radicals ($L^{\bullet}$) that immediately unite with oxygen to form hydroperoxyl radicals:

$$LH + X^{\bullet} \rightarrow L^{\bullet} + XH \quad (19.3)$$

$$L^{\bullet} + O_2 \rightarrow LOO^{\bullet} \quad (19.4)$$

A hydrogen atom from the methylene group between two double bonds (*bis-allylic hydrogen*, -CH=CH-C**H**$_2$-CH=CH-), as is present in linoleic and linolenic acids, is the primary site of dehydrogenation [36–38]. In monoenoic fatty acids, such as oleate, free radicals are formed by the abstraction of a hydrogen atom on either side of the double bond (allylic hydrogen, -C**H**$_2$-CH=CH-C**H**$_2$-) but the activation energy of this reaction is much higher than that required for the abstraction of a bis-allylic hydrogen. Initiation reactions are catalyzed by temperature, initial presence of hydroperoxides, transition metal ions, and lipoxygenase-type enzymes.

Several isoenzyme lipoxygenases (linoleate oxidoreductases, E.C. 1.13.11.12) and lipoxygenase-like activities in foods directly catalyze the oxidation of linoleic, linolenic, and structurally related fatty acids and produce hydroperoxides with specific stereo- and positional selectivity by Reaction 19.1 [39, 40]. In foods and other biological materials, lipoxygenases are commonly accompanied by respective lyases, which cleave hydroperoxides into different low molecular weight compounds. The presence of transition metal ions catalyzes the decomposition of hydroperoxides into two free radicals that will initiate further reaction chains. Therefore, traces of copper and iron, and to lesser degree manganese and cobalt, are important promoters of lipid oxidation.

It has been accepted that the end of the induction period is reached when the antioxidant concentration is diminished and the quantity of formed hydroperoxides reaches a critical micelle concentration (cmc) dependent on the composition and characteristics of the lipid milieu [13–15, 41, 42]. When this cmc is reached, there is enough concentration of lipid hydroperoxide molecules to promote oxidation by degenerate branching with lipids (monomolecular) or between themselves (bimolecular):

$$LOOH + LH \rightarrow LOO^{\bullet} + L^{\bullet} + H_2O \quad (\text{Monomolecular}) \quad (19.5)$$

$$LOOH + LOOH \rightarrow LOO^{\bullet} + LO^{\bullet} + H_2O \quad (\text{Bimolecular}) \quad (19.6)$$

The bimolecular reactions predominate at the end of the induction period. The peroxyl and alkoxyl free radicals formed by these degenerate branching of lipid hydroperoxide molecules react with unsaturated fatty acids initiating new reaction chains. The duration of the induction period is determined by the degree of unsaturation of lipid substrates, the temperature, and the presence and nature of prooxidants, primary antioxidants (phenolic compounds), and a wide range of antioxidant synergists, as will be discussed later.

Fats, oils, and lipid-rich foods, which turn rancid by oxidation, are mostly oxidized by air oxygen, which penetrates foods and is dissolved in both aqueous and lipid phases. If the reaction is catalyzed by enzymes, the oxidant is still air oxygen. Other oxidants (Table 19.2) are of minor importance. In the presence of photosensibilizers (such as chlorophylls) and light, ordinary triplet oxygen is converted to a singlet oxygen (Figure 19.2), which is 100–300 times more reactive [43, 44]. A singlet oxygen molecule is directly added to a double bond of unsaturated lipids to produce hydroperoxides that are easily cleaved to produce initiating free radicals. Carotenoids are efficient quenchers of singlet oxygen, and with this mechanism, these can synergize the effect of tocopherols under low temperatures and low oxygen pressure [45].

19.3.2 Propagation Phase

Peroxyl radicals propagate chain reactions by abstracting bis-allylic or allylic hydrogen atoms from polyunsaturated fatty acids forming a hydroperoxide and an alkyl free radical,

TABLE 19.2
Important Oxidants in Food Products

Oxidant	Importance	Occurrence
Air (triplet) oxygen (autoxidation)	Most important in processed and stored foods	General
Enzymatically catalyzed oxidation	Stored raw materials	Oilseeds, nuts, cereals legumes
Singlet oxygen	In light and presence of sensitizers	Edible oils, green foods
Ozone	Very low in foods	Essential oils
Quinones	In foods subject to enzymic browning	Fruits, vegetables, potatoes
Metals	Initiation of free radical oxidation	Meat, fruits
Superoxide anion	Mainly in in vivo systems	Meat
Hydrogen peroxide	In presence of ascorbic acid	Fruits, vegetables
Lipid hydroperoxides	In presence of polyunsaturated acids and carotenoids	Fruits, vegetables, fatty foods

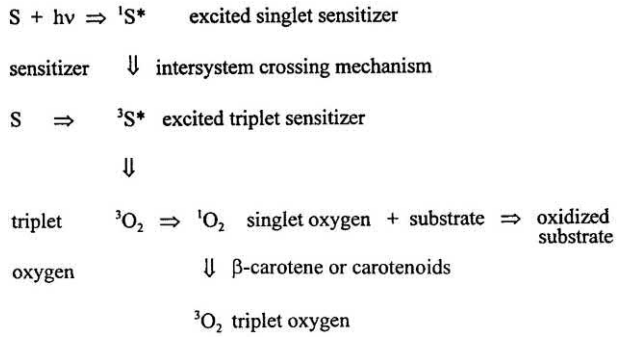

FIGURE 19.2 Generation of singlet oxygen and its quenching during photooxidation.

which easily absorb oxygen forming new peroxyl radicals by Reaction 19.4:

$$LOO^{\bullet} + LH \rightarrow LOOH + L^{\bullet} \tag{19.7}$$

This reaction sequence is repeated several times, therefore, it is called autocatalytic or chain reaction. During this reaction, the double-bond system of the original polyunsaturated fatty acid is usually isomerized into a more stable conjugated diene system. The alkoxyl radicals formed by Reaction 19.6 or by the decomposition of hydroperoxides may rearrange to epoxy alkyl radicals leading to epoxy derivatives [46, 47]:

$$LO^{\bullet} + O_2 \rightarrow (O)LOO^{\bullet} \tag{19.8}$$

During the propagation phase, the unsaturated fatty acid substrates decline and hydroperoxides are formed exponentially. This is accompanied by a significant increase in the concentrations of secondary oxidation products including long-chain hydroxy- and keto- derivatives as well as breakdown products including hydrocarbons, alcohols, aldehydes, ketones, and acids. Hydroperoxides of polyunsaturated fatty acids have no particular odor or flavor, but their decomposition volatile low molecular weight products (3–12 carbon atoms) impart the rancid off-flavor to oxidized fats and oils [48]. Those secondary oxidation products are easily oxidized in turn giving rise to lower molecular weight fatty acids and other tertiary reaction products.

19.3.3 Termination Phase

When the concentration of unsaturated lipid substrates is diminished, the chain of the propagation reaction is interrupted by the recombination of free radicals leading to the last stage of autoxidation, i.e., the termination reaction.

$$LOO^{\bullet} + LOO^{\bullet} \rightarrow \text{non-radical secondary oxidation products} \tag{19.9}$$

$$LOO^{\bullet} + LO^{\bullet} \rightarrow \text{non-radical secondary oxidation products} \tag{19.10}$$

$$LO^{\bullet} + LO^{\bullet} \rightarrow \text{non-radical secondary oxidation products} \tag{19.11}$$

Lipid polymers, mainly dimers and oligomers, are produced besides the cleavage products, but these do not substantially affect the sensory value. Diperoxides are also formed by secondary oxidation of hydroperoxides, especially in advanced reaction stages of polyunsaturated lipids at sufficient access of oxygen.

19.4 ANTIOXIDANTS AND THEIR MECHANISMS OF ACTION

In the broad sense, antioxidants (or oxidation inhibitors) are substances that can protect food and other biological materials from autoxidation by scavenging free radicals [49]. In the presence of antioxidants, the induction period is significantly prolonged as exemplified in Figure 19.3. Antioxidants may also inhibit the decomposition of lipid hydroperoxides that would, otherwise, act as free radical chain initiators [50]. In this chapter, the broader sense is applied. The most important types of antioxidants are summarized in Table 19.3. Phenolic antioxidants and their synergists are the most important representatives of these compounds in food applications [51].

Phenolic antioxidants (AH) exert their protective effects by reacting with peroxyl radicals produced in oxidized lipids forming a hydroperoxide molecule and the free radical of the antioxidant [36, 37]. Antioxidant radicals are relatively stable so that the back reaction is extremely slow. They do not initiate a chain autoxidation reaction unless present in a very large excess. They react in a similar way with an alkoxyl free radical formed during the decomposition of hydroperoxides [52].

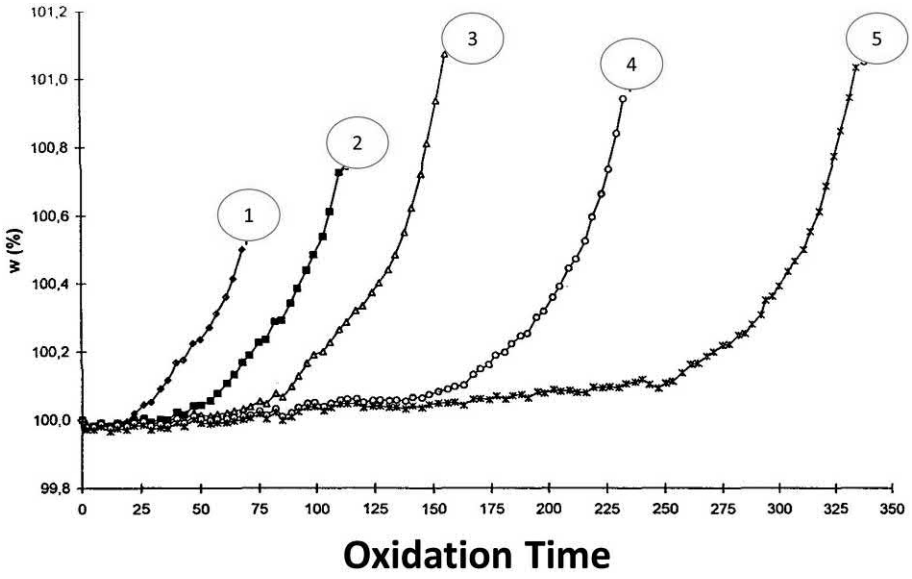

FIGURE 19.3 The course of oxidation reaction during storage of stabilized rapeseed oil stabilized with hexane rosemary extract under conditions of the Schaal oven test at 40°C. The x-axis is the storage time and the y-axis is the percent increase in weight. Curves: (1) control (without antioxidants), (2) 0.01% extract, (3) 0.02% extract, (4) 0.05% extract, and (5) 0.1% extract.

TABLE 19.3
Types of Oxidation Inhibitors (Antioxidants and Synergists)

Group of Compounds	Mechanism of Action	Example of Inhibitors
Antioxidants	Scavenging of free radicals	Tocopherols, phenolic compounds
Chelating agent	Binding heavy metals into inactive complexes	Polyphosphates, citric acid, tartaric acid, EDTA
Singlet oxygen quenchers	Quenching of singlet oxygen and its transformation into triplet oxygen	Carotenoids
Hydroperoxide deactivators	Reaction with hydroperoxides	Cysteine, selenometathione, amino acids, proteins, protein hydrolysates
Antioxidant regenerators	Regeneration of an antioxidants from their radicals	Ascorbates
Surfactants	Stabilize hydroperoxide-loaded micelles	Phospholipids

Antioxidant radicals also react with other lipid hydroperoxyl radicals by combination.

$$LOO^{\bullet} + AH \rightarrow LOOH + A^{\bullet} \quad (19.12)$$

$$LOO^{\bullet} + A^{\bullet} \rightarrow LOOA \quad (19.13)$$

Antioxidants may also stabilize lipid hydroperoxides and inhibit their decomposition into free radicals by the formation of physical bonds [50, 53]. It was shown that the presence of antioxidants, such as α-tocopherol, extends the induction period by increasing the critical micelle concentration necessary for the transition from the induction period to the propagation phase [13–15, 41, 42]. Antioxidant dimers, and even trimers/oligomers, may be formed and contribute a modest antioxidant activity of their own. Antioxidant radicals may react with a molecule of oxygen to form an antioxidant peroxyl radical, especially when both the antioxidant(s) and oxygen are present in excess. Free antioxidant radicals can also react with some labile compounds, such as terpenes, which form easily free radicals. Changes of antioxidants occur under conditions of food processing and storage, including culinary meal preparation [54].

Usually, there is an optimum antioxidant concentration for maximum stabilization of lipids [38]. When the antioxidant is present at higher concentrations than this optimum, the antioxidant and/or its radical(s) may participate in side reactions leading to loss of antioxidant efficacy [55, 56]. This loss of efficacy is manifested as an increase in the oxidation reaction rate during the induction period (increased rate of initiation) as well as faster rate of antioxidant consumption. Although the induction period might be longer due to the high antioxidant concentration, the level of hydroperoxides during the induction period is higher (Figure 19.4).

Kinetic modeling of the oxidation of methyl linoleate in the presence of α-tocopherol including 53 individual reactions was employed to reveal the reactions involved in the peroxidative effect of high concentrations of the antioxidant [57]. At least, three different reactions contributed significantly to this effect of the antioxidant:

1. Reduction of hydroperoxides by the antioxidant molecule leading to the generation of alkoxyl and antioxidant radicals:

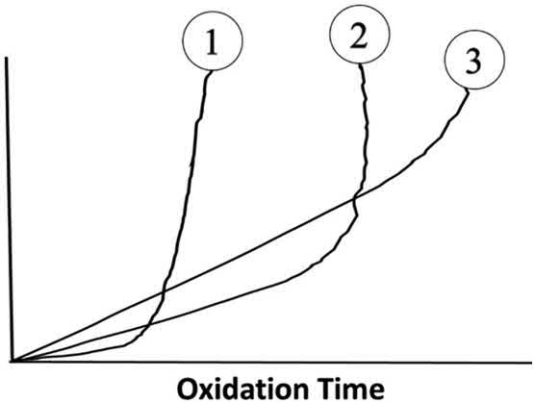

FIGURE 19.4 The effect of antioxidant concentration on its activity during the oxidation of vegetable oils. The x-axis is the storage time and the y-axis is any indicator of change related to hydroperoxide formation. Curves: (1) low antioxidant concentration (e.g., 100 ppm in sunflower oil), (2) intermediate antioxidant concentration (e.g., 500 ppm in sunflower oil), and (3) high antioxidant concentration (e.g., 1000 ppm in sunflower oil). This phenomenon is called loss of antioxidant efficacy and it is very important during the storage of foods.

$$AH + LOOH \rightarrow A^{\bullet} + LO^{\bullet} + H_2O \quad (19.14)$$

2. Abstraction of the hydrogen atom from the methyl linoleate molecule and from the methyl linoleate hydroperoxides by the tocopheroxyl radical suggested by Mukai et al. [58]:

$$A^{\bullet} + LH \rightarrow AH + L^{\bullet} \quad (19.15)$$

$$A^{\bullet} + LOOH \rightarrow AH + LOO^{\bullet} \quad (19.16)$$

3. The homolytic decomposition of quinolide peroxides, which are the combination products of the antioxidant and lipid peroxyl radicals (LOOA) formed in Reaction 19.17 to generate alkoxyl radicals:

$$LOOA \rightarrow LO^{\bullet} + AO^{\bullet} \quad (19.17)$$

The loss of tocopherol antioxidant efficacy can be manifested to a higher degree when oxidation experiments are performed at a lower temperature, i.e., at a low initiation rate [59]. It has been observed that the inhibitory effect of antioxidants on lipid oxidation reactions may be significantly potentiated and the loss of antioxidant efficacy counteracted by the presence of the antioxidant synergists. Synergists are substances that have no antioxidant activity of their own but they can increase the activity of an antioxidant. Antioxidant synergists substantiate the inhibitory effect of antioxidants via different mechanisms.

Metal ions of transient valency (such as copper, iron, cobalt, chromium, or manganese) are very active prooxidants not only in their ionic forms but also as complexes, e.g., heme derivatives and metalloproteins [60–62]. Therefore, substances that are able to bind these metals into inactive complexes can inhibit oxidation reactions of lipids. Many metal-chelating substances are present in foods as natural components, especially in plant materials. The most frequently used metal-chelating synergists include polyvalent inorganic (phosphoric acid) and organic acids (e.g., ascorbic acid and its isomer erythorbic acid or isoascorbic acid, citric and tartaric acids, and different amino acids). In order to increase its solubility in fats and oils, ascorbic acid is often esterified with higher fatty acids, such as palmitic acid. Ascorbyl palmitate is stable against oxidation on storage, but ascorbyl oleate would be better soluble in oils. Citric acid is also added as an ester, e.g., isopropyl ester. Ascorbyl palmitate is active as a synergist to tocopherols in vegetable oils and lard [63]. Citric and ascorbic acids were active inhibitors of rancidity in frozen horse mackerel, where they probably act as metal chelators [64]. Polyphosphates are added to inactivate iron in food, especially in various meat products [65]. Even some phenolic antioxidants may bind metals into complexes, e.g., quercetin. Silicon oil is often added to frying oils to inhibit degradation by protecting against the diffusion of air oxygen; the activity is, however, at least partially, attributed to prevention of dissolution of iron in oil during frying [63]. Phytates (salts of phytic acid, *myo*-inositol hexaphosphate) and oxalates are also common representatives of this group. The chelating activity depends on the pH value, water content, and other factors of the medium. Usually, metals are not completely inactivated by any agent; only their prooxidant activities decrease by at least a partial chelation. We have shown in phosphatidic acids and in pheophytins that the chelating activity is often very high. Nevertheless, it should be kept in mind that even minute traces of free metals (a small fraction not bound in complexes) are sufficient in some cases to promote autoxidation efficiently.

Singlet oxygen, which may be formed from ordinary triplet oxygen by action of light in the presence of a photosensitizer such as chlorophylls and pheophytins (Figure 19.2) or by the Russel mechanism, is a very reactive oxidant. In the presence of high concentrations of photosensitizers, the initiation rate is extremely high:

$$\underset{}{L_1OO^{\bullet} + L_2OO^{\bullet} \rightarrow} \underset{\text{Tetoxide}}{L_1OOOOL_2} \rightarrow \underset{\text{Alcohol}}{L_1OH} + \underset{\text{Ketodiene}}{L_2{=}O} + \underset{\text{Singlet oxygen}}{{}^1O_2} \quad (19.18)$$

Various substances are effective from this standpoint but in food materials, carotene and other carotenoids are the most important singlet oxygen quenchers [66]. Oxygenated carotenoids, or xanthophylls, have similar deactivating activity, even when they have no provitamin activity like that of carotenes. Tocopherols increase the activity of carotenes in this respect [67]. The structurally related vitamin A has a similar activity, but it is usually present in much smaller quantities in foodstuffs than are carotenoids. Ascorbyl palmitate is an active singlet oxygen quencher too [68]. In the presence of tocopherols, carotenoids may also prohibit low-degree

oxidation by adding free radicals and acting as radical sink because of their extended conjugated double bonds:

$$\text{Car} + (\text{LOO}^{\bullet})_n \rightarrow \text{Car-}\left(\text{LOO}\right)_n^{\bullet} \quad (19.19)$$

However, carotenoids would act as prooxidants in a rich oxygen environment [69]. Other synergists, particularly proteins, peptides, and amino acids, may operate by reducing lipid hydroperoxides into less reactive hydroxyl derivatives without the involvement of alkyl radicals [70]. Sulfur compounds are very active substances, which are mostly bound in proteins. Thiols, such as cysteine, are oxidized into cystine, which belongs to disulfides. Cystine may be further oxidized by another molecule of a hydroperoxide into sulfinic acid. Similarly sulfides, such as methionine, react with hydroperoxides, forming sulfoxides. This reaction product may react with another molecule of a hydroperoxide, resulting in the respective sulfone. Onion and garlic contain sulfur compounds possessing hydroperoxide-decomposing activity [71, 72].

$$2\text{R-SH} + \text{LOOH} \rightarrow \text{R-S-S-R} + \text{LOH} + \text{H}_2\text{O} \quad (19.20)$$

$$\text{R-S-S-R} + \text{LOOH} \rightarrow \text{R-S-O-L} + \text{R-S-OH} \quad (19.21)$$

$$\text{R-NH}_2 + \text{LOOH} \rightarrow \text{R-NH-O-L} + \text{H}_2\text{O} \quad (19.22)$$

Selenium-containing amino acids (selenocysteine or selenomethionine) present in traces in natural proteins may react in a similar way and help to retain vitamin E in the body [73]. Selenium has more importance as part of an antioxidative enzyme, selenoglutathione oxidase, inactivating free radicals and other oxidants, particularly hydrogen peroxide. In addition, lipid hydroperoxides may react with free amine groups of proteins; imines are formed from the intermediary products by subsequent dehydration. Various basic groups, such as histamine or indole, can deactivate hydroperoxides following similar mechanisms. Carnosine, a histidine dipeptide, was found to be efficient in decomposing hydroperoxides [74]. Many amino compounds can deactivate free radicals, therefore, these amino derivatives have an anticarcinogenic activity. Free amino acids are present in protein hydrolysates, which are thus active, e.g., in various meat products [75].

Ascorbic acid is a strong reducing agent (mv) capable of regenerating the tocopherol molecule (TOH) from its radical (TO•) [76].

$$\text{Ascorbates} + 2\text{TO}^{\bullet} \rightarrow \text{Dehydroascorbates} + 2\text{TOH} \quad (19.23)$$

Ubiquinine [77] and green tea catechins [78] were also shown to recycle tocopherols in a similar way to ascorbate [79]. As mentioned earlier, it has become clear that lipid oxidation reactions are highly influenced by the molecular organization of the original unsaturated lipids and the emerging hydroperoxides and other polar derivatives [12–27]. As the concentration of hydroperoxides reach the critical micelle concentration by the end of the induction period, the lipids self-assemble into reverse micelles, which enhance the rate of lipid oxidation. The presence of surface-active agents might stabilize these hydroperoxide-loaded micelles and inhibit branching reactions. α-Tocopherol itself may exert part of its antioxidant effect through this mechanism [13–15]. Phospholipids act as potent synergists for α-tocopherol in highly unsaturated fatty acids, such as fish oils [80, 81]. Phosphatidylethanolamine acted as a synergist in fish oil [82]. It was reported as a more active synergist of flavonoids in lard than phosphatidylcholine [83]. The phospholipids seem to exert their synergistic effect by acting as surfactants or emulsifiers stabilizing the hydroperoxide-loaded micelles and preventing the hydroperoxide decomposition and the initiation of new oxidation chains. This effect prolongs the induction period by preserving the primary antioxidants and extending their protective effect(s) [14, 41].

19.5 IMPORTANT ANTIOXIDANTS FOR FOOD STABILIZATION

Many synthetic phenolic compounds have been recognized as active antioxidants but only a few are used for food stabilization because of very strict safety regulations (Figure 19.5). Most of the approved phenolic antioxidants are substituted by more than one hydroxyl or methoxy group(s) in *ortho*- or *para*- position of the phenolic group, while *meta*-substituted compounds are nearly inactive. Synthetic phenolic antioxidants are mostly *para*-substituted due to lower toxicity while most natural phenolic compounds are *ortho*-substituted [84]. Among heterocyclic compounds containing nitrogen, only ethoxyquin (2, 6-dihydro-2, 2, 4-trimethylquinoline) was used but now exclusively in feeds [85]. Diludine (a substituted dihydropyridine derivative) is used for the stabilization of carotene and some pharmaceutical preparations but not in food in spite of its good activity in fats and oils [86]. Synthetic phenolic antioxidants are always substituted by alkyls (e.g., propyl, octyl, and dodecyl ester derivatives) to improve their solubility in fats and oils and to reduce their toxicity [87]. Mixtures of phenolic antioxidants often show synergistic activities, e.g., BHT and BHA [88]. In addition to their antioxidant activity, most phenolic substances possess antimicrobial activity in food [89]. It should be mentioned that synthetic α-tocopherol, D-ascorbic acid, and other antioxidants are considered as nature-identical compounds despite some differences. The mechanism of action of synthetic antioxidants is essentially the same as that of natural phenolic antioxidants. The only difference is that they are usually present in mixtures with related compounds of varying activities and/or with synergists.

By the end of the last century, there were concerns against using artificial chemicals, which led the food industry to turn to natural compounds for food stabilization [90, 91]. Almost all plants, microorganisms, fungi, and even animal tissues contain antioxidants of various types, which for various reasons (e.g., availability, food safety, and economical reasons) can be used as sources of antioxidants only in certain cases. The biosynthesis of antioxidants in plants was reviewed and

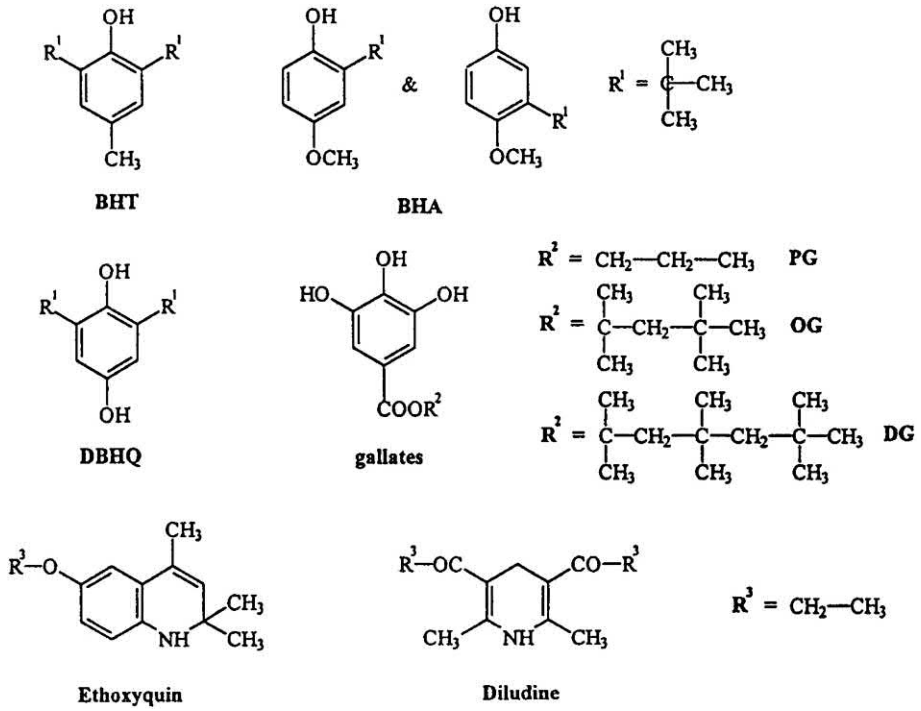

FIGURE 19.5 Chemical structures of the most important synthetic antioxidant used in food protection. BHT, di-tert-butylhydroxytoluene; BHA, tert-butylhydroxyanisole; DBHQ, di-tert-butylhydroquinone; PG, propyl gallate; OG, octyl gallate; DG, tert-dodecyl gallate.

discussed [92]. Research and development laboratories have shown great interest in exploring natural antioxidants and commercialized them as food protectants and life-saving phytochemicals. Since the use of food additives is subject to strict regulations, sometimes antioxidant extracts are added to foods as flavorings, coloring agents, or natural food components. In commercial preparations, natural antioxidants are mixtures of phenolic compounds and other compounds that would act as synergists, For instance, of 147 plants tested, 107 extracts showed appreciable antioxidant activity [93].

Although several natural antioxidant extracts can be used to protect foods against oxidation, their activities are generally low and they present unreproducible effects because they are mixtures of several compounds with different antioxidant properties, inactive impurities, or even prooxidants. When natural antioxidants are added to foods as unprocessed ingredients, the microstructure of the tissue and compartmentalization can play a decisive role in their antioxidant potential. The best method of application of natural antioxidants is to use natural food components (e.g., extracts of oilseeds, cereals, nuts, fruits, and vegetables) because they are regarded as safe, and no special approval for their application is necessary. Another possibility is to use natural food ingredients, such as spices. Natural compounds derived from nonfood materials, such as gingko leaves [94], should be tested for toxicity before application. A natural antioxidant, nordihydroguaiaretic acid (NDGA), extracted from the creosote bush grown in California, was originally used in food stabilization for a long time [95], especially in edible fats, but it is not permitted now because it has not passed more recently introduced safety tests. Because the biological variability of natural antioxidant extracts contributed to their unreliable activity, they were replaced by pure synthetic compounds that are cheaper, possess reproducible activities, and their safety have been tested and approved.

In higher plants, where phenolic compounds are very common, two series of compounds are of particular interest, derivatives of benzoic acid and cinnamic acid series [96]. The aromatic cycles substituted by two or three phenolic groups in the *ortho*- position are particularly important; some hydroxyl groups may be methoxylated. Gallic acid is a typical representative of the benzoic acid series, while caffeic acid is the most typical derivative of the cinnamic acid series. Catechins and flavones are more complicated compounds, where the antioxidant activity is located in a pyrocatechin or pyrogallol radical bound in the molecule.

Tocopherols and tocotrienols (Figure 19.6) are naturally present mostly in foods of plant origin. They are the most common natural antioxidants used in food preservation and they are present, at least in small amounts, in nearly all processed food materials. Tocopherols and tocotrienols are derivatives of chroman with a diterpenic (phytol) side chain; the active configuration is the phenolic group in the benzene cycle, located *para* to the oxygen atom bound in the adjacent dihydropyrone cycle [97]. There are four tocopherols, which differ in methyl substitution, the most important antioxidant of which is d-α-tocopherol, which has lower antioxidant activity than the other tocopherols but has the most vitamin E activity *in vivo*. The *in vivo* activity decreases in the order $\alpha > \beta > \gamma > \delta$ tocopherols [98], while the *in vitro* activity in bulk fats and oils decreases in the order $\delta > \gamma > \beta > \alpha$ tocopherols [99]. Their content in edible oils is particularly high

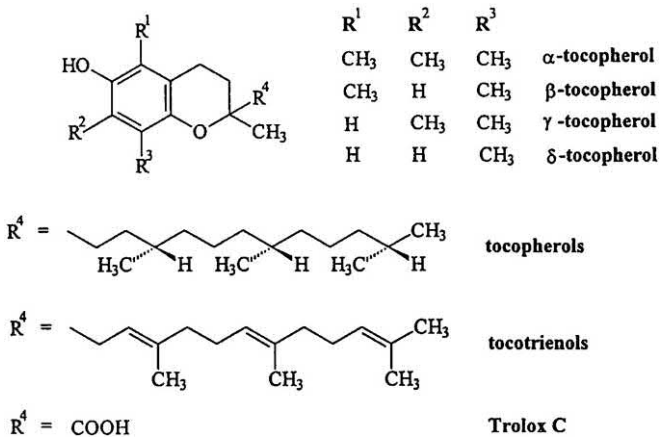

FIGURE 19.6 Chemical structures of tocopherols, tocotrienols, and Trolox.

(Table 19.4). Between 20% and 50% of the natural tocopherols are lost during edible oil refining (especially during the deodorization step), but they are often replaced by addition of α-tocopherol, tocopherol mixtures, or a deodorization concentrate (collected during the deodorization step of oil refining) into refined oils. Tocopherol acetate is added instead of free tocopherol because it is more resistant against oxidation during storage of edible oil. In foods of animal origin, such as butter or meat, tocopherols are present only in negligible amounts. In oilseeds, cereals, and other products, tocopherols are accompanied by dehydrotocopherols, tocomonoenols, tocodienols, and tocotrienols, which have one, two, and three double bonds in the side chain, respectively [100]. The last group is present in cereal flours and in palm fruits and palm oil. The related plastochromanol-8 has activity similar to α-tocopherol [101]. Tocopherols added to food products may be either synthetic products or natural concentrates, obtained most often from deodorization sludges from oil refining, from wheat or corn germs, or from other sources. Natural tocopherols have optical activity, unlike synthetic products. In foods of plant origin, additional tocopherols act as relatively weak antioxidants because vegetable oils already contain tocopherols in concentrations near the required optimum concentration. On the other hand, tocopherols are very active in vegetable oils that were stripped of their natural antioxidants [102]. Tocopherols are very active in foods of animal origin, as they contain nearly no natural antioxidants. A mixture of tocopherols, ascorbyl palmitate, and lecithin efficiently stabilized such a polyunsaturated material as fish oil [103]. By reaction with free radicals, tocopherols are converted into quinones, spirodimers, and various other compounds as well as in copolymers with oxidized lipids [97].

Hundreds of other natural antioxidants are known, some of them are shown in Figure 19.7. Several important oilseeds are sources of natural antioxidants other than tocopherols (Table 19.5) [104]. During the processing of oilseeds or oil-bearing fruits, antioxidants are partially extracted into crude oils. The best-known oxidation inhibitors are those present in olive fruits. Virgin olive oil, produced by pressing fruits under low temperature, contains several antioxidants derived from hydroxytrosol [105]. The antioxidants are present mostly as water soluble glycosides in the pericarp of the fruit and remain mainly in the residue after pressing (pomace). During ripening, storage, or pressing, glycosides may be hydrolyzed into the respective aglycones; for instance, oleoeuropein is present with its aglycone in virgin olive oils, but some antioxidants are partially reduced during pressing [106]. The content and properties of antioxidants depend on the degree of ripeness and the processing conditions [107]. Sesame seeds also contain phenol glycosides of lignan structure [108–111]. These compounds are only partially present in sesame oil where the most active compound is sesamol. The antioxidant activity is affected by roasting and steaming of seeds before extraction [112]. Sesame lignans, added in small concentration, were very active in ground pork and sausages [113]. Sunflower seed hulls are rich in polyphenols including melanins. Polyphenoloxidases oxidize polyphenols into quinones, which react with amino groups of proteins, imparting brown discoloration to seed meals. Therefore, extracted meals are frequently discolored by interactions of enzymatically oxidized polyphenols and protein. The seed contents of chlorogenic acid and related phenolic derivatives are only partially decomposed during processing. Peanuts contain flavonoids, tannins, and various other phenolic compounds concentrated in the hull [114, 115]. Cottonseeds contain gossypol, a polyphenolic compound with aldehydic groups possessing antioxidant properties. Because of the toxicity and contraceptive activity of gossypol, cottonseed meal cannot be used as feed

TABLE 19.4
Tocopherol Content in Vegetable Oils

Oil	α-Tocopherol (mg/kg)	β- + γ-Tocopherols (mg/kg)	δ-Tocopherol (mg/kg)	Total Tocopherols (mg/kg)
Soya bean	80–150	210–780	60–400	300–1400
Rapeseed	120–300	220–450	5–15	380–750
Sunflower	550–900	25–110	0–5	580–980
Corn germ	120–400	420–780	10–50	680–1250
Peanut	80–320	120–280	5–30	90–550
Olive	80–180	0–5	0	80–180
Cottonseed	550–700	200–280	0–5	800–980
Rice bran	500–650	230–340	0–5	750–950

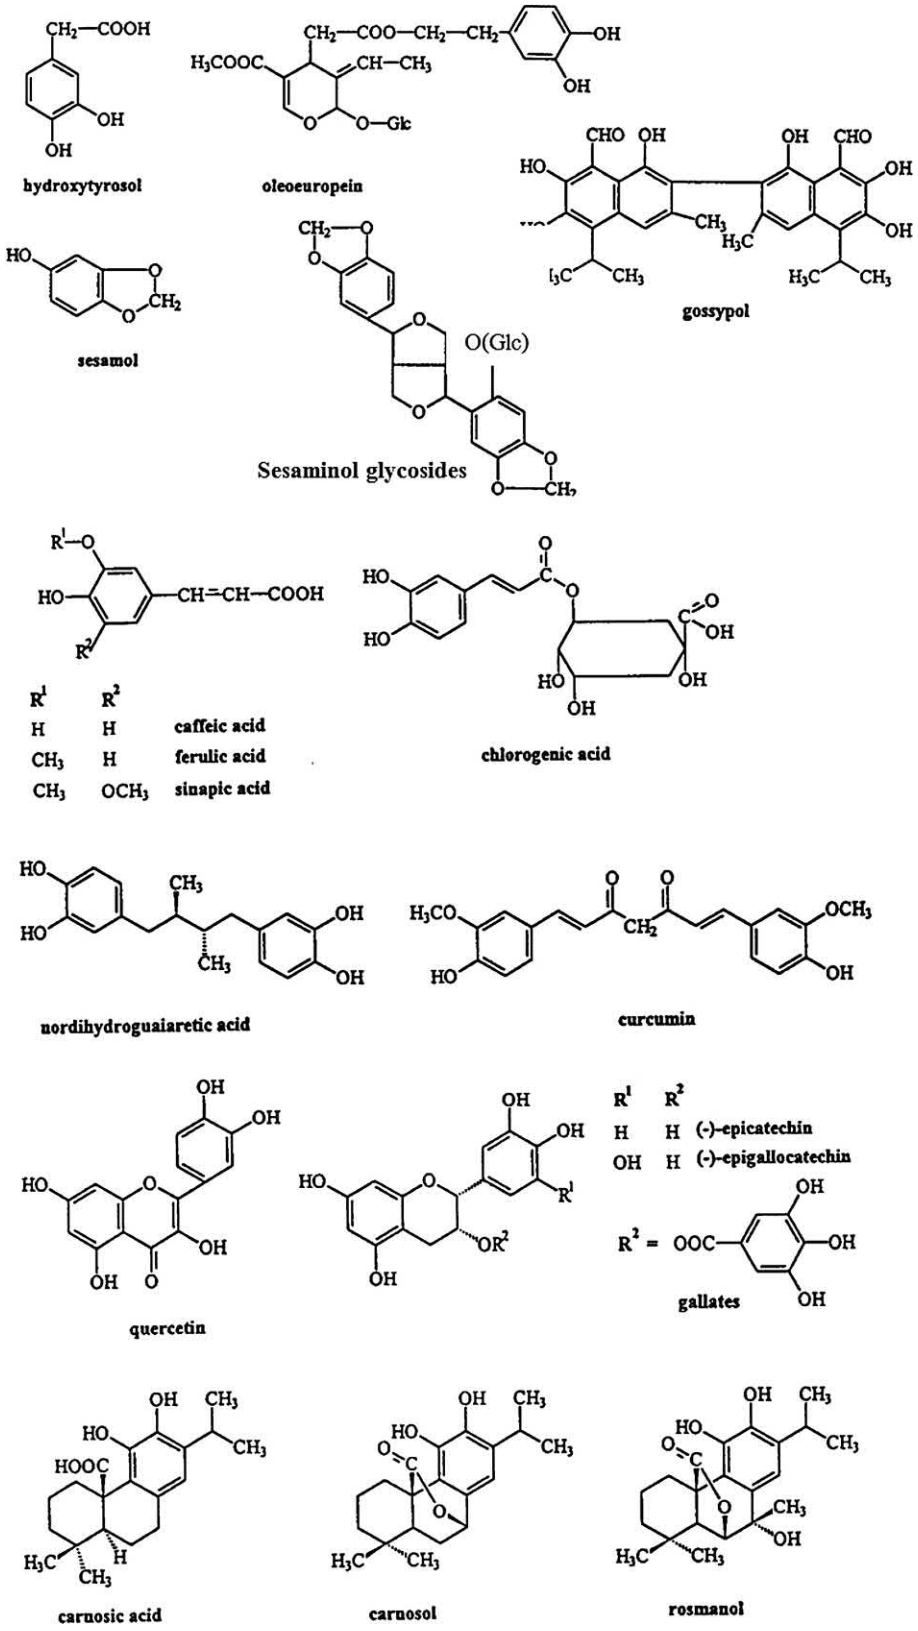

FIGURE 19.7 Chemical structures of selected natural antioxidants from seeds, herbs, and spices.

TABLE 19.5
Examples of Antioxidants from Selected Food Plants

Plant Sources	Latin Name	Main Antioxidants
Oilseeds and Cereal Grain		
Cottonseed	*Gossypium hirsutum*	Tocopherols, gossypol
Flaxseed	*Linum usitatissiumum*	Tocopherols, lignans
Olive fruit	*Olea europea*	Tocopherols, oleoeuropein aglycone
Palm fruit	*Elaeis guineensis*	Tocopherols and tocotrienols
Sesame seed	*Sesamum indicum*	Tocopherols, sesamol, sesaminol glucosides, sesamolin
Rapeseed	*Brassica napus*	Tocopherols, sinapic acid
Rice bran	*Oryza sativa*	Tocopherols, oryzanol
Fruits and Vegetables		
Betel	*Areca catechu*	Oleoresins, eugenol, hydroxychavicol
Carrots	*Daucus carota*	Carotenoids, flavonoids
Citrus	*Citrus* spp.	Flavonoids, carotenoids
Garlic	*Allium sativum*	Sulfides, disulfides
Green pepper	*Capsicum annuum*	Flavonoids
Green olives	*Olea europaea*	Phenolics
Legume	*Leguminosae*	Flavonoids
Mustard	*Sinapis alba*	Phenolics, isothiocyanates
Onion	*Allium cepa*	Sulfur compounds
Persimmon	*Diospyros kaki*	Procyanius, catechins
Pineapple	*Ananas comosus*	Flavanols
Plums	*Prumus spp.*	Phenolics
Red grapes	*Vitis vinifera*	Anthocyanins, co-pigments
Herbs and Spices		
Rosemary	*Rosmarinus officinalis*	Carnosic acid, carnosol
Sage	*Salvia officinalis*	Carnosic acid
Tanshen	*Salvia miltiorrhiza*	Carnosol
Thyme	*Thymus vulgaris*	Thymol, quinones
Savory	*Satureia hortensis*	Flavonoids
Clove	*Eugenia caryophyllata*	Eugenol, gallates
Black pepper	*Piper nigrum*	Ferulic acid
Ginger	*Zingiber officinalis*	Cassumarin, ginerol
Juniper	*Juniperus communis*	Phenolics, resins
Oregano	*Origanum vulgare*	*o*-Substitute phenolic acids
Fennel	*Foeniculum vulgare*	Dihydrocoumarins
Curcuma	*Curcuma longa*	Curcumin
Spearmint	*Mentha piperita*	Flavonoids
Lavender	*Levandula angustifolia*	Flavonoids
Hop	*Humulus lupulus*	Flavonoids, anthocyanins
Allspice	*Pimenta officinalis*	Flavonoids
Ginseng	*Panax ginseng*	Phenolic acids

in large amounts. Glandless, gossypol-free modern cultivars (glandless cottonseed) were developed. Gossypol-free cottonseed cultivars still contain flavonoid antioxidants such as quercetin and tocopherols [114, 116]. Soybeans also contain phenolic compounds with antioxidant activity, mostly flavones and isoflavones [117], which may stabilize lipids not only in beans but also in soy products, such as tofu or tempeh [118]. Isoflavones possess a hormone-like activity, which should be accounted for when evaluating the possible applications as inhibitors. Rapeseed (*Brassica napus*) and the related turnip rapeseed (*B. rapa*) are relatively rich in phenolic compounds, among which sinapic acid prevails and acts as a moderate antioxidant in oils rich in polyunsaturated fatty acids [117]. Rapeseed contains tannins as well as sinapic acid, which is mostly bound to choline, forming sinapine, which is nearly inactive as an antioxidant in oils. Evening primrose seed contains high levels of phenolics, mainly derivatives of protocatechuic and gentisic acids [119, 120]. Flaxseed also contains several lignans and flavonoids active as antioxidants [121].

Cereal gains, the most important components of the human diet, contain several types of phenolic compounds, especially in bran. Oat is considered relatively efficient from this standpoint [122] and oat extracts were the first natural antioxidants studied in detail before World War II. Extracts were patented and used in oils and other foods. Phenolic compounds present in oat seed are partially bound in lipids, and therefore are liposoluble. Rice bran is used for the production of oil; therefore, it is collected and extracted with solvents. During the process, some phenolic compounds, such as oryzanols [123], pass into crude rice oil. Rice oil is particularly rich in antioxidants (including tocopherols) and low in polyunsaturated fatty acids, therefore, it is very stable during storage like olive oil. Maillard products formed during the baking or roasting of food originate from sugars and amino acids; they have a stabilizing effect on lipids in foods, especially in baked products. The content of phenolic substances in grain legumes is mostly low; nevertheless, these might stabilize foods if added in substantial amounts as an ingredient. Phenolic substances (mainly flavanols) are concentrated in legume hulls [124]. These phenolic derivatives may be insoluble (tannins or lignins), but some derivatives are partially soluble in oil. This is why they sometimes become efficient in stabilizing the lipid fraction. Antioxidants from peas were isolated and their antioxidant activities reported [125]. Polar bean extracts showed high activities in lipid emulsions [126]. Lentil seeds are also a rich source of antioxidants, mainly phenolic acids [127].

The most important group of compounds active as antioxidants in fruits and vegetables consists of various flavones and related compounds [128]. Some substances belonging to this group act as cofactors of vitamin C protecting it from destruction by free radicals and increasing its vitamin activity. Ascorbic acid present in fruits increased the antioxidant activity of phenolic components in the linoleic acid–carotene system, e.g., in extracts from acerola fruits [129]. Grapes contain both lipophilic and hydrophilic antioxidants; their concentration is substantially higher in red wine than in white wine [130]. In red wine and deep-colored fruit juices, various anthocyanins are present [131], which are important antioxidants active in the aqueous phase. Red wine has been recommended as a source of antioxidants, such as resveratrol, to protect humans against the development of cardiovascular diseases, but several other factors may be involved so that the antioxidant activity should be confirmed by further experiments. In addition to the above compounds, various terpenic derivatives could act as potent inhibitors of lipid oxidation. The effect of terpenes will be discussed in the next section,

as terpenes are more important in spices. In the category of fruits, the substances investigated in most detail are those isolated from citrus fruits. Their activity is higher in oil-in-water emulsions than in oils because of the hydrophilic character of flavone glycosides and related compounds.

Ethanolic or aqueous extracts (which contain much more hydrophilic substances than hexane or ether extracts) seem to impart higher activities to water-in-oil emulsions. Their solubility also plays a role, therefore, they are more soluble in polar food systems, while hexane and ethyl acetate extracts are more soluble in fats and oils. Various nuts (e.g., macadamia nuts) contain antioxidants [128]; these substances are extracted into the respective oils by pressing. In peanuts and in almonds [132], phenolic antioxidants are concentrated in brown skins. Inhibitors of oxidation have been detected in extracts from hop [133]. Most among them are various pyrocatechol derivatives. Onion and garlic contain efficient inhibitors; because of their pungent flavor, they are suitable only for meat products, snacks, or cheeses [134]. Potent antioxidants can be obtained from various nonfood plant products, such as gingko leaves, but the substances from such sources (i.e., not used for food purposes) should be tested for safety before application.

Herbs are mostly leaves or stems from various plants used for the preparation of infusions, extracts, or soups. Many species of this group of food materials are active [92, 93, 135], mainly because of their content of phenolic compounds. The most important representatives of this group of substances are leaves from tea bush [136]. Green, oolong, and black teas are produced, depending on the technology of leaves processing [137]. Green tea contains a high percentage (about 20%) of catechins and related compounds [138]. The mixture mainly consists of catechins, epicatechins, gallocatechins, and the respective gallates. Extracts from green tea are, therefore, very active; their activity is comparable to that of synthetic antioxidants. Extracts from leaves of fermented, black tea are less active because a substantial part of the catechins has been converted into less active tea pigments [137, 139]. During the fermentation of tea leaves, catechins are partially enzymatically oxidized into the respective quinones, which dimerize into tea pigments—theaflavins and thearubigins. Wastes leftover after the preparation of tea infusions or commercial tea products may be used for the preparation of extracts with antioxidant activity. The antioxidant activity in lard may be ranked in descending order as follows: epigallocatechin gallate > epigallocatechin > epicatechin gallate > epicatechin. Raw materials for the preparation of herbal teas are less efficient, but various herbs used in China, Japan, and other Far East countries contain efficient antioxidants too [140]. Algae contain several brominated 3, 4-dihydroxybenzene derivatives [141]. Seaweed hydrolyzates were found very active as antioxidants, mainly in various animal foods [142]. Spices are used for conditioning meals and bakery products. Several species possess antioxidant activity [143], and the wastes left after the distillation of essential oils from spices could be used as raw material for the extraction of antioxidants.

The most active substances are those spices applied to foods as leaves or extracts of plant leaves [144–162]. Extracts of rosemary leaves are the only commercially available antioxidant of this group, and sage contains several structurally related antioxidants such as carnosic acid, carnosol, or rosmarinic acid. Their activity was tested in various foods, and particularly the lipid soluble fraction was active [161], e.g., in restructured pork steak [161]. Other active spices include thyme, juniper, oregano, ginseng, ginger, nutmeg, etc. In most cases, it is sufficient to add spices to the food products before or after the preparation, but extracts may be added instead of spices [153]. The addition of pure substances (isolated from spices) is not recommended, as the application of pure compounds would be considered as addition of antioxidants, not flavorings, and would be subject to legal restrictions. Some spices alter the flavor of food products, but deodorized material (i.e., after removal of essential oil by steam distillation) could be used without affecting the flavor. Spices that have antioxidant activity often possess antibacterial activity too [143].

In summary, wide ranges of water-soluble and lipid-soluble antioxidants are provided by nature, but as mentioned earlier, they face challenges due to their biological variability and irreproducibility. Currently, there is new room for research for the selection of antioxidant combinations and standardization for specific foods after the new knowledge on the role of antioxidants and synergists in the inhibition of lipid oxidation via chemical (radical scavenging) as well as physical (micelle stabilization) effects. This knowledge opens a new era for research and development, which might allow a combination of optimized antioxidant protection, packaging, and storage of foods.

19.6 APPLICATION OF ANTIOXIDANTS IN FOODS

The inhibition of lipid oxidation by antioxidants depends not only on their structures but also on many other factors, such as the composition of the lipid fraction, the presence of other inhibitors or promoters of oxidation, certain nonlipid components, water, the food microstructure, temperature, and packaging. Therefore, literature data should be always verified by tests in the specific food and its processing or storage conditions. Several synthetic antioxidants have proven to be effective, but their use is restricted to a few compounds, which have passed very complicated and expensive tests to prove their safety [163–165]. Such tests include the generation tests and teratogenic and carcinogenic trials using at least six species of animals, among which at least three species should be vertebrates and at least one species nonrodent. Therefore, no new antioxidants (with a few exceptions) are being tested and permitted, and the addition of the antioxidants to food is usually restricted to 0.02% on fat basis. Permitted antioxidants are different in different countries and subject to change [166]; some examples of antioxidants commonly used in the stabilization of fats and oils are given in Table 19.6. For practical reasons, it is suitable to add mixtures of antioxidants, which usually have higher activities than a single compound and which guarantee that the limits for single compounds have not been exceeded. Many commercial preparations are mixtures of antioxidants, synergists, and emulsifiers, or other substances facilitating

TABLE 19.6
Antioxidants Commonly Used in the Stabilization of Edible Fats and Oils

Antioxidant	Abbreviation	Applications
Propyl gallate	PG	Fats and oils
Dodecyl gallate	DG	Fats, emulsions
tert-Butylhydroxytoluene	BHT	Fats and oils, foods
tert-Butylhydroxyanisole	BHA	Fats and oils, foods
Di-*tert*-butylhydroquinone	DBHQ	Vegetable and fish oils, frying oils
Ascorbyl palmitate	AP	Vegetable oils, synergists
Tocopherols	TOH	General use in fats, oils
Citric acid, esters	CA	Synergists, edible oils
Thiodipropionic acid	ThA	Synergist
Lecithin	Lec	Synergist
Carotenes	Car	Frying oils, edible oils, emulsified oils
Silicone oil	SO	Frying oils

the dissolution of the product in fats and oils. Some natural materials are generally regarded as safe (GRAS); their use is not restricted by legislation (e.g., tocopherols, phospholipids, amino acids, etc.). Some common food ingredients, such as spices, are also not subject to legal restrictions as they are considered as flavoring or coloring substances. For pure compounds isolated from natural materials or extracts from plant materials not used as food, it is necessary to prove that there are no risks associated with their use.

Today, tendencies exist to avoid the "loss of efficacy" of antioxidants by reducing their concentrations in foods and by combining primary phenolic antioxidants with synergists (usually with the GRAS status). The antioxidant effect required by the producer and customers could, thus, be obtained with the lower addition of a primary antioxidant. Many examples have been published, e.g., by Banias et al. [167]. Theoretically, it is possible to prepare stable foods without added antioxidants. The easiest way is to modify the recipe to include components rich in natural antioxidants and to exclude components rich in polyunsaturated lipids. Another method is to prevent the access of oxygen, e.g., by impermeable packaging, often combined with packaging in a vacuum or in an inert gas, such as nitrogen. Oxygen may be removed by addition of oxygen scavengers, such as a combination of D-glucose and glucose oxidase. Storage at very low temperatures may be recommended, too. Nevertheless, there is a danger that when water freezes, ice crystals are produced and the product becomes dry. Under these conditions, the protective layer of hydrated proteins is damaged and the lipid fraction leaks from the natural emulsions or liposomes, so that lipids become exposed to air oxygen. The rapid turnover of foods in computerized food store facilities effectively eliminates the necessity of longer storage with the addition of antioxidants.

The efficiency of added antioxidants in foods depends very much on the food composition, microstructure, and moisture content [168]. Generally, dry foods, such as dehydrated soups, dried milk [169], and dried meat are very sensitive to oxidation, as air oxygen has free access to the film of lipids on nonlipidic particles. It may enter through tiny channels left after removal of water from the original material. The food stabilization is then less effective, as the initiation rate of the autoxidation reaction is relatively high and antioxidants are soon decomposed on storage or heating. In water-containing foods, the lipid fraction is relatively stable, as it is usually protected by a layer of hydrated proteins or carbohydrates against the access of air oxygen. The addition of nonpolar antioxidants is effective, while polar antioxidants may lose their activity by passage into the aqueous phase, similarly as in fat emulsions. Proteins and many other components of foods have protective action and act as synergist of other inhibitors, enhancing the effect of antioxidants [170]. Amine groups present in proteins do react with lipid hydroperoxides so that the level of free radicals decreases, which contributes to longer protection of foods against oxidation. Chelating agents are often present in foodstuffs as natural components, but heavy metals are usually present as well, for instance, heme derivatives in animal products. Because of the complexity of foods, it is necessary to test any addition of antioxidants to stabilize the particular material and to optimize the mixture of inhibitors.

Since vegetable oils contain nearly the optimum concentrations of tocopherols necessary for their stabilization [170, 171], the addition of phenolic antioxidants usually shows limited efficiency, but the addition of synergists is helpful. Ascorbyl palmitate, phospholipids, or organic acids (phosphoric, citric, or other polyvalent acids) are useful as synergists in vegetable oils. Most unsaturated oils are treated with organic acids during processing (the stage of deodorization) so that some residual synergists are often present in refined oils. Oils containing higher levels of natural antioxidants, such as olive oil, sesame oil, rice oil are sufficiently stable on storage without additional stabilization. Tocopherol acetate is sometimes added to increase the vitamin E activity and not to prolong the shelf life. On the other hand, animal fats, such as pork lard, beef tallow or milk fat, contain only very low amounts of natural antioxidants, therefore, their stability against oxidation is low despite their relatively low degree of unsaturation. Fortunately, both synthetic and natural antioxidants are very active in the stabilization of animal fats. Most often, mixtures of antioxidants and synergists are used for stabilization [172]. Lipid-soluble antioxidants show good results, but polar antioxidants could be used, too. When such fats, stabilized with polar antioxidants, are used for the preparation of food, e.g., for cooking or baking, the antioxidant activity is partially lost by extraction of antioxidants into the aqueous phase. Nonpolar antioxidants do not lose their activity as they remain in the lipidic phase creating a good carry-through effect.

Fish oils, including the oils of anchovy (*Engraulis* spp.), capelin (*Mallotus* spp.), cod and cod liver (*Gadus* spp.), herring (*Cupea* spp.), horse mackerel (*Scomber* spp.), tuna (*Euthynnus* spp.), menhaden (*Brevoortia* spp.), salmon (*Salmo salar*, syn. *Oncorhynchus* spp.), rainbow trout (*Oncorhynchus mykiss*), and sardine (*Sardina* spp.), account for about 2–3% of

the world's edible oil production and are the richest sources of nutritional eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). The relative amounts of EPA and DHA in fish oils vary from 5–20% and 3–26% of total fatty acids, respectively [173]. Being highly unsaturated, EPA and DHA are highly susceptible to lipid oxidation and flavor deterioration and require stabilization with antioxidants. Fish oils, nutritional fish, and marine oil capsules are supplemented with tocopherols and other antioxidants, and properly protected from oxygen [174]. The stabilization of fish oils requires a mixture of tocopherols and synergistic phospholipids [175].

Frying oils present a special case, as they are exposed to air oxygen at high temperatures (130–200°C) during frying. Phenolic antioxidants are practically inefficient in frying oils because they are rapidly exhausted by the high rate of initiation reactions and because they are distilled off with water vapor released from fried food. Frying oils are efficiently stabilized by the addition of minute amounts of silicone oils, particularly siloxanes, which form a thin layer on the interface between oil and air [176], protecting against the access of air oxygen. Frying oils with low polyunsaturated fatty acid content, such as palm oil, palm olein, low-linoleic/high-oleic sunflower oil, and high-oleic peanut oil, are usually sufficiently stable under frying conditions that they do not require additional stabilization [177]. Interestingly, because of the low oxygen pressure during frying, carotenes and other hydrocarbons were found efficient in frying oils containing tocopherols as they form a monomolecular film on the surface, protecting frying oil against access of oxygen [178].

The activity of antioxidants in emulsions is very different from that measured in bulk fats and oils [25]. Polar antioxidants, such as propyl gallate or flavonoids, are extracted into the aqueous phase and only a small amount remains in the oil phase. Nonpolar synthetic antioxidants remain in the oil phase and only a very small amount incorporates in the aqueous phase but often they form less efficient micelles [16, 19, 20, 26]. Both polar and nonpolar antioxidants are accumulated at the intermediary layer between the two phases, which explains the polar paradox, i.e. polar antioxidants are more active in a nonpolar medium, whereas non-polar antioxidants are more active in the polar medium [12]. This paradox was shown in the case of the more polar Trolox versus the less polar α-tocopherol on the one hand, and polar ascorbic acid versus the less polar ascorbyl palmitate on the other hand when tested in bulk oil and in emulsion [179]. Some antioxidants of semipolar nature may accumulate on the water–oil interphase and prevent the diffusion of oxygen into the fat phase. The activity depends on the type of emulsion. Oil-in-water (O/W) emulsions are better protected against oxidation than water-in-oil (W/O) emulsions, as oil droplets are isolated from the access of oxygen by the aqueous phase and the interfacial layer. In the presence of tocopherols, phospholipids are active ingredients in oil–aqueous emulsions used as food [180]. When rosemary extracts are applied as antioxidants, the activity of antioxidants present in the mixture depends on the type of stabilized material. Carnosic and rosmarinic acids are more active than carnosol in oils, but carnosic acid and carnosol are equally active in emulsions, more so than rosmarinic acid [181].

Air oxygen penetrates the food material from the outer atmosphere, therefore, it is useful to protect food surfaces. Meat or fish products are often protected by packaging materials, impregnated with antioxidants, or by application of suitable antioxidants on the surface of materials, even when they are not packed. Most often, foods are distributed packed; the packaging material is then of great importance [182]. If the material is permeable for oxygen, antioxidants may be added to the packaging to inhibit the diffusion of oxygen. These antioxidants may enter into the packed food [183], especially foods with high lipid content. Obviously, the only antioxidants that can be used in packaging are those that are allowed in foods, and they should be applied only in such amounts that the content in foods does not exceed the legal limits. Packaging materials may be protected against oxidation by adding antioxidants already in the factory, even when the producer of foods does not intend to stabilize food in this way. This case is the same as earlier, but eventual extraction of antioxidants into food should be accounted for. The degree of migration of antioxidants from packaging should be tested for the respective type of food product.

New technologies such as the encapsulation of unsaturated fatty acids and antioxidants for safe delivery, e.g., in infant formulas, are being developed. In this case, it is very important to eliminate surface free oil that would otherwise spread on a large surface of the microcapsules and oxidize causing rancidity in that part of the food [184]. The encapsulation efficacy needs to be improved, e.g., by the use of multilayer encapsulation and the inclusion of different synergists and encapsulation agents such as protein hydrolyzates, gums, and carbohydrate polymers [185]. The design of the macrocapsules and selection of different materials is an open door for future innovations, especially for the protection of highly unsaturated omega-3 fatty acids [27].

19.7 ANALYSIS OF LIPID OXIDATION AND ITS PROTECTION BY ANTIOXIDANTS

The analysis of lipid oxidation and antioxidant protection is not a trivial task and often a single method is not sufficient and several analytical methods targeting the oxidizing substrate, residual antioxidant(s), and different reaction products are needed to identify and quantify the degree of oxidation [186]. The analysis of lipid oxidation and antioxidants has at least two aims: (i) the description of the status quo of the product and (ii) the prediction of the oxidative stability of the product under certain compositional and environmental circumstances. The methods that can be used are many and variable ranging from traditional methods (such as peroxide and *para*-anisidine values) to more sophisticated chromatographic and spectroscopic methods. Sensory analysis is less frequently used mainly because of the large variability in panelist scores. Measurements of total antioxidant activity or total antioxidant capacity are frequently used in literature to describe the antioxidant potential of plant extracts, but these

methods can only be indicative of high reactivity in a reaction tube and not necessarily in a food system.

Many methods have been used for the prediction of antioxidant activity in foods by determining the time length of the induction period at a given temperature [187]. The relative increase of the induction period due to the addition of antioxidants is called the protection factor. Protection factors are affected by the type of substrate and antioxidant. They are often high for low-unsaturated substrates containing no natural antioxidants, such as pork lard (of the order of 20–70) but low in polyunsaturated substrates containing sufficient tocopherols or other natural antioxidants (of the order of 2–4). Yanishlieva and Marinova [55] argued that the evaluation of antioxidant activity through the determination of the length of the induction period is not sufficient and presented a more complex model including the oxidation rate during the induction period, which is increased with the concentration for some antioxidants. They classified antioxidants as strong and weak; the strong ones increase the rate of oxidation during the induction period and are subject to loss of efficacy, although they might result in longer induction periods.

The best method for the determination of the shelf-life stability of lipids and the antioxidant activity would be storage of the food under the specific conditions, but this procedure would be too long and very expensive. Thus, accelerated methods (using higher temperature or catalysts) are almost exclusively used [188]. The oldest and most precise method is the Schaal oven test where the sample is stored at 40°C, 50°C, or 60°C in the dark under free access of oxygen. Changes are monitored either by determining the peroxide value or increase of weight for several days or months. In the active oxygen method (AOM) or earlier Swift procedure [189], the sample is incubated at 97.7°C (boiling water bath temperature) or 110°C (a glycerol bath). These procedures were used for a long time for rapid determination of antioxidant activity. Gases leaving the apparatus during the test can be monitored by sensory analysis, or they can be collected in water and estimated through changes of the carbonyl content or conductivity of the water phase. The increase in conductivity is due to the presence of lower fatty acids, especially formic acid, which originate in later stages of oxidation by secondary reactions. The Rancimat (Metrohm AG, Herisau, Switzerland) and the Omnion Scientific Oxidative Stability Instrument (OSI; Agilent Technologies Inc., North Kingstown, Rhode Island) are based on the same principle but the procedures are automated [190]. These two methods have been used a greater deal than the AOM method due to their simplicity, availability, reproducibility, and ease. The Oxidograph records changes in the amount of oxygen absorbed by the sample under very similar conditions. The results of accelerated methods do not correspond exactly to the results obtained under actual storage conditions [191]. Frankel raised objections against methods using high temperatures and recommended use of tests at lower temperatures, i.e., in the range of 20–60°C [192].

The American Society of Testing Materials (ASTM) Oxipres and Oxygen Bomb are based on recording the changes in pressure during oxidation at high oxygen pressure but without aeration, which is closer to actual conditions of food preparation and storage. The temperature can also be controlled to shorten the induction period. Various methods operating at lower temperature have been developed; in these cases, the oxidation is catalyzed either by photosensitizers or by the addition of copper ions. Their results may not correlate to those obtained during storage in the dark or without the presence of metals. Another method is the oxidation of an emulsion containing linoleic acid and carotene; changes of coloration or the increases of ultraviolet absorption are used for monitoring the reaction course. The antioxidant activity to scavenge free radicals is sometimes used for screening the suitability of antioxidants; various sources of free radicals are used. The method is rapid and simple, not requiring any expensive equipment.

Azo initiators, A-N=N-A, have been employed to test the activity of antioxidants at a constant initiation rate at a given temperature.

$$\text{A-N=N-A} \rightarrow \left[\text{A.N=N.A}\right]_{\text{cage}} \rightarrow 2\text{A}^{\bullet} + \text{N}_2 \qquad (19.24)$$

For example, lipid-soluble (2,2'-azobis-(2,4-dimethylvaleronit rile), AMVN) and water soluble (2,2'-azobis-(2-amidino-p ropane)-dihydrochloride, AAPH) azo-initiators are available for this purpose and have been used in many studies aiming to evaluate antioxidant potency [193]. However, results obtained with this method are still artificial and cannot account for the discrete reactions involved in the initiation of lipid oxidation during the induction period. In general, the method used for the determination of antioxidant activity should operate under conditions very similar to those of real application.

The degree of oxidation and the end of the induction period may be measured in different ways, such as on the basis of oxygen absorption or decrease of oxygen pressure, weight increase [167], increase of peroxide value, determination of conjugated dienes, or increase of 2-thiobarbituric acid reactive substances. Lipid hydroperoxides, the primary reaction products, are commonly determined by titration or spectrophotometrically. The method most commonly used is the official AOCS method, Cd 8b-90 [194], where hydroperoxides are reacted with iodide ions to form iodine that is titrated with thiosulfate using starch as an indicator:

$$\text{ROOH} + 2\text{I}^- + \text{H}_2\text{O} \rightarrow \text{ROH} + 20\text{H}^- + \text{I}_2 \qquad (19.25)$$

$$2\text{S}_2\text{O}_3^{2-} + \text{I}_2 \rightarrow \text{S}_4\text{O}_6^{2-} + 2\text{I}^- \qquad (19.26)$$

Alternatively, the combination blue complex product of iodine and starch can be measured spectrophotometrically at 550 nm [195]. The peroxide value (PV) is usually expressed as the milliequivalents of peroxides per kilogram of lipids but can also be divided by 2 and expressed as millimoles of active oxygen per kilogram lipids (SI units). Another method that is widely used to measure PV is the thiocyanate method based on the oxidation of ferrous salts to ferric salts by the hydroperoxides under acidic conditions and formation of a red complex

that can be measured by absorbance at 505 nm. The concentration of hydroperoxides with conjugated diene chromophore (CD) is sometimes estimated from the absorbance at 234 nm (molar absorptivity of E ≈ 28,000 $M^{-1}cm^{-1}$ in methanol). Other methods for the determination of PV exist but are used less frequently [196].

Because the PV has no simple relation to the actual rancidity due to the unstability, odorlessness, and tastelessness of hydroperoxides [197], it usually complemented by the *p*-anisidine value (AV), which measures the browning reactions of the respective aromatic amines with the aldehydes or ketones produced by the degradation of hydroperoxides. The resultant color intensity depends not only on the concentration of carbonyl groups, but also on the degree of unsaturation as well as on other factors [198]. The combination of PV and AV is referred to as the TOTOX value, which equals 2 PV + AV [196]. The 2-thiobarbituric acid value (TBA), determined by the spectrophotometric absorption of the condensation products of this reagent with malonaldehyde at 530 nm, is an additional measure of the oxidation of fatty acids containing three or more double bonds. If the condensation products are measured at 450 nm, it correlates better with total aldehydic oxidation products and rancidity than the substances reactive with formation of red products [199]. These spectrophotometric methods are easy, rapid, and cheap; however, their specificity is questionable. Several other spectrophotometric methods were reported in the literature, mostly based on a reaction with aldehydes, e.g., the conversion of aldehydes into 2,4-dinitrophenylhydrazones and the determination of color intensity.

Gas chromatography (GC) can be used for the analysis of unreacted polyunsaturated fatty acids as well as volatile compounds, dynamic headspace analysis, or using other analytical techniques [200]. The contents of propane, hexane, hexanal, 2,4-decadienals, and other products are correlated with the degree of rancidity. For the evaluation of the rancidity degree, the GC determination of volatile oxidation products, such as pentane, hexanal, or 2,4-decadienals, which are responsible for off-flavors, is the common method in use. Solid-phase microextraction (SPME), a solvent-free extraction technique, can be used for the sampling of volatile lipid oxidation products, but the method needs optimization and validation with respect to the extractability of the different compounds and the interpretation of the results [201]. The combination of SPME, GC, and mass spectrometry (MS), and the application of statistical techniques in data analysis improves the separation and allows a better selectivity and high precision [202].

High-performance liquid chromatography (HPLC) has limited applications in the determination of lipid oxidation products. However, it can be used for the analysis of lipid hydroperoxides, lipid hydroxycompounds, and ketodienes [53], especially when coupled with mass detectors. The best method for the determination of lipid oxidation products based on molecular weight is high-performance size-exclusion chromatography (HPSEC). This method has been applied for the analysis of lipid oxidation monomers, dimers, and oligomers e.g., in emulsion, dried-microencapsulated oils, frying oils, etc. [203].

Other methods that have been used in the analysis of lipid oxidation include nuclear magnetic resonance (NMR), electron-spin resonance (ESR), differential scanning calorimetry (DSC), infrared spectroscopy (IR), and chemiluminescence [204–207]. Oxidomics, i.e., monitoring of a number of oxidative changes in lipids simultaneously and evaluation of the results by chemometrics, have recently been applied to olive oil [208]. Application of these techniques is advantageous since it will highlight several changes by the same analysis and allows hypothesis-generation and broader conclusions than those that can be reached by the imprecise PV analysis [209]. Similarly, psychometric sensory analysis and related methods should be fundamental for their analysis of rancidity since it is a phenomenon of perception [197]. The degree of rancidity is the final goal of analysis, but usually sensory profile methods are used to estimate all flavor descriptors responsible for the final perception of rancidity. Even with expert panels of assessors, the analysis should be repeated 10–20 times to obtain reliable results. Electronic noses can provide an alternative and bridge between sensory evaluation and conventional chemical analysis of volatile lipid oxidation products in foods [210].

19.8 ANALYSIS OF ANTIOXIDANT POTENTIAL

In the analysis of the ability of natural antioxidant extracts to provide stability for food lipids, the two aspects are the determination of the content of antioxidants and their activity. The analysis of antioxidant content consists of two subsequent operation stages [165]: (i) isolation of antioxidants from the substrate and the purification of the extract, and (ii) quantification of antioxidants in the extract. Two difficulties are faced by the analyst: (i) how to achieve quantitative yield during the extraction and purification of extracts, and (ii) how to prevent the oxidation of antioxidants during the operation. Usually, antioxidants, being semipolar substances, are extracted using semipolar solvents, and the removal of solvents is performed under nitrogen. The extract may be purified by solid phase extraction on specific cartridges or using traditional column chromatography. Sometimes it is possible to use a precolumn for the subsequent chromatographic separation. Antioxidants naturally present or added to foods as natural components or flavorings may be partially converted into degradation products by reaction with oxygen or free radicals. Therefore, the content found by the analysis needs not exactly correspond to the amount originally present, similarly as in case of synthetic antioxidants. Several methods have been standardized by IUPAC [189] and/or AOCS [194]. Antioxidants are subject to changes during food storage or heating [54] so that it would be correct to isolate and determine not only the original antioxidant but also potential degradation products. Only in such a way, it would be possible to find whether the original content of antioxidants has not exceeded the legal limit.

Methods used for the determination of antioxidant content include spectrophotometric, chromatographic, and electrochemical methods (Table 19.7). Spectrophotometric methods are very simple and do not require expensive equipment but

TABLE 19.7
Methods for Analysis of Antioxidants

Method	Examples	Applications
Spectrophotometric	Redox titration with dichloro-phenolindophenol	Ascorbyl palmitate, propyl gallate, tocopherols
Chromatographic	Emmerie-Engel, Folin-Ciocalteu	Pyrocatechols, BHA, BHT
Electrochemical	GC after derivatization, reverse-phase HPLC, TLC, polarography, voltammetry	All antioxidants, gallates, ascorbic acid, tocopherols

suffer from several disadvantages including lack of specificity and meaning (see later). Antioxidant contents are better determined by HPLC using diode-array, fluorescence, electrochemical, or mass detectors [189]. Antioxidants are best determined with use of reverse-phase chromatography on octadecylated silica gel with ultraviolet detection. For the determination of very polar substances, such as propyl gallate or ascorbic acid, the direct phase would be acceptable. It can also be determined by gas chromatography [194] but after derivatization (silylation of phenolic hydroxyls). Thin-layer chromatography (TLC) was often used before the development of HPLC, and several standard methods based on TLC are still available [211]. TLC might be used with sophisticated equipment [212] such as high-performance TLC, or TLC and flame ionization detection (TLC-FID). Electrochemical methods are based on the determination of the amount of electric energy necessary to oxidize the substrate. The determination of all the three tocopherols, using pulsed voltammetry, is a typical example [189]. It is possible to combine HPLC with an electrochemical detector, e.g., CoulArray, to provide a very sensitive and selective method for sensitive phenolic profiling and quantification [213]. It is indeed possible to analyze phenolic compounds by liquid chromatography–mass spectrometry (LC-MS) of plant extracts, but the separation is complicated by the different forms in which each compound might exist, e.g., glycosylation or esterification forms [214]. Alternatively, plant extracts may be hydrolyzed before HPLC, but hydrolysis leads to considerable losses [215]. Phenolic compounds may also be analyzed by capillary electrophoresis with different detectors including mass detectors [216, 217].

The quantitative analysis of antioxidant extracts is necessary for their standardization and the handling of biological variabilities between cultivars, location, and other environmental variables. When the structures and quantities of component antioxidants are known, their antioxidant activity and stabilization of foods can be measured and related to the composition. For individual phenolic compounds, structure–activity relationships can be estimated based on their structures (hydrogen-donation ability and hydrophobic-lipophilic balance) and concentrations [26, 27]. Theoretical hydrogen-donation ability can be computed, e.g., by *ab initio* and electron functional-density approaches [218, 219], but the environmental effect of the food matrix significantly alters these theoretical values. Thus, new computational methods

TABLE 19.8
Selected Methods Commonly Used in the Determination of Total Antioxidant Activity/ Capacity of Plant Extracts

Method	Principle of the Assay	Detection of Change
Folin-Ciocalteu (Total Phenolic Content)	The antioxidant reduces molybdophospho-tungstic heteropolyacid, Mo(VI) (yellow) + e- (from AH) to give Mo(V) (blue). The assay is performed at alkaline conditions (pH = 10).	The presence of antioxidants decreases the absorbance of Mo(VI) at 765 nm.
DPPH (Diphenyl-Picryl-Hydrazyl Radical Assay)	The diphenylpicrylhydrzyl radical (DPPH), which is pink in color, is reduced by antioxidants to yellow color. The assay is performed at neutral conditions (pH = 7).	The presence of antioxidants decreases the absorbance, of DPPH at 515 nm
ORAC (Oxygen Radical Absorbance Capacity)	Radicals generated by AAPH react with β-phycoerythrin (β-PE) as a fluorescence probe and the reaction is inhibited by antioxidants. Fluorescence of β-PE is measured for 35 min after the addition of (2,2'-azobis(2-amidinopropane) -dihydrochloride, AAPH). The assay is performed at slightly alkaline conditions (pH = 7.4).	The presence of antioxidants restores the fluorescence of β-PE (Ex. 485 & Em. 520 nm).
ABTS (Trolox Equivalent Antioxidant Capacity)	A bluish-green radical cation ($ABTS^{\bullet+}$) is formed by the reaction of ABTS (2,2'-azinobis(3-ethylbenzthiazoline-6-s ulphonic acid) with sodium/potassium persulfate. Antioxidants reduce $ABTS^{\bullet+}$ back to ABTS. The assay is performed at slightly alkaline conditions (pH = 7.4).	The presence of antioxidants reduces the intensity of the initial blue color at 734 nm.
FRAP (ferric ion reducing antioxidant power)	Antioxidants reduce ferric tripyridyl triazine (Fe(III)-TPTZ) to ferrous form having intense blue color. The assay is performed at acidic conditions (pH = 3.6).	The presence of antioxidants inhibits the development of blue color at 595 nm.

and algorithms taking into account the nature of the food are needed for optimum utilization of antioxidant mixtures.

During the last two decades, a large number of methods have been used to determine the total antioxidant activity of plant extracts by reacting them with an oxidizing agent and/or a redox indicator and recording the change by spectroscopy [220–223]. These methods (Table 19.8 on previous page) measure the hydrogen donation ability of the phenolic compounds mixtures, which is the product of antioxidant activity and concentration. The main problem is the method and solvent used for the extraction of phenolic compounds that cover a wide range of polarity from glycosylated to esterified compounds. These methods are not sufficiently selective and their performance is relevant neither to the lipid oxidation mechanism nor to the effects of the food matrix. The reactions are usually performed in ethanol or methanol, intermediate polarity solvents that will eliminate the effects of micellization. These methods may be used to compare samples of the same plant for variation in the quality and antiradical performance of their phenolic compounds.

19.9 FUTURE TRENDS

Since foods are complex and variable systems ranging from simple oil-in-water and water-in-oil to multistructure–multiphase systems, the physical structure of the food significantly affects the rate of the chemical interactions between unsaturated lipids, oxidants, and antioxidants. The concepts of the polar paradox, the interfacial phenomena, and the role of micelles [12–27] are now ready to be refined and applied to different foods. Kinetic modeling of the reactions for individual foods, based not only on peroxide values, can be performed using sophisticated approaches such as oxidomics. In the near future, a better understanding of the antioxidant structure–activity relationship is expected, which will allow the design of more efficient antioxidant protection techniques and designs.

20 pH in Food Preservation

Mohammad Shafiur Rahman and Md Ramim Tanver Rahman

CONTENTS

20.1 EFFECTS OF PH ON MICROORGANISMS AND ENZYMES

20.1.1 pH Values of Foods

The importance of pH on food stability and food preservation is well documented as well accepted by the scientific community. The term pH is the symbol for hydrogen ion [H^+] concentration. The hydrogen ion concentration of a food is a controlling factor in regulating many chemical, biochemical, and microbiological reactions. Hydrogen ion concentration is expressed in moles and pH is the negative log ion concentration. The pH scale ranges from 0 to 14. A neutral solution has a pH of 7.0. A lower scale reading indicates an acid solution, and a value above 7.0 indicates an alkaline solution. The pH scale is logarithmic rather than linear in character. Therefore, a pH of 3.0 is 10 times as acid as a pH of 4.0 [1].

The pH values of different food products are given in Tables 20.1 and 20.2. In general, fruits, soft drinks, vinegar, and wine possess low pH values at which most bacteria are unable to grow, and these products have good keeping qualities. Most meats, seafood, and raw milk have pH values greater than 5.6, which make them susceptible to bacterial spoilage and the possible growth of pathogens. Vegetables also have fairly high pH values and are more prone to bacterial spoilage [2]. Color, flavor, and texture of foods are also affected by pH [3].

The pH may vary considerably even within any given product. Some of the most important factors affecting the actual pH values of a product are [1] variety of cultivar, maturity, seasonal variations due to growing conditions, geographical areas, handling and holding practices prior to processing, and processing conditions. In the United States, the majority (93%, 355 out of 380) of beverages have a pH below 4.0 and 7% (25 of 380) shows a pH ≥4 [5].

20.1.2 Effects of pH on Microorganisms

20.1.2.1 pH Limits for Microbial Growth

Microorganisms require water, nutrients, and appropriate temperature and pH levels for growth. Table 20.3 lists the pH single factor limits for the growth of some important food spoilage and poisoning microorganisms. Minimum pH values for toxin production by *Clostridium botulinum* types A and B in canned foods are given in Table 20.4. This indicates that minimum pH levels are also dependent on the types of foods. The interaction of water activity and pH on toxin production by C*lostridium botulinum* type A and B in cooked vacuum-packed potatoes are given in Table 20.5. In general, heterotrophic bacteria tend to be least acid-tolerant among common food microorganisms [2]. A pH value of 4.5 is especially important because this is the pH below which *Clostridium botulinum* is widely regarded not to grow in foods. McClure et al. [6] reviewed the factors affecting growth and toxin production of *Clostridium botulinum*. They mentioned that grow and toxin production may occur at pH values below 4.6 if there is strict anaerobiosis, a high concentration of protein, and various acidulants used. Below about pH 4.2, most

TABLE 20.1
pH Values of Plant-Origin Foods

Food	pH	Reference
Apples	2.90–3.30	Booth and Kroll [2]
Apples	3.33–3.84	Murray [4]
Apple sauce	3.09–3.40	Murray [4]
Apricots	4.18–4.67	Murray [4]
Apricots (canned)	3.42–3.47	Murray [4]
Asparagus (cooked)	6.03–6.10	Murray [4]
Asparagus (canned)	5.20–5.32	Murray [4]
Bananas	5.00–5.29	Murray [4]
Bananas	4.50–4.70	Booth and Kroll [2]
Beans (cooked)	5.73–6.20	Murray [4]
Beans (canned)	4.62–4.72	Murray [4]
Beets (cooked)	5.23–5.90	Murray [4]
Beets (canned)	4.92–4.98	Murray [4]
Bread (white)	5.29–5.65	Murray [4]
Bread (wholemeal)	5.47–5.61	Murray [4]
Brussels sprouts	6.00–6.15	Murray [4]
Butter (peanut)	6.28	Murray [4]
Cabbage	5.40–6.00	Booth and Kroll [2]
Cabbage (green)	5.79–6.29	Murray [4]
Cabbage (cooked)	6.38–6.82	Murray [4]
Cantaloupe	6.17–7.13	Murray [4]
Carrots	5.88–6.00	Murray [4]
Carrots	4.90–6.00	Booth and Kroll [2]
Carrots (cooked)	5.58–5.88	Murray [4]
Carrots (canned)	5.18–5.22	Murray [4]
Cherries (red)	3.29–3.32	Murray [4]
Cherries (black, canned)	3.82–3.93	Murray [4]
Corn (canned)	5.90–6.44	Murray [4]
Coconut	5.90–6.52	Murray [4]
Cucumber	5.18–5.70	Murray [4]
Figs (canned)	4.92–5.00	Murray [4]
Grapes	2.80–3.80	Murray [4]
Grapefruit	3.22–3.70	Murray [4]
Grapefruit juice	3.00	Booth and Kroll [2]
Honey	3.70–3.78	Murray [4]
Lemon juice	1.98–2.40	Murray [4]
Lettuce	5.89–6.09	Murray [4]
Lime juice	2.00–2.25	Murray [4]
Melons	5.50–6.60	Murray [4]
Olives (green)	3.38–4.00	Murray [4]
Olives (ripe)	6.80	Murray [4]
Onions	5.32–5.85	Murray [4]
Oranges	3.30–4.30	Murray [4]
Orange juice	3.60–4.30	Booth and Kroll [2]
Peaches	3.30–4.05	Murray [4]
Peaches (canned)	3.70–3.82	Murray [4]
Pears (Bartlett)	3.49–4.08	Murray [4]
Pears (canned)	4.00–4.08	Murray [4]
Peas (cooked)	6.22–6.88	Murray [4]
Peas (canned)	5.71–6.00	Murray [4]
Pineapple	3.20–3.64	Murray [4]
Pineapple (canned)	3.39–3.50	Murray [4]
Plums (blue and Damson)	2.78–2.89	Murray [4]
Plums (red and yellow)	3.62–4.95	Murray [4]
Potatoes	5.40–5.90	Booth and Kroll [2]
Quince (stewed)	3.12–3.37	Murray [4]
Raspberries	3.62–3.95	Murray [4]
Rhubarb (stewed)	3.24–3.34	Murray [4]
Spaghetti (cooked)	5.97–6.40	Murray [4]
Spinach (cooked)	6.60–7.18	Murray [4]
Strawberries	3.30–3.35	Murray [4]
Tomatoes	3.99–4.75	Murray [4]
Tomatoes (canned)	4.10–4.28	Murray [4]
Vegetable soup (canned)	5.16	Murray [4]
Vinegar	3.12	Murray [4]
Watermelon	5.18–5.60	Murray [4]
Worcestershire sauce	3.63–3.67	Murray [4]
Yeast	5.65	Murray [4]

other food poisoning microorganisms are well controlled, but microorganisms such as lactic acid bacteria and many species of yeasts and molds grow at pH values well below this. Many weak lipophilic organic acids act synergistically with low pH to inhibit microbial growth. Thus, propionic, sorbic, and benzoic acids are the most useful food preservatives [7]. *Ichthyophonus hoferi* is an internal parasite of various fish species. Its growth was observed at all pH values 3 to 7, from 0°C to 25°C, and from 0% to 6% sodium chloride [8].

TABLE 20.2
pH Values of Animal-Origin Foods

Food	pH	Reference
Beef (broth)	6.14–6.20	Murray [4]
Beef (ground)	5.10–6.20	Booth and Kroll [2]
Beef (raw)	5.60	Murray [4]
Buttermilk	4.41–4.83	Murray [4]
Butter	6.10–6.40	Booth and Kroll [2]
Cheese (Camembert)	7.44	Murray [4]
Cheese (cheddar)	5.90	Murray [4]
Cheese (cottage)	4.75–5.02	Murray [4]
Cheese (Roquefort)	5.41–6.10	Murray [4]
Chicken	6.20–6.40	Booth and Kroll [2]
Cream	6.40–6.60	Murray [4]
Eggs (whole)	6.58	Murray [4]
Eggs (white)	7.96	Murray [4]
Eggs (yolk)	6.10	Murray [4]
Lobster	7.10–7.43	Murray [4]
Milk	6.30–6.50	Booth and Kroll [2]
Oysters	5.68–6.17	Murray [4]
Sardines	5.42–5.93	Murray [4]
Shrimp	6.80–7.00	Booth and Kroll [2]
Soda crackers	5.65–7.32	Murray [4]
Tuna (canned)	5.92–6.10	Murray [4]

Yeasts	1.5–8.5		ASHRAE [2, 12]
Yersinia enterocolitica	4.4-4.6		Booth and Kroll [2], Roberts [9], Walker [10]

[a] Lowest or growth; values may vary according to particular food substrate and especially in the presence of organic acids.

The efficacy of acids depends to a large extent on their ability to equilibrate, in their undissociated forms, across the microbial cell membrane and, in doing so, interfere with the pH gradient that is normally maintained between the inside (cytoplasm) of the cell and the food matrix surrounding it [7, 15, 16]. In addition to the weak lipophilic acid, other preservatives most widely used in foods include esters of benzoic acid, which are effective at higher pH values than organic acids. The inorganic acids, such as sulfate and nitrite, are most effective at reduced pH values, like the organic acids. While these preservatives are employed at hundreds to thousands of parts per million (ppm) levels, the acids used principally as acidulants are often employed at percentage levels [7].

In many products, such as semidry sausages and cheeses, combinations of pH and water activity are used to preserve foods. The combined inhibitory effects of pH and water activity on survival of microorganisms are clearly additive [17]. In addition to pH, the type of acid is also a factor, which influences the extent of inhibition with water activity. Generally, citric and acetic acids tend to be more inhibitory in combination with water activity reduction than do hydrochloric or phosphoric acids [18]. The general effect of water activity and pH on growth of bacteria is shown in Figure 20.1 [17]. FDA's Good Manufacturing Practice Regulations (GMPR) governing the processing requirements and the classification of foods are shown in Figure 20.2. Low-acid foods packaged in hermetically sealed containers must achieve commercially

sterile conditions either by retorting or a combined treatment of pasteurization and water activity (a_w), or a combined treatment of pasteurization and acidification [19]. Viruses, in contrast to bacteria, cannot imitate in food and water. Most of the foodborne viruses are more resistant to extreme pH than most vegetative bacteria [20]. The synergistic effect of pH, water activity, and temperature with different food processing technology can change the value of those parameters. Nonthermal processing technology, such as pulsed electric fields shows influence of pH, water activity, and temperature in killing of *Escherichia coli* and *Saccharomyces cerevisiae* [21].

20.1.2.2 Mode of Action of pH

Generally, bacteria can hardly maintain constant internal pH when they grow on a wide range of media of external pH. The H^+ ions destroy the amino–acid bond in nucleic acids, modify the cytoplasmic pH, and precipitate proteins; OH^- ions saponify the lipids in the enveloping membrane, leading to destruction of the superficial structure. A pH higher than 10.0 disorganizes the structure of the peptidoglycan and causes hydrolysis of the nucleotides of the virus genome. Similarly, the pH must exceed 12.0 to act on mycobacteria [22, 23]. Booth and Kroll [2] from Corlett and Brown [24] summarized three regimes of action:

- Strong acids, which lower the external pH but do not themselves permeate through the cell membrane. These acids may exert their influence by the denaturing effect of low pH on enzymes present on the cell surface and by lowering of the cytoplasmic pH due to increased proton permeability when the pH gradient is very large.
- Weak acids, which are lipophilic and permeate through the membrane. The primary effect of such acids is to lower cytoplasmic pH, and the undissociated acid may have specific effects on metabolism, which amplify the effects of the weak acid.
- Acid potentiated ions, such as carbonate, sulfate, and nitrate, which are more potent inhibitors at low pH.

As long as the internal pH of the microorganism remains constant, the effect of external pH on growth rate must be due to (i) inactivation of one or more essential enzyme activities, which are present on the outer layers of the cell (i.e., the outer membrane), the cell wall, the periplasm, and the inner membrane; and (ii) reduction of transport systems for essential ions and nutrients [2, 25].

At low external pH, the passive influx of protons under the influence of the proton motive force could be a major problem for cells attempting to regulate their cytoplasmic pH [26]. Most bacteria possess membrane-bound proton pumps, which exclude protons from the cytoplasm in order to generate a transmembrane electrochemical gradient of protons, the proton motive force. Those microorganisms, which are tolerant of very low external pH, acidophilic bacteria, and yeasts, have relatively low internal pH values. This may be a specific adaptation to the acidic environment [2]. The external pH has a significant effect on metabolism, often changing the pattern of enzyme synthesis and the nature of end products of metabolism. Booth and Kroll [2] concluded a reasonable generalization that cells produce acidic products when growing at alkaline external pH and neutral or basic products at external acidic pH.

A further counter to acidification of the cytoplasm is the buffering capacity provided by the acidic and basic side chains of the proteins and the phosphate groups of the nucleic acids. In general, buffering capacities in bacteria are approximately 400 nmoles H^+/pH unit/mg protein [27]. The buffering capacity is finite and can be overcome, for example, in the presence of high concentrations of a weak acid at low external pH [2].

In most microorganisms a cytoplasmic pH close to neutrality is essential for growth. For some microorganisms, recovery of cells from sublethal acid injury did not require new macromolecular synthesis, some cases of extensive protein denaturation occur in both bacterial and yeast cells, and protein synthesis is required for recovery [28–30]. DNA damage has also been suggested to occur in cells incubated at low pH [31]. Two generalizations can be made about pH homeostasis in microorganisms. First, the optimum cytoplasmic pH is species-dependent, i.e., acidophiles in the range 4.5–6.0, neutrophiles 7.5–8.0, and alkalophiles 8.4–4.9. Generally, yeasts and fungi exhibit similar values to the acidophilic bacteria [32]. Second, microorganisms exhibit different capacities to regulate their cytoplasmic pH and possibly have different tolerances of pH perturbation. For the purpose of pH homeostasis, it can be subdivided into fermentative and respiratory microorganisms [2].

20.1.2.3 Effects of pH on Heat Stability of Microorganisms

In the canning of foods, one of the most important factors affecting the sterilization times and temperatures is the actual pH value in the foods. The lower the pH values, the lower the degree of heat required for sterilization. The consumers' preference for acidic or nonacidic products also affects the selection of pH values. It is usually considered that a pH of 4.6 is the dividing line between acidic and nonacidic foods. Foods classified with respect to their pH values are shown in Table 20.6 [1]. Acidifying treatments for canned vegetables are also controlled by monitoring the pH values [33].

TABLE 20.6
Foods Classified According to Acidity

Group	Group Name	pH Range
I	Nonacid	7.0–5.3
II	Low or medium acid	5.3–4.6
III	Acid I	4.6–3.7
IV	Acid II	3.7–low

Source: Gould and Gould [1].

Bacterial spores are killed by heat more rapidly at low pH values than at pH values near neutrality [34–36]. Anderson and Friesen [34] showed that the rate of destruction of *Bacillus stearothermophilus* spores suspended in acetate buffer was only slightly more rapid at pH 4 than at pH 7, but below pH 4 the rate of death was much more rapid and appeared to be proportional to the proton concentration. At pH values of 7.0 and 6.0 spores of *Bacillus stearothermophilus* survived 60 min exposure unharmed at 100°C in the presence of lactic acid and sodium phosphate buffer, whereas at pH 4.3 and 3.0 they died with D_{100} (i.e., the decimal reduction times) values of 27 and 2.8 min, respectively. It was suggested that the enhanced death rate was due to toxic effects of undissociated lactic acid [37]. Watier et al. [38] measured the heat resistance of two strains of spoilage bacteria *Megasphaera cerevisiae* at temperatures 50°C to 60°C. The values of D_{50} were lower at pH 5.2 and 6.0, while at pH 4 the heat resistance was 4.2 times lower, thus at low pH the destruction rate was much higher. Koutsoumanis et al. [39] showed that exposure to a mildly acidic (pH 5.0 to 6.0) environment provided protection of the *Listeria monocytogenes* against acid.

20.1.2.4 Enhancement of the Effects of Preservatives

The efficacy of any preservative depends on the pH levels. Michener et al. [40] investigated 650 compounds for the ability to increase the susceptibility of spores to heat at pH 7. *Bacillus stearothermophilus* spores died much more rapidly at 100°C and mean pH 3.5 in the presence of lactic acid than in its absence. At pH 3.5, lactic acid (pK_a, 3.87) is approximately 70% undissociated and it can be suggested that the enhanced death rate was due to toxic effects of the undissociated acid [37].

20.1.3 pH Effects on Enzymes

Lipoxygenase catalyzed the oxidation of unsaturated fatty acids resulting in an off-flavor. Complete inactivation of lipoxygenase was irreversible when treated at pH 3.0 and below [41, 42] and inactivation of (i.e., activity) of urease was reduced to a commercially acceptable level at that pH. No effect on trypsin activity was observed up to pH 2. More than 70% protein dispersion ability was retained in the neutralized

full-fat soy flour after treatment with acid at about pH 3.0 [42].

Pectin esterase de-esterifies pectin, which leads to cloud loss in citrus juice. The thermal inactivation rates of pectinesterase in citrus juices increased at lower pH values [43]. The effect of pH on stability of thermolabile and thermostable pectinesterase was studied by Sun and Wicker [44]. Both isozymes showed stability over a wide pH range. Thermolabile pectinesterase was inactivated irreversibly at pH 2 and 12, whereas thermostable pectinesterase maintained almost the same activity as before pH treatment with slight inactivation at pH 12. Thus, the stability and conformation of thermostable pectinesterase were less likely to be changed by low pH treatment, and the conformational change was nearly reversible.

The enzyme lysozyme has antimicrobial potential to prevent or delay microbial growth in a variety of foods, such as fresh fruits and vegetables, tofu bean curds, meats, seafood, cheese, and wines. The relatively high thermal stability of lysozyme also makes it attractive for the use in pasteurized and heat-sterilized food products, possibly allowing reduced thermal processes, therefore, minimizing nutritional and sensory quality loss [45]. Makki and Durance [45] studied the stability of lysozyme in aqueous buffer solutions at selected temperatures (73–100°C), pH values (4.2–9.0) and sucrose (0%, 5%, 15%), and sodium chloride (0, 0.1, 1 M). Lysozyme was most stable at pH 5.2, and thermal stability decreased sharply as the pH increased to 9.0. At pH 7.2 and 9.0, sodium chloride had a clear stabilizing effect against heat inactivation of lysozyme. Sucrose stabilized lysozyme against heat inactivation at 75°C but not at 91°C. Loss of activity followed first-order kinetics, and a rate constant correlation was developed in the pH 5.2 to 7.2 range and temperatures between 73°C and 100°C as follows:

$$\ln k = \frac{32.90 - 1.62 \times 10^4}{T + 1.19\,(\text{pH})} \tag{20.1}$$

Ibrahim et al. [46] found that heat denaturation of lysozyme at increasing temperatures (80°C at pH 7.0 or over 90°C at pH 6.0) for 20 min resulted in progressive loss of enzyme activity while it greatly promotes bactericidal activity against gram-negative and -positive bacteria. They also observed that action is independent of catalytic function and kills bacteria through the membrane damage mechanism as found from electron microscopy.

20.2 EFFECTS OF PH ON FOOD COMPONENTS

20.2.1 Effects of pH on Gel Formation

The pH also affects many functional properties, such as color, flavor, and texture of foods, although the pH of a food is important for microbial growth. Acid fruit pulps form weak gels that collapse under their own weight [47, 48]. Texture formation of these acid pulps below pH 3.5 involves an important dilution of the pulp, thus pulp should be neutralized by addition of sodium hydroxide [49, 50].

Egg albumen is an important food ingredient because of its ability to incorporate other ingredients through the formation of a three-dimensional gel matrix. Gel properties are dependent upon many variables, including pH and ionic strength as well as the salts present. Savoie and Arntfield [51] studied the gelation of ovalbumin in the presence of salts containing Ca^{+2} and Mg^{+2} at various pH values. The impact of this binding on gel structure was dependent on pH and the technique used to evaluate structure. At pH 5, proteins tended to coagulate regardless of the type or amount of salt. At pH 7, the highest rigidity values from penetration measurements were obtained at salt levels of 0.005 M. At pH 9, the salt concentration for maximum rigidity varied with type of salt, while the storage moduli from dynamic rheology were highest at 0.01 M.

A significant improvement of functional properties, including foaming, emulsifying, and gelling properties of dried egg white (7.5% water) on the protein heating in a dry state at 80°C for several days [52]. Mine [52] found that heating of dried egg white proteins in the dry state at alkaline pH (under 9.5) was an effective method to obtain firm and elastic gels. The degree of unfolding of the proteins upon dry heating may play a crucial role in the gelling process of the proteins. The polymerization of the proteins was also enhanced by alkaline dry heating through the sulfhydryl–disulfide interchange. Alkaline dry heating resulted in a high molecular weight polymer of partially unfolded egg white proteins, which in turn contribute in the formation of low molecular weight and narrow molecular distribution of the aggregate.

The sinapic acid and thomasidioic acid bind to canola protein and affect protein functionality, especially gel formation upon heating of protein. Rubino et al. [53] studied the influences of sinapic and thomasidioic acid on the rheological characteristics of canola protein gels. At pH 4.5, there was binding between sinapic acid and the canola protein through electrostatic interactions, while at pH 7 and 8.5 there appeared to be a hydrophobic association between thomasidioic acid and canola protein. The presence of either compound resulted in deterioration of the characteristics of heat-induced gels for the canola protein. Sunflower protein gelation is strongly pH dependent. Sanchez and Burgos [54] found that gelation was only possible in the pH range 7–11 for sunflower protein, the storage modulus reached its maximum value at pH 8, the gels formed at pH 7 or above pH 9 were very weak, gelation time increased with pH and decreased with protein concentration, and the storage modulus at pH 8 increased exponentially with protein concentration.

20.2.2 Effects of pH on Proteins

The behavior of proteins is pH dependent and each protein has an isoelectric point (pI), where the contributions from positive and negative charges cancel out to give the molecule no net charge. At this pH, proteins tend to coagulate, and therefore it is to be expected that surface rheological parameters of proteins close to their isoelectric point are maximal [55, 56]. At the pI, charge-based contributions to repulsion are minimal, and steric stabilization is minimized since the proteins are

in their least expanded state [55]. The emulsion stability in some systems is greatest at the pI, such as gelatin [57], bovine serum albumin [58], pepsin [58], and soluble muscle protein [59]. This is probably due to the greater surface coverage at the pI with the compacted protein structures, and together with the tendency of the protein to coagulate at the pI gives cohesive films their enhanced stabilizing action [55]. Some proteins are shown to give less stable emulsions at the pI, such as low concentrations (0.004%) of either bovine serum albumin or lysozyme may be due to surface coverage, milk fat/whey protein, which are highly unstable at pH 4.5–5.0, close to isoelectric points [60]. Thus, Dalgleish [55] concluded that the stability of emulsions at the isoelectric point (i.e. pl) is dependent on protein concentration, the volume–surface area of the oil phase, and pH.

At other pH values, proteins may show a distinct dependence on pH [28]. Bovine serum albumin showed increasing emulsifying activity as the pH was increased between 4 and 9, and then decreased sharply as the protein changes conformation [61–63]. In the range of pH 3–8, β-lactoglobulin did not change its emulsifying capacity, although it passed conformational transitions [63]. Shimizu et al. [64] found a strong dependence of the emulsifying power with pH, increasing from pH 3 to 9. The hydrophobicities of the different whey proteins vary with pH, but all of the proteins behave similarly, i.e., their surfaces become less hydrophobic as the pH is increased [65]. Increasing the ionic strength diminishes the charged-based interactions between proteins and produced the same type of effects as changing the pH toward the isoelectric point [55].

Agboola and Dalgleish [66] studied the effects of pH and ethanol on the kinetics of destabilization of oil-in-water emulsions containing milk proteins. Under shear, emulsions containing caseinate were stable between pH 3 and 3.5 and at pH $\geq$ 5.3, while those formed with β-lactoglobulin were stable below pH 4 as well as at pH $\geq$5.6. The kinetics of pH-induced aggregation in emulsions could be explained by orthokinetic flocculation while ethanol-induced association in caseinate emulsions appeared to be a result of Ostwald ripening.

Caseins comprise approximately 80% of the total protein content in milk. Caseins are phosphoproteins precipitated from raw milk at pH 4.6 at 20°C. The α_{s1}-caseins contain more acidic amino acids than basic ones, with a negative net charge of 22 at pH 6.5 [67]. β-Lactoglobulin is remarkably acid-stable, resisting denaturation at pH 2.0. The protein assumes the shape of a prolate ellipsoid with an axial ratio of 2:1 and a hydration ratio of 35% to 40% [68]. It generally exists as a dimer resulting from the association of the monomer at the respective α-helical segments at the isoelectric pH of 5.2 and alkaline pH range. β-Lactoglobulin A at low temperatures and high concentrations, between pH 3.5 and 5.2, tends to form octamers as the predominant species. Below pH 3.5, β-lactoglobulin dissociates into monomers due to electrostatic repulsion between the subunits. Above pH 6.5, the dimers begin to dissociate. A transition in conformation occurs near pH 7.5, which is reversible and involves only a certain region of the molecule [69–71]. This reversible unfolding is followed by slow changes, which become increasingly irreversible with increasing pH [67]. Bovine α-lactalbumin is insoluble at the isoelectric range between pH 4 and 5. In contrast, goat α-lactalbumin forms a clear solution over a wide pH range. In the physiological state, it exists in the calcium-bound form. The calcium is tightly bound and is not removed by isoelectric precipitation and dialysis against phosphate buffer [72, 73].

20.2.3 Effects of pH on Vitamin Stability

The stability of vitamins depends on the pH of the medium and are summarized in Table 20.7 under acid/alkaline conditions. At higher water activity (>0.90), the rate of thiamin hydrochloride (vitamin B_1) degradation in a buffered solution of glycerol at 85–95°C is independent of water activity but highly dependent on pH [74]. Thiamin hydrochloride was less stable in solutions of univalent ions than in glycerol or divalent ions at the same water activity [75]. Riboflavin is also sensitive to pH. Nguyen and Hendrickx [76] studied the degradation of 5-$HCOH_4$ folate as a function of pH. They found some lability in acidic conditions and better stability in a broad zone between pH 5 and 8. Kinetic constants for the degradation of folate vitamins under various pH conditions are reported by Delchier et al. [77] when degradation of folate is first-order kinetics.

20.2.4 Effects of pH on Food Color

The colors of fruits, vegetables, and meats are associated with pigments (e.g., anthocyanins, chlorophyll, carotenoids, and myoglobin) and these pigments are influenced by pH. Wahyuningsih et al. [78] showed anthocyanin with a low pH or high pH has a significant effect on the food colorant.

TABLE 20.7
Stability of Vitamins under Acid/Alkaline Conditions

	Condition[a]		
Vitamin	**pH = 7**	**Acid Medium**	**Alkaline Medium**
Vitamin A	S	U	S
Vitamin D	S	—	U
Vitamin E	S	S	S
Vitamin K	S	U	U
Vitamin C	U	S	U
Vitamin B_1	U	S	U
Vitamin B_2	S	S	U
Vitamin B_6	S	S	S
Vitamin B_{12}	S	S	S
Niacin	S	S	S
Pantothenic acid	S	U	U
Biotin	S	S	S
Folic acid	U	U	S

Source: Murray [4].

[a] S: stable; U: unstable.

There is general understanding that the fundamental cause of green vegetable discoloration during processing is the transformation of chlorophylls to pheophytins by the impact of pH. The green color of vegetables swings to an olive green when warmed or set in acidic conditions. The amount of ferrihemochrome formation from myoglobin during cooking is affected by initial meat pH; mammalian muscle has a pH of around 7 and normal fresh meat has a pH ranging from 5.4 to 5.6 [3].

20.2.5 Effects of pH on Food Texture

Consumers' acceptability of food is influenced by texture and texture is affected by pH. Brandt et al. [79] observed firmed cauliflower, beans, potatoes, peas, and corn at pH 4 in the cooked state. In general, the vegetables are softest at pH 10; at pH 2, the firmness was only surpassed by the action of pH 4. Muscle pH has been associated with numerous other meat quality attributes including tenderness, water-holding capacity, cooking loss, and microbial stability (shelf life). Marination is widely used by consumers to improve meat tenderness and flavor. In this process pH plays a vital role in marinated meat. This improvement is due to the swelling of muscle fibers and/or connective tissue [3].

20.2.6 Effects of pH on Food Flavor

The acceptance of food by consumers is influenced by the flavor of that food. In Maillard reaction, flavoring compounds are formed and the flavor compound formation depends on the type of sugars and amino acids involved, reaction temperature, time, pH, and water content [80]. Several studies on Maillard reaction model systems have demonstrated that the pH of the reaction medium results changed in volatile and colored products. So the pH strongly determined the types of volatiles formed. Furthermore, flavors are very susceptible to change by the action of pH, moisture, acid, salt, and enzymes.

20.3 METHODS OF CONTROLLING PH IN FOODS

The pH of foods can be altered by (i) adding acidulants, such as acetic, citric, ascorbic, and lactic acid; and (ii) the action of microorganisms in many foods, such as cheese, yogurt, meat, and alcoholic beverages; in this method, growth of spoilage microflora is controlled by the production of lactic or acetic acids.

In fermentation, carbohydrates and other reduced substrates are incompletely oxidized in the absence of an external electron acceptor. In this process, all the electrons removed from a fermentable carbon source during its oxidation to release energy must be consumed by the reduction of a carbon metabolite resulting in the formation of a fermentation product [2]. The production of acid by fermentation plays a significant part in the preservation of food. In many dairy products, the production of lactic and acetic acids, and hydrogen peroxide may also be an important factor. With meat, it is considered that the reduction of pH and not the production of lactic acid is primarily responsible for the preserving action [2, 81, 82]. In dairy fermentations, flavor production is very important. The principal flavor components include acetaldehyde and diacetyl, which are by-products of the fermentation [2].

Fermentation processes have been applied to fish for many years and represent a low level and affordable technology for tropical developing countries [83]. Fagbenro and Jauncey [84] studied fermented tilapia stored for 180 days. Fagbenro [83] developed a preservation method for raw shrimp heads by fermenting with 5% (w/w) *Lactobacillus plantarum* as the inoculum at 30°C using 15% (w/w) cane molasses as a carbohydrate source. After incubation for 7 days, a desirable and stable pH <4.5 was attained in the anaerobic treatments, which lasted until 30 days after the start of fermentation. The addition of trona at 5% prior to fermentation restricted protein hydrolysis by inhibiting the activity of endogenous autolytic enzymes. The addition of onion extract at 5 ml/kg proved effective as an antioxidant, as the value of the thiobarbituric acid reactive substances remained low after 30 days of fermentation.

20.4 CONCLUSION

The pH of foods can be altered by adding acids and by adding beneficial microorganisms, such as lactic acid bacteria and fermentation. pH plays a critical role in food processing and preservation by affecting microbial, chemical, biochemical, and physical changes. A pH value of 4.5 is considered critical since *Clostridium botulinum* and most pathogens are unable to grow. In controlling microorganisms, weak acids are more effective than strong acids. In addition to pH, other factors such as water activity, temperature, and preservatives also affect the critical limits as well as the growth and death rate of bacteria. The pH also affects the gelling characteristics, protein, enzyme and vitamin stability, and production of the desired color, flavor, and texture. However, prediction of the stability of the combined effects of pH and other factors is a challenge.

21 Nitrites in Food Preservation

Mohammad Shafiur Rahman

CONTENTS

21.1 NITRITES AS CHEMICALS

Preservatives are compounds used to delay or prevent the chemical and microbiological deterioration of foods. Nitrites and nitrates are used in many foods as preservatives and functional ingredients. Nitrites are critical components used to cure meat and are known to be multifunctional food additives. They are also potent antioxidants. Nitrites are white to pale yellow hygroscopic crystals. Sodium nitrite ($NaNO_2$) is markedly less hygroscopic than potassium nitrite (KNO_2). Nitrites are quite soluble in water and liquid ammonia but much less soluble in alcohol and other solvents. At room temperature, one part of water dissolves one part sodium nitrite or three parts potassium nitrite [1].

21.2 ANTIMICROBIAL EFFECTS

Sodium nitrite plays an important role in inhibiting the growth and toxin production of *Clostridium botulinum* in cured products [2]. Input concentrations in excess of 100 mg/kg are used to produce protection against microflora [3]. The review of Woods et al. [3] indicates a 200 mg/kg at pH 6.0 was capable of inhibiting strains of *Achromobacter*, *Aerobacter*, *Escherichia*, *Flavobacterium*, *Micrococcus*, and *Pseudomonas* species. *Salmonella*, *Lactobacilli*, and *Clostridium perfringens* are more resistant when compared with other clostridia [3]. Times to first swell were 6.7, 29.8, 82.6, and 94.3 days when 0, 50, 100, and 156 mg/kg of sodium nitrite, respectively, were added to the perishable canned cured meat [4]. The primary effect of nitrite appeared in determining the length of the lag phase. Once swelling commenced, the rate at which the cans swelled was not significantly different at 50, 100, and 156 mg/kg of sodium nitrite. At 50 mg/kg nitrite, a 75% probability of toxicity was predicted at 3 months. Hauschild et al. [5] concluded that (i) the degree of safety from *C. botulinum* toxin production can differ by several orders of magnitude depending on the composition of formulation, and (ii) the large reductions in the concentrations of nitrite in the products could produce severe consequences.

21.2.1 Stage of Inhibition

Germination and outgrowth of bacterial spores include five sequential steps: (i) germination (i.e., becoming nonrefractile, stainable, and heat-sensitive), (ii) swelling of the germinated spore, (iii) emergence of new vegetative cell, (iv) elongation, and (v) cell division [6]. The inhibitory effect of nitrite

on bacterial spore formers is apparently due to inhibition of outgrowth and during cell division [7–9]. Duncan and Foster [6] identified points of inhibition in the outgrowth process of anaerobic spores. Up to 0.06% at pH 6.0 or between 0.8 to 1% at pH 7.0 nitrite allowed emergence and elongation of vegetative cells but blocked cell division. Elongated cells did not multiply, and eventually lysed by leaving the empty spore coats. With more than 0.06% nitrite at pH 6.0 or more than 0.8 to 1% at pH 7.0, the spores lost refractility and swelled, but vegetative cells did not emerge. Even as much as 4% nitrite failed to prevent germination (i.e., complete loss of refractility) and swelling of the spores.

Sodium nitrite induced germination of *Clostridium sporogenes* spores [10]. The process was accelerated using increased concentrations of sodium nitrite, a low pH, and a high temperature of incubation. The increase in germination rate with increasing temperature and increasing nitrite concentration may be a reflection in the alteration of the tertiary structure of a spore protein, which in turn may be involved in the calcium–dipicolinic acid complex [10]. The stimulatory effect of nitrite on germination has a dual role in preservation: (i) induction of spores to germinate making them susceptible to a heating process, and (ii) inhibition of the outgrowth of any surviving spores [10]. The lower concentrations inhibited outgrowth of the spore after germination, whereas higher concentrations inhibited germination itself [11]. In the case of *Salmonella*, preservatives (sodium nitrite, pH 6.0; sodium sulfite, pH 6.0; and sodium acetate-citric acid, pH 4.6) in growth media at 22°C can produce biofilm- and virulence-related genes and small RNAs transcription [12]. Nitride exerts a concentration-dependent antimicrobial effect on the outgrowth of spores from *Clostridium botulinum* and other clostridia. The effectiveness of nitride depends on several environmental factors, and the concentration of nitrite required to prevent outgrowth varies with the types of media or foods and environmental conditions.

21.2.2 Factors Affecting the Efficacy of Nitrites

21.2.2.1 Effects of pH

Nitrites have found to be most inhibitory to bacteria at an acidic pH [1]. Tarr [13–15] showed that the preservative action of nitrite in fish was greatly increased by acidification. In a bacteriological medium, the inhibitory action was increased with decreasing pH, particularly at pH 6.0 and below. Grindley [16] suggested that the mode of preservation could be due to the formation of active nitrous acid. Jensen [17] suggested that the increased action of preservation at low pH was due to the undissociated active inhibitor nitrous acid. A tenfold increase in the inhibitory effect of nitride against *Clostridium botulinum* was found when the pH was reduced from 7.0 to 6.0 [18]. A similar tenfold increase for one unit decrease in pH was also observed for *Staphylococcus aureus* [19], *Bacillus* [20], and *Clostridium sporogenes* [21].

The pH dependency of nitrite-induced bacterial inhibition also reflects the conversion of nitrite to nitrous acid [22].

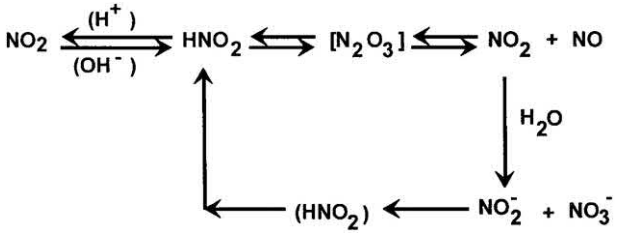

FIGURE 21.1 The dynamics of nitrous acid production in a cyclic reaction. (Adapted from Shank et al. [23].)

Shank et al. [23] mentioned the *nitrite cycle*. The dynamics of nitrous acid production may be visualized in a cyclic reaction where nitrite undergoes a concomitant oxidation–reduction reaction resulting in the formation of nitrate, nitric oxide, and nitrogen dioxide. Nitrogen dioxide reacting with water would generate more nitrate and nitrite with the nitrite reentering the cycle (Figure 21.1). At low pH levels (pH 3 to 4), the cycle rapidly forms NO_3 and NO. At intermediate pH levels (pH 4.5 to 5.5), the cycle rotates more slowly. The presence of HNO_2 is prolonged, thereby increasing its reaction potential. This is the level of maximum bactericidal activity. At higher pH levels (pH 6 to 7), the equilibrium shifts toward $NaNO_2$, the cycle is prevented from functioning, and no bactericidal effects are observed. Nitrous acid and nitric oxide have two fundamental areas of reaction: (i) with the bacterial cell itself, and (ii) with various constituents of the medium making them unavailable for subsequent metabolism. Either or both of these reactions could result in bacteriostasis. Further evidence for bound nitric oxide was presented by Frouin [24]. It was found that all measurable nitrite in various cured products could be volatilized under a high vacuum. In the meat system, nitrite was converted to nitric oxide and may produce a complex equilibrium with other components.

At 20°C, *Clostridium perfringens* growth in laboratory medium was inhibited by 200 mg/L nitrite and 3% salt, or 50 mg/L nitrite and 4% salt at pH 6.2. Fecal *Streptococci* showed growth in the same medium with 400 mg/L and 6% salt [25]. *Salmonella* showed visible growth within 1 week at 20°C in the presence of 400 mg/L nitrite and 4% salt. Significant inhibition by salt and nitrite was achieved only at lower temperatures (10°C or 15°C) and at pH 5.6 or 6.2. *Escherichia coli* was more resistant than *Salmonella*. The inhibition was demonstrated only at the extremes of pH 5.6, salt 6%, nitrite 400 mg/L, and temperature 10°C [26].

Survival of *Listeria monocytogenes* was detected after fermentation and drying, although their number was usually found to be reduced. Surveys of fermented meat products confirmed the presence of *Listeria monocytogenes* in finished products [27]. Junttila et al. [28] concluded that nitrite and nitrate additions to a meat product at officially approved levels did not cause elimination *Listeria monocytogenes*. In broth cultures, acidity and nitrite increased the inactivation rate of *Listeria monocytogenes* [29]. Whiting and Masana [27] studied the effect of nitrite (0–300 mg/L) and pH in uncooked fermented meat products. The time to achieve a 4-log decline as greatly affected by pH, ranged from 21 days at pH 5.0 to less

than 1 day at pH 4.0. Nitrite additions did not affect survival and it was suggested that the effective concentration was the rapidly decreasing residual nitrite level. There is potential for production of bacteriocins by the lactic acid bacteria of the starter cultures in the case of fermented meat [27].

21.2.2.2 Effects of Oxygen

Nitrite provides more inhibitory effects under anaerobic conditions as compared to aerobic [19, 22, 30]. The aerobically cultured *Staphylococcus aureus* were able to grow in the presence of significantly higher concentrations of sodium nitrite than were cultures grown in an aerobic environment [19]. Buchanan and Solberg [22] studied the effect of pH and oxygen pressure on the bacteriostatic accumulation of sodium nitrite toward *Staphylococcus aureus*. They found that the magnitude of inhibition was dependent on the interaction of sodium nitrite concentration, initial pH, and partial pressure of oxygen. Aerobic cultures, after the initial pH decrease, showed a subsequent rise in pH to a level greater than the initial pH, whereas anaerobic cultures remain at the pH level of maximum pH decrease. Injury and cell destruction were most apparent at the lower pH level in the presence of nitrite concentration ≤500 mg/kg. However, 200 mg/kg sodium nitrite in cured meats would offer significant protection against the growth of *Staphylococcus aureus*, particularly if meat product is vacuum packed. Buchanan and Solberg [22] suggested that nitrite may inhibit the growth of *Staphylococcus aureus* by blocking the sulfhydryl sites of either coenzyme A or alpha-lipoic acid, thus blocking the normal metabolism of pyruvate.

21.2.2.3 Effects of Other Food Components

Temperature, salt concentration, and initial inoculum size also significantly influence the antimicrobial role of nitrite [8, 31–34]. It has been reported that sodium chloride alone at concentrations of 9.0% to 10.5% can inhibit growth and toxin production by *Clostridium botulinum*. When nitrite was added in concentrations of 75 and 150 mg/kg, sodium chloride levels of 5.8% and 4.9% were required to inhibit toxin formation. The usual salt levels added to cured meat range from 2% to 3% of the weight of the product. This indicates that salt alone is not always a practical inhibitor of growth and toxin formation by *C. botulinum* [35]. Pierson and Smoot [35] mentioned in his review that the inhibitory effects by the interaction of sodium chloride and nitrite on various bacteria have been widely reported. Riemann [36] found significant inhibition of bacterial spores in a canned meat system by interactions of sodium chloride with sodium nitrite or nitrate as well as pH interactions with sodium chloride. Others also found that inhibition was due to the interaction effects of pH, sodium chloride, and sodium nitrite [37, 38]. Most *C. botulinum* type A and proteolytic type B and F strains would grow in the presence of 150 to 200 mg/kg of sodium nitrite or 6% sodium chloride at pH 6.0, but under the same conditions 200 mg/kg of sodium nitrite plus 3% sodium chloride inhibited almost all of the strains [39]. The combined effects of salt, nitrite, and pH can be synergistic to the inhibition [35].

Roberts et al. [40, 41] studied the combined effect of the following factors on growth of *Clostridium botulinum*: sodium chloride (0–4.5% w/v on water), sodium nitrite (100–300 mg/kg), sodium nitrate (0–500 mg/kg), sodium isoascorbate (0–1000 mg/kg), polyphosphate (0–0.3% w/v), and heat treatment (70–80°C), and storage temperature (15–35°C). Their findings can be summarized as follows:

(i) Increasing nitrite, salt, or heat treatment; adding isoascorbate, polyphosphate, or nitrate; or decreasing storage temperature significantly reduced toxin production.
(ii) The relative effect of increasing nitrite became less in the presence of isoascorbate or high salt levels.
(iii) Increasing salt or heat treatment, adding nitrate, or decreasing storage temperature had less effect if isoascorbate was present.
(iv) The addition of polyphosphate enhanced the effect of adding isoascorbate.

The findings should not be used to assess which combinations give a guaranteed risk of toxin production, since minor changes in product formulation or its production or in experimental conditions might significantly alter the ability to support toxin production and the variability of the system [41].

The combinations of low nitrite (40 mg/kg) plus sorbate/sorbic acid controlled the growth of *Clostridium botulinum* as effective as the level of nitrite (156 mg/kg). The low level of nitrite (40 mg/kg) alone had no significant effect on the growth of *Clostridium botulinum*, but was included to ensure acceptable cured color and flavor [42]. The factors that decreased the toxin production of *Clostridium botulinum* were (i) potassium sorbate, (ii) increasing sodium chloride, (iii) decreasing pH, and (iv) decreasing storage temperature. Heat treatment interacted significantly with some other factors. The effect of sorbate (0.26% w/v) was greater at 3.5% sodium chloride than at 2.5%, at pH values below 6.0, and at low storage temperature [42].

Ethylenediaminetetraacetic (EDTA), isoascorbate, and ascorbate enhance the antibotulinal efficacy of nitrite in canned meat. The degree of inhibition was inversely related to the level of iron and directly related to the level of EDTA. The use of isoascorbate and ascorbate has both positive and negative attributes depending on their level in meat products. At a moderate level, the synergistic effect is due to the sequestering cause of isoascorbate or ascorbate on a cation, iron. On the other hand, excessive levels of ascorbate were shown to decrease the efficacy, because isoascorbate and ascorbate cause more rapid depletion of residual nitrite. EDTA more effectively sequesters iron, thus making iron less available for preventing nitrite inhibition [43]. Tompkin et al. [43] proposed using a minimum of isoascorbate to hasten the curing reaction and stabilize color and flavor, and supplementing with a low level of EDTA for improved botulinal protection. When *Bacillus cereus* was inoculated into uncooked sausage in the presence of 500 mg/kg sodium isoascorbate and 200 mg/kg sodium nitrite and incubated for 48 h at 20°C, no growth was

demonstrated. Sodium isoascorbate alone had no inhibitory effects [44].

21.2.2.4 Effects of Heating

In a bacteriological medium, the inhibitory effect of nitrite is enhanced tenfold after heating due to the formation of an extremely inhibitory substance. This is called the *Perigo effect* [21]. Perigo et al. [21] confirmed that the effect of unheated sodium nitrite was pH dependent and that 200–400 mg/kg sodium nitrite was necessary to inhibit the growth of *Clostridium sporogenes* at pH values around neutrality. They showed that as little as 3–5 ppm sodium nitrite heated in the medium for 20 min at 105–115°C could inhibit growth, and this inhibition was slightly dependent on the pH of the medium. The rate at which this unknown substance is produced was maximal at a temperature of about 110°C. At temperatures exceeding 110°C, the unknown substance appeared to break down or react in such a way that its inhibitory activity declines. Perigo and Roberts [45] confirmed this effect in 30 clostridial strains including *Clostridium botulinum* types A, B, E, and F (14 strains) and *Clostridium welchii* (8 strains). It was reported that a reducing agent such as thioglycollate, ascorbate, or cysteine, and protein hydrolysate were the necessary components of the laboratory medium in order to produce the effect. Roberts and Garcia [46] showed that the inhibition was enhanced due to the Perigo effect in the case of 9 of 14 strains of *Bacillus*. *Streptococcus durans* (*faecium*) was also sensitive to this effect, whereas *Streptococcus faecalis* and *Salmonella* were more resistant.

It has been suggested that one or more new chemical species have been produced [21]. Evidence has been presented that indicates that the media may contain substances such as Roussin's black salt (iron thionitrosyl) [47] and nitrosothiols [48, 49]. Involvement of sulfhydryl groups as well as a nitroso group is probably important [48, 49]. Hansen and Levin [50] mentioned that it may be possible that heat-induced Perigo inhibitors are distinct from these compounds. They suggested that a heat-induced inhibitor presumably of Perigo type was compared with the nitrosothiols of thioglycolate and mercaptoethanol. Phase-contrast microscopy revealed that inhibition of morphological events occurred either before germination or during early outgrowth, depending on inhibitor concentration. The inhibitors derived from nitrite act virtually in every stage of the life cycle of *Bacillus*, suggesting that their mode of action is rather general and that inhibition may be the result of inactivation of several sensitive metabolic systems or steps. A synergistic inhibitory response could help explain the elusive nature of the mode of action of nitrite curing salts as preservatives [50].

An inhibitor of *Clostridium perfringens* formed when low levels of nitrite autoclaved with the defined chemical medium. Only amino acids and mineral salts were involved in the production of this inhibitor. The toxic compound was formed at the sublethal level from cysteine, ferrous sulfate, and sodium nitrite. S-nitrosocysteine, unstable Roussin's red salt, and a complex of cysteine, iron, and nitric oxide were detected. Moran et al. [51] concluded that observed inhibition could be due to the combined effects of sublethal concentrations of each compound. The extended heat treatment of the meat may cause decomposition of the proteins with the liberation of amino acids, peptides, and possibly, amines. Nitrite reacts with amines and amino acids forming N-nitroso compounds, either N-nitosmines or N-nitrosamides, which are toxic and carcinogenic and mutagenic to various species of microorganisms [52].

Johnston et al. [53] found a Perigo-type effect in minced pork. Johnston and Loynes [54] mentioned that the inhibitory effect of nitrite can be increased in the media by the addition of reducing agents, such as cysteine, thioglycolate, and ascorbate. These agents are known to aid in the reduction of nitrite and may affect the formation of nitroso reductants. These intermediate carriers may transfer the nitroso group directly to components of the bacterial cells or release nitric oxide. Johnston and Loynes [54] mentioned that the addition of reducing agents to meat suspensions decreased the redox potential and increased the inhibitory activity by Perigo factor formation. Ashworth and Spencer [55] studied the role of chemical additives in the formation of this inhibition in minced pork and found a similar effect. They added 0.1% of reducing agents in pork slurry containing nitrite and found that its inclusion increased the inhibitory effect of nitrite in the case of sodium ascorbate, cysteine (free base), and thioglycollate, but with sodium formaldehyde sulfoxylate and sodium formaldehyde bisulfite there was a marked decrease in the inhibitory.

Huhtanen and Wasserman [56] suggested that a potent anticlostridial inhibitor can be produced by the addition of iron (ferrous or ferric) without autoclaving nitrite in the medium. They indicated that iron was a limiting factor and sulfhydryl groups were probably necessary for its formation. Similarly, Custer and Hansen [57] found lactoferrin (an iron-binding glycoprotein) and transferrin reacted with nitrite to an inhibitor effective for spore outgrowth of *Bacillus cereus*. The Perigo inhibitor is formed at 105°C or higher, which exceeds the temperatures normally used in the processing of cured meats. Holley [58] mentioned that the Perigo inhibitor is formed in culture medium only when sulfhydryl groups and iron are present. Nitride reacts with various naturally occurring chemical components in the complex system of meat. The heating conditions normally used in the curing process speeds up these reactions, and at the end of the process only about 10–20% of the originally added nitride is analytically detectable. The residual nitride level declines further during storage and distribution [59].

N-nitrosamines, biogenic amines, and residual nitrites are considered as harmful substances, which are often present in cured meats. Initial dry-cured raw sausage contained 5.31 μg/kg of total N-nitrosamines. Cooking by deep-frying or pan-frying resulted in the highest contents (i.e., similar to the raw state) as compared with boiling or microwave treatments. Frying increased N-nitrosodimethylamine (NDMA), N-nitrosodiethylamine (NDEA), and N-nitrosopyrrolidine (NPYR), however it decreased histamine and cadaverine. Cooking (i.e., boiling and microwave treatments) decreased

the total biogenic amines, thus these treatments are suitable methods for cured meat treatments [60].

21.2.2.5 Effect of Irradiation

Pierson and Smoot [35] reviewed the effects of irradiation and mentioned that a limited amount of added nitrite was required to produce acceptable irradiated cured meat products.

21.2.3 Mode of Action to Microflora

A target can be selected from biochemical knowledge in the undesired microorganisms, which is absent from or at least different in the human. This target might be an enzyme or a cellular component involved in a process essential to microbial survival or development [61]. The inhibitory action of sodium nitrite on *Clostridium perfringens* was apparently at the cellular level, since microscopic examination of these organisms indicated no visible difference between inhibited and normal cells. Thus, damage was probably at a submicroscopic level [62]. Yarbrough et al. [63] showed that nitrite has more than one site of attack in the bacterial cell metabolic processes. These are (i) nitrite interferes with energy conservation by inhibiting oxygen uptake, oxidation phosphorylation, and proton dependent active transport; (ii) nitrite acts as an uncoupler, causing a collapse of the proton gradient; and (iii) nitrite inhibits certain metabolic enzymes.

21.2.3.1 Inhibition of the Phosphoroclastic System

In a cell, the oxidation of substrate occurs with concomitant production of adenosine triphosphate (ATP). This can then be used subsequently as an energy source for the synthesis of new cellular material required for growth. In clostridia, an important source of ATP is the oxidation of pyruvate to acetate by the phosphoroclastic system [3]. When nitrite is added to a suspension of cells of *Clostridium sporogenes* incubated in medium containing glucose, there is a large and rapid decrease in the intracellular concentration of ATP and an excretion of pyruvate from the cells [64]. This increase in pyruvate suggested that the phosphoroclastic system is inhibited by nitrite [3]. Iron is required nutrient for clostridial spore germination and outgrowth, and botulinal toxin development. The growth of *Clostridium sporogenes* and *Clostridium botulinum* was inhibited by nitrite through interference with the phosphoroclastic system resulted in an accumulation of pyruvic acid in the medium [64, 65]. The inhibition was due to an interaction occurring between nitrite and intracellular iron-bound protein, i.e., the reaction of nitric oxide with the nonheme iron of pyruvate:ferredoxin oxidoreductase [64]. Nitrite was also shown to inhibit the iron-sulfur enzyme ferredoxin of *Clostridium botulinum* and *Clostridium pasteurianum* [66]. The addition of iron caused a depletion of the residual nitrite levels in cured meats.

The phosphoroclastic system consists of two components: ferredoxin and pyruvate:ferredoxin oxidoreductase. Both of these contain nonheme iron moieties. Pyruvate:ferredoxin oxidoreductase consists of a single protein molecule containing thiamine pyrophosphate and a nonheme iron. Nitric oxide causes inhibition of the phosphoroclastic system by interacting with these components. Nitric oxide is a potent iron ligand that can form coordination complexes with nonheme iron. Pyruvate:ferredoxin oxidoreductase seemed to be more sensitive to nitric oxide [3, 64]. Tompkin et al. [67] also suggested that nitric oxide reacted with iron-containing protein in the cell of *C. botulinum*. Reddy et al. [68] demonstrated the production of iron nitric oxide complexes using electron-spin resonance spectroscopy. The aliphatic and aromatic nitro compounds inhibit the ferredoxin possibly because of formation of S-nitrosothiols by reaction with cysteine residues [69]. Castellani and Niven [19] suggested that the bacteriostatic action of nitrite might be due to interference with the normal metabolism of the hypothetical pyruvate–sulfhydryl complex.

When nitrate and nitrite are added to dry fermented meat sausage, staphylococci experience nitrosative stress [70]. The nitric oxide synthase (NOS) is present in the genome of all staphylococci. NOS produces nitric oxide (NO) and citrulline from arginine. NO is highly reactive with a broad spectrum of activity resulting from targeting metal centers (heme and nonheme) and protein thiols. At low concentration, NO acts as a signaling molecule, while at higher concentration it generates nitrosative stress.

21.2.3.2 Inhibition of Enzyme Systems

At acid pH levels, sodium nitrite exists as nitrous acid, an extremely reactive molecule capable of interaction with a wide variety of substances including myoglobin, ascorbic acid, phenols, secondary amines, amino groups, and thiol groups [71]. Mirna and Hofmann [72] reported that although sodium nitrite reacts with both sulfhydryl (SH) groups and primary amino groups at pH 5.5, the reaction with SH groups is more rapid. Riha and Solberg [62] proposed that nitrite inhibition of *Clostridium perfringens* may be due to a reaction of nitrous acid with SH-containing constituents of the bacterial cell. The nitrite could inhibit enzymes of glucose fermentation such as glyceraldehyde-3-phosphate dehydrogenase and aldolase in *Clostridium perfringens* [71]. Nitrite also inhibited aldolase from *Escherichia coli*, *Pseudomonas aeruginosa*, and *Streptococcus faecalis* [63]. Nitrite inhibited the nitrogenase of *Clostridium pasteurianum*, a system comprised of two nonheme-iron-containing proteins. This inhibition was probably due to the reaction of nitric oxide with a component of the nitrogenase system [73].

McMindes and Siedler [74] reported that nitric oxide was the active antimicrobial principle of nitrite and that pyruvate decarboxylase may be an additional target for growth inhibition by nitrite. These observations are substantiated by the fact that the addition of iron to meats containing nitrite reduces the inhibitory effect of the compound [75]. Chelating agents like sodium ascorbate, ethylenediaminetetraacetate, and polyphosphate enhance the antibotulinal action of nitrite. Muscle pigmentation is due to myoglobin and, to a lesser extent, hemoglobin remaining after carcass bleeding. Heart meat showed no inhibition of *Clostridium botulinum* inoculum even with a 156 mg/kg of sodium nitrite added to the product. Adding hemoglobin to the meat formulation reduced

nitrite after processing and decreased botulinal inhibition. The degrees of pigmentation of the meats are roughly grouped in descending order as follows: heart meat, beef round and turkey thigh meat, pork ham, veal, and turkey breast. Tompkin et al. [67] offered the hypothesis that nitric oxide, which was formed from residual nitrite via nitrous acid, reacted with extracellular iron of cells, thereby blocking some metabolic steps essential for outgrowth. The reaction might involve the iron in ferredoxin or an enzyme in which iron played an essential role [67]. The results of Miller and Menichillo [76] demonstrated that use of blood fractions that increased iron levels in beef above 30 mg/kg interfered with the antibotulinal efficacy of sodium nitrite of 156 mg/kg. Lucke [77] observed that blood sausages were associated with foodborne botulism in Germany. It is advisable to include additional microbial growth barriers when iron-containing compounds are added to cured meats [76].

Ingram [78] first postulated that nitrite inactivated enzymes associated with respiration. The active inhibitory agent outside the cell was closely correlated with nitrous acid, while the mechanism of action may vary for different physiological types of microorganism [63]. Nitrite was shown to inhibit active transport, oxygen uptake, and oxidative phosphorylation of *Pseudomonas aeruginosa* by oxidizing ferrous iron of an electron carrier, such as cytochrome oxidase, to the ferric form [79]. Since glucose transport in *Streptococcus faecalis* and *Streptococcus lactis* is not dependent on active transport or cytochromes, nitrite does not inhibit these organisms [79]. Nitrite inhibited the active transport of proline in *Escherichia coli* but not group translocation by the phosphoenolpyruvate:phosphotransferase system [63]. Inhibition of other enzymes, particularly those containing sulfhydryl groups, can occur, but these effects usually occur at higher concentrations of nitrite [3].

There may be damage to the cell wall or membrane indicated by the graying or browning of *C. perfringens* cells incubated with inhibiting concentrations of sodium nitrite [71]. *Staphylococcus faecalis* and *Streptococcus lactis* were highly resistant to nitrite, although aldolase was sensitive to nitrite. This suggested that these streptococci are impermeable to nitrite [63].

21.3 INTERACTION OF NITRITES WITH FOOD COMPONENTS

A water-soluble or low molecular weight compound was responsible for a large part of the nitrite depletion [80, 81]. Sebranek et al. [82] found that nitrite bound to a hot-water-soluble and insoluble meat residue. An amino acid or oligopeptide (probably with an SH group) could be involved in nitrite reduction. Fox and Nicholas [80] examined the effects of various compounds in meat slurries and found that histidine and reductants such as ascorbate and cysteine caused the nitrite depletion. Knowles et al. [83] investigated the interaction of nitrite with bovine serum albumin at gastric pH 2.5, and obtained 3-nitrotyrosine, 3,4-dihydroxyphenylalanine, and 6-hydroxynorleucine. Miwa et al. [84] mentioned that it is well known that primary amino acids react with nitrite to produce alcohol and nitrogen gas (Van Slyke reaction). Among endogenous acidic substances tested, cysteic acid showed the highest ability to decompose nitrite, accompanying the production of unidentified N compounds. Woolford et al. [85] studied the reaction of nitrite with isolated myosin and showed that a part of the lost nitrite was bound to the protein and identified 3-nitrotyrosine as a major product of the reaction. The nitric oxide formed from nitrite may partly bind to protein [72] or ferricytochrome [86]. Frouin [87] concluded that nitrite was rapidly broken down to NO in meat products and reacted with unsaturated carbon–carbon bonds [88]. If whole adipose tissue was treated with nitrite, it was bound to connective tissue, extracted lipid, and unsaturated carbon–carbon bonds. The experiments on various fatty acids and glycerides showed a binding that was apparently related to the degree of unsaturation [89].

Fujimaki et al. [90] studied the fate of nitrite during curing and cooking in the model solutions composed of myoglobin, sodium nitrite, and sodium ascorbate. After curing and cooking, nitrite was recovered as residual nitrite, nitrate, a nitrosyl group of denatured nitrosomyoglobin, and gaseous nitrogen compounds. Almost all of the nitrite was recovered as nitrate whenever greening occurred in the curing period. The gaseous nitrogen compounds were produced under the condition where both sodium nitrite and sodium ascorbate were abundant as compared with myoglobin, and this reaction proceeded not in the curing period but at the cooking stage. The addition of sodium chloride into the model system increased residual nitrite and nitrosomyoglobin [90]. Emi-Miwa et al. [91] also studied the fate of nitrite added to whole meat, meat fractions, and model systems with added sodium ascorbate. They found residue as nitrite, nitrate, nitrosothiol, denatured nitrosomyoglobin and gaseous nitrogen compounds. Twenty percent of the total nitrite lost was changed to nitrosothiol-N in specific interactions between nitrite and sulfhydryl groups of myosin [92]. Olsman [93] also mentioned that more than half of the free nitrite disappeared on the storage of canned cured meat as bound nitrite, probably as nitrosothiols formed with protein-bound thiol groups. The amount of bound nitrite increased with the addition of ferrous ions. This may be due to the formation of ferric coordination complexes between cysteine residues and nitric oxide [94]. Cassens et al. [95] found typical distribution of nitrite in the proportions: myoglobin 5–15%, nitrate 1–10%, nitrite 5–20%, gas 1–5%, sulfhydryl 5–15%, lipid 1–5%, and protein 20–30%.

Namiki and Kada [96] found the formation of ethylnitrolic acid by the reaction of sorbic acid with sodium nitrite by heating at 90°C. The isolated compound ethylnitrolic acid revealed strong activity in comparison with the original materials. The ethylnitrolic acid, sorbic acid, and sodium nitrite were effective at concentrations of 0.025–0.05, 2–4, and 1.5–3 mg/ml, respectively. They also mentioned that ethylnitrolic acid is necessarily formed in foodstuffs containing sorbic acid and sodium nitrite together [96].

Osawa et al. [97] concluded that the main mutagen formed by the nitrite or sorbic acid reaction was 1,4-dinitro-2-methyl pyrole. Piperine was also the mutagen in the nitrite system. The food components, such as ascorbic acid, cysteine, and

some phenolic compounds, were reported to react with nitrite, thus preventing the formation of nitrosamines *in vitro* as well as *in vivo* [98, 99]. Ascorbic acid was reported to inhibit bacterial mutations induced by N-nitroso compounds [100]. The oxidative desmutagenic action of cabbage peroxidase [101] and myeloperoxidase against the mutagenic principles of tryptophan pyrolysate [102] was also reported. The ascorbic acid, cysteine, and other reducing substances were responsible for the desmutagenic action against the mutagens of sorbic acid or a nitrite system.

21.4 FUNCTIONAL AND SENSORY PROPERTIES IMPROVEMENT

Taylor and Sumner [103] mentioned that food additives play an important role in improving health, increasing supply, enhancing appeal, or improving convenience. Among these, health benefits should be given the greatest consideration, while supply benefits are second in importance, and increased convenience and improved appeal are the least important.

Nitrite salts are used for the curing of meat, poultry, and fish products. Curing with nitrite results in the development of a characteristic pink color and distinctive flavor [2]. The sequence of color changes during curing of meat are [3] (i) the initial purple-red color of myoglobin changes to the brown of metmyoglobin; (ii) in reducing conditions nitric oxide derived from nitrite converts this to the dark red nitrosylmyoglobin; and (iii) if the meat is heated, e.g., in cooking, this pigment is converted to the stable nitrosyl hemochrome, which is pink. Ando et al. [104] described that 5′-inosinic acid, adenosine-5′-monophosphoric acid, reduced glutathione, glutamate, and Fe^{2+} influenced the cured color formation.

Nitrite content of 5 mg/kg can produce a satisfactory color for a short time, but it is generally believed that higher concentrations of about 20 mg/kg are necessary for commercial color stability. Nitrite concentrations of at least 50 mg/kg are thought to be necessary for correct flavor development [3, 35]. The addition of nitrite at a minimum level of 50 ppm was necessary to achieve reasonably typical thuringer flavor and appearance characteristics in sliced and baked pizza topping products. At least 100 mg/kg added nitrite was necessary to produce these effects in fried thuringer. The effect of added nitrite above 100 mg/kg was negligible for further color development. The fresh, fried, or baked thuringer containing neither nitrite or nitrate was judged most rancid, and poorest flavor and appearance quality. No nitrosamines were detected in thuringer regardless of initial nitrite (0–150 mg/kg) or nitrate (0–1500 mg/kg) concentration, storage condition, or kitchen preparation method [105]. Pierson and Smoot [35] reviewed the minimum level of nitrite in different food products. These are 20 mg/kg for cured meat and hams, 30 mg/kg for bacon, 25 mg/kg for wieners, 70 mg/kg for pork loins and country style hams, 52 mg/kg for frankfurters, 26 mg/kg for franks, and 40 mg/kg for turkey frankfurters. The modification of the fresh meat flavor is another change produced in meat by the addition of nitrite. A minimum level of 39–50 mg/kg nitrite was required to develop the appropriate flavor [35].

Nitrite upon addition to meat has been associated with the delay of the development of oxidative rancidity [106]. When nitrite reacts with heme compounds to form cured meat pigments, the ferric iron (oxidized state, Fe^{+++}), which is active in lipid oxidation, is reduced to ferrous (Fe^{++}), which is an inactive catalyst [35]. The addition of nitrite to model lipid systems containing Fe^{++} or Fe^{++}-EDTA and aqueous beef extracts substantially reduced oxidation rates [107]. In bacon formulated without or 15 ppm nitrite, off-flavors were found to be high and to increase more rapidly [108]. A significant reduction in the formation of rancid off-flavors in pork during storage was observed when nitrite was added 50 mg/kg or greater [109, 110].

Nitrites and nitrates inhibit dairy cultures by their effect on the activity of a number of oxidoreduction enzymes and consequently the natural ripening of milk is prevented and undesirable microflora is formed [111]. Lactic acid bacteria culture in yogurt has beneficial effects on health. Korenekova et al. [112] studied the effects of nitrites and nitrates on yogurt culture up to a level of 100 mg/kg. They found that nitrites depending on their concentration were able to exert an inhibitory effect on a yogurt culture and nitrates are not marked inhibitors of lactic bacteria. Thus, nitrates can be used in yogurt to preserve its quality without inhibiting lactic acid bacteria.

21.5 MEDICAL OR HEALTH ASPECTS

Two types of health benefits may be provided by food additives and food components: (i) those that prevent or reduce the incidence of specific diseases, and (ii) those that provide enhanced nutrition [103]. It is a common attempt to develop an agent that inhibits or inactivates the undesired organisms but displays little toxicity toward humans when ingested [61].

The National Academy of Sciences [113] concluded that 39% of dietary nitrite intake was from cured meat, 34% from baked goods and cereals, and 16% from vegetables. Cassens [114] mentioned that nitrate is important in the total picture because it is found in substantial quantities in other foods such as green leafy vegetables and root vegetables and sometimes in drinking water. They observed no detectable nitrate in cured meats in their studies.

Prolonged ingestion of sodium nitrite or sodium nitrate has shown to cause methemoglobinemia, especially in infants. Methemoglobinemia causes production of abnormal hemoglobin [113]. The major adverse effect of nitrites is the possible induction of cancer. In rats it increases the incidence of lymphoma when fed 250–2000 mg/kg nitrite in their food or water [115]. Nitrite results in the formation of carcinogenic N-nitrosamines with secondary amines or with substitutes amides to form nitrosamides. Over 65 different nitrosamines detected in a variety of foods, including cheese, meats, mushrooms, and alcoholic beverages, have been found to be carcinogenic [116]. Epidemiological studies have indicated a possible link between exposure to high levels of nitrites and a high incidence of stomach and esophageal cancer [113, 117]. Another well-known effect of nitrite is the lowering of oxygen

transport by the bloodstream through the mechanism of oxidizing hemoglobin to methemoglobin [35]. Thus, the nitrite level should be reduced in cured products. Ascorbates or erythorbates are added to reduce nitrosamine formation [2].

An oral challenge test with 30 mg of sodium nitrite may cause urticaria, intestinal disorders, or headache [118, 119]. It may cause cellular anoxia and inhibit the protective enzymatic activities of the intestinal mucosa. This may lead to increased permeability of the mucosa to other antigens. In addition, sodium nitrite some way or another enhances the effect of histamine present in many foods [120].

The lethal dose of nitrites in humans is 32 mg/kg body weight or 2 g [121] and 4–6 g [122]. In 1973, the U.S. Department of Agriculture (USDA) established an expert panel on nitrates, nitrites, and nitrosamine. It concluded that (i) the use of sodium nitrate should be discontinued in all meat and poultry products; (ii) the nitrite level permitted for curing of meat should be limited to 156 mg/kg in canned, cured sterile products; (iii) the permitted residual nitrite level should be reduced from 200 to 100 mg/kg in cooked sausage products, 125 mg/kg in canned and pickle cured products, and 50 mg/kg in canned cured sterile products [113]; (iv) sodium nitrite (120 mg/kg) and potassium nitrite (140 mg/kg) be added to bacon along with sodium ascorbate or erythorbate (550 mg/kg) to assist in the prevention of nitrosamine formation [117]. The regulations in 1986 for nitrite in bacon allow one of the following: (i) 120 mg/kg sodium nitrite or 148 mg/kg potassium nitrite plus 550 mg/kg sodium erythorbate or isoascorbate, (ii) 100 mg/kg sodium nitrite or 123 mg/kg potassium nitrite plus 550 mg/kg sodium erythorbate or isoascorbate if a demonstration of adequate process control is met, or (iii) 40–80 mg/kg sodium nitrite or 49–99 mg/kg potassium nitrite plus 550 mg/kg sodium erythorbate or isoascorbate plus 0.7% sucrose and a lactic acid bacterial culture (*Pediococcus*). The level of nitrites allowed is a maximum of 10 ppm in smoked cured tuna fish and 200 mg/kg (input not to exceed 500 mg/kg) in smoked cured stable fish, salmon, shad, cod roe, and in-home curing mixtures. The level in smoked chub is fixed at 100–200 mg/kg. The use of nitrite in other products is limited to a maximum residual level of 200 mg/kg [1].

The product development efforts have resulted in an entire new generation of cured meat products, which are low in fat and formulated with ingredients not previously used [123]. White [124] reported an average residual nitrite in cured meats of 52.5 ppm and a range of 0–195 ppm residual nitride in wieners. Recently, Cassens [114] found 5, 10, and 15 mg/kg residual nitrite on various cured meats in three trials of 164 samples. It is a reasonable conclusion that the current residual nitrite content of cured meats sold at retail in the United States is approximately 10 mg/kg. Cassens [114] mentioned that this change has undoubtedly resulted from (i) lowered ingoing nitrite, (ii) increased use of ascorbates, (iii) improved process control, and (iv) altered formulation. The mean value for the residual ascorbates was 209 mg/kg, which was nearly 40% of the maximum allowable addition of 550 mg/kg. The ascorbates routinely used are ascorbic acid, sodium ascorbate, erythorbic acid, and sodium erythorbate. Mirvish et al. [125] showed intragastric formation of N-nitrosamines in humans with higher doses of nitrate, but ascorbic acid inhibited their formation.

Nitric oxide is synthesized in the human body and is important to several physiological functions [114]. Cassens [114] mentioned that nitrite and its reaction products are important in human physiology. It is known that nitric oxide is formed in human body from nitrite. He reviewed the benefits of nitric oxide, which are (i) it is a biological messenger important to the physiological functions of neurotransmission, blood clotting, blood pressure control, and immune system function; and (ii) generation of salivary nitrite from dietary nitrate may also provide significant protection against gut pathogens in humans.

In some cases, the comparative risks are obvious. The risk of using nitrites and acquiring cancer from exposure to nitrosamines must be balanced against the risk of not using nitrites and acquiring botulism from cured meat. The comparative risks are more obscure or difficult to quantify [103].

21.6 POSSIBLE ALTERNATIVE TO NITRITE

Consumers are now demanding more organic and natural meat products due to the health risk of nitrite and nitrate [126]. It is difficult to find any single compound that performs all functions of nitrite, although focus was given to the alternatives to nitrite in meat products [127]. Therefore, nitrate and nitrite are still common additives in the meat industry.

21.6.1 Effects of Nitrite Reduction

The reduction of nitrite and nitrate affects the types of bacterial growth, and volatile formation in dry fermented sausages (i.e., maximum amount allowed by the European Union: combination of 150 mg/kg KNO_3 and 150 mg/kg $NaNO_2$, 50% and 25% reduction and control). There was a relation between ingoing and residual nitrite, which was 3.5-fold higher when the maximum amount was used in comparison to the 50% reduction [127]. The concentration affected gram-positive catalase-positive cocci (which numbers were 1 and 2 log cfu/g higher in the 50% reduction and control batches, respectively) and Enterobacteriaceae. A higher amount of volatiles derived from amino acid degradation, and carbohydrate fermentation was related to the microbiological changes [127].

Volatiles and aroma development in meat products is a complex process of many factors and their interactions. These include raw material and ingredients by contributing to major precursors (proteins and lipids), presence of additives (salt and curing agents), and methods of processing (i.e., wet, dry cured, and fermented) [128]. The cured odor is a balance between aldehyde compounds (green odor notes) formed during oxidation reactions and sulfur, key odor compounds producing meaty odors [129, 130]. In wet meat products, the main reactions for aroma development are lipid degradation (oxidative reactions), Maillard reactions, Strecker degradation, and thiamine degradation, while in dry meat products the reactions are lipid degradation (oxidative reactions), thiamine

degradation, microbial carbohydrate fermentation, and microbial metabolism including complex interactions (such as the amino acid degradation produced by lipid oxidation products) [131]. Nitrite sausages showed high aroma values for ethanol, 1-hexanol, propanoic acid, (E)-2-heptenal, and nonanal, while nitrate sausages showed high aroma values for phenylacetaldehyde and 3-methylbutanal [132]. In addition, fermentation conditions of fast or slow also affect the aroma profile [133].

In the case of slow fermented sausage, Perea-Sanz et al. [134] studied the effects of ongoing nitrite (i.e., control, 250 mg/kg; 15% and 25% reduction) on microbiology and chemical parameters, volatile compounds, and aroma production. The pH, water activity, and color decreased during ripening, without being affected by nitrate reduction. Lipid oxidation increased during ripening and it was higher in control sausages; residual nitrate decreased during ripening, with higher reduction in 25% decreased sausages. The fermentation time mainly influenced microbial counts and 15% reduction did not affect the microbial counts, while 25% reduction caused slightly different yields in yeasts and molds. Nitrate reduction resulted in an increase of volatile compounds derived mainly from amino acid degradation, and lesser extent esterase activity; key aroma compounds altered the sausage aroma profile. The affected microbial metabolism can cause nitrate reduction into nitrite and hence its effect on lipid oxidation. In the case of dry fermented sausages (i.e., different levels of reduction of nitrite and nitrate), Hospital et al. [135] identified that environmental factors such as pH, a_w, and the competitive microbiota could exert a more relevant role than nitrite in the inhibition of the growth and toxin production by *Clostridium botulinum*, therefore all technological factors need to be carefully considered.

The growth of *Listeria* and *Salmonella* in French dry fermented sausage was affected by the nitrate/nitrite formulation [136]. In the presence of nitrate alone, despite the hurdles (low water activity, pH. and salt level), both pathogens could not be inhibited due to the slow conversion of nitrate to nitrite, thus nitrite was a relevant hurdle. A reduction of 47% nitrite provided the same effect as the regulatory dose (i.e., 250 mg/kg sodium nitrate or 150 and 150 mg/kg of sodium nitrate and sodium nitrate). This is similar to the guidelines of the Food Chain Evaluation Consortium, which concluded that the range of 80 to 100 mg/kg sodium nitrite added in sausage formulation would be reasonably safe for a majority of products when used in combination with other hurdles [137].

Majou and Christieans [138] reviewed the mechanisms of the bactericidal effects of nitrate and nitrite in cured meats. In this system, anaerobic and acidic conditions are the most effective parameters at different stages. The bacterial stress is highly pH-dependent and non-oxygen-dependent, and enhanced by the nitrate–nitrite–peroxynitrite (ONOO–) system (strong oxidant). When homeostasis is unbalanced by acidity and anaerobic condition, nitrate and nitrite have a synergistic and aggravating effect depending on their concentration. Other hurdles, such as sodium chloride, ascorbate, and water activity enhance or reduce stress (i.e., effectiveness) on the bacterial system. The most resistant are gram-negative aerobic/facultative anaerobic bacteria (*Escherichia coli*, *Salmonella*), and the most fragile are gram-positive anaerobic bacteria (*Clostridium botulinum*).

21.6.2 Alternatives to Nitrite

Alahakoon et al. [126] reviewed the potential alternatives to replace (i.e., partial and complete) nitrite salts in meat products. They grouped the alternatives into use of plant materials, organic acids, microbial source compounds (such as bacteriocin and nisin), and additional hurdles, such as high pressure.

21.6.2.1 Natural Extracts or Materials

Carotenoprotein from the shells of blue crabs was incorporated to improve the quality and the shelf life of reduced-nitrites turkey meat sausages [139]. It exhibited antioxidant activity (i.e., degree of lipid oxidation) in a dose-dependent manner (i.e., inhibited thiobarbituric acid substances, TBARS, and conjugated dienes formation) and antimicrobial potential (i.e., shelf life of 10 days based on total mesophilic flora, at 4°C). It also showed scavenging effects of 1,1-diphenyl-2-picrylhydrazyl (DPPH) free radical, inhibited myoglobin oxidation inhibition, improved the transformation of the heme iron and lower free fatty acids (FFAs) contents, and improved stability in the color parameters.

Vegetables such as celery, spinach, radish, and lettuce have been reported to contain more than 2500 mg nitrate/kg [140]. Plant-based curing ingredients could also meet the demand for natural products. The effects of celery juice powder as a natural source of nitrite and reducing agents (i.e., no reducing compound or sodium erythorbate/ascorbic acid from cherry powder) were compared with the sodium nitrite considering color development and residual nitrite in a cured meat model system [141]. Only sodium nitrite (i.e., 156 mg/kg) showed 74.7 mg/kg pigments and 79.7 mg/kg residual nitrite, while addition of the reducing agent sodium erythorbate (495 mg/kg) showed 130.9 mg/kg pigments and 62.6 mg/kg residual nitrite. Celery juice powder (0.44% addition provides 100 mg/kg sodium nitrite) alone contained 51.9 mg/kg pigments and 59.3 mg/kg residual nitrite, while addition of 440 ppm of ascorbic acid from 0.4% cherry powder showed 124.8 and 31.6 mg/kg, respectively. The treatments with reducing compounds showed greater cured pigment, displayed increased redness and decreased yellowness, and reduced residual nitrite. However, chemical sodium nitrite treatments showed greater cured meat pigment, increased redness, and decreased yellowness. Therefore, it is important to include a reducing agent when using plant-based curing ingredients that contain lower amounts of ingoing nitrite to produce a product similar those cured with sodium nitrite and sodium erythorbate.

The beetroot powder (0.12% beetroot powder and 100 mg/kg sodium nitrite, 0.24% beetroot powder and 50 mg/kg sodium nitrite; and 0.35% beetroot powder) in Turkish fermented beef sausage (sujuk) was used as a nitrite (150 mg/kg) alternative [142]. The lactic acid bacteria count was highest in the case of 0.35% beetroot powder, and sensory evaluation scores were comparable with the control. Considering

oxidation (i.e., thiobarbituric acid reactive substance [TBARS] value), a 56-day storage period was suggested for the with no or low sodium nitrite, while 84 days at 4°C for others. Two mixtures of natural antioxidants—(i) grape seed extract and olive pomace hydroxytyrosol (GSE) and (ii) chestnut extract and olive pomace hydroxytyrosol (CHE)—proved effective in nitrite-replaced dry fermented pork sausages [143]. *Listeria monocytogenes*, *Salmonella*, and *Clostridium botulinum* were not found, whereas replaced additives showed a slightly lower antioxidant activity. The volatile profile showed a similar aromatic profile among the three treatments for overall acceptability, except that color-related traits were underscored in the sausage with replaced ingredients. Lactic acid is currently permitted as an additive in the production of organic foodstuffs of either plant or animal origin, with no specific upper limit of usage [126]. Bacteriocins and nisin are also commonly used as alternative or additional hurdles.

21.6.2.2 Organic Acids

Lactate, sorbate, citrate, and benzoate are used to reduce the nitrite level in meat products [126]. Lactate (organic acid) is used as an antimicrobial agent in meat systems. It also enhances meat flavor owing to its salty taste [144], improves color stability [145, 146], and imparts its taste buffering ability and humectant properties [147]. The improved color stability may be due to replenishing of the reduced form of nicotinamide adenine dinucleotide (NADH) when lactate is converted to pyruvate by lactate dehydrogenase. This increased the metmyoglobin-reducing activity. In addition, deoxymyoglobin can convert nitrite to nitric oxide, thus the production of more nitric oxide caused reduced residual nitrite levels [148]. Lactate shows the effectiveness in inhibitory activity against aerobic and anaerobic microorganisms in meat [146]. It showed inhibitory effects on different strains of *Clostridium Botulinum* [149, 150] and *Listeria* [151, 152].

21.6.2.3 Other Hurdles

The combination of high pressure with another hurdle technique can result in a synergy between the different hurdles and thereby possibly be used with nitrite. The combined effect of high pressure (up to 500 MPa at 20°C for 6 min) with sodium chloride (0–3 mg/kg) or sodium nitrite (0–100 mg/kg) on the outgrowth of endogenous flora of pork meat, including aerobic mesophiles, lactic acid bacteria, and Enterobacteriaceae members showed that 350 MPa or salt alone was not sufficient to delay the growth [153]. However, a combination of high pressure with 1.5 and 3 mg/kg of salt was found to reduce the microbial counts of less than 2 log cfu/g. High pressure 600 MPa for 3 min in combination with nitrite resulted in an immediate reduction of 3.9–4.3 log cfu/g in the *Listeria monocytogenes* populations in ready-to-eat sliced ham [154]. More examples of the combined effects of high pressure and nitrite are given by Alahakoon et al. [126].

21.7 CONCLUSION

Nitrite and nitrate are mainly used to maintain microbial quality, flavor, and color, and to prevent lipid oxidation. The addition of 200–400 mg/kg is commonly effective for microbial growth and toxin production. The factors affecting their efficacy are pH, aerobic or anaerobic conditions, salts, acids, and compositions of the products. Because consumers now demand organic or natural meat products due to the health risk of synthetic additives, the meat industry is currently focusing on the development of nitrite alternatives. The alternatives, such as natural extracts and biomaterials, acids, and other hurdles (such as high pressure) are being attempted. However, replacing the nitrite should be carefully applied considering the risk–benefit balance between chemical and microbiological hazards.

Part IV

Preservation by Controlling Water, Structure, and Atmosphere

22 Modified-Atmosphere Packaging of Produce*

Leon G. M. Gorris and Herman W. Peppelenbos

CONTENTS

22.1 MODIFIED-ATMOSPHERE PACKAGING: RATIONALE*

Immediately after harvest, the sensorial, nutritional, and organoleptic quality of fresh produce will start to decline as a result of altered plant metabolism and microbial growth. This quality deterioration is the result of produce transpiration, senescence, ripening-associated processes, wound-initiated reactions, and the development of postharvest disorders. In addition, microbial proliferation contributes markedly to postharvest quality loss. The relative importance of individual deterioration processes in determining the end of the shelf life will depend upon specific product characteristics as well as upon external factors. Low temperature and proper hygienic handling of the material are the prime factors that control these processes. In addition, modified-atmosphere packaging (MAP) is a preservation technique that may further minimize the physiological and microbial decay of perishable produce by keeping them in an atmosphere that is different from the normal composition of air [1–6].

* This chapter has not been updated from the first edition.

MAP of respiring food products such as fresh and minimally processed produce requires a different approach than MAP of nonrespiring foods. With nonrespiring foods, modified atmospheres without oxygen are used to minimize oxidative deterioration reactions, such as brown discoloration of meat or rancidity of peanuts, or to reduce microbial proliferation, e.g., the growth of molds in cheese and bakery products. High gas barrier films or laminates are used to exclude the exchange of gases (especially O_2) through the package, which would result in a less beneficial in-package gas atmosphere. In contrast, respiring products stay metabolically active after harvest, and this activity is essential for keeping their quality.

Aiming at the extension of the shelf life of respiring products through MAP, a prerequisite for a suitable packaging system will be that the composition of the gas atmosphere allows for a basic level of metabolism, which means that a certain amount of O_2 should be available. The required basic level of metabolism is highly at variance with different commodities (type, maturity) and heavily depends on the storage temperature and the degree of processing (trimming, cutting, slicing, etc.) applied. Due to the significant respiratory activity of the product, the gas atmosphere inside the package changes during the course of the storage period, and expert knowledge about these changes is necessary to tailor the package design of an individual product to optimize quality shelf life.

MAP of fresh and minimally processed fruits and vegetables is a preservation system that is nonsterile by design. Fruits and vegetables are characterized by an elaborate microflora, consisting of many different types of bacteria, molds, and yeasts, most of which are involved in the spoilage of produce but are harmless to the human consumer. Microorganisms that are dangerous to humans (pathogens that are toxic or cause infectious diseases) normally cannot establish a dangerous population density because they have to compete with the spoilage microflora. However, packaging the produce will change the microenvironment perceived by the microorganisms and may well impair this safe balance. Consequently, evaluation of the impact of package design and use in the logistic chain is a mandatory exercise to ensure consumer safety.

22.2 EARLY RESEARCH ON MODIFIED-ATMOSPHERE PACKAGING

Packaging techniques based on altered gas conditions have a long history. Ancient Chinese writings report the transport of fruits in sealed clay pots with fresh leaves and grass added. The respiratory activity of the various plant products generated a low oxygen and high carbon dioxide atmosphere, which retarded the ripening of the fruit [7, 8]. At the beginning of the 19th century Berard demonstrated that fruit placed in closed containers did not ripen [9]. By the end of the 19th century, the first patent was granted covering the use of a CO_2/CO mixture to extend the shelf life of meat [3]. Extensive research on the use of altered gas conditions for fruits tailed early in the 20th century, with the work of Kidd and West [10]. Commercial storage under altered gas conditions was undertaken in England in 1929 when apples were stored in 10% CO_2 and ambient O_2 [11]. Reduced O_2 concentrations and increased CO_2 concentrations also proved to be beneficial for harvested products other than apples. Products with a high potential for a successful commercial application in MAP include apple, banana, broccoli, cabbage, cherry, chicory, and brussels sprouts. The first commercial application of MAP did not take place until 1974 when the technique was used for meat [3]. The use of modified atmospheres (MA) for storage and packaging has increased steadily over the years and contributed strongly to extending the postharvest life and maintaining the quality of fruits and vegetables [12]. In fact, the biggest growth in the use of MA has been for fresh fruits and vegetables, especially for minimally processed salads [3]. The technique of MA is now applied at a range of different sizes, i.e., for bulk storage packages (e.g., red currants), transport packages (e.g., bananas, strawberries), and consumer packages (e.g., apples, broccoli).

22.3 EFFECTS OF MODIFIED GAS ATMOSPHERES

The strategy of packaging produce under modified atmospheres is to slow down the metabolic activity of the product as well as of the growth of microorganisms (both spoilage and pathogenic) present by limiting O_2 supply and by application of an elevated level of CO_2. Because the same strategy underlies refrigerated storage, MAP of respiring produce is usually combined with this technique. Many commodities, for instance, avocados, mangoes, papayas, and cucumbers, are very sensitive to low-temperature injury and should not be stored below about 13°C. Commodities like apples, broccoli, and pears are not sensitive to chilling and can be stored near 0°C without ill effect [13].

22.3.1 Reduction of Oxidative Reactions

Plant parts such as seeds, fruits, leaves, or roots continue to live after harvest. The energy plant cells need to stay alive and/or to proceed with ripening is generated by aerobic respiratory processes. Respiration involves the consumption of O_2 and the production of CO_2. A reduction of respiration results in a lower energy supply and a reduced rate of changes within the product, like ripening [5]. To extend storage periods, conditions should be created that reduce respiration, for instance, by using low-temperature and low-O_2 concentrations. In general, the reduction of the respiration rate is regarded to be the process that is most strongly affected by altered gas conditions [14, 15]. For certain fruits, low O_2 levels inhibit the production and action of the plant hormone ethylene, which results in reduced ripening as well [2]. Because respiration has such an important central position in the overall metabolism of a plant (part), its measurement is often used as a general measure of metabolic rate. Specific metabolic changes, however, may occur without measurable changes in net respiration [11].

Nevertheless, good quantification of the effect of reduced O_2 on respiration rates is essential for MA, as this process helps to generate the modified atmosphere inside MA packages.

With both whole, fresh produce and minimally processed produce, oxidative reactions do not only relate to respiratory activity. In addition, oxygen also has an effect on the activity of certain enzymes present in bruised or wounded tissue. Such enzymes are involved in wound repair reactions and in the defense against intruding microorganisms. Their activity depends on the presence of oxygen and is driven by the metabolic activity of the produce. Most studied is polyphenol oxidase (PPO), an enzyme that causes browning of plant tissues. In the case of minimally processed products (i.e., chopped, cut, sliced, and peeled), the level of tissue injury is much higher than with whole produce. Consequently, the level of metabolic activity and thus the respiration rate of minimally processed produce is often orders of magnitude higher than that of the raw material. Also, enzymes such as PPO will be more active and may cause visible browning of cut surfaces. Such responses should be considered and overcome by choosing the correct MAP design. In the case that different types of minimally processed products are included in a MAP, which is often the case in mixed vegetable salads, conflicting levels of O_2 and CO_2 may be optimal for the individual components. A designer's solution for this problem needs to integrate all the different aspects that are important with regard to the quality features of the end product.

22.3.2 Fermentation Reactions

The most optimal MA condition for a product is often considered to be the O_2 concentration, which is as low as possible with regard to product respiration without initiating fermentative reactions [2, 14]. Fermentative reactions lead to the production of compounds such as acetaldehyde, ethanol, lactic acid, and ethyl acetate. Alcoholic fermentation is always found in plant tissues exposed to an environment without O_2 [16]. An increased concentration of ethanol and/or ethyl acetate is often related to quality problems such as off-taste and off-odor [17, 18]. A strong correlation was found between ethanol and ethyl acetate concentrations [17]. A relationship between other fermentative metabolites and off-flavors is less clear. With improved detection techniques, compounds like ethanol and acetaldehyde can even be detected at O_2 concentrations higher than those considered to be optimal for the packaging of certain produce [19]. It seems that fermentation cannot be completely avoided and that it is not absolutely necessary to be avoided from the point of view of package design. Rather, it is important at what concentration of ethanol (or ethyl acetate) the consumer experiences off-odors or off-flavors. The package design should allow O_2 concentrations to be high enough to avoid an accumulation to that concentration. A complicating factor is that a relatively short period of too low O_2 concentrations can cause irreversible quality damage, because it has been found that strong off-flavors do not disappear once favorable O_2 levels have been reestablished.

22.3.3 Selective Impact on Microbial Growth

For many minimally processed products, the main factor causing quality loss is not ripening or senescence, but microbial growth. The modified-atmosphere composition has a marked impact on the growth of spoilage microorganisms as well as on pathogens that occasionally occur in minimally processed produce [20]. The very low O_2 (typically 2–3%) and moderately high CO_2 (5–20%) levels prevailing inside a package slow the proliferation of aerobic spoilage microorganisms [4, 6, 8, 21–25]. The antimicrobial effect of CO_2 on microorganisms has been intensively documented [26–35]. However, it has been shown recently that only CO_2 levels well above 20–50% significantly affect the growth of psychrotrophic pathogens that are relevant to MA-packaged produce [36]. This contradicts the general belief that CO_2 has very pronounced antimicrobial properties. At levels of O_2 and CO_2 that are generally favorable for storage of produce, there is certainly no beneficial effect of CO_2 [36, 37].

In *in situ* studies, it was established that the specific conditions of MAP (reduced oxygen, increased carbon dioxide) can lead to marked changes in the epiphytic microflora, especially in chicory endive [38]. Thus, whereas there may be no direct antimicrobial effect of CO_2, there is an influence on the composition of the microflora and on the competition that pathogens may experience in this ecosystem. A specific safety hazard is that psychrotrophic, facultative aerobic pathogens such as *Listeria monocytogenes* are not suppressed under MA conditions that are optimal for respiring produce [36, 37, 39, 40]. On the contrary, growth may be enhanced in certain cases [38, 41], especially because the MA conditions diminish the growth of spoilage microorganisms that would be competitors of the pathogens.

22.4 TYPES OF PACKAGES

With MAP, the gas composition surrounding the produce inside the package is different from the gas composition outside the package. Outside, the gas composition is always close to 78.1 kPa nitrogen, 20.95 kPa oxygen, 0.93 kPa argon, and 0.036 kPa carbon dioxide. Several different types of packages and packaging techniques have been developed to accommodate modified atmospheres around the produce, and these will be explained in detail next. The modification of the atmosphere generally implies a reduction of O_2 content and/or an increase of the CO_2 concentration, but in some cases changing the level of carbon monoxide (CO), ethylene, ethanol, or other compounds in the atmosphere can also contribute to shelf-life extension. Modified atmospheres can be created passively by the respiration activity of the product inside the package (product-modified MAP) or actively by introducing the desired gas mixture (gas packing). Other active ways of obtaining modified atmospheres are the use of gas generators and scrubbers (controlled-atmosphere packaging), evacuation of air (hypobaric storage, vacuum packaging), or addition of chemical systems that absorb or generate gases or volatile compounds (active packaging) in packages.

22.4.1 Modified-Atmosphere Packaging

In modified-atmosphere packaging the gas composition within the package is not monitored or adjusted. Therefore, the term passive atmosphere packaging (PAP) is sometimes used in this respect. Depending on the oxygen sensitivity and metabolic activity of the product to be packaged, air or a predetermined gas mixture is used to flush packages before closing. The use of ambient air as the packaging gas obviously is most economical, but is an option mainly when the respiration activity under the prevailing storage conditions is high enough to reduce the in-pack O_2 level fast enough to lower levels that do not cause physiological or microbial deterioration. With produce highly sensitive to O_2 (e.g., many minimally processed fruits) or that have a low level of respiratory activity, flushing with a gas mixture composed of low oxygen and moderately high CO_2 is often used to shorten the time needed to reach the desired in-pack gas composition. After closing the package, the respiration of the product will cause a decrease in the oxygen content and an increase in the carbon dioxide content. These altered gas concentrations, however, cause a decrease in the respiration rate. Finally, an equilibrium concentration inside the package is reached, which is the result of a balance between metabolic rates of the packed product and diffusion characteristics of the package materials. This explains the use of another term, equilibrium-modified atmosphere (EMA) packaging. The package is often designed in such a way that the equilibrium concentrations resemble the optimal gas concentrations found in experiments where products are stored under a range of stable gas conditions.

The course of the atmosphere modification is determined by three interacting processes: respiration of the commodity, gas diffusion through the commodity, and gas permeation through the film. Each of these processes is in turn strongly influenced by several commodity- and environment-generated factors. Respiration of a certain commodity depends, among others, on its physiological stage and temperature, O_2 and CO_2 partial pressures, relative humidity, and ethylene concentration. Gas diffusion is affected by temperature; the gas gradient across the limiting barrier; and the commodity's mass, volume, respiration rate, membrane permeability, and gas diffusion path. Some of these variables may vary with the maturity stage of the product or even the degree of illumination. Some variables affecting gas permeation through the film are temperature, gas gradient across the film and film structure, water vapor gradient, thickness, and surface area. A change in product amount, free volume, or any of the aforementioned variables will affect the EMA and/or the time in which the steady-state conditions are established. Flushing a package with a premixed gas will influence the time needed to attain the EMA.

Strict temperature control in the distribution chain would be a prerequisite for optimal use of MAP in practice, but in most countries, the cooling chain between production, distribution, retail, and the consumer has many uncontrolled links. The changes in the permeabilities of most packaging films to gases in response to changes in temperature are generally lower than changes in product respiration. Most of today's existing plastic films do not have the proper O_2:CO_2 permeability ratio to provide the ideal MA for many commodities at a given temperature. In view of all these variables and knowing that any change within or around the package will alter the dynamic equilibrium between the product and its environment, it is clear that knowledge about the limits of tolerance of a certain commodity is even more important for MAP than it is for controlled-atmosphere packaging.

22.4.2 Controlled-Atmosphere Packaging

In controlled-atmosphere packaging (CAP) the altered gas composition inside the package is monitored and maintained at a preset level by means of scrubbers and the inlet of gases. This method closely resembles the practices used in large controlled-atmosphere (CA) storage facilities where produce is stored essentially unpacked in bulk, except that CAP is used for storage or transport of smaller quantities of produce.

Additionally, new areas of attention in CA storage today are ultra-low oxygen (ULO) storage and dynamic CA storage. Obviously, these techniques can be used in CAP as well. ULO storage uses O_2 levels close to the minimum level required for maintenance of plant tissues; lower levels will induce disorders such as browning and tissue necrosis. Using ULO storage at 1–2°C with preset levels of 0.5–1% O_2 and 2–3% CO_2, for instance, Elstar apples can be stored for almost a whole year without unacceptable quality loss. In the case of dynamic CA storage, sometimes referred to as interactive CA storage, gas levels are not controlled at preset levels but are continuously adapted to the physiological response of the produce [42], for instance by monitoring fermentation products or cell degradation products. In this way, an optimal match is made between the physiological demand and tolerance of a product and the storage conditions. Although this concept is still in development for CA packages [43], comparable ideas have been described (see later).

22.4.3 Active Packaging

In some cases, a package cannot be designed in such a way that optimal conditions will be reached passively. "Active packaging" can then provide a solution, by adding materials that absorb or release a specific compound in the gas phase. Compounds that can be absorbed are carbon dioxide, oxygen, water vapor, ethylene, or volatiles that influence taste and aroma. For some leafy vegetables, carbon dioxide levels can induce browning of tissues, while for most fruits increased ethylene levels cause an acceleration of ripening. Even at rather low levels, depending on the type of produce, ethylene can induce senescence and maturation processes that reduce the fresh product quality. The inclusion of ethylene scrubbers like potassium permanganate counteracts the effect of ethylene, although the capacity of such scavengers is finite. In transport packages for grapes pouches are often added that slowly release sulfur-containing chemicals to reduce fungal growth. Recently research has been directed to replacing chemicals

with compounds retrieved from plant tissues ("green chemicals"). How much of the active compounds needs to be added will depend on a range of interacting factors, such as production rates (carbon dioxide, ethylene), concentrations to be reached, and how long the package should be functional. Various possibilities exist, although precise control of O_2 in such packages is not possible [2].

Recently a number of new "intelligent" concepts have been introduced that involve more than only scrubbing or emitting compounds. These types of packages will only become "active" when a specific prerequisite has been met. Most of these packages focus on the prevention of problems associated with anaerobic conditions. In one such system, holes are introduced in the package upon exposure to high temperatures for a certain time; originally, the holes are closed by solid hydrocarbons that have melting points between 10°C and 30°C [2]. Because respiration of a product often increases at a faster rate than the diffusion of gases with a rise in temperatures, the holes in the package will prevent the depletion of O_2. Another idea is a sensor for ethanol mounted on a package that informs possible buyers of the history of the package in terms of possible mechanical damage or temperature abuse [2]. Yet another concept that has seen some use in, for instance, France and the United States, is the "time–temperature indicator" or "time–temperature integrator" (TTI). TTIs used now are in most cases small devices that, attached to the package, will indicate the combined time and temperature history of that product by a gradual change in color [44, 45]. TTIs integrate the time and temperature by specific enzymatic or chemical reactions that, ideally, have an identical rate constant to the quality or safety feature of the packed product. The consumer can compare the actual color at the time of intended purchase with the indicated sell-by limit color. A TTI is an elegant and user-friendly improvement that informs consumers of the expected shelf life at the point of sale. The concept could well be extended to the home situation.

22.4.4 Vacuum Packaging

Whereas MAP and CAP mostly operate at ambient pressure (101 kPa), storage at reduced atmospheric pressures has been experimented with and, in some cases, has been used for bulk storage (e.g., in the so-called hypobaric storage systems designed by Stanley Burg almost a quarter of a century ago) [46, 47]. In the Burg system, produce is stored under atmospheric pressure in the range of about 1–10 kPa at refrigerated temperatures. At this low pressure, a constant circulation of fresh air, substantially saturated with water (RH 80–100%), is maintained. Facilities to constantly scrub CO_2 and ethylene could be included as well. Although the system performed rather well, and shelf lives of different horticultural and floricultural products could be extended 3- to 10-fold, it was technically complex and for this reason was never used as widely as CA or MA storage. Vacuum packaging (VP) may be regarded as a special type of MAP, since part of the normal headspace is removed, leaving an altered initial atmosphere that is not controlled after packaging. VP puts quite a pressure strain on produce and is only suitable when the product is sufficiently durable.

Using a VP system—called a moderate VP system because it operates at 40 kPa—a significant prolongation of quality shelf life at 8°C was obtained with a range of minimally processed fruits and vegetables [48]. In this system, the initial gas composition is that of normal air, but because of the reduced partial gas pressure, the amount of O_2 available at the start of storage is about one-third of the normal amount. As with MAP, the lower O_2 content stabilizes the postharvest product quality by slowing the metabolism of the produce and the growth of spoilage microorganisms. Compared to refrigeration-only storage, refrigerated storage under moderate vacuum was found to improve microbial quality (e.g., red bell pepper, chicory endive, sliced apple, sliced tomato), sensory quality (e.g., apricot, cucumber) or both (e.g., mung bean sprouts and a mixture of cut vegetables). In some instances no beneficial effect (mushroom, green bell pepper, and a mixture of cut fruits) or an impeded decrease in sensory quality (strawberries, alfalfa) was noticed. With cut products (vegetables and fruits salad mixes, chicory endive, apple), VP strongly retarded enzymatic browning of the cut surfaces.

22.4.5 Modified-Humidity Packaging

MAP, CAP, and VP all focus on changing the metabolic gases oxygen and carbon dioxide. Modified-humidity packaging (MHP), however, is designed for products where dehydration causes the most important quality losses, and therefore focuses on controlling water vapor levels. When products such as leafy vegetables or bell peppers are not packed, very soon quality losses can be observed (e.g., wilting and shriveling). In most "closed" packages such as MAP, CAP, and VP, the relative humidity is close to saturation due to the water exchange between the product and the headspace. This high humidity increases the probability of condensation and free water accumulating directly on the product, especially when the package is exposed to changing temperatures. Therefore, MHP systems are designed to control not only dehydration but also condensation. The in-pack relative humidity (RH) is influenced by the rate of water loss (transpiration) of the product and the transmission rate for water vapor of the package, which are dependent on the prevailing water vapor pressure and temperature of storage. Temperature is one of the most important factors determining the in-pack RH. Weight loss relates more exactly to the vapor pressure deficit than to relative humidity, but at constant temperature, weight loss has a linear relationship with relative humidities above 75–85% [49]. At higher temperatures the air can contain more water vapor, thereby decreasing the RH value. A package designed to have a high relative humidity at a high temperature will show condensation on the package surface or on the product if the temperature is decreased substantially. To counteract the effect of condensation, films have been developed that are coated with an antifog layer, due to which moisture forms a continuous layer rather than separate droplets on the surface

of a film. This allows a clear view of the product and prevents water from forming a pool at the bottom of the package.

For many products, transpiration must be reduced in order to maintain quality. Products with a large surface area such as lettuce and endive are very susceptible to wilting. Bell peppers and tomatoes also benefit from good control of relative humidity [50, 51]. Reducing water loss is one of the main aspects related to packaging of minimally processed products, despite the usual emphasis on gas levels [2]. On the other hand, for products such as onions and flower bulbs, humidity should not be too high, as it results in increased sprouting. Like O_2 and CO_2, water vapor levels can be too high or too low, and an optimum level should be reached. For (Israeli) bell peppers this level was estimated to be 92% relative humidity at 8°C [52]. A lower relative humidity caused too much weight loss, while a higher relative humidity caused decay. Especially for products where water loss is the predominant cause of quality changes (e.g., bell pepper and tomato), MHP can be effectively used to minimize loss of quality. In such cases, the concentrations of oxygen and carbon dioxide in MHP are often close to that of ambient air.

Many commercially available packaging materials that have favorable gas-permeability characteristics for a certain commodity cannot be used because they have a rather low permeability for water vapor. When the in-pack RH is very high (≥95%), a small fluctuation in storage temperature results in condensation, which greatly enhances the proliferation and spread of spoilage microorganisms. Especially for fruits, the high RH conditions cause heavy losses due to microbial decay. Control of the in-package RH may be pursued through the use of packaging materials with high water vapor permeabilities; by inclusion of sachets containing water absorbers like $CaC1_2$, sorbitol, or xylitol in the package ("active packaging"); or by use of packaging materials with suitable gas permeabilities onto which such desiccants are coated [51, 53].

22.5 IMPORTANT PARAMETERS IN PACKAGE DESIGN

22.5.1 Product Characteristics

Before a package can be designed, detailed knowledge about the physiological characteristics of the product to be packed and the environmental conditions the package is exposed to after production is essential. Many specific parameters need to be known. Not only are optimal O_2, CO_2, and water vapor levels important, but so too are the upper and lower limits of these components beyond which damage can be expected. When low O_2 and/or high CO_2 is beneficial, it becomes important to quantify the relationship between gas conditions and gas-exchange rates. For good quantification, O_2 uptake and CO_2 production should be measured under a range of O_2 and CO_2 concentrations. Such data sets, however, are still scarce.

Another important product aspect is the influence of light on color changes, for instance, with chicory endive, which changes from the preferred yellow-white to the undesired green color under excess illumination. It is also important to know what mechanical properties the package should have when delicate products such as berries are to be packaged without mechanical damage.

22.5.2 Package Characteristics

An important aspect of package design is the selection of the packaging material, and this can be a cumbersome exercise. Exama et al. [54] studied the possible application of 20 different types of polymer films and was still not able to find a suitable match for products with a high respiration rate. Using too high barrier package film, O_2 will be fully depleted and fermentation will lead to off-odors and off-flavors. In addition, the right combination of low O_2 and high CO_2 is crucial. This highlights two decisive aspects in selecting films: (i) the permeability for O_2 and CO_2 at the temperature to be used, and (ii) the ratio between O_2 and CO_2 permeability. A serious drawback is that gas permeability specifications given by film manufacturers are usually determined under conditions remote from the high-humidity refrigerated storage conditions of respiring produce. Thus, it is impossible to deduce only from the specifications provided by film manufacturers whether a specific film would provide for an in-package gas atmosphere with tolerable O_2 and CO_2 levels when applied in practice. Thus, the suitability of a film must be tested with the product under the correct practical conditions.

In addition to the permeability of the metabolic gases, permeability for water vapor, ethylene, and volatiles can be important. A low permeability for water vapor can increase the risk of condensation. Condensation should always be avoided since it generates an ideal climate for microbial growth. Also, discoloration of the product can result from condensation.

Currently, polyethylene (PE) and polyvinyl chloride (PVC) films are the most often used polymers. In the past decade, a new type of film was introduced, with very small holes (microperforation) as the main pathway for diffusion [55]. The interesting aspect of these films is that diffusion of O_2 and CO_2 through the film is equal. This enables the creation of packages with both low O_2 and high CO_2 concentrations. Such atmospheres are especially suitable for minimally processed products but also for unprocessed products with extremely high respiration rates like asparagus, broccoli, mushrooms, or mung bean sprouts.

In addition to the selection of the type of film, other important aspects include the thickness of the film, the surface area used, the package volume, and for films with microperforation, the number of holes per area. Film thickness, film area, and the number of holes influence the equilibrium gas composition inside the package. Varying package volume and the free volume inside the package influences the rate at which gas concentrations are changing. The final equilibrium concentrations will be equal, but the moment in time at which these concentrations are reached can differ by varying the volume.

22.5.3 Modeling

Since there are so many variables to take into account in package design, a trial-and-error type of approach can lead to numerous

attempts to find the best package. The risk is that the best package will not be found. Sufficient control of the many different factors interacting in determining the atmosphere change in a MAP can only be achieved with the help of mathematical modeling [56]. Mathematical models may provide a means to determine and predict important packaging specifications. When optimal (equilibrium) gas conditions are known as well as the respiratory response to various O_2 and CO_2 concentrations, the suitable permeability characteristics of the package can be mathematically deduced. The most frequently used models that relate gas conditions to O_2 uptake and CO_2 production are based on Michaelis–Menten kinetics [2, 14, 57]. Although inhibition of CO_2 on respiration is not found for all products, Peppelenbos and van 't Leven [58] examined which type of inhibition best described the influence of CO_2. The models of Banks et al. [14] or Peppelenbos et al. [59] can be applied best when not only respiratory CO_2 but also fermentative CO_2 production needs to be calculated. An example of gas-exchange modeling is given in Figure 22.1, where at low O_2 concentrations CO_2 production increases due to enhanced fermentation.

The description of gas diffusion through packaging materials is mostly done by applying Fick's law [2]. Although all models mentioned earlier are static, they can be incorporated into dynamic models to be used for the prediction of changing gas conditions inside a package [60]. Packages can be easily designed with such dynamic models by changing variables such as film type, surface area, and amount of product packed. A very useful extension of simulation models would be the incorporation of the expected variance of the achieved equilibrium conditions. Using expected variance, not only can optimal packages be designed, but so can suboptimal packages that are also safe. A survey of this variance has already been carried out for broccoli by Talasila et al. [61].

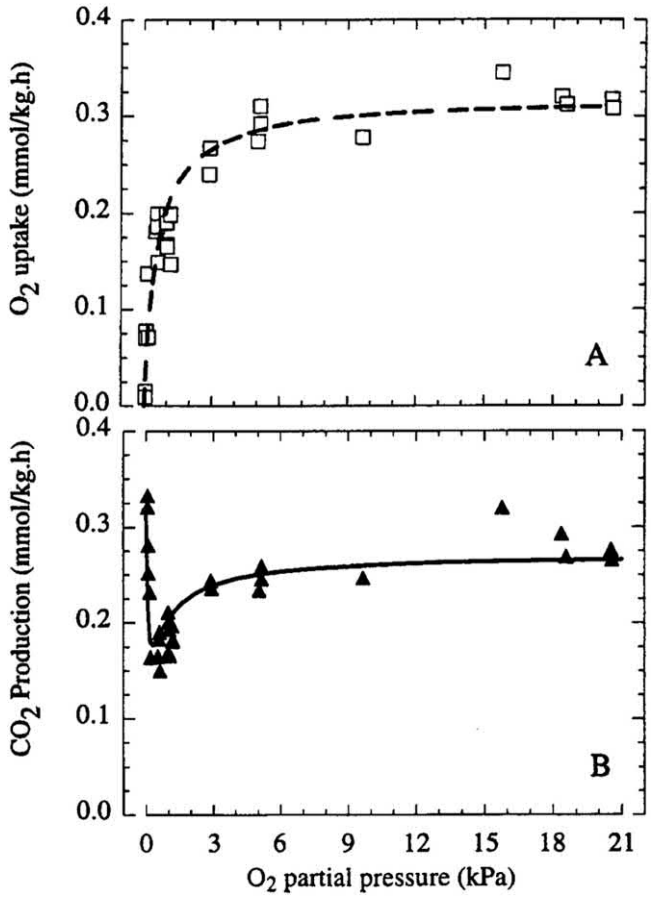

FIGURE 22.1 Gas exchange rates of strawberries (*Fragaria ananassa* cv. *Elsanta*) at 4°C. (A) O_2 uptake rates (□) with O_2 uptake model. (B) CO_2 production rates (▲) with CO_2 production model. (From Peppelenbos et al. [59].)

Since temperatures in the distribution chain often cannot be strictly controlled, another interesting feature of dynamic modeling is the possibility of simulating products passing through the different links of the distribution chain. Using simulation, for instance, the dynamics of the gas composition inside the package can be evaluated in order to determine whether gas conditions will remain within the limits of tolerance of the commodity. When necessary, the use of different packaging films can be simulated in order to obtain the most optimal equilibrium modified atmosphere condition. The end result of the modeling exercise, however, could be that there is no suitable packaging film available commercially that would be suitable for use. Instead of not packing the product, this information could be used to further improve distribution chains or to give suggestions to the packaging industry, defining the requirements for new films in terms of their temperature sensitivity, CO_2:O_2 permeability ratio, etc.

Once proper models have been created and integrated in package design, they should be mandatory in the development of packages that achieve optimal gas conditions at dynamic temperatures encountered in practical situations and/or of packages that can overcome fluctuations in temperature, which temporarily cause gas conditions to exceed tolerance limits but do not affect product quality.

22.6 MICROBIAL GROWTH UNDER MODIFIED ATMOSPHERES

22.6.1 Spoilage Microorganisms

Fresh fruits and vegetables normally have an elaborate spoilage microflora, due to intensive contact with various types of microorganisms during growth and postharvest handling. The high acidity of many fruits (pH <4.6) limits spoilage to acid-tolerant molds, yeasts, and lactic acid bacteria. Vegetables generally have a pH of around 6.0–7.0 and lack this intrinsic protection. Microbial spoilage of undamaged, healthy products can only be effectuated by microorganisms able to penetrate through the skin, which requires the presence of specific enzyme systems. In vegetables, pectinolytic gram-negative bacteria of the genera *Pseudomonas* and *Enterobacter* are often involved in spoilage. The effect of MAP, and in particular carbon dioxide, on spoilage organisms is distinctly selective, but it is possible to make some broad generalizations. Molds exhibit sensitivity, while yeasts are comparatively resistant. Different species of bacteria, on the other hand, vary greatly in sensitivity. For example, aerobic organisms such as

Pseudomonas, *Micrococcus*, and *Bacillus* are inhibited by CO_2, while the *Lactobacillus* species are more resistant. On the other hand, facultative anaerobes such as *E. coli* are less affected by the level of CO_2 but more by the level of O_2. Most spoilage organisms that pose a quality problem in produce are aerobic, thus a limited supply of O_2 hampers their growth potential. Nitrogen has little inhibitory effect except in displacing oxygen.

Spoilage microorganisms usually pose no safety problem for consumers. The main concern is that applications of modified atmospheres diminish the competition for oxygen, carbohydrates, other nutrients, and space between spoilage microorganisms and pathogens. This may allow the growth of certain pathogens to hazardous levels, especially during extended shelf life. In addition, the problem of product temperature abuse, either during manufacture, distribution, and retail or by the consumer, must also be considered. In those cases spoilage microorganisms may be important safety indicators, giving an organoleptic warning signal to consumers that the food product has been mishandled or kept beyond its shelf life and therefore may not be safe to eat. However, when technologies such as MAP are used to extend the product shelf life by suppressing spoilage organisms but not all hazardous pathogens, situations could occur in which the packaged food is organoleptically unspoiled but very unsafe to eat.

22.6.2 Pathogenic Microorganisms

Most fruit products have too low a pH to permit the growth of pathogenic bacteria—only figs, peaches, and tomatoes, whose pH is potentially in the range 4.6–4.8, may permit pathogenic growth. In the early days of MAP, attention was focused primarily on anaerobic pathogens, especially proteolytic *Clostridium botulinum,* which produces a deadly toxin but does not grow below 10°C. Since nearly all MAP foods are refrigerated, focus has been mainly on the survival and outgrowth of cold-tolerant pathogens such as *Yersinia enterocolitica* and *Listeria monocytogenes* that can proliferate under low-oxygen conditions [6, 39]. An important factor with respect to microbial safety is whether the MAP food is intended for direct consumption or requires heating before consumption. With MAP foods that are cooked before being eaten, vegetative pathogens should all be killed, provided the cooking instructions are properly followed. However, the majority of MAP produce is sold as "ready-to-eat." The main potential sources of pathogenic bacteria in fresh and minimally processed produce are the raw material, ingredients, plant workers, as well as the processing equipment and environment. In the following, the main pathogens of possible concern to MAP are described.

22.6.2.1 *Clostridium botulinum*

Because of the potency of their toxin, the potential growth of *Clostridium* species in MAP foods has been of especially great concern [62]. The organisms can be present in soils and can thus come into contact with fruits and vegetables easily. *C. botulinum* is not markedly affected by the presence of CO_2, and growth is encouraged by the anaerobic conditions that may exist in MAP. Most strains of *C. botulinum* do not grow at temperatures below 10°C, although nonproteolytic *C. botulinum* types B, E, and F have been recorded as growing and producing toxins at temperatures as low as 3.3°C. Botulism has been linked to coleslaw prepared from MA-packaged, shredded cabbage mixed with coleslaw dressing [63, 64]. Shredded cabbage onto which spores of *C. botulinum* types A and B were inoculated and that subsequently was MA packaged and held at room temperature was found organoleptically acceptable after 6 days, yet type A toxin production was apparent on day 4. A pungent odor was produced and released on opening the bag, after which the cabbage smelt normal. A recent survey by Lilly et al. [65] on the incidence of *C. botulinum* in MAP and VP vegetables involving 1118 packages of a variety of precut produce (including cabbage, pepper, coleslaw, carrot, onion, broccoli, mixed vegetables, stir-fry vegetables, and various salad mixes) found that 1 package each of shredded cabbage, chopped green pepper, and Italian salad mix contained *C. botulinum* type A spores, while an additional salad mix (main ingredient, escarole) contained both *C. botulinum* type A and type B spores. The overall incidence rate (0.36%) of *C. botulinum* spores thus may be quite low in commercially available precut vegetables.

22.6.2.2 *Listeria monocytogenes*

The widespread presence of this organism in the environment and its ability to grow at low temperatures makes it a pathogen of special concern. A serious outbreak of listeriosis was thought to be derived from cabbage fertilized with manure from infected sheep [66]. In many studies of a variety of produce carried out since this outbreak, it was frequently established that *L. monocytogenes,* when the organism was inoculated onto vegetables, grew as well under MA or CA conditions as in air at 4°C or 15°C [37, 41, 67–71]. By now, growth of this pathogen under MA conditions has been reported for asparagus, broccoli, cauliflower, lettuce, and chicory endive. Studies by Carlin et al. [40] investigated the fate of *L. monocytogenes* in minimally processed foods in the presence of nonpathogens and at temperatures ranging from 3°C to 20°C. It was shown that on unspoiled products *L. monocytogenes* would hardly grow more than 2 log units whatever the storage temperature, but that spoilage of the salad leaves would permit a rapid multiplication. Low storage temperatures reduced growth of *L. monocytogenes* more than that of the spoilage microflora and are therefore a factor improving safety. Carbon dioxide concentrations of 10–20% reduce spoilage development and growth of the spoilage microflora, whereas higher concentrations slightly increased growth of *L. monocytogenes.* On minimally processed green endive, it was found that that high inoculum concentrations overestimated the maximum growth of *L. monocytogenes.* Again, the epiphytic microflora of green endive leaves had a barrier effect against *L. monocytogenes.*

22.6.2.3 *Aeromonas hydrophila*

This psychrotrophic organism is also widespread in the environment and is mainly waterborne. It has been found in drinking water, fresh and saline water, and sewage water. Cytotoxic strains have been found on seafood, meats, and poultry, as well as on fresh produce, parsley, spinach, celery, and endive. The pathogen grows rapidly at refrigeration temperature [72]. Berrang et al. [73] observed that *Aeromonas* could grow to population densities exceeding 10^6 CFU/g within 2 weeks at 4°C on asparagus, broccoli, and cauliflower, and that CA conditions did not markedly affect its growth potential.

22.6.2.4 *Yersinia enterocolitica*

Animals, specifically swine, are the predominant natural source of *Yersinia enterocolitica*. However, this cold-tolerant pathogen has also been isolated from raw vegetables. As with the former two pathogens, modified atmospheres optimal for produce do not hamper its growth at refrigeration temperature. With little oxygen (1.5%) present, carbon dioxide levels as high as 50% were found to be required before its growth was significantly reduced [36].

22.6.2.5 *Bacillus cereus*

This bacterium, a common contaminant of vegetables, does not usually grow below 10°C [74]. However, recent reports have shown that some enterotoxigenic strains can grow at temperatures as low as 4°C and produce toxin at 8°C. *B. cereus* is rather susceptible to the antimicrobial effects of CO_2 [36], and CO_2-rich environments severely reduce the ability of the spores to germinate.

22.6.2.6 *Salmonella* spp.

This organism is most commonly associated with animals and birds and is only present on vegetables through cross-contamination. Nevertheless, two large outbreaks of salmonellosis have been attributed to fresh produce, both involving tomatoes stored at ambient temperatures [75, 76]. *Salmonella* species have also been implicated in smaller outbreaks in which raw bean sprouts and different types of melons were the vehicles. Although high levels of CO_2 retard the growth of *Salmonella,* generally the inhibitory effect on the organism is largely dependent on decreased temperature. Most *Salmonella* species are mesophilic bacteria, but many isolates survive well during storage at 5°C [77].

22.6.2.7 *Staphylococcus aureus*

S. aureus does not grow well under chill conditions or in the presence of competing microorganisms. The pathogen has been found on fresh produce and ready-to-eat vegetable salads. It is known to be carried by food handlers. Generally, CO_2 has an adequate inhibitory effect on the growth of *S. aureus* when combined with low-temperature storage.

22.6.2.8 *Escherichia coli*

E. coli is a mesophilic bacteria often used as an indicator of fecal contamination. Enterotoxigenic *E. coli,* the common cause of travelers' diarrhea, is regularly detected on raw vegetables. Strains can grow at temperatures below 10°C, but not usually below 7°C. Some strains reportedly are able to grow and produce toxin at 5°C. The growth of this organism can be inhibited by high levels of CO_2. Enterohemorrhagic *E. coli* O157:H7 is recognized as an important emerging pathogen. Outbreaks of this pathogen have been associated with unpasteurized apple cider and cantaloupe. Also, broccoli is suspected to have carried this type of *E. coli.* MAP had no effect on pathogen growth on shredded lettuce and cucumber in experiments in which storage temperatures were 12°C and higher [78, 79].

22.6.2.9 *Campylobacter jejuni*

This organism is still one of the major causes of bacterial enteritis. Poultry and other foods of animal origin are the main sources. The pathogen has been implicated in diseases caused by consumption of fruits and vegetables. Cross-contamination of fresh produce with *C. jejuni* from poultry meats has been suspected. The pathogen has been found to survive sufficiently on sliced watermelon and papaya to be a risk for consumers. Total absence of oxygen was noted, whereas survival, without growth, was enhanced in an atmosphere of 100% N_2. Optimal growth has been documented to occur under atmospheres of reduced oxygen level and high temperatures (42–45°C). The minimum growth temperature reportedly is 32°C, so the risk with consumption of refrigerated MAP produce should be minimal.

22.6.2.10 Disinfectant Usage

The use of disinfectants to reduce the microbial load of minimally processed fresh salads is permitted and practiced in many countries around the world. It has been found that after disinfection, the surviving spoilage microorganisms have an increased growth rate and rapidly reach the same level found on nondisinfected products [38, 40]. In the case of contamination with *L. monocytogenes* during processing, disinfection of salad leaves would reduce the antagonism from epiphytic bacteria and might increase the growth of the foodborne pathogen. Therefore, the major role of disinfectants may be to prevent the build-up of contamination in washing water during processing rather than to reduce microbial load of raw salad leaves. In the production of MAP produce, good manufacturing practices should be observed that avoid recontamination of disinfected produce with hazardous pathogens.

22.7 RECOMMENDED MA CONDITIONS FOR PRODUCE

The benefits of CA and MA packaging vary greatly according to the plant product. Storing some products, like apples, under low O_2 conditions can increase the storage period by months. Also some products, like carrots [80], do not respond positively to low O_2 or high CO_2 concentrations. Generally, altered gas conditions are regarded as positive only within a certain range of concentrations, so-called optimum concentrations.

Much research effort has been devoted to the determination of the optimum gas concentrations for individual products [81–83]. Table 22.1 gives a recent update on recommended storage conditions for a range of fruits and vegetables. Traditionally, lists of recommended storage conditions have been developed by national research organizations conducting extensive laboratory research [8]. A common experimental procedure is to store products under a range of O_2 and CO_2 concentrations and to monitor quality changes. The lower O_2 limit for stored fruits is accomplished empirically by lowering the storage O_2 concentration until intolerable damage occurs. Each commodity and new cultivar requires a large investment in time, equipment, and materials [42, 84]. By repeating the trials year after year, it is possible to sense the importance of climatic variation on product behavior [8].

Some caution is needed in the application of optimal concentrations. For the various apple cultivars, for instance, the advised optima differ according to country [82]. Growing conditions like climate and orchard factors influence crop growth and contribute to these differences [85–87]. Although this is probably also the case for other plant products, this is never specified.

Another important aspect of optimal values for temperature, and O_2 and CO_2 concentrations is that they are often established separately, although interactions between temperature, and O_2 and CO_2 concentrations (and probably also humidity) are known. Optimal O_2 concentrations are found to shift to a higher value when CO_2 concentrations are increased [5, 88–90], when products are more mature [5, 91–93], when they are kept at a higher temperature [17, 90, 94, 95], or when products sensitive to chilling injury are stored at too low temperatures [89]. For apples, the CO_2 limit at low O_2 concentrations decreases when the temperature is decreased [10]. The effect of relative humidity is often an interacting factor as a cause for, or in the symptom expression of, a disorder. Relative humidity, however, is often not mentioned and frequently not (accurately) measured [43]. The conclusion is that it is very hard to recommend absolute values for optimum O_2 and CO_2 concentrations or O_2 and CO_2 limits for a product without knowledge of other factors. The understanding of actual physiological processes determining the potential of products for MA is developing steadily and will help the further development of optimal and safe packaging techniques.

TABLE 22.1
Recommended Optimal Storage Conditions

Commodity	Temperature (°C)	RH (%)	$[O_2]$ %	$[CO_2]$ %	Potential
		Fruits			
Apples	1–4	90–95	1–3	0–6	A
Avocado	5–13	90	2–5	3–10	B
Banana	12–14	85–95	2–3	8	A
Blackberry	0–2	90–95	5–10	15–20	A
Blueberry	0–2	90–95	2–5	12–20	A
Cherry	0–2	85–90	3–10	10–15	B
Kiwi	0–2	85–90	1–2	3–5	A
Mango	10–15	90	3–7	5–8	B
Melon	8–10	85–90	3–5	5–15	B
Nectarine	0–2	85–90	1–2	3–5	B
Peach	0–2	85–90	1–2	3–5	B
Pear	0–1	90–95	2–3	0–2	A
Persimmon	0–5	90	3–5	5–8	B
Plum	0–2	85–90	1–2	0–5	B
Raspberry	0–2	85–90	5–10	15–20	A
Red currant	0–2	90	5–10	15–20	A
Strawberry	0–2	90	5–10	12–20	A
Sweet corn	0–2	90	2–4	5–10	B
Tomato	1–13	90	3–5	2–4	B
		Vegetables			
Artichoke	0–2	90	3–5	0–2	B
Asparagus (green)	0–2	95	10–15	7–12	A
Broccoli	0–1	90–95	2–3	8–12	A
Brussels sprouts	0–1	90–95	2–4	4–6	A
Cabbage	0–1	95	2–3	3–6	A
Celery (stem)	0–2	90–95	3–5	1–4	B
Chicory (witloof)	0–2	90–95	2–3	5–10	A
Leek	0–2	90–95	3–5	3–6	B
Lettuce	0–2	90–95	2–3	2–5	B
Mung bean	0–2	90–95	1–2	1–3	A
Onion	0–2	70–80	1–4	2–5	B
Spinach	0–2	95	21	10–20	B

Source: Adapted from Kader [12].

Note: Value based on the proceedings of the 6th and 7th International Controlled Atmosphere Research Conferences (Ithaca, New York, 1993; and Davis, California, 1997, respectively). Potential: A = excellent, B = fair. Products with a low potential or no potential are not listed.

22.8 FUTURE OUTLOOK

Fruit and vegetable consumers increasingly demand high-quality products. An important quality feature is freshness. No signs of senescence, decay, wilting, or shriveling are accepted. In general, consumers are willing to pay more for products with better quality. Often consumers also have specific expectations as to ripening stage. For instance, consumers in Northern Europe want firm, not mealy tomatoes (i.e., the fruits should not be too ripe) but also tomatoes with taste and flavor (i.e., the fruits should not be harvested in a very unripe stage). These quality demands result in strict criteria for storage conditions, transport conditions, and shelf conditions. MA packaging is a tool of increasing importance in meeting these criteria.

MA packages are increasingly being used. The total European MAP market handles on average 300 million package units of produce per year with a market value of about $1 billion [96, 97]. In the United States, a market share of about $8 billion in MAP products has been predicted for the year 2000. Often, successful applications are due to good control of the whole distribution chain, from the moment of packing the product until it is displayed on the retail shelf. When film

permeabilities or respiration rates are not well characterized, package designers have to resort to empirical studies with MA packages that can be described as "pack and pray" [2]. A thorough understanding of principles and processes will lead to a more rational selection of packaging materials [5]. Nevertheless, even a package that has been well designed in a laboratory may not necessarily perform well in practice, when no information on the actual storage, transport, or shelf-life conditions was considered at the design stage.

Current state-of-the-art MAP systems for minimally processed produce have been optimized mainly for product quality. Safety and cost aspects have not yet been optimized. Also, quality deterioration still occurs, and further improvements can still be achieved through, for example:

- A systematic approach to select appropriate gas conditions in MAP for specific products
- Availability of more data on the interaction between produce and gas composition
- Development of better computer software to aid in the selection of suitable packaging systems (gas compositions plus foils) for use under dynamic conditions (temperature, humidity)
- Combating microbial hazards in MAP systems (i.e., psychrotrophic pathogens) using improved MAP systems or new hurdles to microbial growth
- Use of "smart" films that compensate for temperature fluctuations by changing permeability properties
- Studies on more environmentally friendly MAP systems (e.g., simple foils, biodegradable foils)
- Minimizing packaging in MAP systems (including biocoatings as part of the packaging concept)

Table 22.2 lists these and other trends foreseen in modified-atmosphere packaging. A misconception of MAP is that it can overcome hygienic abuses in the production or handling of a product. MAP is not a panacea for the preservation of food products, but, if used correctly, it slows the natural deterioration of a product. There is no enhancement of product quality but, when starting with a good clean product, the initial fresh state of the product may be prolonged. Strict codes of practice should be enforced to ensure the maximum quality shelf life and safety of MA-packed foods.

With the increasing importance of MA worldwide, the role of temperature and of its control in the successful use of MAP should be considered. MA packages will not be a substitute for adequate temperature management. For all nontropical products, only cooling is always better than only MA. However, when only MA can be applied in cases where cooling is not possible, stable temperatures are necessary since no films are yet available that respond to temperature fluctuations of the packed product [54].

Modern consumer demands for convenient and fresh, wholesome produce together with the recent reorganization of the distribution chain will further stimulate the use and the broadening of the application area of MAP. Continued basic physiological and microbiological research on the action of MAs will minimize the risks of loss and safety associated with the use of MAs and will allow for faster MAP optimization using models. New technological developments, especially in the area of more suitable packaging films, will contribute to the success of MA as a preservation technique. The main limiting factors for further expansion of MAP may arise out of environmental concerns. A solution for the huge waste problem, in the long run, may be found in the use of edible and biodegradable films that are able to create a modified atmosphere [98]. The integration of different preservative hurdles, such as refrigeration, MAP, active components, and/or green chemicals in accordance with the concept of combined processing [99], may not only minimize potential microbial problems but also contribute to optimized product quality. The range of powerful technologies we have at our disposal today will help to ensure a good supply of minimally processed, fresh, safe, and ready-to-eat products.

TABLE 22.2
New Developments in Modified-Atmosphere Packaging

Packaging	Active Packaging
Tailoring gas transmission/selectivity (new plastics, microperforation)	Absorbers (O_2, ethylene, water, off-flavors)
Water vapor transmission/selectivity (modified humidity storage)	Generators (CO_2, antifungals, flavors)
Biodegradability—environment (multi/mixed layered plastics fortified with biodegradable mass)	Controlled release (antimicrobials, antioxidants)
Composites (metals/cartons with plastics/liners)	Dynamic packaging
New concepts (high oxygen, noble gases, optimization)	Temperature dynamic films
	Humidity dynamic films
Chain optimization (controlling basics: chilling, handling, logistics)	Biopackaging
	Biodegradable/edible films
	Custom-made physical properties
Minimal packaging	Biocoatings
Integrating functionalities	Edible, physical protection (invisible)
Simpler/less films, better recyclable films	Functional features (antimicrobials)

23 Glass Transition Concepts in Food Preservation

Mohammad Shafiur Rahman

CONTENTS

23.1 INTRODUCTION

Mechanical, physical, chemical, and microbial effects are the leading causes of food deterioration and spoilage. Damage can start at the initial point by mishandling of foods during harvesting, processing, and distribution; this may lead to ultimate reduction of shelf life. Factors of food spoilage can be extrinsic (environment) and intrinsic (i.e., food compositions and structure). During storage and distribution, foods are exposed to a wide range of environmental conditions. Environmental factors such as pressure, temperature, humidity, oxygen, and light can trigger several reactions that may lead to food degradation. As a consequence of inappropriate use of these factors, foods are altered to such an extent that these rejected or significantly reduced the quality.

In the literature, new concepts and hypotheses are being developed and proposed in the areas of food properties in order to bring food science from empiricism to the strong scientific foundation [1–4]. The stability of foods is of utmost interest to both food scientists and engineers, and a better understanding of the factors controlling stability or reaction rates is clearly needed [5, 6]. In the 1800s, Nicolas Appert gave his method of food preservation by heating foods (i.e., in boiling water) in airtight bottles without understanding of bacterial spoilage. A

theoretical understanding of the benefits of heating (i.e., canning) did not come until Louis Pasteur observed the relationship between microorganisms and food spoilage. The safety criteria of food preservation in canning (i.e., D-value, z-value and F-value), drying (i.e., water activity and glass transition), freezing (i.e., critical temperature and glass transition) and chilling (i.e., critical temperature), and acidic medium (i.e., critical limit of pH) were developed. Water activity and glass transition concepts are the two most successful theoretical foundations developed for determining food stability during processing and storage. This chapter presents the glass transition concept and food stability by explaining its dynamics, theoretical understanding, and applications.

23.1.1 Background

In the middle of the 20th century, scientists began to discover the existence of a relationship between the water contained in a food and its relative tendency to spoil [7]. In the 1980s, Labuza and his group generated significant data on food stability as a function of water activity. They also began to realize that the active water could be much more important to the stability of a food than the total amount of water present [7]. Thus, it is possible to develop generalized rules or limits for the stability of foods using water activity. For example, there is a critical water activity below which no microorganisms can grow. For most foods, this critical range is in the 0.6–0.7 values of water activity. Pathogenic bacteria cannot grow below a water activity of 0.85–0.86, whereas yeasts and molds are more tolerant of a reduced water activity of 0.80, but usually no growth occurs below a water activity of about 0.62. A food product is most stable at its monolayer moisture content, which varies with the chemical composition and structure. This was the main reason why food scientists started to emphasize water activity rather than total water content. Since then, the scientific community has explored the great significance of water activity in determining the physical characteristics, processes, shelf life, and sensory properties of foods. It is now used to predict the endpoint of drying, process design and control, ingredient selection, product stability, and packaging selection.

Recently, the limitations of water activity have been pointed out and alternatives proposed [3, 4]. Water activity is defined at equilibrium, whereas foods with low and intermediate water content may not be in a state of equilibrium and be time–temperature–moisture dependent. The critical limits of water activity may also be shifted to higher or lower levels by other factors, such as pH, salt, antimicrobial agents, heat treatment, and temperature to some extent [4]. The third limitation is the specific solute effects [8], which demonstrated that minimum water activity for the growth of microbial organisms was dependent on the solutes employed to adjust the water activity of a medium [7]. It was observed later that some solutes were more inhibiting. Thus, the water activity of a medium is not the only determining factor regulating microbial response. The nature of the solute used also plays an important role, thus the concept of generalization with water activity is questioned. Moreover, water activity does not provide any indication of the mobility of water and its binding nature to the substrate [9]. In addition, many physical characteristics, such as crystallization, caking, stickiness, gelatinization, collapse, molecular mobility, and diffusivity could not be completely explained based on the water activity concept alone. In this case, the glass transition concept was put forward.

23.1.2 Glass Transition Concept and Food Stability

Glassy materials have been known for centuries, but it is only in the last 70 years or so that scientific understanding of these systems has evolved [10]. Early attempts to describe vitrification concluded that glass is a liquid that has lost its ability to flow, thus instead of taking the shape of its container, glass itself can serve as the container for liquids. Food materials are in an amorphous or noncrystalline state below the glass transition temperature and are rigid and brittle. Glass is not crystalline with a regular structure, but retains the disorder of the liquid state. Physically it is a solid, but thermodynamically it is a liquid. Molecular mobility increases 100-fold above glass transition. In kinetic terms, Angell [11] described a glass as any liquid or supercooled liquid whose viscosity is between 10^{12} and 10^{13} Pa s thus effectively behaving like a solid, which is able to support its own weight against flow due to gravity. To put this viscosity into context, a supercooled liquid with a viscosity of 10^{14} Pa s would flow 10^{-14} m/s in the glassy state compared to the flow rate of a typical liquid in the order of 10 m/s. In other words, a glass is a liquid that flows about 30 μm in a century [12].

The early papers on glass transition in food and biological systems appeared in the literature in the 1960s [13–15]. White and Cakebread [15] first highlighted the importance of the glassy state of foods in determining its stability. They were perhaps the first food scientists to discuss the importance of the glassy and rubbery states in relation to the quality control (i.e., collapse) of a number of high-solids systems. The significant applications of the glass transition concept in the 1980s emerged in food processing when Levine and Slade [16, 17] identified its major merits. Other groups around the globe generated significant data on the glass transition and components of state diagrams for a number of food components.

It has been mentioned in the literature that foods can be considered very stable at the glassy state, since below glass temperature compounds involved in the deterioration reactions take many months or even years to diffuse over molecular distances and approach each other to react [18]. The hypothesis has recently been stated that this transition greatly influences food stability, as the water in the concentrated phase becomes kinetically immobilized and therefore does not support or participate in reactions. Formation of a glassy state results in a significant arrest of translational molecular motion, and chemical reactions become very slow [19]. The rules of the glass transition concept are (i) food is most stable at and below its glass transition (i.e., T_g for samples containing unfreezable water, T_g' or T_g''' for samples containing freezable water), and (ii) the higher the T-T_g or T/T_g or T/T_g' or T/T_g''' (i.e., above glass transition), the higher the deterioration or reaction

rates. Similarly, mechanical and transport properties of biological materials could be related to their glass transition. It is very interesting to see that this concept has been widely tested in foods. In many instances the glass transition concept does not work alone, thus it is now being recommended to use both the water activity and glass transition concepts in assessing process ability, deterioration, food stability, and shelf-life predictions [20].

23.1.3 Dynamics of Glassy State

Phase transitions in foods can be divided into two groups: first-order and second-order. At first-order transition temperature, the physical state of a material changes isothermally from one state to another (e.g., solid to liquid, liquid to gas) by release or absorption of latent heat (e.g., melting, crystallization, condensation, evaporation). Second-order transition occurs (e.g., amorphous state to glassy state) without release or absorption of latent heat [19]. Glass transition is a second-order time–temperature-dependent transition, which is characterized by a discontinuity (i.e., shift) or change in slope in physical, mechanical, electrical, thermal, and other properties of a material when plotted as a function of temperature [19]. The process is considered as second-order thermodynamic transition in which the material undergoes a change in state but not in phase. It is more meaningful to define the nature second-order change in the properties because each measurement technique is based on monitoring change in a specific property, and because a change or break in properties is achieved within a certain temperature range rather than a specific temperature. A perfect second-order transition occurs at a specific temperature.

Glasses are formed when a liquid or a rubbery system is cooled so rapidly that there is no time for the molecules to rearrange themselves and pack into crystalline domains [21]. With continued cooling, the system shows a significant change in thermal, mechanical, and other physical properties at the glass transition region. Experimentally this is supported by calorimetric studies on supercooled glycerol, which produces a step change in heat capacity as a function of temperature at 190 K [22]. During heating, devitrification of polydisperse food materials does not occur at a fixed point with the change of specific heat. Instead, networks soften over quite a large range of temperatures [23]. Researchers may prefer to refer to the molecular processes as glass transition rather than as second-order transition in order to avoid implying a thermodynamic state at which equilibrium conditions are achieved. This is due to the increasing rates of cooling, which shift the glass transition at higher temperatures and produce a less dense glass, arguing that equilibrium glass conditions lie below the experimentally accessible values [24].

23.1.4 Equilibrium and Nonequilibrium State

Complex foods exist in states of either unstable nonequilibrium or metastable equilibrium, but never in true thermodynamic equilibrium [25]. Fennema et al. [25] defined the terminology as follows. Any food consisting of only one phase requires minimization of free energy to attain thermodynamic equilibrium. For foods containing two or more phases, thermodynamic equilibrium requires that the chemical potential be equal, in every part of the system, for each substance present. Chemical potential determines whether a substance undergoes a chemical reaction or diffuses from one part of a system to another.

An *equilibrium state* can be attained through many possible paths, i.e., the same properties must be obtainable at a given temperature regardless of whether the temperature is approached by cooling or warming. Metastable equilibrium refers to a state of pseudoequilibrium, or apparent equilibrium, which is stable over practical periods but is not the most stable state possible. A *metastable state* can exist (i.e., conversion to a more stable equilibrium state does not occur) when the activation energy for conversion to a more stable equilibrium state is so low that the rate of conversion is of no practical importance. *Nonequilibrium* refers to a state that is inherently unstable, i.e., change to a more stable state is likely to occur at a rate of practical importance. The exact rate of destabilization depends on the particular system and the conditions to which it is exposed.

23.1.5 Cooling, Heating, and Different States

The transformation of a material from one state to another depends on heating or cooling as well as their rate and annealing (i.e., history of the sample). Figure 23.1 shows the effect of the heating or cooling rate on the transformation of one state to another state. For example, the fast rate of heating or cooling can transform the material from melt to glass or glass to melt without the transformation of crystalline and rubbery states. In addition, annealing at specific conditions can form the types and characteristics of the states.

23.1.6 State of Water in Foods

Different states of water, such as bound, free, capillary, mobile, nonsolvent, and unfreezable, are defined in the literature [19]. The state of water can be measured with different techniques or methods. The water sorption isotherm is based on the three types of water: monolayer, multiplayer, and mobile or free water [27]. The Brunauer-Emmett-Teller (BET) monolayer is estimated from the water sorption isotherm and commonly presented in the literature. It could be mentioned that only the BET monolayer has strong theoretical basis and should be

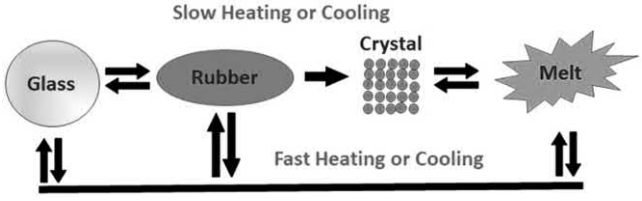

FIGURE 23.1 Effect of cooling rate on the state changes of glass, rubber, crystal, and melt. (Revised from Bhandari and Howes [26].)

used in stability determination. The BET monolayer for large numbers of foods and their components are compiled and presented in the literature. It is not recommended to use the Guggenheim-Anderson-de Boer (GAB) monolayer value due to the number of defects in estimating its real value, although it is popular for its validity up to a water activity of 0.9 [19].

Unfreezable water content can be estimated by comparing differential scanning calorimetry (DSC) endotherms of samples having freezable water. Paakkonen and Plit [28] measured the unfreezable water of cabbage by this method. Unfreezable water can be estimated from the plot of meting enthalpy as a function of water content. This procedure was used for model crackers [29], strawberries [30], dates [31], sucrose [32], and garlic [33]. Usually unfreezable water is independent of total water present in the system. In the case of chitin, unfreezable water increased with the increase of total water, and the amount of freezable water is relatively very low compared to the unfreezable water 106]. In the case of water–gellan systems, unfreezable water increased with the size of the junction zone [34].

Using the nuclear magnetic resonance (NMR) technique, Li et al. [35] studied the mobility of freezable and unfreezable water in waxy corn starch by DSC. Water was found to be isotropically mobile for samples over a range of water contents (6.3–47%) at room temperature. Mobility increased with increasing water content and temperature. A large fraction of unfreezable water was relatively mobile comparable to a liquid state even down to –32°C. The decreasing fraction of mobile water with decreasing temperature suggested that only some of the so-called unfreezable water could be progressively immobilized as temperature decreased. Much of the water remained high in mobility, regardless of the relatively rigid starch molecules in the glassy solid state. This means that water in the glassy state of starch can greatly influence reactions at both ambient and freezing temperatures. At least in this example, the glassy state of the solid materials is not an appropriate term to imply or to predict the molecular dynamics of water and its influence on food stability. Bell et al. [36] determined water mobility in polyvinylpyrrolidone (PVP) systems as determined via NMR and found that water mobility was not affected by the glass transition. PVP systems at constant water activities and water contents, but different physical states (glassy and rubbery), had the same water mobility. An evaluation of four chemical reactions showed no relation between water mobility and kinetic data. The effect of water on chemical reactions is multidimensional and cannot be reduced to a single physicochemical parameter.

It is always found that BET monolayer values are much lower than the unfreezable water [37]. Other techniques used to determine the state of water are dielectric spectroscopy, Fourier transformation infrared spectroscopy (FTIR), x-ray scattering, nuclear magnetic resonance (NMR), magnetic resonance imaging (MRI), electrical resistance, and self-diffusion [9, 38–40]. Three states of water (polymer, capillary, and free) were identified in whey by NMR [41]. The NMR and dielectric measurements of starch paste showed one type of water whereas agar gels contain two types of water when samples contain less than 55% moisture [42]. Lang and Steinberg [43] studied the types of water in corn starch, sugar, sodium chloride, and a mixture of starch and sugar by NMR. It was found that sucrose is a structure-former, while sodium chloride is a structure-breaker. Three types of water mobility were observed in sucrose solution by NMR techniques [44]. Solute–solvent and solute–solute interactions via hydrogen bonding are suggested as mechanisms to explain the observed decrease in water mobility. Lai et al. [45] studied the water mobility in starch-based food products when fat is replaced by fat mimetic components. The active water in the starch–sucrose system was strongly dependent on sucrose content [46]. Molecular mobility of starch and water in starch–water mixtures were studied with the NMR technique and related with the water sorption isotherm [47]. The effect of bound water on glycinin was studied by FTIR spectra [38]. In addition to the aforementioned techniques, many techniques are being used to determine the mobility and state of water and solutes available for chemical reactions, but their interpretation is far from straightforward [9].

23.1.7 Multiple Glass Transition

α-Relaxations are linked to glass transition, which determines the large-scale mechanical stability of the system. The stability of proteins against denaturation and chemical reactivity is much more determined by β-relaxations, which also drive the diffusion of solvents [48]. In many matrices, multiple glass transitions are observed [48]. In the case of freeze-dried tuna fish at moisture content 4.6 g/100 g sample (i.e., unfreezable water), Rahman et al. [49] observed three glass transitions at different temperatures: first one onset at 28.3°C, second one at 97.6°C, and third one at 148.5°C. However, samples at higher moisture content (i.e., 10.0–20.0 g/100 g sample) showed only two glass transitions: one at low and the other one at a higher temperature. The lower glass transition was unaffected by moisture content, whereas higher temperature glass transitions decreased with increasing moisture content (i.e., plasticized). Similarly, in the case of kingfish muscle, the first glass transition was not affected by moisture [50]. In the case of fish muscle, a single glass transition [51–53] as well as two glass transitions [50] were observed. Other multicomponent food systems also showed multiglass transition (i.e., up to three) [54–56]. In the case of sugar-based foods containing freezable water, two glass transitions are commonly observed, one at low temperature and another just below ice-melting temperature [31]. The glass transition temperature before melting decreased with the increase of water, while the lower one remained nearly constant. In the case of rice, three glass transitions were observed, and the second transition showed a decrease with increasing moisture, whereas the first and third ones remained stable (i.e., not plasticized) [55]. Cao et al. [55] hypothesized that only transition decreasing with increasing moisture (i.e., plasticized) would be considered as glass transition. The multiple glass transition could be explained by the natural heterogeneity of biological materials and inhomogeneity due to molecular incompatibility of the

different compositions [49]. In addition, this could be due to the phase separation into biopolymer-rich and plasticizer-rich regions in the matrix [48].

23.2 THEORETICAL UNDERSTANDING OF GLASSY STATE

The present knowledge about glass transition is essentially phenomenological; significant progress on the theoretical aspects is required [57]. Champion et al. [57] reviewed different proposed theories for understanding the glass transition. They are free volume theory, entropy-controlled cooperative motions, mode-coupling theory, frustration-limited domains, and hierarchical correlated molecular motions. A basic and deeper understanding could determine the real applications of glass transition in food technology.

23.2.1 Free Volume Theory

Among all the theories, the free volume theory and relaxation phenomena are beginning to contribute to explaining some changes in foods below glass temperature. Although there is no fully satisfactory theory of the glass transition in polymers, the free volume approach has been widely employed in a quantitative fashion to interpret glassy phenomena in terms of molecular processes [58]. The useful and simple concept argues that total volume per mole of a material is the sum of the free volume and occupied volume. The latter includes not only the van der Waals radii but also the volume associated with the vibrational motion of atoms. The free volume is therefore an extra volume, which is required for larger-scale vibrational motions than those found between consecutive atoms of the same chain [59]. On the free volume concept, glass transition is defined as that temperature at which free volume collapses sensibly to zero and the mobility is restricted, keeping only movement allowed by the occupied volume [60]. Quantitatively, the Williams-Landel-Ferry (WLF) equation is proposed as [60]

$$\log\left(\frac{\mu}{\mu_g}\right) = \frac{-C_1(T - T_g)}{C_2 + (T - T_g)} \tag{23.1}$$

where T and T_g are the experimental and reference temperature, and C_1 and C_2 are the WLF constants (phenomenological coefficients), which are related to the free volume. Other properties, such as shift factor (a_T), G', G'', and rate constant could also be used instead of μ. The universal values of C_1 and C_2 are –17.4 and 51.6, respectively as given by Williams et al. [61]. Soesanto and Williams [62] found these coefficients valid for the WLF correlation of the viscosity of sugars. Ferry [63] identified that these values fluctuate slightly as a function of material types. The VTF equation is also used and expressed as

$$\mu_g = A\exp\left(\frac{BT_o}{T - T_o}\right) \tag{23.2}$$

where T_o is the reference temperature, and A and B are parameters. Angell et al. [64] and Angell [65] classified material as strong or fragile through the glass transition based on the variations of B and C_2. The fragility parameter, m, was introduced to differentiate fragile systems ($100 < m < 200$), which are highly sensitive to temperature changes above glass transition, from strong ones ($16 < m < 100$), which are less disturbed by passage through the glass transition. The applications of various methods to estimate m for food materials are available in the literature [66, 67]. Champion et al. [57] discussed different values of m for food components and their practical significance of the strong/fragile classification with respect to foods. They mentioned that a small variation in the m value for two products may result in a large difference in stability, as the sensitivities to temperature around glass transition are different. It could also benefit from a better knowledge of the strong/fragile behavior of the material processed, such as extrusion, puffing, or flaking. The theory of free volume has been quite successful in following the temperature dependence of viscoelastic functions in the glass transition region and relating parameters to molecular characteristics. The complex nonlinearity and nonexponential character could not be explained much with free volume approach. The popularity of the WLF/free volume approach is due to its simplicity, and it considers that all relaxation processes have the same temperature dependence. In addition, it does not consider the intermolecular interactions, which are more fundamental and the ultimate determining factors of molecular dynamics in densely packed polymers [68].

23.2.2 Relaxation in the Glassy State

The glass transition temperature is a kinetic and relaxation process associated to the primary relaxation of the material [57]. The relaxation time (characteristic time of mobility) is the time that is necessary for the recovery of equilibrium conditions after perturbation of one property of the material. As a relaxation phenomenon, the glass transition temperature can be studied with techniques such as mechanical or impedance spectroscopies, termed α-relaxation (main relaxation). When the temperature is well above glass transition, the molecules or the structural units (such as the repetitive element of a polymer) can move independently from each other because there is enough free volume between entities. The molecular organization in the material is strongly dependent on the temperature above glass transition, but it is relatively stable below glass: molecules stay in an isoconfigurational state, the cooperativity effect being restricted [57].

Within the glassy state, the change in dynamic properties obeys the Arrhenius law. Relaxation processes can be observed in the glassy state with mechanical or impedance spectroscopies. This is also evident with endothermic features on DSC curves. In addition to the main relaxation α, several secondary relaxation β are observed. Its origin still being investigated and it corresponds to more localized molecular motions (for example, in the case of sugars molecule it is linked to the presence and motions of –OH groups), the

molecular structure of carbohydrates, and the rotation of the whole molecule in heterogeneity of the matrix [69–74]. Below glass, a microstructural change may take place, which corresponds to the system approaching the metastable equilibrium, with some extra loss in enthalpy and volume. This *physical aging* can be regarded as a continuation of the α relaxation. The more compact molecular organization and the strengthening of interactions result in changes in mechanical and in transport properties. Its relevance is being increasingly recognized with cereal products [57, 69].

Physical aging is responsible for the appearance of various features on DSC curves: endothermic overshoot that expresses rapid enthalpy recovery after aging below glass transition, but also an exothermic event when a rapid cooling is followed by a much slower rewarming [67]. Two other characteristics need to be explained in the glass transition domain: nonlinearity, which means that the characteristic is changing with time, as it depends on the structure of the glass; and nonexponential behavior, which means that the process of α-relaxation cannot be described by a single relaxation function, due to microstructural heterogeneities. Nonexponential nature is most commonly interpreted as a distribution of relaxation times and mathematically represented by a so-called stretch exponential function [57].

$$\Phi = \exp[-(\theta / \tau)^k] \tag{23.3}$$

where ϕ is the mechanical property, and exponent k is close to 1 for strong liquids (nearly exponential relaxation). For fragile liquids, it changes from near 1 at high temperature to a value close to 0.3 to 0.5 near glass transition [57]. In this situation, Ngai et al. [68] used the Kohlrausch–Williams–Watts (KWW) stretched exponential function. In the case of the stress relaxation modulus:

$$\Phi = \left(\Phi_g - \Phi_e\right)[\exp(\theta / \tau)^{1-n}] + \Phi_e \tag{23.4}$$

where ϕ_g is the glassy mechanical property, ϕ_e is the equilibrium mechanical property of the local segmental motion, θ is the time after the application of a fixed strain, τ is a measured relaxation time, and n is the coupling constant, which ranges from 0 to 1.0. It was found that strongly coupled (interacting) systems have high values of n and an apparently broad distribution of relaxation times, which is the cornerstone of the coupling theory [75]. The parameter n need not be constant during a relaxation, hence the theory is not thermorheologically simple. Kasapis [23] anticipated that much attention will be focused in the area of coupling theory in the future. Other types of theoretical models are discussed by Champion et al. [57].

23.2.3 Critical Temperature of LF-NMR Relaxation and DSC Glass Transition

In the case of rice, low-field nuclear magnetic resonance (LF-NMR) relaxation showed three types of protons from their relaxation times: strongly bound (T_{2b}), moderately bound (T_{21}), and weakly bound (T_{22}) [76]. The T_{2b} and T_{21} increased with the increase of temperature and reached a plateau followed by a sharp increase with a peak (Figure 23.2). It was observed that the second critical temperatures (i.e., end of plateau or onset of sharp increase) were close to the DSC glass transition [76, 77]. The LF-NMR critical temperature was 5°C lower than the DSC onset glass transition (i.e., non-waxy rice: 28.5°C and waxy rice: 26.3°C, moisture: 10.0 g/100 g sample) [78]. In the case of pomegranate skin powder (moisture: 7.7 g/100 g sample), it was observed that this critical temperature was the same as DSC glass transition (i.e., 20°C) or 9°C higher than modulated DSC (MDSC) glass transition (i.e., 11°C) [79]. Similarly, critical temperature was observed lower than the DSC glass for maltodextrin [80] and freeze-dried γ -globulin formulations [81]. It was pointed out that proton mobility was more sensitive to the protein stability as compared to the DSC glass transition. The lower critical temperature from proton mobility could be explained from the mobility distance scale. The LF-NMR measured lower mobility distance (i.e., only proton mobility), while DSC observed a transition when the main chain or substantial proportion of the matrix showed an increased mobility [77]. In the case of biodegradable polymers, the critical temperature (i.e., 75°C) was 5°C higher than the DSC glass transition (i.e., 70°C) [82].

23.3 APPLICATIONS OF GLASSY STATE IN FOOD SYSTEMS

A low glass transition temperature means that at room/mouth temperature, the food is soft and relatively elastic, and at higher temperatures, it may even flow. In contrast, a food with a high glass transition temperature is hard and brittle at ambient temperature. Glass transition and state diagram concept are widely applied in foods to explore its validity. The following section provides a review of this aspect.

23.3.1 Diffusion Process

Glass transition affects diffusion-controlled chemical reactions through the decrease of the diffusion coefficient [83, 84]. The decrease in diffusivity is due to the changes in viscosity and mobility. The diffusion time of a water molecule over 1 Å distance should be more than 10^6 years at room temperature in a glassy matrix based on the Stokes-Einstein relation [57]. The time scale for the loss of stability in food at low water content is not so large. Ablett et al. [85] measured translational diffusion coefficients of water using the pulsed-field gradient NMR technique in 81% pullulan. They showed that diffusivity of water is around 4×10^{-11} m^2/s at glass transition. There was no important drop below the glass, although there was a change in the slope above or below glass transition when diffusivity was plotted as a function of temperature. The diffusion coefficient of water in low-moisture food polymers decreased with the decrease of moisture content without any break in the glass transition when plotting diffusivity versus

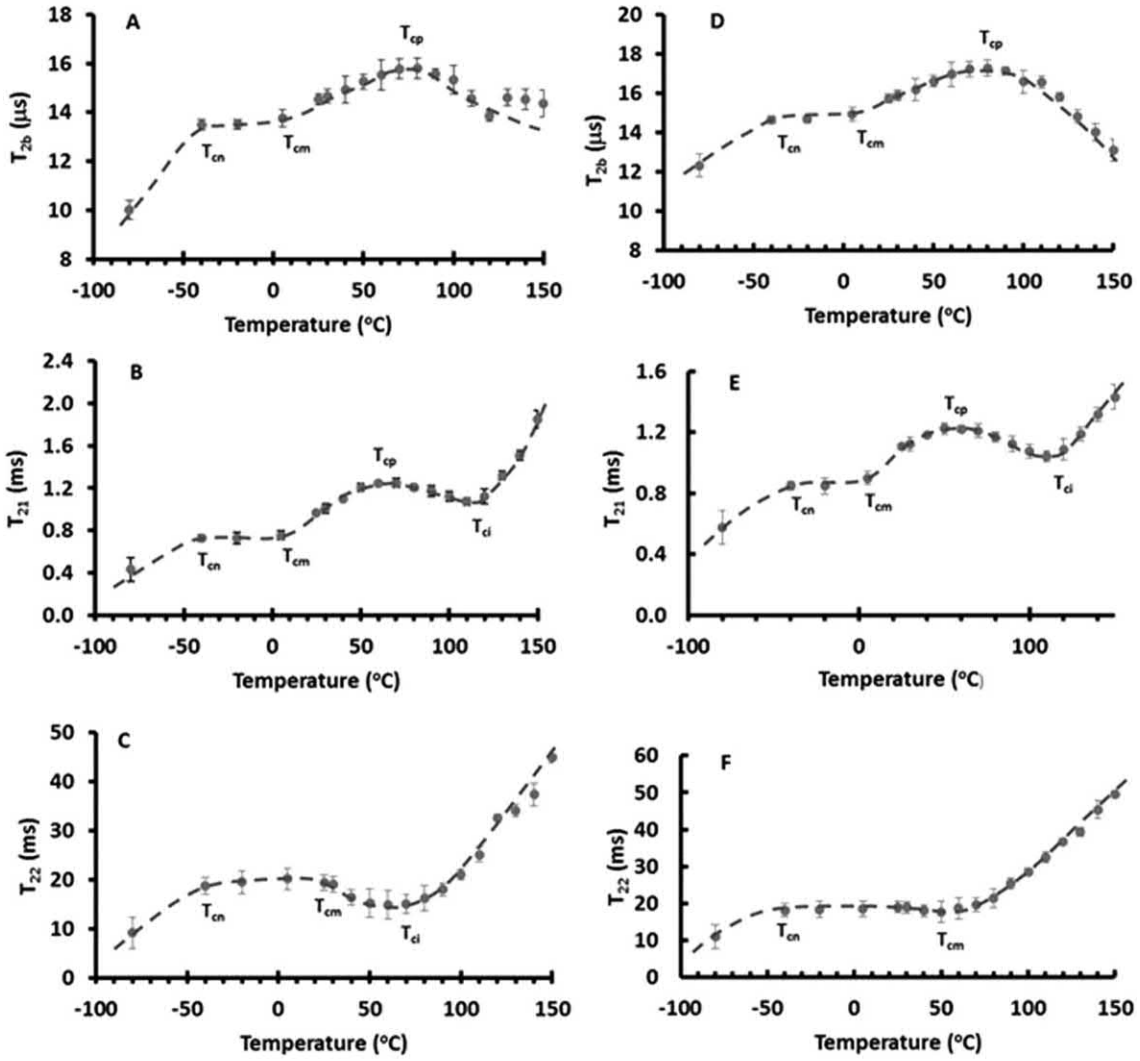

FIGURE 23.2 Relaxation time as a function of temperature. A–C: Nonwaxy rice. D–F: Waxy rice. (From Srikaeoa and Rahman [76].)

water content. The diffusivity depends mainly on moisture content and exhibits a low sensitivity to the nature of surrounding polymer [86]. In case of water diffusivity in maltose–water mixtures above and below glass transition, Parker and Ring [87] plotted diffusivity and viscosity as a function of T_g/T and found that the slopes for diffusivity and viscosity with temperature were not parallel, but instead were extremely divergent when $T_g/T > 0.8$. This decoupling evidence (between viscosity of the diffusion medium and diffusion of small molecule) indicated that the decrease of diffusivity near or below glass is not solely due to the decrease of viscosity. Other important factors that affect the diffusivity in addition to the glassy state are porosity, porous structure, and the structural collapse of foods. The release of entrapped volatiles and flavors are important in food stability. The Arrhenius plot of diffusivity of helium, methanol, and ethyl bromide and glass transition temperature of the sucrose:raffinose matrix showed changes in slope at glass transition [88].

When the molecular size of the diffusing molecule is very small compared to the molecules of the matrix, the Stokes-Einstein relation is inadequate to predict the reactant diffusion. In the case of solute diffusion, macroscopic viscosity did not significantly reduce the diffusion of small molecules [89–91]. The decoupling effect from Stokes-Einstein based on viscosity was also observed for diffusion of fluorescein in sucrose solutions [57]. The decoupling started at $T_g/T > 0.86$ and the discrepancy increases as temperature reached close to glass transition. The motion of small probes in such viscosity materials may be facilitated by the presence of nanodefects and/or by local motions in the material (secondary relaxations).

23.3.2 Texture and Structure

If the moisture content of crispy products, such as chips, crackers, corn flakes, and extruded products, increases due to water sorption or if the temperature is increased during storage, the crispy structure is lost [57]. Roudaut et al. [92] showed that the loss of the crispy texture of dried white bread corresponds to critical water content of 9–10% for which

samples are in the glassy state. A sharp decreasing trend was observed when the compressive failure stress of the frozen sample is plotted as a function of temperature. This change was defined as the brittle–ductile transition. It is not generally true that the brittle–ductile transition appears at the glass transition, although in certain cases the brittle-ductile transition coincided with the glass transition temperature [93]. Nicholls et al. [94] clearly demonstrated that the brittle–ductile transition occurred within gelatinized starch, whereas it was still in the glassy state as defined by the DSC. Watanabe et al. [95] found that there for fish meat. They pointed out that the reasons why these are different needs lengthy and detailed experimentation because the brittle–ductile transition depends on a number of extrinsic factors including strain rate, temperature, stress state, specimen geometry, and the presence of notches and flaws.

23.3.3 Crystallization

Temperatures above glass transition allow molecular mobility and the rearranging of molecules to the crystalline state [16]. Crystallization releases adsorbed water, which in closed containers further plasticizes the remaining amorphous portion of the material [96, 97]. Crystallization causes the most drastic changes to the physical properties of food polymers. It may considerably affect food stability and it may cause impaired rehydration properties of food powders [96–98]. It also affects textural properties, e.g., crystallization of starch in bakery products causing staling [84]. Lactose crystallization in milk powders leads to increased free fat and flavor deterioration, and it may promote nonenzymatic browning [96, 99]. The crystalline materials are not able to entrap other compounds, which become completely released due to crystallization, thus volatiles are lost and lipids become exposed to oxygen.

Increasing $T–T_g$ causes an increasing rate of crystallization with increasing crystallinity. Sandiness in ice cream resulted from lactose crystallization [100]. The crystallization time of amorphous lactose can be predicted using the WLF equation [97]. The extent of crystallization and melting behavior of gelatinized cornstarch was affected by ($T–T_g$) [101]. Crystallization under low $T–T_g$ conditions appears to produce smaller and less perfect crystallites than those produced under high $T–T_g$ conditions, due to lower molecular mobility. The crystallization of isomalt in plasticized form was reduced by adding hydrogenated starch hydrolysates (HSH). The low molecular HSH appeared to be more effective in reducing crystallization than high molecular HSH showing that high glass transition is not necessarily the best inhibitor of isomalt crystallization [102]. In honey stored at 20°C coarse crystals were formed with melting temperatures between 45°C and 65°C, whereas honey stored at –20°C granulated as a finely grained, fondant-like honey, with melting between 25°C and 45°C . In honeys stored at 10°C and 4°C big and small crystals were produced having intermediate characteristics when compared with honeys stored at 20°C and –20°C [103].

23.3.4 Stickiness

Initiation of viscous flow, caking, and stickiness depends on the glass transition temperature. In the case of spray-dried lactose, caking and collapse was increased with the increase of $T–T_g$ [104]. The sticky point of an amorphous sucrose and fructose was found 10°C higher than glass transition [105].

23.3.5 Grain Damage by Drying

It was found that for Bengal variety rice grain at moisture content of 15% (wet basis), the values for thermal expansion coefficients β_{glass} and β_{rubber} were $8.60 \times 10^{-5}°C^{-1}$ and $4.99 \times 10^{-5}°C^{-1}$, respectively [106]. Similarly for Cypress at 14% moisture content, the values for β_{glass} and β_{rubber} were $8.80 \times 10^{-5}°C^{-1}$ and $4.26 \times 10^{-5}°C^{-1}$, respectively. As it can be seen, there is a considerable difference between the values of β_{glass} and β_{rubber} in the two zones on the state diagram. A hypothesis based on glass transitions inside rice kernels was proposed to explain rice fissure formation during the drying process [106–108]. Similarly, when drying occurred in the glassy region, head rice yield was not reduced noticeably after drying. When drying occurred in the rubbery region and no tempering was performed immediately following drying, head rice yield reduction would be marginal if the drying durations were shorter than the maximum moisture content gradient time [109, 110].

23.3.6 Pore Formation in Foods

The glass transition theory is one of the concepts that have been proposed to explain the process of shrinkage, collapse, fissuring, and cracking during drying [111–115]. The hypothesis indicates that significant shrinkage can be noticed during processing only if the temperature of the drying is higher than the glass transition of the material at that particular moisture content [116]. The methods of freeze-drying and hot air drying can be compared based on this theory. In freeze-drying, with the drying temperature below or close to T_g' (maximally freeze-concentrated glass transition temperature, it is independent on solids content) or T_g (glass transition as a function of solids content), the material is in the glassy state. Hence, shrinkage is negligible. As a result, the final product is very porous. With hot air drying, on the other hand, with the drying temperature above T_g' or T_g, the material is in the rubbery state, and substantial shrinkage occurs causing fewer pores.

Karel et al. [88] performed freeze-drying under high vacuum (0.53 Pa) and reduced vacuum conditions (90.6 and 209.3 Pa) to obtain varying initial sample temperatures that were below (–55°C), near (–45°C), and above (–28°C). Collapse was determined by measuring apparent shrinkage before and after freeze-drying of apple, potato, and celery. Samples dried at –55°C showed no shrinkage (more pores), while shrinkage increased with the increase of drying temperature justifying the glass transition concept. Recent experimental results dictate that the concept of glass transition is not valid for freeze-drying of all types of biological materials indicating

the need of the incorporation of other concepts [117], thus a unified approach needs to be used. In the case of freeze-drying, pore formation in food materials showed two distinct trends when shelf temperatures were maintained at a constant level between –45°C to 15°C [117]. The materials in group I (i.e., abalone, potato, and brown date) showed a decreasing trend, whereas group II (i.e., apple and yellow date) showed an increasing trend in pore formation. This may be due to the structural effects of the materials. However, the actual temperature history of the sample passing through freeze-drying was measured. The temperature and moisture history of the sample during freeze-drying could explore fundamental knowledge in explaining the real process of pore formation or collapse.

In many cases during convection air-drying, the observations related to collapse or pore formation are *opposite the glass transition* concept [118–121]. The mechanism proposed for this was the concept of case hardening and internal pressure development [116, 120, 121]. They indicated that at a low drying rate (low temperature), the moisture gradient within the product is small and internal stresses are low and hence the material shrinks down fully onto a solid core, and shrinkage is uniform. At a high drying rate (higher temperature), the surface moisture decreased very fast so that the surface became stiff (i.e., case hardening), limiting subsequent shrinkage, thus increasing pore formation [120]. In the case of case hardening, the permeability and integrity of the crust play a role in maintaining the internal pressure inside the geometric boundary. The internal pressure always tries to puff the product by creating a force to the crust.

The glass transition concept cannot explain the effect of crust and internal pressure. For tuna meat, vacuum-drying produced higher porosity compared to air-drying when both samples were dried at 70°C [122]. The porosity of dehydrated products increased as the vacuum pressure decreased, which means shrinkage can be prevented by controlling pressure [123]. Microwave vacuum drying creates a massive vaporization situation causing puffing [124]. This indicates that in addition to the temperature, environment pressure also affects the pore formation, and this effect cannot be explained by the glass transition concept. Similarly, in the case of extrusion, processing temperatures above 100°C created higher porosity, which is contrary to the glass transition concept [125]. This is due to the rapid vaporization of the water vapor at the exit of the die. After analyzing experimental results from the literature, Rahman [115] identified that the glass transition theory does not hold true for all products or processes. Other concepts, such as surface tension, pore pressure, structure, environment pressure, and mechanisms of moisture transport play important roles in explaining the formation of pores. Rahman [115] hypothesized that capillary force is the main force responsible for collapse, so counterbalancing this force caused formation of pores and lower shrinkage. The counterbalancing forces are due to generation of internal pressure due to vaporization of water or other solvents, variations in moisture transport mechanism, and pressure outside the material. Another factor could be strength of solid matrix (i.e., ice formation; case hardening; surface cracks formation; permeability of water through crust; change in tertiary and quaternary structure of polymers; presence or absence of crystalline, amorphous, and viscoelastic nature of solids; matrix reinforcement; and residence time). However, some of these factors are related to the glass transition.

23.3.7 Microbial Stability

The microbial stability of food has long been estimated by its water activity. The rules are (i) the lower the water activity, the more microbiologically stable the food; and (ii) foods are most stable at its BET monolayer moisture content. The water activity at the monolayer water content is also called the *critical water activity*. One defect in this concept is that microbial stability is affected by the nature and type of solute at a given water activity. Another weakness is that water activity is defined at equilibrium, whereas foods at low and intermediate moisture are not in a state of equilibrium. In the dynamic state, water may be migrating from one component of food to another. This nonequilibrium state is difficult to predict by the equilibrium state defined by water activity.

Slade and Levine [126] and Franks [127] maintained that water activity could serve as a useful but not sole indicator of microbial safety. Slade and Levine's [126] hypothesis was that water dynamics or glass–rubber transition may be applied instead of water activity to predict the microbial stability of concentrated and intermediate-moisture foods. Sapru and Labuza [128] studied the inactivation of bacterial spores and their glass transition temperature. Spores at glass transition have high heat resistance, and above glass transition they are easy to inactivate. At a given temperature, the inactivation rate decreases with the increase of glass transition temperatures of spores. Chirife and Buera [129] maintained that glass–rubber transition would not be useful in predicting with confidence the microbial stability of foods. They analyzed data from the literature and concluded that water activity and glass transition are two different entities. The mobility factors (i.e., glass transition) in addition to water activity are not useful for a better definition of microbial stability of foods. Water activity is a solvent property and glass is a property related to the structure of food. Thus, both properties are needed for understanding food–water relationships at different conditions [129–131].

Macroscopic heterogeneities in a food material can induce the presence of areas with a higher mobility [57]. Chirife et al. [132] investigated microbial stability in glassy white bread and maltodextrins. They showed mold growth was possible below glass transition, if nonglassy microregions exist. Champion et al. [57] advocated for further studies to investigate effects of nonhomogeneous water distribution and/or phase separation on reaction rates. Hills et al. [133] first studied NMR relaxation and electrical conductivity to actually distinguish the effect of local rather than global water activity on microbial stress in porous media. They found that the microbial stress does not correlate with the global water activity measured for the whole assemble but rather with the local water activity of the water actually surrounding the cells.

23.3.8 Desiccation-Tolerant Organisms

Desiccation-tolerant organisms (anhydrobiotes), such as seed and pollen, are capable of surviving the removal of their cellular water. The lifespan of seeds can be remarkably long, ranging from decades to centuries [134, 135, 136] and even millennia [137]. In the late 1980s, Burke [138] forwarded the hypothesis that cytoplasm of seeds could enter into a glassy state. He suggested that in dry anhydrous organisms, glasses could be formed from cell solutes like sugars that were known to provide protection from denatured of large molecules and formation of molecular aggregates, and high viscosity may stop all chemical reactions that require molecular diffusion. Thus, the glass concept turned out to be an interesting hypothesis to account for the survival in the dry state. The physiological importance of the glassy state in desiccation tolerance and storage longevity was also assessed. More recently, in addition to the measurement of glass transition temperature, efforts focused on the assessment of additional physical properties, such as molecular density and local viscosity of the intracellular glassy matrix [12]. When the concept of glasses was introduced in seed science, sugars were thought to have an important part in composition and properties of glassy matrix. Many studies were conducted to explore the biological and physicochemical properties of the intracellular glassy matrix. Several techniques have been developed to provide further insights into the molecular properties of glasses, such as electron paramagnetic resonance (EPR) and Fourier transform infrared (FTIR) spectroscopy. Recently Buitinik and Leprince [12] reviewed these molecular properties of glasses. They considered that the protective effect is improved by hydrogen bonding, water replacement of the sugars with proteins, increasing T_g and T_c (collapse), and filling the small voids. A *perfect biological glass* would exhibit a high T_g and T_c, low molecular mobility, and high density, existing as a mixture of molecules that have high hydrogen-bonding capacity to undergo direct interactions with their neighboring molecules, as well as to prevent phase separation and crystallization [12].

23.3.9 Oxidation

Oxidation phenomena occur in low moisture food systems, such as fat or ascorbic acid oxidation. The oxidation of unsaturated lipids entrapped in sugar-based matrices is affected by physical changes such as collapse or crystallization occurring above glass transition [98, 139]. The encapsulated oil was released as a consequence of the crystallization of amorphous lactose. The released oil underwent rapid oxidation, while encapsulated oil remained unoxidized.

23.3.10 Nonenzymatic Browning

Phase transitions with physical aspects of the matrix are factors affecting the rates of nonenzymatic browning reactions [140–142]. Nonenzymatic browning below glass transition was very slow. The systems used were vegetables, dairy products, and model food systems with amino acids and sugars in a PVP matrix. Karmas et al. [141] showed that the rate of the reaction is low at temperatures below glass and increases with the increase of $T–T_g$. They also indicated that the reaction is also controlled by several other factors, such as structural changes and water content, independently of its plasticizing effect. In this case, both moisture and glass transition affected the reaction rate [140]. This is due to the changes in diffusion coefficient below glass transition when nonenzymatic reactions take place in the diffusion-limited region. Roos and Himberg [143] also showed that it is not stopped by the glass transition temperature of the maltodextrin, lysine, and xylose matrix, and is possible in the glassy state. The WLF equation was valid to predict the reaction rate constant as a function of moisture and temperature above glass [140].

There is not a general rule observed whether water activity or glassy state of the system as dictated by glass transition temperature impacts the rates of chemical reactions in reduced moisture solid food systems. Bell [144] studied the kinetics of nonenzymatic browning pigment formation in a model PVP (different molecular weight) matrix. The browning rates of matrices having different glass temperature, but constant water activity, were significantly different except when all were in the glassy state. As the system changed from a glassy state to a rubbery state, the rate of browning increased sevenfold. The rate of browning also increased as water activity increased from 0.33 to 0.54, but then appeared to plateau with further increases in water activity. In addition, the concentration of reactants in the aqueous microenvironment had a significant impact on the rate of brown pigment formation.

Bell et al. [145] studied the glycine loss and Maillard browning as a function of glass transition temperature. At water activity 0.54, pH 7, and storing at 25°C, the rate constants were very low when $T–T_g$ was close to zero and increased with the increase of $T–T_g$. O'Brien [146] studied the rate of nonenzymatic browning in freeze-dried model systems containing lysine with glucose or sucrose or trehalose at pH 2.5 and a water activity of 0.33. The temperatures were at 40°C, 60°C, and 90°C. All systems were in rubbery state at 90°C, whereas at 40°C and 60°C trehalose was in mixed amorphous glass–crystalline system, and glucose and sucrose were in rubbery state. The rate of nonenzymatic browning in the trehalose system was much lower than that in the sucrose or glucose depending on temperature. The rate constant was in the order glucose > sucrose > trehalose. The presence of crystalline material in the trehalose system at 40°C and 60°C may have influenced the overall rate of hydrolysis, stabilizing the system. At 90°C, all systems were in rubbery state and there were substantial differences between the stability of sucrose and trehalose. Thus, glass transition not only controls the rate of browning but also the rate-limiting sucrose hydrolysis step since glucose has a much higher rate than sucrose. The effect of glass transition was much less than previously reported. Karel et al. [88] developed correlation for the browning rate constant as a function of $1/T$, moisture content, and $T–T_g$.

Bell and Hageman [147] studied the kinetics of aspartame degradation in the PVP model system at constant temperature

(25°C) and pH (7.0) as a function of water activity and glass transition independently. Degradation reaction rates at constant water activity but different glass transition temperature were not significantly different, and rates at a similar distance from T_g but different water activities were significantly different. Thus, the rate of aspartame degradation was significantly influenced by the water activity, while the effect of the glass transition temperature on the reaction was negligible.

23.3.11 Enzymatic Reaction

Several enzymatic reactions can occur at low water contents [148, 149] or in the frozen state [25, 150–153] such as those catalyzed by alkaline phosphatase, lipoxygenase, lipase, or invertase. The effect of temperature on the reaction rate depends on the relative value of the diffusion of the reactants and the activity of the enzyme in such concentrated media. Champion et al. [57] pointed out that there is a risk in proposing a unified theoretical model to predict the reactions in such concentrated materials. Torreggiani et al. [154] found no clear relationship between the anthocyanin loss and $T–T_g'$ of strawberry juices. Other important factors such as the pH of the unfrozen phase could influence anthocyanin pigment stability. It could be hypothesized that sorbitol showing stability could alter the nucleophilic power of the water or could play a specific protective role, due to its chemical nature, in the enzymatic breakdown of the anthocyanin pigments.

23.3.12 Denaturation of Protein

The properties and functionality of the protein depend on whether it exists in the native or denatured state, and maintaining protein structure and functionality is important in food science. The kinetics of aspartame degradation were evaluated in the PVP model system [147, 155]. Reaction rates at constant water activity but different glass transition values were not significantly different. Moreover, rates at the same values of $T–T_g$ were significantly different with changing water activity. The temperature of denaturation decreased with increasing moisture content to some plateau, where further increases in moisture no longer influenced the denaturation temperature [156]. Bell and Hageman [147] studied the denaturation temperature of globular proteins (β-lactoglobulin, ovalbumin, and ribonuclease) in dry state as a function of glass transition temperatures of polyhydroxy compounds (water, glycerol, sorbitol, sucrose, and trehalose). The component was in the 25–33% w/w. They found thermal stability of protein correlated with glass transition temperatures of polyhydroxy component, and the lower the T_g of the component, the greater was the degree of protein destabilization. They hypothesized that in dry state, the additives were acting as plasticizers, enhancing the mobility and thus the unfolding of the globular proteins.

23.3.13 Hydrolysis

The effect of glass transition on different chemical reactions is not as clear as in the cases with physical changes. This is due to the multiple roles of water in foods, such as plasticizer, reactant or product of chemical reactions, and pH [157]. One of the chemical reactions that were proposed to occur only in the rubbery phase (i.e., above glass transition) is sucrose inversion in acid-containing amorphous powders [158]. Buera et al. [157] investigated the effect of glass transition on the rate of acid-catalyzed sucrose hydrolysis in an amorphous polymeric matrix of PVP. No direct relationship was found between sucrose hydrolysis in a PVP matrix and T_g or $T–T_g$. Glass transition is not a key factor determining the rate of sucrose hydrolysis. The major effect on the rate of hydrolysis was related to changes in pH, which is moisture dependent. Knowledge of the actual pH of a system, and the possible changes that may occur during concentration or drying are necessary for better understanding of chemical changes in low and intermediate moisture foods. Sucrose hydrolysis in an acid-containing (low pH = 3.1) amorphous starch powder (native or pre-gelatinized) occurred to a significant extent in the glassy state [159]. The mobility effects are not controlling the extent of reaction. Hydrolysis (31% to 85% remaining sucrose) was observed at different water contents and temperature below glass. Little reaction occurred at moisture contents below the so-called BET monolayer. Temperature was a critical factor controlling sucrose inversion.

23.3.14 Enzyme Inactivation and Other Chemical Reactions

The stability of enzymes in low-water systems was analyzed based on glass concept. The stability of lactase during heating at 70°C was studied in different amorphous glassy matrices: trehalose, maltodextrin, and PVP [160]. The protective effect of the maltodextrin and PVP matrices on the enzyme was attributed to their glass transition temperature, but the trehalose matrix is much more efficient for enzyme stability independent of its glass transition value. Schebor et al. [161] studied the stabilization of the enzyme invertase (β-fructofuranosidase) by its incorporation in aqueous model systems of trehalose, maltodextrin, and PVP, followed by freeze-drying and desiccation to zero moisture content. When the systems heated at 90°C for thermal inactivation of invertase, the enzyme was protected by maltodextrin and PVP, but not significantly protected by trehalose, although all systems were in the glassy state. Cardona et al. [162] observed significant inactivation of invertase when maltodextrin and PVP were kept well below their glass transition, but the enzyme was fairly stable in rubbery trehalose systems. At this moisture content, trehalose crystallization rapid thermal inactivation of invertase was observed. The invertase inactivation in heated systems of reduced moisture could not be predicted based on glass transition, and this was particularly true for trehalose (i.e., it was evident that the glassy state was not the main stabilizing factor).

The relevance of glass transition as a reference temperature for predicting the rate of chemical or enzymatic reactions was studied, but no clear relationship has been established [57]. Bell and White [163] studied thiamin loss as a function

of water activity and glass transition temperature. The maximum rate constant appeared to be around $T–T_g = –23°C$. Below glass transition (i.e., lower $T–T_g$), the rate constant decreased and correlated reasonably well with decreasing value of $T–T_g$. In the rubbery region (i.e., water activity more than 0.4) the rate constants no longer correlated with $T–T_g$ but rather with water activity. The reason could be attributed to the collapse of the matrix.

23.3.15 Vitamin C

Zhang et al. [164] studied the stability of vitamin C and other quality attributes (i.e., hardness, drip loss, and color) of mango (i.e., cube shape) within four different states of frozen storage (i.e., $T < T_g'$, $T_g' < T < T_g''$, $T_g'' < T < T_m'$, $T > T_m'$). They observed that vitamin C continued to decrease at the frozen glassy state even without temperature fluctuations. In addition, a higher rate of decrease was observed above frozen glassy state with temperature fluctuations. This indicated that the reaction rate could be slow in the glassy state but not zero. Therefore, when considering stability, it is important to identify the time frame. For example, if we are looking for 3 years of shelf life, then it needs to be considered what low rate would be good for the time frame of 3 years.

23.3.16 Sensory Properties

The effect of molecular weight on glass temperature of starch hydrolysis products (SHPs) shows a plateau region, which indicates the useful range of gelation, encapsulation, cryostabilization, thermochemical stabilization, and facilitating of drying process. The lower end corresponds to the area of sweetness, browning reactions, and cryoprotection. The intermediate region at the upper end of the steeply rising portion represents the area of antistaling ingredients. The map can be used to choose individual SHPs or mixtures of SHPs and other carbohydrates to achieve the desired complex functional behavior for specific product applications [16]. For example, the synthesis of SHPs capable of gelation from solution should be designed to yield materials of dextrose equivalent (DE) ≤6 and $T_g' \geq 8°C$. Similarly, potato starch maltodextrins of 5-6 DE (25% w/w) produced thermoreversible, fat-mimetic gels; and tapioca SHPs of DE ≤5 also form fat-mimetic gels from solution to develop fat-replaceable ingredients [165–167]. Levine and Slade [16] developed a linear relation between DE and glass transition temperature of a maximally freeze-concentrated solution of commercial SHPs. Thus, the correlation can be used to approximately calculate DE for dextrin and maltodextrin of unknown SHP, which can make unnecessary more tedious and time-consuming classical experimental methods for DE determination [168].

Glass transition alone could not be considered as generic rules for food stability criteria since numbers of instances, such as pore formation, diffusion, microbial stability, nonenzymatic browning, and other factors or mechanisms play important roles. However, it is definitely one of the factors affecting the stability, and a future challenge to combine the glass concept with other mechanisms or factors, such as water activity, pH, and preservatives [6].

23.4 CRITICAL TEMPERATURE CONCEPT

It is expected that there should be a break in the plot of k (i.e., reaction rate) versus T/T_g at T/T_g equal to 1 (i.e., change in slope between above and below glass transition), if the glass transition concept is valid. Similarly, a plot of k versus X_w/X_b should have a break at X_w/X_b equal to 1, if the water activity concept is valid. The molecular mobility measured by ST-EPR and ^{1}H-NMR showed two distinct changes: (i) a minor shift just close to T_g and (ii) an abrupt decrease due to a solid-like to liquid-like shift defined as T_c (i.e., critical temperature) [169]. In the case of sugars, T_c was observed at 17–35°C higher than T_g, and for biological materials it was more than 50°C. This variation was also explained by the density of hydrogen bond and molecular packing measured by FTIR. This higher T_c from T_g was also correlated with the observed collapse or softening of sugars at 10–17°C above glass transition [170–172] and crystallization onset above 22.1°C to 28.3°C higher than glass transition considering the level of moisture in date syrup [173].

In the case of browning of banana as a function of moisture content at different storage temperatures, the rate constant as a function of temperature (sample containing only unfreezable water, i.e., moisture: 0.04 g/g sample) is shown in Figure 23.3 [174]. Figure 23.3 shows a change of slope at a critical temperature, 45.0°C, which is higher than the onset glass transition (i.e., 11.7°C). This shows that the critical temperature is 33.3°C, which is higher than glass transition. The Arrhenius plot also shows a change in slope at 45.0°C, and this indicated that there was a change in reaction mechanisms above 45.0°C (Figure 23.4). Similarly, the deactivation of α-amylase in freeze-dried trehalose matrices (moisture: 0.50 g/g sample, temperature: 45–100°C) showed a change in the slope at 85°C, while the glass transition temperature was 45°C (i.e., 40°C higher than glass transition) [175]. However, the rate of browning in food systems showed a change in slope in the Arrhenius plot, and the critical temperature was observed either at glass transition or above/below the glass transition depending on the types of matrices [142]. In addition, in some instances the reaction rate

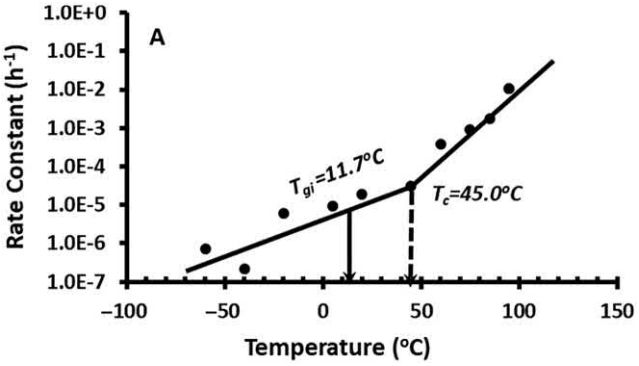

FIGURE 23.3 Plot of log k (reaction rate) as a function of temperature for the sample moisture 0.04 g/g sample. (From Rahman and Al-Saidi [174].)

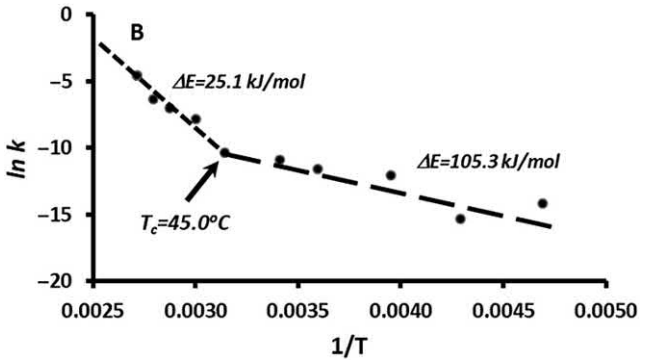

FIGURE 23.4 Arrhenius plot for the sample moisture 0.04 g/g sample. (From Rahman and Al-Saidi [174].)

increased in the glassy state instead of decreased as compared to the rubbery state. In the case of browning of banana, the activation energy values of freeze-dried banana below and above critical temperature were determined as 105.3 and 25.1 kJ/mole, respectively. Similarly, the activation energy of the decay of α-amylase in freeze-dried trehalose matrices (moisture: 0.50 g/g sample) showed 128 and 40 J/mole, respectively, below and above critical temperature [175].

In the case of browning of banana containing freezable water, a shift was observed when reaction rate was plotted as a function of temperature (i.e., two changes in the slope) (Figure 23.5). The first change in slope was observed close to the T_g''' (i.e., –40.9°C, critical temperature), thus supporting glass transition concept [174]. The enzyme decay in the frozen fish protein showed that the critical temperature existed at, below, or above T_g''', depending on the molecular weight of the used cryoprotectant (i.e., maltodextrin) [102].

Crystallization over a practical time scale occurred above glass transition, and some reports showed it was 30°C above glass temperature [176]. α-Amylase was more stable in rubbery matrices, of lactose or trehalose than in a glassy PVP matrix and the protective efficiency of saccharides, maltodextrins, and PVPs did not increase with their respective glass transition temperature [177, 178]. In addition, dielectric and other spectroscopy determined relaxations (i.e., β and γ) below glass transition [179]. However, it is not clear how these

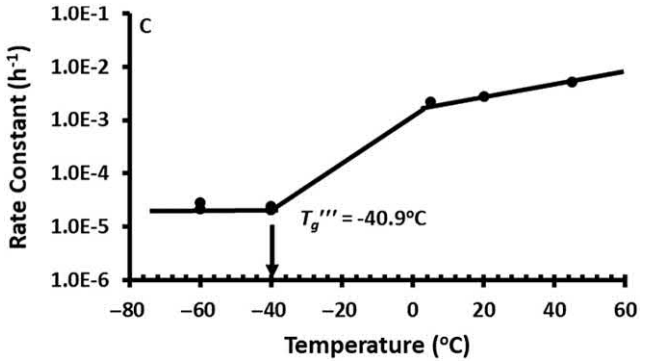

FIGURE 23.5 Plot of log *k* as a function of temperature for the sample moisture 0.869 g/g sample. (From Rahman and Al-Saidi [174].)

multiple relaxations linked to the stability of foods, as related to the physical and chemical changes.

Considering the fact that glass transition is not the critical limit, Rahman [3] tested the hypothesis that there is a critical temperature as a ratio of T_c/T_g (T_c is the critical temperature) that could vary with moisture content. Above the critical temperature, an increase in the water content or temperature significantly increased the reaction rate; while below the critical temperature, the rate was less affected by water content and temperature. Rahman [3] observed values of T_c/T_g that varied from 0.78 to 1.5 depending on the types of reaction and the matrices. In some instances, the values of T_c/T_g were close to 1.0 indicating that only in specific cases did glass transition explain the mechanism. Moreover, the deviations of T_c/T_g from 1 explain why in many instances in the literature both stability and unstability were observed above and below glass transition. Thus, the critical temperature in relation to glass transition depends on the types of chemical reactions as well as the physicochemical and structural characteristics of the matrices [174].

The molecular relaxation, as measured by different methods, determines relaxation at different scales (i.e., macro, micro, and nano ranges). The transition by thermal or mechanical relaxations measure mobility in a 20–300 nm range, while other relaxation techniques, such as NMR, measure the molecular relaxation in a 1–2 nm range [180]. Recently, tremendous emphasis has been given to understanding the multidimensional aspects of molecular mobility. Although, it is not yet very clear how this knowledge could be applied universally in determining the stability of foods in relation to microbial and physical-chemical changes.

23.5 CONCLUSION

It is clear from the literature that not all experimental results can be explained by the glass transition rules, thus further developments are necessary. The limitations of water activity and glass transition concepts do not invalidate the concepts completely but rather make them difficult to apply universally. The water activity concept is based on the binding nature of water molecules in the matrix. When water is bound (i.e., unavailable to take part in reactions) to the solid matrix or nonsolvent, then no deterioration reactions could be expected. The glass transition concept is based on the molecular mobility of the reacting components at microlevel in a matrix, thus diffusion of the reactants through the system is very slow and stability is achieved. Thus, a successful combination of water activity and glass transition concepts could open more precise and unified determination of stability criteria. There is a need to combine multiple concepts for better predictions of food stability.

24 State Diagrams and Their Applications in Food Preservation

Mohammad Shafiur Rahman

CONTENTS

24.1 BACKGROUND AND PROGRESS

The glass transition concept was advanced further by the development of state diagrams for foods. A state diagram is a stability map of different states and phases of a food as a function of water or solids content and temperature. Most probably, Levine and Slade [1] presented the first state diagram in the food science literature by illustrating glass line, freezing curve, and the intersection of these lines as T_g'' by extrapolation of the extended freezing curve by maintaining similar curvature (Figure 24.1). The main advantage of drawing a map is to help in understanding the complex changes that occur when the solids content (or water content) and temperature of foods are changed. It also assists in identifying the stability of foods during storage as well as selecting suitable conditions in terms of temperature and moisture content for processing to achieve the desired product characteristics. This chapter provides the components of the state diagram by discussing macro- and micro-regions, and by explaining selected applications in determining food's stability during processing and storage.

24.1.1 Macro-Region State Diagrams

The initial state diagram based on the freezing curve and glass transition provided four macro-regions: region I (i.e. below the glass transition), region II (above the glass transition and below the maximal freeze concentration, i.e. completely frozen), region III (above the maximal freeze concentration condition and below the freezing curve, i.e. partially frozen), and region IV (i.e. above the glass transition and above the freezing curve) [1] (Figure 24.1). It is important to understand the state diagram first before applying it in food processing and food storage.

24.1.2 State Diagrams Combining Water Activity and Glass Transition

Recently many papers have presented data on the water activity as well as glass transition as a function of water content. However, it was not clearly identified where the link was between them in order to determine stability. Karel et al. [2] attempted to relate water activity and glass transition by plotting equilibrium water content and glass transition as a function of water activity. By drawing a vertical line on the graph, stability criteria could be determined from the isotherm curve and glass transition line. At any temperature (say 25°C), the stability moisture content from the glass transition line was much higher than the stability moisture from the isotherm. However, this approach is unable to relate this to experimental food stability. At present, it is a real challenge to link them.

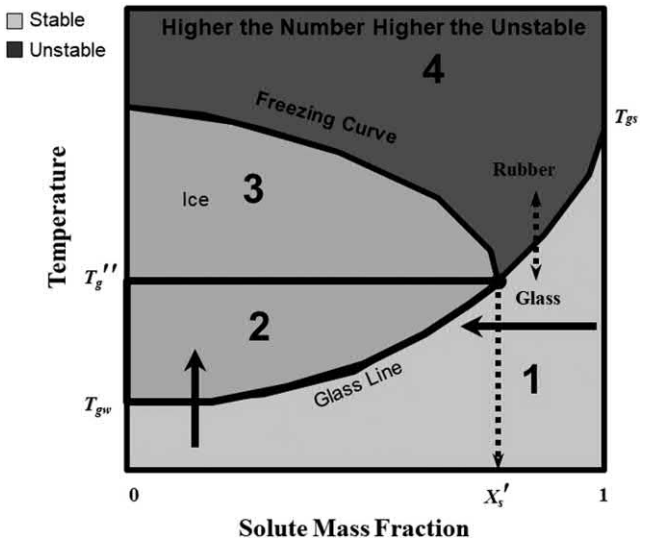

FIGURE 24.1 Macro-region state diagram; 1, 2, 3, 4 indicate the degree of stability, 1: most stable and 4: least stable. (From Levine and Slade [1].)

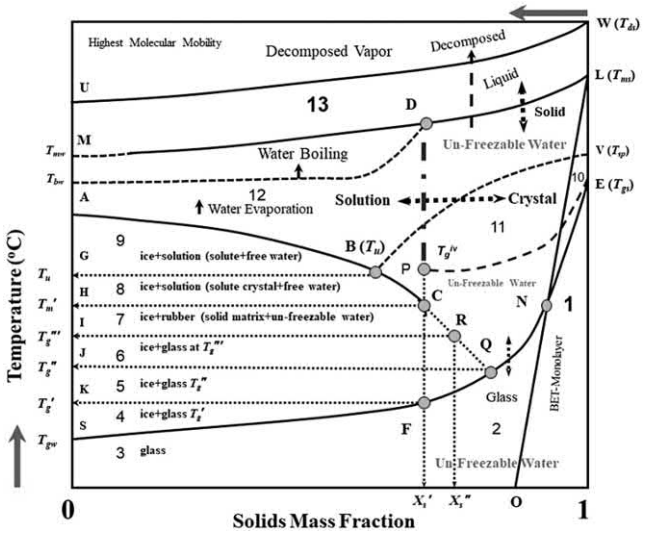

FIGURE 24.2 State diagram showing different regions and state of foods (updated from [3–6]) T_{ds}: solids-decomposition temperature, T_{ms}: solids melting temperature, T_{sp}: soluble solids melting, T_{gs}: solids–glass transition temperature, T_g^{iv}: end of solids-plasticization temperature, T_u: eutectic temperature, T_{gw}: glass transition of water, T_u: solute crystallization temperature during freeze-concentration, T_m': maximal-freeze-concentration condition, i.e. end point of freezing, T_g''': glass transition of the solids matrix in the frozen sample as determined by differential scanning calorimetry (DSC), T_g'': intersection of the freezing curve to the glass line by maintaining the similar curvature of the freezing curve, and T_g': glass transition at maximal-freeze-concentration, i.e. at the end point of freezing, T_{bw}: boiling temperature of water, T_{mw}: extension of solids-melting line to y-axis.

Most approaches to combining both concepts are reviewed by Rahman [3, 4].

Rahman [5] combined the water activity and glass transition concepts in the state diagram by plotting the BET-monolayer as a function of temperature. This makes four macro-regions: above freezable (i.e. unfreezable region) moisture content; below the BET-monolayer, one above and one below; and above the BET-monolayer, one above and another below (Figure 24.2). In the literature, it was emphasized that a combination of the water activity and glass transition concepts could be a powerful tool in predicting food stability. A successful combination of water activity and glass transition could lead to more in-depth knowledge on stability criteria [5]. Recently, attempts have been made to add other structural changes, such as glass line, freezing curve, and solubility line, to the state diagram.

24.1.3 Micro-Regions in the State Diagram

Using a state diagram, Rahman [6] hypothesized 13 micro-regions with the highest to the lowest stability based on their location relative to the glass and BET-monolayer lines. Figure 24.2 presents the most advanced state diagram. For example, region 1 (a relatively non-reacting zone, below the BET-monolayer line and glass line) is the most stable, and region 13 (a highly reacting zone, far from the BET-monolayer line and glass line) is the least stable. The stability decreases as the zone number increases. Table 24.1 shows the states or phases in different micro-regions. Applications of this hypothesis in food processing are presented by Rahman [3, 4, 6]. Schebor et al. [7] studied sucrose hydrolysis in the micro-regions 1 and 2, and their results evidenced the validity of the hypothesis (i.e. the reaction rate in micro-region 2 is higher than in micro-region 1). The advantages of the micro-region concept are as follows: (i) stability rules could be developed for each micro-region (i.e. narrow moisture and temperature range) as compared to the macro-region (i.e. broad moisture and temperature region), and (ii) the states or phases of the material could be identified in each micro-region, and (iii) a reference point could be identified where the BET-monolayer line and glass line intersect, and any location in the state diagram could be assessed in relation to the reference point [3, 4, 8].

TABLE 24.1
State Diagram Developed for Different Foods and Food Components

Material	Components	References
Apple, grape, onion, strawberry, sucrose, fructose, bacterial suspension, tomato, garlic	Freezing curve, glass line, X_s'', and T_g''	[19, 35, 59–68]
Honey	Freezing curve, glass line, X_s'', T_g'', and T_g'''	[69]
Sucrose	X_s'', T_g''	[70]
Sucrose, lactose, maltose, glucose, maltodextrins, starch, arabinoxylan	Freezing curve, glass line, X_s', T_m', and T_g'	[30, 71–74]

In the case of banana, Rahman and Al-Saidi [9] identified the crossing point of the glass line and BET-monolayer line at X_s equal to 0.92 g/g solids, and T_r (i.e. crossing point of glass and BET-monolayer line) equal to 1.4°C. However, the methods of combining other hurdles such as pH and preservatives could be linked with these concepts. We are far away from developing a unified theoretical basis combining multi-hurdles or multi-mechanisms of food stability.

24.2 MICRO-REGION STATE DIAGRAMS AND THEIR COMPONENTS

This section presents different characteristics of micro-region state diagrams and the prediction models of the phase or state boundary. Examples of recent state diagrams for broccoli (Figure 24.3, [10]), banana (Figure 24.4, [9]), and crystallized date fruit syrup (Figure 24.5, [11]) are presented in the literature. Table 24.1 shows other sources of state diagrams for foods.

24.2.1 Freezing-Related Process

In Figure 24.2, the freezing line (ABC) and solubility line (BV) are shown in relation to the glass transition line (EFS).

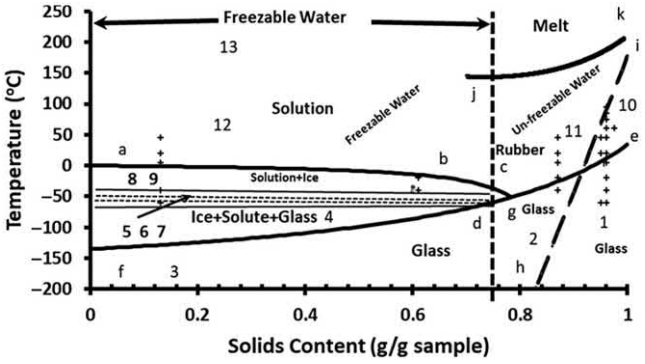

FIGURE 24.3 State diagram of freeze-dried broccoli; numbers show the locations of the micro-regions. (From Suresh et al. [10].)

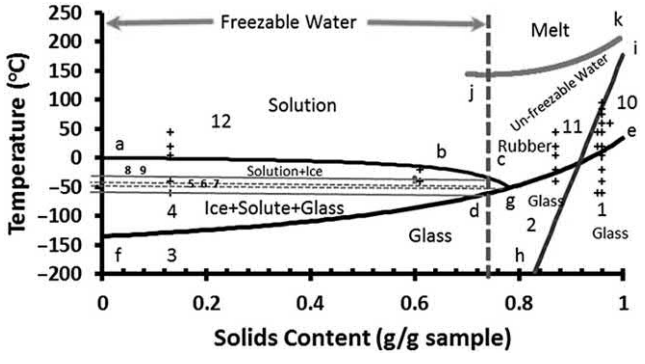

FIGURE 24.4 State diagram of ripe banana; abcg: freezing curve, fdge: glass line, c: ultimate maximal freeze concentration condition, d: vertical line passing through maximal-freeze concentration condition and crossing glass line, g: intersection of the freezing curve keeping the same curvature as the Chen [5] model and glass line, hi: BET-monolayer line, jk: solids-melting line [9].

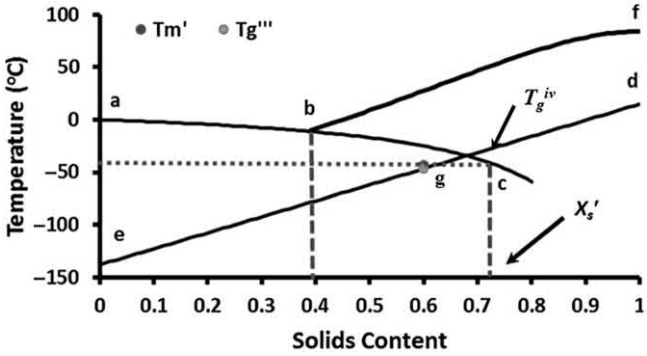

FIGURE 24.5 State diagram of crystallized date syrup (abc: freezing curve, g: T_m', de: glass line, c: maximal freeze concentration conditions, bf: sugar crystals melting line, b: eutectic point). (From Al-Farsi et al. [11].)

The freezing line decreased with the increase of solids due to the freezing point depression. The cooling curve is one of the most simple and popular methods to measure the freezing point of foods. The complete discussion is not presented here since details of the cooling curve method are given by Rahman [12] and Rahman et al. [13]. The cooling curve method was used to measure the freezing point of milk [14, 15], coffee extract [16], dates [17], tuna flesh [18], and garlic [19].

A typical DSC heating thermogram of fruits and vegetables is shown in Figure 24.6 for a sample containing freezable water [20]. The sample containing freezable water shows two shifts, one at low temperature (i.e. the first glass transition, marked as G_1) and another one (i.e. the second glass transition, marked as G_2) just before the ice melting endothermic peak (i.e. marked as M). The values of maximal-freeze-concentration conditions (i.e. T_m' and T_g''') are determined from the second transition as shown in Figure 24.2. The freezing point and ice melting enthalpy can be determined from the endothermic peak. The initial or equilibrium freezing point was considered as the maximum slope in the ice melting endotherm (marked as m) as suggested by Rahman [20]. The ice melting (i.e. freezing point) is commonly characterized from the endothermic peak during melting [20, 21]. This method provides very accurate determination for a sharp peak. In the case of a wider peak, the freezing point is difficult to determine. The wider peak appears due to the wide variation in the state of water in foods. In this case, the maximum slope of the endotherm (point m in Figure 24.6) or the extra-plotted peak onset temperature of the ice melting can be considered the freezing point [21, 22]. When the sample contains mainly free water, it shows a sharp endothermic peak on melting at a melting point similar to pure water. Multi-peak natures of the DSC curves are found for the metastable states of water in gum from *Acacia senegal* [23] and gellan [24]. The sample containing unfreezable water shows no first-order transition (Figure 24.7) for ice melting, instead only showing a solids-melting endotherm.

The extended theoretical-based Clausius–Clapeyron equation is commonly used to model the freezing point of foods as a function of solids content [25]. The improved model is

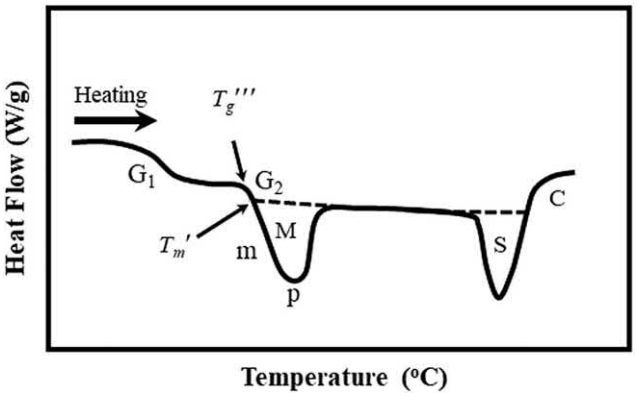

FIGURE 24.6 A typical DSC thermogram for the sample containing freezable water. M: ice melting peak, S: solids-melting peak, G_1: lower glass transition, and G_2: glass transition just before ice melting, T_m': end of ice formation, and T_g''': onset and end of G_2. (From Rahman [58].)

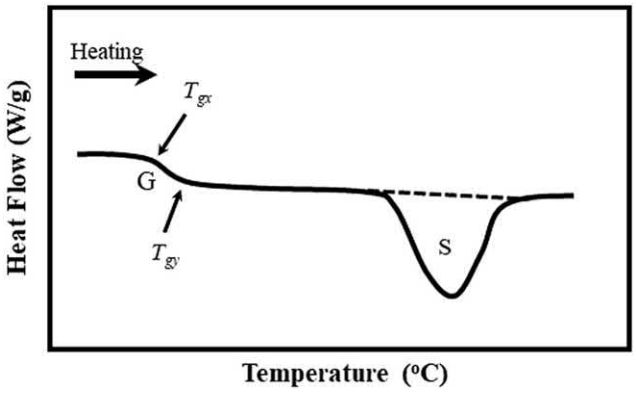

FIGURE 24.7 A typical DSC thermogram for the sample containing unfreezable water. G: glass transition, S: solids-melting. (From Rahamn [58].)

adapted for non-ideal solutions by introducing parameters for the fraction of total water unavailable for ice formation. The unfreezable water content B (g water/g dry-solids) can be defined as the ratio of unfreezable water to the total dry-solids. The unfreezable water is defined as the water which never forms ice even at very low temperatures (e.g. –40°C). The Chen [25] model can be written as:

$$\delta = -\frac{\beta}{\lambda_w}\ln\left[\frac{1 - X_s^o - BX_s^o}{1 - X_s^o - BX_s^o + EX_s^o}\right] \qquad (24.1)$$

where δ is the freezing point depression, $\delta = (T_w - T_F)$, T_F is the freezing point of food (°C), T_w is the freezing point of water (°C), β is the molar freezing point constant of water (1860 kg K/kg mole), λ_w is the molecular weight of water, X_s^o is the initial solids mass fraction before freezing (g/g sample), B is the unfreezable water (g/g dry solids), and E is the molecular weight ratio of water and solids (λ_w/λ_s). The values of model parameters B and E for different foods are shown in Table 24.2.

The point F (X_s' and T_g') lower than T_m' (point C) is a characteristic transition (ultimate maximal freeze concentration condition) in the state diagram, and it is defined as the intersection of the vertical line from T_m' to the glass line EFS [5]. The water content at point F or C is considered the unfreezable water ($1 - X_s'$) (i.e. water mass fraction which remained unfrozen even at very low temperatures, e.g. –40°C). It includes both uncrystallized free water and bound water attached to the solids matrix. The point Q is defined as T_g'', and X_s'' as the intersection of the freezing curve and the glass line by maintaining the similar curvature of freezing curve. Matveev [26] proposed a method for estimating the T_g'' and X_s'' intersection point in the state diagram of a frozen solution using the glass transition temperature of the solute.

Point R is defined as T_g''' as the glass transition of the solids matrix in the frozen sample, which is determined by DSC considering ultimate annealed conditions (Figure 24.6). This is due to the formation of the same solid matrix associated with unfreezable water and the transformation of all free water into ice although the sample contains a different level of total water before the start of DSC scanning [19]. This specific procedure needs to be followed to determine the ultimate maximal-freeze-concentration conditions (ultimate T_m', T_g''') when DSC protocols are used. First, samples (i.e. containing freezable water, 0.05–0.6 g/g sample) need to be cooled from 25 to –90°C at 5°C/min and then heated to the desired end temperature at 5–10°C/min (i.e. depending on what the temperature thermal characteristics are intended to determine, 60–300°C) (Run 1). Rahman et al. [27] experimentally showed that 10°C/min was the best for measuring the freezing point, maximal-freeze-concentration condition, and enthalpy. The freezing point and apparent maximal freeze concentration (apparent T_m', T_g''') are determined (Figure 24.6). In this practical cooling and heating step, all freezable water would be unable to form ice during cooling and all ice would not be melted during heating, since crystallization and melting are kinetic processes. In the second step, the protocol is as follows: samples (i.e. containing freezable water, 0.05–0.6 g/g sample) need to be cooled from 25°C to apparent $T_m' - 1$ (i.e. if apparent T_m' is –40°C, then annealed at –41°C) for 30 min, and samples are then again cooled to –90°C at 5°C/min and then heated to the desired end temperature at 5–10°C/min (i.e. depending on what the temperature thermal characteristics are planned to determine, 60–300°C) [20, 28]. This protocol provides the annealed maximal-freeze-concentration (annealed T_m', T_g'''). The annealed T_m' and T_g''' decreased with the increase of solids [19]. In most of the cases, the annealed T_m' and T_g''' remained constant after X_s above 0.6 g/g sample (i.e. moisture 0.4 g/g sample) [19]. This end point could be experimentally determined or T_m' and T_g''' for the sample at solids 0.6 g/g sample (or experimentally determined optimum solids) could be considered as ultimate freeze-concentration condition and used in the state diagram as shown in Figure 24.2. Al-Farsi et al. [11] observed that annealed T_m' and T_g''' increased after solids content 0.6 g/g sample, instead of decreasing as expected due to the freezing point depression with increasing solutes content. This indicated the optimum traceable condition to determine the uninterrupted ice melting, and above solids 0.6 g/g sample, the matrix would be very

viscous, and it would take much longer to crystallize all water. Table 24.2 shows the compiled ultimate T_m' and T_g''' values for different foods.

Below the region ACH, the phases present are ice and rubber (i.e. matrix of solids and unfreezable water). Below point B, the first crystallization of solute occurs; thus the HCBG region transforms into three states: ice, solution, and solute crystals. There is no free water (i.e. water able to form ice) existing on the right side of point C (T_m', end point of freezing with ultimate maximal freeze-concentration-condition), and after this point the very concentrated solution is transformed to glass–rubber transition only without freezing. The ultimate maximal-freeze-concentration condition could be achieved using optimum conditions by slow cooling and annealing of the samples as mentioned earlier. The region IRCH contains ice, rubber, and solute crystal. The point R is the T_g''' (as shown in Figure 24.2); below this point a portion of the rubber state is transformed to the glass state, and thus the region JQRI contains glass, ice, and solute crystal. The point F is the vertical line passing through point C and crossing the glass line (i.e. T_g'). The rate of cooling can shift the points B, C, R, Q, and F. Therefore, specific procedures must be used for ultimate maximal freeze concentration and freezing point as discussed earlier. More detailed effects of cooling on the shift are discussed by Rahman [20].

24.2.2 Glass Transition Line

The regions BQEV and BVLD are important in food processing and preservation, since many characteristics such as crystallization, stickiness, and collapse are observed in these regions [29, 30]. In the case of cereal proteins, Kokini et al. [31] determined the entangled polymer flow region when both G' (i.e. storage modulus) and G'' (i.e. loss modulus) decreased with the increase of temperature and showed a minimum peak. A reaction zone was defined when both G' and G'' increased from the minimum peak and started to separate from each other and then decreased again starting the softening region. All these transitions observed in the region BQEV and the lines of entangled, reaction, and softening regions could be drawn as a function of solids content in the state diagram. This could identify additional states or phases in the state diagram beyond the glass line, such as solids-melting and soluble-solids-melting lines.

A typical thermogram for a sample containing unfreezable water is shown in Figure 24.7. It shows a shift for the glass transition (marked as G) followed by an endothermic peak for solids-melting (marked as S). Line EQFS is the glass line when onset glass transition is plotted as a function of solids contents (Figure 24.2). Glass transition decreased with the increase of solids (i.e. plasticization with the increase of water). Glass line modeling is important in identifying the glass–rubber transition boundary. Considering the free volume concept and that the effect of free volume is additive, the glass transition temperature of a polymer–water system can be written as [32]:

$$T_{gm} = \frac{\varepsilon_s T_{gs} + \phi \varepsilon_w T_{gw}}{\varepsilon_s + \phi \varepsilon_w} \tag{24.2}$$

where, T_{gm}, T_{gs}, and T_{gw} are the glass transition temperatures of the mixture, dry solids, and water (°C); ϕ is the volume expansion coefficient difference of polymer and diluent; and ε_w and ε_s are the volume fractions of water and solids or polymer, respectively. The influence of water content on the glass transition temperature is commonly modeled by the Gordon–Taylor equation [33]:

$$T_{gm} = \frac{X_s T_{gs} + k_g X_w T_{gw}}{X_s + k_g X_w} \tag{24.3}$$

where k_g is the Gordon–Taylor parameter. The values of k_g are compiled in Table 24.2 for different foods. This equation is valid if the glass transition follows the line EQFS in the state diagram (i.e. maximum plasticization). If experimental data do not follow the line EQFS in Figure 24.2, the interaction deviates from the Gordon–Taylor model at low moisture (for example, line EP). In this case, Rahman [6] proposed the modified Gordon–Taylor–Rahman model as:

$$T_{gm} = \frac{X_s T_{gs} + k_c X_w T_c}{X_s + k_c X_w} \tag{24.4}$$

In the above equation, T_c is considered as critical temperature (°C) instead of T_{gw}, and it is related to $T^{iv}{}_g$ (i.e. point P, vertical line passing through C and F at X_s' and crossing glass line EP) as defined in the state diagram as shown in Figure 24.2 [27]:

$$T_c = T_g^{iv}\left(1 - X_s\right) \tag{24.5}$$

This correction is needed since the origin of Gordon–Taylor equation is now shifted from 0 to X_s'. The point $T^{iv}{}_g$ is on the same vertical line as T_g' and T_m'. The parameter, $T^{iv}{}_g$ is compiled in Table 24.2.

24.2.3 Solids Melting Line

The line LDM is the melting line, which is important when products are brought to high temperatures during processing, such as frying, baking, roasting, or extrusion cooking. In the case of multi-component mixtures, such as food, the melting peak temperature shifted with the heating rate due to the reactions between components when the heating rate is varied (i.e. total annealed time is varied). In this case, it is considered as apparent melting. Below LDM, solid and liquid phases are present, and above only the liquid phase is present. In foods, some (for example starch and gelatin) show melting phase changes from solid to liquid (i.e. above line LD); however many foods (for example bran and cellulose) do not transform from solid phase to liquid phase; instead these decompose from solids to vapor with solids residue (i.e. directly below LD to above WU). The line WU is defined as the decomposition line as material decomposes to vapor with or without solids residue. The line AD is the water boiling line below

the solids melting (line MD). This line does not intersect the y-axis at the right since boiling is difficult to observe in very concentrated solutions, where the water is strongly bound with solids. The solids-melting line LDM (i.e. loss of crystals or molecular order) is commonly modeled by the theoretical Flory–Huggins equation as [34]:

$$\frac{1}{T_{mp}} - \frac{1}{T_{ms}} = \left(\frac{R}{\Delta H_u}\right)\left(\frac{V_u}{V_w}\right)\left(\varepsilon_w + \chi\varepsilon_w^2\right) \tag{24.6}$$

where T_p and T_s are the peaks of melting temperature for the polymer (i.e. crystallized date syrup) with diluent (i.e. water), and for pure polymer (i.e. only dry solids) (K) respectively, R is the gas constant (8.314 J/g mole K), ΔH_u is the heat of fusion for repeated polymer units in the diluent (J/g), V_w is the molar volume of the diluent (m^3/g mole), V_u is the molar volume of polymer unit (m^3/g mole), ε_w is the volume fraction of the diluent, and χ is the Flory–Huggins polymer–diluent interaction parameter. Equation 24.6 was first developed independently by Flory [35, 36] and Huggins [37] from the thermodynamics of (binary) regular polymer solutions. The model was described in great detail by Flory in his famous book *Principles of Polymer Chemistry* [34]. The volume fraction of water in Equation 24.6 can be calculated from the following equation considering the volume of water and volume of solids estimated from the mass fractions and density values of water and solids [38]:

$$\varepsilon_w = \frac{\left(X_w/\rho_w\right)}{\left(X_w/\rho_w\right) + \left(X_s/\rho_s\right)} \tag{24.7}$$

where X_w is the mass fraction of water (g/g sample), ρ_w is the density of water (kg/m^3), X_s is the mass fraction of solutes content (g/g sample), and ρ_s is the density of dry solids (kg/m^3). It is assumed in Equation 24.7 that excess volume due to mixing of water and dry solids is negligible. The values of T_{ms}, $RV_u/\Delta H_u V_w$, and χ for broccoli were estimated as 178.4°C, 5.07×10^{-4}, and 0.69, respectively [10]. The values of χ were reported as 2.2 for gelatin (Rahman et al. 2010), 0.48–0.5 for starch [39], 0.0088 for artificial rice [40], and 0.0068 for date-pits [41]. The value of χ indicates the water–solids interaction during the melting process. The low value indicates the low power of the solvent (i.e. water) to interact with the solids while molecular degradation progresses within the melting process. This indicates that stiff molecules (e.g. artificial rice and date pits) show low interaction with the water molecule during the melting process. In the case of broccoli, the value of 0.69 as compared to high (i.e. 2.2) and low (i.e. 0.0068) values indicated that water moderately interacted with the solids during its melting process [10].

24.2.4 Crystal Melting Line for Soluble Solids

The line BV is the crystal-melting line and is mainly identified in the case of solution with dissolved solute(s). The right side indicates that solute crystal(s) is formed from solution and the left side indicates that crystal(s) is dissolved within the solution. Al-Farsi et al. [11] developed the crystal-melting line for date syrup and modeled the peak temperature by the Flory–Huggins equation as shown in Equation 24.6. The eutectic conditions (i.e. eutectic temperature and eutectic solids content, T_u and X_{su}) were determined from the intersection point of the crystals-melting curve as modeled by the Flory–Huggins equation and the freezing curve as modeled by the Chen [25] model. The T_{sp} (i.e. soluble solids melting) of pure crystal (i.e. only dry solids) was estimated as 84.0°C (point f in Figure 24.5), $[(R/\Delta H_u)/(V_u/V_w)]$ was estimated as 3.583×10^{-8}, and the Flory–Huggins polymer–diluent interaction parameter, χ, was estimated as 5.438×10^4, respectively. The eutectic point of date syrup was estimated from Figure 24.5 as T_u equal to –10.2°C (i.e. b in Figure 24.5) and eutectic solutes content 0.39 g/g sample. Similarly, the eutectic points of orange and bitter gourd juices were observed as –10.0°C [42] and –37.5°C, respectively [43]. However, the eutectic temperatures of α-D-glucose and β-D-glucose were shown to be –4.9°C (eutectic solutes 0.31 g/g sample) and –21.0°C (i.e. eutectic solutes 0.62 g/g) [44].

24.2.5 BET-Monolayer Line

Rahman [5] plotted the BET-monolayer value as the LNO line in the state diagram as shown in Figure 24.2. It intersects at point N with the glass line EQS, which shows that at least in one location (point N) glass and water activity concepts provide the same stability criterion. This approach forms more micro-regions, which could give different stability in the state diagram. Suresh et al. [10] developed a linear regression equation as:

$$T_b = 1003.2\,X_{bs} - 903.6 \tag{24.8}$$

where T_b is the temperature (°C) at BET-monolayer moisture, and X_{bs} is the solids content (g/100 g sample) at the BET-monolayer, respectively. This equation shows that the point L (Figure 24.2) is 99.6°C when solids content is 1. Equation 24.8 is used to develop the BET-monolayer line in the state diagram [5, 45] (i.e. line LNO). Similarly, Rahman and Al-Saidi, [9] developed an equation for ripe banana:

$$T_b = 2198.2X_{bs} - 2020.9 \tag{24.9}$$

The above equation shows that the BET-monolayer approached zero at 178.2°C (i.e. X_{bs} equal to 1). Rahman and Al-Saidi [9] defined the isokinetic temperature (T_{is}) (i.e. the temperature at which all reactions of the series proceeded at the same rate) from the linear plot of the slope of enthalpies (ΔH) and entropies (ΔS) according to Exner [46]. At specific moistures (i.e. M_w: 0.1, 0.2, 0.3, and 0.4 g/g dry-solids), the enthalpies ($\Delta H/R$) and entropies ($\Delta S/R$) were estimated from the slopes and intercepts of the linear plots (i.e. ln a_w *versus* 1/T), according to the following Equation 24.10 [47]:

$$\ln a_w = \frac{\Delta H}{RT} - \frac{\Delta S}{R} \tag{24.10}$$

Where a_w is the water activity, and ΔH and ΔS are enthalpy (kJ/kg) and entropy (kJ/kg), respectively. The isokinetic temperature was then estimated from the slope of the plot of enthalpies ($\Delta H/R$) and entropies ($\Delta S/R$) [46, 47]. The isokinetic temperature was estimated as 192.4°C for banana [9], which is close to the T_{bs} (i.e. 178.2°C). In the case of mango, the isokinetic temperature was estimated 228.0 and 190.0°C from desorption and adsorption isotherms [47]. Table 24.3 summarizes the states or phases in different micro-regions.

24.3 APPLICATIONS OF MACRO-REGION AND MICRO-REGION IN FOOD PROCESSING

24.3.1 Stability and Chemical Reaction

It is important to determine the applications of the macro- and micro-regions for stability or reactivity within different phase or state boundaries [5, 8]. Rahman and Al-Saidi [9] tested the validity of the macro-micro-region concept in the state diagram. They considered the browning of raw and freeze-dried banana slices as a function of moisture content and storage temperature (i.e. at different micro-regions). The reaction was modeled by first-order chemical reaction, and the variation of the reaction rate constant was analyzed based on the glass transition, water activity, and macro/micro-region concepts. The rate constants are plotted as a function of micro-region (Figure 24.8), and it shows an increasing trend, which supports the proposed concept (i.e. reaction rate increases as the micro-region number increases). However, there are variations of rate constant at each micro-region, which is expected as the moisture and temperature also varied in each micro-region.

TABLE 24.3
Phase/State and Other Characteristics of Foods in the Different Micro-Regions

Micro-Region	Phase/State and Other Characteristics
1	Solids, glass, strongly bound water
2	Solids, glass, unfreezable water
3	Solids, fast-cooled glass, unfreezable water, ice
4	Solids, slow-cooled glass-T_g', unfreezable water, ice
5	Solids, slow-cooled glass-T_g'', unfreezable water, ice
6	Solids, slow-cooled glass-T_g''', unfreezable water, ice
7	Solids, slow-cooled ice-T_m', unfreezable water
8	Solids, slow-cooled ice, unfreezable water, solute crystal-T_u
9	Solids, slow-cooled ice, unfreezable water, solution (dissolved solids and freezable water)
10	Solids, rubbery, bound water, unfreezable water
11	Solids, rubbery-T_g', unfreezable water
11	Solids, rubbery-T_g^{iv}, unfreezable water
12	Solids, solution (dissolved solids, freezable water, unfreezable water)
13	Solids, solution (dissolved solids, freezable water, unfreezable water), vapor

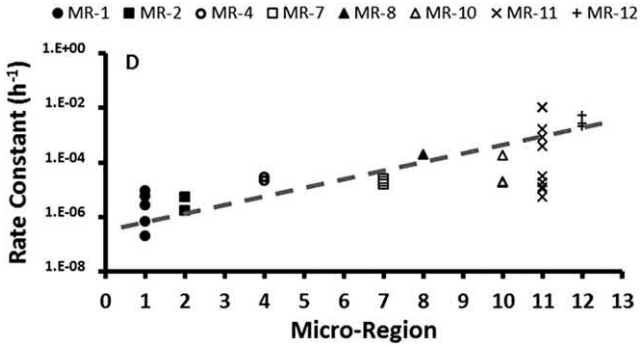

FIGURE 24.8 Plot of log k as a function of micro-region. (From Rahman and Al-Saidi [9].)

Rahman and Al-Saidi [9] pointed out that this plot could not solve the problem completely, but it would help in developing generic rules in each micro-region (i.e. smaller range of moisture and temperature within the same phase or state) rather than macro-region (i.e. wider range of moisture and temperature having different phases and states).

24.3.2 Drying

The glass–rubber transition is central for the successful use of the freezing and drying process as these are visualized in the state diagram [3, 4, 48]. In addition, the final state of the products could be located to determine their stability. Figure 24.9 shows the dynamics of the drying process in the state diagram. Point a in Figure 24.9 represents fresh foods with a high moisture content at room temperature before drying. The air-drying path is shown by the paths abc, abcd, or abcdg. The sample temperature is increased to wet bulb temperature during the progress of drying and solids content is increased due to loss of moisture. At the end of drying, sample is reached at a point after cooling, i.e. c or d as a rubbery state or g as a glassy state. After cooling the dried sample reaches the glassy state at point f if it follows the path of df, and it becomes stable. Alternatively, it could reach point e as unstable rubbery

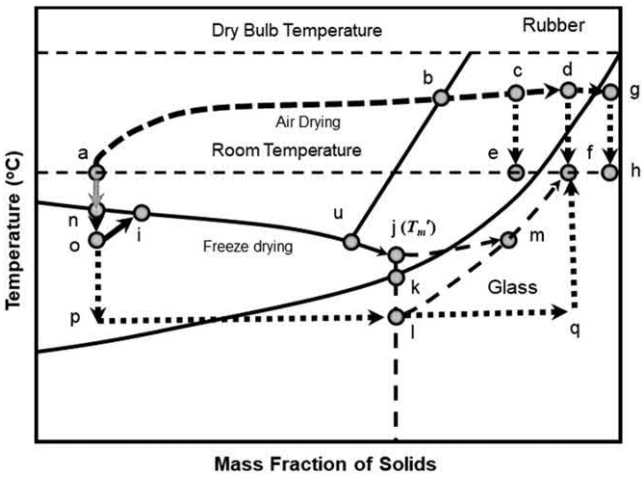

FIGURE 24.9 Paths of air- and freeze-drying processes in the state diagram. (From Rahman [3, 4].)

state, and the product is unstable. If drying ends at point g then it reaches the glassy state even during the drying process and cooling moves the sample even much lower than the glassy state (i.e. point h).

Collapse or shrinkage occurs in the sample since the air-drying process occurs through the rubbery state. The extent of collapse depends on the air-drying temperature and exposure time in the rubbery state. For example, in the cabinet dryer, the process takes in the order of days, while spray-drying may take in the order of minutes. Thus, in spray drying the quality deterioration is usually low due to the short exposure time. In addition, the time from b to c, or b or d, or b to g is also important since a number of deteriorative changes, such as crystallization, collapse, stickiness, and deteriorative reactions, could occur in the rubbery state. When the product reaches point b, soluble solute(s) is transformed to crystals (for example, sucrose). In addition to time and temperature, pressure could play a significant role, for example, at the low pressure used in vacuum and freeze-drying processes, gases and water vapor could form bubbles inside the product.

In the case of freeze-drying, product is first cooled from point a to n and ice crystal is formed (i.e. ice nucleation). The freezing process continues and follows the path iuj while the amount of ice is increasing due to the formation of ice, causing freeze-concentration in the liquid aqueous phase (if the freezing process is relatively slow). If the freezing process is very fast, then the sample is moved from a to p. After the freezing process, the pressure on the sample is reduced below 612 Pa so that the sublimation process can start rather than melting of ice. Sublimation starts at point p if it is the freeze-drying temperature, and the sample moves from p to l (i.e. end of sublimation), and at the end of freeze-drying, it reaches point q. In this case freeze-drying occurs below the maximal freeze concentration and maximum ice formation (i.e. T_m' or T_g'''), and minimal collapse could occur when ice sublimates. This is due to the glassy matrix around pores (i.e. formed due to ice sublimation) which would be able to support its own weight against flow under gravitational stress and so maintains its porosity (i.e. less collapse) [48].

In the case of slow cooling the sample reached point l from j (i.e. freeze-drying temperature) and sublimation continued. It is important to mention that point p to l is the sublimation process and point l to q is the vacuum drying (i.e. desorption) of unfreezable water at low pressure, since after point l there is no ice to sublimate. The characteristics of the final freeze-dried materials depend on the freeze-drying temperature (i.e. below or close to T_m' or T_g''') and the time to reach from point a to f. If freeze-drying occurs at T_m' or a higher temperature, then the sample will follow j to m. If the freeze-drying temperature continuously increases above T_m' or T_g''', then the sample will follow the path jmf or lmf. It is important to mention that the collapse temperature usually occurs above T_g'''. For example, microscopic observation showed that the onset collapse temperature of protein and sugar mixtures as measured was always higher than 1°C at a protein/sugar ratio 10/90, whereas the difference increased to 10°C for a mixture ratio 65/35 [49]. Another point that needs to be considered is that freeze-drying below the gassy state is very slow and causes significant operating cost. An increase of only 1°C in product temperature during freeze-drying was found to shorten process time up to 13% [50]. In this case, a state diagram could be used to determine or optimize the freeze-drying process by keeping the sample just below or close to the glass line (i.e. path jmf or lmf) [4].

A step rise in the freeze-drying temperature can be used to control the freeze-drying process using a state diagram [51], and it could lead to an optimum strategy for an instant food powder with desired attributes. Three strategies of freeze-drying (i.e. progressing rise in temperature, and step rise in temperature just above and below the glass line) are shown in Figure 24.10. The initial stage of freeze-drying is performed in the micro-region 9, when frozen water was sublimated, and the drying temperature needs to be below the collapse temperature. This preserves the supra-molecular microstructure. When food passes beyond the maximal freeze concentration condition (i.e. T_m'), unfreezable water is removed by desorption at low pressure (i.e. in micro-region 11). In this drying stage, the temperature should be gradually (or step-wise) increased by following the glass transition line (i.e. just above EQ) in order to accelerate dehydration (Figure 24.2). In this way, the matrix is maintained in a viscosity range for which water diffusion is favored and crystal growth is still slow. Avoiding sucrose crystallization during the desorption step (i.e. micro-region 11) of the unfrozen water in the concentrated matrix enhanced sweetness perception since the amorphous sucrose coating dissolved faster in an aqueous solution as compared to crystalline one. Consequently, this approach of the smart use of the state diagram could guide the development of reduced-sugar food products [52].

24.3.3 Baking

The four stages of the baking process can be visualized and their structural characteristics could be explained using a

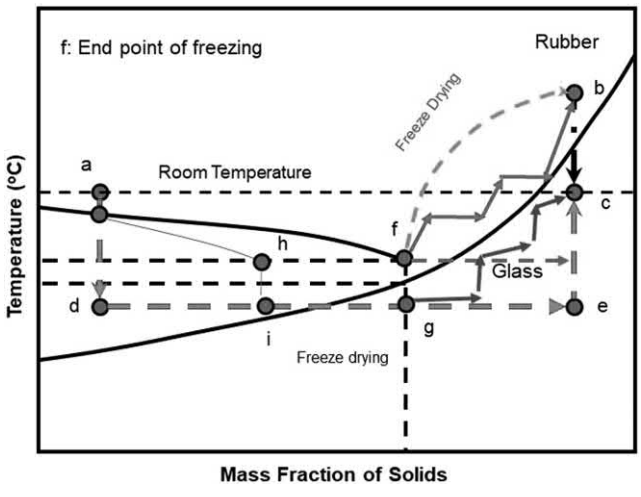

FIGURE 24.10 Freezing-drying strategies with progressive rise to the final freeze-drying temperature (line fb), drying just above the glass line (point f to b with step rise in drying temperature), and drying just below the glass line (point f to c with step rise in drying temperature).

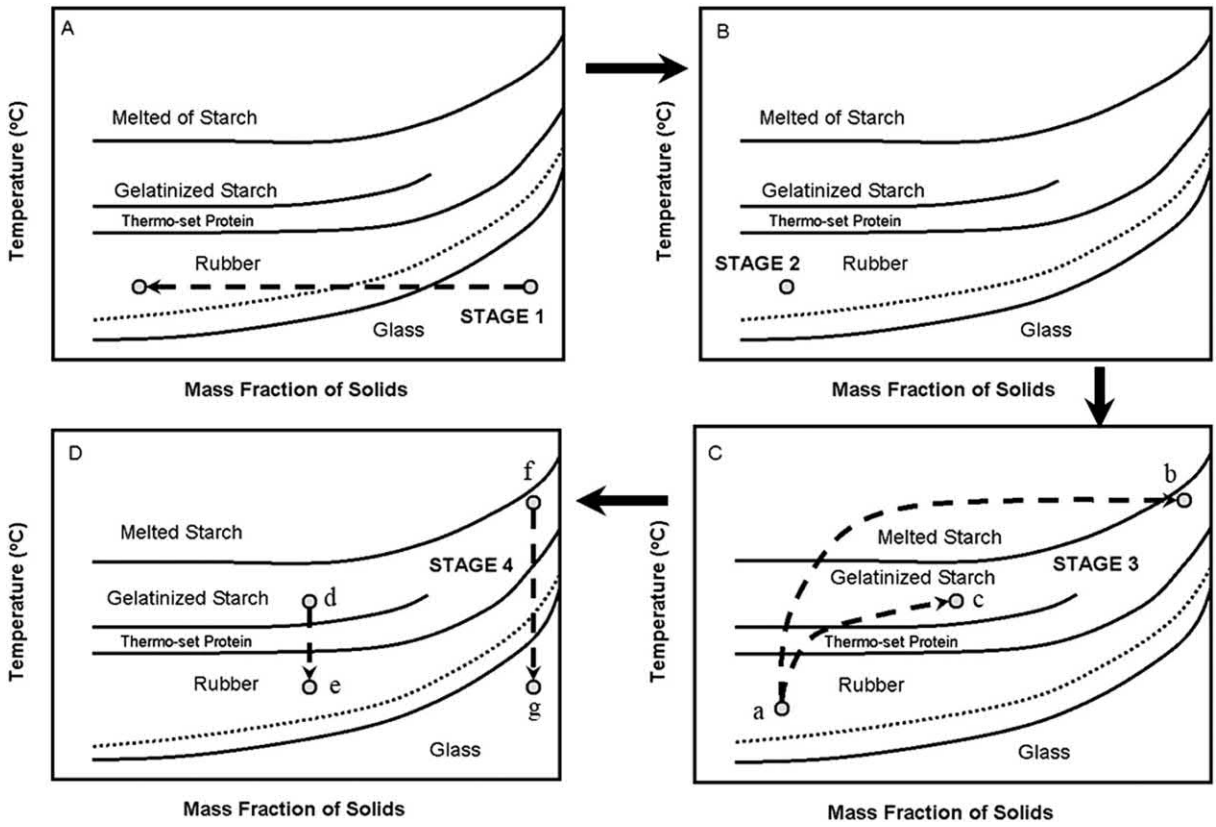

FIGURE 24.11 Paths of the baking process in the state diagram, A: STAGE 1, B: STAGE 2, C: STAGE 3, D: STAGE 4. (From Rahman [4].)

state diagram [3, 4, 53]. Figure 24.11 shows the glass lines of starch and gluten protein, the gelatinized line, the thermosetting line of protein, and the solids-melting line of starch. The glass transition range of proteins appeared to be at slightly lower temperatures than for wheat starch. The drying ingredient mixture is at the state marked STAGE 1 (Figure 24.11A). The second step is associated with a water–flour mixing process until the final water content reaches a level so that it can hold the expanded bubbles (for example, moisture 0.78 g/g sample) (i.e. STAGE 2, Figure 24.11B). This stage is the beginning of kneading and continues until the flour particles are fully hydrated. Flour particle hydration is a very important stage because the wheat gluten proteins pass their glassy state, indicating an increase in protein molecular chain mobility. Protein mobility alone is not sufficient for proteins to interact with other components to form a continuous structure. Hydration also needs to occur in starch, which causes swelling of starch granules and transformation of amorphous molecular organizations above glass transition. In this stage, simultaneous hydration and mechanical kneading induce interactions between proteins and starch, and lead to a rubbery state by the continuous interlinked viscoelastic structure of dough. In this stage fermentation continues, and rubbery dough can hold the gas bubbles like a balloon without collapsing.

In the third stage (STAGE 3, Figure 24.11C), the baking process continues, and dry crust is formed through the path a to b and crumb follows through path a to c. The dough surface is exposed to high temperatures (i.e. 200°C) and substantially dehydrated with irreversible reactions, such as dextrinization, caramelization, non-enzymatic browning, and thermal degradation. These reactions result in the formation of colored and aromatic substances, which characterize fresh bread.

The crust restricts the water loss from dough and forms bread crumbs by gelatinization of the starch and gluten network as a thermosetting rubbery state. The final stage (STAGE 4, Figure 24.11D) is obtained after baked product is cooled (i.e. crumbs d to e and crust f to g) and the crumb (e.g. moisture: 0.35–0.40 g/g sample) forms rubbery and the crust (e.g. moisture: 0.03–0.07 g/g sample) forms glassy states. Consequently, structural hardening occurs and is responsible for crust crispness, while the smooth texture of crumb is due to the rubbery state.

24.3.3 Enzyme Stability as Affected by Crystallization

The enzyme stability was analyzed in a frozen matrix (marked as A in Figure 24.12) and a dehydrated matrix (marked as B in Figure 24.12) in relation to the sugar (dried systems) or water (frozen systems) crystallization [54]. Honey (T_g': –46°C) and trehalose (T_g': –44°C) as solids were considered, and these are stored as frozen systems at –26°C, while the dehydrated systems were stored at 55°C. It was observed that the amount of ice formed also affected the stability in addition to T_g'''. The

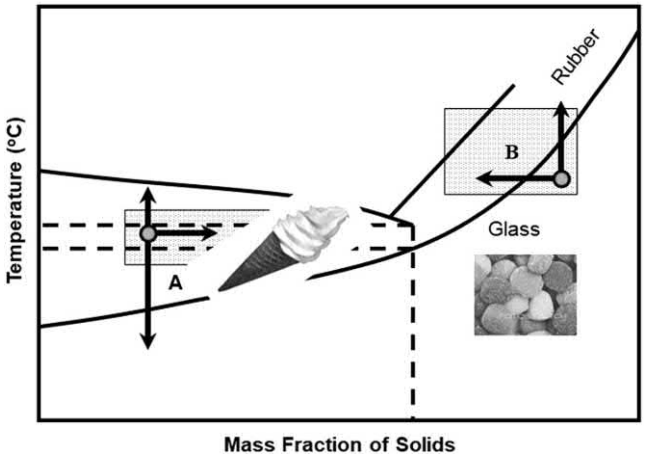

FIGURE 24.12 Crystallization or re-crystallization process in the samples containing freezable and unfreezable water, A: frozen state, B: dried state.

amount of ice may surround the reacting aqueous phases, thus reducing the reactivity of the system. It was also observed that the salts could have positive or negative effects (depending on the types of matrix) both in frozen (region A) and dried systems (region B) although the addition of salts lowered the T_g or T_g''' values. The negative effect of salt due to crystallization could be explained by the change in pH and/or ionic strength. Therefore, a state diagram could be the starting point for analyzing the stability of biomolecules with complementary knowledge of molecular interactions within the matrix [4, 54].

24.3.4 Rice Quality during Drying and Tempering

The drying process can be visualized as a state diagram (Figure 24.13) [4, 55]. The drying process of rice could start from point 1 (either glassy or rubbery depending on the moisture contents) and reach point 2. The drying process occurs in the rubbery state. However, a gradient (moisture or temperature) could exist within the kernel. The rice kernel could have a rubbery core and glassy surface based on the drying

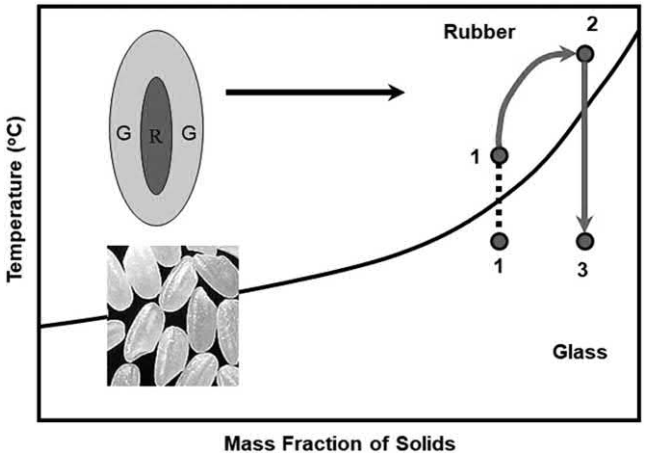

FIGURE 24.13 Air-drying path of rice in the state diagram. (From Rahman [4].)

conditions used, and this can create a differential thermal expansion coefficient. This process may create stresses within the kernel, and if greater than the kernel's tolerated limit, this stress could cause the kernel to fissure (i.e. quality loss) [55, 56]. After the completion of drying, the rice kernel reaches point 3 during cooling. This mechanical stress could be avoided or reduced if all regions in the rice are maintained at the rubbery state. This could be achieved using a drying temperature much higher than the glass line and keeping higher relative humidity of the drying air (i.e. ability to keep the surface rubbery rather glassy). This approach could reduce the fissure. Overall slower drying did not cause sufficient moisture gradients. Alternatively, we could run the complete drying process in the glass state (i.e. path 1 to 3); however drying rates from path 1 to 2 would be very fast as compared to path 1 to 3, due to the very high water diffusivity in the rubbery state (i.e. path 1 to 2). The consequence is the high processing cost for longer operation.

Another alternative is to use an annealing step. Cnossen et al. [56] proposed two options (one in the rubbery state, i.e. point A, and another one in the glassy state, i.e. point B) for tempering as shown in Figure 24.14. Cnossen et al. [57]) showed experimentally that drying and tempering at location A above glass transition (i.e. 60°C) tempering reduced the number of fissured rice kernels. However, drying at location B below glass transition (i.e. 40°C) did not require tempering, and even tempering at 40°C did not decrease fissured kernels further. This example indicates that a state diagram could guide the identification of the location of tempering in order to avoid rice fissure.

24.4 EMPIRICAL APPROACH TO COMBINE WATER ACTIVITY AND GLASS TRANSITION CONCEPTS

An attempt was made to explain the browning of banana as a function of water content and storage temperature by combining the glass transition and water activity concepts [9]. At a specific moisture content, the reaction rate constant showed a shift (i.e. sample containing freezable water) or change in slope (i.e. sample containing unfreezable water), when plotted as a function of temperature (Figure 24.15). However, it was difficult to find any validity above or below glass transition (or BET-monolayer) when all data points (i.e. all moisture and temperature) were plotted (i.e. rate constant with moisture or temperature). An Arrhenius plot at moisture content 0.04 g/g sample showed two linear regions (i.e. below and above critical temperature 45°C) with activation energy values of 105.3 and 25.1 kJ/mol, respectively. Two dimensionless terms, X_w/X_{wb} and T/T_g were defined based on water activity and glass transition. Figure 24.15 shows the plot of rate constant (s^{-1}) as a function of X_w/X_{wb} and T/T_g (i.e. for samples containing unfreezable water) or T/T_g''' (i.e. for samples containing freezable water), respectively. The scattered points of these plots showed that there was no pattern below or above the critical limits of X_w/X_{wb} =1 and T/T_g or T/T_g''' =1, when both moisture

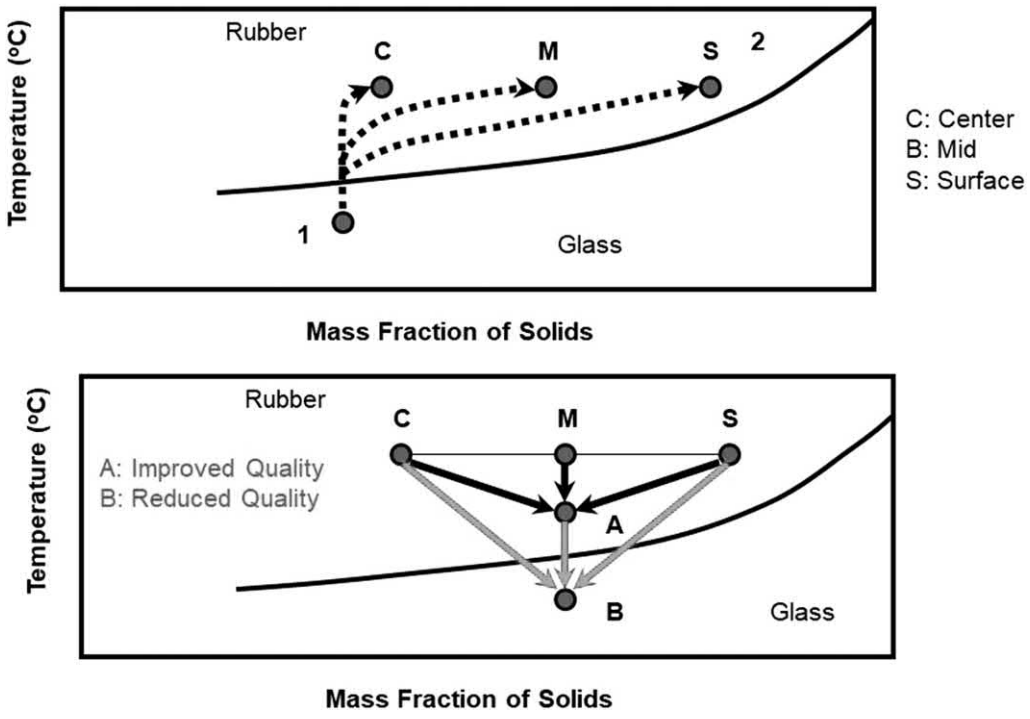

FIGURE 24.14 Rice-tempering strategy using state diagram. (From Rahman [4].)

and temperature changed in combination rather keeping moisture content fixed and only temperature varying or *vice versa*. This indicated that the combination of water and temperature interacted differently at each point, and other structural and physicochemical factors also played a role instead of only glass–rubber or BET-monolayer concepts based on water content.

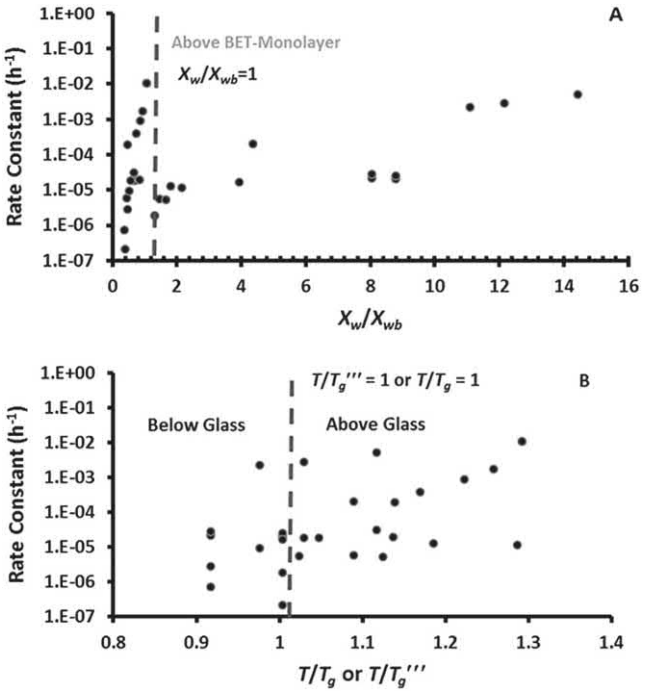

FIGURE 24.15 A: plot of log k as a function of X_w/X_{wb}, B: plot of log k as a function of T/T_g or T/T_g'''. (From Rahman and Al-Saidi [9].)

It was observed that the rate constant showed much higher correlation with T/T_g as compared to X_w/X_{wb} when the whole spectrum of moisture content and temperature was considered (Figure 24.15). This is expected since glass transition could consider the effects of both temperature and moisture contents to some extent, but water activity could handle mainly the effect of moisture (i.e. minimal effect of isotherm with temperature). Rahman and Al-Saidi [9] developed an empirical correlation as ($p < 0.001$ and $r^2 = 0.631$):

$$\ln k = -30.874 + 0.417\left(\frac{X_w}{X_{wb}}\right) + 18.123\left(\frac{T}{T_g}\right) \quad (24.11)$$

where X_{wb} is the BET-monolayer in weight basis (g/g sample), T_g is considered if the sample contains unfreezable water, otherwise T_g''' needs to be used if the sample contains freezable water, and temperature used in the above equation is in K. The individual r^2 for using only terms 1 or 2 was shown to be 0.144 and 0.295, respectively, while the combination provided $r^2 = 0.631$. Figure 24.16 shows a plot of the predicted line with the experimental points. Therefore, the prediction could be further improved if other hurdles, such as pH and compositions, are included in the model. These variabilities indicated that other factors, such as pH, reduction potential, and structure forming or breaking in the matrix affected the reaction rate constant. However, this model could not be considered as generic and unified until other factors, such as different types of reaction, varied matrices, and other hurdles, are included in the model.

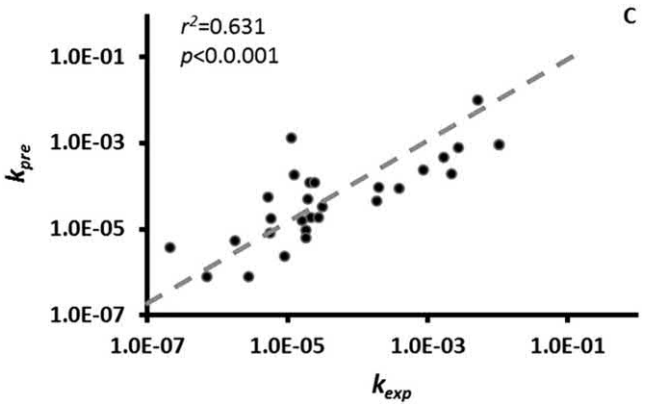

FIGURE 24.16 Plot of predicted (k_{pre}) and measured (k_{exp}) rate constants. (From Rahman and Al-Saidi [9].)

24.5 CONCLUSION

The micro-region state diagram could be a powerful tool in determining food stability during processing and their stability during storage. Although an initial state diagram was developed considering only the freezing curve, glass line, and maximal-freeze-concentration condition, currently different state or phase lines are being included for example, the BET-monolayer line, solids-melting line, soluble solids crystal-melting line, and eutectic point. Currently the micro-region state diagram could be very useful for determining different state or phase boundaries of foods when these are exposed to different temperatures and moisture content.

25 Concentration Using Membranes

Shyam S. Sablani

CONTENTS

25.1 INTRODUCTION

Separation processes based on membrane utilize semipermeable membranes of the appropriate physical and chemical nature to separate molecules primarily on the basis of size and to a lesser extent on shape and chemical composition [1]. In these processes, the membrane acts as a selective barrier, enriching certain components in a feed stream and depleting it of others. Reid and Breton [2] who used cellulose acetate membranes for desalination of water made the first real breakthrough. Shortly thereafter, Loeb and Sourirajan [3, 4] developed the casting procedure for asymmetric cellulose acetate membranes. The most attractive feature of the process is its simplicity. It involves only bulk movement of fluids using mechanical energy (i.e., pumping). Membrane concentration processes have several advantages over conventional concentration processes, i.e., evaporation. Undesirable heat-related changes such as color, aroma, and viscosity characteristics are avoided because membrane processes can be operated at room temperature. Unlike evaporation or freeze concentration, membrane separation does not involve a phase change for separation; thereby energy is used more efficiently.

Membrane processing in the food industry has been applied mainly for the clarification of fruit juices using microfiltration and ultrafiltration, and for concentration of fruit juices and dairy products. Clarified fruit juices may have better quality and stability, while concentrated beverages are desirable for transport and storage. Filtration rate and product quality are influenced by pretreatment of product, selection of membrane system, and operating parameters. This chapter presents the principle of membrane separation processes, membrane materials and modules, performance measurement of the membrane system, and application of membranes for selected food groups.

25.2 PRINCIPLES OF MEMBRANE SEPARATION

Membrane processes include a wide range of unit operations from sieving to reverse osmosis. Filtration of coarse particles, i.e., in the micron range, is carried out by conventional dead-end filtration where particles are retained by the filter and

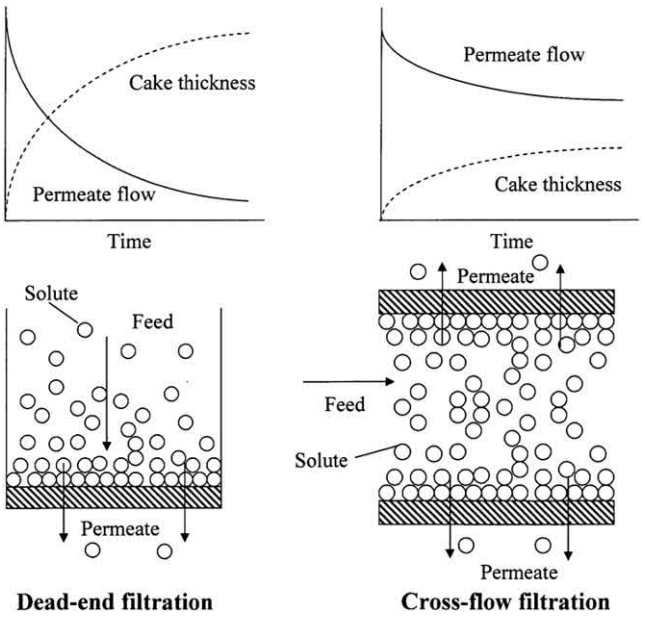

FIGURE 25.1 Dead-end and cross-flow filtration. (a) Dead-end filtration. (b) Gas-flow filtration. (Adapted from Mannapperuma [5].)

later form a cake layer, resulting in increased resistance to filtration. This requires frequent cleaning and replacement of filters. The most common membrane configuration used in the industrial setup is cross-flow membrane filtration. It is a continuous type and used to separate particles, which are about 10 μm to solute molecules that are a few angstroms [5]. In cross-flow membrane separation, the bulk phase is forced to flow along the membrane surface using external pressure. The permeate (less particle concentration) is collected on the low-pressure side of the membrane, while on the high-pressure side the concentrate sweeps the retained particles so that the cake layer remains relatively thin and the resistance to filtration remains low (Figure 25.1). The flow of the liquid through the membrane is driven by the hydraulic pressure gradient. while flow of the solute through membrane is by diffusion driven by concentration gradient [5].

The membrane filtration is divided into four narrower ranges based on particle size: microfiltration (MF), ultrafiltration (UF), nanofiltration (NF), and reverse osmosis (RO) (Table 25.1). The size of particles retained in these processes range from 0.1 to 10 μm (microfiltration), 1000 to 500,000 molecular weight cut-off (ultrafiltration), and 100 to 1000 molecular weight cut-off (nanofiltration). The reverse osmosis membranes can retain the smallest solute molecules, such as sodium chloride, and these are classified by percentages rejection of sodium chloride in an aqueous solution under specified conditions and ranges from 95% to 99.5%. The operating pressure ranges are 10 to 50 psi (microfiltration), 20 to 200 psi (ultrafiltration), 100 to 500 psi (nanofiltration), and 200 to 1500 psi (reverse osmosis). Mechanisms of membrane transport proposed are sieve mechanism, hydrogen-bonding mechanisms, solution-diffusion mechanism, and preferential sorption-capillary flow mechanism [1].

25.3 MEMBRANE MODULES

Materials are used for the manufacturing of membranes including sintered metals, ceramics, and polymers (Table 25.2). The membrane structure varies in its chemical nature, microcrystalline structure, pore size and pore size distribution, and degree of asymmetry. Two simple parameters, membrane permeate flux and solute rejection, are used to describe the characteristics of membranes. Since the properties of membrane material can be influenced by environmental conditions and time, secondary properties such as resistance to compaction, temperature and chemical stability, and resistance to microbial attack are also important. Additional requirements for food processing are good tolerance of cleaning and disinfecting solutions, and lack of toxicity of the contact materials [1].

Membranes are assembled as modules that are easily integrated into systems containing hydraulic components. The modules are designed to contain a large membrane area in a small volume, to withstand the pressures required during separation, and cross-flow velocities required to maintain

TABLE 25.1
Membrane Filtration Range

Filtration Spectrum	Diameter of Pores in Membrane (Micron)	Molecular Weight (of Solute)	Filtrate
Microfiltration	0.05–5.0	> 1,000,000	Latex, blood, paint pigment, indigo dye, yeast, bacteria, plant gums, amylopectin
Ultrafiltration	0.005–0.1	4000–10,000	Colloidal silica, virus, enzymes, protein, gelatin, amylose
Nanofiltration	0.0005–0.01	100–5000	Synthetic dye, antibiotics, colorant, amino acids, sugars
Reverse osmosis	0.0001–0.001	<800	Atoms, metal ions, fragrance, flavors, salts

a clean membrane surface [5]. The most common module configurations are flat plate, tubular, hollow fiber, and spiral wound (Figure 25.2). Each design has its own advantages and disadvantages.

In flat plate modules, two flat sheets are separated by a support plate that also contains the permeate channels. These membrane sandwiches are separated by a spacer, which also has feed-flow channels. Alternate layers of membrane sandwiches and spacers are assembled and held together by bolts. Advantages of such a system are (i) fairly low holdup and moderately high packing density, (ii) easy membrane replacement, (iii) flexible with regard to membrane usage, (iv) simple to increase the capacity, and (iv) the module can withstand high pressures. The main disadvantages are the system is susceptible to fouling by suspended particles and high initial capital cost. Tubular modules consist of membrane cast inside a porous support tube, typically 6 to 25 mm in diameter. Several such tubes are housed within one pressure vessel in a shell and tube arrangement. Advantages of tubular modules include (i) high turbulence, (ii) ability to handle suspended particles of 1 to 1.5 mm; and (iii) easy cleaning. The major disadvantages are low surface area to volume and high energy costs for pumping.

Hollow fiber modules consist of hollow fibers typically 0.5 to 3 mm in diameter sealed into a plastic header and assembled in permeate castings. The feed passes through the central bore and permeate collects in the outer casing. These can accommodate moderate levels of suspended particles and can withstand low pressures. Hollow fine fiber modules are made with strands of fine fiber about 50 to 100 μm in diameter. A bundle of fibers is formed into a U-shape and the ends are formed into a single header, and U bundle is placed in a tube. The feed liquid is outside the fibers while the permeate flows into the fibers. Some advantages of this configuration are (i) compact, very high packing density; (ii) relatively low holdup; and (iii) high resistance to compression hence it can withstand high pressures. Some disadvantages are (i) extremely susceptible to fouling by suspended particles, (ii) difficult to operate in sanitary mode and to clean, and (iii) individual membrane elements (i.e., fibers) cannot be replaced when damaged. Spiral wound modules utilize flat sheet membranes. Two membrane sheets are sandwiched with a permeate spacer between them and three edges are sealed. The fourth edge is connected to a central perforated tube. A feed channel spacer is placed on top of one layer, and the membrane-screen composite is rolled into a spiral configuration around the central collection tube. The module is placed inside the tubular pressure vessel. Feed flows longitudinally in the feed channel, while permeate flows between the membrane sandwich and spirally around to the permeate collection tube [1]. The advantages of such systems are (i) relatively high packing density, (ii) low cost per unit membrane area, (iii) easy replacement of modules from the pressure vessels, and (iv) low energy consumption. Some disadvantages are difficulty in cleaning when fouled with large amount of suspended matter and prefiltration is needed. The selection of module configuration and membrane material depends on the feed type and economics.

25.4 PERFORMANCE OF MEMBRANE SEPARATION SYSTEMS

The performance of membrane separation systems is calculated in terms of permeate flux and solute rejection. Permeate flux is defined as the volume of permeate produced in a unit time period through a unit area of membrane:

$$\text{Permeate Flux} = \frac{\text{Permeate volume}}{\text{Membrane area} \times \text{Time}}$$

It is measured as liters per square meter per hour. It indicates the ability of the module to produce volumes of filtrate in a given time. Solute rejection is defined as the solute retained by the membrane as a fraction of the solute in the original feed stream and it is expressed as

$$\text{Solute rejection} = \left[1 - \frac{\text{Solute concentration in permeate}}{\text{Solute concentration in feed}}\right] \times 100$$

Solute rejection indicates the ability of a membrane to produce a degree of purity of permeate with respect to the solute concentration. The major objective in the design and selection

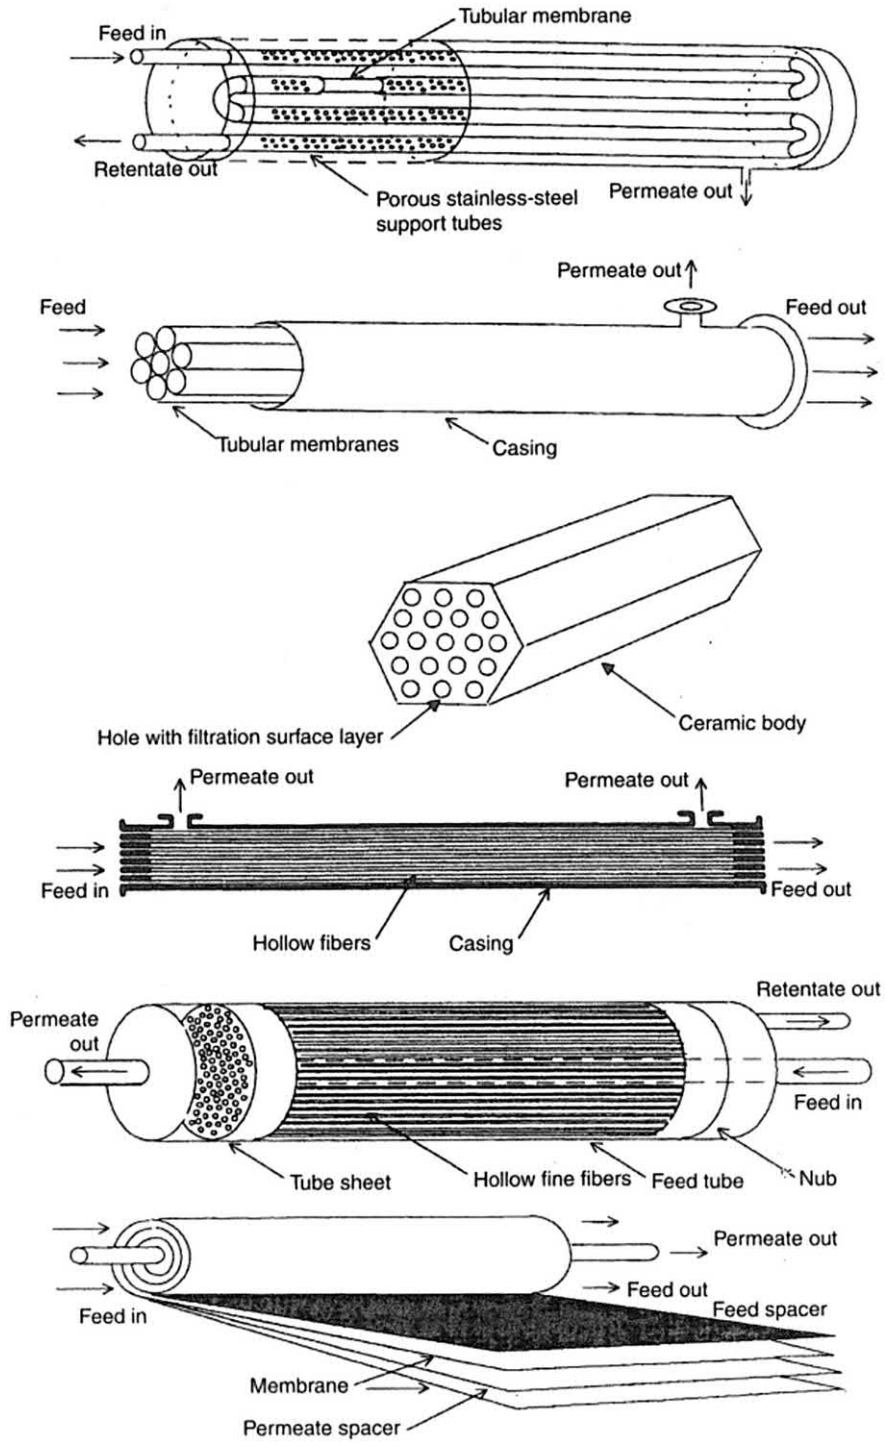

FIGURE 25.2 Membrane modules. (Adapted from Mannapperuma [5].)

of a membrane module for a given feed is to maximize permeate flux and solute rejection.

Permeate flux and solute rejection depends on operating conditions during the filtration process (Figure 25.3). Permeate flux increases with feed pressure, but the osmotic pressure at the membrane surface also increases due to the concentration polarization of the solute. There is a moderate increase in solute rejection with the increase in feed pressure. The feed temperature increases the permeate flux due to decrease in viscosity of feed and change in membrane structure. The concentration of solute in the feed decreases the permeate flux due to the increase in osmotic pressure. The solute rejection also decreases due to the increase in solute concentration in the feed. The increasing cross-flow velocity of feed increases the permeate flux due to the enhanced mass transfer coefficient, which increases with the increase in cross-flow velocity. The solute rejection increases with the increase in velocity and is similar to its variation with pressure.

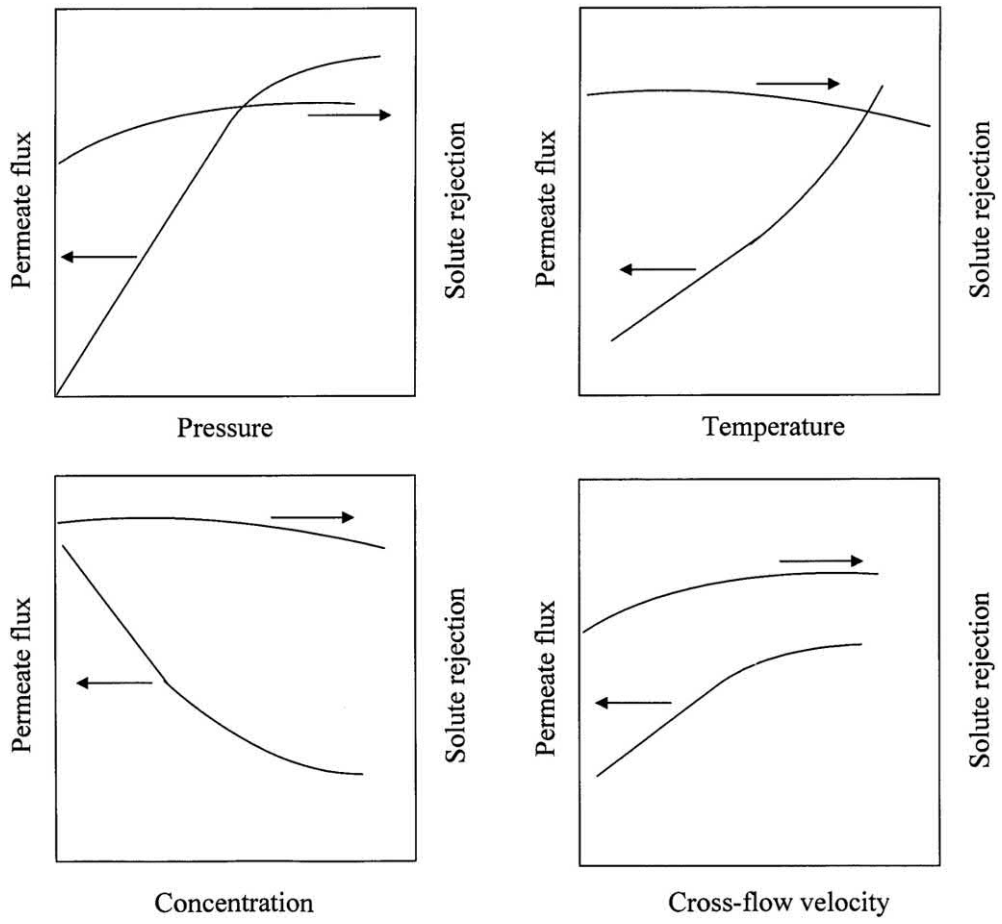

FIGURE 25.3 Performance characteristics of reverse osmosis. (Adapted from Mannapperuma [5].)

25.5 APPLICATIONS IN THE FOOD INDUSTRY

In recent years, the application of membranes in the food industry has increased tremendously. The application ranges from the use of microfiltration to reverse osmosis membranes. In terms of products, it includes fruit juices, dairy, wine and brewery, and fats and oils.

25.5.1 Fruit Juices

25.5.1.1 Clarification

The main application of membrane technology to the fruit juice industry has been for clarification [6]. UF and MF allow the combination of fining and filtration to clarify fruit juices such as apple, pear, cranberry, grape, and citrus (Table 25.3). The main advantages of using membrane technology in the fruit juice industry could be savings in enzymes; short processing time; no addition/removal of fining agents (diatomaceous earth, gelatin, bentonite) required; no problems with wastewater due to fining agents; no over- or underfining, which can result in haze formation; energy savings; no clouding of concentrate; and simple cleaning-in-place. Though juices produced by membrane filtration and traditional methods have mostly been shown to have similar properties, some differences have also been noted. Rao et al. [7] found the retention of odor-active volatile in UF apple juice was intermediate to traditional plate and frame filtration and vacuum drum filtration. Plate and frame filtration gave the highest retention. Rwabahizi and Wrolstad [8] found that strawberry juice clarified through a hollow fiber membrane had an average of 55% anthocyanin loss compared with 17% loss by conventional filtration. Drake and Nelson [9] reported that the UF apple juice had lower turbidity, 5% higher soluble solids, and less color than the traditionally clarified juice.

Pretreatments of fruit juices are important to obtain higher flux and better quality of clarified juice. Depectinization is needed to achieve high flux and concentration factors in membrane clarification processes. Polygalacturonase treatment has been found to decrease the size of granule particles in apple juice as well as to remove their web-like aspect [10]. Reduction in the size of particles and the subsequent decrease in viscosity could improve flux. Depectinization is therefore needed to achieve high flux and concentration factors in membrane clarification processes [6]. Prefiltration and decantation reduce the particulate matter in a juice, which improves flux and allows higher concentration to be achieved. Wucherpfennig et al. [11] reported that the high-molecular weight (>500 kDa) neutral polysaccharides in sloe juice and

TABLE 25.3
Applications in Fruit Juice Clarification

Juice	Membrane Material and Module	MWCO kDa	Operating Parameters*	Flux (L/m²h)	Reference

* Temperature and transmembrane pressure.

wine created difficulty in filtration. Citrus juices and tropical juices contain many hydrophobic compounds and clouds that result in lower fluxes.

25.5.1.2 Membrane Selection

The choice of membrane depends on the type of juice and the desired properties of the clarified juice (permeate). The factors that need to be considered while selecting a membrane include its configuration, material, and molecular weight cut-off. Tubular configurations are widely used for fruit juices [12]. They are recommended for clarification because their channels of larger diameters allow for the filtration of feed streams with high solids content and high yields can be obtained. In terms of power consumption per unit permeate of apple juice, Wu et al. [13] found that laboratory systems such as a tubular ceramic MF system (0.1 μm) and a spiral wound polysulfone UF (5 kDa) were comparable (1.15 W-h/L). The total energy requirement for a commercial ultrafiltration process using a two-stage tubular system has been reported to be at approximately 5.3 W-h/L for the production of clarified apple juice.

The choice of membrane material for a given juice is mainly determined by its pressure resistance, temperature resistance, pH resistance, and chemical compatibility. Many materials are suitable under the conditions needed for UF and MF clarification of juices: 1 to 10 bar, 20°C to 55°C, and pH 2.5 to 4. The cleaning protocol for membranes, however, often depends on the choice of membrane material. Other factors to be considered in material selection are its approval for food use, its durability, its availability, and its cost. Polymeric membranes have a life of at least 1 year and ceramic membranes of at least 5 to 7 years under continuous use. However, ceramic membranes are more expensive [6]. Some studies have found that membrane material can have some influence on UF and MF processing. Braddock [14] reported a decline in flux after contact with limonene. Polysulfone membranes had the most severe decline followed by cellulose acetate and Teflon. Rao et al. [7] found that apple juice permeate from polyamide membrane contained more volatile than the polysulfone membrane.

In general, the flux increases with pore size or molecular weight cut-off (MWCO) because the membrane permeability is proportional to the square of the pore radius. For a solute of a given size, retention decreases as pore size increases. Ideally, flux and retention of the haze compound (to be separated) should be as high as possible. The flux always need not increase with pore size [15–17]. Membranes of larger pore size tend to be more susceptible to fouling, as the proportion of smaller particles and colloids in juice increases and can lead to pore blocking and plugging. Juice quality did not appear to be significantly affected by MWCO, although more colored compounds and haze precursors were retained with lower MWCO [6]. The UF and MF membranes have very low

retention of low-molecular-weight compounds such as minerals, acids, vitamins, and sugars. Larger components such as pulp, starch, and pectin show very high retention. Volatiles such as alcohols, aldehydes, and esters in fruits such as apple have low retentions in the retentate [7]. The retention of intermediate weight compounds like enzymes depends on their molecular weights and the pore size of the membrane.

25.5.1.3 Concentration

Several studies have reported the use of membrane processes such reverse osmosis for concentration of a variety of fruit juices, including orange, apple, tomato, pears, grapefruit, kiwi, and passion fruit (Table 25.4). The major constraint with RO is that high concentrations are difficult to obtain due to the high pressures reached by juice retentate. The most important components in fruit juices contributing to osmotic pressure are sugars (hexoses and disaccharides) and organic acids [18]. Table 25.5 lists some osmotic pressures for different juices. The maximum concentration of apple juice by conventional RO is limited to around 30–35°Brix, and the most efficient recovery was 20–25°Brix [19, 20]. With current advances in membrane technology, most juices can be concentrated up to 65°Brix. This can be viewed as a first-stage process with other methods like freeze concentration or evaporation completing the concentration system.

Reverse osmosis has been used commercially to concentrate tomato juice from 4.5°Brix to 8.5°Brix. Later it can be concentrated in evaporators up to 30°Brix. This RO preconcentration can effectively double operating capacity and improve color and flavor characteristics. Similarly, orange juice from 11–12°Brix to 18–20°Brix has been concentrated using RO prior to flash evaporation for producing high-quality concentrate. RO has also been a useful application for maple sap concentration where up to 75% of water can be removed at 1/20 [21].

As in the case of fruit juice clarification using UF and MF, the pretreatment before RO concentration is not always beneficial in terms of flux. It has been reported that both clarified and cloudy pineapple juice had similar flux [22]. However, enzyme treatment may also be useful to assist juice components separation. Invertase catalyzes the hydrolysis of sucrose into glucose and fructose. The use of invertase with pectinase affected a 23% reduction in retained soluble solids and an additional fivefold increase in pigment concentration on a fresh weight basis when processed during RO [23]. Flux of RO is influenced by pressure, temperature, membrane type, flow rate, and concentration [22, 24]. The optimal operating parameters for various fruit juices during RO concentration are reported in Table 25.4. Increasing transmembrane pressure and temperature improve the permeate flux. At higher feed temperature, the membrane permeability coefficient is higher, the diffusivity coefficient in the solution increases, and the viscosity coefficient decreases. The flux has been shown to increase with cross-flow velocity when using RO on liquids containing protein, starches, or other micromolecules.

The membrane material plays an important role in determining the permeation of solutes through the RO membrane due to the interaction of solute and solvent at the membrane surface. Retention of compounds like alcohols and organic acids with a cellulose acetate membrane strongly depends on their polarity or hydrogen bonding capacity. Aromatic polyamide membranes have greater retention of flavor components of apple juice water, but lower fluxes. Recovery of apple juice volatiles during RO concentration to 20°Brix was reported about 80% when using a composite membrane [25].

25.5.2 Dairy

Membrane processes have been investigated in the dairy food industry for concentration of fluid milk and whey. Maubois et al. [26] proposed the use of ultrafiltration of milk before cheese making. The advantages of using ultrafiltration milk were 16–20% increase in the yield of cheese, better control of dry matter and milk fat in the cheese, reduced the quantity of coagulant up to 80%, and reduced environmental pollution due to protein/fat-free permeate/whey.

25.5.2.1 Quality of Ultrafiltered Milk

Milk fat is completely retained in concentrated milk and this increases the yield of cheese due to greater retention of fat in curd than curd made from unfiltered milk [27, 28]. Most of the protein of milk is also retained in the retentate and this increases nitrogenous material in cheese made from UF-treated milk. Calcium in the milk exists in two forms: free ions; and partly bound to casein, phosphate, and citrate. The free ions in the aqueous phase of the milk are not concentrated by the UF. However, the level of calcium-bound casein micelles increases in retentate as the concentration factor increases. The lactose retention in UF milk is very low (~10%). This could cause textural defects and excessive acid production in cheese during ripening if the retentate is used to make cheese. Hence, the level of lactose must be obtained in the cheese curd [27]. The fat-soluble vitamins and water-soluble vitamins, folic acid and B_{12}, bound to protein are completely retained by the UF. Ascorbic acid is mostly destroyed; however, the milk and milk products are not considered as good sources of dietary ascorbic acid [27–29]. The viscosity of concentrated milk is increased drastically due to the increase in the concentration of protein content. This creates difficulty in mixing the coagulant and starter culture in the concentrated milk that may lead to the textural problem in the cheese. Another problem associated with the viscous retentate is entrapment of air that can lead to a spongy-type texture of cheese [30, 31]. The texture abnormalities in the cheese made from homogenized and pasteurized whole milk are fewer than nonhomogenized concentrated milk [32]. The synthesis of curd made from UF milk tends to be slower than by curd from unfiltered milk. The curd obtained by UF milk is relatively difficult to cut, stir, and transport by conventional methods, hence a special coagulator is used [28].

25.5.2.2 Microbiology of UF Milk

The conditions for growth and inhibition of bacteria in UF concentrated milk differ from those of regular milk.

TABLE 25.4
Concentration of Fruit Juices by Reverse Osmosis

Juice	Membrane Material and Module	Operating Parameters	Flux L/m²h	Reference
Orange	Cellulose acetate, flat sheet	2000 psi 10.5–42.0°Brix	0.79–2.83	Merson and Morgan [18]
Maple sap	Cellulose acetate; spiral wound	600 psi 5 gal/min 5.5–10.3°Brix	9.0	Underwood and Willits [21]
Concord grape	Cellulose acetate, flat sheet	1500 psig 0.06–0.55 m/s 15.7–25.3°Brix	0.5–6.2	Lowe et al. [104]
Passion fruit	Cellulose acetate, flat sheet	40 atm 6°C 8L/min 16–26°Brix	1.5–10	Pompei and Rho [105]
Apple juice	Thin film composite, flat sheet	40 bar 30–60°C	9.6 to 21.7	Sheu and Wiley [20]
Apple juice	CA and PA, spiral wound	690–703 psi 21–27°C 13–22°Brix	3–14	Chua et al. [106]
Orange	Plate and frame, spiral configuration	1200 psig 10–12 cycles/min 0.3–0.9 fps 12–14°Brix	2–16	Lowe and Durkee [107]
Apple juice	CA, plate and frame	35–45 bar 20°C 12–25°Brix	8–37	Sheu and Wiley [108]
Beet	CA, plate and frame	30–40 bar 20°C 7–31	12–106	Lee et al.,[23]
Pineapple	Plate and frame, tubular (PCI)	6000 kPa 40°C 13–25°Brix	16–18	Bowden and Isaacs [22]
Orange	Osmonics, 192 MS02-P, spiral wound	6.21 MPa 20°C 15 L/min 10.3–17.8	9–28	Medina and Garcia [109]
Tomato	ZF-99, tubular (PCI)	41.4 bar 40–78°C 4.7–9.5°Brix	18.5–41	Merlo et al. [110]
Tomato	Cellulose acetate, plate and frame	3.0 MPa 20°C 4.8–12.5°Brix	2.3–15.1	Dale et al. [111]
Orange	Cellulose acetate, flat sheet	70–80 kg/cm² 27°C 9.9–46.6°Brix	7–12	Nomura and Hayakawa [25]
Mandarin	Polyacrylamide, flat sheet	711 psi 20°C 5–25°Brix	2–18.5	Fukutani and Ogawa [112]
Grape	Plate and frame	70 atm 6°C 8L/min 10–25°Brix	3.1–14.2	Peri and Pompei [113]
Grape	ZF-99, tubular (PCI)	40 bar 16°C 16.5–22.5°Brix	3.2–13.2	Duitschaever et al. [80]

Haggerty and Potter [33] reported that growth and death of *Staphylococcus aureus*, *Streptococcus faecalis*, and *Escherichia coli* in UF-concentrated and unconcentrated milk was not significantly different. Rash and Kosikowski [34] found that *E. coli* serotype 0124 had a greater survival and growth in Camembert cheese made from UF-concentrated milk, and this was attributed to the differences in physicochemical properties of cheese. El-Gazzar et al. [35] reported that *L. monocytogenes* (V7 and California) grew faster and achieved higher counts at 4°C in UF-concentrated milk than in skim milk. Dega et al. [36] previously also reported that heat resistance of several strains of *Salmonella* and *E. coli* increased as the solids content of reconstituted skim milk increased from 10% to 50%.

25.5.2.3 Cheese and Other Dairy Foods

Several studies have been reported on the use of ultrafiltered milk for the production cheese of different varieties. Geilman [37] concentrated skim milk up to 14.5% solids using UF and made cottage cheese of commercial quality. In order to develop a soft coagulum, trisodium citrate was added at the rate of 0.3% of total concentrate. The pH was maintained close to the normal isoelectric point of casein. Lelievre and Lawrence [38] also showed the possibility of making ricotta and cream cheese from UF concentrated milk since these varieties of cheese are not ripened. Olson and Qvist [39] used pasteurized (72–78°C for 15 s) UF concentrate of whole milk to manufacture Feta cheese. Fermentation was carried out using a strain of *S. lactis.* The minimum pH of less than 4.8 was maintained to prevent softening of the cheese during storage. They also indicated that Cast Feta cheese made from UF concentrated milk had favorable characteristics and became popular in Greece. Cast Feta cheese has 3–4% more moisture; a smoother texture; and a strong acid, rancid, and salty flavor. Abd-El-Salam et al. [40] manufactured Domiati cheese using UF concentrated buffalo skim milk (concentration factor 3.5) mixed with fresh cream of 35% milk fat at the rate of 4:1. The Domiati cheese showed less weight loss when stored without salt brine than occurred when cheeses were stored in 5% brine solution or in salted (5%) permeate.

Camembert-type cheeses have successfully been manufactured using UF concentrated milk [29, 41, 42]. For this, skim milk is initially pasteurized and then concentrated about fivefold by ultrafiltration. It was reported that the yield of cheese was 20% higher [41], whey drainage was eliminated [29], and time of production was reduced [42]. Mahaut and Maubois [43] described the manufacturing of blue cheese from UF milk. Cheeses made from concentrate containing 12% protein were as good as or better than traditional blue cheese. Mozzarella cheese can also be manufactured from milk concentrated (two- to fivefold) using ultrafiltration [44, 45]. Colby and brick cheeses were manufactured by Bush et al. [46] using UF skim milk standardized with cream. They reported a reduction in the amount of milk-clotting enzyme used and elimination of curd washing. The brick cheese was more firm and it had a more acid flavor, less typical cheese flavor, and ranked lower in overall preference than did cheese made from regular milk. However, the characteristics of Colby cheese made from UF milk were reasonably close to those of commercial cheeses. Rao and Renner [47] manufactured cheddar cheese from UF milk and reported that the extent of proteolysis was highest in cheese made from unfiltered milk, followed by cheese made from unheated UF concentrate and lowest in the cheese made from heated retentate. There was no significant difference in sensory appearance and constancy among ripened cheese samples. Sharma et al. [48] reported that the cheddar cheese manufactured using UF milk resulted in faster acid development, promoted more proteolysis, caused faster disappearance of lactose, and contributed a smoother body and texture. They used a lower cooking and cheddaring temperature of 35°C. Use of starter culture at 2% by weight of unconcentrated milk together with lowering the cooking and cheddaring temperature caused the pH to be reduced at a faster rate and shortened the cheese-making time by approximately 45 min compared to cheese made using traditional temperature (39°C).

El-Gazzar and Marth [27] concluded from their review that UF concentrated milk can be used for making soft cheese such as Feta, Cast Feta, and Domiati since these cheeses can be consumed without ripening. However, cheese types that require ripening may have problems in sensory properties because of the high content of whey proteins. It has been reported that a significantly slower degradation of casein occurs, and thus cheese from UF milk ripens more slowly than traditional cheese. The higher mineral content in UF-concentrated milk leads to an acid taste and sandy texture in cheese. Acid and bitter flavors also can arise from excessive lactose in the precheese. Also, the behavior of lactic acid bacteria and pathogenic microorganisms differ in retentate from UF milk compared to unfiltered milk. Hence, additional work is needed to solve such problems before it is used more widely in the dairy industry.

The use of reverse osmosis in the dairy industry has been limited. Few studies have reported manufacturing of cheese

from RO-concentrated milk and concentration of whey [49–51]. These studies reported using less starter culture and rennet. However, the major limitation of RO of skim and whole milk has been membrane fouling.

25.5.3 Oils and Fats

Soybean, palm, rapeseed, and sunflower oils are most important in terms of volume of production. Most oils are used for food applications including salad and cooking oils, mayonnaise, margarine, and chocolate. The crude oil extracted from biological material contains fatty-acids, mono-, di- and triglycerides, phosphatides (gums), sterols and tocopherols, and pigments (e.g., chlorophyll). Low concentrations of trace metals, flavonoids, tannins, hydrocarbons, and glycolipids may also be found in some oils. The crude oils need to be refined before they can be sold commercially. This involves removing unwanted components and concentrating the desired products. Usually agricultural oils are extracted using an organic solvent such as hexane, and so the product also needs to be removed from an organic phase. These processes require large amounts of energy and generate large quantities of wastewater. The membrane technology has also potential applications in oil processing. Table 25.6 summarizes some of the research that has been conducted on the use of membrane processing for refining of agricultural fats and oils.

25.5.3.1 Solvent Recovery

Cellulose acetate (CA) RO/NF membranes were used to recover ethanol from cottonseed–ethanol mixtures [52]. The rejection of triglycerides was higher initially. Later, the performance of the system degraded due to alcoholysis of membranes. The polyamide (PA) membranes were also affected by ethanol. Kuk et al. [52] reported that RO/NF membranes with pore sizes 2 nm or less and with a pore density of $10^{12}/cm^2$ were the most appropriate for recovering ethanol from oil. In laboratory tests, Koseoglu et al. [53] found that CA RO and PA RO/NF membranes were most suitable for the separation of *iso*-propanol and ethanol, respectively. However, pilot plant tests showed higher levels of oils in permeate. The increasing temperature in the feed stream also showed poor rejection of oil.

25.5.3.2 Degumming

Sen Gupta [54] found that membranes made with different materials such as PA, polysulphone (PS), polyvinylidene fluoride (PVDF), polyimide (PI), or polyacrylonitrile (PAN) could be used in a UF module for removal of phospholipids from soybean oil in hexane. He reported that phospholipids content of soybean oil was reduced to less than 300mg/L, glycolipids to less than 50mg/L, and green pigments to less than 0.5 mg/L. The concentrations of free fatty acids and tocopherol were unchanged, but the concentrations of copper, iron, magnesium, calcium, and phosphorus were reduced. Sun and Koseoglu [55] found that UF membranes can reduce the

TABLE 25.6
Applications to Agricultural Oil Refining

Membrane Type	Membrane Material	Membrane Module	MWCO kDa	Oil	Process Objective	Reference
RO/NF	PA composite	Flat sheet, tubular	1	Cottonseed	Ethanol recovery	Kuk et al. [52]
RO/NF	PA composite	Flat sheet, tubular	0.5–1.0	Cottonseed	Hexane recovery	Koseoglu et al. [53]

UF	Ceramic	Honeycomb monolithic elements (1.9 mm)	0.05–0.2 μm pore size	Soybean	Removal of catalyst	Vavra and Koseoglu [65]
Dialysis membrane	Cellulose	Hollow fiber	6	Soybean	Removal of metals	Keurentjes et al. [59]

phospholipids in cottonseed oil in hexane and *iso*-propane by 98.1% and 70%, respectively. Iwama [56, 57] also reported phospholipid concentrations of 10 to 50 mg/L in permeate of soybean oils in hexane. These values are well within limits acceptable for industrial use. The permeate flux of the hexane-oil mixture varied from 6 to 60 L/(m^2h) at 50°C and a transmembrane pressure of 0.4 MPa.

25.5.3.3 Lipid Separations

Koike et al. [58] found that CA membrane gave the better flux among 18 membranes tested for their ability to separate fatty acids, mono-, di-, and triglycerides from lipase hydrolysate of high oleic sunflower oil. There was a large difference in rejection between free fatty acids and glycerides. The polyvinyl alcohol, PA, and polyether membrane gave high rejections of both glycerides and free fatty acids, but there was little difference between the different components. The permeate flux and rejection were lower in hexane than in the ethanol. Keurentjes et al. [59, 60] found that PAN and cellulose membranes gave complete rejection of triglycerides while separating fatty acids from oil. However, the permeate flux for PAN membrane was 30-fold higher. Sahashi et al. [61, 62] reported a study on the concentration and purification of n-3 polyunsaturated fatty acids (PUFAs). A hydrophilic PI UF membrane was found most suitable for the separation of solvent phase containing free fatty acids as permeate. The permeate flux was in the range of 40–80 liters/(m^2h). Kuk et al. [52] observed differences in rejection between triglycerides of different fatty acid composition when separating cottonseed oil from ethanol using PA RO membrane. They attributed these differences due to variations in viscosity and diffusivity. Tristearin, which had the highest viscosity, was completely rejected, whereas tripalmitin, and mixed triglycerides containing oleic acid, palmitic acid, and lauric acid, were rejected to varying degrees.

25.5.3.4 Dewaxing

In edible oil processing, dewaxing is done between decolorization and deodorization, and is one of the areas where membrane processing has been applied successfully. Asahi Kasei Corporation has carried out membrane dewaxing of sunflower oil on an industrial scale in Japan for more than 15 years. Chayamizu and Kikuchi [63] and Watanabe and Chayamizu [64] reported 97% of wax rejection using a MF membrane of 0.2 μm pore size. Periodic backflushing by gas and with 80°C hot oil was necessary to maintain the permeate flux and to remove any wax that accumulated at the membrane surface. The oil flux was 4.8 to 27 L/(m^2h) under a pressure of 0.3 MPa and the feed oil temperature was 5–10°C.

25.5.3.5 Removal of Contaminants

Keurentjes et al. [59] used a hollow-fiber cellulose membrane module to remove copper from soybean oil. Vavra and Koseoglu [65] and Koseoglu and Vavra [66] used ceramic membranes to separate nickel catalysts from hydrogenated soybean oils. The rejection varied from 82% to 100%. while the permeate flux ranged from 8.5 to 42.5 L/(m^2h). However, the permeate flux with a co-polyalkoxyether-imide (PEI) membrane was 113 L/(m^2h). Kuk et al. [52] and Hron et al. [67] used PA RO/NF membranes to concentrate aflatoxin B1 from cottonseed oil in ethanol or *iso*-propanol.

25.5.3.6 Removal of Pigments

Vegetable oils contain numerous pigments, including chlorophyll, carotenoids, xanthophylls, and their derivatives, that need to be removed to give the oil an acceptable color. Koseoglu et al. [68] identified 5 suitable membranes out of 15 tested for their ability to remove pigments, phosphorous, and gossypol (a yellow pigment) from crude cottonseed, soybean, canola, peanut, and meadowfoam seed mixtures. Chlorophyll and β-carotene rejection efficiency varied between membranes and between oils. Typically the color readings of the permeate were about one-tenth that of the crude oils. Diosady et al. [69] suggested the use of a combination of techniques including membranes to reduce chlorophyll by more than 90% from canola oil. Reddy et al. [70] found that PE membrane had a poor rejection of chlorophyll (<4%), but PI composite membrane gave over 95% rejection from sunflower and soybean oils in stirred batch test cells.

25.5.3.7 Membrane Bioreactors

In recent years there has been lots of interest in the enzymatic modification of fats and oils to produce high-value products from cheap and plentiful raw agricultural materials. The process involves the use of lipase to catalyze hydrolysis, ester synthesis, and interesterification reactions. In the process, membranes can be used to provide a solid-supported interface and recover enzymes for reuse. Many research groups have used membrane bioreactors for the modification of fats and oils. Snape and Nakajima [71] have reviewed the choice of membrane material, membrane characteristics, and reactor configuration.

25.5.4 Potential Applications of Membrane Processes

Pectic enzymes are used in the clarification of apple juice before membrane filtration. The membranes clarification can be used to recover these enzymes to reduce industrial processing costs [72]. The isolation and purification of pectin from fruits can be achieved using ultrafiltration [73, 74]. UF can also be used to recover colloidal carbohydrates that withstand the hydrolytic conditions of commercial pectolytic enzyme preparations during juice clarification [75]. Other major by-products of the fruit juice industry are essential oils and essences. Many of these components are immiscible with and poorly soluble in water, hence making UF and RO potential recovery techniques. Membrane processing techniques have been investigated for the purification and concentration of various pigments such as anthocyanins and betanins [23, 76, 77].

The membrane processes can be combined with ion exchange to deacidify fruit juices. Snir et al. [78] used ultrafiltration permeate of passion fruit juice and deacidified using ion-exchange chromatography and obtained a less sour

product with a flavor similar to the original juice. Koseoglu et al. [79] treated the UF permeate of citrus juice with RO and ion exchange for deacidification, while UF retentate was heat sterilized. The treated permeate was combined with sterilized retentate to obtain better flavor and aromas.

25.5.4.1 Wine

Reverse osmosis has been investigated for concentration and dealcoholization of wines [6]. Wines of low alcohol are difficult to preserve and market. In order to increase the sugar concentration in these wines, reverse osmosis has been applied as an alternative method to evaporation and freeze concentration. Duitschaever et al. [80] used thin film composite membranes in a plate frame module to increase sugars by 2.4%. Spiral wound and hollow fiber membranes have also been used for partial concentration and grape musts clarification prior to RO using centrifugation or microfiltration [81–83]. The initial must from immature grapes can be concentrated with excessive malic acid content and reinforce the vegetal character using RO [84]. A low-acid, light-colored, and light-bodied red wine can be concentrated using RO to produce a full-bodied, dark-colored, high-acid product. Dick and Dixmier [85] used polyhydroxymethylacrylamide RO membrane with 85% to 90% ethanol rejection increases ethanol concentration from 10% to 12.5%, while the alcohol content in the permeate remained below 2%. Most other constituents were found at trace levels in the permeate except methanol, which can cross membrane freely [85, 86].

Selective RO membranes have been used to dealcoholize wines. The process involves wine as a feed and the RO membranes allow water and ethanol to permeate, while most flavor and all color compounds are retained. The wine is recycled across the membranes until the required degree of concentration is achieved. The permeate containing water and ethanol is distilled and water is combined with concentrated wine to produce a low alcohol product [6]. It is feasible to produce wine with 3% ethanol with acceptable quality [87]. The sensory properties of dealcoholized wine started to change significantly below 9% of alcohol. The wine appears to have less body and a more watery mouthfeel. In order to have acceptable products, organic acid and grape juice/concentrate are added to wines to obtain 6 g/L titratable acidity and 5°Brix [88]. Wucherpfennig et al. [89] used the dialysis process for the dealcoholization of wine using another alcohol-free wine produced using vacuum distillation. As a concentration gradient exists only for alcohol, little change in concentration of other constituents occurs. The alcohol diffusing into the second wine is eliminated by vacuum distillation, allowing reuse of the wine in the dialysis process. This way, heat damage to the wine is eliminated. Bui et al. [90] used two reverse osmosis modules, one equipped with ethanol permeable polysulfone membranes and the second with selective ethanol retention polyacrylamide membrane. The ethanol retention membrane produced concentrated wine (12–13% ethanol) and permeate (mainly water and 2% ethanol) is mixed with original wine (10–11% ethanol) and used as feed to ethanol permeable membranes to produce light wine with 6–7% ethanol. Because membranes were impermeable to anthocyanins, two different wines, such as rose and red wine, can be used simultaneously for the light and enriched streams [6]. The effects of membrane filtration on the aromatic profile and phenolic quality of Cabernet Sauvignon wine was studied by Arriagada-Carrazana et al. [91]. The results of their study showed that concentration of tannins (4.8%), anthocyanins (2.4%), and total phenolic index (10%) decreased. This was attributed to absorption in the membrane filter.

25.5.4.2 Pervaporation

Mass transport during pervaporation is achieved by partial vaporization through a nonporous selectively permeable membrane. The flux of any compound to be separated is determined by its partial pressure gradient across the membrane and its permeability in the membrane matrix. The difference in partial pressure is created on the permeate side, usually vacuum generated. The process results in a liquid retentate and a vapor permeate that is condensed using low temperatures [6]. One of the first pervaporation applications considered for the food industry was the production of dealcoholized beverages including wine and beer [92, 93]. Hydrophobic membranes can preferentially permeate ethanol over water vapor, and this can be used to extract ethanol from alcoholic beverages. In order to reduce the aroma loss, hydrophilic membranes can be used. Another promising application of pervaporation is aroma compound recovery and concentration. Bengtsson et al. [94] used pervaporation to concentrate a natural aroma condensate from an apple juice concentrate plant. Rajagopalan and Cheryan [95] evaluated pervaporation membranes using a model flavor, i.e., methyl anthranilate compound of Concord grapes. Like other membrane techniques, pervaporation allows a low-temperature extraction and makes it possible to treat heat-labile products, such as beverages or fermentation media. Pervaporation has also been demonstrated as a possible means for juice concentration. Buvet and Idier [96] developed a hydrophilic membrane for extracting water from juices, syrups, and other aqueous solutions. Karlsson and Tragardh [97] investigated the effect of high ethanol concentrations during aroma compound recovery. Though pervaporation has not yet had a major commercial impact in the food industry, it is a very attractive approach to certain separations requiring the avoidance of high mechanical, thermal, or chemical stresses. The potential application of pervaporation is in the aroma recovery in fruit juice processing.

25.6 CONCENTRATION POLARIZATION AND FOULING

The major goal of the membrane system is to achieve required separation with economically acceptable permeate flux. Both concentration polarization and membrane fouling influence the performance of the membrane system (Figure 25.4) [24]. Membrane lifetime and permeate fluxes are primarily affected by the phenomena of concentration polarization (i.e., solute build-up) and fouling (e.g., microbial adhesion, gel layer formation, and solute adhesion) at the membrane surface.
