Somewhere about the soma of most neurons emerges a single, cablelike process called the *axon* or axis cylinder. It arises from a small, conical elevation (axon hillock; Fig. 21A) or from the stem of a major dendrite (Fig. 21B). Its departure may be virtually straight, presaging a clearly directed flight to a distant location (via a tract or nerve), or meandering, as if lost in the neuronal shrubbery near its origin (Fig. 22). Such direct or rambling courses provide the long-distance trunk lines and myriad local circuits over which neuronal signaling and communication take place.

The conductile axon conveys impulses to other neurons, a muscle, or a gland. In primary sensory neurons (Fig. 15, DRG) innervating the skin, impulses arise in axonal endings: naked, with minute expanded tips, or encapsulated (A), as shown. The action potentials travel to the CNS via a cranial or spinal nerve.

Compared to dendrites, the axon is relatively long (2–3 μm to 1 m), slender (0.1–20 μm), and untapering. Like dendrites, it may branch, as *axon collaterals*, but these typically depart at right (not acute) angles. Collaterals distribute neuronal output to several or many places, depending on circuit design and how many collaterals the axon has. Axonal collateralization is as expressive of neuronal interrelationships as

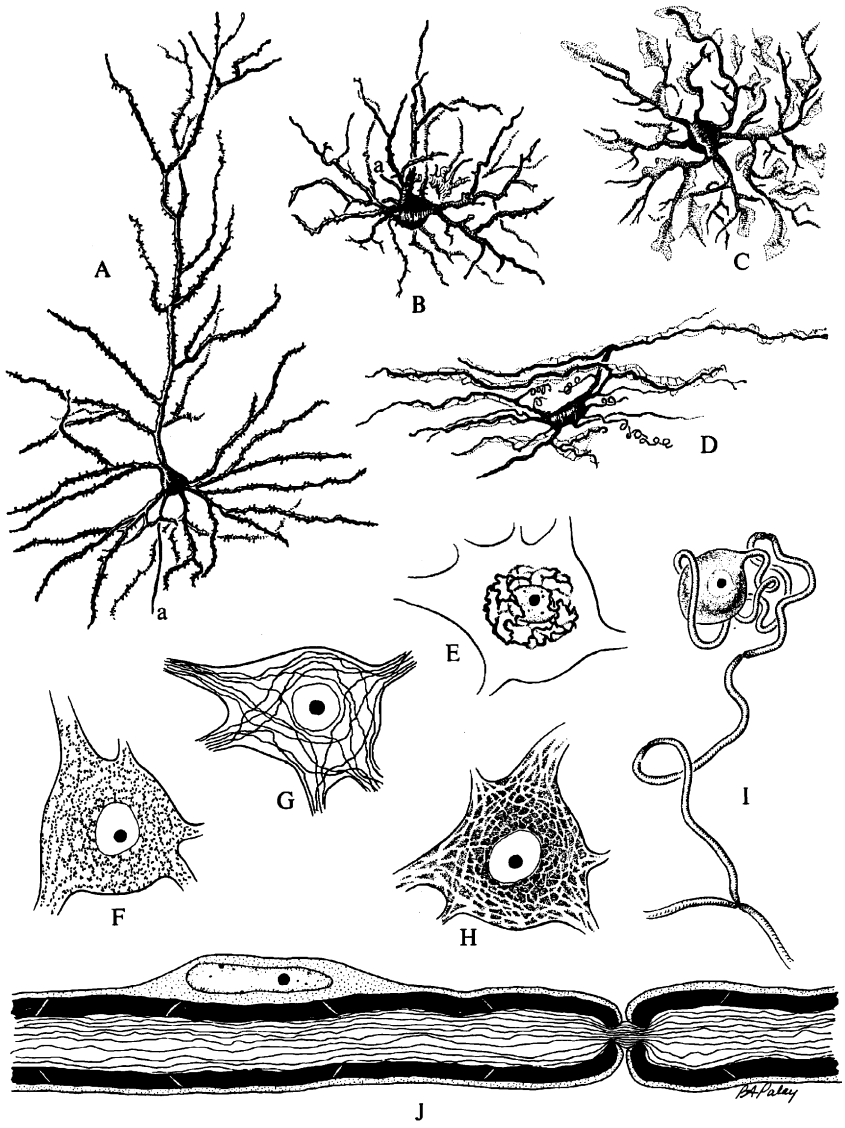

Figure 21 LM potpourri: (A) Small pyramidal cell in visual cortex, axon (a), Golgi method. (B) Small neuron in dentate nucleus of cerebellum, axon (a), Golgi method. dendritic branching. Dendrites signify the integrative power of a neuron and axons and their collaterals its distributive power, as well as the routes and addresses of impulse dissemination.

The axon is usually single, but can be double, as in bipolar neurons, or missing, as in *amacrine* cells (having no long processes), which intercommunicate through their dendrites. It is thinner and much longer than any dendrite, but most CNS neurons have a greater total length of dendrites than axons.

Single or double, short or long, branched or not, if an axon is present, it is the functional axis of the neuron, the hub along which nerve impulses travel. Over this main line speed the "all-or-none" action

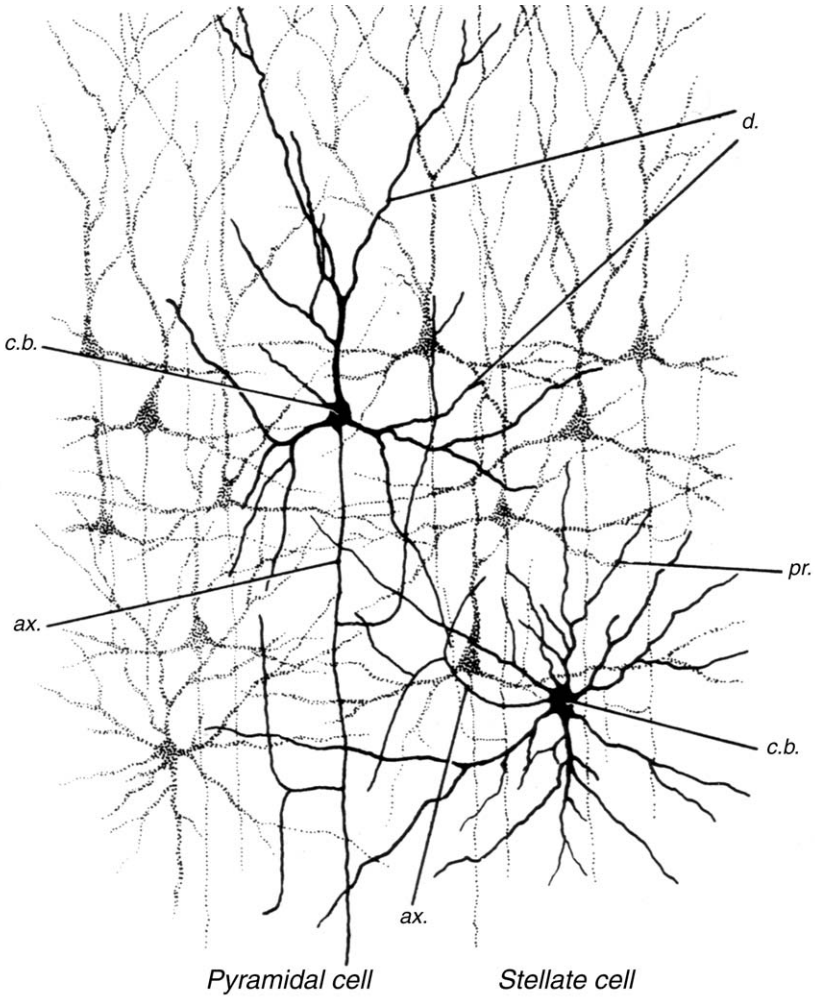

Figure 22 Direct and wandering axons: the pyramidal cell and stellate cell of the cerebral cortex shown here typify the two major modes of axonal departure: in the one, virtually straight, presaging flight to a distant location (e.g., the spinal cord), and in the other, meandering among the dendrites of the neuron of origin and those of others nearby. The former course characterizes the long-distance trunk lines of the CNS and the latter its myriad local circuits. Abbreviations: dendrites (d and pr.), cell body (c.b.), axons (ax.). From J. Z. Young, *The Life of Mammals*, 1957, copyright 1957 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (preparation by D. A. Sholl).

potentials (spikes), encoding output in spike trains or bursts superimposed on a discharge frequency characteristic of the neuron under given conditions. In motor neurons and other large nerve cells, these spike potentials originate in the axon hillock and axon initial segment, the "spike trigger zone" (Fig. 23).

4. Axon Terminals

Specialized terminations of axons or of their preterminal branches, these have many shapes and names: bulbous, buttonlike, claw-shaped, and so forth. Similar beaded structures may lie along the course of an axon. All are sites where frequency-coded messages are transmitted chemically to some part of the target neuron or the muscle fiber across a synapse or neuromuscular junction and where trophic effects may pass in both directions. Axon terminals are the effector parts of neurons, whereas dendrites, the cell body, and axons are the receptive, trophic, and conductile parts, respectively.

5. Flexibility of the Parts of Neurons

The parts of neurons are adaptable. There are many exceptions to these conventional definitions, and

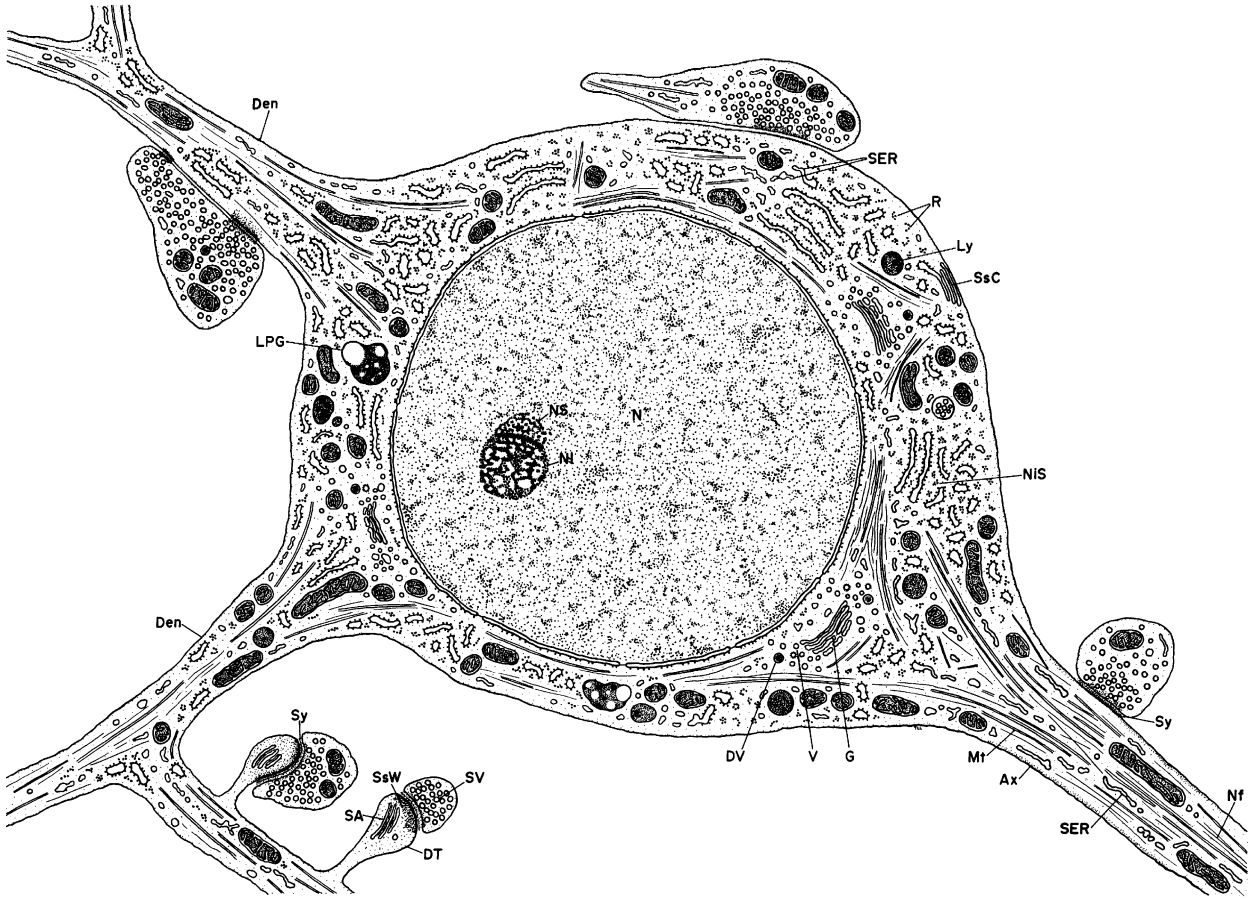

Figure 23 Schematic EM of neuron, its organelles, and inclusions: dendrites (Den), axon (Ax), nucleus (N), nucleolus (Nl), nucleolar satellite (NS), Nissl substance (Nis), rough-surfaced endoplasmic reticulum (not labeled), ribosomes (R), smooth-surfaced endoplasmic reticulum (SER), subsurface cisternae (SsC), Golgi apparatus (G), dense core vesicles (DV), lysosomes (Ly), lipofuscin pigment granules (LPG), microtubules (Mt), neurofilaments (Nf), dendritic thorns or spines (DT), spine apparatus (SA), synapses (Sy), synaptic vesicles (SV). awareness of them enhances understanding of neural function and neurologic disease. Certain regions of the axon may serve receptive functions: with axoaxonic input at the axon hillock or on its presynaptic end bulbs. Dendrites may conduct impulses swiftly in an all-or-none manner like axons (as in the towering hippocampal pyramidal cells). They may also act as effectors (like axon terminals) and transmit activity fractionately, as in dendrodendritic synapses. Thus, the chemical membrane and subjacent organelles of a neuron constitute a *functional mosaic*.

It is helpful to regard neuronal design as flexible. Almost any part can perform any communication function, if circumstances or circuit design make it advantageous. The only invariant component of a neuron is the cell body. It, and only it, is the trophic part.

Flexibility is striking in relationships between neurons. Neuroscientists used to think in terms of serial progressions of neurons through axodendritic and axosomatic synapses and of similar sequences through axonal collateral channels. Now other arrangements are known (Fig. 25): *parallel* coupling (axoaxonic and somatosomatic synapses), *reciprocal* coupling (dendrodendritic synapses), *parallel–serial* coupling (axoaxodendritic synapses), and *atypical* coupling (somatoaxonic synapses). These more complex modes of cell-to-cell interplay, along with gap junctions and the unpredictable results of synaptic activity, illustrate the versatility of neural communication. More than

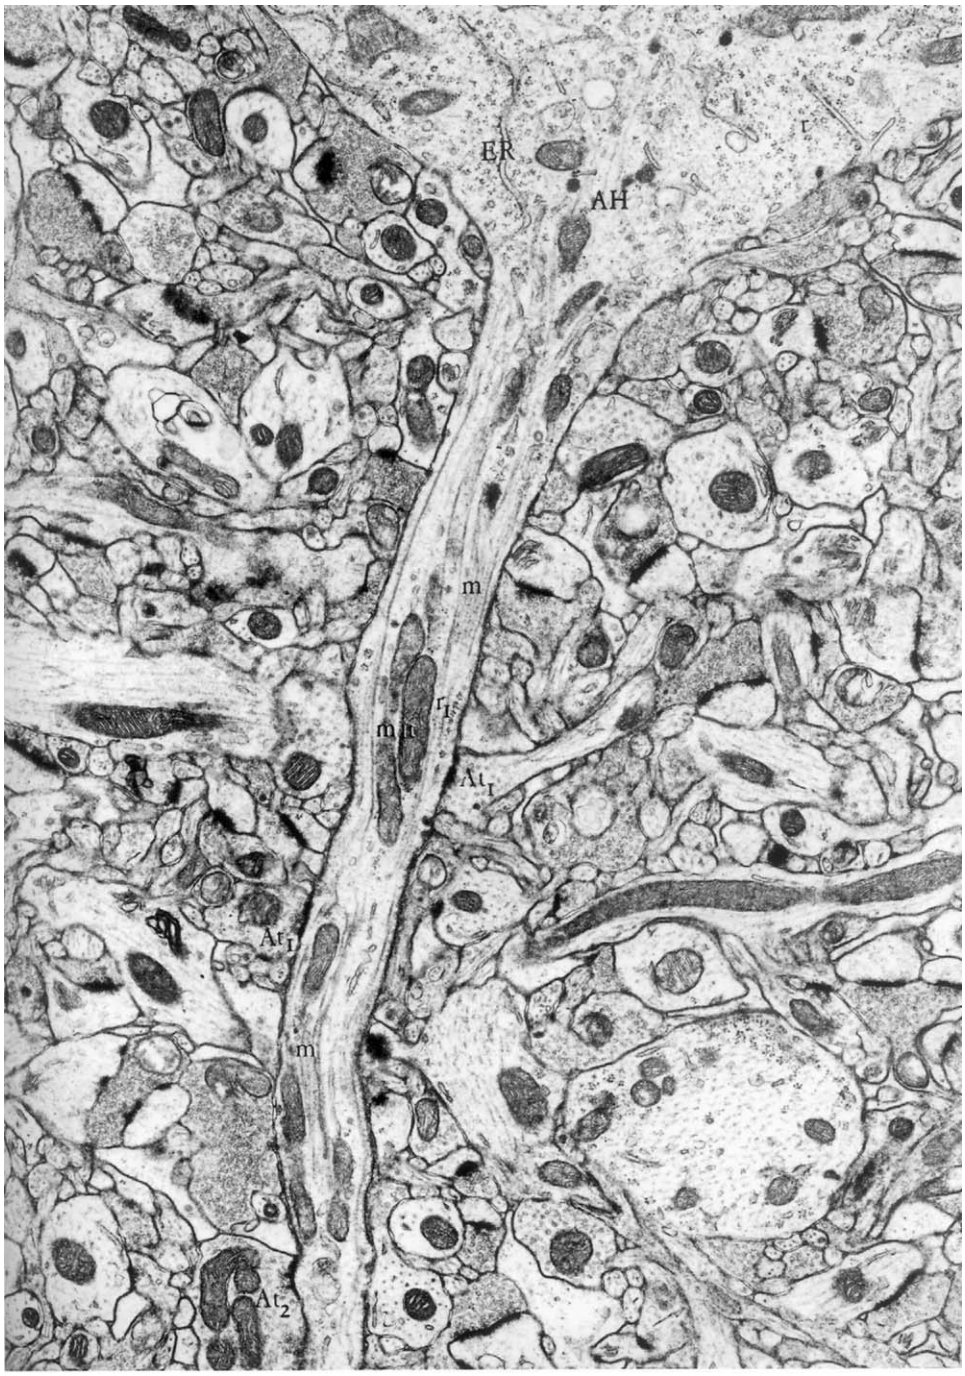

Figure 24 Axon hillock and initial segment: the axon is shown leaving the perikaryon of a pyramidal neuron at the axon hillock (AH), wherein ribosomes (r) and rough endoplasmic reticulum (ER) are seen, and descending through richly varied and epithelially organized neuropil. In the initial segment, ER is absent and ribosomes (r1) decrease in number. Mitochondria (mit) and neurofilaments enter the axon freely; microtubules (m) also enter but become bundled. Such bundling and the presence of an undercoat to the axonal plasma membrane characterize the initial segment. Three axon terminals are seen synapsing with the initial segment: two proximal (AT1) and one distal (AT2). From *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells*, 3rd ed., by Alan Peters, Sanford L. Palay, and Henry de F. Webster, copyright 1990 by Alan Peters. Figure 25 Neuronal coupling paradigms: for a century, neurons were considered to be coupled linearly by axodendritic and axosomatic synapses. But by 1972, as shown schematically here by David Bodian, it was clear that many paradigms of parallel coupling existed. These illustrate the adaptability of the parts of neurons, the flexibility of neuronal design, and, as Dr. Bodian observed, "the diversity of life and its processes." See also text. From Neuron junctions: a revolutionary decade, D. Bodian, *The Anatomical Record*, Copyright © 1972. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. (illustration by Elinor W. Bodian).

that, they show, as neuroanatomist David Bodian observed, "the diversity of life and its processes."

6. Polarity of Neurons

In terms of *polarity*, (number of cytoplasmic processes), three kinds of neurons are recognized: unipolar, bipolar, and multipolar (Fig. 26). The probable location and functional significance of each may be inferred by inspection, but an explanation is necessary.

Unipolar *neurons* are not found in vertebrate nervous systems, although young neurons have but one process at certain developmental stages and look like them. But in invertebrates, they represent the dominant population and, hence, the largest number of nerve cells on earth.

Bipolar neurons are simple modifications, with fusiform cell bodies, of the columnar epithelial cells from which they evolved. In humans, they form primary sensory neurons in the olfactory epithelium, retina, and vestibulocochlear ganglia. Terminal ramifications in the periphery (e.g., in the organ of Corti) respond fractionately to stimuli and may be considered distant dendrites. By contrast, the long process leading to the soma, like the other process departing, is by all criteria axonal, even having a myelin sheath for increased

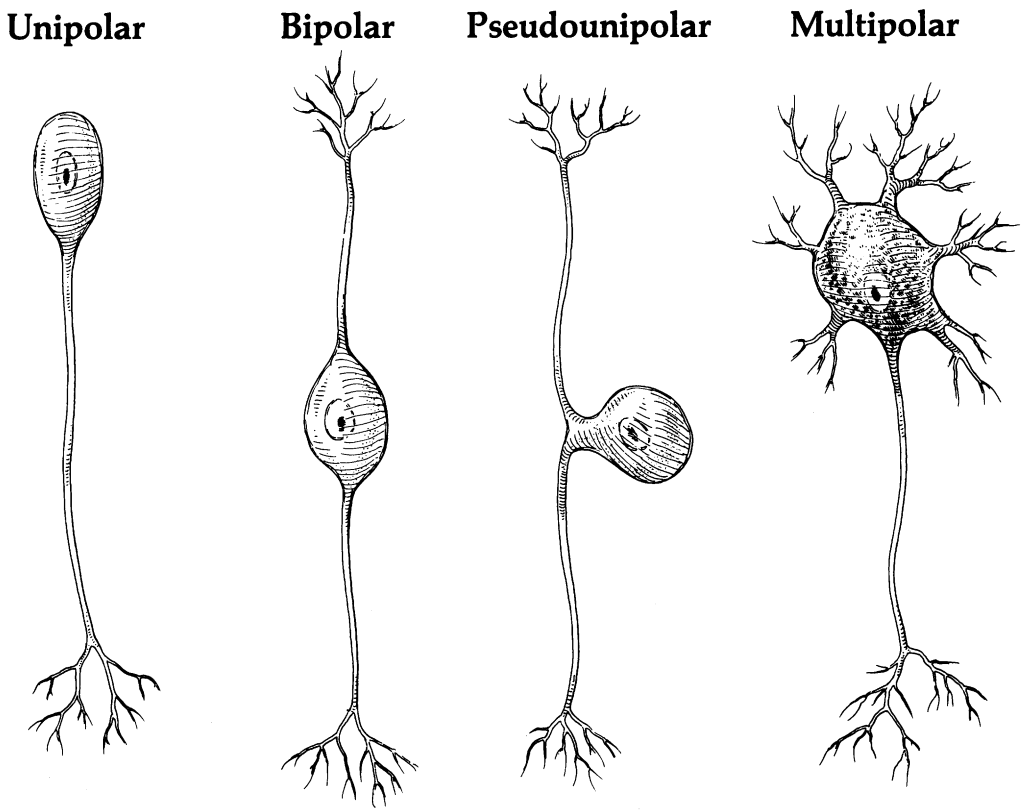

Figure 26 Polarity of neurons. In number of cytoplasmic processes, three general kinds of neurons are recognized: unipolar, bipolar, and multipolar. True unipolar neurons are not found in the adult vertebrate nervous system. Bipolar neurons and a variant, pseudounipolar neurons, make up all the primary sensory neurons of the PNS. Multipolar neurons have many variably branched processes extending in many directions; as the most common type of vertebrate neuron, they are the hallmark of the human CNS. See also text. From *Principles of Neuroanatomy*, by Jay B. Angevine, Jr., and Carl W. Cotman, copyright 1981 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc. (illustration by Steven J. Harrison).

speed of impulse conduction. By the interposition of an axonal cable between the receptive region and the cell body, spikes triggered peripherally pass swiftly to the soma, over which they flow to the other process and on to the CNS, wherein their central ramifications distribute impulses to secondary sensory neurons.

Pseudounipolar *neurons* are modified bipolar cells. The opposing processes shift around the soma during development and combine into one, at least proximally. This process takes a short, often convoluted course and then branches like the letter T: one branch going to the periphery and the other to the CNS (Fig. 21I), as in bipolar neurons. Nerve impulses in these cells pass from one branch to the other, subsequently "backfiring" the single process and soma. Pseudounipolar and bipolar cells make up all primary sensory neurons in the PNS. Both have limited integrative domains in distant dendritic tufts and no input on their somata, which are limited to trophic and housekeeping duties. Their central terminals, however, receive presynaptic endings, providing efferent modulation of their transmission to secondary sensory neurons. This arrangement is important in suppressing the receipt of painful stimuli. It is an enkephalinergic component of a complex brain stem analgesia system.

Multipolar neurons have many variably branched processes projecting in many directions. The most common type of vertebrate neuron, they comprise virtually all neurons of the human CNS. With their diversified input (from 10^4 to 3×10^5 apiece), they have tremendous integrative capacity. In the shape, size, and position of their somata, in the number, length, and branching pattern of axons and dendrites, and in neuroactive substances synthesized and released, a panoply of multipolar neurons is found in the CNS (Fig. 27). This variety is so extraordinary that neurobiologist Pasko Rakic has said, "I believe it is safe to estimate that there are more forms of cells in the

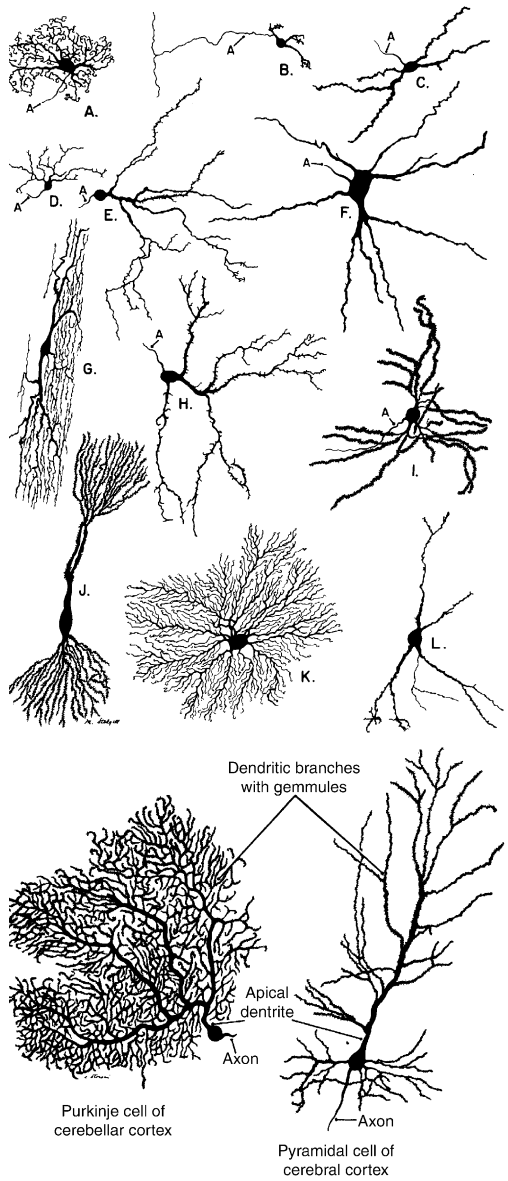

Figure 27 A panoply of neurons: a huge variety of multipolar neurons is found in the CNS. The dendrites express the integrative power of a neuron, the axon with its collaterals (or lack of same), its sphere of influence, the cell body with its minute to huge size and varied shape, its area available for axosomatic synapses, the length of its axon, and its amenability to high or low packing density. brain of a mammal than in all the rest of the entire body." Functionally, their vast number (100 billion, maybe 1 trillion) falls into two groups: a small number of motor neurons (about 2 million), sending axons to muscles and glands, and the remainder a host of interneurons.

As stated, the dendrites of multipolar neurons are the most intriguing variables, expressing their integrative power. They vary from few to profuse, from straight and smooth to curving and spiny, and from meagre shrubbery to magnificent arboreal extravaganzas. The axon comes next, being short or long, unbranched or rectilinearly, almost obsessively collateralized, and ruler-straight and departing the locale or sinuous and wandering through the local neuropil. Then the soma: ovoid, spherical, pyriform, fusiform, fat, skinny, big, small: miniscule (4 μm, half the size of a red blood cell) in dwarf neurons to huge (150 μm) in giants. Teased out in a tissue preparation, the Betz cells in the human cerebral cortex can be seen with the naked eye.

7. Specialization of Neurons

The variety of cell structure in the human nervous system is far more complex than in other tissues. Whereas cells elsewhere (e.g., erythrocytes, hepatocytes) are highly redundant, neurons are highly individualized. Indispensable, decision-making *command neurons* are known in invertebrate nervous systems (e.g., in the ganglia of certain arthropods). But in vertebrates, a great redundancy of neurons seems the rule: to iron out individual peculiarities of cells and for safety's sake.

The human nervous system has many neuronal subpopulations. Within each, a neuron shows its individuality by form, function (speed of response, endurance, or fatigability), position in a circuit, chemical coding of impulses, and sheer size. Neuronal specialization gives our nervous system speed, flexibility, fidelity, and staggering integrative power.

8. Schemes of Classifying Neurons

To understand such complex cells as neurons, it helps to have some means of categorization. Many classifications exist, each with advantages and limitations. Neurons are grouped as to size, shape, polarity, dendritic pattern, axonal length, long-distance or local-circuit service, presence and nature of neurosecretory activity, neuroactive substances synthesized and liberated, and identifiability as a circuit

component from one nervous system to another. But perhaps the most useful scheme is the position of a neuron in the fundamental circuit plan: a functional classification into sensory, motor, and intermediate neurons.

a. Sensory Neurons *Primary sensory neurons* are the initial neurons in sensory data processing. Derived from neural crest cells near the embryonic neural tube, their cell bodies lie outside the CNS: rod cells of the olfactory membrane, bipolar ganglion cells of the vestibulocochlear nerve (cranial nerve VIII), and pseudounipolar ganglion cells of spinal nerves and cranial nerves (CNs) V, VII, IX, and X. They are sentinals posted outside the CNS, reporting news (good and bad) from the periphery. Their number is small, perhaps 20 million.

Secondary sensory neurons are the second echelon in sensory data processing: cells in the CNS on which axons of first-order neurons terminate. Clusters of them lie in the dorsal horn of the spinal gray and brain stem nuclei (e.g., the cochlear nuclei). Whereas their afferent domain is weighted by sensory input, they are interneurons, between the first and last neurons in the plan of the nervous system. They receive input from sources beside primary sensory neurons (even from the cerebral cortex) and are multipolar, not bipolar or pseudounipolar, thereby meeting all criteria for interneurons.

b. Motor Neurons Multipolar in design, the cell bodies of *somatic motor neurons* are located entirely within the CNS. Whereas sensory neurons are the first cells in neural data processing, motor neurons are the last. They send impulses to the effector organs: muscles and glands. Like sensory neurons, their number is modest: about 2 million. Yet their role is profound. Derived from the mantle layer of the neural tube, they include the large α and small γ motor neurons in the spinal cord and brainstem that innervate *extrafusal* and *intrafusal* skeletal muscle fibers: those that do work and those that report muscle stretch, respectively. They also include the *visceral motor neurons* of the ANS, the dual arrangement of a preganglionic motor neuron in the CNS and a postganglionic one in an autonomic ganglion.

c. Interneurons Once called internuncial or "go-between" neurons, *interneurons* as originally defined are neurons interposed between sensory and motor neurons. The CNS is their domain and neuroanatomy is largely the study of them and their connections. The number of interneurons is extremely large: 10^{11} is the figure currently cited, but because large populations of minute cerebellar and hippocampal neurons may be greatly underestimated, some see it as closer to 10^{12}. They comprise almost all of our neurons. These countless separate, yet richly interconnected cells are more than responsive to stimuli, though they serve homeostasis with computer speed and reliability and in ways nineteenth century opponents of the neuron doctrine could hardly have comprehended. Interneurons are the source of endogenous neural activity, the cells that initiate new programs of behavior and, if need be, abandon old ones.

Interneuron is a useful term in invertebrate neuroscience. But it loses meaning for the staggering numbers of such cells in vertebrates, especially in the human CNS, where as noted they represent 99.9997% of the total. It is now used for neurons confined to particular regions of vertebrate nervous systems. A newer scheme of classification offers an alternative. It recognizes two major classes of neurons: *projection neurons* and *local-circuit neurons* (LCNs). Projection neurons are interneurons in the original sense, with axons running between regions of the CNS but also including sensory and motor neurons, with axons extending from the CNS to receptors and effector organs, respectively. LCNs are also interneurons, but they have axons restricted in their sphere of influence to other neurons nearby. Projection and local-circuit neurons are not classified by cell size, length of axon, or type of contact. It is only their service in long-distance or local communication that separates them.

d. Projection Neurons Most large neurons are of this class. They fit the classic mold of a neuron: multipolar, with an ample cell body, many dendrites emanating from it, and a long axon over which impulses pass to one or more distant regions, with the amino acid glutamate as the primary transmitter (usually eliciting excitation of the target cells). Pyramidal cells in the cerebral cortex and Purkinje cells in the cerebellar cortex (Fig. 27) are familiar examples. Motor neurons in the brain stem and spinal cord are others. They perform long-range signaling in the CNS (the corticospinal tract) or from CNS to muscles (the sciatic nerve). Central projection fibers (region to region), association fibers (area to area in a region), and commissural fibers (association fibers that cross the midline) arise from such cells. During neural development, projection neurons originate earlier than LCNs, as if sketching in the basic circuit plan.

e. Local-Circuit Neurons As noted, LCNs usually have a short axon or sometimes none (as in the amacrine cells of the olfactory bulb and retina). They are involved in local activity within a group of cells, not transactions between distant groups. They are far more numerous than projection neurons in the human CNS and arise later and longer in neural development. The dentate gyrus of the hippocampal formation and the cerebellar cortex have huge numbers of them. In the cerebral cortex, they are also numerous but comprise only 20–25% of the grand total; this region is noted for its long-distance, direct output (Table III). Some of these large subpopulations take a long time to produce and put in place. Indeed, millions of LCNs arise after birth and even in adulthood in some mammals, including humans.

LCNs are of great interest. With the growing appreciation that regions of the CNS are specialized for different functions, their roles in circuits peculiar to these regions are now high-priority issues. Their general structure and connections have been known for years, but until relatively recently their functions were elusive due to the difficulty of studying them. Some LCNs elicit inhibitory effects by the transmitter γ-aminobutyric acid (GABA), whereas others elicit excitatory effects by glutamate. Many LCNs are recognized in the cerebral cortex, differing in location, size and branching of processes, patterns of connectivity, places of termination on target neurons, and other features, especially the presence and corelease of other transmitters. A few LCNs, however, have been understood for years: the GABAergic basket cell in the cerebellar cortex exerts *surround inhibition* on rows of Purkinje cells, thus providing *enhanced contrast* between them and the excited Purkinje cells in nearby rows.

VII. THE FINE STRUCTURE OF THE NEURON

Despite their enhanced capacity to communicate, neurons are cells, showing familiar membranous, filamentous, and granular formed components. Yet the amount, arrangement, and function of these are distinctive, and a new component, the *synaptic vesicle*, unique to neurons is present.

A neuron has two major compartments: the *nucleus* and the surrounding *cytoplasm*. Within each, based on assumptions as to function, lie two categories of formed components: *organelles*, found in all cells and considered minute, metabolically active structures serving specific vital functions, and *inclusions*, varying from cell to cell and considered metabolically inert accumulations of cell products (pigments) or metabolites (lipids, carbohydrates). This categorization is still useful but was made when little was known about neurons' fine structure and specific function. Today, the list of organelles is increasing and that of inclusions is debatable or decreasing as highly organized internal structure and enzymatic activities of them are uncovered. Although the organization of the human nervous system is hypercomplex, simplifying principles are at hand.

Neurons, as noted, are cells of a superepithelium and, as such, are structurally and functionally polarized to play secretory and absorptive roles and to regulate traffic in solutes and ions between the outside and inside of the body. This polarity is seen in specializations for increased surface area, in the apical location of secretory products and parent Golgi complex, in basolateral adhesive and communicative junctions, and in basal membrane peculiarities serving substrate contact.

An "epithelial blueprint" of a neuron specifies its dendritic aspect as equivalent to the basolateral surface of an epithelial cell and its axonal aspect to the apical surface. This homology requires inclusion of the axon between the supranuclear Golgi complex on the one hand and the axon terminals, where secretory (synaptic) vesicles dock and discharge their contents into the synaptic cleft, on the other. An overview of neuronal fine structure follows.

A. The Cell Membrane

The external membrane or *plasmalemma* of a neuron (Fig. 23) has the general composition of all biological membranes: a bimolecular layer of opposing phospholipid molecules, with hydrophilic phosphorylated heads at the external and internal membrane surfaces and hydrophobic chains in the water-free interior. Cholesterol, proteins, glycoproteins, and glycolipids are interspersed in the phospholipid bilayer. The lipids form a barrier to prevent ions and water-soluble molecules from entering and to retain the cytoplasm. They also provide a fluid matrix in which protein molecules lie in a fluid mosaic manner. The proteins permit selective passage of certain materials through pores, as carrier enzymes, antigens, and receptor sites for bonding neuroactive substances. The apparent uniformity of the plasmalemma is misleading. Regional peculiarities in the distribution of membrane proteins and lipids are known. The apical, lateral,

basolateral, and basal domains of the columnar epithelial cell noted previously are good examples.

B. The Nucleus

Large and either spherical, or ovoid, the nucleus lies centrally located in the soma in most healthy neurons, (Figs. 20 and 21E-21I). The nucleoplasm in large, synthetically active neurons is euchromatic (lacking dense chromatin particles), amorphous, and pale. The chromosomes in these postmitotic cells no longer replicate DNA and double themselves but engage only in gene expression as partly uncoiled, indistinct, sprawling threads. Such a configuration makes the genome easily available for transcription and reflects the constant interplay between the nucleus and cytoplasm. In small neurons, the nuclear contents are concentrated and heterochromatic clumps are seen. In humans, the *sex chromatin* (condensed, genetically inactive X chromosome of the female) lies near the inner surface of the bilaminar *nuclear envelope*. In some mammals (mouse, rat, cat), it is satellited to the nucleolus (Fig. 23). In some neurons, the nucleus is shaped irregularly, with deep infoldings of the nuclear envelope.

1. Nuclear Envelope

The *nuclear envelope* displays numerous *nuclear pores* (Fig. 23). Seemingly closed by a diaphragm, each pore is a complex of eight radial spokes and a central granule that provides a 10-nm channel. The pores permit two-way traffic of molecules of less than 10 nm by passive diffusion. Because outgoing ribonucleoproteins and incoming newly synthesized nuclear proteins require a 20-nm opening, such molecules are thought to have a signal sequence of amino acids that binds to the nuclear envelope and somehow triggers opening of the channel.

2. Nucleolus

The *nucleolus* in neuronal nuclei is prominent (Figs. 21E–21I), and there may be more than one. As in most cells, it is a rounded structure, deeply stained by basic dyes, but unreactive to the Feulgen reaction for DNA. It transcribes ribosomal RNA. Newly synthesized ribosomal subunits, together with messenger RNA (mRNA) assembled in the nucleus, then pass to the cytoplasm through the nuclear pores, traveling along actin filaments within the nucleus and microtubules once outside it.

C. The Cell Body

The neuronal cytoplasm is crowded by filamentous, membranous, and granular organelles arranged concentrically about the nucleus.

1. Neurofibrils

Neurofibrils are best seen in large neurons, but are present in almost all (Fig. 21G). With metallic-impregnation, they are thin, interlacing, silver-loving threads (up to 2 μm in diameter) running through the cytoplasm and extending into dendrites and axon. With electron microscopy (EM), three kinds of filamentous structures are seen in neurons: *microfilaments* (diameter of 3–5 nm), *neurofilaments* (about 10 nm), and larger *microtubules* (20–28 nm).

Microfilaments resemble actin filaments in other cells, e.g., muscle fibers: they are polar polymers of globular (G) actin wound into two helically arranged strands. Like microtubules, they contribute to the cytoskeleton and provide rails along which organelles and proteins are driven by molecular motors, such as myosins. Neuronal myosins are also important to the production of neuronal growth cones, the retraction of axonal processes by a neuron and extension of others, and the generation of microdomains on the neuronal surface. Neurofilaments (Fig. 23) consist of three types of polypeptide threads twisted helically in a complex fashion to look like minute tubules in cross section. Microtubules (Fig. 23) are like those in most cells (e.g., mitotic spindle fibers), with differences and spatial distributions of microtubule-associated proteins (MAPs) that regulate their stability and facilitate their assembly.

The neurofibrils of classical cytology are probably bundles of neurofilaments, which have a high affinity for silver nitrate (microtubules may also be mixed in, but are not impregnated). They form roadways in the neuron, curving around and between other organelles and inclusions. Their functions are not fully understood, but as the *cytoskeleton* they support the organelles and change the shape of the cell as a whole. In the axon, neurofilaments run parallel to the fiber and may help to maintain the gelated state of axoplasm. If extruded, axoplasm is a firm gel, but it soon becomes a sol if exposed to calcium ions, triggering proteolytic neurofilament degeneration.

Microtubules, as noted, serve cell division by forming the mitotic spindle in neuronal precursors, but not in neurons, which are largely postmitotic. Microtubules play a vital role in the *intracellular transport* of vesicles and organelles that move along their surface through the cell body and along the axon (see later discussion). They turn over constantly. Their effects on cell shape are expressed not by contraction but by length changes due to polymerization or depolymerization or by self-assembly of new microtubules of different orientation. Neurofilaments are less dynamic. In degenerative diseases like Alzheimer's, their protein structure seems modified, forming characteristic lesions known as neurofibrillary tangles.

2. Nissl Substance

Nissl substance, named after Franz Nissl, a neurologist in Heidelberg in the late nineteenth and early twentieth centuries, this organelle is also termed chromophilic substance, as in other cells. It takes the form of clumps of cytoplasmic material more or less large and conspicuous, which stain deeply with basic aniline dyes (Fig. 21H). In living neurons, they are visible in phase contrast microscopy. The Nissl bodies represent the protein-synthetic machinery of the cell. Key constituents are ribosomes; they disappear in toluidine blue preparations after treatment with RNAase. The EM (Fig. 20) shows that Nissl substance is the granular or rough-surfaced endoplasmic reticulum (rER) found in other cells, especially those that synthesize protein in large amounts. Like the acinar cells of the pancreas, which contain a spiral nebula of rER about the nucleus, neurons show orderly, distinctive arrangements of it in parallel, broad cisternae stacked one atop another like empty pillowcases (Fig. 23). Anastomoses of cisternae and fenestrations of cisternal membranes are frequent. Nissl substance is a reticulum of channels within neurons. Its external membranes are studded with rows, loops, and spirals of ribosomes, although some regions are smooth.

Ribosomes also lie free in the cytoplasm as polysomal rosettes between cisternae. Rough ER is evident in the soma and proximal reaches of dendrites, wherein it mainly appears as branching and anastomosing tubules and short cisternae. It is not seen in the axon hillock, nor in the axon itself, which contains only agranular reticulum (Fig. 23). The soma is the major site of protein synthesis.

Neurons show a broad range of protein-synthetic functions, expressing far more genetic information than other cells. Like gland cells, neurons synthesize protein substances for export. But much of that produced is for maintaining and renewing its own protoplasm: of the axon and axon terminals, of the cytoskeleton, and of the watery cytosol in which all of the organelles lie suspended.

In the early stages of synthesis of neuronal proteins, mRNA molecules in the cytosol associate with free ribosomes and link them into clusters as *polysomes*. If the products are secretory, membrane, and vacuolar system proteins (ER, Golgi complex, etc.), the polysomes attach to the outer surface of the rER, continuing to assemble amino acids into polypeptides in a mRNA-determined sequence. As the amino acids are added, the polypeptide chains elongate from the larger ribosomal subunit into the lumen of the ER. When the chains attain full length, they are released from their ribosomes. Now free within the ER, these products are eventually exported as transport vesicles either to the Golgi complex or to the cell surface. All other neuronal proteins (cytoskeletal, cytosol, mitochondrial, peroxisomal, nuclear, and other vacuolar types) are synthesized on free ribosomes.

The visibility, size, form, and distribution of Nissl substance vary greatly in neurons. These variations are important in neuropathology. Nissl bodies appear as large chunks of basophilic material in pyramidal cells and motor neurons, cells with long axons and distant terminals to maintain. By contrast, they are dispersed in powdered form in sensory ganglion cells, which also have long axons. Normally, Nissl bodies are evenly distributed in the soma and proximal dendritic regions, but in a few healthy neurons they are concentrated near the plasmalemma. Such outward dispersion usually indicates a neuronal reaction to injury, anoxia, or disease and is aptly termed central chromatolysis.

Neuronal protein-synthetic machinery is eloquently expressive of cell activity (rest, work, fatigue) and sensitive in reflecting damage to the neuron of any sort. For example, when the axon of a neuron is severed (as in penetrating wounds), the Nissl substance disappears (retrograde chromatolysis), with its deeply basophilic material becoming diffused in the cytoplasm as it labors to repair that great loss.

3. Golgi Complex

The Golgi apparatus resembles a stack of inverted saucers, but it is a smooth-surfaced network of channels and spaces. Now called the *Golgi complex*, it is always present in neurons. Impregnated with silver even more deeply than the neurofibrils, it forms a rete of wavy strands encircling or apically surmounting the

nucleus (Fig. 21E). EM resolves these strands as closely apposed, flattened cisternae in stacks, as in other cells, with many small vesicles nearby (Fig. 23). The whole lies close to granular ER, from which it receives polypeptide secretory products in the form of transport vesicles. The cisternae frequently interconnect by tubules and also have pores in register between their curved aspects.

The Golgi complex is polarized with three compartments: an internal *cis* or *forming face* near the rER, where vesicles derived from it arrive and are initially sorted and incorporated; an *intermediate compartment*, comprising the bulk of the cisternae, through which delivered proteins pass stepwise, some by continuous channels but mainly by vesicular budding and fusion; and an external *trans* or *releasing face*, from which large vesicles, *secretory granules*, are liberated. A branched web of small tubules, the *trans-Golgi network* (TGN), borders the terminal cisternae. Here, small vesicles of various types and destinations bud off and depart, following the secretory pathway leading to the plasmalemma, wherein they fuse by exocytosis.

Many modifications to secretory proteins occur in transit through the Golgi complex and TGN. These include changes aimed at concentrating and packaging them, enhancing their effectiveness, binding to other macromolecules, resisting degradation, and addressing them to destinations. The last was thought to occur in the TGN, but other evidence suggests that this may occur earlier in the complex.

Reflecting its roles in refining and distributing secretory, plasmalemmal, and vacuolar proteins in the neuron, the Golgi complex is even more sensitive to changes in neuronal activity or to neuronal injury or disease than the rER. Under such circumstances, it migrates from its normal perinuclear position to the periphery of the cell body (retispersion), dissolves (retisolution), and then reconstitutes itself during repair after injury (e.g., severance of the neuron's axon).

4. Mitochondria and Peroxisomes

These organelles are considered symbiotic invaders of eukaryotic cells early in evolution. They stand apart from the vacuolar or tubulovesicular system of cells. Mitochondria self-replicate, have a short life span, and reproduce by division similar to the binary fission of bacteria. They have their own DNA and ribosomal, transfer, and messenger RNAs, but are not self-sufficient. They rely on their hosts to code and synthesize most of their proteins. Peroxisomes are less understood: mature forms may be recruited from a precursor reticulum from which they arise by budding.

Mitochondria are minute capsules of respiratory, phosphorylative, and other enzymes; they are the "power plants" of cells, which the unresting neuron, with a great need for oxygen and glucose and low energy reserves, requires in profusion. In oxidative phosphorylation, mitochondria produce large amounts of adenosine triphosphate (ATP), the chief molecule upon which the energy requirements of electrically active neurons depend. Neuronal mitochondria are rodlike or filamentous and usually more slender than those in other cells, ranging from 0.1 to 0.8 μm in diameter. They may associate closely with Nissl bodies, but generally are ubiquitous: in the dendrites and soma (Figs. 16 and 21F), along the axon, and in profusion at axon terminals (Fig. 23). A peculiarity of neuronal mitochondria is that their cristae often lie parallel (not transverse) to their long axis: cross sections of such forms appear as concentric light and dark rings. Another feature is the paucity of electron-dense granules in their matrix. Microcinematography of cultured neurons shows that mitochondria are constantly moving: along microtubules, within the soma, between it and the dendrites, and along axons. Mitochondria have intrinsic circular DNA, but most of their protein is synthesized in the nucleocytoplasmic system.

Peroxisomes are tiny (0.2–1.0 μm), spherical, membrane-limited bodies, smaller than lysosomes and aptly (if not helpfully) called microbodies when first described. They lack hydrolases but contain oxidases, which generate hydrogen peroxide, and catalase, which detoxifies it to water and oxygen, as well as over 40 other enzymes. They produce energy by oxidizing substrates, but unlike mitochondria they cannot store it as ATP for subsequent cellular use. With few exceptions in vertebrates, peroxisomes have a homogeneous structure. Clinical interest in them derives from several inherited diseases in which there is deficiency in one or more of their enzymes or defects in their assembly.

5. The Centrosome and Cilium

The centrosome, containing a pair of centrioles, is conspicuous in preneuronal proliferative cells during early neural development. It is seldom noted in light micrographs of adult neurons but sometimes seen in electron micrographs (Fig. 28, right), usually associated with a cilium. Because adult neurons, with a few

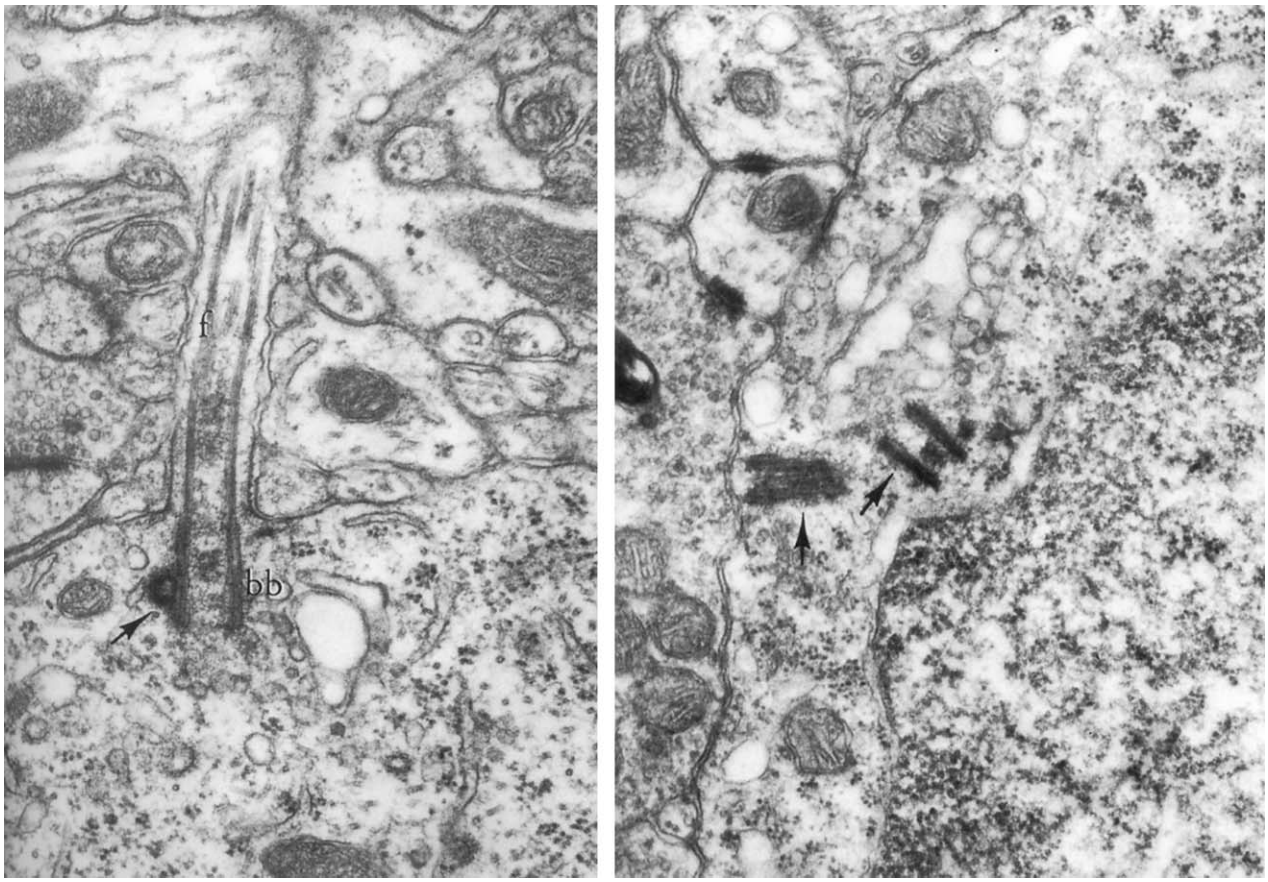

Figure 28 Cilium and centrosome: left EM shows a longitudinal section of a cilium arising from a neuron. At its base is a basal body (bb) with attached parabasal body. The microtubules in the ciliary shaft have a 9 + O configuration and continue into the basal body. Right EM shows part of the perikaryon of a cerebellar granule cell containing two longitudinally sectioned centrioles (arrows). The wall of each is formed by nine triplets of short tubules oriented parallel to its long axis. From *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells*, 3rd ed., by Alan Peters, Sanford L. Palay, and Henry de F. Webster, copyright 1990 by Alan Peters. Used by permission of Oxford Unviersity Press, Inc. (EMs from collections of authors).

exceptions that may reflect the residual presence of antecedent cell types, do not divide, the role of the centrosome is puzzling: possibly it is a nondisposable relic of the mitotic apparatus of parental cells. But the recognition of the centrosome in neurons and in other cells as the *microtubule-organizing center* gives a new perspective. A cloud of proteins surrounds the centrioles. Microtubules attach to it at their minus ends and grow from it by addition to their plus ends.

The cilium (Fig. 28, left) has nine radial pairs of microtubules, distally dwindling to eight, with short connections but no arms or spokes between them as in other cilia. Distally a central pair appears. In kinocilia it is thought to switch the other pairs from power stroke to recovery stroke. Here it seems nonmotile.

6. Neuronal Inclusions

Golden brown *lipofuscin* (lipochrome or fatty pigment) granules are found in neurons of the CNS. They are harmless byproducts of lysosomal activity, a "wear-and-tear" pigment increasing with aging. Lipofuscin may eventually displace the nucleus and organelles severely to one side of the cell body. Black *melanin* pigment is seen in certain clusters of specialized neurons. The substantia nigra of the midbrain and the locus ceruleus of the pons are the prime examples. The presence of lipofuscin seems related to the synthesis of certain catecholamines, notably dopamine. *Glycogen* is found in embryonic cells of the CNS but not adult neurons. The consequences of a lack of

energy stores in neurons are obvious. *Iron* particles are seen in some neurons of older persons. In some instances, they may represent the uptake of blood pigments in hemorrhagic areas.

D. Dendrites

These extensions of the soma contain Nissl substance, mitochondria, parallel microtubules, and a less conspicuous population of neurofilaments (Fig. 23). Components of the Golgi complex may also be seen in first-order dendrites of some neurons, especially in those with a small soma. In a given neuron they may appear in some primary dendrites and not others (some speculate that the Golgi complex slips in and out in response to unknown commands). Most of the other organelles dwindle out toward the finer branches of the dendritic tree, but the number of mitochondria remains constant or even increases, reflecting the high degree of activity in these receptive cell processes.

E. The Axon

At its origin in the axon hillock, the arrangement of structures changes between that of the soma and the axon proper (Fig. 23). The microtubules funnel into bundles, the number of ribosomes wanes, and the rER almost vanishes, in keeping with the lack of Nissl substance seen in the light microscope (Fig. 24). Beyond the initial segment, the axon contains longitudinally oriented smooth agranular reticulum, long slender mitochondria, numerous vesicles, modest numbers of microtubules (not profuse as in dendrites), many neurofilaments (but fewer than in dendrites), and microfilaments.

1. Axonal Transport

Impulse conduction is not the sole function of the axon. Macromolecules essential to structure flow from the soma down the axon. Other substances, e.g., tired axon terminal membrane requiring degradation and recycling, move up. Rates of *axonal transport* of these commodities vary strikingly; some, including newly synthesized protein for neuronal repair, move slowly, at 0.2–5 mm/day, whereas others related to transmitter synthesis travel 100–400 mm/day. Two modes of axonal transport are known: *fast*, *bidirectional* (anterograde and retrograde) and *slow*, *unidirectional* (anterograde only).

Mechanisms of axonal transport have been studied intensively. Microtubules play a critical role in fast transport. Axonal microtubules are polarized: their "plus" ends face the axon terminal and their "minus" ends the cell body. Microtubules constantly turn over; tubulin dimers are added at the plus ends and depolymerized at the minus ends. Neuronal products are shipped down the axon as small vesicles. Kinesin, a microtubule-associated protein, is the motor responsible for this transport. One end of a kinesin molecule attaches to a vesicle while a binding site on the other end interacts in a cyclical manner with the wall of a microtubule, resulting in movement of the vesicle toward the plus end at about 3 μm/s.

In *fast anterograde* axonal transport, outbound materials are membrane-bound organelles from the rER and Golgi complex, synaptic vesicle precursor membranes, large dense-core vesicles, parts of the smooth ER, and mitochondria. This transport travels along microtubules, stationary raillines and fast tracks along which shipments are moved by molecular motors (kinesin and related proteins) at high speed (100–400 mm/day). It meets the critical, unceasing needs of neurotransmission.

In *fast retrograde* axonal transport, the incoming materials are endosomes (micropinocytotic vesicles) from nerve terminals, mitochondria, and ER elements returning to the soma from axon terminals. This transport travels on microtubules as in the preceding paragraph, but at half to two-thirds the speed. The motor is a microtubule-associated ATPase similar to dynein in cilia and flagella. It provides for degradation and further recycling in cell body lysosomes of worn-out membrane components, which may have already been recycled a few times in the terminals. It also implies processing and repackaging events there, much as one must evaluate and rewrap damaged goods prior to returning to the sender.

Slow *anterograde-only* axonal transport is for cytosol proteins and cytoskeletal elements. It has two rates: slow and slower. *Slow* (rate b: 2.5–5 mm/day) conveys hundreds of polypeptides from cytoskeletal proteins (like actin) to soluble metabolic (e.g., glycolytic) enzymes. *Slower* (rate a: 0.2–2.5 mm/day) is mainly (75% of the total moved) neurofibrillary protein: neurofilament and microtubule subunits. Motors are uncertain; dynein may be one. Neurofilaments seem unable to move on their own but may hitchhike on microtubules, which can extend themselves (see previous discussion). Slow axonal transport maintains the structural and functional integrity of remote regions of the neuron: perhaps 10,000 times the diameter of the cell body away.

The mechanisms of axonal transport have been explained to a degree that is a triumph for molecular

neurobiology. Study of the perpetual movement of materials along the axon clarifies other aspects of neuronal activity, especially the regeneration of PNS axons, which takes place at about 1–3 mm/day, and the daily shipment and delivery of neuroactive substances and their precursors.

Axonal transport is vital to the life of the neuron and its communicative and neurotrophic functions. It permits rapid replacement of catabolized protein in the axon and its terminals. Most constituents of such a protein cannot be synthesized in the axoplasm devoid of rER. It permits the transport of enzymes synthesized in the soma down to the axon terminals; such enzymes are necessary for transmitter synthesis there. It permits the movement of macromolecules and other dynamic cellular components within the soma itself and out into the dendrites, which have modest protein-synthetic capability.

In retrospect, "axonal transport" exemplifies tunnel vision. "Intraneuronal transport" might have been a better way to designate mechanisms of moving materials within neurons had we known then what we know now. It permits feedback from the periphery (axon terminals and dendrites) and regulation of the metabolic activity of the parent cell body: adjusting rates of protein and enzyme synthesis or reprocessing worn-out membrane components in accord with peripheral use and demand.

Experimental benefits and some risks accrue from axonal transport. A powerful neuroanatomical method for tracing axons back to their cells of origin rests upon the uptake by axon terminals of tiny enzyme particles (the glycoprotein horseradish peroxidase) and retrograde axonal transport to the somata. There, these markers can be demonstrated histochemically as a colored, insoluble polymer. Unfortunately, retrograde transport also may convey pathogens (tetanus bacterial toxin, herpes simplex, and rabies viruses) directly to nerve cell bodies, once the microorganisms are endocytosed at nerve endings. A technique exploiting anterograde axonal transport is the autoradiographic method. Radioactively labeled amino acid is injected near a nerve cell body, taken up by the cell, incorporated into newly synthesized protein, and then transported down the axon to its terminals. There, the radioactivity can be detected by autoradiography (a process similar to photography).

2. The Axonal Myelin Sheath

Axons in CNS tracts and peripheral nerves are, to varying degrees, ensheathed by sleeves of spirally wound cell membrane derived from nearby supportive cells and compacted into a substance known as *myelin* (Fig. 18). Chemically, myelin consists of a 4:1 ratio of various lipids to proteins. In the unfixed state it is glistening white. It acts as an insulator, increasing nerve conduction velocity from perhaps less than 1 m/sec in slender, unmyelinated axons to 120 m/sec in large, well-myelinated fibers. Peripheral and central *myelin sheaths* are similar but made by different cells and in different ways. In the PNS and ANS (but not the CNS, which has no intrinsic connective tissue), the myelin sheath is additionally invested by protective, supportive, and nutritive connective tissue layers.

a. Peripheral Myelin Just beyond their exit from the CNS to near their distal endings, peripheral axons are enveloped by serially arranged, flattened neurilemmal or *Schwann cells* (Fig. 15, S_1). Newly regenerated or thin axons lie in shallow indentations of the Schwann cell surface (S_2). Such fibers are "unmyelinated." The term is misleading: they are not uncovered, but minimally myelinated. The plasmalemma of the slender bay of cytoplasm enclosing them is the same membrane, as discovered by pathologist Betty Ben Geren in 1954, that when rolled into a tight spiral of many turns constitutes the myelin sheath. Such inward spiraling of Schwann cell membrane may involve only a few turns to up to 50 or more about the axon. As the spiral is compacted, cytoplasm within it is displaced outward in the spiral toward the cell body (as toothpaste is displaced upward when the tube is rolled from the bottom) and longitudinally to the edges of the sheet, where it appears as a bead of material in paranodal loops.

The larger the axon, the more myelin layers about it. In electron micrographs, myelin has alternating dark and light lines with 12-nm periodicity. The cytoplasmic surfaces of the Schwann cell appose to form the *major dense line*, and the external surfaces form a less dense *intraperiod line* with 2-nm *intraperiod gap* separation, a cleft allowing the passage of tracer molecules. Tight junctions block the passage of larger molecules and impart strong adhesion to facing cell surfaces (like Velcro). The myelin spiral starts with a tongue of Schwann cell about the axon and continues a few more turns, when compaction begins. Yet 46 years after its discovery, how the myelin spiral forms remains an unsolved mystery.

Cordons of Schwann cells along an axon segmentally ensheath it to prevent current from leaking out. *Nodes of Ranvier*, periodic gaps of myelin (250–1000 μm apart in human nerves) between Schwann

cells, expose the axonal membrane, which has a high concentration of voltage-gated Na^+ channels. Action potentials spread electrotonically and virtually instantaneously along the insulated *internodal segments*. At the nodes (Fig. 21J), they are regenerated rapidly, but with sufficient delay to suggest that they "leap" from node to node.

b. Central Myelin Central myelin is formed similarly to peripheral myelin, resembles it in almost every way, and serves equally to speed nerve impulse conduction. In its abundance along the axons of central tracts, the darkly stained myelin sheaths seen in whole brain sections strikingly demonstrate the long-distance routes of communication in the human nervous system. Key differences are described next.

Central myelin is made by *oligodendrocytes*. By producing (by unknown means) many helical turns of plasmalemma at the tips of its processes, an oligodendrocyte makes 15–40 internodal segments on several to many axons (Fig. 21D). But whereas a Schwann cell may harbor many unmyelinated or regenerating axons around its circumference, it constructs only one internode on one axon.

Other differences in central myelin are a paucity of associated cytoplasm, periodic thickenings of the axolemma at points of contact with paranodal myelin loops, a longitudinal ridge of cytoplasm outside the spiral (instead of an enveloping ring), and the absence of basal lamina around the oligodendrocyte (a cell proper to the neuroepithelium, not needing delimitation). Connective tissue investments do not surround the myelin sheath as in peripheral nerves.

As cells that myelinate CNS axons, oligodendrocytes line up along axons in tracts or diffuse white matter as *interfascicular glia*. In human fetal and postnatal development, tracts are myelinated and thus become fully functional at different times. Motor nerve roots are well-myelinated by birth, but optic nerves and sensory roots lag behind until the 3rd and 4th months after birth, respectively. The corticospinal tracts require 1 year to achieve full myelination, whereas cerebral commissural fibers requuire up to 10 years. This staggered ensheathment has important functional correlates for the developing individual: when she or he can move, see, begin to walk, perform directed movements, and so on. One intracortical plexus is not completely myelinated until middle age: the stripe of Kaes–Bechterew in layer IIIa (Fig. 8, right panel). Neuropathologist Paul Yakovlev called it "the wisdom stripe."

c. Functions of Myelin The preeminent role of this phospholipid sheath is to greatly increase the speed of nerve impulse conduction in select nerve fibers or central pathways. It acts as a high-resistance, low-capacitance insulator, confining the ionic current set up within the axon by the action potential generated at a node of Ranvier and forcing it on to the next node, where membrane depolarization regenerates the potential. But in some neural pathways, such as in the ANS and certain central pain tracts, this high velocity may be neither necessary nor desirable. Reliable delivery and persistent arrival of impulses may be more important. Thin myelin sheaths and shared sheaths of axons by oligodendroglia and Schwann cells, respectively, meet these requirements and save precious space as well.

A putative, unsubstantiated nutritive role for myelin rests on observations that tracers pass from the outer collar of Schwann cell cytoplasm inward along tunnels of residual cytoplasm in the myelin spiral (termed "incisures" from their apparent interruption of the myelin sheath as seen in light microscopic preparations; Fig. 21J) and that these molecules later show up in the axoplasm. It is unknown whether metabolites follow this path. There are also speculations about metabolic interactions between the myelin sheath and the axon and how these might change with neuronal activity.

Other functions may exist. Myelin is not confined to axons. Somata and dendrites may be loosely wrapped in it. Myelin may be protective, assuring continued connectivity. In demyelinating diseases like multiple sclerosis, demyelinated axons conduct impulses, but less rapidly and efficiently. During remission, the improvement in conduction may be greater than the remyelination that has occurred.

VIII. SYNAPTIC ORGANIZATION OF THE NERVOUS SYSTEM

This subject lies at the heart of the organization of the human or any other nervous system. A synapse, by definition, includes presynaptic and postsynaptic membranes separated by a narrow cleft about 12–20 nm across. As noted, EM demonstration of this cleft provided definitive proof of the anatomical tenet of the neuron doctrine: nerve cells are separate. The cells that face each other across this cleft may be two neurons, a neuron and a skeletal or smooth muscle fiber, or a neuron and a gland cell (usually a smooth muscle fiber in that gland).

A. Significance of the Synapse and Dual Modes of Synapses

The synapse is a region of specialized contact between neurons or between a neuron and a muscle cell for cell-to-cell communication. The estimated number of synapses in the human nervous system is 10^{14} (100 trillion), and in light of newly appreciated synaptic diversity it may be even higher. Two modes of synapses have been identified: electrical and chemical. The first has been touched on in the discussion of gap junctions and the neuron doctrine. The second is by far the more common.

1. Electrical Synapses

Electrical synapses are gap junctions. When present between neurons, they are very different from chemical synapses where the separateness of the cells is not in question. They allow the direct spread of current from one cell to another, without delay or need for receptor and decoding systems. But the individuality of the coupled cells is partly lost, and hence their utility is diminished for large nervous systems with labeled lines like those of mammals. Electrical synapses are common in invertebrate and nonmammalian nervous systems but infrequent in mammals except between neuroglial cells, where they offer the chief mode of communication. Yet they have been found between mammalian neurons and shown to transmit in a few cases. In the embryonic CNS, they are seen in many places, even in the cerebral cortex, but decline in number as chemical synapses develop. In the adult, they are usually found in cell clusters that fire action potentials synchronously, as in the lateral vestibular nucleus, which effects a rapid increase in ipsilateral extensor tone for postural maintenance, or clusters that spread influences widely, like the horizontal cells of the retina. Studies show that electrical synapses can be modulated, that they may have mechanisms favoring unidirectional conduction, and that electrical and chemical synapses have important reciprocal influences.

2. Chemical Synapses

Chemical synapses are the standard mode of neuronal communication in mammals. Many studies have been made on their structural, functional, and neuropharmacological properties. They mediate the transfer of neuronal activity by releasing a neuroactive substance of some sort. Along with the law (usually enforced) of dynamic polarization of neurons, they help to establish the one-way traffic of the nervous system. Synapses act as turnstiles that permit activity to pass in one direction only (two-way synapses exist and are now well-known, but these are a pair of oppositely polarized synapses juxtaposed). This unidirectional feature of the chemical synapse is of cardinal importance: the other parts of neural circuits (dendrites, cell bodies, and axons) can and do, in some instances, conduct both ways. Even in the chemical synapse, important effects are exerted by the postsynaptic neuron upon its presynaptic partner (see discussion to follow). Still, the polarity of the chemical synapse largely determines the forward traffic flow seen in most routes and regions of the CNS.

B. Varieties of Synapses and General Principles of Synaptic Activity

1. Synaptic Mechanisms and Second Messenger Systems

Molecular neurobiology has bared submicroscopic details of the organization of the axon terminal and clarified the complex mechanisms of synaptic transmission. Two kinds of transmission exist: rapid and slow. *Rapid transmission* depends on transmitter-gated ion channels. *Slow transmission* relies on postsynaptic receptors (membrane-spanning proteins) linked to G (guanine-nucleotide-binding) proteins. Most postsynaptic responses are depolarizing or hyperpolarizing changes in membrane electrical potential (excitatory and inhibitory postsynaptic potentials or EPSPs and IPSPs), but some are electrically silent metabolic or membrane alterations.

In rapid synaptic transmission, the synthesis of neurotransmitter, packaging and transport in vesicles, clustering, cytoskeletal anchoring, subsequent dissociation, docking at the presynaptic membrane, fusion, release of contents upon arrival of the action potential, membrane re-uptake, and recycling are stages, fleeting or time-consuming, in a continuous and widespread process inside a nerve cell. We take a closer look at rapid transmission in a subsequent section.

In slow transmission, EPSPs and IPSPs are also produced by alterations in current flow through membrane ion channels, but a staged process occurs in which transmitter binding to a G-protein-coupled receptor leads to dissociation of a subunit of it, which then moves laterally in the membrane and exerts effects ranging from ion-channel binding and

conductance alteration to enzyme activation altering concentrations of second messengers (cyclic AMP, inositol triphosphate, arachidonic acid metabolites) to alteration of gene expression.

2. Functional Specialization of Synapses

The structural diversity of presynaptic components is great: one finds club endings, large end bulbs, small end bulbs, spiral endings that wrap around the axon hillock and initial segment of the target neuron, fibers of passage merely brushing the dendrites as they pass by, claw-shaped endings that seem to seize the cell body of a neuron or grasp a dendritic spine, extended zones of apposition of an axon and a dendrite, as in the case of the cerebellar climbing fiber, where numerous synapses are made, and other types. All of these structural variations reflect functional specialization. A synapse *en passant* allows an axon (like that of a cerebellar granule cell) to distribute its influences to multiple target cells along its course, whereas the obsessive climbing fiber ending on a Purkinje cell provides the focused protracted connectivity underlying the most powerful excitatory synapse in the human brain.

3. Spatial Distribution of Synapses

The various inputs to a neuron are distributed in a precise way on the postsynaptic cell. Virtually all neurons in the human CNS show the same location specificity: pyramidal cells, Purkinje cells, mitral cells, and motor neurons. The giant pyramidal cells in the hippocampus have perhaps the most striking *lamination of afferents*, as this input distribution is called. David Bodian, a pioneer in the study of synapses, had another term for it: *mosaic segregation*. The location of the end bulb or terminal bouton indicates the source of input, efficacy of action, and local biochemical diversity of the postsynaptic membrane.

C. Fine Structure, Elements, and Stabilization of Chemical Synapses

1. Fine Structure of the Chemical Synapse

As in the neuromuscular junction, the axon terminal typically contains a few neurofilaments, many mitochondria, and an organelle unique to neurons: the synaptic vesicle (Fig. 29). The vesicles release their contents into the synaptic cleft upon the arrival of nerve impulses in the axon terminal. The substance liberated is then recovered and recycled after exerting effects on receptor sites in the postsynaptic neuron.

2. Elements of Chemical Synapses

When the two synaptic elements are both parts of neurons (dendrites, somata, axons), several combinations are possible, with terms to match. Thus, axodendritic, axosomatic, and axoaxonic synapses are recognized. These three arrangements are the "conventional" ones dominating the field until the late 1950s.

"Unconventional" synapses (Fig. 30) were then uncovered: dendrodendritic synapses are the best known, but dendroaxonic, somatosomatic, somatoaxonic, and axoaxodendritic (serial junctions) are described. Yet the most arresting ones are *glomeruli*, which are clusters of axons and dendrites (Fig. 17). These neuronal microcosms illustrate Charles Sherrington's key principles of divergence and convergence.

3. Adhesion of Neurons and Stabilization of Synapse

An unsung type of intercellular junction in the CNS is the *punctum adherens*: a small region of close contact and adhesion between adjacent cells. It corresponds to the zonula adherens on the lateral surfaces of cells in various epithelia (e.g., the simple columnar epithelium of the small intestine). In epithelia, the role of zonulae adherentes is obvious. They bind cells together and, with nearby occluding junctions, prevent the extracellular passage of materials that otherwise would leak past them. In the CNS, puncta adherentia hold nerve cells together and stabilize their points of synaptic contact, just as soldered circuits provide such stability. Without them and with sudden movements of the head, our central circuits might come unglued, neuroglia or not.

D. Mechanism of Rapid Synaptic Transmission

Arrival of an action potential at an axon terminal causes voltage-gated ion channels to open, thereby allowing Ca^{2+} ions to enter the terminal. Within 100 μsec, their presence triggers quantal release of neurotransmitter into the synaptic cleft by exocytosis

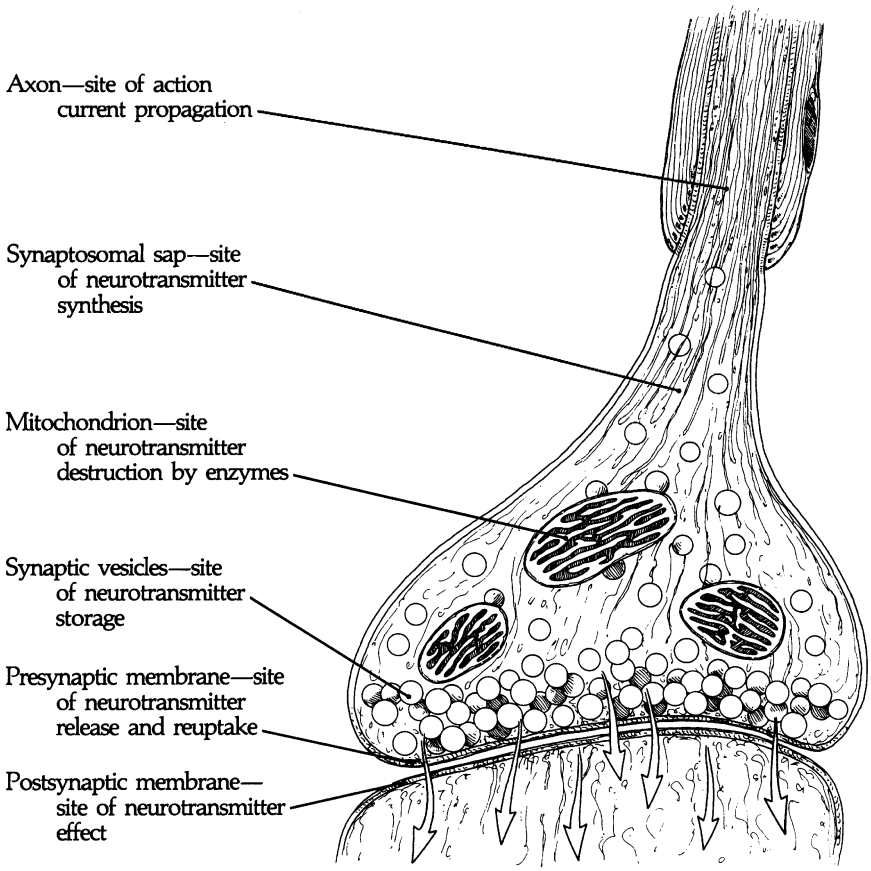

Figure 29 Chemical synapse: an axon terminal typically shows a few neurofilaments, many mitochondria, and numerous synaptic vesicles. These spherical organelles, unique to neurons, are found attached to the actin cytoskeleton in relatively large numbers or in smaller numbers released to positions of readiness or docked for immediate use at the presynaptic membrane. They release their contents into the synaptic cleft (12–20 nm wide) by coalescing with the plasma membrane upon the arrival of nerve impulses in the axon terminal. Following release, transmitter diffuses across the cleft and binds to specific receptors in the postsynaptic membrane. These receptors undergo immediate conformational change that leads to the opening of channels so as to alter the permeability of the membrane to certain ions, thus changing the membrane potential. After release, presynaptic membrane is taken up by endocytosis and synaptic vesicles are reloaded with locally synthesized transmitter. From J. B. Angevine, Jr., Dendrites, axons, and synapses, *BNI Quarterly*, Vol. 4, No. 2, 1988 (illustration by Steven J. Harrison).

from synaptic vesicles docked in the active zone of the synapse. This exocytosis is far more rapid than anywhere else. It is virtually instantaneous, probably because a subset of vesicles is already docked at the *active zone* (where the presynaptic membrane appears thickened) and evanescent fusion pores form between the vesicles and the presynaptic membrane. The transmitter diffuses directly across the synaptic cleft and binds to specific receptors in the postsynaptic membrane. The receptors undergo conformational changes that open ion channels, resulting in depolarization and excitation or hyperpolarization and inhibition of the target cell. By this time, all of 200 μsec has elapsed.

Within the axon terminal are two pools of synaptic vesicles: a relatively small releasable pool from which vesicles fuse with the presynaptic membrane when the action potential arrives and a larger reserve pool in which vesicles are bound to the actin cytoskeleton and mobilized as required. After transmitter release, membrane is taken up by endocytosis and vesicles are reloaded with transmitter synthesized locally from precursors transported to the terminal by kinesin-mediated axonal transport. As for the transmitter just released, its molecules must be removed quickly after receptor binding to prepare the postsynaptic membrane for new releases. Removal may be performed in one or more ways, acting in concert or in combinations

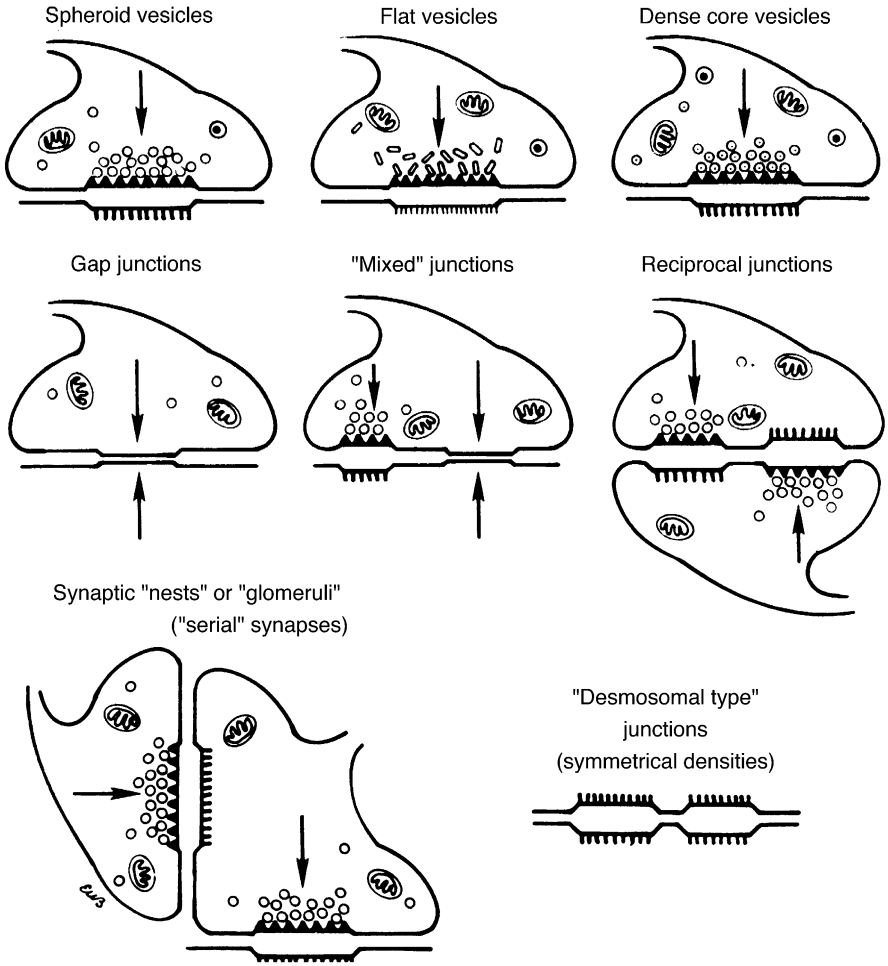

Figure 30 Synaptic variety: until the late 1950s, chemical synapses of axodendritic, axosomatic, and (later) axoaxonic types dominated the field of neurobiology. These familiar synapses were considered "conventional." But by 1972, many "unconventional" junctions had been recognized. That year, David Bodian reviewed these "unconventional" coupling paradigms. He included the intriguing glomeruli: many of these are problematic, but some exemplify, in a reductionist manner, Sherrington's key principles of divergence and convergence in the organization of brain circuitry. The desmosomal type junction shown is a punctum adherens (plural: puncta adherentia), a small region of contact and adhesion between neurons corresponding to the zonula adherens found on the lateral surfaces of cells in various nonneural epithelia (e.g., simple columnar epithelium of the small intestine). See also text. From Neuron junctions: A revolutionary decade, D. Bodian, *The Anatomical Record*, copyright 1972. Reprinted by permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc. (illustration by Elinor W. Bodian).

peculiar to a given synapse: enzymatic inactivation, reuptake by the axon terminal, uptake by a nearby astrocytic process, uptake by the postsynaptic region of the target neuron, and simple diffusion away from the synaptic cleft into the extracellular space, which although narrow in the CNS (2–4 nm) would allow some movement of transmitter molecules away from the cleft. It is too slow, however, to be an effective mechanism by itself.

E. Overview of Synaptic Transmission

Synapses vary in their mode of action (electrical or chemical), form and ultrastructure, number and specified laminar organization on postsynaptic neurons, types and rapidly increasing numbers of chemical messengers (now including gases and growth hormones), functional effects, and affiliations with the neuroglia.

We have noted puncta adherentia: sticky spots that hold neurons together and make fast their synapses. They are widely distributed in the nervous system, prominent between astrocytes, and evident *everywhere*: between dendrites, cell bodies, dendrites, and axons, dendrites and cell bodies, axon terminals and axon initial segments (at axoaxonic synapses), axon membranes and their sheaths, and neuronal processes and astrocytes. The larger *zonula adherens* is seen between the lateral surfaces of ependymal cells, cells of the choroid plexus, and the subventricular tanycytes. Although these surface specializations play purely adhesive roles, they are often seen close beside synapses, chemical or electrical, and at nonspecific sites. Some see the *active zone* of a synapse, the site of transmitter release, as a modified zonula or punctum adherens. Unlike these symmetrical adhesive junctions, a chemical synapse has become structurally and functionally *asymmetrical* and, hence, polarized. If this is true, the site of transmission and permanence of place of neuronal communication evolved from simple adhesive junctions found universally in epithelial tissues.

Three key points on neuroactive substances: First, *multiple* transmitters and the *corelease* of transmitters seem now to be the rule for neurons. Second, a given transmitter may elicit *different* functional effects in different situations. Third, the effect of a neuroactive substance on its target cell depends *exclusively* on the postsynaptic receptors to which it binds.

IX. THE NEUROGLIA: BACKUP ELEMENTS OF THE NERVOUS SYSTEM

The peculiar branched, diversified cells of the neuroglia outnumber the 100 billion neurons 10–50 times, making up half the volume of the CNS. Though largely held together by means common to epithelia (puncta adherentia), neurons lie in a sea of glia. These chiefly (maybe entirely) ectodermal derivatives are not just supportive cells, though they offer mechanical support during neurogenesis and in adulthood. They are metabolically active cells that assist neurons in the performance of their communicative and integrative functions.

A. Categories of the Neuroglia

Five major categories of the neuroglia are generally recognized (Fig. 15).

1. Astrocytes

Although two major types exist, astrocytes show extreme variations in size, shape, and relationships with other structures. The Bergmann astrocyte or candelabra cell of Golgi is extreme in all three respects. *Protoplasmic astrocytes*, found mainly in gray matter, have a stellate cell body with many branching processes (Fig. 15, PA). Some of these terminate on blood vessels as end feet. Sometimes the soma itself lies against the vessel. Astrocytes near the surface of the neuraxis send similar processes to the pia mater, beneath which their end feet are apposed, fastened by puncta adherentia and displaying gap junctions. Taken together with the overlying pia, this barrier is the *pia–glial membrane*.

Protoplasmic astrocytes, as their name implies, have abundant cytoplasm with a generous number of organelles and a large, pale nucleus that helps to distinguish them from other glial cells and nerve cells in dye-stained preparations. Smaller examples lie close to neuronal cell bodies as satellite cells. *Velate astrocytes* (Fig. 21C) extend thin veils between neurons and their processes and in the case of the Bergmann astrocytes, partition input to neurons.

Fibrous *astrocytes* are found mainly in white matter, but some regions of the periventricular gray matter also show them (Fig. 15, FA). They have the familiar euchromatic nucleus and a soma with relatively few organelles: long, thin, smooth processes that branch infrequently and extend to blood vessels and the pia with end feet like the protoplasmic forms. As noted, CNS blood vessels and the subpial border of the neuraxis are surrounded by basal lamina. Protoplasmic and fibrous astrocytes may be a single cell type, varying in form in different locales, or two distinct subtypes; more study is necessary. The former expand into whatever space is available, and this may account for their irregular outline.

The shapes of astrocytes are shown, not in dye-stained material but by special metallic impregnation techniques, along with cytoplasmic fibrils, which are numerous in the fibrous type, less so in the protoplasmic type, and highly variable in number within the cell and regionally. In the EM, glial fibrils are resolved as bundles of slender intermediate filaments. Unlike neurofibrils, they are thinner (8 nm) and packed more closely. Chemically they are distinct, consisting of *glial fibrillar acidic protein* of 51,000 Da molecular weight. GFAP is specific to astrocytes, and antibodies to GFAP selectively stain and identify these cells in tissue preparations and cell cultures. The high content

of astrocytic fibrils accords with their supportive functions.

2. Oligodendrocytes

Oligodendrocytes resemble astrocytes and may be related to them, but they have fewer processes, which branch infrequently (Figs. 15, Ol and 21D). The soma is small and the nucleus distinctive. It is much smaller than the large, pale nucleus in astrocytes: round, heterochromatic, and deeply staining. The dense cytoplasm also stains darkly because as it is rich in rER and free ribosomes, with a conspicuous Golgi complex and many mitochondria. This dusky quality is perhaps the most characteristic feature, as striking in the EM as in dye-stained sections. Oligodendrocytes are usually the darkest cells around.

Interfascicular *oligodendrocytes* make and maintain central myelin (see preceding discussion). In white matter, they lie in rows between bundles of axons (Fig. 15, Ol). In gray matter, *satellite oligodendrocytes* closely associate with nerve cell bodies. The relationship is unclear. EM shows a smooth zone of apposition between glial cell and neuron, with nothing to suggest what transpires between them. Oligodendrocytes in culture show shallow rhythmic pulsations. The significance of such activity is not known.

3. Microglia

The *microglia* comprise tiny cells throughout the CNS (Fig. 15, M). Resembling oligodendrocytes, they are even smaller and darker, with dense oval, elongate, or triangular nuclei, meagre somata, and short tortuous processes with minute pointed thorns (also found on the soma).

The embryologic origin of the microglia is disputed. Most believe they are of mesodermal origin, invading the young CNS with the blood vessels. In context, the mesoderm in question derives from the neural crest: cells at the crests of the neural folds that break free to enter the mesodermal compartment at the time of neural tube closure. These cells undergo ectomesenchymal transformation. Accordingly, many embryologists characterize them as ectomesoderm. Almost taken up in the CNS, at the final moment they depart, differentiate, and rapidly migrate away to form a host of derivatives, including dorsal root ganglion cells, autonomic ganglion cells, and Schwann cells, i.e., peripheral neurons and glia. Thus, it may be that the microglia are not invading the young CNS, but coming home.

Others favor hematopoietic origin of the microglia, citing blood-borne mononuclear cells derived from bone marrow. Most neuropathologists recognize this added source of macrophages after brain insult. If vessels are damaged (they usually are), both the resident microglia and monocytes from the blood participate in repairs. Microglial cells proliferate, enlarge, and become puffy and phagocytic, clearing away cellular debris and ingesting products of degenerating myelin. Blood-borne macrophages do the same. The term *microglia* has been suggested for the minimally active resident population and *phagocytes* for cells responding to insults. The latter is appropriately noncommittal. Phagocytes may derive from the microglia, circulating monocytes, capillary pericytes, and outlying connective tissue. A third origin that has been postulated is that microglial cells arise from the same neuroepithelial stem cells that give rise to the macroglia: the astrocytes and oligodendrocytes.

4. Ependymal Cells

Ependymal cells line the brain ventricles and central canal of the spinal cord (Figs. 15, E, and 19). They arise from the pseudostratified neuroepithelium from which neurons and neuroglial cells originate. That surface is ciliated here and there, and some cilia are seen in the ependyma. They form an apparent simple cuboidal or columnar epithelium with microvilli and occasional cilia, but in fact the bases of certain cells taper into long, slender, outward processes.

In the embryo, some processes reach the surface of the neuraxis, establishing end feet there or on nearby capillaries. Later, they shorten and ultimately disappear, ending somewhere in the neuropil. Where the CNS wall is thin, as near a choroid plexus, they extend the whole way between central canal and pia, expanding into end feet that collectively make up a thin, smooth, external limiting membrane under the pial surface. Shorter processes entangle with those of astrocytes in a dense subependymal layer, the *internal limiting membrane*, close beneath the ventricular surface.

Modified ependymal cells are found in the choroid plexuses and third ventricle. In the former, they form a simple cuboidal secretory epithelium, with moderately extensive rER, many mitochondria, and irregularly oriented microvilli at their free surfaces, some with bulbous expansions at their tips. In the latter, *tanycytes* have processes extending into the hypothalamus to end near neurosecretory cells and the capillary plexus of its portal circulation. Their function is uncertain. They

may transport hormones in the CSF to these neurons to regulate the release of adenohypophyseal hormones into the portal system or from these neurons into the CSF.

5. Satellite Cells and Schwann Cells

The Schwann cell arises from the neural crest cell population that leaves the closing neural tube. As noted, it invests peripheral axons, forming and maintaining their myelin sheaths (Fig. 21J). These cells are crucial to nerve regeneration. With assistance from macrophages, they clean up debris from degenerating axons and myelin and, in cordons, guide axonal sprouts peripherally. Schwann cells, along with endoneurial and epineurial collagen and elastic fibers, provide structural support and limited elasticity to axons, which are subject to stretch during limb movements. Other functions include collagen synthesis during development and presentation of endogenous antigens to lymphocytes in autoimmune peripheral nerve disease.

A satellite cell (Fig. 15, S_3) is a type of Schwann cell that is more rounded than its counterpart and apposed to the soma of a sensory or autonomic ganglion cell. Like the satellite oligodendrocyte in the CNS, it seems to play sustaining functions, but little is known about either. In the ganglia of the VIIIth cranial nerve, satellite cells myelinate the bipolar cell bodies as well as the axons. The number required is proportional to the surface area of the soma. The ratio is fairly constant, whatever the neuronal size. One satellite cell may partially encircle the axon as it exits, so that the same cell may cover part of the cell body and part of the axon. Whether one cell type or two, Schwann and satellite cells are considered the neuroglia of the PNS.

B. Functions of the Neuroglia

1. Physical Support

We have noted the physical support afforded PNS nerve fibers by Schwann cells. In the adult CNS, astrocytes form an elaborate framework in which the neurons and their processes are deployed in an intricate, regionally distinctive way. Astrocytes have a robust cytoskeleton dominated by GFAP intermediate filaments, with many actin filaments and microtubules. They are ideal candidates for structural support. Similarly, radial glia in the embryonic neural tube support and maintain the patency of its lumen. Fluid pressure therein is crucial to normal forebrain development. Astrocytes derived from the radial glia may serve a similar function for the ventricles of the adult brain.

2. Parcellation of Input

In this astrocytic labyrinth, inputs are often individually enveloped and isolated from one another. In electron micrographs, wherever a neuron or a neuronal process is not engaged in a synapse, it is frequently enveloped by the somata or processes of glial cells. Yet exceptions are easily found. Small unmyelinated CNS axons are virtually bare, brushing by other neuronal and neuroglial elements. The extent of coverage of neurons varies greatly too, from heavily draped motor neurons and Purkinje cells, where only specifically directed axons effecting synapses attain surface contact, to almost bare neurons in the cerebral cortex bounded by few or no astrocytic processes (Fig. 16).

The distribution of astrocytic processes appears neither random nor to provide only mechanical support and nutrition to neurons. Cajal held that they are always disposed to prevent the contact of neuronal processes at points other than those suited to specific circuits. His belief is supported by electron microscopy. Sanford Palay and Alan Peters suggest that astrocytes ensure that terminals act in a discrete and localized manner. Each neuron has a distinctive pattern of glial investment suited to its pattern of synaptic connections. Velate astrocytes may play this role in the neuropil. A multineuronal, polysynaptic glomerulus is always heavily guarded by astrocytic sheets in instances forming capsules several layers thick. Thus, by isolating the diverse input converging on a neuron, astrocytes seem to play a key role in the communication functions of the nervous system.

3. Occupation of Injured Areas and Vacated Synaptic Sites

Astrocytes comprise a major part of the limited resources available to the CNS for responding to damage or disease and subsequent repair. Astrocytes or their precursors multiply in a mysterious manner. Mitotic figures are never seen; hence, the process of division is said to be *amitotic*. As a result, an increase in astrocyte number occurs along with an enlargement of cell size. Collectively, this hyperplasia and hypertrophy constitute *astrocytosis*. The hypertrophy involves both cell bodies and processes and is usually accompanied by *astrogliosis*: enlargement and excessive

production of astrocytic fibrils. Astrogliosis can also occur without hypertrophy, especially in chronic diseases, but here we focus on the destructive injury of brain tissue. Hence, the astrocyte responses are secondary to the degeneration of neurons and myelin, however caused.

4. Presynaptic Glial–Neuronal Interaction

The rapidly emerging chemical and molecular complexities of synaptic transmission are beyond the scope of this entry. But the processes of neuroglial cells, especially astrocytes, are usually on site at synapses, in some cases almost everywhere and in others less so. The intimate participation of these cells, not just in supportive, shielding, and inactivating roles but in chemical interplay with interacting neurons, is striking. Presynaptic interaction is seen in many of the synapses currently described.

5. Regulation of Electrolytes and pH in CNS Extracellular Space

As noted, astrocytes are connected by numerous gap junctions, permitting electronic coupling and passage of small molecules, especially ions. This feature enhances their spongelike ability to take up unwanted elements from the limited extracellular space in the CNS. Regulation of potassium ions therein is critical, because potassium ions could otherwise reach values incompatible with normal synaptic activity. Other significant astrocytic regulation involves extracellular pH by removal of CO_2.

6. Transmitter Reabsorption

We have already emphasized the necessity of rapid removal of neurotransmitter molecules after neurotransmission and described five ways in which this imperative could, and may in some cases, be done. One of these is uptake by astrocytic processes. The presence of these around synapses, in places close and in others not distant (see preceding discussion), facilitates the regulation of transmitter uptake and inactivation of synaptic activity. The entities removed by these processes are transmitters (notably glutamate, but including GABA and serotonin), ions (notably K^+), and toxins (e.g., metals).

7. Phagocytosis

As described, the cells of the microglia are the major in-house scavengers of the CNS. They may be reinforced by blood-borne macrophages. Astrocytes also seem to be capable of phagocytosis in situations, such as in degenerating optic nerves, where scar tissue prevents access by other phagocytotic cells. In the PNS, the ubiquitous Schwann and satellite cells play a major role in ingesting axonal and myelin fragments, supplemented by nearby connective tissue histiocytes (phagocytes) and hematogenous monocytes.

8. Participation in Neuroendocrine Regulation

Many functions are postulated for ependymal cells, as well as for intraventricular nerve endings lying between them and at the free surface. Ependymocytes seem to play roles in relation to the CSF: stir it by ciliary action, remove debris, microorganisms, and alien cells by adhesion to a cilium-borne lectin, produce the subependymal layer of the adult, which serves as a continuing source of neurons and neuroglial cells, possibly support the ventricular wall and maintain its patency, and provide sensory and secretory functions. As noted, the tanycytes in the basal third ventricle may play one or more of several neuroendocrine roles: transport hormones in the CSF to hypothalamic neurons to regulate the release of hormones into the portal system or carry them from these neurons into the CSF.

9. Myelination of Axons

Ensheathment of axons, by oligodendrocytes centrally and Schwann cells peripherally, to enhance nerve impulse conduction velocity in some or save space in bundling others was reviewed earlier.

10. Induction of Barrier Properties in Capillary Walls

Blood–brain barrier properties are encouraged by cells in the developing brain. Fenestrations and loose association of endothelial cells are obtained when the CNS is vascularized, but these properties are unsuited to CNS homeostasis. Thus, the windows shortly disappear and tight junctions begin to form. In tissue culture, these refinements are shown to require the presence and influence of brain tissue. The cells exerting these influences could be neurons, oligodendrocytes, or astrocytes, perhaps two of these, or all of the above. Through their processes and end feet upon the outer surface of blood vessels, astrocytes in some way appear to induce, along with other cells of the CNS, capillary endothelial barrier properties.

Together with cAMP agonists, they increase the interdigitation and total area of endothelial cell tight junctions.

11. Developmental Guidance of Neuronal Migration

The neuroglia are crucial to CNS histogenesis. Primitive glial cells, the radial glia, provide a structural scaffolding for migratory young neurons. Their migration involves translocation of cell bodies along a pre-existing neuronal process: *outward*, as for neurons leaving the ventricular zone for the cerebral cortex, or *inward*, as for cells of the transient external granular layer of the cerebellar cortex. These descend along inward processes past the Purkinje cell layer into the internal granular layer. In the developing cerebral hemisphere, the distances involved may be great (3000 μm in the case of the neocortex in primates). Hence, glial guidance and assistance are necessary, as follows.

Migrating young neurons shifting their somata outward in the intermediate zone of the hemisphere are apposed to radial glial fibers. At its leading and trailing processes and at its bipolar cell body, a neuron may partly encircle the vertical glial shaft (like someone climbing a rope, wrapping arms and legs around it and hugging it tightly). At such points, interstitial junctions are seen: widening of the space between, with filamentous material in it. Arrangements for descending cerebellar granule cells are similar: neuroglial contact guidance for neurons. This assistance is much enhanced by *astrotactin*, a glycoprotein neural receptor offering control of cell position along the radial fiber system.

12. Release of Neuronal Growth Factors

As noted, astrocytes produce growth factors, which may act alone or in combination to regulate the structure, proliferation, differentiation, and longevity of neurons and the development of astrocytes and oligodendrocytes and their functions as well. The organizing principle emerging is all too familiar: unified function of the cellular elements of the human nervous system.

13. The Dark Side of the Neuroglia

The neuroglia gives rise to mitotically dysfunctional forms. It has ghastly potential for abnormal growth. Glial cells (especially astrocytes, but also oligodendrocytes and ependymocytes) can wreak havoc in the CNS. Excepting metastatic cancer, these intrinsic elements of the brain comprise the largest source (50–60%) of primary brain tumors.

The neuroglia is a central topic of neuropathology. Glial tumors are now confronted by remarkable advances in treatment, stemming from molecular biology, genetics, immunology, and other fields. Reactive changes of the various glial cells, especially increased numbers of astrocytes and their fibers and the swelling of oligodendrocytes, follow almost every type of brain disease or injury and, in addition to playing phagocytic and reparative role as described, provide key early indications of abnormality. These warning signs have mainly been noted postmortem. But they can be detected or inferred from modern brain imaging and during neurosurgical procedures on the brain. Someday, we may have some high-technology methods of detecting these subtle reactions before it is too late.

X. CONCLUSIONS

The human nervous system is similar in cellular elements, structure, function, and basic plan to the nervous systems of all vertebrates, especially those of its fellow mammals. This article has highlighted many organizing principles of the human nervous system: anatomical pervasiveness, physical and functional coherence, centralized organization, structural specialization, use-designed components, phyletic uniformity with versatile adaptability, inherent plasticity, and recourse to chemical messengers (diversified neuroactive substances that perform short- and long-range tasks). These generalizations afford perspective and context for more complex principles and bewildering details.

In documenting these, this article has overviewed the three major divisions of the human nervous system, its seven principal CNS regions, its major neuronal and neuroglial subpopulations, and its diversified cellular, subcellular, and molecular features.

As is apparent, the structure and organization of the human CNS are multifaceted and complex. Those concerned with functional circuitry seek to discern the fine details of the pathways serving specific functions and unite these with the neuroanatomy described earlier. Certainly, the major pathways are defined at an anatomical level, but what remains is the integration of anatomy with function. In this task,

we must consider models of brain organization and bring these together with real structures and real connections.

First, the *linear* model. Stimuli are processed in a *pathway-specific* manner: like a road map. This is classical neuroanatomy. Whatever model pre-vails, this one will always be valuable, in the clinic and in the grand history of neuroscience before anyone recognized this supreme discipline or called it that.

Second, the multiple pathway concept, the *lens model*, of neural processing, converging on a single endpoint. Particular stimuli can select many pathways and still arrive at common endpoints. These features embody the concept of *focused output*, where the pathways are several but the output convergence points obligatory, e.g., as in recovery of function after brain damage and probably in several neurodegenerative diseases.

Third is the *network* model. It is the most versatile, addressing functional neuroanatomy in terms of probabilities and multiple cross-communicating pathways that develop a *consensus output* but nonetheless activate many outputs and options. A particular stimulus may be processed over many pathways and arrive at several outcomes, depending on variables not well-understood.

All of these models, and perhaps others, are valid. All apply, both to discrete stimuli and to output transformations. Neuroscientist Carl Cotman observes, ''Functional neuroanatomy posits we know the basic circuits. From these we elucidate pathways serving function, covering a range from normal sensory activity to the neuronal plasticity operational in brain damage and disease. It is unlikely that one model will be involved in or satisfy all computational transactions of the human nervous system, nor adequately explain them.''

From what we know of the seamless interplay of neurons, neuroglia, the central and peripheral regions, functional subsystems, chemical substances, and non-neural components of the human nervous system (notably its autoregulatory vasculature), it may be that many models of the widest sort will come together, if and when we have an explanation of the human mind.

Neural Networks

PAUL SAJDA
Columbia University

GLOSSARY

action potential Also called a "spike," the all-or-none response elicited by a neuron, the frequency of which depends upon the total input to the neuron. A sequence of action potentials is called a "spike train."

binding problem The problem of how activities of neurons, which are distributed across the brain, are linked to represent the same object.

compartmental model A biophysical model of a neuron based on a series of circuit elements representing passive and active electrical properties of cell membranes.

credit-assignment problem The problem of determining the contribution of each neuron and connection weight to the output of the network.

emergent computation Computation resulting from the interactions of many neurons within a network.

objective function The function that is optimized in training artificial neural networks and usually includes a term related to the error of the network.

supervised training A training procedure that is based on a set of exemplars composed of sample input data and the correct or desired output—"truth data." The error between the actual and desired output is directly incorporated into the objective function.

synapse From the Greek word "to clasp," the location of electrochemical communication between connected neurons. In artificial neural networks synapses are represented by connection weights.

unsupervised training A training procedure that does not rely on labeled "truth" data. Often used in data clusters and the construction of associative memories.

Neural networks are interconnections of simple units, called neurons, capable of computing complex functions. Hallmarks of a neural network are nonlinear response properties of single neurons, a high degree of interconnectivity between neurons, and adaptation and learning of connectivity and associated parameters. Neural networks are often divided into two general classes, biological and artificial, though this is less of a dichotomy than a spectrum. In the strictest sense, a biological neural network is a network comprising real neurons (i.e., constructed from living neural tissue) and found within a biological nervous system. Models of biological neural networks have been developed that abstract and simplify, at some level, biological realism in order to study a specific aspect of the network or reduce it to the hypothesized key elements underlying its behavior. These models are termed biologically based neural network models, though they do not capture all the complexity of the real biological system. As the level of abstraction increases, the tendency is toward less of a direct link with neurobiology. Artificial neural networks lie at the end of the spectrum at which mathematical description and compactness become more important than biological plausibility. Nonetheless, much of the research in the world of artificial neural networks has, at its origin, the study of biological neural networks. Computer models of both biological and artificial neural networks have been employed in the study of brain function, as well as in the development of "brainlike" systems

for prediction, recognition, and control in real-world environments.

I. THE NEURON AS A BASIC COMPUTATIONAL ELEMENT

In some sense, neurons in a neural network play the same basic computational role that transistors play in a digital computer, though they are far from isomorphic, e.g., the method of computation and the representation of information are quite different. The concept of the neuron as a basic unit in the nervous system has at its origins the "neuron doctrine," which was formulated by Wilhelm Waldeyer in the 1890s and is largely based on the seminal neuroanatomical work of Santiago Ramon y Cajal and the nerve cell stain discovered by Camillo Golgi, both of whom shared the Noble prize in 1906. The neuron doctrine states that the nervous system is composed of discrete units or cells, called neurons, which are both structurally and functionally discrete, having their own cell membranes and functioning as a fundamental signaling unit. Further, the doctrine states that the connection between these discrete units is highly specific. At the time, this was in contrast to competing theories that hypothesized the nervous system as a syncytium or as an amorphous collection of cell bodies that essentially share a common cell membrane, implying no real connection specificity. The neuron doctrine has been important in establishing the currently accepted definition of a neural network, namely, that discrete units can be connected in highly specific ways to enable complex behaviors in biological and artificial nervous systems.

There are several hundred types of excitable nerve cells in the cerebral cortex, some of which have differences in their biophysics of computation. Most classes, however, have similarities related to the nature of information flow within and between neurons, their input–output characteristics or transfer function, and the coding and representation of information.

The biophysical basis of information flow within a neuron rests in the dynamics of ionic concentration gradients. Biological neurons are described as having a set of neural processes, which include their dendrites

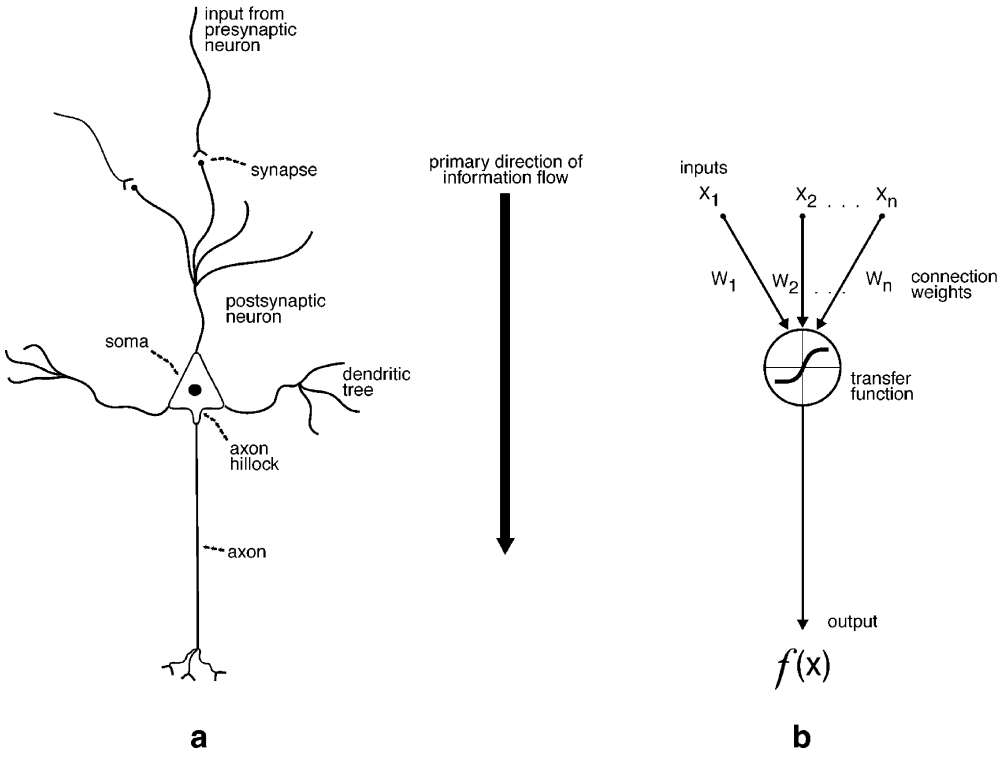

Figure 1 Modeling a neuron: (a) biological neuron, including neural processes, (b) artificial neuron.

and axon, as shown in Fig. 1a. Ionic gradients across the cell membrane produce voltage changes that propagate down the neural processes. The voltage changes are typically graded until they reach the soma where, at the axon hillock, they sum and generate, with some probability, an all-or-none response, termed a spike or an *action potential*. Action potentials travel down the axon until they reach *synapses*, where they induce the release of a neurotransmitter. There are many types of neurotransmitters, however, two of the most prominent in the brain are glutamate and gamma amino butyric acid (GABA). Neurotransmitters are often characterized by whether they excite or inhibit the postsynaptic neuron, with glutamate being excitatory and GABA being inhibitory. Neurotransmitters diffuse across the synaptic cleft and bind to the cell membrane of a neighboring neuron. Binding of neurotransmitter changes the conductance of ionic channels so that a voltage change is induced in the postsynaptic cell. At the synapse, the transduction of the electrical signal (voltage) to a chemical signal (neurotransmitter) and back to an electrical signal can amplify or attenuate the signal received postsynaptically, depending on the strength of the synapse. This ''synaptic weighting'' plays an important role in the input–output characteristics of a neuron as well as being important for learning and adaptation. The postsynaptic voltage travels down the dendrites of the second neuron and, in this way, information is communicated between the two neurons.

Information flow is thought to be primarily in the direction from the dendrites to the soma (cell body), down the axon and finally across synapses to other neurons. The concept of unidirectional information flow in a single neuron has been an important element of many artificial neural network models, although more recent experimental evidence has shown that the neurobiology is more complex. For example, there is evidence that action potentials propagate back through the dendrites. This backpropagating signal can be important for different types of adaptation and learning, including long-term potentiation (LTP) and Hebbian learning, as will be discussed later.

Neurons are interesting computational elements because of the nonlinear way in which they transform their inputs. From a purely computational point of view, complex behaviors and functions can only be computed if there is a source of nonlinearity in the information processing flow, e.g., to implement multiplication requires a nonlinearity. Warren McCulloch and Walter Pitts in 1943 formulated a nonlinear model that is a binary device, with the output of the neuron being either 1 (''on'' state) or 0 (''off'' state). The state of the McCulloch-Pitts neuron, as it became called, is determined by the synaptic input mediated by both excitatory and inhibitory synapses. The neuron transitions to the ''on'' state if the sum of its excitatory synaptic input is greater than a threshold value and no inhibitory synapses were active, otherwise it transitions to an ''off'' state. The work of McCulloch and Pitts was one of the first attempts to understand the computational properties of the nervous system through consideration of the nonlinear properties of single neurons.

The McCulloch–Pitts neuron, though having some interesting computational properties, was far removed from the neurobiology and biophysics of real neurons. In biological systems, nonlinearities are the norm, so it is important to consider which nonlinearities in real biological neurons are utilized for computation. In the 1950s, Alan Hodgkin and Andrew Huxley's Nobel prize winning work describing the properties of excitable cells began to shed light on this question. By using the giant squid axon as their subject, Hodgkin and Huxley demonstrated how action potentials are generated by the nonlinear properties of voltage-dependent ion channels in the cell membrane. They modeled this complex physiological behavior by using a set of coupled differential equations, fitting the parameters of their model to experimental data. The Hodgkin–Huxley model is still widely used for modeling biologically based spiking neurons.

Though there are other sources of nonlinearity in biological neurons, the Hodgkin–Huxley model is important for establishing the nonlinearity of action potential generation. The relationship between a neuron's postsynaptic potential (i.e., its input) and the generation of action potentials is often termed the neuron's transfer function. The transfer function determines how a neuron will map its input to an output. To simplify things mathematically and to focus more on the computation of entire networks rather than individual neurons, the biophysically based model of Hodgkin and Huxley has been abstracted in various ways to yield a variety of transfer functions. One such abstraction is the ''integrate-and-fire'' neuron. The basic biophysical mechanism governing the behavior of an integrate-and-fire neuron is the change in membrane voltage due to injection of a current, for example, at a synapse. In the integrate-and-fire neuron, the membrane essentially acts like a capacitor. If enough current is injected into the cell, the voltage will increase until it reaches a threshold, at which time an action potential is generated, the

membrane potential resets, and all of the charge is dissipated. The integrate-and-fire neuron can be made more realistic by adding a resistance into the membrane equation, allowing for the leakage of current that is observed in real neurons. These models are termed leaky integrate-and-fire neurons.

Even simpler models ignore the finer temporal information of individual spikes and condense a sequence of spikes—the spike train—into a single number called the firing rate, which represents the number of spikes generated by the neuron over a given time interval. The advantage of this abstraction is that the transfer function, which captures the relationship between input and firing rate, can be represented accurately by classes of functions with nice mathematical properties: such as, they are continuously differentiable. One such class of function is the sigmoid. For these model neurons, shown in Fig. 1b and often used in artificial neural network models, the firing rate encodes the information represented by the neuron and all information related to spike-timing is lost, e.g., when a spike occurred relative to some other spike. In biological neural networks, firing rates of a population of neurons are believed to be used for encoding movement direction. The population vector response in the primate motor cortex, first observed in the monkey by Apostolos Georgeopoulos, has each neuron encoding a movement direction. The monkey's intended movement can be predicted from the sum of the neurons' direction vectors, each weighted by their relative firing rate.

In more recent years there has been considerable debate on whether firing rate or spike timing is the more optimal coding–representation strategy. For example, humans can recognize familiar objects in 150 ms, which corresponds to <25 ms per processing stage between retina and cortical recognition areas. The biology thus dictates that each processing stage must be capable of integrating and responding to the initial wave of arriving spikes without requiring additional processing iterations. The biology also indicates that the computation cannot depend upon traditional rate coding (40 Hz firing rate=25 msec between spikes). One mechanism that allows sufficiently fast analog computation for recognition is "space–rate coding." In space–rate coding, stimulus information is encoded by the fraction of neurons in a population that are active within a short time window (e.g., 5 msec). Because the fraction active can change on a millisecond time scale, space–rate coding allows a rapid and high-resolution readout of network computations.

II. BIOLOGICALLY BASED NEURAL NETWORKS

The complex behavior of neural systems perhaps has less to do with the specifics of the individual units and more with the connection of units to form networks, leading to *emergent computation*. Computational neuroscience focuses on the modeling of biologically based neural networks. Computational neuroscience developed into its own field in the 1980s largely due to advances in neurophysiological recording and the continued development of low-cost digital computers. More recent advances in noninvasive neuroimaging, for example, the development of functional magnetic resonance imaging (fMRI), high-density electroencephalography (EEG), and magnetoencephalography (MEG), have led to a new set of tools and data for supporting the construction and validation of biologically based neural network models.

In terms of neural modeling, the hippocampus is a brain structure that has received much attention. The hippocampus plays an important role in memory, seemingly acting like a buffer for the storage of short-term memories, as well as being involved in spatial navigation tasks. Roger Traub and colleagues have constructed a neural network model of the mammalian hippocampus, which consists of roughly 10,000 neurons, each neuron built using realistic models of several types of ionic channels. Consistent with anatomical data, the neurons in the network are sparsely connected (less than 5% connectivity). Network simulations produce a population-based rhythmic activity of 4–8 Hz known as the θ rhythm, which is observed in normal hippocampus. The activity is population-based because individual neurons do not fire regularly at the θ rhythm. Only by considering the population or network response does one see this emergent behavior. The model reproduces a variety of responses observed *in vivo*; specifically, the network can generate "seizures" similar to those seen in humans and monkeys. Because the hippocampus is involved in a variety of neurological diseases, including epilepsy, Alzheimer's disease, and Down's syndrome, one promising area of research is the development of computational models for evaluating the efficacy of various types of treatment.

Other neural network models of the hippocampus, including those by John Lisman and colleagues, have exploited two types of rhythms observed *in vivo*, the θ rhythm and the γ rhythm (40–60 Hz). In Lisman's model, a short-term memory is stored in each cycle of a γ oscillation and all short-term memories are packaged in the θ rhythms. The model predicts that roughly

seven short-term memories can be stored at any given time, consistent with well-known psychological data.

Neural networks have been used to model oscillatory and rhythmic phenomena in areas other than the hippocampus. For example, several network models have been developed that hypothesize a role for oscillations and temporal patterns of spikes for solving the so-called *binding problem*. The binding problem in audition is the well-known "cocktail party problem." When attending a noisy cocktail party with multiple speakers and noise sources, you will notice it is relatively easy to separate out the voice of a single speaker and understand what he or she is saying. This is in spite of the fact that the signals from the sound sources in the room are mixed together, often in very complicated ways due to reverberation and attenuation. The brain ultimately must deal with this mixture, separating the neural signals that belong to the target speaker from those that belong to the background noise. In vision, the problem is compounded by the fact that the first thing the visual system appears to do is decompose objects into their associated color, motion, depth, position, etc. In fact, this decomposition occurs in two different streams, termed the "what" and "where" streams by Robert Desimone and Leslie Ungerleider. These streams are in different parts of the cortex—temporal and parietal lobes—and no region has been identified in the brain in which all of the information converges, implying that the representation remains distributed.

Charles Gray and Wolf Singer have found evidence that temporal patterns may play a role in binding a distributed neural representation. On the basis of their neurophysiological recordings, they propose that neurons representing the same object fire in synchrony. In a network having excitatory and inhibitory neurons, this synchronous firing could also lead to oscillations. Several neural network models have been developed that use synchrony and/or oscillatory activity as a coding scheme for representing and binding objects. John Hopfield and Carlos Brody have developed a neural network model constructed from integrate-and-fire neurons that is selective for specific spatiotemporal patterns in the input stimulus. In their model, the presence of a stimulus is signaled via transient synchrony among a population of neurons in the network. One important element of the model is that the network easily and rapidly desynchronizes when no recognized spatiotemporal patterns are present. Desynchronization is just as important as synchronization if the network is to use these temporal patterns as a coding mechanism for objects. The recognition event, that being transient synchrony, is detected by a neuron that acts as a coincidence detector.

Whether the brain explicitly solves the binding problem in order to recognize objects is still under much debate. A neural network model developed by Maximilian Reisenhuber and Tomaso Poggio illustrates that impressive visual object recognition performance is achievable using a purely feedforward model, which does not explicitly necessitate binding or segmentation. The model is based on the neurophysiological experiments of Keiji Tanaka and colleagues and their recordings from the anterior portion of the inferior temporal cortex (IT) in the monkey. IT is believed to be an important visual area for object recognition, and recordings in IT have shown cells having high specificity for individual objects, such as faces. Tanaka and his group developed a set of complex visual stimuli (e.g., starbursts, junctions of lines, bull's-eyes), which are quite different from the bars and edges traditionally used as stimuli by neurophysiologists. They found that individual IT neurons respond preferentially to these features—one neuron only fires for bull's-eyes, another only for T junctions. One hypothesis is that they function as a large set of complex feature detectors. Reisenhuber and Poggio constructed a neural network that builds up a large set of complex feature detectors using a hierarchy of linear and nonlinear combination rules. In their model, neurons at higher levels in the hierarchy have response properties, which are very similar to those observed by Tanaka *in vivo*. Reisenhuber and Poggio argue that these responses are a good basis for representing visual objects because individual objects will tend to uniquely cluster in small regions of this high-dimensional feature space. By feeding these representations into an artificial neural network, they have shown that the representation captured the necessary information for robust, rotation invariant object recognition—a difficult visual recognition problem.

Further evidence that argues against oscillatory behavior of neural networks being a necessity for solving the binding problem comes from models of the piriform cortex by Matt Wilson and James Bower. Piriform cortex is the primary cortical area for olfaction (e.g., sense of smell). It is well-known that the EEG of the piriform cortex in rats exhibits γ oscillations when the rat sniffs an odor. Wilson and Bower constructed a *compartmental model*, consisting over 4000 neurons, to investigate the nature of these oscillations. Their findings showed that even when random inputs were given to the model, γ oscillations

continued. This implies that the oscillations are not involved in olfactory computation and odor recognition, rather they are an epiphenomenon of the network architecture. The debate over the computational role of oscillations in the cortex and subcortical areas thus is not resolved.

In addition to neurophysiology, anatomical data has been important in the development of biologically based neural networks. Many regions of the neocortex are organized topographically, with precise connectivity mapping the sensory world into the brain. For example, much of the visual system is retinotopically mapped, meaning that adjacent regions in the visual cortex are stimulated by adjacent positions in the visual environment, as projected onto the retina. Other prominent areas having topographic representations are the motor cortex and somatosensory cortex. One of the unique aspects of many of these topographic maps is that they have been shown to be adaptive. Leif Finkel, Gerald Edelman, and John Pearson developed a network model consisting of approximately 1500 neural units of somatosensory cortex that exhibited this adaptive behavior, often termed plasticity. Stimulation of the network model by repeated tactile input on one of the simulated fingers results in an increase in the representation of that finger within the network model. Simulated transection of afferent nerves, eliminating input from that finger, causes the corresponding region in the model to shrink, being taken over by regions receiving active tactile input. The phenomenon of a phantom limb, where an amputee patient experiences the sensation of their limb shrinking into their body and disappearing, is the analog of the dynamic remapping observed in this model.

The learning rule governing plasticity in many biologically based neural network models is based on the classic Hebb rule. In 1949, Donald Hebb formulated a learning rule that stated how the strengths of synapses are modified on the basis of pre- and postsynaptic activities. The basic notion was that, if neurons' activities are correlated or coincident, then the synaptic strength between them should be increased. In mathematical terms, one of the simplest forms of the rule is

$$\Delta w_{ij} = \eta \cdot o_i \cdot o_j$$

where Δw_{ij} is the change in synaptic strength, η is the learning rate, and o_i and o_j are the outputs or firing rates of the presynaptic and postsynaptic neurons, respectively. In this case, the synaptic strength is increased if the presynaptic cell and postsynaptic cell fire at the same time. A symmetric rule allows the synapse to be weakened if the cells fire at different times. Computationally, the Hebb rule strengthens synapses between neurons that have correlated activity and weakens those synapses between neurons having uncorrelated firing patterns. One of the issues with the classic Hebb rule is that it is a local rule based on the generation of action potentials by the pre- and postsynaptic neurons. Because this adaptation occurs directly at the synapse, which can be far removed from the axon hillock and axon, it is unclear how information about whether the postsynaptic neuron generated action potentials would be communicated back to the synapse. Several researchers have reformulated the Hebb rule so that the change in synaptic strength is based on pre- and postsynaptic potentials (local voltages), not firing rates. However, as mentioned earlier, more recent neurophysiological evidence has shown that action potentials can quickly back-propagate from the soma to the synapse, serving as a means to communicate the firing of the postsynaptic cell to the local synapse. Regardless of which formulation is used, the Hebb rule has provided modelers with a biologically plausible activity-dependent mechanism for constructing highly specific connection patterns, leading to emergent computation.

The specificity of the connections in the visual cortex has led to the development of several models hypothesizing a computational role for these connections. Leif Finkel, Shih-Cheng Yen, and Elliot Menschik, for example, have developed a biologically based network model, which reproduces several interesting quantitative psychophysical results of contour perception. The computation in the model is largely mediated by the specificity of long-range horizontal connections in layers 2 and 3 of the visual cortex. Anatomically, these connections extend over several millimeters and subtend over 10° of visual field. In their model, horizontal connections mediate facilitation of neurons representing collinear/cocircular contour elements, as shown in Fig. 2.

Biologically based network modeling has as its goal understanding how the biophysics, neurophysiology and neuroantomy give rise to complex behavior and computation within the brain. One of the challenges has been that a mathematical analysis of biologically based networks is difficult due to the complexity of the detailed neurobiology. This has also limited the size of the models, in terms of the number of neurons in the network, and therefore puts limitations on their evaluation with more complex and realistic input. As a result, some researchers have developed neural network models that trade off biological realism in

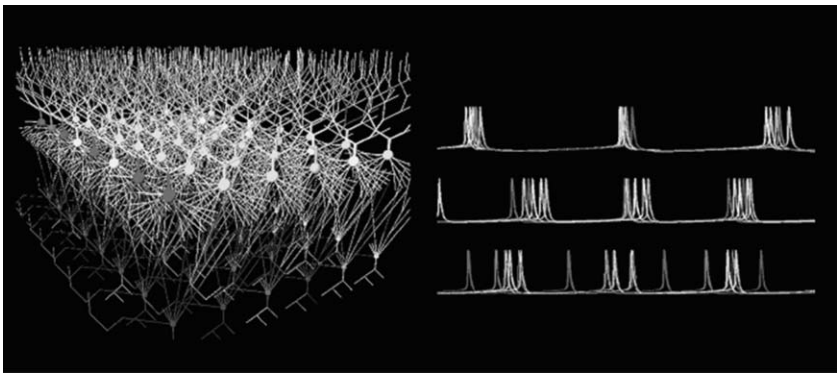

Figure 2 Cortical simulations of horizontal connections between columns of neurons in the visual cortex. Spike traces show the degree of synchronization in response to a six-element contour. Each column of neurons "sees" just one contour element; the spacing between elements determines the salience of the contour relative to background clutter. As the salience increases (top trace most salient, bottom trace least salient), the degree of synchronization decreases. Six hypercolumns are simulated with eight pyramidal cells and eight interneurons per orientation column. Each pyramidal cell is a 64-compartment model, and interneurons are 51-compartment models (reprinted with permission from L. Finkel).

favor of larger network size and whose overall behavior, through mathematical analysis, is tractable.

III. ARTIFICIAL NEURAL NETWORKS

A network whose architecture is not strongly linked to neurobiology is often termed an artificial neural network (ANN). ANNs are built by using simplified models of a neuron, for example, sigmoidal units mentioned earlier. The pattern of connections between the neural units is most often established via learning rules and gives the network its ability to compute complex functions and develop emergent behavior. The importance of connectivity in ANN models has resulted in the coining of the term "connectionism" for describing this research area.

ANN research has its origins in the development of the "perceptron" by Frank Rosenblatt in 1958. ANNs are often characterized by the number of layers of modifiable connections or synapses. The perceptron is a network consisting of a single layer of connections with output units having a nonlinear transfer function, as shown in Fig. 3a. The output, $f(\mathbf{x})$, of the perceptron is given by

$$f(\mathbf{x}) = \mathrm{sgn}\left(\sum_{i=0}^{N} w_i x_i\right)$$

where w_i are the connection weights and x_i are the inputs, with x_0 often chosen to be a constant equal to 1, called the bias. The sgn() function is equal to 1 if its argument is greater than or equal to 0 and -1 if it is less than 0. The perceptron is a linear network in that the output "decision" is linearly dependent on the input. The perceptron classifies its input, by outputting either a 1 or a -1, on the basis of how it projects onto its connection weights. Therefore, determination of the values for the weights is important for giving the perceptron its ability to classify. The connection weights are usually learned via *supervised training*.

Training ANNs involves formulating and minimizing an *objective function*. For the perceptron, the objective function, H, is given by

$$H(w) = \sum_{x_i \in S} (-w_i x_i)$$

where S is the set of examples that are misclassified, given the connection weights. One can see that $\sum_i w_i x_i \leq 0$ if x_i is misclassified. Thus, the minimum of H is 0.

Minimization of the objective function for the training data requires taking the gradient of H with respect to the connection weights and then updating the weights by moving in the direction opposite to the gradient (e.g., gradient descent). This is simply

$$\frac{dH(w)}{dw} = \sum_{x_i \in S} (-x_i),$$

and the update rule for the perceptron from time step t to $t+1$ becomes

$$w_i(t+1) = w_i(t) + \eta \frac{dH(w)}{dw} = w_i(t) + \sum_{x_i \in S} x_i.$$

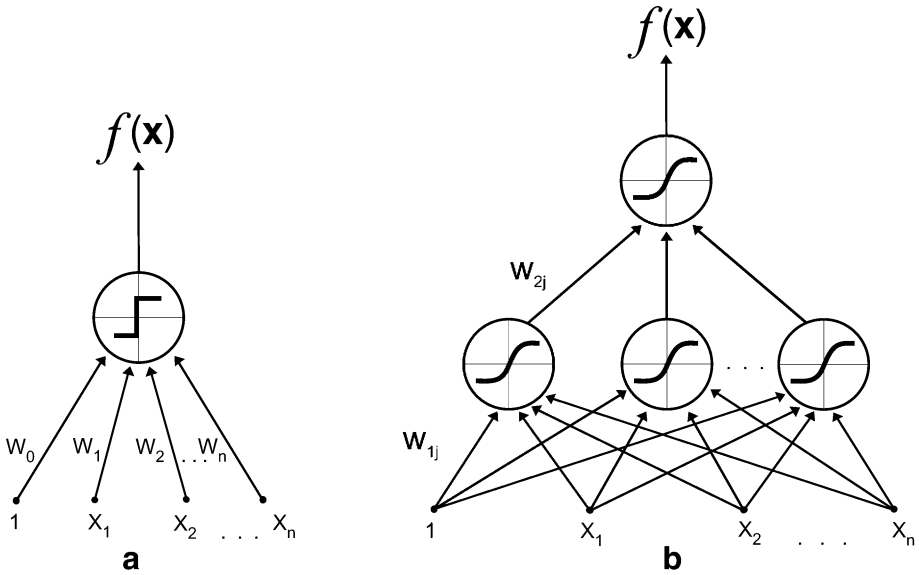

Figure 3 Artificial neural network architectures: (a) perceptron, (b) multilayer preceptron.

After learning on the training data, new data are input to the perceptron network with the goal being that it gives correct results on the new data, a property called "generalization." The perceptron generated much excitement over its ability to perform "brainlike" computation. This excitement, however, was squelched in 1969 when Marvin Minsky and Seymour Papert published their book *Perceptrons*, which clearly outlined the computational limitations of the perceptron architecture. The single-layer architecture made it impossible for the network to solve anything but linearly separable problems. A classic example in which the perceptron had difficulty was the exclusive-OR (XOR) problem shown in Fig. 4. Minsky and

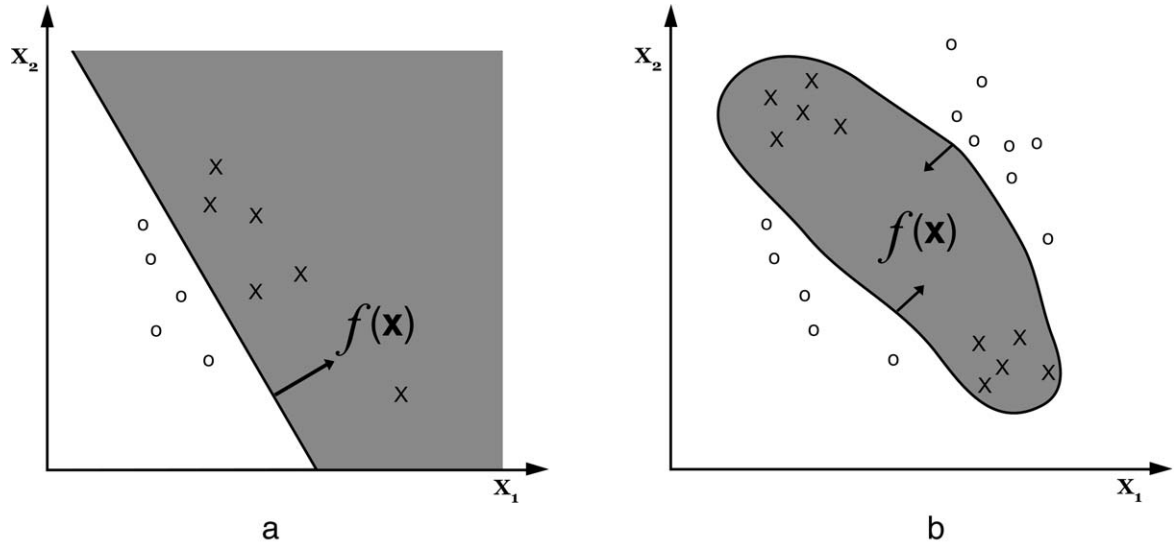

Figure 4 Linear versus nonlinear separable classification. (a) Linearly separable classification problem in x_1, x_2 feature space. A perceptron can learn the function $f(\mathbf{x})$ for solving linearly separable problems. (b) The exclusive-OR (XOR) problem is not linearly separable. In the XOR problem, data in x_1, x_2 feature space are distributed in much the same way as the exclusive-OR function in Boolean logic. A perceptron is not capable of learning a function $f(\mathbf{x})$ that classifies all the X's and O's correctly. An MLP, however, can learn $f(\mathbf{x})$ because the output unit combines the decision surfaces generated by all of the hidden units, thereby "piecing together" a complex decision boundary separating all X's from O's.

Papert's seminal work was a blow to the field, which lay largely dormant until the 1980s, when the development of a learning rule for training multilayer perceptrons (MLPs) was formulated.

MLPs, shown in Fig. 3b, consist of several layers of modifiable connection weights. Neural units in layers that are not directly connected to the output are called "hidden units." Connections are usually feedforward, with units in layer N connected to all units in layer $N-1$. The multilayer architecture enables the MLP to solve problems that are not linearly separable. In fact, the eminent Russian mathematician Andrei Kolmogrov proved that any continuous function can be implemented in an MLP with a sufficient number of hidden units. An important development for the field was the publication in 1986 by David Rumelhart, Geoffrey Hinton, and Ronald Williams of the back-propagation learning rule for training MLPs. The back-propagation learning rule was able to solve the classic *credit-assignment problem* for MLPs. The formulation of the back-propagation learning rule follows the same basic structure as the perceptron learning rule, namely, defining an objective function based on the training error, differentiating the objective function with respect to the connection weights, and then generating a weight update equation based on gradient descent. One of the important differences is that, because for an MLP the outputs are not directly connected to the inputs, the back-propagation learning rule requires the use of the chain rule of calculus to compute the required derivatives. The publication of the back-propagation algorithm started a flurry of development in the field, with ANNs being built that could learn to recognize printed characters to networks that could be trained to "talk." For example, the NETtalk network, consisting of 203 input units, 80 hidden units, 26 output units, and a total of 18,629 connections, learned to translate written text into phonemes that could be pronounced by a speech synthesizer. Today, MLP architectures and the back-propagation learning rule continue to evolve with new variants having better convergence properties, leading to more powerful networks.

ANNs are not limited to feedforward connection architectures, particularly considering how feedback connectivity can give rise to interesting dynamic properties in biological neural networks. Recurrent networks have architecture similar to feedforward MLPs, except that there are feedback connections between layers. John Hopfield, motivated by concepts in statistical physics, developed one particularly interesting class of recurrent networks. In a Hopfield network, all neurons are connected to one another—the network is termed "fully connected." Neuron responses are represented as binary states (1/0 or 1/-1), analogous to the spin of a particle ($+\frac{1}{2}$ or $-\frac{1}{2}$) in physics. Interactions between neurons, via their connectivity, influence their individual states much as interactions between particles influence their collective spins. As in the physical system, a network architecture, with a particular set of connections, will have an "energetically favorable" equilibrium state, which can be viewed as an attractor in a dynamic system. Training a Hopfield network involves learning the set of connections that makes a particular binary state of neurons an attractor. Input of a similar pattern, or the original pattern corrupted by noise, results in the network activity eventually converging to the closest attractor, with the output being the stored pattern. Hopfield networks, therefore, implement "associative memories" with properties similar to what has been observed in the hippocampus.

Many subtle issues are related to the construction, training, and evaluation of ANNs. For instance, there are issues on how to objectively select the best set of features for input to an ANN and even on how to select the best ANN model itself, e.g., what is the optimal number of layers, neural units, and connection weight given a particular data set and problem. A related issue is the "bias–variance trade-off," which can be thought of as the trade-off between the expected error of the network, d (the bias), and the variation of the error (the variance) for different subsets of training data. Ideally, one would like to minimize both the bias and variance; however, these two terms tend to vary diametrically. An overly simple network, with few parameters, will tend to have a large error across training subsets (high bias); however, the value of this error will not vary considerably across training subset (low variance). An overly complex network will tend to estimate the training data well (low bias); however, this estimate will likely vary considerably across different training subsets (high variance). The challenge is to find the optimal network that minimizes the combination of bias and variance. Readers interested in more detail are referred to Bishop (1995) and Duda, Hart, and Stork (2001).

Cognitive neuroscientists have used ANNs as tools for studying brain function, particularly for modeling high-level cognitive processing. Martha Farah and Jim McClelland have built a connectionist model composed of fewer than 200 neurons to study the organization of semantic memory and its role in agnosia, which is a failure in object recognition. They

use their model to test two hypotheses, the first being that semantic memory is organized into categories and the alternative being that the organization is based on object properties. For instance, a category-based organization might be based on living versus nonliving things, whereas a property-based system would organize on the basis of the visual and functional attributes of objects. By using a network model based on object-property organization, Farah and McClelland simulated "lesioning" their ANN by deactivating a percentage of the units in the semantic layer. These simulated lesion studies showed that loss of function in the visual and functional semantic units results in a specific categorical agnosia, with lesions to the visual units causing a loss in memory of living things and lesions to functional units resulting in a loss in memory of nonliving things. These results, consistent with neuropsychological literature, demonstrate that category-specific deficits are an emergent property of a network that is organized based on object properties.

ANNs have been used to solve very complex signal processing problems. The well-known cocktail party problem described earlier is the problem of unmixing individual speakers and other acoustic sources from a set of microphone signals. If little or no information is available about the sources or the environment in which the recordings took place, then the problem is often termed *blind source separation* (BSS). One technique for BSS that has proven very successful is independent component analysis (ICA). The goal of ICA is to find the mixture components that are most statistically independent. In 1995, Tony Bell and Terry Sejnowski of the Salk Institute showed that ANNs are very good at implementing ICA and, thus, could be used for BSS. By using a single-layer neural network with sigmoidal output units and trained with an entropy-based *unsupervised learning* rule, they demonstrated impressive results in separating acoustic sources. Since Bell and Sejnowski's original work, many researchers have developed neural network models for BSS applications. In neuroimaging, for example, electroencephalography (EEG) and magnetoencephalography (MEG) are being used to record millisecond resolution electromagnetic signals related to brain activity. High-density EEG and MEG systems, having more than 100 sensors recording activity across the brain, pick up a mixture of electromagnetic signals originating from different populations of neurons. To analyze these signals, it is often useful to separate them into independent sources, such as separating signals from the auditory cortex from signals originating in the visual cortex. ANNs are being used to recover independent sources in EEG and MEG signals for improved brain activity analysis.

IV. NEURAL NETWORK SIMULATION

Computer simulation plays an important role in neural network research. It was not until fast and inexpensive digital computers were available that it became possible to study the behaviors of biologically detailed neural network models or large connectionist ANN networks. A variety of software-based simulators have been developed that enable researchers and students to more readily construct biological and artificial neural network models and evaluate their behavior and performance using different stimuli. Three simulation packages of note are GENESIS, NEXUS, and the Neural Network Toolbox from MATLAB, which span the spectrum of neural network modeling. Each simulator typically includes a language for specifying a network architecture, numerical and optimization tools for training and simulation, and graphical tools for visualizing results.

GENESIS (GEneralized NEural SImulation System) was developed by James Bower and David Beeman and represents one of the most comprehensive efforts to provide a simulation system to the research and academic communities for modeling biologically realistic neural networks. At the core of GENESIS is an object-oriented programming language for constructing various biophysical elements, such as compartmental elements, voltage-dependent ion channels, and spike generators. A hierarchical representation is used to represent relationships between the different elements, including the connection of individual neurons into complex networks. A message passing scheme connects objects in the hierarchy. Several biologically realistic models have been developed using GENESIS, including the models of the piriform cortex and contour perception in the visual cortex described earlier.

NEXUS (Network EXperiments Using Simulation) was developed by Paul Sajda and Leif Finkel and is designed for building and simulating highly interconnected computational maps. NEXUS provides a language for describing complex connectivity patterns between maps of neural units. Though neural units can be programmed to have arbitrary complexity, units are typically abstracted as integrate-and-fire or sigmoidal activation neurons. Researchers interested in modeling the biophysical properties of single neurons and

small networks should consider using GENESIS. Many models developed using NEXUS have focused on the visual cortex, because it is well-designed for constructing retinotopic connectivity. Specific models have included textured discrimination and segmentation in the visual cortex, perceptual grouping in areas V1 and V2, and color constancy and color contrast in area V4.

The Neural Network Toolbox for MATLAB, developed by Mathworks, is a simulator for building artificial neural networks. The toolbox runs under MATLAB, a linear algebra based mathematical simulation package. The Neural Network Toolbox supports a variety of predefined neural network architectures, including MLPs, self-organizing networks, and recurrent networks. Many classes of transfer functions are supported, and a variety of learning rules can be implemented.

In addition to software simulation, hardware implementations of neural networks have proven quite useful. Often termed "neuromorphic engineering," these neural hardware systems are based on integrated circuit technology that enable real-time simulation of highly interconnected neural networks, as well as processing that is closely coupled with sensors, e.g., visual processing coupled with a silicon retina. Carver Mead and colleagues were the early developers of neuromorphic hardware systems, which have included arrays of spiking neurons, retinomorphic chips, a silicon cochlea, and reconfigurable neural network circuits. Neuromorphic systems enable researchers to analyze the information processing in neural networks at very fast time scales, as well as providing hardware platforms for accelerating their software implementations.

V. CONCLUSION

Research into the computational capabilities and limitations of neural networks is fundamental to understanding information processing in the brain. Biologically based neural network models have proven important for integrating biophysical, physiological, and anatomical information for performing experiments (simulations) that currently are not feasible for experimentalists. Artificial neural networks have proven utility in their own right, providing tools for nonlinear signal processing and pattern classification, as well as providing a mathematical framework for gathering insight into a more abstract level of brainlike computation. The challenge for the future will be to develop a tighter integration between the computational framework and neurobiology, while at the same time incorporating molecular and genomic data for discovering the basic principles governing brain function.

Neural Transplantation

DOUGLAS KONDZIOLKA, ELIZABETH TYLER-KABARA, and CRISTIAN ACHIM
University of Pittsburgh

GLOSSARY

Huntington's disease A genetic brain disorder characterized by abnormal motor and behavioral effects.

neurons The functional cellular units of the brain.

Parkinson's disease A degenerative brain diseased characterized by rigidity, tremor, and slow movements due to lack of brain dopamine.

stem cell A primitive body cell that holds the potential to become one or more mature cells in distinct body organs.

stereotactic surgery Precise, image-guided surgery of the brain using a localization frame.

transplantation Surgical transfer of cells or tissue from one patient source (donor) to another patient (host).

This article reviews the basic principles of neurotransplantation research, discusses appropriate neurodegenerative disorders and describes current science in this field.

I. PRINCIPLES OF NEUROTRANSPLANTATION

Modern restorative neurosurgery began over 25 years ago when neurosurgeons and neurobiologists envisioned the possibility of replacing human neurons in neurodegenerative diseases like Parkinson's and Huntington's diseases. Early clinical trials were first based on a direct approach targeting the replacement of missing specific neurotransmitters rather than regenerating the damaged neuronal circuitry. More recently, with the advent of therapeutic strategies developed from experimental work with stem and progenitor cells, there is hope that the final goal of reconstructing neuronal pathways may be achieved. We can summarize the goals of this field as replacement, release, and regeneration. Dead neurons have to be replaced, the grafts have to be able to release neurotransmitters, and circuits have to be rebuilt. Of course, all of these goals can be fulfilled only if our understanding of molecular mechanisms of disease will keep up the pace with the development of new bioengineering strategies. Since the pioneering work of Björklund *et al.* almost three decades ago, much progress has been made. Rather than reviewing these advances in detail, a task already performed very well by other authors, we will outline some of the current challenges and discuss potential areas of further development. For a more indepth analysis of the clinical outcome of many ongoing clinical studies, the interested reader is strongly encouraged to read one of the most comprehensive analyses to date, the work edited by Freeman and Widner (1998), a true textbook of neurotransplantation.

The field of neural transplantation for the treatment of neurological diseases first became a potential therapeutic modality in 1979 when Björklund and Perlow showed that transplantation of dopamine containing neurons in rat striatum improved functional deficits induced by damage to the nigrostriatal pathway. Since that time, advances in neural transplantation have moved from the animal model to the human model with varying degrees of success. Animal models encompass a wide variety of disease states from degenerative diseases to trauma and stroke models. Tissue used for transplantation ranges from fetal tissue to tumor lines to stem cells. In some models, implants provide a source of neurotrophic factors. Successes in animal models have led to transplant trials in the human population. Patient trials include transplantation for Parkinson's disease, Huntington's disease, spinal cord injury, and stroke. As research in animal models progresses, transplant trials may be initiated for the treatment of multiple sclerosis, traumatic brain injury, cerebral palsy, amyotrophic lateral sclerosis (ALS), Alzheimer's disease, hereditary ataxias, and other disorders.

II. NEURAL TRANSPLANTATION: CLINICAL TRIALS AND EXPERIMENTAL MODELS

A. Background

The concept of using dissociated central nervous system (CNS) tissues for transplantation was promoted by Schmidt *et al.*, who argued that this protocol may be used for intraparenchymal implantation. The same group of investigators later showed, including detailed methodology, that mesencephalic, dopaminergic rich cell suspensions can be injected in various regions of lesioned rat brains to promote regeneration. Since these early attempts, a whole field has grown largely on the idea of using human fetal tissues to replace human degenerating neurons. Parkinson's disease (PD) has become the frontier in neurotransplantation.

The hypotheses tested and lessons learned from transplantation studies in PD have been extended to other problems, like Huntington's disease (HD) and spinal cord regeneration. Some of the therapeutic principles are similar, and the obstacles to be conquered to secure graft survival and functional recovery are identical. For this reason, our article will emphasize PD studies as the benchmark for any new experimental approaches in CNS cell transplantation, although promising advances have been reported in stroke. However, the reader must be aware that many of the scientific principles pertinent to Parkinson's disease are not the same for other disorders and that our understanding of many neurodegenerative disorders is far from complete. Among the challenges to any transplantation protocol are the source and preparation of donor tissue, surgical protocol, posttransplantation hypoxia, local toxic factors like free radicals and excitatory amino acids, deprivation of neurotrophic factors (NTF), necrosis, and neuronal apoptosis. Any factors alleviating these limitations will have a significant impact on the cell transplantation protocol in any neurodegenerative disease.

B. Clinical Trials in Parkinson's Disease: The Prototype for Cell Transplantation

Parkinson's disease is characterized primarily by the degeneration of dopaminergic neurons projecting from the substantia nigra to the corpus striatum. Parkinsonian clinical symptoms like rigidity, tremor, and postural imbalance, accompanied by the histopathologic findings of nigral distrophy and Lewy bodies, are well-described and correlate with the loss of dopamine production and release in the brain. The importance of cerebral dopamine became apparent in the late 1950s, and since then our knowledge about the neuroanatomy, physiology, and especially pharmacology of this neurotranmsitter has increased immensely. Readers interested in the topic may start by consulting the chapter in the popular neuropharmacology textbook by Cooper, Bloom, and Roth. Logically, the first therapeutic approach in diseases associated with parkinsonian symptoms, for a long time equated primarily with rigidity, was based on replacing the natural neurotransmitter with precursors like levodopa. This has proved to be a highly effective treatment and is still the first choice in PD. Nevertheless, some of its limitations derived from extended use and coupled with the significant progress in developmental neurobiology have led to clinical trials using human fetal tissues as potential replacements for the degenerating adult dopaminergic neurons. For more than two decades, experimental and clinical data have accumulated to suggest that this can be a beneficial strategy for PD patients (especially those with poor response to traditional medication) and that dopamine replacement can be achieved through cell transplantation.

An important issue to be considered in brain cell transplantation is the availability and suitability of tissues from abortions. Besides the obvious ethical concerns, the basic science and clinical studies are still in progress and many questions have yet to be answered. For example, in an extensive study of 5 tissue banks funded by the National Institutes of Health (NIH), out of approximately 1500 embryonic donors, only 7 were considered to be suitable for transplantation in PD patients. Of course, this is based on the older concept that only first trimester mesencephalic tissues from multiple donors are to be used for transplantation in one patient. Fortunately, more recent studies have shown that the use of multiple donors or first trimester tissues is not an absolute requirement to generate long-term surviving human brain grafts. Furthermore, of great promise is the current work with stem cells, which are neuronal precursors and cell lines that may soon replace the use of primary human brain cells as the main donors (Fig. 1). Finally, as will be discussed in more detail later in the article, the use of neurotrophic treatments along with viral vector technology is another exciting area in this field and may become an important approach to promote brain regeneration in PD.

C. Fetal Mesencephalic Transplants

The majority of current clinical trials are based on using human fetal mesencephalic tissues from first trimester abortion specimens. The use of tissue fragments is still popular. The clinical outcome of some of the studies discussed later depends more on the surgical technique and underlying host condition rather than the quality of the donor tissue. The autopsy studies are few, and the *in vivo* assessment of the grafts is still limited by the accuracy of positron emission tomography (PET). Nevertheless, clinical symptoms do appear to improve in some patients, often for extended periods of time, and the overall results are encouraging. The investigators agree on the need for standardized tissue processing and

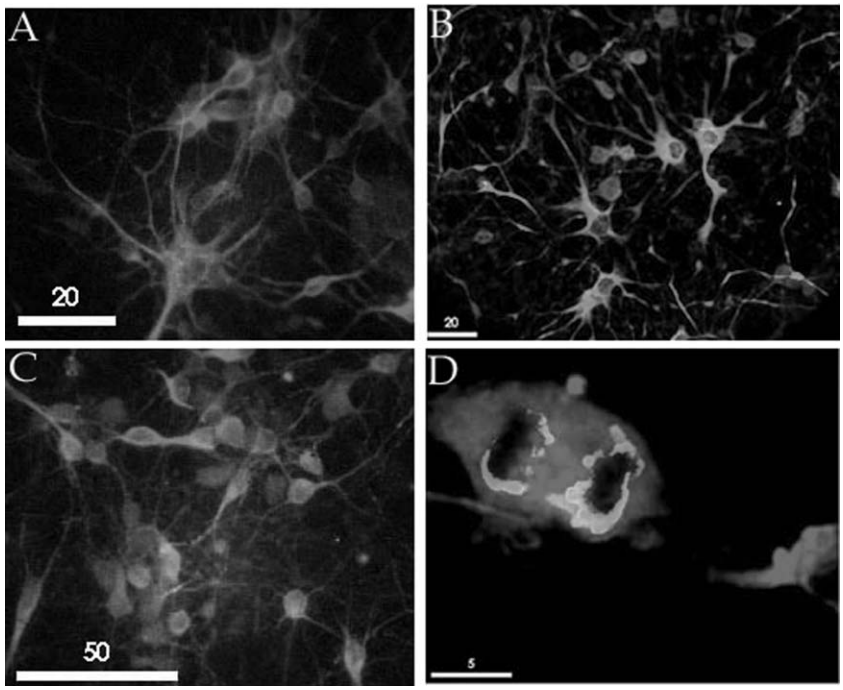

Figure 1 *In vitro*, grown in conditioned serum-free medium, fetal brain cultures differentiate into all major human brain cell populations at a physiologic ratio between various phenotypes. In these mixed cultures, (A) differentiated astrocytes (GFAP) and neurons (MAP-2) are abundant. (B) Staining for TH is abundant by day 14 *in vitro* on cells that are not GFAP negative cells, presumably neurons. (C) A subpopulation of MAP2-positive neurons express the high-affinity receptor for BDNF, TrkB. (D) Following treatment with BDNF, some of the MAP-2-positive neurons labeled with BrdU can proliferate.

implantation protocols as well as the need for more sensitive imaging techniques.

Current clinical trials explore some fundamental concepts like the need for immunosuppression and the relative contribution of the graft versus the host response in promoting dopaminergic regeneration. Since 1991, the idea that immunosuppression (discussed further later) may not be necessary has been tested in a landmark study by Henderson *et al.* In 12 advanced PD patients with grafts implanted in the caudate nucleus, long-term clinical benefits could be seen in the absence of immunosuppression. Furthermore, the authors challenged the idea of using only first trimester embryonic donors and used second trimester fetal tissues. Current discussion also centers on the number and topography of the implantation sites and the ongoing debate about the use of immunosuppressants.

In a representative study, Spencer *et al.* implanted cryopreserved first trimester tissues (one donor per host) in the caudate of advanced PD patients with 6 months of cyclosporine immunosuppression. Three out of four patients showed motor improvement and greater benefit from medication use. Similar results were reported by Freed *et al.*, who studied a larger series of patients for a longer time. Some of these patients received bilateral putaminal grafts. Also, some of the patients did not receive immunosuppresion. Interestingly, whereas the clinical outcome was largely positive, no significant differences existed between the patient groups. These studies showed that fetal transplantation was feasible and that further research should be encouraged.

The difficulty of using clinical improvement (measured on various standardized scales) or PET imaging in establishing the *direct* benefit from graft survival was overcome by Kordower *et al.* who in a detailed autopsy report showed that, in a PD patient who died of unrelated causes at 18 months postsurgery (bilateral grafts), the fetal mesencephalic tissue was surviving, was relatively well-integrated, and contained a significant number of dopaminergic neurons. Surprisingly, no host dopaminergic neuronal sprouting occurred. This appeared to be in contrast to findings from adrenal medullary grafts, which did not survive well but were accompanied by host dopaminergic sprouting. Nevertheless, the same group of investigators reported more recently that the use of abundant donor tissue (from seven donors) has resulted in significant clinical and PET improvements in one patient, even in the absence of host dopaminergic sprouting in the graft. At autopsy, the majority of the host putamen receiving the graft was positive for tyrosine hydroxylase (TH), and this may explain the postsurgery benefits.

Unilateral implantation is still used by many investigators who report significant clinical benefits when grafts are placed in the putamen with or without additional seeding in the caudate. At the same time, bilateral implantation in the putamen is gaining ground and seems to show more consistent clinical benefits. In a review of the long-term benefits of bilateral implantation, Hauser *et al.* concluded that clinical improvement appeared to be related to long-term survival and host integration of the graft. Nevertheless, the advantages of a sequential bilateral second graft have yet to be determined. It may be that ultimately the survival and long-term benefit of a graft, in addition to the quality of the initial donor cells, depend on the quality of the stereotactic surgical procedure.

From various clinical trials using fetal mesencephalic tissues, one of the most interesting observations is that the grafts appear to survive for long periods of time, even if the underlying disease affecting the host dopaminergic neurons does not change its course. These results are encouraging, to say the least. When we can overcome problems in generating reliable, high-quality, thoroughly assessed grafting material, cell transplantation could become a standard adjuvant in pharmacotherpies for PD or other novel interventions like deep-brain stimulation. PET imaging is of utmost importance in assessing these therapeutic interventions. Traditionally, dopamine production was measured by imaging of fluorodopa, but newer radiotracers, like CFT (a dopamine transporter ligand), SCH (D1 receptor), and raclopride (D2 receptor), may give a more accurate picture of the disease progress and also the survival and function of the grafted cells (Fig. 2).

D. Adrenal and Carotid Body Transplants in Parkinson's Disease

After early observations that adrenal chromaffin cells transplanted in rats can survive in the host brain, clinical trials were initiated in humans. The early results, encouraging to some extent, were questioned later, especially due to poor graft survival. One of the proposed explanations was the contamination of adrenal grafts with nonchromaffin cells. When this was corrected, improved survival and graft function

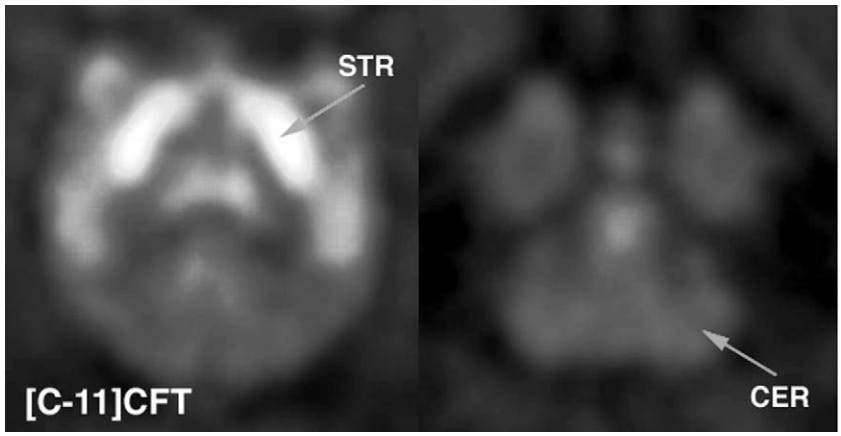

Figure 2 PET imaging of a baboon using the [C-11]CFT DAT tracer. Prominent striatal (STR) tracer activity is shown, whereas the cerebellum (CER) had no significant DAT binding.

were noted. Purified chromaffin cells can be grown and differentiated *in vitro* preimplantation or manipulated to express growth factors that may further benefit the graft *in vivo*. An intriguing but promising alternative is the use of carotid body cell aggregates that have been shown to be of significant benefit in parkinsonian rats and more recently in pilot studies in monkeys.

E. Xenografts in Parkinson's Disease

Human xenografts have been used in animal models to study principles of neurotransplantation or mechanisms of brain degeneration. More often, xenotransplantation has been tested with the goal to explore alternative sources of mesencephalic fetal tissues for grafting into the degenerating brain. Studies using porcine fetal cells in rats showed that the grafts survived and integrated successfully in the host. Currently, there are several ongoing clinical trials to assess the feasibility of porcine xenografts in PD and HD patients, and the preliminary data suggest that this may be a safe procedure. The efficacy still has to be determined, although initial reports note measurable improvement in some patients. We believe that xenotransplants will not play a significant role in neural restoration if human cells and tissues can be obtained.

F. Other Neurodegenerative Diseases

As mentioned earlier, the majority of the principles tested in PD eventually will be applied to other neurodegenerative diseseases. As another example of chronic brain degeneration, HD could potentially benefit from cell transplantation. Another instance in which graft cells could make a dramatic difference is the acute brain degeneration associated with stroke.

III. HUNTINGTON'S DISEASE

The rationale for intrastriatal grafting in HD patients in many ways is similar to that for, PD but the methodological challenges could be greater due to the more complex neurophysiological substrate. Nevertheless, extensive efforts are under way to establish a series of large-scale clinical trials, and the preliminary data are currently under evaluation. More promising are the studies analyzing the benefits of cell grafts in primate models of HD. Like in PD, much hope is invested in developing neuronal cells that can be manipulated *in vitro* to promote their *in vivo* functional integration into the degenerating striatum of HD patients.

Based on successful animal models, human trials of striatal transplantation for the treatment of Huntington's disease have been initiated. The first human transplant for Huntington's disease was performed in 1990 in Mexico using an open surgical procedure. Follow-up of this patient and a second treated by the same group showed slowed progression of the disease. Clinical studies have also been initiated in the United States. Twelve-month follow-up showed increased striatal tissue volume by MRI and improved measures of mobility and cognition. Hopefully, as human trials for the treatment of Huntington's disease progress,

large, organized, and controlled studies will emerge that will effectively evaluate this treatment modality.

A. Other Disease Models

Animal models of other neurodegenerative diseases have been developed and transplantation studies are being initiated. Huntington's disease has been modeled by injections of excitotoxic agents into the rodent striatum. Several groups have investigated transplants of fetal striatal tissue in this model with good results. Studies conducted in the nonhuman primate model also showed improvement of motor function. In these studies, transplanted neurons formed synaptic connections leading to the restoration of function. Because Huntington's disease can be identified genetically before the onset of symptoms or evidence of striatal degeneration, investigators have explored the potential of nerve growth factor to prevent striatal degeneration. Studies in the excitotoxic model and the mitochondrial dysfunction model show that grafts of fibroblasts genetically modified to secrete nerve growth factor protect striatal cells from degeneration. A murine model with Purkinje cell degeneration has been used to study hereditary ataxias. After transplantation of fetal cerebellar cells in these mice, transplanted cells migrated to the molecular layer and formed synaptic connections.

In addition to models of degenerative diseases, animal models of trauma and ischemia have been developed. Animal transplant studies in both traumatic brain and traumatic spine injuries have been initiated. Transplantation has also been evaluated in animal models of cortical and lacunar infarcts.

IV. STROKE

Transplantation of human neuronal cells is a new approach for ameliorating functional deficits caused by central nervous system (CNS) disease or injury. Several investigators have evaluated the effects of transplanted fetal tissue, rat striatum, or cellular implants into small animal stroke models. One of the best studied models of brain ischemia is the murine hippocampal stroke that results in well-defined lesions, especially in the CA1 region. The standardization of this model is invaluable to the reliable testing of various experimental protective and regenerative therapies. Among them, cell transplantation of fetal hippocampal neurons has shown that they can survive and integrate in the ischemic brain. Methodological issues are still to be resolved because subsequent studies questioned the capacity of rat fetal neocortical tissues, implanted in an infarcted area, to integrate in the surrounding host tissue. However, it has been shown that the chronic ischemic region can support graft tissue.

Because the widespread clinical use of primary human tissue is likely to be extremely limited due to the ethical and logistical difficulties inherent in obtaining large quantities of fetal neurons, much effort has been devoted to developing alternate sources of human neurons for use in transplantation. One alternate source is the Ntera 2/cl.D1 (NT2) human embryonic carcinoma-derived cell line. These cells proliferate in culture and differentiate into pure, postmitotic human neuronal cells (LBS-neurons) upon treatment with retinoic acid (RetA). Thus, NT2 precursor cells appear to function as CNS progenitor cells with the capacity to develop diverse mature neuronal phenotypes. When transplanted, these neuronal cells survive, extend processes, express neurotransmitters, form functional synapses, and integrate with the host. The final product is a $>95\%$ pure population of human neuronal cells that appear virtually indistinguishable from terminally differentiated postmitotic neurons. The cells are capable of differentiation to express different neuronal markers characteristic of mature neurons, including all three neurofilament proteins (NFL, NFM, and NFH), microtubule-associated protein 2 (MAP2), the somal–dendritic protein, and τ, the axonal protein. Their neuronal phenotype makes them a promising candidate for replacement in CNS disorders as a virtually unlimited supply of pure, postmitotic, terminally differentiated, human neuronal cells.

In support of different mechanisms for efficacy, animal transplantation studies of LBS-neurons revealed graft survival, a mature neuronal phenotype, and integration into the host brain *in vivo*.

In patients disabled by stroke, the concept of restoring function by transplanting human neuronal cells into the brain is innovative. Research in a rat model of transient focal cerebral ischemia demonstrated that transplantation of fetal tissue restored both cognitive and motor functions. Sanberg, Borlongan, and colleagues were the first to show that transplants of LBS-neurons could also reverse the deficits caused by stroke. The preclinical studies of LBS-neurons were carried out in a model of transient focal, rather than global, ischemia in order to maximize the chances of

functional recovery. Animals that received transplants of LBS-neurons (and cyclosporine treatment) showed amelioration of ischemia-induced behavioral deficits throughout the 6-month observation period. They demonstrated complete recovery in the passive avoidance test, as well as normalization of motor function in the elevated body swing test. In comparison, control groups receiving transplants of rat fetal cerebellar cells, medium alone, or cyclosporine failed to show significant behavioral improvement. A second study that evaluated response in comparison to the number of cells transplanted, confirmed the efficacy of transplanted LBS-neurons in reversing the behavioral deficits resulting from transient ischemia in an MCA occlusion rat model.

The initial objectives of the first clinical study performed at the University of Pittsburgh were to demonstrate the safety and feasibility of the neuronal-cell implantation procedure. These goals were met, in that no adverse events related to the implantation have occurred in at least 36 months of follow-up in 12 patients (Fig. 3). The adverse events that did occur in these patients were thought to be unrelated to the implantation of the neuronal cells and can be considered typical of a population with known cardiovascular disease and advanced age. This study was also intended to provide some information on the efficacy of neuronal-cell implantation in improving stroke-related neurologic deficits. In both treatment groups, mean NIHSS (National Institutes of Health Stroke Scale) total scores decreased and mean ESS (European Stroke Scale) total scores increased; both changes indicated improvement. For the ESS, the increases tended to be larger in the group of four patients receiving 6 million cells, both in the total scores and in the composite motor subscale scores. Both the Barthel Index and the SF-36 scores decreased in the group receiving 2 million cells and increased in the group receiving 6 million cells. All outcomes measurements were consistent in identifying a trend toward improved scores in the group of patients who received 6 million neuronal cells. The PET scan results also provide a suggestion of efficacy, in that increased activity at the area of the stroke was seen in 6 patients.

The neuronal cells could improve neurologic function through a number of different mechanisms. These include the provision of neurotrophic support (acting as local pumps to support cell function), provision of neurotransmitters, reestablishment of local interneuronal connections, cell differentiation and integration, and improvement of regional oxygen tension. Transplanted cells also may act to limit the reactive glial response and to limit retrograde degeneration, although this may be less feasible in a chronic injury. We believe that axonal reconnections through the grafted cells (serving as a ''bridge'') over large distances are less likely, although this phenomenon has been observed in spinal cord injury models. Phase 2 dose–response trials in patients are ongoing to evaluate further the role of neurotransplantation for patients with chronic motor deficits caused by basal ganglia region infarction.

V. ANIMAL MODELS FOR TRANSPLANTATION

A. Animal Models of Brain Degeneration in Parkinson's Disease

Among the chronic brain degenerative diseases, PD has the best characterized and most consistent models. Although the underlying mechanism of disease in these models may be significantly different from the human condition, they reproduce rather closely the pathology in the final stages of dopaminergic degeneration in PD and constitute a crucial basis to test novel therapies. Due to its well-defined neuroanatomical distribution, the nigrostriatal dopaminergic pathway can be lesioned or severed at various locations and the benefit of various cell grafting methods can be studied. Because this approach is more labor intensive and sometimes postsurgical complications may interfere with the experimental results, most investigators prefer to use chemical lesioning. The best characterized and most extensively used models are the rat 6-OHDA and the primate and murine (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) (MPTP) models. Both are based on the induction of a cytotoxic lesion in the dopaminergic neuronal population of the substantia nigra, resulting in massive or complete loss of striatal projections. The neurologic deficits can then be measured in various functional assays and now through PET imaging for dopamine connectivity. The autopsy findings are remarkable for many similarities with the human PD brain.

B. The Rat 6-OHDA Model for Transplantation

The rat 6-OHDA model is characterized by massive loss of dopaminergic neurons accompanied by obvious motor dysfunction that can be exacerbated by amphetamines. The effects of various treatments on the motor asymmetry can be measured over time and correlated with autopsy findings. For example, in a

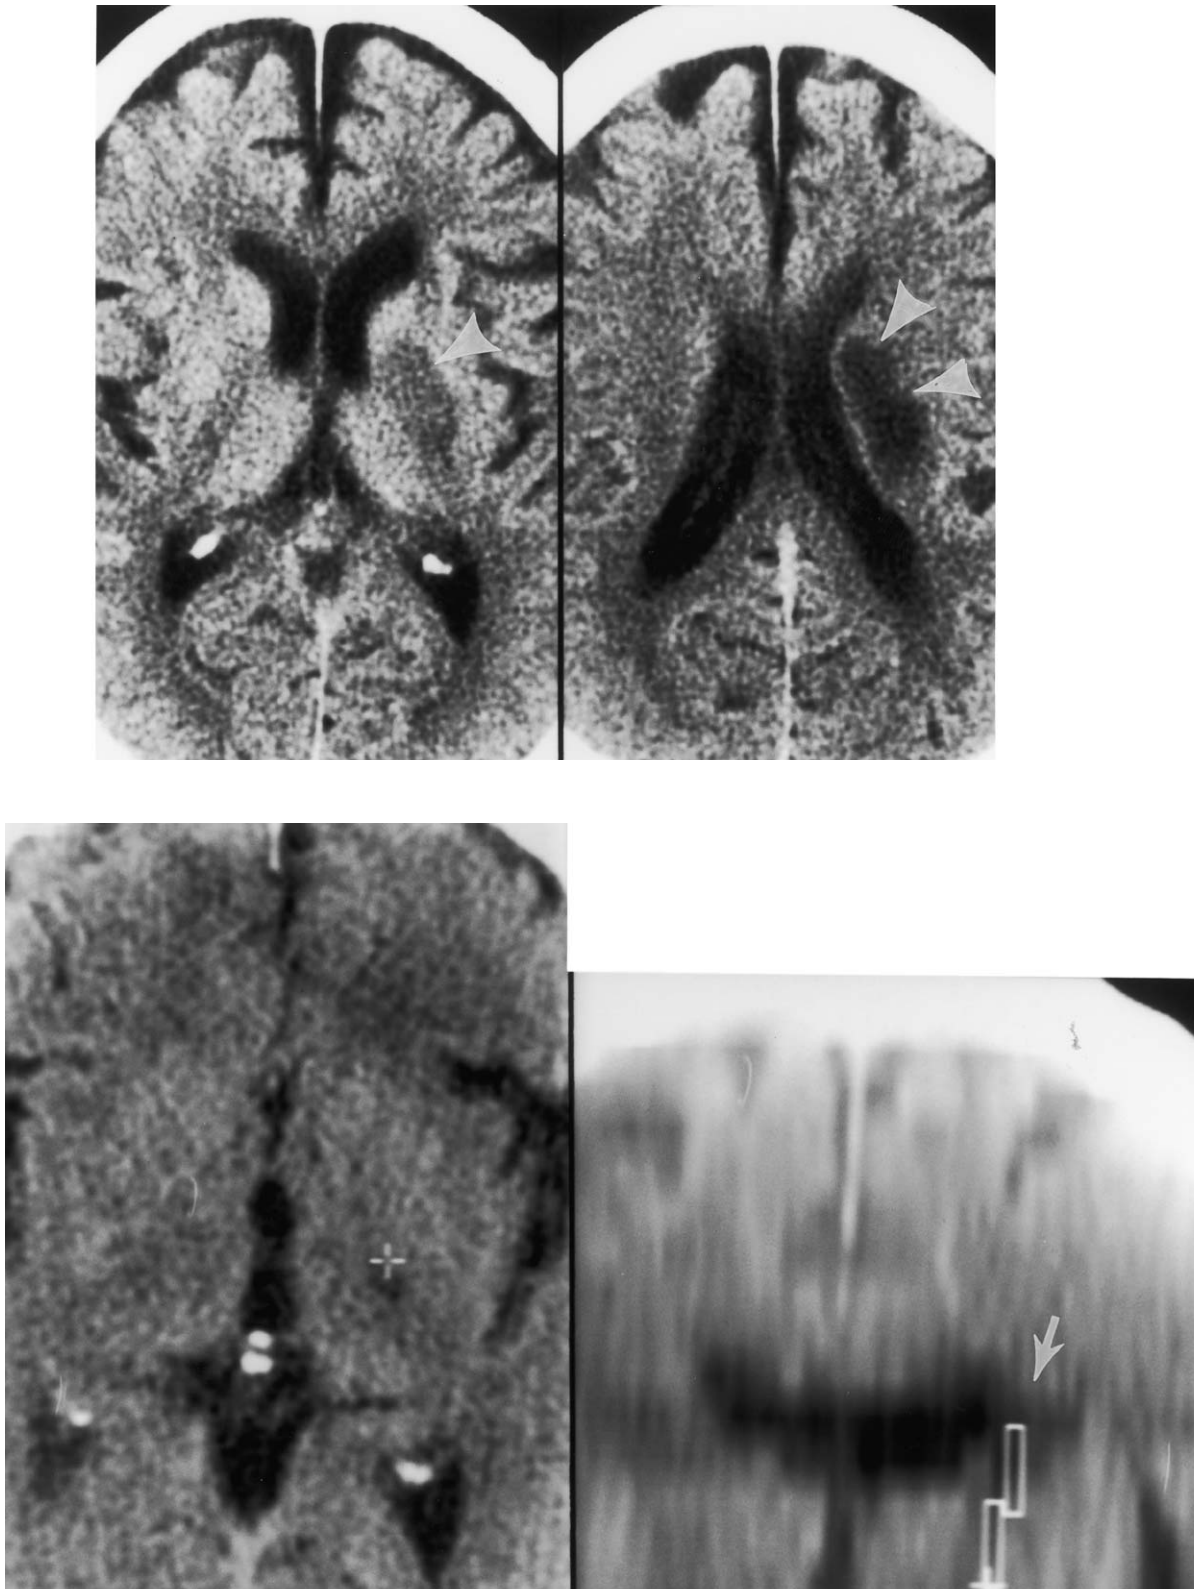

Figure 3 CT scans showing a cerebral infarction of the left basal ganglia region (top). The left scan shows the inferior target site for cell placement, and the right image shows a coronal view of the planned neuronal cell deposits (bottom).

detailed study of human fetal dopamine neurons implanted in parkinsonian rats, Clarke *et al.* showed that the functional effects of the graft were evident only when, as confirmed by serial autopsy histologic studies, they developed dopaminergic synaptic contacts with the host. This occurred at a rather late time points (4–5 months postgrafting), emphasizing again the fact that long-term survival is not sufficient if it is not accompanied by functional connectivity. These results were confirmed by other groups, who extended the studies for up to 2 years posttransplantation. In general, the grafts continue to differentiate and are characterized by abundant TH-positive neurites with many synaptic contacts. The host astroglial reactivity surrounding the graft can be detected and does not appear to be affected by host treatment.

To improve graft survival and integration, Nikkhah *et al.* developed a microtransplantation technique consisting of multiple small deposits of fewer cells rather than a single large-volume graft. This approach resulted in an increased functional benefit as measured by the significant reduction of rotational asymmetry. Another improvement in the grafting protocol in parkinsonian rats was made by Constantini *et al.*, who showed that cotransplantation of striatal tissues enhanced the benefit of the nigral dopaminergic implants, probably by offering some trophic support. This is an interesting concept and will be further discussed in this article (under trophic factors). Finally, Winkler *et al.* showed that the efficacy of nigral–striatal cotransplants can be further increased when the striatal grafts are implanted in the host nigra, with the mechanism proposed being a donor-derived, GABA-mediated, inhibitory activity on the host projection neurons.

C. The MPTP Model

The story of the MPTP model based on a series of intriguing observations in several heroin addicts with parkinsonian symptoms is well-known to all readers interested in PD. The clinical progress of these patients was followed and reviewed numerous times over the years. Burns *et al.* have reported a primate model of selective destruction of dopaminergic neurons in the pars compacta of substantia nigra (the same region affected in PD patients) following the administration of MPTP, the toxin that caused the disease in the drug users. Since then, numerous attempts have been made to develop similar models in other species, including a mouse version that shows promise, if attention is paid to the variability in the strain-related host susceptibility.

Due to its potential to mimic the human disease for testing early diagnostic methods (e.g., PET imaging), pharmacologic interventions, surgical procedures including cell grafting, and neuropathologic analysis, the primate MPTP model is one of the most powerful tools available to the PD investigators. Still, there is much to be done in terms of consistency of effects following the MPTP lesion. The diversity of protocols used by various groups, the individual response of the animals even within the same species and age group, the often subtle clinical changes, and sometimes the spontaneous recovery continue to limit our ability to measure accurately the changes made in the course of the disease following various treatments. Fortunately, increased sensitivity of neuroradiologic diagnosis to dopamine loss and more sophisticated histologic studies at autopsy could soon make this model the standard for preclinical trials in PD.

A systematic effort to improve the MPTP model was made by Bankiewicz and colleagues who demonstrated that unilateral injection in the internal carotid artery induced specific destruction of the dopaminergic nigrostriatal pathway, with sparing of other dopaminergic neurons and minimal or no injury on the contralateral side. The specific neuroanatomical injury was mirrored by limited, unilateral neurologic deficits that did not impair animal grooming and survival. This experimental development opened the door for long-term preclinical studies in nonhuman parkinsonian primates. For example, the transient efficacy of adrenal medullary transplants in humans was similar to observations in hemiparkinsonian monkeys. In similar fashion, the fundamental principles of fetal mesencephalic grafting can be tested in this model. For example, an interesting observation was that in hemiparkinsonian monkeys, the functional benefit postsurgery may be due to the host dopaminergic sprouting rather than to the donor tissue, raising the intriguing possibility that the graft itself may not need to contain dopaminergic neurons to promote a functional recovery in MPTP lesions.

D. Graft Survival: Transplantation Strategies

Significant progress has been made in the transplantation protocol itself, but we have much to learn about the intrinsic potential of various donor brain tissue

preparations and the *in vivo* cues to determine the fate of the neuroglial graft. In general, it is still believed that first trimester human fetal mesencephalic tissue is the best source for harvesting and grafting of dopaminergic neurons. This ''window'' can be somewhat extended (comparable numbers of surviving TH-positive grafted neurons) if cell suspensions are used instead of solid grafts. This finding was confirmed by different groups in various animal models, and most data suggest that, if survival of TH-positive cells is used as the main criterion of assessing the grafting efficacy, the younger embryonic tissues are superior to older fetal donors. Nevertheless, as discussed previously, several reports challenge this concept.

Although it may sound mostly of academic interest because all PD patients are adults, the influence of host age on graft survival merits discussion for identifying potential *in vivo* cues that are responsible for the integration of the implanted cells. One of the first observations made was that, in the neocortical transplants in older rats, both types of grafts, with high (early embryonic) or low (late embryonic) growth potential, survived and integrated to similar extents versus clear *in vivo* differences when younger host animals were used. Further studies have confirmed that migration of donor cells and integration of the grafts decrease in older hosts. On the other hand, studies analyzing host dopaminergic sprouting in the graft, in general very limited, find that it is not significantly different in young versus adult rats. Furthermore, these results were confirmed by functional studies showing that, even if the cytoarchitecture of the grafts in hosts of various ages may be different, the benefits are comparable. It is interesting to speculate on the clinical implications of these observations because several authors agree that the host responses are most critical to the functional benefits of fetal grafting.

VI. *IN VITRO* PROCESSING OF FUTURE GRAFTS

As mentioned earlier, the first limiting factor in the success of fetal grafting is the availability of suitable tissues. Banking of cryopreserved tissues is still employed and considered to be feasible by several authors. Most investigators now agree that, ideally, cryopreservation could be avoided, and optimized *in vitro* processing of fresh tissues for long-term survival and growth should become the standard. The University of Pittsburgh stroke transplantation trial was the first to use a cryopreserved cell line in patients. Another approach is to maintain fetal cells as aggregates in long-term suspension cultures that may even allow their expansion. However, this approach may not be feasible for processed neuronal cell lines.

There are benefits to *in vitro* processing of brain cells before implantation. First, processing may select for a viable, better characterized neuronal donor population. Second, it can help identify the donor glial–neuronal interactions that are critical *in vivo*, potentially protecting the graft from detrimental host reactions. Third, it can offer a setting for trophic and genetic manipulations (discussed later) that will enhance *in vivo* survival and integration. Finally, neuronal apoptosis in fetal grafts is well-described and appears to be significant during the first 10–15 days postimplantation. The mechanisms of neuronal death are predominantly mediated by caspases, and inhibitors of this process may have important benefits in improving the viability of the grafts.

A. Implantation Techniques

The majority of the TH-positive neurons (around 90%) within fetal grafts appear to die within the first week after implantation. Besides the pharmacologic trophic and protective treatments discussed later, changes in implantation protocols may have an important impact on the survival of the graft. One approach is to include a biologic adjuvant at the time of implantation, often as a cograft of peripheral nerve, that may offer continuous trophic support, promoting the survival and differentiation of the donor dopaminergic cells. Over the past decade, this approach was tested several times and the results, though mixed, are generally positive. Another bioengineering protocol, proposed by Brecknell *et al.*, is based on providing a ''bridge'' for the implanted dopaminergic neurons to grow into the striatum by using cells transformed to secrete growth factors. At present, stereotactic techniques are used to deposit cells at distances such that the ''sphere of influence'' of each graft might determine the distance between individual graft locations.

The most direct strategies to increase transplant integration in the host dopaminergic pathways is the use of cografts of mesencephalic and striatal donor cells or simultaneous mesencephalic grafts in the nigra and striatum of the host. Both of these interesting approaches are currently being explored in clinical trials in PD patients. Finally, the idea of using the nigra

(versus striatum) as a site of dopaminergic fetal cell grafting has gained momentum again, and studies propose it as a feasible alternative in PD. However, intranigral grafts alone fail to innervate the striatum without some additional therapy.

B. Host Immune Response

Another potentially serious limiting factor in graft survival, despite optimal *in vitro* tissue processing and efficient implantation protocol, is host rejection of the graft. Whereas the brain is still considered to be an organ with a limited immue response (historically called "immunoprivileged"), rejections of grafted tissues can occur through the classic cell-mediated immune response. The immune reactions to neural grafts have been studied for a long time, but the necessity of immune suppression is still debated. A review by Widner emphasizes the complexity of the immune response in the brain and also questions the impact of immunosupressive therapies on allo- or even xenograft survival. Furthermore, it should be noted that another host reaction, the degeneration of the graft mediated by brain macrophages that does not involve the presence of lymphocytes, can also be considered a form of rejection. The role played by reactive microglia in graft survival is the object of intense dispute. Finally, following an interesting observation in rats implanted with fetal dopamine cells, Hudson *et al*. suggested that host immunocompetence to the allogeneic graft is necessary but not sufficient to cause rejection.

Early studies in rats showed that immunosupression with cyclosporin A (CsA) was critical for graft survival and function of dopaminergic human xenografts. The benefit of CsA was confirmed in other animal xenograft models, but graft degeneration in nontreated animals was not evident. Furthermore, the lack of a detectable systemic immune response in primates with embryonic brain grafts raised the possibility that aggressive immune suppression may not be necessary and that local immune modulation or evasion strategies can be developed. If one assumes that the immune response is exclusively detrimental, which is not clear yet, methods proposed to modulate it include the cografting of Sertoli cells that seem to have both a trophic effect and a surprising immunosuppressive activity on the host response. Another proposed approach is to use specific anti-T-cell antibodies capable of inducing immune tolerance or, as suggested in an interesting report, a short course of treatment with an anti-IL-2 receptor antibody (CD25), which may be as effective as long-term CsA.

C. Vascularization and Blood–Brain Barrier Development

The next challenge in the survival of a healthy graft is the development of functional vascularization and a blood–brain barrier (BBB). The origin of angiogenesis in fetal brain grafts is still disputed. There is evidence that donor-derived vasculature already contained in the implanted tissue fragments can survive and rapidly develop connectivity with the host. When cell suspensions were used for allo- and xenografting, the BBB also appeared to form relatively soon and did not seem to be affected by concomitant treatments with CsA. These results were further confirmed, and additional findings suggest that early vascularization is determined intrinsically by the graft, possibly through locally produced growth factors (discussed later in the article).

Contrary to these reports, Geny *et al*. found that angiogenesis in the human fetal grafts is a much slower process, including a delayed redifferentiation of the endothelial cells present in the graft at the time of implantation, a phenomenon possibly dependent on the maturation of the fetal neuroglial tissue. Adding another twist to this debate, Pennel and Streit proposed that their studies with rat fetal allografts demonstrated early vascularization, but this was directly dependent on graft colonization by donor-derived microglia. In another similar study, Rostaing-Rigattieri *et al*. showed that not only microglia but also host-reactive astroglia and endothelial cells infiltrated the graft and participated in the reorganization of its cytoarchitecture. Finally, pilot studies in our lab showed that, in human fetal xenografts, the early development of a BBB, facilitated by *in vitro* manipulations before implantation, is crucial for long-term donor neuronal survival and differentiation.

D. Intraparenchymal Reaction to the Graft

It has become increasingly clear that the host parenchymal reaction to the fetal graft is possibly the decisive factor in determining its survival, integration, and functional benefit. Since the early studies with

murine models of neurotransplantation, the investigators have suspected that part of the functional benefit may be due to the host reaction to the graft or just to the various surgical procedures (e.g., cavitation). Not surprisingly, prime candidates as mediators of these effects are growth and trophic factors or other molecules produced by the host-reactive neuroglial millieu. The effects of the host-guided migration of donor-derived neurons to selective targets have been convincingly demonstrated. Nonetheless, the opposite may be as important clinically: host sprouting in a dopaminergic graft may be specific and extensive. The most intriguing observations were made in the MPTP model of PD. Bankiewicz and colleagues have demonstrated, in a long-term study of hemiparkinsonian monkeys, that cavitation alone leads to clinical improvement similar to that of autografting dopamine-secreting adrenal medullary chromaffin cells. Furthermore, similar results were obtained following implantation of fetal amnion. Both studies suggest strongly that the regenerative capacity of the host brain plays a primary role in functional recovery, at least in this primate model of PD.

Among the most prominent but least understood host reactions to the graft is the microglial response. It is well-known that reactive microglia are important immune mediators as antigen presenting cells infiltrating the grafted tissues. Still, several reports suggest that their presence and less defined activities are critical for the survival of the graft and host brain regeneration. Increasing evidence suggests that microglia are associated not only with pathological but also with normal functions in the brain. Microglia react to injury, usually by responding to and producing NTF. Furthermore, other growth factors produced by microglia, like HGF, were shown to have neurotrophic activities in the CNS. Finally, in a direct experiment, activated macrophages transplanted into a CNS injury site were crucial in triggering a regenerative cascade. *In vitro*, microglia promote the survival and differentiation of TH-positive neurons, probably through production of NTF or factors like plasminogen that enhance neurite growth. *In vivo*, nigrostriatal dopaminergic neurons develop neurites around the wound or graft, and this process appears to correlate with the neurotrophic factor production by activated macrophages and microglia.

From this brief summary of the supportive and guidance role played by the surrounding host neuroglial environment, it has become apparent that neurotrophic support is crucial in promoting graft survival and differentiation in the host.

VII. GRAFTING SUPPORTIVE TREATMENTS

In our opinion, the most important factor deciding the fate of the future graft is the trophic support offered by the intrinsic milieu, the host environment, or administered *in vivo* postgrafting. Neurotrophic factors have been the focus of intense studies discussing them as therapeutic agents in neurodegenerative diseases. Future testing in primate models will be necessary. In the field of neurotransplantation, the studies proposing NTF as *in vitro* and *in vivo* adjuvants to the graft have been significantly more successful. Overwhelming evidence from developmental neuroscience experiments demonstrated that growth factors are crucial in the differentiation of neural progenitor cells or, in general, less differentiated cells that are abundant in the fetal grafts. Among these factors, epidermal and fibroblast growth factors were most important in promoting the mitogenic capacity of neuroglial progenitors. Whereas work by Gage and colleagues established FGF as a principal mitogenic factor in the developing neuronal population, other growth factors may participate in the expansion and differentiation of the neuronal precursor cell population, as demonstrated by *in vitro* and *in vivo* experiments with insulin-like growth factor and hepatocyte growth factor. Interestingly, the latter seems to function as a primer for other trophic signals.

Hepatocyte growth factor is only one of the newer trophins for the CNS. Today, the family of growth and trophic factors proposed to affect the survival and development of neuroprogenitor cells is probably the largest in this ever expanding field. Factors like cytokines, once considered to be exclusively neurotoxic (e.g., TNF), are now studied for neurotrophic properties. Among them, leukemia inhibitory factor (LIF) and ciliary neurotrophic factor (CNTF), in addition to more traditional growth factors like platelet-derived growth factor (PDGF), are considered to be potent promoters of neuroprogenitor cell proliferation and eventually differentiation. *In vivo*, CNTF produced by reactive astrocytes can prevent the degeneration of dopaminergic neurons in adult rats. Astrocytes and endothelial cells surrounding or infiltrating the transplant are susceptible to the effects of PDGF, which may control the survival of graft through neovascularization.

In addition to the proliferative support offered to neuroprecursor cells, NTFs are key players in their differentiation to the mature phenotype. This function may be critical for the graft integration in the host environment. It was shown that, at least when cell lines

were used (e.g., PC12), *in vitro* pretreatment with NGF is crucial for the *in vivo* phenotype of the graft: differentiated (NTF-treated cells) versus nondifferentiated, tumorlike (nontreated cells). The *in vivo* effects of NGF become even more obvious when fetal grafts are continuously treated through *in situ* injection or when regeneration is promoted through gene delivery using transformed cells.

A. Brain-Derived Neurotrophic Factor

Brain-derived neurotrophic factor (BDNF), another member of the neurotrophin family (which includes NGF, NT-3, and NT-4/5), has been shown to have great potency in modulating the growth and survival of dopaminergic cells and their precursors. It is now widely accepted that the pluripotent BDNF and its high-affinity receptor trkB are widely distributed in both the developing and mature nervous system. Our increasing understanding of neurotrophin binding to their receptors, signal transduction following trk, and p75 dimerization and activation has lead to a series of exciting developments in designing experimental models to test novel trophic treatments. In addition to dopaminergic cells, BDNF was found to be potent on cholinergic and glutamatergic motor and sensory neurons, in both the central and peripheral nervous systems.

Among the most exciting new discoveries in the field of neurotrophic factor research is the ability of BDNF to be transported in an anterograde fashion. For example, it was shown that, in development, BDNF produced by dorsal interneurons stimulates the proliferation and differentiation of motor neuron progenitors after anterograde transport. Another piece of evidence comes from the studies by Kokaia *et al.*, who have shown that BDNF levels increase significantly in a rat model of focal ischemia but then decrease rapidly, suggesting anterograde transport. Finally, additional supporting data for the anterograde transport of BDNF in the adult CNS were reported by Conner *et al.*, who demonstrated that its distribution parallels axonal flow, including storage in terminals within the target.

One of the most important implications of anterograde transport of BDNF is probably its participation in synaptic transmission. This theory is supported by data suggesting that enhancement of long-term transmission is manifested through synapse consolidation rather than neuronal growth. Also, in an *in vitro* explant model using hippocampal slice cultures, Frerking *et al.*, showed that BDNF may enhance transmission in CA1 neurons by decreasing the postsynaptic inhibition through a presynaptic mechanism. There is evidence that, at the presynaptic level, BDNF potentiation is mediated by cAMP. In addition, BDNF is reported to also be able to mediate agrin-induced postsynaptic differentiation. All of these functions obviously can be critical steps in the establishment of a functional cell graft.

In spinal cord injuries, neurotrophin treatments are proposed to present significant clinical benefits. For example, BDNF infused at the site of spinal cord injury in rats showed a positive but transient effect on local reflexes. The most dramatic impact of BDNF occurred in fully transected spinal cords. When these chronic infusions were stopped, the behavioral effects disappeared. BDNF was also shown to stimulate sprouting of cholinergic fibers at the injury site, but did not affect serotonergic fibers or total axon density. In an effort to promote directional regeneration, cells transformed to secrete BDNF were grafted in trails in the transected spinal cord, and the results showed a significant positive effect on axons from trkB expressing neurons. In another study by Broude *et al.*, it was shown that in spinal cord transplants the addition of BDNF increased axonal outgrowth of axotomized neurons.

BDNF has been proposed to have an autocrine effect on dopaminergic neurons that express abundant trkB, and if these results are confirmed in humans, new hypotheses may be formulated about the mechanisms of disease in parkinsonism. Supporting this theory, several studies showed reduced BDNF protein in the substantia nigra of PD patients. In this context, BDNF treatments (similar to GDNF, discussed later) pre- and posttransplantation may serve a dual purpose: stimulate the growth of a functional dopaminergic population within the graft and promote the regeneration of dopaminergic pathways in PD.

Interestingly, some reports suggested that BDNF enhanced the function rather than survival of the grafts enriched with dopamine cells. *In vitro*, BDNF can protect dopaminergic neurons from hydroxydopamine toxicity. *In vivo*, similar protective functions were observed in rats with BDNF producing grafts, after being challenged with the active metabolite of the dopaminergic toxin MPTP. The regenerative capacity of BDNF on dopaminergic projections was shown to be both direct and indirect, mediated through improved fetal grafts. Still, only a subpopulation of nigral dopaminergic cells may be susceptible to these effects, depending on their capacity to express the high-affinity receptor trkB. Furthermore, there are some concerns

about the effects of long-term *in situ* delivery of BDNF *in vivo*, at least in the rat striatum. Currently, it still appears that the most consistently positive use of BDNF in cell transplantation is to promote dopaminergic differentiation preimplantation. When rat and human nigral fetal cell aggregates were treated with BDNF, the number of TH-positive neurons increased significantly. These effects were further enhanced when GDNF was used in combination with BDNF.

B. Glial-Derived Neurotrophic Factor

In general, GDNF has similar or even enhanced trophic functions on dopaminergic neurons and their precursors. *In vivo*, GDNF was also shown to be relatively potent in animal models of dopaminergic protection or regeneration, but human clinical trials have not been so encouraging. Nonetheless, its potential use in PD has made GDNF the prime candidate for NTF treatments in association with fetal mesencephalic transplants of dopaminergic neurons.

GDNF, a related member of the TGF-β family, was first identified and characterized in 1993 by Lin *et al.* From the beginning, it was evident that GDNF has a potent but specific–selective activity on dopaminergic neurons, inducing their differentiation in the absence of overt neuroglial proliferation. Shortly after, *in vivo* studies demonstrated that GDNF injected into the substantia nigra produced a significant decrease in the motor deficits associated with 6-OHDA lesioning in rats. When GDNF was injected in developing or mature mesencephalic grafts, *in oculo*, its primary effect was to promote dopaminergic neuritic growth rather than survival of TH-positive cells. Interestingly, administration of GDNF in a murine MPTP parkinsonian model had both protective and regenerative effects. The *in vivo* protective effects were also demonstrated in a rat nigral axotomy model, suggesting again that GDNF has a high specificity for dopaminergic neurons.

Further *in vitro* studies showed that a mixture of slow-release GDNF, fibrin glue, and fetal mesencephalic neuroglial cells resulted in a significant increase in the number of TH-positive cells and neuritic density. Another *in vitro* study indicated that GDNF may offer protection from continuous cell death after the removal of toxins and even stimulate dopaminergic fiber regrowth. When another neurotoxin, quinolinic acid, was used, GDNF showed selective protection of dopaminergic neurons against excitotoxicity.

In vivo studies using fetal mesencephalic grafts showed that injections of GDNF in the vicinity of the rat brain implant resulted in significantly increased survival and growth of TH-positive cells accompanied by marked functional improvement. The improved survival and differentiation of dopaminergic fetal grafts treated with GDNF pre- or postimplantation have been independently confirmed in numerous studies focused on the therapeutic benefits in parkinsonian models. A more recently identified member of this family of growth factors, neurturin, was found to be similarly potent in preventing dopaminergic cell death but lacked the support for TH-positive neuritic growth associated with GDNF treatments. Finally, in clinical studies, two patients with PD who received fetal dopaminergic implants pretreated *in vitro* with GDNF showed increased graft survival. The benefits of GDNF treatments in PD patients appear to be restricted to association with fetal grafts. When GDNF was injected into the cerebroventricular system of a PD patient that did not receive a graft, the results appeared detrimental. Further research is continuing on this approach.

C. Other Protective and Trophic Factors

In addition to the beneficial effects of neurotrophic factor treatments, the ganglioside GM1 has been shown to enhance effects even at minimal concentrations of BDNF. The lazaroids are another intriguing class of compounds that demonstrated a strong trophic effect on promoting the survival of embryonic mesencephalic tissues and their development *in vivo*. Interestingly, the lazaroids promoted *in vivo* survival of dopaminergic neurons but did not increase target striatal innervation. These agents have now been incorporated into clinical trials.

Mechanisms of grafted cell death include excitotoxicity and apoptosis. Among the excitotoxic inhibitors, the calcium channel–NMDA receptor antagonist MK-801 is one of the most studied. *In vivo*, this compound was not able to enhance dopaminergic neuronal survival in the graft, suggesting that cell death in the grafts may not be due to excitotoxicity. The other mechanism of cell death in transplants, apoptosis, is under intense scrutiny because caspase inhibitors seem to reduce neuronal death in the grafts. Furthermore, the combination of pretreatment with a caspase inhibitor and a lazaroid may have a significantly higher positive effect on transplanted dopaminergic neurons.

Finally, debates in neural cell grafting gravitate around the potentially beneficial effects of new generation immunosupressive drugs that have been shown to be less toxic to the brain. A representative member of this family is the FK-506 drug. This compound, together with CsA and rapamycin (approved for clinical trials), binds to receptors called immunophilins. Many of the immunophilin ligands have be shown to possess neurotrophic activities. This field is under intense scrutiny, especially since immunophilins have been proven to be abundant in the brain. Among the newer members of the immunophilin ligand family, the non-immunosuppressive drug GPI-1046 shows much promise in promoting regenerative neuritic growth from surviving neurons in various CNS lesions. Furthermore, the immunophilin ligand V-10,367 has been shown to specifically increase the growth of dopaminergic neurons (mostly neurite branching) and protect against MPTP lesioning, in a manner superior to FK-506.

D. Nonneuronal Primary Human Cells

On the basis of the observations discussed previously regarding the importance of the trophic host response in promoting regeneration posttransplantation, often independent of graft survival or function, some investigators have proposed alternate sources of donor cells that will primarily serve as promoters of host regeneration. Among the nonneuronal brain cells, astrocytes are prime candidates. A study of neuroglial cell grafting in a murine model of lesion-induced memory deficits showed that astrocytic grafts induced significantly more improvement compared to the cholinergic neuronal grafts. Another interesting method is based on transplanting activated macrophages to promote CNS regeneration. One of the rationales is that grafted macrophages may compensate for the failure of host macrophages to provide trophic support or potentially overcome their inhibitory activity. Finally, one of the most intriguing sources of donor cells is the bone marrow stroma. Azizi and colleagues have shown that human marrow stromal cells grafted in the rat brain can survive, spread, and differentiate into a neuroglial phenotype in the absence of a host immune response or any signs of rejection. An important comment is that the donor cell mixture may include a significant population of nonhematopoietic tissue precursors. If any of these methods proves to be consistent among various laboratories and disease models, they could become a powerful strategy for promoting "natural" regeneration or an important platform for delivering gene therapy.

VIII. STEM CELLS AND NEURONAL PRECURSORS

The advances in our ability to manipulate embryonic stem cells have opened a whole new spectrum of potential therapies in tissue regeneration in general and the brain in particular. It has also reignited interest in brain stem cells and neuroprecursors that show many analogies with the considerably better characterized hematopoietic system. The definition of brain stem cells versus neural precursors is increasingly more precise and tends to better delineate the distinction between totipotent, multipotent, and lineage committed. Excellent reviews about the immense potential of using stem cells in regeneration have been published. The reports that stem cells are present not only in the developing brain but can also be identified in adults have further contributed to the excitement about new possibilities to promote CNS regeneration.

Many of the early studies have often reported successful harvesting of progenitor cells from various regions of the brain (the subventricular zone being the most popular but not singular) that can be expanded *in vitro* and then differentiate *in vivo* into functional neurons. The challenge is to still better identify the neural progenitor cells and understand the mechanisms of growth and differentiation from embryonic stem cells. An important characteristic of neuroepithelial stem cells, described more than a decade ago and still widely used, is expression of the intermediate filament protein, nestin. More recently, new markers of neuronal progenitor cells, conserved in their evolution and useful for early lineage selection, include Musashi-1 and an epitope recognized by the 2F7 monoclonal antibody. The mechanisms of progenitor cell maturation appear to be similar in various brain regions and seem to depend primarily on a cascade of signals mediated by specific combinations of growth factors and molecules (like noggin) that can modulate their activity.

An understanding of the dynamics of gene expression and specific protein production in the development of the neural lineage from stem cells is critical for designing new isolation and purification methods to be used *in vitro* for preimplantation neuronal enrichment of future grafts. In addition to the traditional marker nestin, Li and colleagues reported that the transcription factors Sox1 and Sox2 could identify progenitor

cells restricted to the neural lineage with higher specificity. Furthermore, expression of a neuron-specific promoter (like Hu and TuJ1/β-III tubulin) offers another opportunity to intervene through gene engineering in the development of neural progenitor cells and select for this cell phenotype.

Regardless of their origin, fetal or adult, neural precursor cells show much promise in brain repair. They can survive and differentiate in the host lesioned brain, although it seems that their predominant differentiation *in vivo*, posttranplantation is along the astrocytic lineage. Not surprisingly, the migration and differentiation of the grafted precursor cells are significantly influenced by local cues that may even overcome the *in vitro* manipulations. Nonetheless, the potential for *in vivo* survival of grafted neural precursor cells can be fully exploited when they are used as platforms for gene delivery or engineered to modulate the neurotrophic factor environment in the host brain.

A. Neuronal Cell Lines

The use of "primitive" neuroglial cell lines that preserve their mitotic potential *in vitro* but will differentiate *in vivo* was proposed for a long time to be a feasible alternative to primary cell cultures. Whereas the PC12 line is well-established as the workhorse of a plethora of *in vitro* experiments studying neurotoxic or neurotrophic mechanisms in the CNS, its capacity to differentiate and integrate *in vivo* in the host brain is limited at best. Because the usefulness of this cell line in humans may be seriously hampered by its uncontrolled capacity to proliferate in a nondifferentiated state, significant efforts were made to identify new human neuronal cell lines that will overcome this obstacle. One of the candidates that, under certain conditions, can differentiate into a "mature neuronal phenotype" is the human cortical neuronal cell line HCN-1, which has many of the characteristics of immature neuroepithelial cells but, interestingly, does not respond to traditional growth factors for CNS cells, like βFGF. Another example is the human neuroblastoma cell line SH-SY5Y, which can synthesize dopamine *in vitro* and differentiate *in vivo*. Still, a puzzling observation seen, as discussed earlier, with primary cell grafts too is that in parkinsonian animal models the functional benefit postgrafting may not be due to dopamine release by the implanted cells. The use of immortalized primary cell cultures has become a popular approach. Experiments with SV40 tumor antigen immortalized dopaminergic cells showed that they can be used for *in vitro* analysis (e.g., the SN4741 line) of the effects of BDNF on mesencephalic cultures. *In vivo*, similar immortalized dopaminergic cells (the 1RB3AN27 clone) survived for more than 1 year in grafts and were associated with clinical improvement but, again, did not show significant differentiation and integration in the host brain.

One of the most studied neuronal cells is the NT2 line derived from a human teratocarcinoma that can differentiate *in vitro*, following treatment with retinoic acid, into cells with a mature neuronal phenotype known as "hNT" (or the older designation "NT2N") cells. *In vivo*, grafted hNT cells aquired a mature phenotype (including growth of neuritic processes and synaptic contacts) and could survive for more than a year in the mouse CNS. Interestingly, later studies showed that *in vitro* treatments of NT2 cells are not critical to their *in vivo* differentiation. One of the most convincing applications of using these cells in transplantation comes from experiments using a rat CNS ischemic model, in which hNT cells induced a more robust recovery than fetal rat striatal grafts. In the rat 6-OHDA parkinsonian model, hNT cells grafted into the striatum and substantia nigra were shown to survive in the host parenchyma and generate TH immunoreactivity when pretreated with LiCl. When made for human use, these cells are called LBS-neurons.

B. Polymer Encapsulation

As discussed earlier, one of the major challenges to graft survival in the CNS is modulation of the host immune response. Most neuroglial cells (including *in vitro* adapted lines like PC12) could, at least theoretically, benefit from protection against the host immune response and rejection by using an encapsulating physical barrier. Though many grafted cells can survive, the connectivity between the host and implanted neurons is limited and a significant number of donor cells die. In an early study by Jaeger *et al.*, dopaminergic cell lines survived within a semipermeable membrane. Shortly after, Winn *et al.* proposed that polymer-encapsulated cells may provide a means of neurotransmitter and growth factor delivery *in vivo*. This approach was proposed early on as an alternative treatment in PD, and its feasibility was demonstrated in animal models. In MPTP monkeys that showed clinical improvement after grafting, encapsulated cell implants were shown to be able to uptake and metabolize dopamine.

Another promising application of this approach is the delivery of trophic factors in the regenerating brain. The main problem with using genetically engineered cells for *in vivo* delivery of growth factors is their uncontrolled growth in the host brain. This can be readily solved when the donor cells, modified to secrete trophic factors, are encapsulated in a semipermeable membrane. Intrastriatal implants of polymer-encapsulated cells producing NGF induced a significant increase in the cholinergic neuronal immunoreactivity at the site of implantation. The long-term production of NTF by encapsulated grafts is physiologically relevant and associated with a positive host response in the absence of any detectable side effects. In parkinsonian animal models, encapsulated grafts engineered to produce GDNF added a significant functional benefit to the dopaminergic cografts.

IX. VIRAL VECTORS

The traditional strategy for viral vector mediated gene transfer into the CNS was based on a herpes simplex virus construct. Some of the limitations associated with this approach, like limited long-term robust gene expression in the CNS, have been overcome by new adenoviral vectors. MPTP lesioned mice receiving GDNF via an adenoviral vector showed significantly higher levels of dopamine in the striatum. The use of adenoviral vectors is accompanied by only a limited inflammatory host response. As mentioned earlier, primary neuroglial cells (e.g., astrocytes) are excellent candidates for gene delivering *in vivo*. In a study by Ridet *et al*., astrocytes were infected with an adenoviral construct containing the human *TH* gene. The cells transformed produced significant amounts of TH and released L-dopa. A similar approach was proposed to be used with human neural progenitor cells.

A newer category of vectors increasingly used in CNS applications is represented by adenoassociated viruses (AAVs). In the experimental MPTP model, AAVs expressing TH were introduced in monkey brains, and expression of the donor gene was restricted to neurons in the host striatum. In a similar approach, AAV–TH kindey cells infected with an AAV packaging the TH and aromatic amino acid decarboxylase genes showed increased production of dopamine *in vitro*. *In vivo*, the same viral vector construct used in dopamine-depleted MPTP monkeys induced sustained high levels of TH immunoreactivity. When the *BDNF* gene was incorporated in to an AAV vector also containing a neuronal specific promoter, no significant effects could be seen in a rat parkinsonian model.

Another class of viral vectors tested for CNS delivery is represented by retroviruses. Astrocytes transformed to produce dopa by infection with a TH containing retroviral vector induced a significant functional improvement postgrafting in parkinsonian rats. Nevertheless, the apparently shorter time course of transgene expression in this system may limit its use in brain regeneration. Finally, perhaps the most interesting and potentially useful strategies are based on using lentiviral vectors to deliver therapeutic genes to the CNS. Lentiviruses are characterized by the capacity to infect postmitotic cells (e.g., neurons). If one assumes that all of the theoretical concerns regarding the *in vivo* replication and potential lethal effects of this family of viruses, which includes HIV, are addressed, they may become ideal tools for long-term, stable, transgene expression *in vivo*. In a study of lentiviral gene transfer to the monkey brain, Kordower *et al*. reported that striatal and nigral cells infected with a vector containing β-Gal showed robust, long-term transgene expression in the absence of significant inflammatory host response.

X. SUMMARY

Tremendous achievements in neuroscience over the past three decades have provided a solid foundation for basic and clinical research in neurotransplantation. Restorative neurosurgical procedures will develop from different directions, and it is likely that a combination of approaches will be necessary to maximize patient outcomes.

Neuroanatomy

CHRISTOPHER M. FILLEY
University of Colorado School of Medicine and Denver Veterans Affairs Medical Center

GLOSSARY

brain stem The most caudal part of the brain, linking the cerebrum with the spinal cord and consisting of the midbrain, pons, and medulla.

cerebellum The brain structure posterior to the brain stem, the major divisions of which are the laterally placed cerebellar hemispheres and the midline vermis.

cerebrum The paired cerebral hemispheres and diencephalon, which are located rostral to the brain stem and cerebellum.

cortex A thin sheet of neurons and synapses that constitutes the outermost layer of the cerebral hemispheres.

gray matter One of the major types of brain tissue, consisting of neuronal cell bodies and synapses found in either the cortex or the subcortical nuclei.

neuron An excitable cell that serves as the basic functional unit of the nervous system because of its capacity to transmit information electrically.

synapse The point of contact between neurons at which a chemical signal from one neuron influences the excitability of another.

ventricles A series of cavities within the brain—the paired lateral ventricles, the third ventricle, and the fourth ventricle—filled with cerebrospinal fluid.

white matter The term used to describe tracts of myelinated axons responsible for providing structural and functional links between gray matter areas.

The human nervous system is a highly complex assembly of nervous tissue that is responsible for a wide range of homeostatic, motor, sensory, cognitive, and emotional functions. Neuroanatomy is the discipline devoted to the structure of the nervous system. Broadly viewed, the nervous system can be divided into several major components (Table I). The first such division is between the central nervous system (CNS), which consists of the brain and spinal cord, and the peripheral nervous system (PNS), made up of numerous spinal and cranial nerves that transmit information to and from the CNS. In this article, we consider the anatomy of the brain, which stands literally and figuratively at the top of the nervous system as the highest integrative organ in the entire body. The cranial nerves, while strictly speaking part of the PNS, will also be included in this account as they are intimately related to brain structure and cannot be omitted in describing its anatomy. This review will necessarily be confined by space limitations to salient features of the brain's anatomy and further details can be found in several comprehensive textbooks. An attempt will be made herein, however, to emphasize the aspects of brain anatomy most relevant to the phenomena of human behavior.

I. OVERVIEW OF THE BRAIN

Encased securely in the skull, or cranium, the brain is a roughly symmetric, soft, and delicate organ weighing about 3 lb (approximately 1400 g) in the adult human. At the lower end of the brain, the medulla oblongata of the brain stem is continuous with the spinal cord, which descends into the spinal canal below an opening in the base of the skull called the foramen magnum; thus, the CNS is a distinct and connected whole that is protected throughout by the skeletal system. The brain is also surrounded by three layers of covering tissues: the thick dura mater just below the skull, the weblike arachnoid attached to the inner surface of the dura, and the thin pia mater directly adjacent to the surface of the brain.

The brain is customarily divided into three gross anatomic segments: the cerebrum, cerebellum, and brain stem (Fig. 1). The cerebrum consists of the paired cerebral hemispheres, which are joined by a large white matter tract called the corpus callosum, and the diencephalon, which includes the thalamus and hypothalamus. The cerebellum is a relatively large structure situated posterior to the brain stem. The brain stem itself is made up of the midbrain, pons, and medulla (short for medulla oblongata). Also within the brain are four cavities known as ventricles: the two lateral ventricles in the cerebral hemispheres, the third ventricle between the two thalami, and the fourth ventricle between the brain stem and the cerebellum. The ventricles are filled with a clear, colorless liquid called cerebrospinal fluid (CSF). The blood supply of the brain comes from four major arteries in the neck that provide a rich source of blood to meet the high oxygen demand of the brain. There are two carotid arteries and two vertebral arteries that link together in an anastomotic structure called the circle of Willis at the base of the brain, where major arteries irrigating specific cerebral areas originate. Venous drainage is accomplished by a complex network of venous sinuses that ultimately terminate in the paired internal jugular veins in the neck.

A source of confusion to many in studying the gross anatomy of the brain is the use of the singular descriptor in discussions of what are evidently paired structures. For example, it is commonplace to refer to the "cerebrum" when in fact both cerebra are implied.

Thalamus
Hypothalamus
Cerebral cortex
Frontal lobe
Temporal lobe–limbic system
Parietal lobe
Occipital lobe

This convention, well-entrenched in the scientific literature, is maintained for simplicity because the singular serves as a convenient shorthand. In this article, use of the singular descriptor for gross anatomic regions will imply that a pair of these regions exists unless otherwise specified.

A vast number of cells are found within the brain itself. The cellular composition of the brain includes neurons, or nerve cells, which are the basic functional units of the nervous system, and glial gells, or glia, which have a variety of supporting roles. Estimates vary, but it is possible that the brain contains up to 100 billion neurons and perhaps 10 times as many glial cells. Neurons are excitable cells that function to integrate signals they receive and transmit impulses to other neurons, and each one is connected to many others at points of juncture called synapses. Thus, the brain can be considered to be a densely interconnected electrical organ. The ongoing neuronal activity that results permits an impressive range of integrative functions that the brain maintains over all bodily and mental processes.

A final anatomic distinction to be made in the brain is between the gray matter and white matter. The cell bodies of neurons are concentrated in the gray matter, which largely consists of neuronal somata and their extensive synaptic connections. In gross anatomic terms, gray matter includes both the cortex of the brain, its outer layer, and a number of structures below the cortex known as nuclei. In contrast, the white matter consists of the axons of neurons, which travel throughout the brain and allow gray matter areas to communicate with each other. The white matter is characterized by myelin, a fatty substance that imparts a glistening white appearance to the cut brain. Myelin serves to insulate axons and in so doing greatly increases the efficiency of interneuronal communication by increasing the speed of neuronal conduction. White matter tracts course within and between the hemispheres to connect gray matter areas in functionally unified networks subserving many functions.

II. MICROSCOPIC ANATOMY

As indicated earlier, the brain contains extraordinary numbers of neurons and glial cells. The remarkable capacities of the brain result in part from the wealth of neurons and their connections, and the glia provide important support for the optimal function of the neuronal population. In this section, we consider microscopic aspects of the major cell types in the brain.

The neuron is the fundamental functional unit of the nervous system. Neurons are anatomically specialized to transmit information, which may take the form of a sensory stimulus received from the periphery or a motor signal destined to produce movement in a muscle. In the brain, neurons have many additional functions that can be generally termed "information processing", and presumably this category includes all of the cognitive and emotional operations traditionally associated with mental activity and behavior. Most brain neurons, in fact, are classified as interneurons because they are interposed between sensory input and motor output and mediate these other, "higher" functions. To accomplish all of these various tasks, neurons have a typical arrangement that includes a cell body, a variable number of dendrites, and an axon (Fig. 2). The cell body, also known as the soma or perikaryon, contains the cell nucleus and other organelles that maintain the metabolic status of the neuron and synthesize macromolecules essential for its function. Dendrites are relatively short processes extending from the cell body that receive input from adjacent neurons via synaptic contacts (see later discussion).

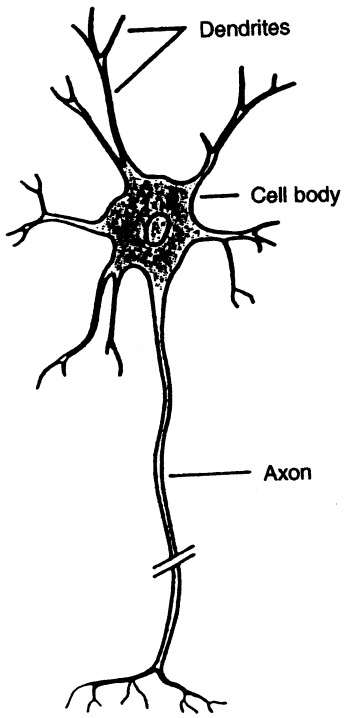

Figure 2 Drawing of a typical neuron, with its characteristic cell body, dendrites, and axon. Reprinted with permission from Kandel, E. R., Schwartz, J. H., and Jessell, T. M., Eds. (2000). *Principles of Neural Science*, 4th ed., p. 24. McGraw-Hill, New York.

The axon is a long, cylindrical process that provides for the output of the neuron, again via synaptic contact with adjacent neurons.

The transfer of information in the nervous system is both electrical and chemical in nature (Fig. 3). Within a single neuron, the signal is electrical and takes the form of an action potential. This is an electrical impulse (often referred to as a spike) propagated along the axon by virtue of a sudden influx of sodium ions that transiently reverses the polarity of the axonal membrane. The resting membrane potential is quickly restored after the action potential passes, and after a short refractory period another spike can be propagated. The action potential is an all-or-none phenomenon that depends on the balance between excitatory and inhibitory input received by the neuronal dendrites.

Whereas the neuron itself conducts information electrically, the junction between neurons, known as the synapse, operates by means of chemical transmission (Fig. 3). A synapse is a specialized region at which a chemical messenger known as a neurotransmitter from one neuron (presynaptic) diffuses across a narrow synaptic cleft to activate another neuron (postsynaptic). When the neurotransmitter binds with the receptor on the postsynaptic membrane, it acts to produce either a depolarization (excitatory stimulus) or hyperpolarization (inhibitory stimulus), and the summation of these many postsynaptic potentials determines whether an action potential is generated in the postsynaptic neuron. Neurotransmitters are generally small amines, amino acids, and neuropeptides, and their pharmacology promises many avenues for the successful manipulation of abnormal physical and mental states.

Far more abundant even than neurons in the brain are glial cells. Glia of the brain and spinal cord are classified into four types: astrocytes, oligodendrocytes, microglia, and ependymal cells. Astrocytes are star-shaped cells found in both gray and white matter that have a role in the mechanical support of neurons, contribute to metabolic regulation of the microenvironment of the brain, and participate in its response to injury. Oligodendrocytes are confined mainly to white matter, where they are responsible for the myelination of brain axons, just as Schwann cells perform this function in the PNS. Microglia are small cells found in gray and white matter that serve as the phagocytes of the brain, migrating as necessary to damaged areas where they consume pathogens and neuronal debris.

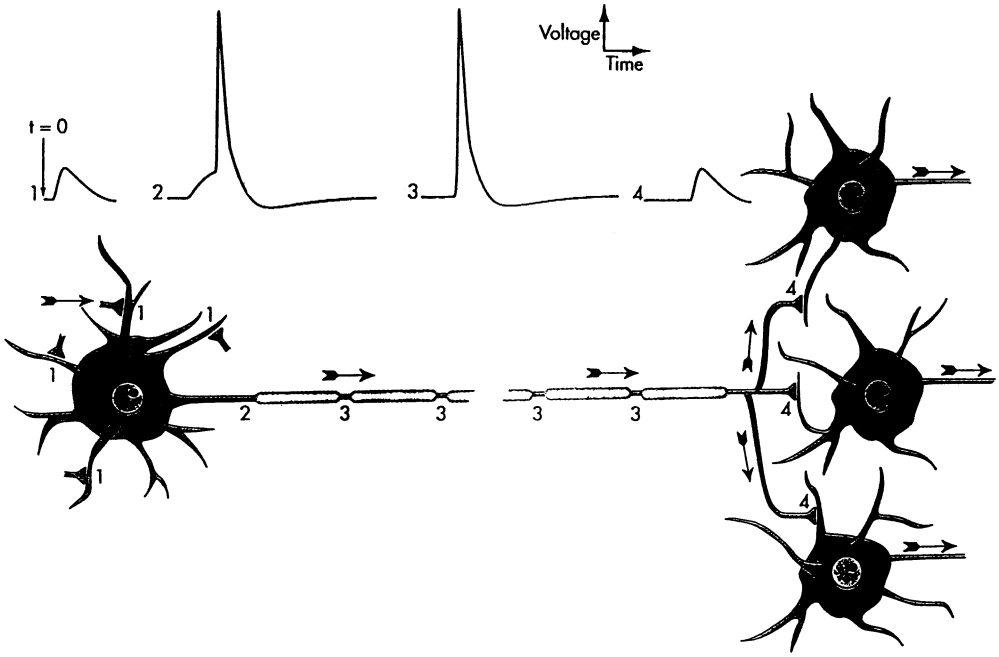

Figure 3 General depiction of information transfer between neurons. Chemical signaling by neurotransmitter release onto a neuron (1) causes the generation of an action potential (2), which is an electrical signal propagated down the axon (3). The action potential then causes further neurotransmitter release onto subsequent neurons (4). Reprinted with permission from Nolte, J. (1999). *The Human Brain*, 4th ed., p. 145. Mosby, St. Louis.

Ependymal cells line the ventricles of the brain, and at a specialized structure called the choroid plexus, one of which is found in each ventricle, ependymal cells form a secretory epithelium that produces the CSF that fills the ventricles and bathes the entire CNS.

III. BLOOD SUPPLY

The brain is extremely vulnerable to even a momentary reduction in or loss of blood flow, and an uninterrupted supply of well-oxygenated blood is critical. A complex system of arteries and veins convey blood to and from the brain, and interruption of the vascular system may result in stroke, one of the most common and devastating neurologic disorders.

The arterial supply of the brain comes entirely from four major vessels that originate in the neck (Fig. 4). The right and left common carotid arteries arise from the right subclavian artery and ascending aorta, respectively, and within a few centimeters each bifurcates into an external branch, which supplies extracranial structures, and an internal carotid artery (ICA), which irrigates major portions of the brain. The paired vertebral arteries are somewhat smaller and arise from the subclavian arteries; these ascend in parallel to a level just below the pons, where they join to form the single basilar artery.

The two internal carotid arteries and basilar artery then contribute to a vascular structure at the base of the brain called the circle of Willis. This is a continuous vascular loop comprising paired posterior cerebral arteries (PCAs) that bifurcate from the top of the basilar artery and go on to supply posterior parts of the brain, paired posterior communicating arteries (PCoAs) that connect the PCAs with the ICAs, paired anterior cerebral arteries (ACAs) that arise from the ICAs and go on to irrigate anterior regions of the brain, and a single anterior communicating artery (ACoA) that joins the two ACAs. Another important artery arising from the circle of Willis is the middle cerebral artery (MCA), one of which ascends to each hemisphere and nourishes the lateral aspects of the brain. Clinically, the MCA, ACA, and PCA are the most important cerebral arteries in that the majority of strokes occur in these distributions and lead to major neurologic deficits because of the large areas of the cerebrum that may be damaged (Fig. 5).

The venous drainage of the brain is accomplished by a complex system of superficial and deep veins, all of which are richly anastomosed with each other. The superficial veins drain into the superior sagittal sinus and the deep veins into the straight sinus. The final destinations of venous blood from the brain are the paired internal jugular veins in the neck, by which the blood is conveyed ultimately to the heart. Disorders of the venous system are far less common than those affecting the arterial system of the brain.

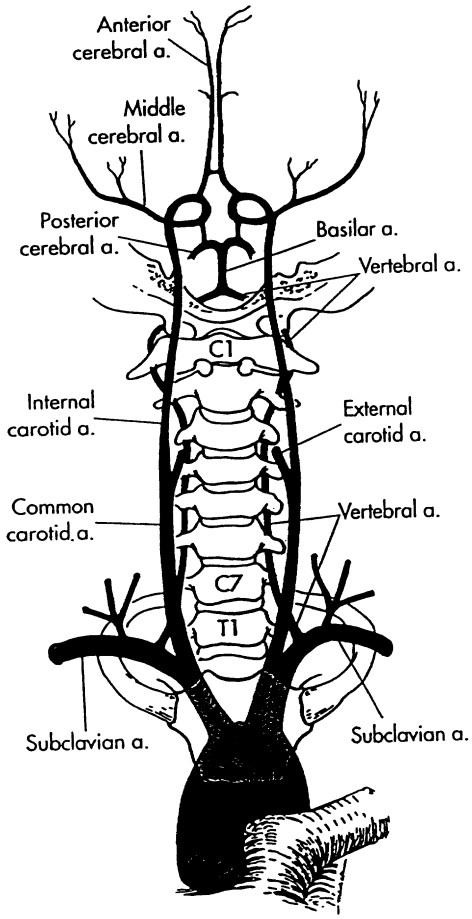

Figure 4 The blood supply of the brain, originating from four major arteries that arise from the aorta. Reprinted with permission from Nolte, J. (1999). *The Human Brain*, 4th ed., p. 145. Mosby, St. Louis.

A final point regarding the blood supply of the brain is the existence of a blood–brain barrier. This term refers to an anatomic–physiologic complex at the level of the capillary endothelium that prevents the entry of many substances into the brain from the blood stream. The blood–brain barrier offers clear advantages, as in the case of barring the intrusion of blood-borne pathogens, but it also carries the liability that antibiotics and other drugs may have difficulty reaching the sites in the brain where they are needed.

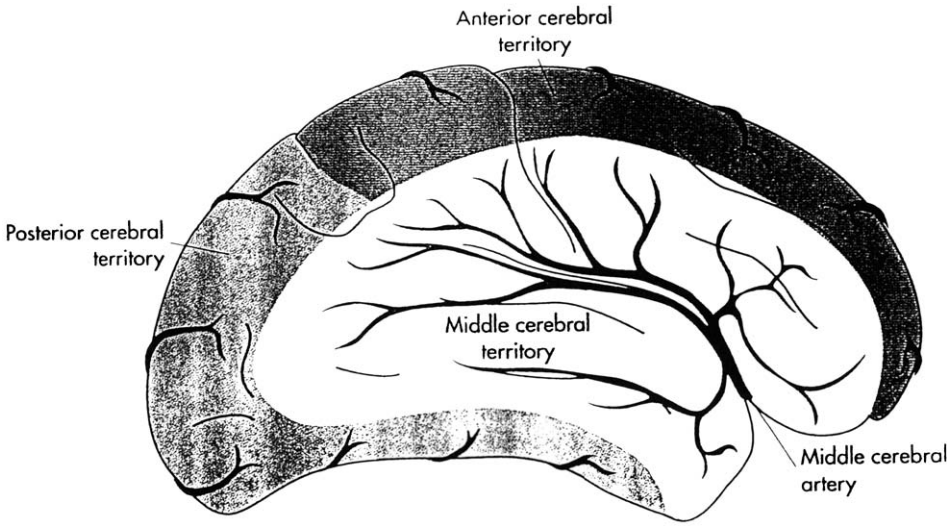

Figure 5 Distributions of the middle cerebral, anterior cerebral, and posterior cerebral arteries on the lateral surface of the brain. Reprinted with permission from Nolte, J. (1999). *The Human Brain*, 4th ed., p. 122. Mosby, St. Louis.

IV. VENTRICLES AND CEREBROSPINAL FLUID

The brain contains four internal cavities called ventricles (Fig. 6). These cavities are filled with CSF, which is produced in the ventricles and serves to bathe the entire CNS. An understanding of the ventricular system is important for an appreciation of fluid and pressure dynamics in the brain, as well as for its anatomy.

The two largest ventricles are the lateral ventricles, one in each hemisphere, which underlie the frontal, parietal, occipital, and temporal lobes. These communicate with a single third ventricle, narrow and situated between the two thalami, via an opening in each lateral ventricle called the foramen of Monro. Finally, the tent-shaped fourth ventricle, just dorsal to the brain stem, is connected with the third ventricle by a small conduit in the midbrain called the cerebral aqueduct. The fourth ventricle, in turn, empties into a region of subarachnoid space called the cisterna magna through three apertures, the midline foramen of Magendie and the two lateral foramina of Luschka. More caudally, the CSF flowing from the ventricles travels down around the spinal cord to the lower end of the spinal canal and also circulates rostrally to the convexities of the brain, where it is eventually absorbed into the cerebral venous sinuses through structures known as arachnoid villi.

CSF is produced by the choroid plexus in all four ventricles, and the entire volume of the CSF in and around the CNS is about 140 ml. The volume of the ventricular system is actually rather small, about 25 ml. Because CSF is produced at the rate of about 450 ml/day, the entire CSF volume turns over more than three times daily. The CSF has an obvious supportive role in that it provides a buoyancy that keeps the brain from settling down upon rigid, bony surfaces. The CSF also takes part in regulating the chemical environment of brain neurons.

In clinical terms, the ventricular system and the CSF have many implications. For example, CSF analysis

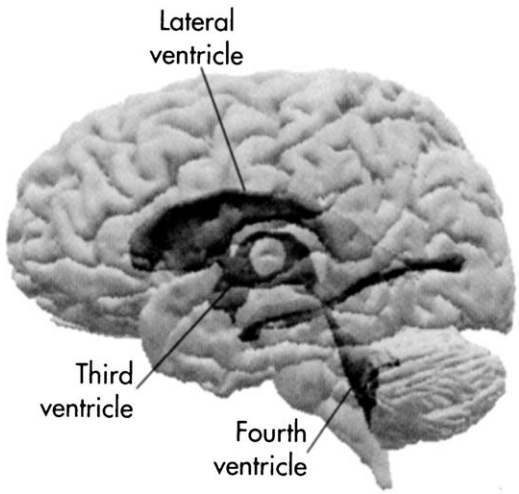

Figure 6 The position of the four ventricles—the two lateral ventricles, the third, and the fourth—within the brain. Reprinted with permission from Nolte, J. (1999). *The Human Brain*, 4th ed., p. 65. Mosby, New York.

after lumbar puncture is essential in the diagnosis of many neurologic disorders, such as meningitis and encephalitis. Moreover, enlargement of the ventricles due to an excess of CSF, as is seen in hydrocephalus or with certain mass lesions, can have major neurologic consequences.

V. CRANIAL NERVES

The 12 cranial nerves are important for providing motor and sensory innervation of the head and neck, and their anatomy is inextricably linked with that of the brain. Although the cranial nerves are generally regarded as belonging to the PNS, the second cranial nerve, the optic nerve, is in fact considered a part of the CNS. All cranial nerves exist in pairs, and their crossed and uncrossed connections with central structures are important for an appreciation of the neuroanatomy of the brain.

A. Cranial Nerve I

Olfaction is the sense of smell. Although lower animals have a more highly developed olfactory system, this chemical sense persists in humans. The olfactory system originates in the roof of the nasal cavity with the olfactory epithelium, which is a collection of olfactory receptor cells. The axons of these cells are known collectively as the olfactory nerve. Ascending through the cribriform plate of the ethmoid bone, the olfactory nerve terminates in the olfactory bulb at the base of the frontal lobe. From there the olfactory tract projects to the olfactory cortex in the medial temporal lobe.

B. Cranial Nerve II

The visual system is extremely important in human life, and a substantial percentage of CNS neurons is devoted to its function. Incoming visual stimuli are first processed in the eye, where photoreceptor cells in the retina, called rods and cones, transduce patterns of light into electrical signals that travel to the brain. The optic nerve begins at the back of the eye, where it is visible with an ophthalmoscope as the optic disk. Visual information is first transmitted via the optic nerve to the lateral geniculate nucleus of the thalamus, and then additional relays through the temporal and parietal lobes project to the primary visual cortex in the occipital lobe (Fig. 7). As it travels to the thalamus, the optic nerve splits into two components, one remaining on the same side as the eye from which it came and the other passing over to the other side. The importance of this anatomic feature is that each hemisphere receives visual input from the contralateral visual field; thus, the right hemisphere interprets visual input from the left side of vision and vice versa. This aspect of crossed function is typical of the organization of many brain systems and has important clinical and behavioral implications.

C. Cranial Nerves III, IV, and VI

These three nerves are grouped together because they all are exclusively involved with eye movements, and routine clinical testing of these movements permits a quick survey of the function of each nerve. The oculomotor nerve (CN III) originates from the oculomotor nucleus in the midbrain and innervates the following muscles: the levator palpebrae, which raises the eyelid; the superior rectus, inferior rectus, medial rectus, and inferior oblique, which mediate most voluntary directions of gaze; and the pupillary sphincter, which constricts the pupil of the eye when light stimulation is provided. The trochlear nerve (CN IV) also begins in the midbrain but innervates only the superior oblique muscle; this muscle moves the eye downward and laterally. The abducens nerve (CN VI) comes from the pons and supplies the lateral rectus muscle, which allows lateral deviation (abduction) of the eye.

D. Cranial Nerve V

This nerve, known as the trigeminal nerve, carries out important sensory and motor functions for the face. The trigeminal nerve is the general sensory nerve for the head; it mediates somatic sensation in the face by means of three subdivisions—the ophthalmic (V1), maxillary (V2), and mandibular (V3) branches—which converge in the trigeminal ganglion outside the brain stem and then enter the pons. A secondary relay to the brain then sends this facial somatosensory information to the ventral posterior medial nucleus of the thalamus, where it is processed and brought to consciousness. Somatic sensation for the head posterior to the face is mediated by the second and third

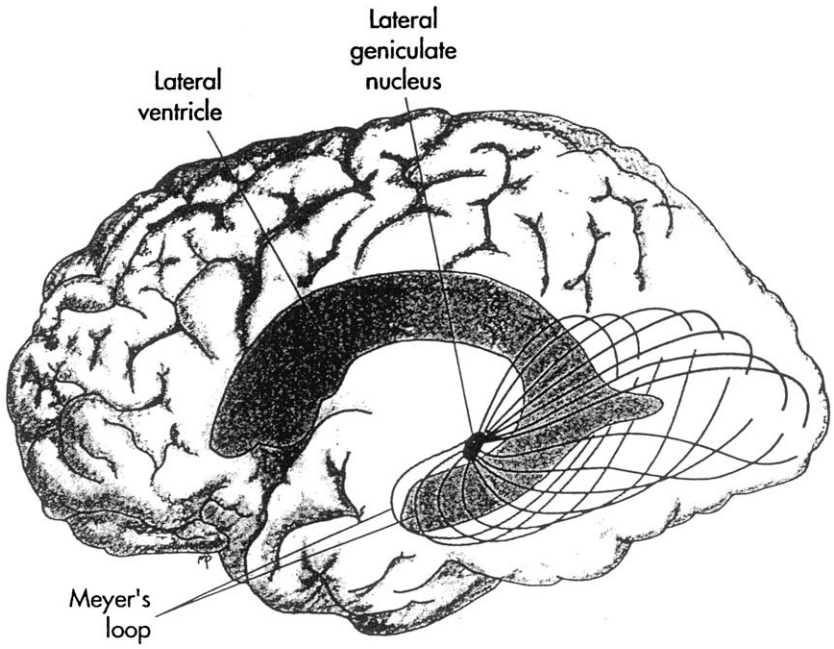

Figure 7 Central connections of the visual system. Fibers from the eyes reach the lateral geniculate nucleus, whence relays proceed to the occipital cortex. The relay in the temporal lobe is known as Meyer's loop. Reprinted with permission from Nolte, J. (1999). *The Human Brain*, 4th ed., p. 419. Mosby, New York.

cervical nerves that enter the spinal cord before traveling to the thalamus. The trigeminal nerve also has a motor division that originates in the pons and supplies the muscles of mastication (chewing).

E. Cranial Nerve VII

This is the facial nerve, which has a primary motor function. The facial nerve originates from the facial nucleus in the pons, where it receives input from the corticobulbar tract, the source of motor innervation from the precentral gyrus of the cerebral cortex. After its axons leave the pons, the facial nerve innervates the ipsilateral muscles of facial expression. Damage to the facial nerve or its nucleus thus produces weakness of one entire side of the face. However, damage to the corticobulbar fibers arriving at the facial nucleus in the brain stem produces a somewhat different pattern of weakness. In this instance, typically following a contralateral stroke in the brain, only the muscles of the lower face are weak because the upper facial muscles are supplied by corticobulbar fibers from both hemispheres and the intact side can compensate for the damaged side. This anatomic feature permits the crucial clinical distinction between a stroke and the less ominous situation of weakness from seventh nerve involvement. The facial nerve also has one notable sensory function, which is to convey taste from the anterior two-thirds of the tongue, via a branch called the chorda tympani, to the solitary tract in the pons and medulla.

F. Cranial Nerve VIII

The eighth cranial nerve is known as the vestibulocochlear nerve because it is made up of two special sensory components called the vestibular division and the auditory division. Correspondingly, this nerve has a dual role: it participates in the vestibular or balance system and also in the sense of audition or hearing. Each division makes use of mechanoreception; cells of the vestibular division are sensitive to positional movements of the head, and those of the cochlear division are sensitive to sound stimuli. The receptors for both divisions are found in the inner ear, well-protected deep within the temporal bone of the skull. By means of complex processes of tranduction, mechanical and auditory stimuli are sent to vestibular and cochlear nuclei, respectively, in the lower pons. From these sites, vestibular input is extensively processed in the brain stem and cerebellum, whereas auditory input is sent rostrally up the brain stem to the

medial geniculate nucleus of the thalamus and finally to the primary auditory cortices in the temporal lobes (Heschl's gyri). One of the central functions of hearing in humans is that it serves as a necessary precursor to language.

G. Cranial Nerve IX

The glossopharyngeal nerve participates in motor, sensory, and autonomic functions. Motor fibers of CN IX arise from the nucleus ambiguus in the medulla and innervate the stylopharyngeus muscle of the pharynx. Sensory fibers from the tongue, nasopharynx, and middle and outer ear travel to the spinal trigeminal nucleus, and taste fibers from the posterior one-third of the tongue terminate in the solitary tract. Finally, there is parasympathetic innervation of the parotid gland that originates from the inferior salivatory nucleus.

H. Cranial Nerve X

This nerve, the vagus, is the most widely distributed cranial nerve, as it provides parasympathetic innervation to many thoracic and abdominal visceral organs from neurons situated in the dorsal motor nucleus of the vagus in the medulla. The vagus nerve also shares many similarities with the glossopharyngeal nerve. Motor fibers of CN X arise from the nucleus ambiguus and innervate most of the muscles of the larynx and pharynx, taste fibers from the epiglottis enter the solitary tract, and somatosensory fibers from the outer ear enter the spinal trigeminal tract. In clinical practice, the gag reflex allows for the simultaneous testing of both the ninth and tenth cranial nerves, as the afferent and efferent limbs of this reflex are mediated by the glossopharyngeal and the vagus nerves, respectively.

I. Cranial Nerve XI

The XIth nerve is also called the accessory nerve, and it contains only motor fibers. These arise from the lower medulla and upper spinal cord and innervate the ipsilateral sternocleidomastoid and trapezius muscles.

J. Cranial Nerve XII

Like the accessory nerve, the hypoglossal nerve (CN XII) is purely motor. It arises from neurons in the hypoglossal nucleus of the medulla and enters the tongue from below to supply its musculature.

VI. BRAIN STEM

The brain stem is the most caudal portion of the brain, and structurally it serves to connect the cerebrum with the spinal cord as well as to anchor the cerebellum behind it. Its three major segments are the midbrain, which lies just below the diencephalon and is continuous with the thalamus, the pons, which is below the midbrain and anterior to the fourth ventricle, and the medulla, which is continuous with the spinal cord below. In addition to harboring many cranial nerve nuclei and tracts, the brain stem contains long ascending and descending tracts to and from higher structures, as well as an important integrative structure called the reticular formation.

As reviewed previously, cranial nerves III–XII all have their central termini in the brain stem. Thus, the brain stem serves as a general relay station conveying sensory, motor, and autonomic information between the CNS and the tissues and organs of the face and body. Damage to the brain stem can thus have a wide range of effects on cranial nerve function that can often be detected clinically, as is well-described by the observations of classic neurology.

The long tracts that are found within the brain stem are all continuations of tracts that begin above or below. Four major tracts deserve mention. First is the corticospinal tract, which begins in the precentral gyrus of the frontal lobe and descends to the spinal cord, where it provides supraspinal input to motor neurons that directly innervate voluntary muscles. In the brain stem, this tract occupies the ventral portion of the midbrain, pons, and medulla, and near the bottom of the medulla it crosses (decussates) so that most corticospinal fibers travel to the opposite side of the spinal cord. Thus, as in the visual system, there is a crossing of neural systems that renders one side of the brain responsible for nervous activity on the other side of the body. The second major tract is the corticobulbar tract, which performs a role similar to that of the corticospinal tract, but terminates in various brain stem motor nuclei. The other two long tracts of the brain stem are sensory. The first is the medial lemniscus, which is a continuation of the dorsal column system in the spinal cord that conveys information about vibration and position sensation to the ventral posterior lateral (VPL) nucleus of the

thalamus and thence to the somatosensory cortex of the parietal lobe. The other is the spinothalamic tract, a similar fiber system that transmits pain and temperature sensation from the spinal cord again to the VPL nucleus of the thalamus and ultimately the parietal cortex.

The integrative function of the brain stem is carried out by a collection of diffusely organized nuclei and tracts in the brain stem core called the reticular formation. This area is defined more by its physiological characteristics than by discrete anatomic boundaries, and it includes some important neurotransmitters, among them norepinephrine from the locus ceruleus and serotonin from the dorsal raphe nuclei. The reticular formation participates in sensation, movement, and autonomic function, but perhaps its most important role is in the maintenance of consciousness. A portion of the reticular formation in the upper pons and midbrain, called the ascending reticular activating system (ARAS), sends projections to the intralaminar nuclei of the thalamus, which in turn project to the entire cerebrum (Fig. 8). By virtue of the general cerebral activation enabled by this system, the ARAS has a crucial role in wakefulness and is largely responsible for the sleep and wakefulness cycle of normal humans. Damage to the ARAS, as from a brain stem stroke or traumatic brain injury, may produce a loss of arousal and result in the clinical state of coma. Thus, the ARAS is necessary for the level of consciousness; conversely, the content of consciousness, as will be seen, is elaborated by more rostral structures in the brain.

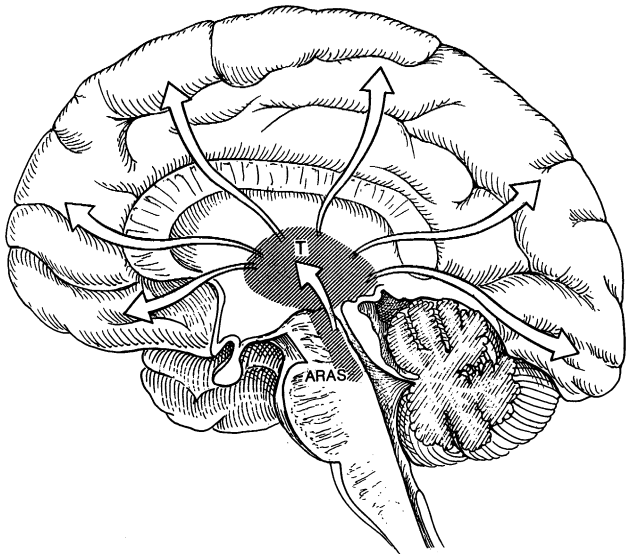

Figure 8 Drawing of the ascending reticular activating system (ARAS), which is found in the upper pons and midbrain and sends projections rostrally to the thalamus. Reprinted with permission from Filley, C. M. (2001). *Neurobehavioral Anatomy*, 2nd ed., p. 42. University Press of Colorado, Boulder, CO.

VII. CEREBELLUM

The cerebellum is a large, semidetached region of the brain lying behind the brain stem, to which it is extensively attached. Even though the cerebellum receives substantial sensory input, it is considered a part of the motor system because of its primary involvement with coordination, postural control, equilibrium, and muscle tone.

In gross anatomic terms, the cerebellum can be divided into the body of the cerebellum (corpus cerebelli) and the much smaller flocculonodular lobe. A more useful functional distinction, however, can be made between the two lateral cerebellar hemispheres and the centrally located vermis (Fig. 9). This division is important because the cerebellar hemispheres are concerned with coordination of the limbs, and the vermis is devoted to postural adjustment. Thus, damage to these regions causes, respectively, limb ataxia and postural instability (also known as trunkal ataxia).

Like the cerebrum, the cerebellum contains both gray and white matter. The gray matter includes billions of cerebellar cortical neurons, which are arranged in three layers: a superficial molecular layer, an intermediate Purkinje cell layer, and a deeper granular cell layer. In addition, there are four cell collections deep within the cerebellum called the dentate, globose, emboliform, and fastigial nuclei (Fig. 9). The white matter consists in part of axons traveling to and from the cerebellar cortex. There are also three prominent cerebellar peduncles—inferior, middle, and superior—that connect the cerebellum with the medulla, pons, and midbrain, respectively (Fig. 9).

The major role that the cerebellum plays in the motor system results from its intermediate position between multiple sensory inputs and its output to motor areas in the cerebral hemispheres. Through projections in the inferior and middle cerebellar peduncles, the cerebellum receives a variety of vestibular, spinal, and cerebral cortical inputs that reach the cerebellar cortex where extensive processing takes place. From this point, cerebellar output occurs mainly by relays in the four deep nuclei, which send axons through the superior cerebellar peduncle to the

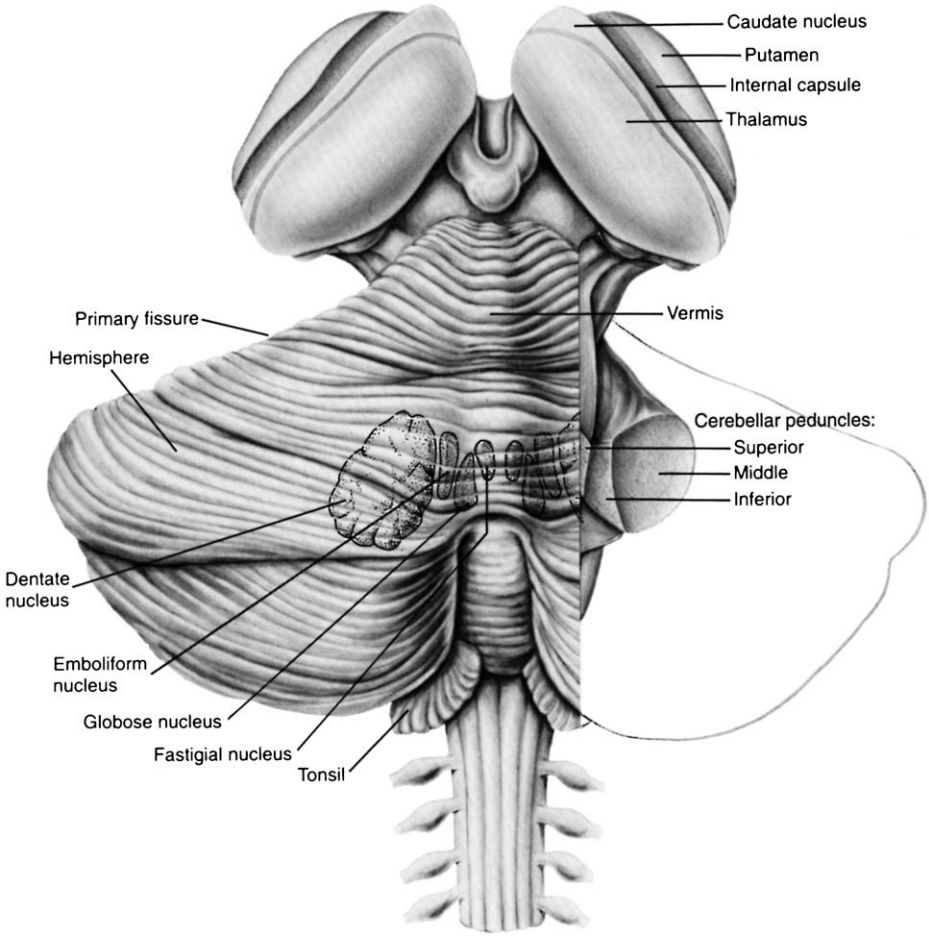

Figure 9 The cerebellum, as depicted schematically from behind. The major divisions are the two hemispheres, situated laterally, and the single midline vermis. Reprinted with permission from Kandel, E. R., Schwartz, J. H., and Jessell, T. M., Eds. (1991). *Principles of Neural Science*, 3rd ed., p. 628. Elsevier, New York.

midbrain and eventually the ventral anterior and ventral lateral nuclei of the thalamus. These thalamic connections allow the cerebellum to exert a powerful influence on motor regions of the cerebral cortex, providing fine-tuning of movements of the limbs and trunk. An important clinical point is that ataxia on one side of the body is ipsilateral to the side of the cerebellar lesion. Because the cerebellar output crosses to the opposite thalamus and then the subsequent corticospinal system crosses again, the bodily deficit is on the same side as the cerebellar damage.

Cerebellar lesions are most often associated with the clinical findings of ataxia, which may affect the limbs, trunk, or even speech (producing a specific type of dysarthria known as scanning speech), dysequilibrium as manifested by a wide-based gait, and muscular hypotonia. Findings have also suggested that the cerebellum has a contribution to higher motor and even cognitive functions. The acquisition of a motor skill such as playing the piano, an example of procedural learning, seems to depend in part on the cerebellum, and there are increasingly frequent reports of individuals with cerebellar lesions who develop cognitive deficits.

VIII. DIENCEPHALON

The diencephalon consists of four structures located deep in the cerebral hemispheres just rostral to the midbrain and surrounding the third ventricle: the thalamus, hypothalamus, subthalamus, and epithalamus. Despite its small size, the diencephalon has major importance in brain function, particularly through the

activities of the thalamus and hypothalamus. The subthalamus is a very small region inferior to the thalamus that contains the subthalamic nucleus and zona incerta; these areas have connections to the basal ganglia and cerebral cortex, but their functions are largely unknown. The epithalamus is found superior and caudal to the thalamus and contains the pineal gland and the habenular nuclei. The pineal gland is an unpaired structure that was once thought to harbor the seat of the soul; today, it is known to secrete a hormone called melatonin, hypothesized to have a role in sleep and gonadal function.

The thalamus is an egg-shaped collection of nuclei that makes up about 80% of the diencephalon (Fig. 10). It consists of a collection of nuclei that participate in sensation, movement, cognition, emotion, and arousal. The most characteristic thalamic function is to serve as a sensory relay station for stimuli that will eventually reach the cerebral cortex. All sensory systems with the exception of olfaction pass through the thalamus en route to their respective cortical areas. Thus, somatosensory information from the body and face reach the VPL and ventral posterior medial (VPM) nuclei, respectively, and taste fibers also project to the VPM nucleus. Visual projections from the optic nerve synapse in the lateral geniculate nucleus and auditory fibers in the medial geniculate nucleus. The ventral anterior and ventral lateral nuclei receive fibers from the cerebellum and in turn send projections to the basal ganglia, so that they contribute to the motor system. The dorsal medial nucleus and the pulvinar are the major association nuclei, connected with the frontal and the parietal–temporal–occipital cortices, respectively. The anterior nucleus has a role in the limbic system (see following discussion). Finally, the intralaminar nuclei, the two largest of which are the centromedian and the parafascicular, receive input from the ARAS in the brain stem and then relay this general information rostrally to activate the cerebrum as a whole.

The hypothalamus is considerably smaller than the thalamus, but it exerts powerful effects on autonomic, endocrine, and emotional functions. Located inferior to the thalamus and superior to the pituitary gland, the hypothalamus is a collection of many tiny nuclei that

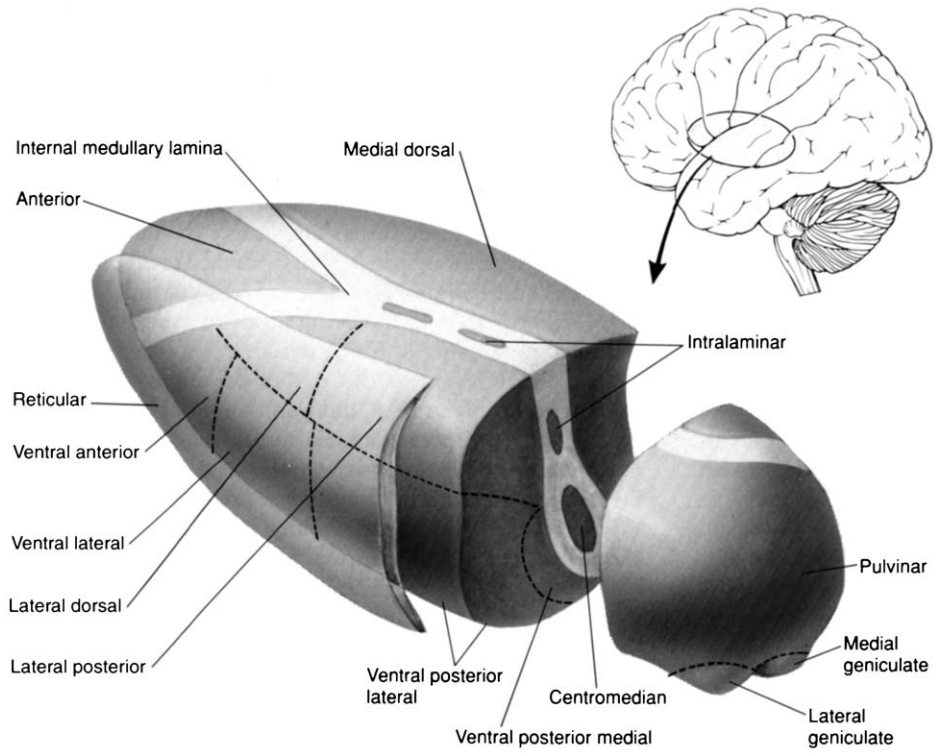

Figure 10 The thalamus, with its many nuclei depicted. These nuclei act as relay stations for information traveling to and from the cortex. Reprinted with permission from Kandel, E. R., Schwartz, J. H., and Jessell, T. M., Eds., (1991). *Principles of Neural Science*, 3rd ed., p. 291. Elsevier, New York.

contribute to the regulation of the body's homeostasis. The hypothalamus is the control center of the autonomic nervous system, an involuntary portion of the nervous system that regulates aspects of body temperature, digestion, circulation, water balance, and sexual function. The autonomic nervous system is divided into the parasympathetic branch, which is generally associated with the anterior regions of the hypothalamus, and the sympathetic branch, which is associated with posterior sites. Endocrine function is also governed by the hypothalamus by virtue of its strong neural and vascular connections with the two lobes of the pituitary gland. Finally, the hypothalamus shares the mammillary bodies in common with the limbic system and, in part because of this linkage, plays a role in emotional function. Hypothalamic lesions in experimental animals and in humans, for example, have sometimes been noted to produce rage behaviors.

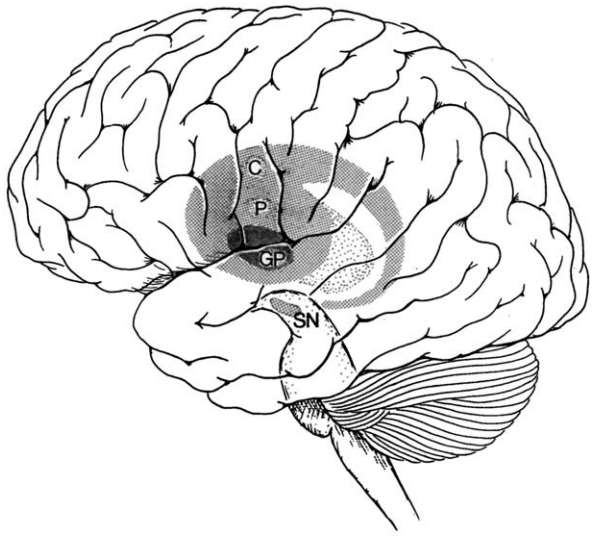

Figure 11 The positions of the basal ganglia and the substantia nigra within the hemispheres. Abbreviations: C, caudate; P, putamen; GP, globus pallidus; SN, substantia nigra. Reprinted with permission from Filley, C. M. (2001). *Neurobehavioral Anatomy*, 2nd ed., p. 181. University Press of Colorado, Boulder, CO.

IX. BASAL GANGLIA

The basal ganglia are a group of large nuclei located deep in the cerebral hemispheres. They are important because of their exclusively motor affiliation and because of the many disorders of movement that result from damage to these structures.

There is no uniformity of opinion about which structures should be included among the basal ganglia, but there is general agreement that the caudate nucleus, putamen, and globus pallidus should be listed under this heading. Many authors also include the midbrain substantia nigra and the subthalamic nucleus of the diencephalon as basal ganglia as well. In any case, the caudate, putamen, and globus pallidus are all generally situated at the base of the hemispheres, lateral to the thalamus and medial to the cerebral cortex (Fig. 11). The caudate is separated from the putamen and the globus pallidus by a thick band of white matter called the internal capsule, among the functions of which is the conveyance of motor impulses from the cortex to the motor neurons of the face and body below. Combinations of the basal ganglia also have frequently used names; hence, the caudate and putamen are known as the striatum, and the putamen and globus pallidus are referred to as the lenticular nucleus.

The principal function of the basal ganglia as an integrated unit is to modulate the activity of the motor cortex in the cerebrum as it organizes voluntary movement of the bodily musculature. Consistent with this role, the basal ganglia are connected with the cortex via a series of parallel loops that permit extensive involvement in cortical motor output. The primary such loop consists of the following: multiple cortical inputs reach the striatum by way of the internal capsule and another white matter tract called the external capsule; from there, connections proceed first to the globus pallidus and to then the ventral anterior and ventral lateral thalamic nuclei; the final link involves connections that return back to the motor cortex, again via the internal capsule. Thus, the basal ganglia join the cerebellum as regions strongly connected to the voluntary motor system by relays in specific thalamic nuclei. This anatomic linkage provides powerful modulatory input to the motor system, integrating two other brain areas into the organization of movement and emphasizing the general importance of motor action in human life. As reviewed previously, the cerebellum has a prominent role in coordination; the basal ganglia, in contrast, can be thought of as contributing to the initiation and timing of movements, although the exact contribution of these nuclei is still being clarified.

A final aspect of basal ganglia anatomy to be considered is its neurochemical input that arises from the substantia nigra of the midbrain (Fig. 11). Pigmented cells of the substantia nigra send axons rostrally, where they deliver the neurotransmitter

dopamine to the striatum. Dopamine serves as an activator of the basal ganglia and the motor system as a whole, and its deficiency or absence results in dramatic alterations in motor function. Individuals with Parkinson's disease, characterized by a loss of dopaminergic cells in the substantia nigra, display the classic clinical features of bradykinesia (slowness of movement), rigidity, and tremor. This is the most important movement disorder because of its high prevalence and because of the fact that the provision of dopamine or similar agents can significantly alleviate the clinical symptoms of the disease.

X. LIMBIC SYSTEM

The limbic system is a loosely defined collection of structures at the junction of the diencephalon and the cerebral hemisphere. Some authors consider the limbic system a discrete lobe of the brain, but because of its extensive thalamic and hypothalamic connections, we will regard the limbic system as a transitional region between the diencephalon and the hemisphere. Its two most important structures—the amygdala and the hippocampus—are found within the temporal lobe. The name "limbic" derives from the Latin *limbus*, meaning "border," and the limbic system was originally named by the French neurologist Paul Broca in 1878 to reflect the location of a number of cortical areas at the margin of the hemisphere. These cortical regions—the cingulate gyrus, the parahippocampal gyrus, and the hippocampus—are typified by phylogenetically primitive cortex, and it was long thought that they were devoted to the sense of smell because of their connections with the olfactory system at the base of the frontal lobe (Fig. 12). However, later studies provided ample evidence that, whereas the limbic system in animals is indeed strongly linked with olfaction, the limbic system in humans is dedicated to other, more important functions. It is now widely accepted that the human limbic system has a prominent role in both emotion and memory.

In 1937, an influential paper by James Papez proposed that an interconnected series of structures —the cingulate gyrus, the parahippocampal gyrus, the hippocampus, the fornix, the mammillary bodies, the mammillothalamic tract, and the anterior nucleus of the thalamus—comprised the cerebral basis of emotion. This group of limbic structures came to be known as the Papez circuit (Fig. 13), and despite decades of debate, this region endures as a central concept in the neuroanatomy of emotion. Studies in the past decade have also demonstrated that the amygdala, located adjacent to the hippocampus (Fig. 13), has an important role in emotional learning, and this nucleus has joined the Papez circuit as a core constituent of the limbic system. Sensory input to the limbic system undergoes processing in the amygdala, and the emotional significance of a stimulus is thereby determined. In this way, the experience of emotion is mediated by limbic structures. There is also an effector component of the limbic system; connections with the hypothalamus account for the important autonomic and endocrine reactions to powerful emotions that have been referred to as the "fight or flight" response.

In a parallel development, the hippocampus came to be understood as a key area for the processes of memory formation. The acquisition of declarative memory, which refers to facts and events as opposed to the skills that are associated with procedural memory, of course is vital for successful human existence. This capacity is apparently dependent on the hippocampus, a three-layered cortical region tucked deep within the medial temporal lobe and connected with other regions also concerned with recent memory, including the dorsal medial nucleus of the thalamus and the basal forebrain (Fig. 14). Whereas lesions in these latter regions have also been associated with memory dysfunction, the most dramatic demonstrations of recent memory disturbance have been observed in individuals with bilateral destruction of the hippocampus. The overlap of brain systems mediating emotions and memory is an intriguing neuroanatomic feature and suggests that those events with the most emotional significance are most likely to be encoded in memory; this aspect of mental life generally can be confirmed by common experience.

XI. WHITE MATTER

The white matter of the brain constitutes nearly one-half of its volume and serves the important general function of linking cortical and subcortical gray matter regions with each other. White matter consists of collections of axons ensheathed with myelin that are most often called tracts, but that may also be termed fasciculi, bundles, lemnisci, funiculi, and peduncles. Traveling extensively throughout the brain to link widely dispersed gray matter areas, these groups of fibers integrate cortical and subcortical regions into functionally unified neural networks. These networks subserve the many unique functions of the brain, from basic sensory and motor activities to complex cognition and emotion. By virtue of the dramatic increase in axonal conduction velocity that is afforded by myelin, rapid and efficient transfer of information across white matter tracts occurs, which enables the highest functions in the cerebral hemispheres. The many neurologic and neurobehavioral deficits sustained by individuals with the white matter disease multiple sclerosis (MS) testify to the importance of white matter in brain function.

White matter tracts in the brain can be considered under three general categories: projection fibers, commissural fibers, and association fibers. Projection fibers are those that ascend to the cortex from lower structures (corticopetally) or descend from the cortex to lower regions (corticofugally). Major corticopetal tracts are the thalamic radiations, relaying somatosensory information from the thalamus to the parietal cortex, and the optic radiations, projecting from the

lateral geniculate body of the thalamus to the occipital cortex. The major corticofugal tract is the corticospinal tract, which projects from the motor cortex to lower motor neurons in the spinal cord. A similar role is played by the corticobulbar tract, which also originates in the motor cortex but terminates on lower motor neurons in the brain stem. Both of these tracts first travel through the large internal capsule; corticobulbar fibers then cross to join various brain stem motor nuclei, whereas corticospinal fibers continue rostrally to the spinal cord, with most first decussating in the lower medulla. Projection fibers are therefore involved solely with elemental sensory and motor functions.

More important for behavior are the commissural and association fiber systems (Fig. 15). Commissural fibers are those that travel between the hemispheres in the cerebral commissures. The largest of these by far is the corpus callosum, a massive white matter tract that connects the four lobes of the brain on each side with their counterparts on the other. Much smaller commissural fiber systems include the anterior commissure and the hippocampal commissure. The association fibers join gray matter regions within each hemisphere. Among these, anatomists have distinguished two types: short and long association fibers. Short association fibers, also called arcuate or U fibers, connect adjacent cortical gyri and are found throughout the cerebrum. Long association fibers primarily link the lobes of the brain: these are the superior occipitofrontal fasciculus, the inferior occipitofrontal fasciculus, the arcuate fasciculus, the uncinate fasciculus, and the cingulum. All of these tracts have one termination in the frontal lobe, whereas their other terminus is variably in more posterior regions.

Two other white matter tracts deserve mention. The fornix is a prominent curved structure in the limbic system that connects the hippocampus and the mammillary bodies. The medial forebrain bundle connects the hypothalamus with both caudal and rostral brain regions and participates in hypothalamic control of the autonomic nervous system.

XII. CEREBRAL CORTEX

Cortex is the Latin word for "bark," and the cerebral cortex is the outermost layer of the cerebrum. The surface of the brain is virtually entirely composed of cortex, which consists of a thin sheet of neurons averaging 3 mm in thickness. The number of cortical neurons in the brain is estimated at 25 billion, and the number of synapses in the cortex may be an astonishing 300 trillion. The computational power made possible by this extraordinary number of connections renders the cortex the site of the most advanced functions of the human brain. For the neuroscientific study of the mind and all of the capacities implied by this concept, an understanding of neocortical structure and function is indispensable.

At the microscopic level, the cortex is made up mainly of pyramidal cells, neurons named for the shape of their cell body, which each have a long axon projecting to other cortical areas or to subcortical sites. More than 90% of the cortex is a six-layered structure called neocortex, a term that refers to the relatively recent arrival of this brain structure in the course of evolution. Thus, the neocortex has a horizontally laminated pattern in which can be found, in sequence from the outermost layer inward, the molecular layer, the external granular cell layer, the external pyramidal cell layer, the internal granular cell layer, the internal pyramidal cell layer, and the multiform layer. There is also a vertical organization to the neocortex, such that cells arranged in a column perpendicular to the cortical surface are linked so as to respond as a unit to a given stimulus. Hundreds of millions of these vertical modules exist, and they are extensively linked to other modules by the axons of pyramidal cells.

The remaining 10% of the cortex is known as allocortex, which is made up in turn of paleocortex and archicortex, cortical types of ancient origin that are

more prominent in lower animals. Much of the allocortex is concerned with the olfactory system, which has limited importance in humans. However, as has been discussed, an important allocortical region is the hippocampus, a three-layered cortical region that, as part of the limbic system, plays a crucial role in memory and emotion. The three layers of the hippocampus are the molecular layer, the pyramidal cell layer, and the polymorphic layer.

Many attempts have been made by anatomists to divide the neocortex into discrete zones. The best known of these cortical parcellations is that of Korbinian Brodmann, a German anatomist who described about 50 areas of the cortex, each with distinct histological features (Fig. 16). Although it is not clear in many cases whether these anatomically distinct zones reflect functional distinctions, the cortical map of Brodmann has endured for almost a century, and reference to his numbered zones is customary in discussions of neocortical anatomy and function. Many of Brodmann's areas will be mentioned in the discussion that follows.

The neocortex forms the most superficial portion of all four lobes of the brain, and these lobes have much clinical utility in considering the functional affiliations of cortical regions and their underlying connections. Thus, the cortical surface can be divided into the frontal, temporal, parietal, and occipital lobes (Figs. 17 and 18). Each of these lobes has important functional affiliations (Table II), which will be discussed later. The frontal lobe is the most rostral of the four, lying anterior to the Rolandic fissure and superior to the Sylvian fissure. The temporal lobe is positioned inferior to the Sylvian fissure, and its posterior boundary is determined by the junction of two lines: one from the parietal–occipital junction to the preoccipital notch and the other running posteriorly from the end of the Sylvian fissure. The parietal lobe lies posterior to the Rolandic fissure, and its inferior margin is also defined by the two lines that form the posterior extent of the temporal lobe. The occipital lobe is situated posterior to both the temporal and parietal lobes. Another small neocortical region that is not visible on the surface of the brain is the insula, or island of Reil, which is concealed under the Sylvian fissure by portions of the frontal, temporal, and parietal lobes.

The frontal lobe is the largest of the four lobes, accounting for more than one-third of the entire cortical surface. As the most recently acquired cortical region in the course of evolution, the frontal lobe houses a variety of motor, cognitive, and emotional functions. First, the frontal lobe contains two areas important for voluntary movement: the precentral gyrus (Brodmann area 4), from which originate the corticospinal and corticobulbar tracts that descend to the spinal cord and brain stem, and the adjacent supplementary motor area (area 6). The remainder of the frontal lobe consists of the prefrontal cortex, a confusing term that simply means frontal association cortex not devoted to motor function. The prefrontal regions mediate many of the highest functions of the human brain. Among these advanced functions are the motor aspects of language: the fluency of language, for example, is mediated by Broca's area on the left (areas 44 and 45), whereas the expression of prosody, the emotional content of language, is provided by the homologous region of Broca's area in the right frontal lobe. Working memory, the capacity to hold information in mind long enough to apply it to the solution of a problem, is another important role of the frontal lobe, specifically the dorsolateral prefrontal cortex (areas 9 and 46). Working memory is thus an aspect of the general phenomenon of attention, which is also represented in the right hemisphere (see later discussion). In addition, working memory contributes to the concept of executive functions, a term meaning the ability to plan, carry out, and monitor a sequence of actions that culminates in the attainment of a goal. Executive functions are thought to be mediated by areas 8, 9, 10, 46, and 47. Another critical ability of the frontal lobe is in the realm of comportment, by which is implied the control of limbic impulses so that a socially appropriate behavioral repertoire is maintained. The orbitofrontal cortex (areas 11, 12, and 25) is extensively connected with the limbic system, and the normal function of this region prevents the dramatic behavioral disturbances that may occur with disinhibition. Finally, the medial frontal cortex (areas 24, 32, and 33), which corresponds essentially to the anterior cingulate gyrus, seems to have a role in motivation and the initiation of voluntary action.

The temporal lobe has a prominent role in hearing, language, memory, and emotion. Audition is represented at the cortical level by the primary auditory cortex (Heschl's gyrus, areas 41 and 42). From there, auditory input is relayed to an adjacent temporal region, the posterior part of area 22, for further processing. On the left, this is known as Wernicke's area, and it is here that the comprehension of spoken language is organized. The homologous region in the right temporal lobe mediates the comprehension of the emotional content of language, which has been called sensory prosody. The hippocampus, folded into the

medial temporal lobe, is essential for the learning of new declarative information. The amygdala, immediately adjacent to the hippocampus, is a key nuclear structure in the cerebral organization of emotion. In a manner recalling hippocampal function, the amygdala is responsible for emotional learning; one powerful emotion, for example, is fear, and it is through amygdalar function that an individual learns to avoid dangerous environmental stimuli.

The parietal lobe has both sensory and cognitive roles in brain function. Immediately posterior to the motor cortex lies the primary sensory cortex (areas 3, 1, and 2), which receives sensory information from the thalamus below. Higher order sensory association cortex is located posterior to this region, in areas 5 and 7, and here further processing occurs. This arrangement permits the reception and interpretation of tactile stimuli from the opposite side of the body and face. On

the right, the parietal lobe is primarily involved in the capacity known as visuospatial function, which is the ability to orient within three-dimensional space and respond appropriately to it. The right parietal lobe is also central to the processes of attention, the ability to survey external space and focus on relevant stimuli while excluding those that are irrelevant; this lobe is the most prominent of a series of linked right cerebral

regions that renders the right hemisphere dominant for attention. On the left, important areas of the parietal lobe are the angular gyrus (area 39) and the supramarginal gyrus (area 40), which are involved in reading, calculation, and other cognitive domains.

Th occipital lobe is the smallest and most posterior lobe of the brain, but its importance lies in its singular affiliation with the visual system. Primary visual input from the thalamus is received here in the calcarine cortex of the medial occipital lobe (area 17), and then further processing occurs in the higher order visual association cortices adjacent to the calcarine cortex (areas 18 and 19). Reception of visual information is therefore as dependent on the visual cortex as it is on the eyes themselves. In addition, perception of visual aspects such as color, shape, form, motion, and location is made possible by the participation of the visual association areas.

A final point to be discussed in considering cortical structure and function is the specialization of the cerebral hemispheres. It is true that the two halves of the cerebrum are roughly symmetrical in a gross anatomic sense, and for elemental sensory and motor functions the two hemispheres can be considered comparable. However, there are significant interhemispheric differences in the organization of the higher functions. One of the most apparent of these is in the realm of language, as it has long been known that the left hemisphere is specialized for language in most individuals. This asymmetry of language function is linked to handedness, in that people who are right-handed (about 90% of the population) nearly always have left hemisphere dominance for language. However, it is important to recognize that the term ''dominance'' applies not just to language but to other cognitive functions as well. For example, the right hemisphere is dominant for visuospatial function and for attention, both of which are equally critical for successful human existence. Thus, the assumption that dominance only applies to language is misleading.

The two hemispheres, as is true of all areas of the brain, each contribute in their unique fashion to the extraordinary range of human capacities. These functions in general are becoming increasingly well-understood, and neuroanatomy continues to provide the foundation for understanding their neurobiological organization. From this basis, contemporary neuroscience is achieving an ever expanding knowledge of brain function, and, as further advances in neuroanatomy and related disciplines are made, a richer and more complete appreciation of the wide variety of human behavior can be expected.

GLOSSARY

cognitive domain Various modalities of behavior as expressed by the terms attention, executive function, memory (short-term and remote), visuospatial ability, motor function, and mood and affect.

critical effect The earliest discernible or measurable effect of exposure to a toxic substance.

critical organ The initial tissue to be affected by an exposure to a toxic substance.

encephalopathy A state of impaired functioning of the brain, which may include motor, sensory, and cognitive abnormalities and changes in mood and affect, as well as disturbances in attentiveness and consciousness.

executive function The behavioral process by which a person utilizes current sensory input and previously stored information and the complementary interactions of several cognitive domains to process and carry out complex independent, purposive, and problem-solving behaviors.

The adverse effects of exposure to neurotoxic chemicals on the brain manifest themselves behaviorally as changes in mood and in cognitive function. Neuropsychological testing has emerged as a means of documenting and measuring these changes. This methodology has several advantages for use in both the clinical diagnosis of chemically induced disorders and the epidemiologic investigation of neurotoxicant exposure–outcome relationships. These advantages include the documented validity and reliability of neuropsychological tests and their known sensitivity for detecting the effects of cerebral pathology and for localizing the probable specific anatomical sites associated with many neuropathological and neurodegenerative processes. In addition, methods of neuropsychological testing used to estimate premorbid intellectual abilities allow investigators to uncover acquired changes in cognitive functioning associated with brain insults, including the effects of exposure to neurotoxicants. The pathological effects following brain insults that may produce measurable deficits on formal neuropsychological testing may or may not be detectable by conventional magnetic resonance imaging (MRI), computed tomography (CT), and electroencephalography studies. Although the newer imaging technologies [i.e., positron emission tomography (PET), single photon emission computed tomography (SPECT), functional MRI (fMRI), and magnetic resonance spectroscopy (MRS)] can provide additional objective evidence of an organic basis of the neurobehavioral manifestations, formal neuropsychological assessment nevertheless remains the principal means for documenting impaired function among patients exposed to neurotoxicants. This article discusses the neurobehavioral syndromes related to neurotoxicant exposure and presents a review of the clinical diagnostic approaches most utilized in their evaluation.

I. DEFINITIONS AND ACTIONS OF NEUROTOXICANTS

A. Functional and Structural Effects

Many naturally occurring (neurotoxins) and synthetic chemicals (neurotoxicants) can cause damage to the

nervous system. Disruptions of neuronal cell homeostasis occur when natural protective mechanisms fail to detoxify and eliminate a potentially hazardous chemical substance before it causes tissue damage. A neurotoxic chemical is defined as a substance that is directly and/or indirectly capable of the following: (1) altering the integrity of nerve cell membranes, thereby affecting neuronal excitability, neurotransmitter release, and synaptic activity of neurons; (2) disturbing the flow of axoplasm, thereby interfering with the transport of neurotransmitters and nutrient substances along the axon to and from the cell body; (3) disrupting cellular respiration processes; (4) disrupting protein synthesis; (5) affecting neuronal functions indirectly by damaging Schwann cells and peripheral myelin, oligodendrocytes, and central myelin and/or disrupting the normal functioning of astrocytes and microglia; and (6) disturbing extracellular fluid volume and flow by damaging capillary endothelium, thereby resulting in disruption of the integrity of the blood–brain barrier (BBB) or blood–nerve barrier (BNB). Alterations in the normal functioning of the various affected target cellular elements, such as neurons, glial cells, myelin sheaths, or blood vessels, result in neurobehavioral manifestations.

Symptoms of exposure appear when tissue concentrations of a neurotoxic chemical reach a critical threshold level, above which intracellular processes such as oxidative respiration and axonal transport become impaired. Initially, reversible functional alterations occur; often these early effects are subclinical and may only be detectable by electroencephalography, evoked potential studies, or peripheral nerve conduction velocity testing. Irreversible damage to neural systems permanently interferes with function, resulting in impaired or disabled performance of ordinary activities of daily living.

B. Behavioral Manifestations

The severity of the behavioral manifestations associated with exposure depends on the potency and the dose of the particular neurotoxicant or neurotoxin. The total dose is dependent on the intensity and duration of the exposure. Acute exposures to higher concentrations of a neurotoxic chemical require less time than do more prolonged, lower levels of exposure to reach a threshold at which there is a clinical effect. The reversibility of a neurobehavioral change also depends upon the dose and type of neurotoxicant or neurotoxin. Chronic exposures are often associated with more gradual development of behavioral changes, which may be reversible or permanent.

Neurotoxicants and neurotoxins affect brain structures that mediate motor, sensory, and/or cognitive functioning. Many neurotoxic chemicals affect overall neurological and cognitive performance, and behavior to some degree, irrespective of their predilection for producing focal effects. Thus, diverse patterns of symptoms, signs, and neuropsychological performance deficits are not uncommon. Patients exposed to neurotoxic chemicals often complain of symptoms of encephalopathy, including changes in mood and affect, and of attention and memory problems. Overt signs of neurotoxicant exposure-induced motor system dysfunction may include spasticity, paralysis, bradykinesia, dyskinesia, dystonia, tremor, and incoordination. Subtle dysfunction of the motor system may not produce overt signs but may, nevertheless, affect performance on tests of motor function such as the Santa Ana Formboard, Purdue Pegboard, or Wechsler Digit Symbol Test. Neurotoxic chemicals affecting structures of the extrapyramidal motor system including the basal ganglia, such as manganese, produce overt signs of parkinsonism (e.g., tremor, dystonia, dyskinesia, and bradykinesia). Damage to the basal ganglia can directly and indirectly affect performance on neuropsychological tests of motor function. Cerebellar structures are sensitive to the effects of neurotoxic chemicals. These various patterns of clinical manifestations and neuropsychological performance deficits reflect an underlying neuropathology, which is dependent on the mechanism of action of the particular neurotoxicant, the exposure dose, and the type of exposure (acute or chronic) (see Table I).

II. DIAGNOSIS OF NEUROBEHAVIORAL DISORDERS

A person exposed to neurotoxic chemicals may be completely unaware of his or her own changes in behavior. This unrecognized impairment carries a risk for work-related accidents and injuries. Co-workers and/or family members often are the first to recognize changes in the patient's attention, memory, and mood and affect. If a source of chemical exposure is not immediately suspected or if the possible neurotoxic effects of a particular chemical are not well-known, the

Table I
Categories of Toxic Encephalopathies[a]

Disorder	Symptoms	Symptom duration	Pathophysiology
Acute Organic Mental Disorders			
Acute intoxication	Depression of CNS, attention and psychomotor deficits;	Minutes to hours	Reversible disruption of neutrotransmission
	No permanent sequelae		
Acute toxic encephalopathy	Confusion, seizures, coma; Cognitive deficits may persist	Hours to days	Hypoxia, disruption of BBB, cerebral edema
Chronic Organic Mental Disorders			
Organic affective syndrome	Disturbances of mood and affect including depression, irritability, anxiety, and fatigue;	Days to weeks	Reversible disruption of neurotransmission
	No permanent sequelae		
Mild chronic toxic encephalopathy	Disturbances of mood and affect plus cognitive deficits;	Weeks to years	Reversible disruption of neurotransmission
	Improvement with cessation of exposure but mild cognitive deficits may persist indefinitely		Limited neuronal/glial cell loss but no frank neuropathology
Severe chronic toxic encephalopathy	Disturbances of mood and affect plus severe cognitive deficits (including memory impairments) that interfere with activities of daily living;	Years	Cortical atrophy and/or loss of white matter in CNS; focal lesions may also be seen
	Deficits persist indefinitely		

[a]From White, R. F., *et al*. (1992).

patient's behavioral changes may be attributed to other possible neurological conditions. Risk of further exposure before removal from the source(s) of exposure is thus increased. The possibility that a neurotoxic illness may underlie the patient's presenting complaints should be fully investigated using the patient's medical history, laboratory findings, and occupational and environmental exposure histories.

The observations made by the clinician during a neurological examination can be used to infer the probable anatomical site(s) of nervous system dysfunction and to describe the patient's functional status. Abnormal neurologic symptoms and signs are expressions of impaired function or damage to particular neural structures, regardless of the specific etiology of the lesion. Thus, neurologic findings arising from the effects of exposures to neurotoxicants may resemble those found in primary or non-neurotoxic neurologic illness. The diagnostic process integrates the clinician's observations of the patient and the results of tests on physiological, anatomical, and behavioral functions, along with his or her acumen and judgment accumulated from experience with similar cases, and reference to a background of information contained in previously published literature.

A. Assessment of Behavior

The neurological examination begins with an assessment of the patient's ability to comprehend speech, follow simple instructions, perform complicated cognitive tasks, and perceive and identify sensory stimuli. The patient's spontaneous remarks and movements as well as those made in response to commands are evaluated for any digressions from expected norms of behavior, noting indications of the patient's orientation to person, place, time, and circumstances. Disturbances in mood and affect emerge during conversation. Engaging the patient in a conversation often reveals difficulties with attention if he or she is unable to focus well enough to follow the verbal exchange. Language comprehension is assessed by having the patient repeat simple phrases and follow simple commands. Expressive language is assessed by

listening to the patient's free speech for dysarthria, paraphasias, and neologisms. A clinical test of attention and mental control is to ask the patient to spell a word backward or to recite lists of words or numbers backward. Memory can be assessed through the details a patient is able to recall concerning medical history or through brief clinical assessment. Visuospatial and constructional ability can be assessed by having the patient draw the face of a clock with the hands set at a particular time.

Although these brief tests often reveal gross cognitive deficits associated with severe acute intoxication, acute toxic encephalopathy, and/or severe chronic toxic encephalopathy, patients with less severe or mild chronic toxic encephalopathy may present with subtle performance deficits that require formal neuropsychological assessment to detect and document. All patients exposed to neurotoxic chemicals who present with complaints of central nervous dysfunction should have formal neuropsychological testing to ascertain whether they are suffering from toxic encephalopathy.

B. Assessment of Motor and Sensory Functions

Neurological examination of motor functioning assesses the functional integrity of neurons in the cerebral cortex as well as their connections with subcortical, brain stem, cerebellar, and spinal cord pathways and the effector muscles that produce observable actions. Dysfunction in the motor cortex (upper motor neurons) results in weakness and spasticity of the limbs that are contralateral (i.e., on the opposite side of the body) to the site of the lesion. Basal ganglia dysfunction alters muscle tone and speed of response, causing bradykinesia (i.e., slowness of movement). Midbrain and brain stem structures control the coordination of cranial nerve functions such as conjugate eye movement, articulation of speech, and swallowing. Impaired cerebellar functioning results in ataxia of gait and tremulous trunk, head, and outstretched extremities. Tremors resulting from cerebellar and vestibular dysfunctions appear during actions and increase upon intention, whereas the tremor associated with Parkinson's disease appears during rest and disappears during action.

Spinal cord function is assessed by observing and recording the patient's gait, posture, muscle tone, fine motor control, and coordination. These features must be differentiated from those arising from damage to the brain. Reflexes are evaluated and muscle tone is noted. Spinal cord lesions produce motor dysfunction on the same side (ipsilateral) as the lesion. Weakness in the arm and leg indicates disturbance in the spinal pathways on the same side if a lesion exists below the foramen magnum. In such instances, muscle atrophy occurs as well. Loss of muscle tone and total paralysis without spasticity reflects dysfunction in the lower motor neurons.

Dysfunction in the structures of the brain responsible for processing sensory information can result in syndromes of contralateral neglect, visuospatial disturbances, or cortical blindness. Sensory deficits associated with exposure to neurotoxic chemicals can be detected by studies of brain stem auditory evoked responses and visual evoked responses. (see Section III.A). Impairments in sensory function indicate the probable location of disturbed anatomy in the spinal cord, thalamus, or sensory cortex. Sensory disturbances may be ipsilateral or contralateral to the site of the spinal cord lesion, depending on the specific sensory modality affected. Clinical assessment of sensory function is readily accomplished at bedside with a wisp of cotton, a new safety pin, a tuning fork, and a reflex hammer. Fibers carrying information about light touch, vibration, and position sensation ascend without crossing in the cord (these fibers cross in the medial lemniscus); thus, sensory dysfunction is found ipsilateral to the site of the cord lesion. Conversely, fibers carrying pain and temperature sensation cross immediately after entering the cord; thus, spinal cord lesions affecting these fibers produce sensory impairments on the side of the body contralateral to the site of the lesion. The loss of sensation to pain and temperature suggests dysfunction in the ventral spinal thalamic tracts (anterolateral system) of the spinal cord, whereas position and light touch represent anatomical structures in the dorsal columns of the spinal cord.

III. DOCUMENTATION BY FORMAL DIAGNOSTIC TESTS

A. Neuropsychological Testing

1. History Taking and Clinical Interview

The questions included in the interview should address information about the patient's current symptoms as well as his or her past medical history. This process can be facilitated by having the patient complete a standardized questionnaire such as the "Boston

Occupational and Environmental Neurology Questionnaire.'' Information about the patient's performance in school and work should be obtained. It should be determined whether the patient has had any previous psychiatric, neurological, or developmental–academic problems that could affect his or her performance on neuropsychological tests. The patient should also be questioned about the history of his or her immediate family members, including details about education levels and occupations as well as medical and psychiatric histories. Past and present recreational use of drugs, alcohol, and prescribed medications that may affect performance on neuropsychological tests should be noted. The particulars of the circumstances surrounding the alleged exposure to neurotoxicants must be defined and documented. Material safety data sheets and documentation of current and past exposure levels should be obtained whenever possible.

2. Methods of Neurobehavioral Assessment

The clinical approach to the neuropsychological assessment of cognitive deficits and behavioral changes attributable to exposure to neurotoxicants is essentially the same as that applied to any neuropsychological assessment situation. The clinician must be familiar with the expected or likely behavioral effects of the various neurotoxic chemicals found in the workplace and environment to which the patient may have been exposed. An experienced neuropsychologist will be able to carry out the differential diagnostic process of determining the most likely etiology of any deficits that may be revealed by testing.

The clinical neuropsychological evaluation of patients with possible toxic encephalopathy necessitates that the clinician perform a careful and thorough examination of each patient. Many areas of cognitive function must be assessed so that exposure-related effects can be detected and other possible diagnoses comprehensively evaluated and ruled in or out. Because there is overlap between the behavioral effects of exposure to certain neurotoxic chemicals and those associated with developmental disorders (e.g., learning disabilities, attention deficit disorder), psychiatric conditions (e.g., posttraumatic stress disorder, bipolar disorder), neurological diseases (e.g., multiple sclerosis, cerebrovascular disease, primary progressive dementia, parkinsonism), and the exposure to ethanol, medications, and illegal drugs, the test battery must allow for consideration of these alternative or contributing conditions.

The literature on behavioral toxicology includes the results of epidemiologic studies of exposed populations as well as clinical case reports. A number of batteries have been proposed for the assessment of neurotoxic effects of industrial chemicals. It is important to note that, whereas these batteries may be well-suited to the *epidemiological* investigation of neurotoxic effects, they are too brief and lack some tests essential to the process of making a clinical differential diagnosis. In addition, some of these batteries contain tasks with no available norms upon which a clinical diagnosis could be based. The results from epidemiological studies using these test batteries are nevertheless important to the neuropsychologist performing clinical case assessments. They can provide insight into the domains of function expected to be affected and unaffected by exposure to specific neurotoxicants and aid in the selection of appropriate tests expected to be sensitive to the effects of a particular toxic chemical.

There are fundamental differences between epidemiologic and individual clinical testing endeavors. In the epidemiologic setting, tests are designed or selected to ascertain dose–response relationships between the degree of exposure and neurobehavioral outcomes among members of a group of exposed persons. In the clinical setting, one is looking for deficits relative to the expected premorbid level of performance for an individual. In the epidemiologic setting, neuropsychological test scores within the ''normal'' range nevertheless may support an adverse effect of exposure based on dose–response outcomes. In the clinical setting, however, scores must be at least 1–2 standard deviations below normative expectation for the subject in order to be considered indicative of a deficit. Thus, clinical examinations may require a greater degree of dysfunction in order to conclude that an exposure is having (or has had) an effect than might be seen in the research setting.

The field of neuropsychology has a number of assessment approaches, including the Halstead–Reitan method, which typically employs a set battery of tasks, and the behavioral neurology or Process Approach, which employs a flexible battery in evaluating patients with specific kinds of referral issues or who show certain types of processing deficits during the evaluation itself. We have developed a battery of tests sensitive to the effects of neurotoxic chemical (Table II).

The neuropsychologist typically employs tests with which he or she is familiar and uses frequently to examine the toxicant-exposed patient. These tests are generally classified according to the cognitive domains

Table II
Boston Extended Neurotoxicologic Battery: Clinical Version[a]

Behavioral test	Cognitive domain assessed
WAIS; WAIS-R: WAIS-III	
Information	Basic academic verbal skills
Vocabulary	Verbal concept formation
Comprehension	Verbal concept formation
Similarities	Verbal concept formation
Digit Spans	Attention
Arithmetic	Attention and calculation
Picture Arrangement	Sequencing and visual spatial
Block Design	Visual spatial
Object Assembly	Visual spatial
Digit Symbol	Psychomotor speed
WMS-R	
Information	
Orientation	
Mental control	Attention and cognitive tracking
Digit Spans	Attention (verbal)
Visual Spans	Attention (visual)
Logical memories	Verbal memory
Verbal Paired Associates	Verbal memory
Visual Paired Associates	Visual memory
Visual Reproductions	Visual memory
Figural Memory	Visual memory
Continuous Performance Test	Attention (vigilance) and reaction time
Trail-Making Test (A and B)	Attention, cognitive tracking and sequencing
Wisconsin Card Sort Test	Set formation and set shifting
FAS-verbal fluency	Language
Boston Naming Test	Language
Boston Diagnostic aphasia Exam - reading comprehension subtest	Language
Wide Range Achievement Test	Basic academic skills
Boston Visuospatial Quantitative Battery	Visuospatial
Santa Ana Form Board	Psychomotor speed
Milner Facial Recognition Test	Visuospatial and visual memory
Benton Visual Rention Test	Visual memory
Difficult Paired Associates	Verbal memory
Albert's Famous Faces Test	Retrograde memory
Profile of Mood States	Affect
Minnesota Multiphasic Personality Inventory	Personality and affect

[a]From White, R. F., and Proctor, S. (1995). In "Neurotoxicology: Approaches and Methods" (L. W. Chang and W. Slikker, eds.), Ch. 46, Academic Press.

they tap. Though no test is so pure that it taps only one type of cognitive processing skill or functional domain, many load heavily on one area of function or another. The most commonly assessed functional domains in neuropsychology include attention, executive function, fine manual motor skills, visuospatial abilities, language and verbal skills, anterograde (short-term) and retrograde memory, and affect and personality. Regardless of the battery of tests used, it is essential that the clinician determine an estimate of premorbid ability patterns for the patient. Any deficits uncovered on neuropsychological testing should be related to this estimate of baseline function. Neuropsychologists are typically interested in academic skills such as reading and arithmetic (which are often helpful in determining premorbid ability patterns) and in motivation to perform well on testing which can be influenced by aspects of secondary gains such as monetary compensations. The reader is referred elsewhere for descriptions of the tasks assessing these domains. The various domains mentioned earlier as well as the expected changes in performance associated with exposure to neurotoxicants are described next to provide additional insight into the neurobehavioral features of toxic encephalopathy.

a. Language–Verbal Function Language and verbal functioning are typically preserved in adults exposed to neurotoxicants. This aspect of cognitive function is relatively resistant to the effects of neurotoxic exposure-induced brain damage compared with dynamic cognitive processes, such as encoding of new memories. This is in stark contrast with the effects of stroke and other focal lesions, which may have profound impacts on language function. However, patients exposed to certain neurotoxic chemicals (e.g., carbon monoxide) may show deficits on tests requiring the application of verbal and language skills. Motor aspects of writing may be affected in those patients with movement disorders (e.g., tremor) resulting from neurotoxic exposure, whereas the grammatical aspects of writing remain intact. Exposure to neurotoxic chemicals is more likely to produce language deficits in children than in adults because disruption of encoding processes occurs during development and, thus, can lead to problems with language acquisition. The severity of the deficits seen depends upon the age of the child at the time of exposure; younger children are more vulnerable.

b. Attention and Executive Function Deficits in *attention* and *executive function* may be found on

formal testing of patients with exposures to neurotoxicants. Tests of attention measure the following: (1) *simple (immediate) attention*, i.e., how much information can be grasped at once; (2) *divided attention*, which is the ability of an individual to attend to more than one task simultaneously; and (3) *vigilance or sustained attention*, which measures the ability of the subject to remain focused on a single task for long durations of time. Attention deficits impair the patient's ability to selectively focus on relevant stimuli and, therefore, may have a direct effect on concentration and an indirect effect on memory function.

Executive function is a higher order behavioral process involving the ability of the subject to appreciate and respond to complex changes in neurobehavioral task demands, including recognizing, maintaining, and shifting set as necessary to carry out such tasks. *Cognitive tracking* is an aspect of executive function often found to be impaired in those patients exposed to neurotoxic chemicals. Trail making (Trails A and B) is a cognitive tracking task that has been shown to be sensitive to problems associated with exposure to neurotoxic chemicals. *Cognitive flexibility* is another aspect of executive function that is affected in toxic encephalopathy. Difficulties in cognitive flexibility may be revealed by tasks such as the Wisconsin Card Sorting Test. Although some patients show deficits on tests of both cognitive tracking and cognitive flexibility, other patients exhibit deficits on one but not the other. It is impossible to predict which type of deficit will be seen in a patient with toxic encephalopathy, and it does not appear to be related to the type or severity of the exposure. Patients with severe deficits in executive function may have problems with their activities of daily living.

c. Memory Function Memory can be affected at several levels, including encoding of new information, retrieval of encoded information, ability to inhibit interference during learning and retrieval, and retention of encoded information. Many patients exposed to neurotoxic chemicals have relative deficits on tests of short-term or anterograde memory function compared with retrograde memory or long-term memory function. This dichotomy reflects the sensitivity to neurotoxic exposure-induced brain damage of the complex dynamic processes involved in short-term memory function, particularly encoding processes, and the relative resilience of the previously stored information tapped by tests of retrograde memory function, which is considerably more dependent upon retrieval mechanisms. Because of the divergent patterns of memory impairment possible following toxic exposure, a rather extensive memory battery is used to assess these patients.

d. Motor Skills Motor function is affected in some patients exposed to neurotoxic chemicals. Patients may show performance deficits on tests sensitive to motor deficits, including Finger Tapping and the Santa Ana Formboard. Motor function deficits can interfere with the patient's performance on many neurobehavioral tests (e.g., Digit Symbol). For example, a patient with bradykinesia may perform poorly on timed tasks measuring performance in domains other than motor function because they simply move more slowly. The neuropsychologist using the behavioral neurology or Process Approach can take into consideration the effects of motor deficits on other neurobehavioral tasks and utilize this information in his or her assessment and interpretation of the patient's performance.

e. Visuospatial Abilities Visuospatial deficits are seen following exposure to certain neurotoxicants (e.g., mercury). Performance on tests such as Block Design and the Rey–Osterreith Complex Figure (copy trial) may be below expectation in a patient exposed to neurotoxicants.

3. Strengths of Neuropsychological Tests

Neuropsychological test procedures have some inherent strengths and weaknesses with regard to making clinical diagnosis.

A. They are reliable because they have been standardized with regard to scoring and administration. For this reason, they can be given in the same manner by different clinicians.

B. Normative values are available for these tests so that performance can be judged with regard to level of performance. These norms allow the clinician to compare the patient's performance to that evidenced by persons of the same age and, often, of the same gender and educational achievement. For some tests, norms specific to countries outside of the United States are available, as are norms for specific groups within the U.S. population (e.g., Hispanics).

C. The tests have been well-validated, and a great deal is known about how performance on one test relates to performance on similar tests. In addition, extensive information is available concerning the brain structures that participate most directly in the completion of tasks (brain–behavior relationships revealed

by the tasks) and the patterns of performance on the tests among patients with specific developmental, neurological, motivational, and psychiatric disorders.

4. Weaknesses of Neuropsychological Tests

A. In persons with low premorbid intellectual abilities, it can be difficult to identify subtle deficits in function because they are performing at the floor of the tests already (many tasks have high floors).

B. When there is a long delay between exposure and neuropsychological testing, physiological recovery and/or use of compensatory strategies by the patient may occur, obscuring changes in function that may have been evident at the time of exposure. Among patients whom we have seen longitudinally from the time of exposure until several years after exposure ceased, it is clear that for some cases we would not have been able to diagnose the toxicant-related effects or determine the minor residuum of those effects had we not seen the patient early.

C. For some subgroups of patients within the U.S. population, particularly immigrants who do not speak English as a first language, normative values may be unavailable or available only for a limited number of tests.

D. In patients for whom sick-role playing or embellishment is an issue, inconsistencies in test performance or exaggeration of performance deficits may obscure mild or subtle brain dysfunction associated with exposure to toxic chemicals.

E. Conditions with overlapping pathologies can make differential diagnosis difficult. For example, patients with white matter lesions may have multiple sclerosis, a toxicant-induced condition, or both. Similar problems hold for parkinsonism affecting basal ganglia function, which can occur secondary to toxicant exposure, infections, infarcts, or a combination of these brain insults. Cerebrovascular disease is also a problem because it presents with a frontal–subcortical picture on neuropsychological testing similar to that of many toxic chemicals. Furthermore, exposure to certain neurotoxicants (e.g., mercury) that may be associated with hypertension can lead to brain dysfunction.

B. Neurophysiological Testing

Neurophysiological tests of central nervous system functioning, such as electroencephalography and evoked potentials, are obtained to provide additional objective evidence of an organic basis for the clinical behavioral findings. These tests can be used to detect possible diseases other than the disorder attributable to exposure to neurotoxicants. Abnormalities are not always revealed by these tests, but, when present, they may lend further support to a diagnosis of toxic encephalopathy.

1. Electroencephalography

The electroencephalogram (EEG) seen in a healthy adult has a relatively consistent pattern under normal waking, resting, and sleeping states. Disruptions of normal brain electrical activity are associated with changes in the symmetry, amplitude, and/or frequency of the EEG patterns. For example, epileptic activity is associated with a paroxysmal quality to the waveforms and sharp, spiked discharges. A focal concentration of sharp, slow, and/or paroxysmal waves in a particular area may indicate an underlying structural lesion, such as a neoplasm, stroke, or traumatic brain injury. Marked asymmetry of the EEG pattern suggests lateralized pathology. In contrast, encephalopathy due to endogenous or exogenous toxic disturbances is associated with diffuse bilateral slowing of the background rhythm and the disappearance of normal resting frequencies. As with all laboratory tests, the significance of the EEG report depends on correlation with other clinical information. In the differential diagnosis of neurotoxic syndromes and non-neurotoxic, neurological disease, the EEG is most helpful when an abnormality is seen during or in close chronological proximity to neurotoxicant exposure because the EEG pattern normalizes in reversible acute encephalopathy when the patient is removed from the source of exposure. The EEG tracing may not return to normal after the patient is removed from exposure to certain neurotoxicants (e.g., trimethyltin) and, therefore, is useful in documenting the presence of organic changes attributable to exposure.

2. Evoked Potentials

Evoked potentials (EPs) are used to assess the integrity and function of sensory pathways and are recorded after stimulation of peripheral sensory (afferent) nerve fibers in the extremities and/or by direct recording over the dorsal columns of the spinal cord. The EPs consist of visual evoked potentials, brain stem auditory evoked potentials, and somatosensory evoked potentials.

Visual evoked potentials (VEPS) are used to assess the integrity of the pathways of the optic system, including the optic nerve and chiasm, the optic tract to the geniculate nuclei, and the calcarine cortex. Two types of VEPs, flash visual evoked potientals (FVEPs) and pattern shift visual evoked potentials (PSVEPs), have been used to study the effects of exposure to neurotoxic chemicals.

Brain stem auditory evoked potentials (BAEPs) arise following stimulation of the auditory nerve. The auditory pathway generates a complex waveform that is recorded through electrodes attached to the patient and projected on the screen of an oscilloscope. Wave I reflects activation of the auditory nerve, whereas waves II and III reflect the activation of structures in the pontomedullary region. The sources of waves IV and V are less clearly defined but appear to be related to functions of the upper pons and lower midbrain. The absolute latencies of each wave are recorded, but interpeak latencies of waves I–III, III–V, and I–V are more consistent and reproducible and, therefore, are utilized in clinical testing. Brain stem auditory evoked potentials can be used to detect insults caused by ototoxic substances.

Somatosensory evoked potentials (SEPs) are recorded from electrodes placed over the sensory cortex after activation of a peripheral sensory or mixed nerve. The stimulus is conveyed centrally in the spinal cord and is then projected to the contralateral cerebral cortex. Technique is important in obtaining reliable measures. SEPs are usually tested in both upper and lower extremities, and interpeak latencies are more consistent and can help to localize pathology along the path of the peripheral nerve through the spinal cord, brain stem, and thalamus to the cortex.

Because many neurotoxic chemicals affect peripheral nerves, it is commonly the most distal sites of sensory conduction that are slowed and affect the cortically evoked SEPs in patients exposed to neurotoxic chemicals. Therefore, it is uncertain whether SEPs offer any advantage over standard nerve conduction velocities, except for studies of conduction through the spinal cord posterior columns and in instances where proximal nerve blocks or asymmetrical problems are being considered in the differential diagnosis.

C. Neuroimaging Studies

Highly sophisticated, computerized radiological methodologies can delineate images of the cerebral hemispheres and ventricular systems, as well as differentiate between cerebral cortex and white matter structures. The sensitivity of neuroimaging techniques in the detection of neurotoxic effects is limited. Nonetheless, there have been reports of clinical correlations between images obtained with magnetic resonance imaging (MRI), single photon emission computerized tomography (SPECT), and positron emission tomography (PET) in the presence of exposure to various neurotoxicants.

1. Magnetic Resonance Imaging

Magnetic resonance imaging studies are invaluable in the differential diagnosis of various encephalopathies. These studies often demonstrate structural abnormalities due to strokes and neoplasms; MRI studies of severe acute and chronic toxic encephalopathy may reveal white matter changes. However, the MRI studies of patients with less severe chronic toxic encephalopathy may appear normal, despite clinical neurological and neuropsychological evidence of behavioral abnormalities and performance deficits.

In cases of hypoxia or carbon monoxide poisoning, the MRI findings show signal intensity changes in the basal ganglia (globus pallidus) that may be bilateral or unilateral. Changes in cerebral white matter are seen upon brain MRI following chronic exposure to toluene; these findings have been correlated with changes in neuropsychological performance. MRI changes are also associated with exposure to organolead compounds and inorganic mercury.

2. Magnetic Resonance Spectroscopy

Magnetic resonance spectroscopy (MRS) has emerged as a possible sensitive measure of the structural and functional abnormalities associated with central nervous system dysfunction. It is an advanced level of the technology used in conventional MRI, which can detect chemical characteristics in addition to image data. Three main peaks reflecting the concentrations of *N*-acetyl-L-aspartate (NAA), creatine–phosphocreatine (Cr), and choline-containing compounds (Cho) are recorded from selected areas of interest. NAA is present within all neurons, and its concentration is elevated in several degenerative neurological conditions including amyotrophic lateral sclerosis. The Cr peak seen on MRS reflects levels of creatine and phosphocreatine, which serve as a reserve for high-energy phosphates in the cytosol of neurons. The Cho peak represents choline-containing compounds.

Choline is a precursor for the neurotransmitter acetylcholine and for the membrane constituent phosphatidylcholine. Additional chemicals of interest detectable with MRS include lactate, glutamate, glutamine, myoinositol, and γ-aminobutyric acid (GABA). Lactate is an end product of anerobic respiration and may be elevated following exposure to hypoxia-inducing neurotoxicants such as carbon monoxide and hydrogen sulfide.

The value of MRS in the diagnosis of exposure to neurotoxicants has not been fully elucidated, but published reports indicate that this technology holds considerable promise as a diagnostic tool. For example, MRS studies of a 10-year-old boy who had documented elevated blood lead levels of 51 μg/dl at 3 years of age revealed spectra that deviated from the expected pattern in all metabolite ratios analyzed, with a reduction in the NAA : creatine ratio for both gray and white matter. The conventional MRI of his brain done at the same time was normal. Formal neuropsychological assessment of the child was also performed at this time and revealed deficits in attention and mental control. The child also had reading, writing, and linguistic performance deficits. In contrast, his scores on tests of general knowledge were within normal limits. These neuropsychological and MRS findings were in stark contrast with those obtained for his cousin, a 9-year-old boy who was not exposed to lead and who served as a control. The neuropsychological assessment of the cousin was within normal limits and no abnormalities were seen on his MRI or MRS studies. Furthermore, the MRS findings in the patient's unexposed cousin were entirely consistent with the spectral pattern reported in previous studies of healthy individuals.

IV. BEHAVIORAL MANIFESTATIONS FOLLOWING EXPOSURE TO SELECTED CHEMICAL NEUROTOXICANTS

A. Lead

The acute symptoms of exposure to lead include abdominal colic, constipation, anorexia, vomiting, headaches, lightheadedness, dizziness, forgetfulness, anxiety, depression, irritability, excessive sweating, and muscle and joint pain. Acute symptoms subside following cessation of exposure and the reduction of blood lead levels. Chronic lead exposure results in more persistent neurological manifestations, including peripheral neuropathy and encephalopathy. Encephalopathy is the most serious consequence of acute and chronic lead poisoning in adults and children. Seizures and coma are seen in both children and adults with inorganic lead encephalopathy, and death occurs in the most severe cases. Early recognition of the symptoms and signs of lead poisoning can minimize the neurotoxic effects of lead exposure and prevent permanent brain damage or death.

The neuropsychological testing of lead exposed children reveals impaired performance on tests of memory, visuospatial abilities, and concept formation. Meta-analysis of the published data on the effects of lead on the brain suggests that children's IQ scores are inversely related to their lead body burden. Residual cognitive deficits and behavioral disturbances have been reported in middle-aged adult survivors of childhood lead poisoning. Language function is typically spared in lead-exposed adults but is often impaired in those individuals exposed to inorganic lead as children.

We previously reported the results of comprehensive neuropsychological assessment of 18 adults (7 male, 11 female) who had been exposed to lead as children 50 years earlier. All of the exposed subjects were under the age of 4 years at the time of exposure; the mean age of the exposed subjects at the time of neuropsychological testing was 54.4 years. Eighteen age- and sex-matched subjects with no history of lead exposure served as controls. All of the exposed subjects exhibited lead lines (metaphyseal bands) upon the X ray of at least one long bone and had presented during childhood with symptoms consistent with overt lead poisoning, indicating that blood lead levels in all cases had exceeded 60 μg/100 ml. The neuropsychological test battery used included four subtests from the *Wechsler Adult Intelligence Scale-Revised* (*WAIS-R*), including Similarities, Vocabulary, Picture Completion, and Block Design, the *Wechsler Memory Scale* (*WMS*), Trail Making Tests A and B (attention and visuomotor functioning); controlled word association test (verbal fluency), *Raven Progressive Matrices* (nonverbal reasoning), finger tapping (motor speed), and the *Profile of Mood States* (*POMS*).

Results of neuropsychological testing revealed significant deficits on the Picture Completion and Logical Memories subtests of the *WAIS-R* and *WMS*, respectively. In addition, the lead-exposed subjects showed impaired performance on the *Raven Progressive Matrices* and Trail B. These findings are consistent with persistent impairment of function in the cognitive domains of attention, executive function, concept formation, and short-term memory. Furthermore,

these findings indicate performance deficits on complex cognitive tasks that may impede the exposed individual's ability to learn new information. Whereas such subtle cognitive deficits may not be apparent during most activities of daily living, they can interfere with the exposed individual's academic and occupational achievements and advancement. Subtle cognitive deficits such as those reported in this study are particularly significant among those individuals whose premorbid IQ was below average.

Neuropsychological testing can also be used to detect and document the subclinical and clinical central nervous system effects of inorganic lead poisoning in persons exposed to lead as adults. Neuropsychological assessment of asymptomatic workers with blood lead levels greater than 50 μg/100 ml reveals cognitive deficits on tests of psychomotor and memory functioning. Although comparisons of responses of workers on the *Profile of Mood States* (*POMS*) before and after reductions in levels of lead exposure indicate that tension, anger, depression, fatigue, and confusion are decreased by reductions in exposure, neurobehavioral performance deficits may not be entirely ameliorated by a similar reduction in lead exposure levels.

We examined a 31-year-old woman who had personally undertaken the job of deleading her recently purchased home. She developed symptoms indicative of inorganic lead encephalopathy after approximately 9 months of exposure. Her blood lead level when she first presented was 146 μg/100 ml of whole blood. Neuropsychological testing revealed poor attention and impaired memory for new material, especially visual information. Specific tests revealing impairments of central nervous system function included Digit Span, Digit Symbol, and Block Design. We reported on a similar pattern of performance in a 19-year-old man who had worked as a professional deleader for approximately 10 months. His lead levels ranged from 70 to 100 μg/100 ml of whole blood. He sought medical attention because of problems with attention and memory. Neuropsychological testing revealed impaired performance on tests of attention, short-term memory, and visuospatial and visuomotor functioning. Specific tests revealing impaired functioning included Digit Span, Digit Symbol, Block Design, and Picture Arrangement. Performance on tests of language and vocabulary were within expectation.

The trialkyl metabolites of the organolead antiknock agents tetramethyllead and tetraethyllead (i.e., trimethyllead and triethyllead) are potent neurotoxicants. Very few studies have specifically evaluated the persistence and/or severity of the cognitive effects associated with chronic exposure to organic lead in humans. The severity of the encephalopathy associated with organic lead poisoning has been related to the patient's body burden of inorganic lead as reflected by measurement of blood lead levels.

The findings on formal neuropsychological testing of patients with organic lead encephalopathy may be correlated with the findings on EEG studies. Both of these markers of neurotoxicant effect may show improvement after cessation of exposure, and these findings may be further improved with chelation therapy. Cognitive functioning was assessed in a 41-year-old woman who presented with symptoms of organic lead poisoning (blood lead level = 110 μg/100 ml) and an 8-month history of sniffing leaded gasoline for its euphoric effects. Neuropsychological testing revealed her to be well-oriented with intact remote memory, but her attention span and short-term memory functioning were severely impaired. The patient was unable to perform simple oral arithmetic problems, indicating deficits in attention and working memory. In addition, her performance on delayed recall tests of short-term memory indicated that she had severe deficits in this cognitive domain as well. Her attention and memory as well as other symptoms of lead poisoning were improved after chelation therapy.

Neuropsychological functioning has been assessed in a group of 39 organic lead manufacturing plant workers with a mean exposure duration of 14.7 years. The mean lifetime blood lead level among these workers was 26.1 μg/100 ml. Eighteen (46.2%) of them had neuropsychological performance deficits on tests of attention, memory, and psychomotor function. These 18 workers all underwent additional testing to rule out the existence of metabolic, infectious, or structural etiologies for their performance deficits. No alternative explanation could be found for the neuropsychological deficits seen in any of these workers.

The associations between neurobehavioral functioning and tibial bone lead and chelatable lead levels in former organic lead workers have also been investigated. Higher peak tibial lead levels were significantly associated with poorer performance on the *Wechsler Adult Intelligence Scale-Revised* vocabulary subtest, serial digit learning test, *Rey Auditory–Verbal Learning Test*, Trails B, finger tapping, Purdue pegboard, and the *Stroop Test*. Chelatable lead concentrations were significantly associated with choice reaction times. These findings suggest that past exposure to organic lead may be associated with persistent neurobehavioral performance deficits,

particularly in the domains of manual dexterity, executive function, verbal intelligence, and verbal memory, and that the severity of these deficits is related to the peak tibial lead levels that occurred during the exposure period.

B. Mercury

Symptoms of acute exposure to elemental mercury vapor include respiratory irritation, headache, fever, chills, chest pain, general malaise, nausea, and vomiting. These symptoms are often referred to as "metal fume fever syndrome." Emotional lability, depression, social withdrawal, tremors, delirium, and coma develop within 24 hr after exposure to elemental mercury. The respiratory symptoms typically resolve within days to weeks after cessation of exposure, but the CNS disturbances persist.

The tremor associated with mercury poisoning begins in the fingers and hands, then progresses to affect the eyelids and face, and eventually affects the head, neck, and torso. The tremor is rapid, may be quite severe, and is accentuated by activity and emotional excitement, increasing in amplitude of excursion upon activation. The tremor is not a resting tremor and thus its frequency is faster and differs from the characteristic resting pill-rolling tremor seen in Parkinson's disease. Continued exposure to mercury vapor results in worsening tremor, gingivitis, mood changes, withdrawal from social interactions, greater memory loss. Abnormalities also include deficits in attention, executive functioning, short-term memory, and visuospatial ability. Language, basic academic skills, and retrograde memory are usually unaffected.

Neurobehavioral effects of acute exposure to elemental mercury vapor include depression, anxiety, and social withdrawal. Assessment of cognitive and emotional functioning conducted after cessation of exposure in workers exposed elemental mercury vapor may reveal persistent cognitive deficits on tests of motor coordination, processing speed with and without a motor component, cognitive flexibility, verbal fluency, verbal memory, and visual problem-solving and conceptualization.

Adults chronically exposed to elemental mercury may demonstrate cognitive impairments, including deficits in attention, executive function, short-term memory, visuospatial ability, and motor function. Language function and long-term memory are typically spared in adults but may be impaired in persons exposed *in utero* or during childhood. A case study of a 19-year-old man with a history of chronic exposure to mercury vapors during childhood (ages 4–9 years) revealed persistent tremor and behavioral abnormalities indicative of developmental toxin-induced encephalopathy secondary to mercury exposure, including deficits on tests of language, executive function, visuospatial skills, and fine motor control. The *POMS* revealed irritability and depressive affect.

The neuropsychological effects of mercury exposure can be correlated with current and cumulative exposure doses. For example, Digit Span has been used in research settings to document a correlation between current urine mercury levels and impairments of short-term memory function among exposed persons. The Bender–Gestalt test has also revealed impairments of visuospatial skills in persons with elevated tissue mercury levels. Impaired short-term memory functioning has been correlated with the duration of exposure to mercury. The serial neuropsychological assessment of construction workers exposed to elemental mercury revealed acute and persistent CNS effects. Initial testing revealed impaired performance on tests of attention and executive functioning (Trails A and B, *Stroop Test*) and motor skills (finger tapping, grooved pegboard). Performance was correlated with cumulative excretion of mercury. Performance on Trails A and B was improved following chelation therapy. However, performance on finger tapping and the *Stroop Test* remained unchanged and performance on the grooved pegboard worsened after cessation of exposure. Thus, our experience and a review of the literature suggest that elemental mercury exposure can be expected to affect performance on tests of attention, executive functioning, and motor functioning.

Persistent impairments in short-term memory, coordination, and simple reaction time may be seen up to 10 years after removal from exposure to elemental mercury. Research studies comparing the neuropsychological functioning of former chloralkali workers with that of age-matched unexposed controls with similar educational levels reveal that performance on certain tests, including the grooved pegboard and *Benton Visual Retention Test*, is worse among those previously exposed to mercury. Formerly exposed subjects may also perform worse on other tests sensitive to attention and psychomotor function, such as Trails A and B and Digit Symbol.

The clinical picture of methylmercury encephalopathy differs somewhat from that associated with

exposure to elemental mercury. Exposure to methylmercury during critical developmental periods can lead to severe mental retardation. Neuropsychological development was reported to be so severely delayed in an individual exposed to methylmercury *in utero* during the Minimata outbreak that she never learned to speak. Adult exposure to methylmercury is associated with lesions in the occipital cortex, and performance deficits may be seen on tests of visuospatial ability. Deficits have also been reported on tests of manual dexterity in adult women exposed to methylmercury.

C. Manganese

Occupational exposure to manganese (Mn) occurs among miners and welders. Frequently encountered organic Mn compounds include methylcyclopentadienylmanganese tricarbonyl (MMT), which is used as an antiknock additive in gasoline. Encephalopathy and basal ganglia dysfunction with parkinsonian signs including rigidity, gait abnormalities, dysarthria, hypomimia, and bradykinesia have been reported in patients with increased brain Mn levels due to chronic liver failure. The similarities between the clinical manifestations associated with Mn intoxication and those seen in Parkinson's disease suggest that occupational and environmental exposures to this and other neurotoxic chemicals may be involved in the pathogenesis and/or alter the prognosis of certain neurodegenerative diseases. It has not been established whether exposure to Mn precipitates the occurrence of progressive idiopathic Parkinson's disease, but research suggests that the prognosis may be poorer among those persons who are predisposed to develop idiopathic Parkinson's disease who also have a history of exposure to Mn.

The initial clinical manifestations of manganese poisoning often include behavioral changes referred to collectively as "manganese psychosis." The clinical symptoms include mood changes, emotional lability, uncontrolled laughter, and hallucinations. Performance on formal neuropsychological tests may be impaired at this time. Motor disturbances, characterized by tremor, dysarthria, gait disturbance, slowness and clumsiness of movement, and postural instability, emerge with continued exposure to Mn. If exposure continues, the psychosis typically subsides, and dystonia and an awkward high-stepping gait emerge. The gait disturbance associated with Mn poisoning is easily distinguishable from the shuffling gait of idiopathic Parkinson's disease. In some cases, the extrapyramidal symptoms of Mn poisoning may progress following cessation of exposure.

Formal neuropsychological testing can be used to document the behavioral and cognitive effects of Mn exposure in clinical and research settings. Tests of psychomotor functioning such as the Santa Ana Formboard, Digit Symbol, and finger tapping are sensitive to the neurotoxic effects of Mn. Attention and memory impairments induced by Mn exposure are revealed by tests sensitive to functioning in these two cognitive domains. Language and verbal functioning are typically spared in Mn-exposed adults, but children exposed to Mn may develop persistent impairments of language function.

Research studies investigating neuropsychological performance among Mn-exposed persons have revealed deficits at concentrations ranging from 1 to 28 mg/m^3. Tests in research settings used to document deficits have included finger tapping, reaction time, and digit spans. Visual spans and tests of visual spatial ability have also been used successfully in research settings to document the effects of Mn.

The neuropsychological test performance of Mn-exposed workers with parkinsonism has been compared with those of normal controls and patients with idiopathic Parkinson's disease. Mn-exposed workers with parkinsonism perform significantly worse than do unexposed controls on the *WAIS-R*, *Milner Facial Recognition Test*, Purdue pegboard, and the Continuous Performance Test. Mn-exposed workers with parkinsonism typically perform better on the Purdue pegboard than do patients with Parkinson's disease.

Neurobehavioral testing has been performed on a group of workers from a ferromanganese alloy plant. The workers had been exposed for 1–28 years, and the mean duration of exposure was 13 years. They were divided into three groups on the basis of their Mn exposure histories. The *low-exposure* group comprised foremen, clerks, and laboratory technicians exposed to Mn concentrations of only 0.009–0.15 mg/m^3 (mean blood Mn = 6.0 μg/liter, mean urine Mn = 1.7 μg/liter). The *medium-exposure* group consisted of maintenance workers with exposure levels ranging from 0.072 to 0.76 mg/m^3 (mean blood Mn = 8.6 μg/liter, mean urine Mn = 2.3 μg/liter). The *high-exposure* group consisted of those workers with the highest levels of exposure of up to 2.6 mg/m^3 (mean blood Mn = 11.9 μg/liter, mean urine Mn = 2.8 μg/liter). Cumulative exposure indices (CEI) were determined for each subject. Cognitive domains assessed included

attention (simple and complex reaction times), executive function (arithmetic), psychomotor function (Digit Symbol and finger tapping), short-term memory (Digit Span), and verbal understanding (vocabulary). The results of tests of psychomotor function (finger tapping and Digit Symbol) and short-term memory (Digit Span) were correlated with environmental exposure levels, as represented by individual CEI scores.

D. Trichloroethylene

Trichloroethylene (TCE) is commonly used as a degreasing solvent in industrial settings. The neurotoxic effects of TCE are associated with exposure to the parent molecule and to its environmental degradation product, dichloroacetylene (DCA). Because DCA is derived from TCE, individuals working with TCE or encountering it in nonoccupational settings are at risk for the neurotoxic effects of both chemicals.

Acute exposure to TCE induces narcosis characterized by subtle behavioral changes and subjective symptoms of drowsiness and an inability to concentrate. At higher levels of exposure, nausea, vomiting, headache, dizziness, confusion, stupor, and loss of consciousness occur. Acute exposure to very high levels of TCE has been associated with persistent neurological symptoms and death. The salient persistent effects of a severe acute exposure to TCE include facial anesthesia, reduced perception of taste, dysarthria, flattening of the nasolabial folds, ptosis, reduced pupillary response, constricted visual field, and sensorimotor neuropathy.

The 25-year serial follow-up examination of a 26-year-old man who experienced toxic encephalopathy after a single severe exposure to TCE was reported by us. Initial neuropsychological assessment of this individual revealed difficulty with sequential problem-solving and short-term memory tasks. Although daily functioning improved over the course of several years, the patient felt chronically depressed and apathetic and continued to experience problems with attention and short-term memory. These problems, which were severe enough to interfere with his ability to perform his daily activities, were documented by serial neuropsychological assessments. At a follow-up examination 16 years after the exposure incident, his performance IQ (PIQ) was 19 points lower than his verbal IQ (VIQ). Significant visuospatial deficits accounted for a large part of the discrepancy between the patient's PIQ and VIQ. Tests of short-term memory showed deficits in both immediate and delayed recall of verbal and visual information. Tests revealing deficits included the *Benton Visual Retention Test*, Logical Memories, Paired Associates, and Visual Reproductions. In addition, the *Minnesota Multiphasic Personality Inventory* (*MMPI*) indicated that the patient was depressed.

Toxic encephalopathy was also seen in a 62-year-old machinist who experienced a brief acute exposure to TCE. A follow-up neuropsychological assessment of this patient performed 5.5 years after the incident revealed performance deficits on the Digit Symbol and Object Assembly sections of the *Wechsler Adult Intelligence Scale* (*WAIS*). Furthermore, the patient exhibited overt impairment of executive function, lack of insight, and low motivation, all of which were associated with his past exposure to TCE.

Symptoms of chronic exposure to TCE develop insidiously whether intake occurs via a pulmonary or oral route. Memory and affect are affected by chronic exposure. For example, subjective symptoms among residents of Woburn, MA, who were exposed to TCE-contaminated well water, included headache, dizziness, fatigue, irritability, insomnia, memory and concentration impairments, and paresthesias. Effects associated with chronic occupational exposure to TCE vapors include forgetfulness, dizziness, headache, sleep disturbances, fatigue, irritability, anorexia, trigeminal nerve symptoms, sexual problems, and peripheral neuropathy. Speech and hearing disorders have been reported among children exposed to TCE through the use of contaminated drinking and bathing water. The cognitive domains most frequently affected by TCE include attention, executive functioning, short-term memory, and visuospatial ability; language and verbal skills are typically spared in adults. Children exposed to TCE may develop persistent impairments of verbal functioning, which interfere with learning later in life.

Neuropsychological testing documented mild-to-moderate encephalopathy in 24 of 28 individuals who were chronically exposed to TCE-contaminated drinking and bathing water. Impaired cognitive performance was seen on the following tests: Visual Reproductions, Logical Memories, Word Triads, and the *Benton Visual Retention Test*. Significant memory impairments were seen in 24/28 cases. Attention and executive function deficits were seen in 19/28 persons, whereas visuospatial deficits and manual motor function deficits were seen in 17/28. Language and verbal functioning among the adults were almost

always within expectation. However, the neuropsychological evaluations of the children in this group indicated that the developmental stage at the time of exposure is related to the type of neurobehavioral deficits seen postexposure. Children exposed before age 18 years were shown to have deficits in a greater number of neuropsychological domains than individuals exposed as adults. In addition, these children showed a decrease in performance on the *Boston Naming Test* that was not seen in their parents. These findings suggest that children exposed to TCE suffer more diffuse damage to the brain and are more likely to develop learning disabilities.

E. Organophosphorus Compounds

Organophosphorus compounds (OPCs) are used primarily as pesticides, but many (e.g., Sarin and VX) are also used as chemical warfare agents. These compounds inhibit the activity of acetylcholinesterase, resulting in the accumulation of acetylcholine at receptors on neurons in the central and peripheral nervous systems.

Exposure to OPCs is associated with three clinically distinct syndromes: (1) acute cholinergic crisis; (2) intermediate syndrome; and (3) organophosphate-induced delayed peripheral neuropathy (OPIDN). The clinical presentation of these three syndromes reflects the different pathophysiological mechanisms that underlie each. The *acute cholinergic crisis* develops within hours of exposure to OPCs and may last as long as 96 hr. The signs and symptoms seen during the acute cholinergic crisis are due to the inhibition of acetylcholinesterase. The clinical manifestations reflect excessive stimulation of nicotinic and muscarinic receptors. Clinical manifestations include weakness, muscle fasciculations, tachycardia, miosis, lacrimation, excessive salivation, seizures, and coma.

The *intermediate syndrome* follows the acute cholinergic crisis. Symptoms begin to emerge within 24–96 hr after removal from exposure. Symptoms are due to adverse effects on muscle cells, and can persist for up to 6 weeks and include weakness of the proximal muscles of the limbs and neck. Tendon reflexes are also reduced. The cranial nerves and respiratory muscles may also be involved. Weakness of the diaphragm may necessitate intubation and respiratory support. Death may occur in the most severe cases. Prognosis is good if the patient survives, and clinical recovery is typically complete.

Organophosphate-induced delayed neuropathy (OPIDN) is characterized by clinical and electrophysiological signs and symptoms of neuropathy that emerge 1–5 weeks after exposure. The clinical features of OPIDN include flaccid paralysis of the distal muscles of the lower and upper extremities. This clinical picture is in contrast with that of the intermediate syndrome, which involves the more proximal limb muscles. Deep tendon reflexes are reduced or absent in those patients with OPIDN. Patients report sensory symptoms of numbness and paresthesias that are aggravated by exercise. The prognosis for patients with OPIDN is variable, with clinical recovery requiring at least several months; recovery of function may be incomplete in the legs and feet of the most severe cases. Signs and symptoms indicative of CNS pathology are also noted in those patients with OPIDN. Patients with greater CNS involvement show increased tendon reflexes and the Babinski sign may be present.

Acute and chronic behavioral effects have been associated with exposure to OPCs. Changes in mood and affect including irritability, nervousness, and depression are seen during the acute cholinergic crisis. Cognitive deficits associated with the acute cholinergic crisis range from overt confusion to mild forgetfulness. These neurobehavioral manifestations may subside within days or may persist indefinitely. Formal neuropsychological testing reveals deficits in attention, executive functioning, psychomotor skills, and short-term memory. Significant neuropsychological performance deficits have been found in these patients up to several years after cessation of exposure, indicating that toxic encephalopathy can occur in some individuals exposed to OPCs.

Neuropsychological functioning has been assessed in workers with chronic exposure to OPCs who have not experienced any episodes of overt acute poisoning. The exposed workers show significantly slower reaction times when compared with unexposed controls suggesting that psychomotor processing is slowed.

Serial neuropsychological testing was completed in a 44-year-old EPA field inspector who was soaked with a large quantity of phosmet released from a crop duster airplane that was flying overhead. His acute symptoms included nausea, excessive sweating, salivation, blurred vision, and headache. He remained symptomatic over the next several days and reported experiencing anxiety, irritability, weakness, photophobia, and insomnia. He soon recovered from the acute cholinergic symptoms such as excessive sweating and salivating, but noted that he was now experiencing attention deficits and dizziness that he had never before experienced. A neurological examination and a brief neuropsychological assessment were performed 6 months

after the exposue incidant. The patient's cognitive performance was within the normal ranges on Digit Span, the *Benton Visual Retention Test*, Block Designs, *Wisconsin Card Sort Test*, and the Purdue pegboard. Despite this reassurance that he was cognitively "normal," the patient continued to experience difficulty with his activities of daily living.

A more detailed neuropsychological assessment was performed approximately 2 years after the exposure incident. At testing the patient's verbal IQ was 126 and was significantly greater than his performance IQ (106). Performance deficits were noted on Trails B (attention and executive function) and Digit Symbol (psychomotor speed). Memory deficits were noted on delayed recall of both visual and verbal material; immediate recall was within expectation. His answers tended to be concrete and he missed the gestalt on tests of complex verbal reasoning. The *Profile of Mood States* (*POMS*) revealed depression, anger, and fatigue.

A follow-up neuropsychological assessment was performed 13 months later at 40 months after the OPC exposure incident. Overall improvement was noted on tests of executive function, visuomotor speed, and retrieval of information on delayed recall. However, the patient continued to show deficits on tests of attention and had difficulty with recall of verbal paired associates. His major problem on this testing continued to be difficulty with complex verbal reasoning tasks. The *POMS* revealed only irritability. It was concluded that the overall improvement in cognitive functioning with some residual impairments seen in this patient is consistent with recovery from an acute toxic encephalopathy that could have resulted from OP exposure. Of interest in this case is that the patient went on to complete law school, and his only residual complaints reported 10 years after the OP exposure were that he occasionally experienced unexplained symptoms of nausea, blurred vision, and anxiety. Such an instance was when he entered a local grocery store for a brief period of time and became nauseous and had blurred vision. He went home and contacted the store manager by telephone, inquiring about the possibility that he might have been exposed to a chemical used in the store. The manager informed him that the store had been spayed with an insecticide earlier that same day. In addition, he has recognized that he feels anxious and has nonspecific discomfort at those times when he can detect aromatic substances in the air, such as perfumes, petroleum products, or auto exhaust. He has adjusted to his apparent multiple chemical sensitivity (MCS) by simply avoiding such circumstances.

The number of individuals who experience the preceding constellation of symptoms is sufficiently large that a clinician should recognize it as a behavioral syndrome. The exact pathogenesis of MCS syndrome is still unclear. Components of autonomic nervous system reactivity, olfactory triggers of emotional responses, and PTSD and features of depression make it difficult to identify a specific therapeutic intervention. Much further work is needed on this condition before it can simply be dismissed as psychogenic in origin.

V. CONCLUSION

Behavioral syndromes following exposure to neurotoxic chemicals must be differentiated from other neurological disorders. This is only accomplished with careful analysis of the time line relationship between reported exposure conditions and the emergence of symptoms. Markers of exposure such as air or water samples and biological specimens also should be obtained whenever possible to support the diagnosis. Clinical findings and/or corraborative diagnostic test data are of value when these results are interpreted in the context of developmental, academic, and social history, medical and psychiatric history, information gleaned from interviewing the patient and/or significant others, the patient's behavior in the test situation, and qualitative findings observed in the test material. Follow-up testing is useful in documenting prognosis, confirming the effect of exposure to neurotoxic chemicals, and that a neurodegenerative process is not responsible for the individual's symptoms and signs of neurologic disfunction.

Neurodegenerative Disorders

LEE J. MARTIN
Johns Hopkins University School of Medicine

GLOSSARY

antioxidant An enzyme or chemical that inactivates reactive oxygen species.

apoptosis A form of programmed cell death that has a characteristic structural appearance and occurs through the activation of intrinsic cell death pathways.

apoptosis–necrosis continuum The concept that neuronal cell death can occur as typical apoptosis, typical necrosis, or as intermediates or hybrids of cell death with varying, overlapping contributions of apoptosis and necrosis.

astroglia Glial cells in the central nervous system that have long radial processes that ensheathe neurons and synaptic complexes. Astroglia regulate the extracellular chemical and ionic environment and secrete peptides, growth factors, cytokines, and chemokines.

axotomy Experimental injury to the neuronal axon (or bundles of axons) by transection, avulsion, or trauma.

central nervous system The brain and spinal cord.

death protein A protein that regulates programmed cell death.

excitotoxicity A neurotoxic process that is mediated by excessive activation of excitatory glutamate receptors.

experimental neuropathology The study of neurodegeneration in animal or cell culture model systems.

glial cell Nonneuronal cell in the nervous system (e.g., astrocyte, oligodendrocyte, microglial cell, Schwann cell).

glutamate receptor A family of cell membrane proteins located on neurons and glia that bind glutamate or related chemicals, causing depolarization by ionic conductance or activation of enzymes resulting in the production or release of intracellular second messengers.

microglia The resident small phagocytic cells of the brain and spinal cord that are related to the mononuclear phagocyte lineage and function as immune accessory cells that secrete cytokines and chemokines.

mutation Change in the DNA nucleotide sequence of a gene.

necrosis A form of cell death that has a characteristic structural appearance and occurs through the failure of homeostatic mechanisms (e.g., energy production, cell volume).

neurotransmitter Signaling molecule secreted by the presynaptic terminal of a neuron at chemical synapses to relay a signal to a postsynaptic neuron (e.g., glutamate).

NMDA receptor A type of ion channel glutamate receptor that controls neuronal excitation and is very important for synaptic plasticity. It regulates intracellular Ca^{2+}. Overactivation of NMDA receptors causes excitotoxic neuronal death.

oligodendroglia Glial cells that provide myelin sheaths for axons within the CNS and secrete peptide growth factors.

programmed cell death A form of cell death that is brought about by intrinsic cellular pathways involving specific death proteins.

reactive oxygen species An oxygen molecule containing an odd number of electrons rendering it chemically reactive due to an open bond (e.g., superoxide, hydroxyl radical, nitric oxide).

stem cell Relatively undifferentiated cell that can divide into daughter cells that can undergo terminal differentiation into particular cell types (e.g., neurons).

target deprivation The removal or ablation of a brain region or peripheral tissue that is the site with which a group of neurons connects.

Neurodegeneration is the pathology of neurons instigated by an acute insult or a chronic perturbation in cell function. The process of neurodegeneration can be rapid or it can be slow and progressive, and it can result in neuronal loss and neuronal dysfunction with neurological consequences. Acute neurodegeneration is caused by cerebral ischemia (stroke and cardiac arrest), toxins, and trauma. Chronic neurodegeneration is caused by diseases such as Alzheimer's disease, amyotrophic lateral sclerosis, Huntington's disease, and Parkinson's disease. In different neurological disorders, different groups of neurons are selectively vulnerable to the molecular pathology of the degenerative process. The basis for this selective vulnerability may be intrinsic to the different groups of neurons. Models of experimental neuropathology are essential for discovering the mechanisms for selective neuronal vulnerability to injury and neurodegenerative disease.

I. INTRODUCTION

A variety of neurodegenerative disorders affect the brain or spinal cord of humans (Tables I–III). The degeneration of nervous tissue can result from acute injury and from chronic disease. Acute neuropathology in adults, children, and infants can arise from head or spinal cord trauma, infection, toxicity, liver failure, and cerebral ischemia resulting from stroke, cardiac arrest, or asphyxiation. Chronic, progressive neuropathology occurs in adult disorders such as Alzheimer's disease, amyotrophic lateral sclerosis (Lou Gehrig's disease), Huntington's disease, multiple sclerosis, and Parkinson's disease and in infants and children with spinal muscular atrophy. These disease processes involve the degeneration of neurons and glial cells. Different populations of neurons in different nervous system regions have differential susceptibilities to disease and injury (Table I). This differential susceptibility of groups of neurons provides the basis for the yet to be understood concept of selective vulnerability (Table I). The underlying mechanisms for selective vulnerability are possibly related to specific properties of neurons, including size, axonal length, connections, metabolism, and gene mutations. This neuronal degeneration causes tragic neurological and behavioral disabilities ranging from memory loss to paralysis. For example, neuronal degeneration is responsible for the memory disturbances that occur in individuals with Alzheimer's disease (AD) and in people that have experienced cardiac arrest, asphyxiation, or strokes. Nerve cell loss is also responsible for the profound abnormalities in movement that occur in individuals with amyotrophic lateral sclerosis (ALS), Parkinson's disease, or Huntington's disease and in children with cerebral palsy or spinal muscular atrophy.

The impact of neurodegenerative disorders on our society is revealed by epidemiological studies. AD affects approximately 4 million adults (most are >65 years of age) and is the 4th-leading cause of death in the United States. AD accounts for $>100{,}000$ deaths annually. ALS affects approximately 30,000 Americans (4–6 people in 100,000), whereas Huntington's disease annually affects 4–7 people per 100,000. Estimates of the incidence of Parkinson's disease vary depending on the populations of individuals studied, with the annual incidence ranging from 7 to 19 affected people per 100,000. More than 100,000 Americans under the age of 18 years have some degree of neurological disability attributable to cerebral palsy.

Table I
Selective Vulnerability of the Human Central Nervous System in Neurodegenerative Conditions

Neurodegenerative disorder	Vulnerable neurons–brain regions
Alzheimer's disease	Neocortex, hippocampus, amygdala, basal forebrain cholinergic neurons, brain stem monoaminergic neurons
Amyotrophic lateral sclerosis	Lower motor neurons (spinal cord and brain stem) and upper motor neurons (motor cortex)
Cerebral ischemia (cardiac arrest and stroke)	Neocortex, hippocampus, striatum, cerebellum
Huntington's disease	Striatum
Multiple sclerosis	White matter
Parkinson's disease	Substantia nigra
Spinal muscular atrophy	Lower motor neurons (spinal cord and brain stem)

No drugs are available yet that can prevent the degeneration of neurons in the brain and spinal cord in people with these neurodegenerative disorders (Table I).

II. ALZHEIMER'S DISEASE IS A PROGRESSIVE NEURODEGENERATIVE DISEASE OF ELDERLY INDIVIDUALS THAT CAUSES SYNAPSE DEFECTS AND DEMENTIA

Alzheimer's disease is the most common cause of dementia occurring in middle and late life. About 70% of all cases of dementia are due to AD. It affects 7–10% of individuals >65 years of age and up to 40% of people >80 years of age. The prevalence of AD is increasing proportionally to increased life expectancy. AD thus will continue to be a major health concern because estimates predict that $\sim 25\%$ of the population will be >65 years of age in the year 2050. AD now affects >4 million people in the United States. Most cases of AD have unknown etiology and are called sporadic; however, some cases of AD, particularly those with early onset, are familial and are inherited as an autosomal dominant disorder linked to mutations in the gene that encodes amyloid precursor protein or in the genes that encode for presenilin proteins (Table II). For late-onset sporadic cases, a variety of risk factors have been identified in addition to age. The apolipoprotein E (apoE) allele is a susceptibility locus with the apoE4 type showing dose-dependent contributions. Cardiovascular disease and head trauma are additional risk factors for AD.

The mechanisms that cause the profound brain atrophy (Fig. 1), neuronal degeneration and progressive impairments in memory and intellect that occur with AD are not understood. Atrophy of the cerebral cortex (i.e., loss of cerebral cortex volume) correlates strongly with cognitive decline. Normal cognition and memory, as well as neuronal survival, depend on synapses (Fig. 2A). Regulated release of neurotransmitter-containing vesicles is necessary for normal synaptic function. Some proteins that control synaptic operation are abnormal in AD (Fig. 2B). These proteins function in the presynaptic terminal by controlling the regulated exocytosis of neurotransmitter packets. Particular proteins are reduced in the hippocampus of individuals with AD who have moderate to severe abnormalities in memory (Figs. 2 and 3). Another important discovery is that the synaptic proteins that control neurotransmitter vesicle translocation and priming at the release site of the presynaptic nerve terminal are more vulnerable than proteins involved in vesicle exocytosis at the cell membrane. It appears that these proteins begin to be lost in individuals in the early stages of AD who do not yet have detectable cognitive impairments, but as the synaptic defects progressively become more severe, individuals manifest more severe memory impairment. Abnormalities in the presynaptic proteins that regulate neurotransmitter release may be an early pathological process in the development of AD (Fig. 2).

A variety of brain lesions occur in people with AD. The major lesions are called neurofibrillary tangles and senile plaques (Fig. 4). These brain lesions are formed abundantly in individuals with AD and patients with Down's syndrome and less frequently in people aging

Table II
Gene Mutations Associated with Some Neurodegenerative Diseases

Neurodegenerative disease	Gene mutation–deletion	Prevalence
Familial amyotrophic lateral sclerosis[a]	Copper–zinc superoxide dismutase	10% of all FALS cases
Familial Alzheimer's disease[b]	Amyloid precursor protein	$<10\%$ of all familial AD cases
Familial Alzheimer's disease	Presenilin-1	$<10\%$ of all familial AD cases
Familial Alzheimer's disease	Presenilin-2	$<10\%$ of all familial AD cases
Huntington's disease	Huntingtin	100% of cases
Parkinson's disease	α-Synuclein	Very rare
Spinal muscular atrophy	Survival motor neuron, neuronal apoptosis inhibitory protein	Majority of cases

[a]ALS occurs as a familial or sporadic disease. Approximately 5–10% of all ALS cases are familial. The majority of cases are sporadic, with no yet identified mutations.
[b]AD occurs as a familial or sporadic disease. Approximately 10% of all AD cases are familial. The majority of AD cases are sporadic.

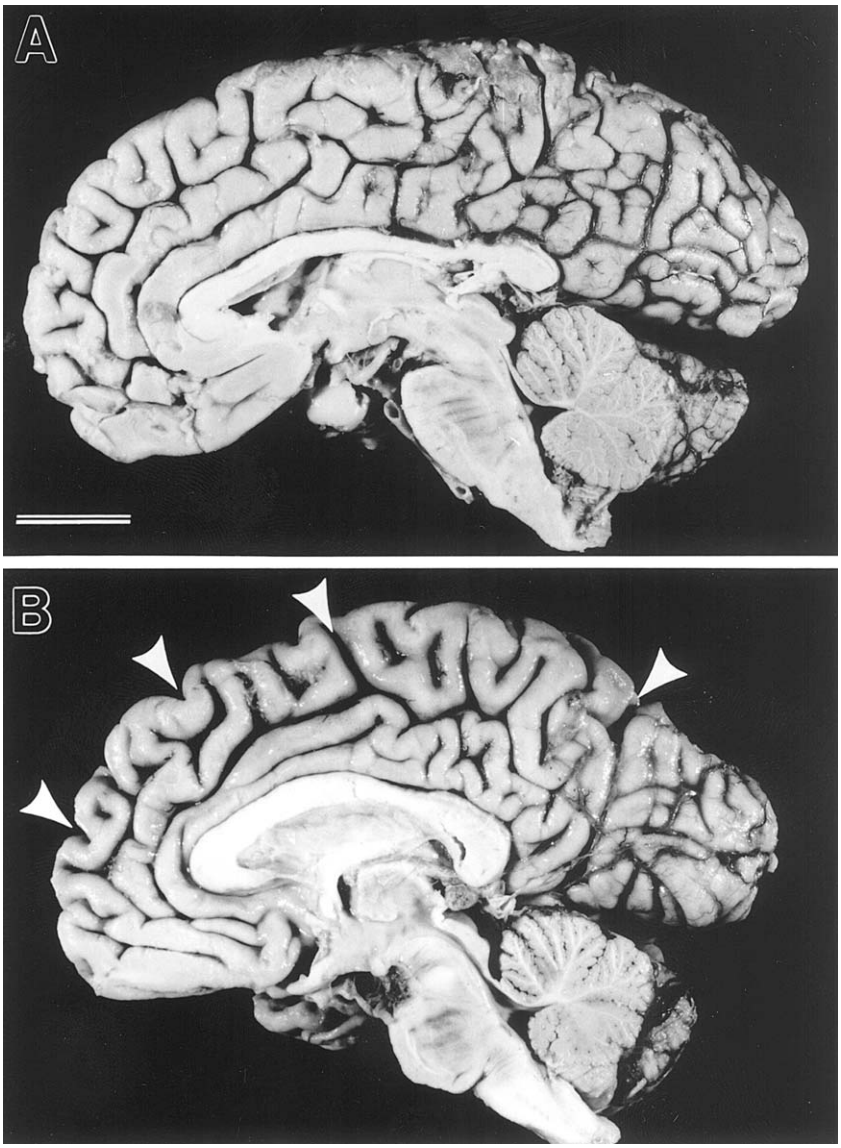

Figure 1 Severe atrophy of the brain occurs in Alzheimer's disease. (A) Midsagittal view of the brain from an 86-year-old normal, individual. The cerebral cortex is normal, with broad gyri and narrow sulci. Scale bar = 23 mm (same for B). (B) Midsagittal view of the brain from an 85-year-old individual with Alzheimer's disease. The cerebral cortex is atrophic, as indicated by widening of the sulci and narrowing of the gyri (white arrowheads).

normally. Pyramidal neurons in the neocortex and hippocampus (Fig. 4A, Table I) are highly vulnerable to the formation of neurofibrillary tangles. Neurofibrillary tangles are abnormal bundles of protein filaments that occur within neurons (Fig. 4B). These tangled masses consist of paired helical filaments containing τ protein (Fig. 4C). Senile plaques are formed throughout the brain parenchyma, and in AD they occur in large numbers (Fig. 4D). The composition of senile plaques is very complex (Figs. 4D and 5), consisting of dystrophic neurites (damaged and swollen dendrites or axon terminals), activated astrocytes and microglia, and extracellular deposits of insoluble amyloid. Amyloid occurs as fibrils composed of a small peptide (Aβ) consisting of 40–42 amino acid residues. This abnormal protein fragment is derived proteolytically from the amyloid precursor protein (APP), a cell surface protein. APP may participate directly in the pathogenesis of AD because mutations have been identified in the APP gene that are linked to early–onset AD in some families (Table II).

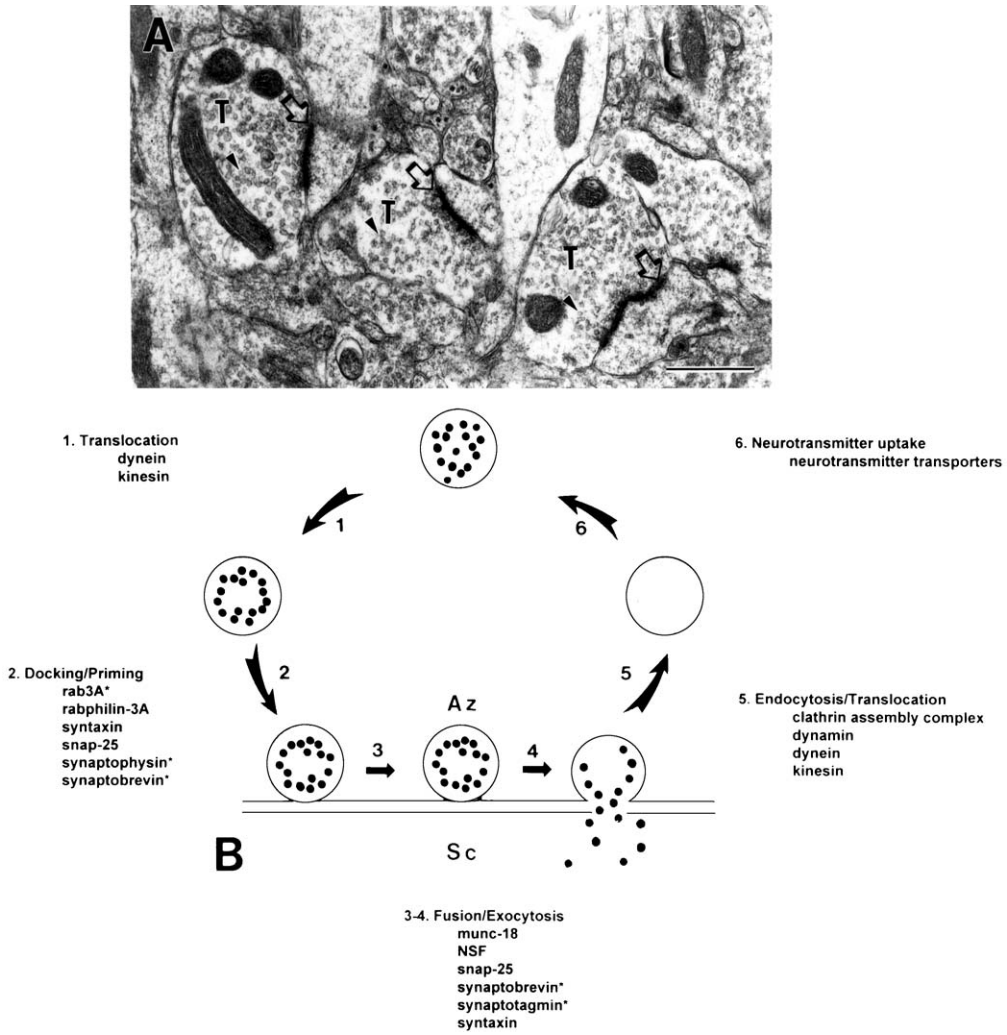

Figure 2 The synaptic vesicle cycle may be abnormal in Alzheimer's disease. (A) Electron micrographs of synapses in the cerebral cortex of a rhesus monkey. Axon terminals (T), containing many small clear synaptic vesicles (arrowheads), from synapses (open arrow) with postsynaptic structures. Synaptic vesicles cluster at the active zone of the presynaptic membrane. The narrow space between the presynaptic and postsynaptic components is the synaptic cleft. Scale bar = 1.0 μm. (B) Diagram of the synaptic vesicle cycle. This cycle functions in the regulated release of neurotransmitter-containing vesicles (filled circles) from the presynaptic terminal. Abbreviations: Az, synaptic active zone; Sc, synaptic cleft. The synaptic vesicle cycle can be divided into six major components, as indicated. Some of the specific proteins that function at each phase of the cycle are indicated. Some of these proteins (indicated by the asterisk) appear to be selectively vulnerable in individuals with Alzheimer's disease.

The functions of APP are still not well-defined, although it appears that APP functions at synapses. APP is an abundant and ubiquitous protein within CNS and other tissues. APP has structural features similar to some cell surface receptors and may be a G-protein-coupled receptor. Secreted and nonsecreted forms of APP exist, with different APP derivatives having neurotrophic or neurotoxic actions. APP is incorporated into the extracellular matrix and, thus, may have roles in cell–cell and cell–substrate adhesion. Furthermore, APP may function in the regulation of neurite outgrowth, perhaps by modulating the effects of neurotrophins and cytokines in the responses of neurons and glia to brain injury.

In cell culture, APP normally undergoes constitutive proteolytic cleavage by an α-secretase. This enzyme cleaves APP within the Aβ region at or near the plasma membrane, thereby generating secreted forms of APP and precluding the formation of full-length Aβ peptide fragments. APP is also metabolized by an endosomal–lysosomal pathway that, unlike the α-secretase pathway, yields amyloidogenic fragments of Aβ that are deposited in senile plaques (Fig. 4D). Aβ can be formed normally *in vivo* and *in vitro*, and studies of

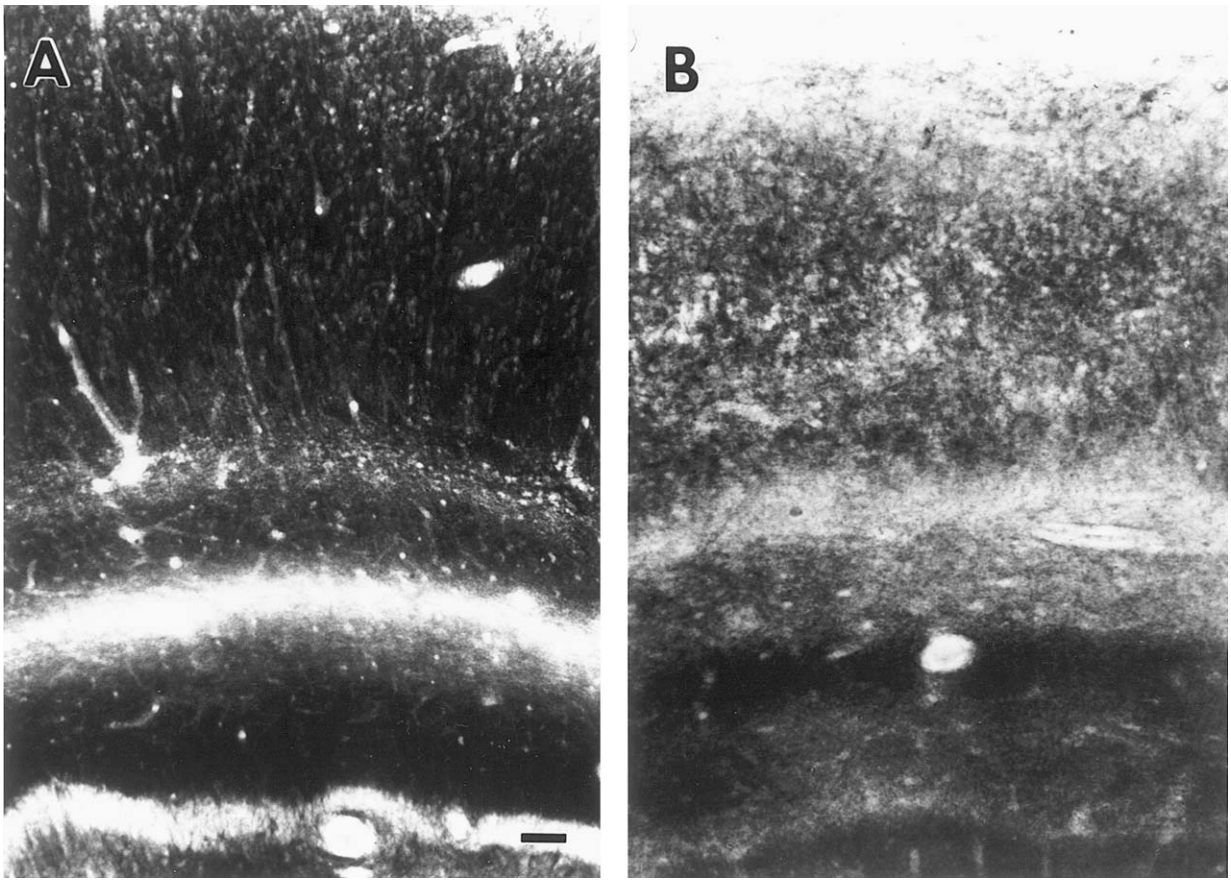

Figure 3 Synapses in the hippocampus of individuals with Alzheimer's disease are abnormal. (A) The hippocampus of normal, aged control humans has very high levels of synapses, as revealed by the synaptic vesicle protein synaptophysin (the intensity of the black staining reflects the amount of synaptophysin immunoreactivity). Scale bar = 42 μm (same for B). (B) The hippocampus of an individual with Alzheimer's disease shows a marked depletion of synaptophysin immunoreactivity (as reflected by the less intense black staining).

cultured human cells and aged non-human primates show that it is generated intracellularly.

Although Aβ has been shown to be neurotoxic in cell culture, a causal role for Aβ in neuronal degeneration within the brain remains speculative. A β-secretase cleaves APP at the N-terminus of Aβ, and a γ-secretase cleaves APP at the C-terminus of Aβ, causing the formation of Aβ that is either 40 or 42 amino acids long. This pathway for APP metabolism is found within the endoplasmic reticulum and Golgi apparatus of neurons. Mutant presenilins (Table II) promote Aβ42 generation. Presenilins, which are present at relatively low levels in the brain, localize to the endoplasmic reticulum and Golgi apparatus. Mutant presenilin is processed differently from normal presenilin, and fragments that are normally subject to endoproteolytic cleavage tend to accumulate. Thus, metabolism of APP through the β- and γ-secretase pathways may be promoted by *presenilin-1* and *presenilin-2* gene mutations linked to early-onset familial AD (Table II).

We and others have shown that APP is present in essentially all neurons and in some astroglia, microglia, and vascular endothelial cells. The most prominent neuronal localization of APP is within cell bodies and dendrites and is particularly enriched postsynaptically at some synapses. The expression of APP in nonneuronal cells in the brain is low in comparison to the dominant expression of APP within neurons and their processes. It appears that astroglia and microglia constitutively express APP at low levels in the resting state. However, the relative enrichment of APP within these neuroglial cells changes in response to brain injury and synaptic abnormalities. This idea is supported by our finding that APP is expressed prominently by activated astroglia and microglia within senile plaques of aged nonhuman primates and by other reports showing that APP is localized to

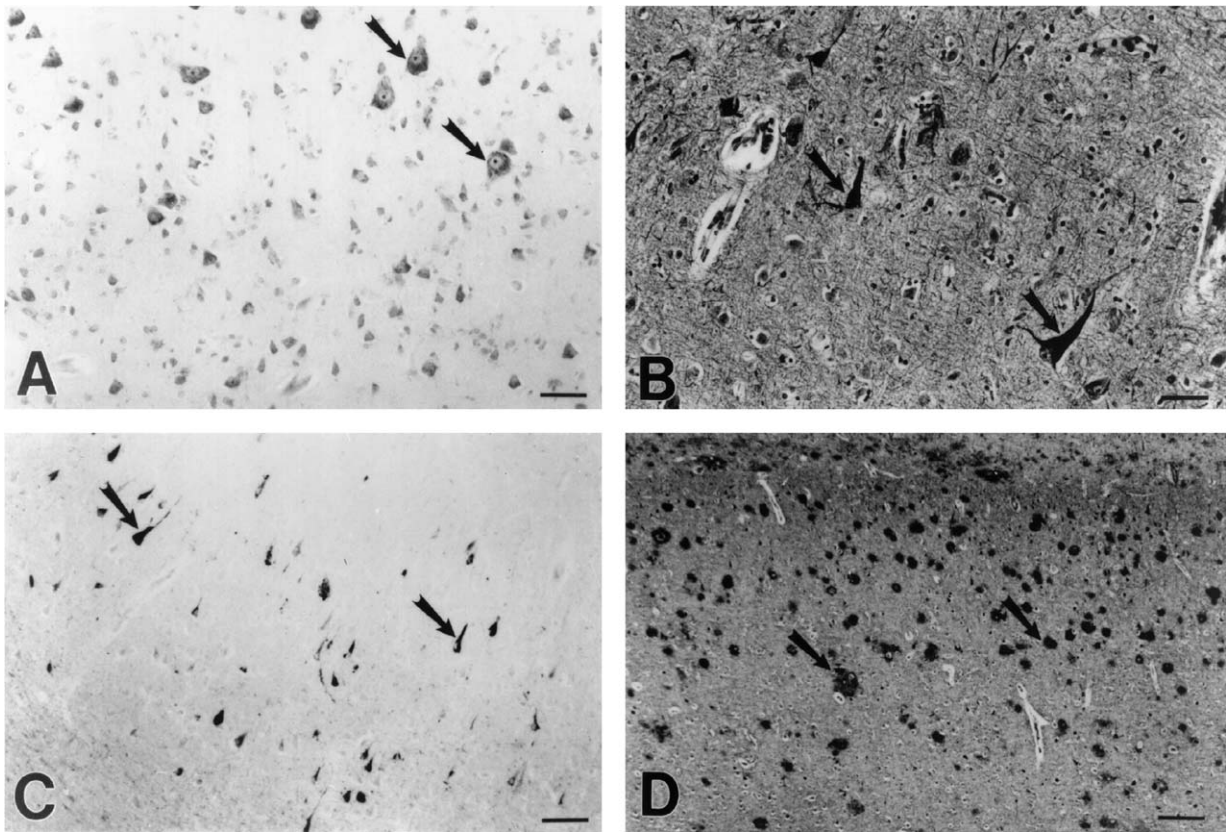

Figure 4 Neurofibrillary tangles and amyloid deposits are brain lesions that are formed in patients with Alzheimer's disease. (A) Pyramidal neurons in the neocortex (arrows) are vulnerable in individuals with Alzheimer's disease. Scale bar = 50 μm. (B) Neurofibrillary tangles, which are abnormal intracellular aggregates of protein (arrows), are formed in pyramidal neurons in patients with Alzheimer's disease. Scale bar = 50 μm. (C) Neurofibrillary tangles are composed of τ proteins (arrows). Scale bar = 100 μm. (D) Individuals with Alzheimer's disease form numerous abnormal extracellular deposits of Aβ amyloid protein in the brain (arrows). Scale bar = 200 μm.

astrocytes in senile plaques in cases of AD. Other studies have shown that some forms of APP are expressed in reactive astrocytes in the early stages of brain damage. Because levels of APP in some neurons and nonneuronal cells are increased by the cytokine interleukin-1, it is likely that the expression of APP is inducible in glia when these cells are activated in response to neuronal injury.

Several theories for the formation of senile plaques and Aβ deposits have been presented. The genesis of senile plaques may begin with the abnormal processing of APP via β-secretase and the formation of extracellular Aβ before the degeneration of cellular elements within these brain lesions. Alternatively, Aβ may be derived from degenerating axonal nerve terminals or dendrites containing APP that evolve into neurite-rich foci that form Aβ at the cell plasma membrane by aberrant processing of APP within neurons. In addition, invading reactive microglia and astroglia as well as capillaries may actively produce Aβ from APP.

We have found that senile plaques are dynamic brain lesions that evolve from early defects in synapses within the neuropil to mature plaques and extracellular deposits of Aβ (Figs. 4D and 5). The staging of these lesions is thought to be the degeneration of neuritic structures, followed by the attraction of reactive glia and the subsequent deposition of extracellular Aβ derived from microglia or astrocytes. Studies demonstrate that structural and biochemical perturbations within neuronal and non-neuronal cells, importantly glia, occur before the deposition of extracellular Aβ fibrils. Furthermore, these results suggest that focal abnormalities in synaptic contacts within the neuropil (synaptic disjunction) may instigate this complex series of events resulting in the formation of diffuse senile plaques and deposits of Aβ (Figs. 4D and 5). In

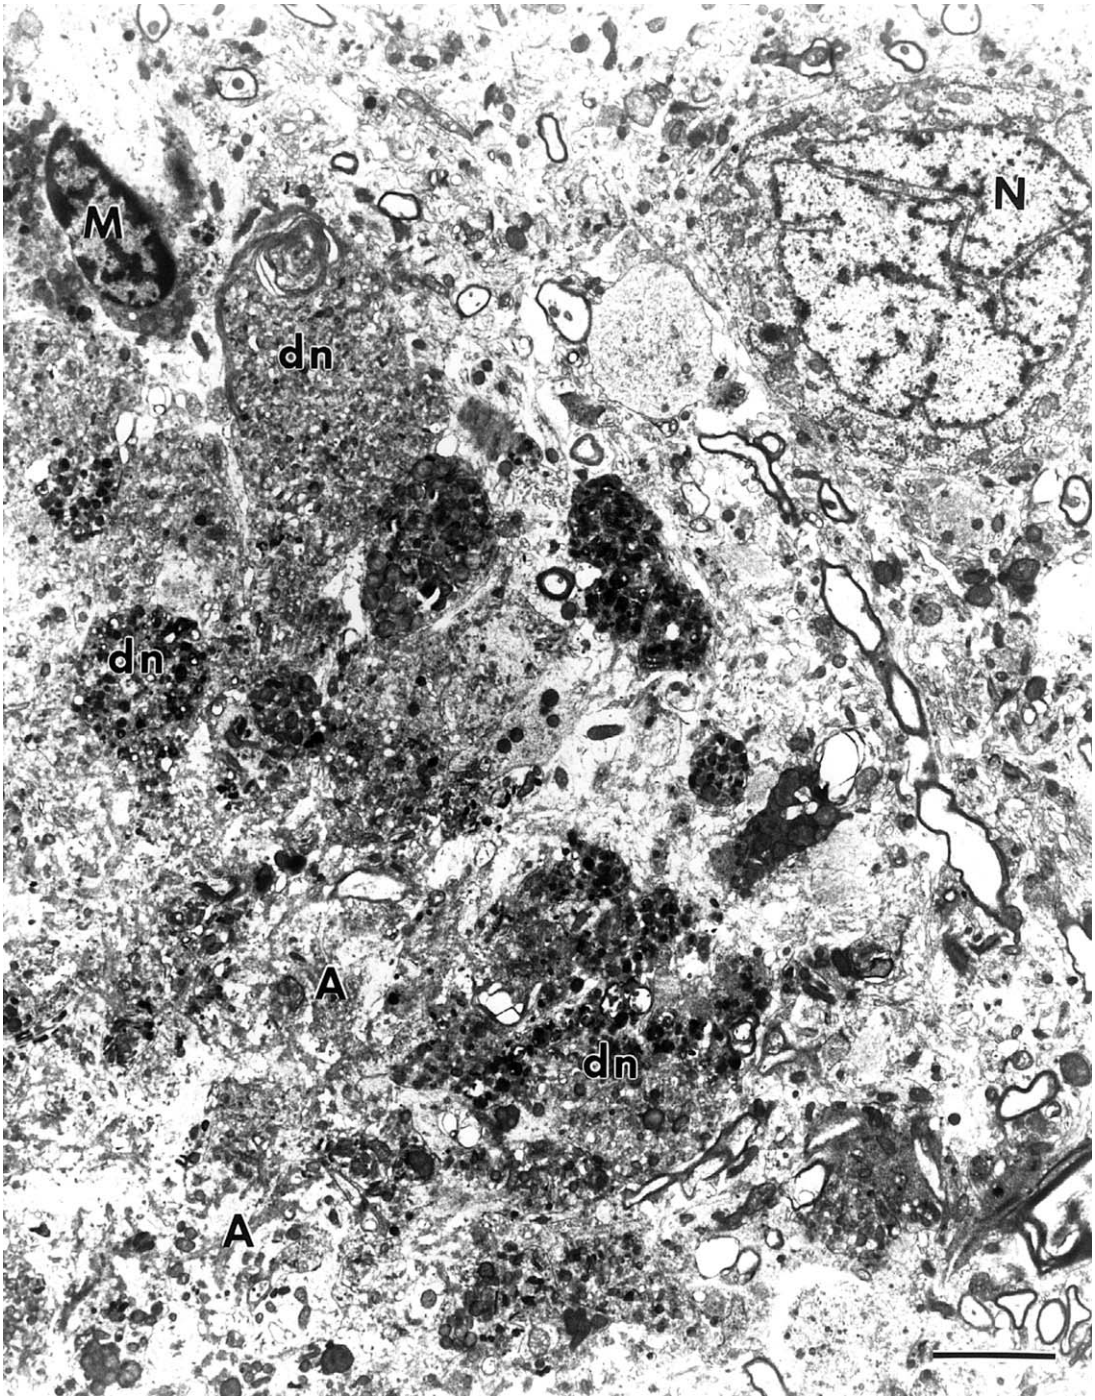

Figure 5 Electron microscopy reveals the complexity of the senile plaques that are formed in the cerebral cortex. Extracellular amyloid (A) is surrounded by numerous dystrophic, swollen neurites (dn), which are filled with abnormal membranous organelles. Microglia (m) infiltrate into the plaques. A nearby neuron (N) appears structurally normal Scale bar = 4 μm.

response to synaptic disjunction in the aged brain, astroglia and microglia produce Aβ. The molecular pathology we and others have identified at the synaptic level in humans with AD (Figs. 2 and 3) may be related to senile plaque lesions and Aβ deposits (Figs. 4D and 5). Defects in the synaptic vesicle cycle (Fig. 2) and synaptic disjunction in the neuropil may lead to abnormal APP processing

within neuroglia and could be early events in the formation of senile plaques and Aβ lesions.

III. ALS IS A DISEASE OF MOTOR NEURONS

ALS is a fatal neurological disease that causes a movement disorder (Table III) characterized by progressive muscle weakness, muscle atrophy, and eventual paralysis. Individuals affected with ALS die within 3–5 years of clinical onset. This disease is neuropathologically characterized by progressive degeneration of the upper and lower motor neurons in the brain and spinal cord (Table I, Fig. 6). The neuropathology of ALS is primary degeneration of the upper (motor cortical) and lower (brain stem and spinal) motor neurons. The amyotrophy refers to the neurogenic atrophy of affected muscle groups, and the lateral sclerosis refers to the hardening of the lateral white matter funiculus in the spinal cord (corresponding to degeneration of the corticospinal tract) found at autopsy. Because the mechanisms for the motor neuron degeneration in ALS are not understood, this disease has no precisely known causes and no effective treatments. Two major forms of ALS exist: idiopathic (sporadic) and heritable (familial). The vast majority of ALS cases are sporadic with no known genetic component. The familial forms of ALS (FALS) are autosomal dominant and make up about 10–20% of all ALS cases. In a subset of familial ALS cases (about 5–10%), missense mutations have been identified in the gene for superoxide dismutase 1 (SOD1), also called copper–zinc superoxide dismutase (Table II).

A variety of theories have been proposed for the possible causes of neurodegeneration in ALS (Table VI). A major center of attention is the mutant forms of SOD1 found in FALS. Because SOD1 is widely expressed in cells throughout the body and in CNS tissue the expression is very ubiquitous, the basis for the selective vulnerability of motor neurons in the presence of SOD1 mutations is still not clear. Initial experiments hinted that mutations in SOD1 could lead to motor neuron degeneration by decreasing enzymatic activity, resulting in neurotoxicity of reactive oxygen species, notably superoxide radicals that are inefficiently scavenged by mutant SOD1. However, it was found that FALS-linked mutations in SOD1 generally do not impair enzymatic activity but instead decrease protein stability. It was then proposed that mutant SOD1 acquires a neurotoxic gain in function. Mutations in SOD1 may convert this enzyme from a protein with antioxidant–antiapoptotic functions to a protein with apoptosis-promoting effects. In addition to the dismutation of superoxide, SOD1 also has peroxidase activity, and this peroxidase activity is enhanced in mutant SOD1 compared to normal SOD1. This gain of function could lead to the enhanced production of reactive oxygen species that could damage motor neurons. In mice with forced expression of mutant forms of the gene encoding for SOD1, motor neuron degeneration does occur. Unfortunately, however, this degeneration in transgenic mice overexpressing mutant forms of SOD1 is neuropathologically different from the degeneration of motor neurons in people with sporadic and familial ALS.

Studies have identified that the degeneration of motor neurons in ALS is a form of apoptotic cell death that appears to occur by a programmed cell death (PCD) mechanism (Fig. 7). PCD is a type of cell death that is triggered by intrinsic cellular pathways involving specific death proteins. This PCD of motor neurons in ALS could be due to a gain in function of the tumor suppressor protein p53. p53 is a DNA-binding phosphoprotein that functions in genome surveillance, DNA repair, and gene transcription. p53 commits to death cells that have sustained DNA damage from genotoxic agents and reactive oxygen species. DNA lesions have been found in individuals with ALS possibly because of free radical damage and defective DNA repair. Thus, p53 may participate in the mechanisms for motor neuron death in ALS in response to DNA damage. The gene expression of some cell death proteins is promoted by p53. For example, the levels of a protein called Bax (see Table IV) are regulated by p53. Bax is critical for neuronal

Table III
Classification of Some Movement Disorders in Humans

Motor neuron diseases	Akinetic disorders	Hyperkinetic disorders	Ataxic disorders
Amyotrophic lateral sclerosis	Parkinson's disease	Huntington's disease	Spinocerebellar degeneration
Spinal muscular atrophy	Progressive supranuclear palsy	Dystonia	Ataxia–telangiectasia

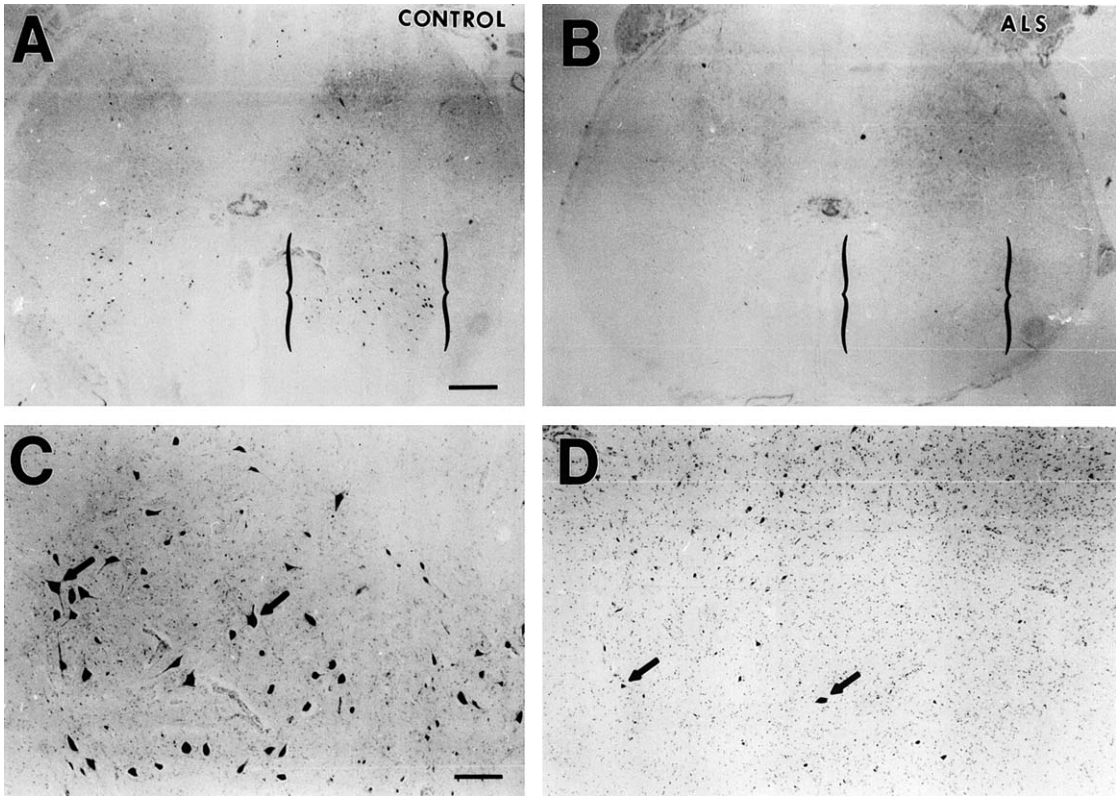

Figure 6 Motor neurons degenerate in patients with ALS. (A) In normal control individuals, the anterior horn of the spinal cord (brackets) is populated with many neurons (black dots within brackets). Scale bar = 0.7 mm (same for B). (B) In ALS, the anterior horn is depleted of neurons (brackets). (C) The anterior horn of the spinal cord in normal subjects is populated with large, multipolar motor neurons (arrows). Scale bar = 200 μm (same for D). (D) In ALS, the anterior horn contains many shrunken neurons (arrows) instead of large multipolar cells.

apoptosis. In ALS, we have found that p53 levels are elevated and that this p53 has competent DNA binding activity; moreover, Bax levels are elevated in individuals with ALS. This information is novel and is conceptually very important for further understanding the pathobiology of motor neuron death in ALS. It suggests that critical molecular mechanisms for regulating human cancer are overactive in vulnerable CNS regions in a human-age-related neurodegenerative disease. This theory may advance the

Table IV
Leading Theories on the Possible Causes of Motor Neuron Degeneration in ALS

Mechanism	Comment
SOD1 mutation	Found in some FALS cases. Resulting in a toxic gain in function or modified stability of SOD1.
Excitotoxicity	Resulting from abnormal glutamate receptor activation and defects in glutamate transport.
Neurotrophin withdrawal	Resulting from insufficient muscle cell- or glial-cell-derived trophic support or defective neurotrophin receptor signaling.
DNA damage–repair defects	Resulting from oxidative stress or inefficient DNA repair enzyme function. May involve both mitochondrial and nuclear DNA damage.
Autoimmunity	Resulting from autoantibodies to motor neuron antigens.
Aberrantly occurring programmed cell death	May be triggered by all of the precedings mechanisms.

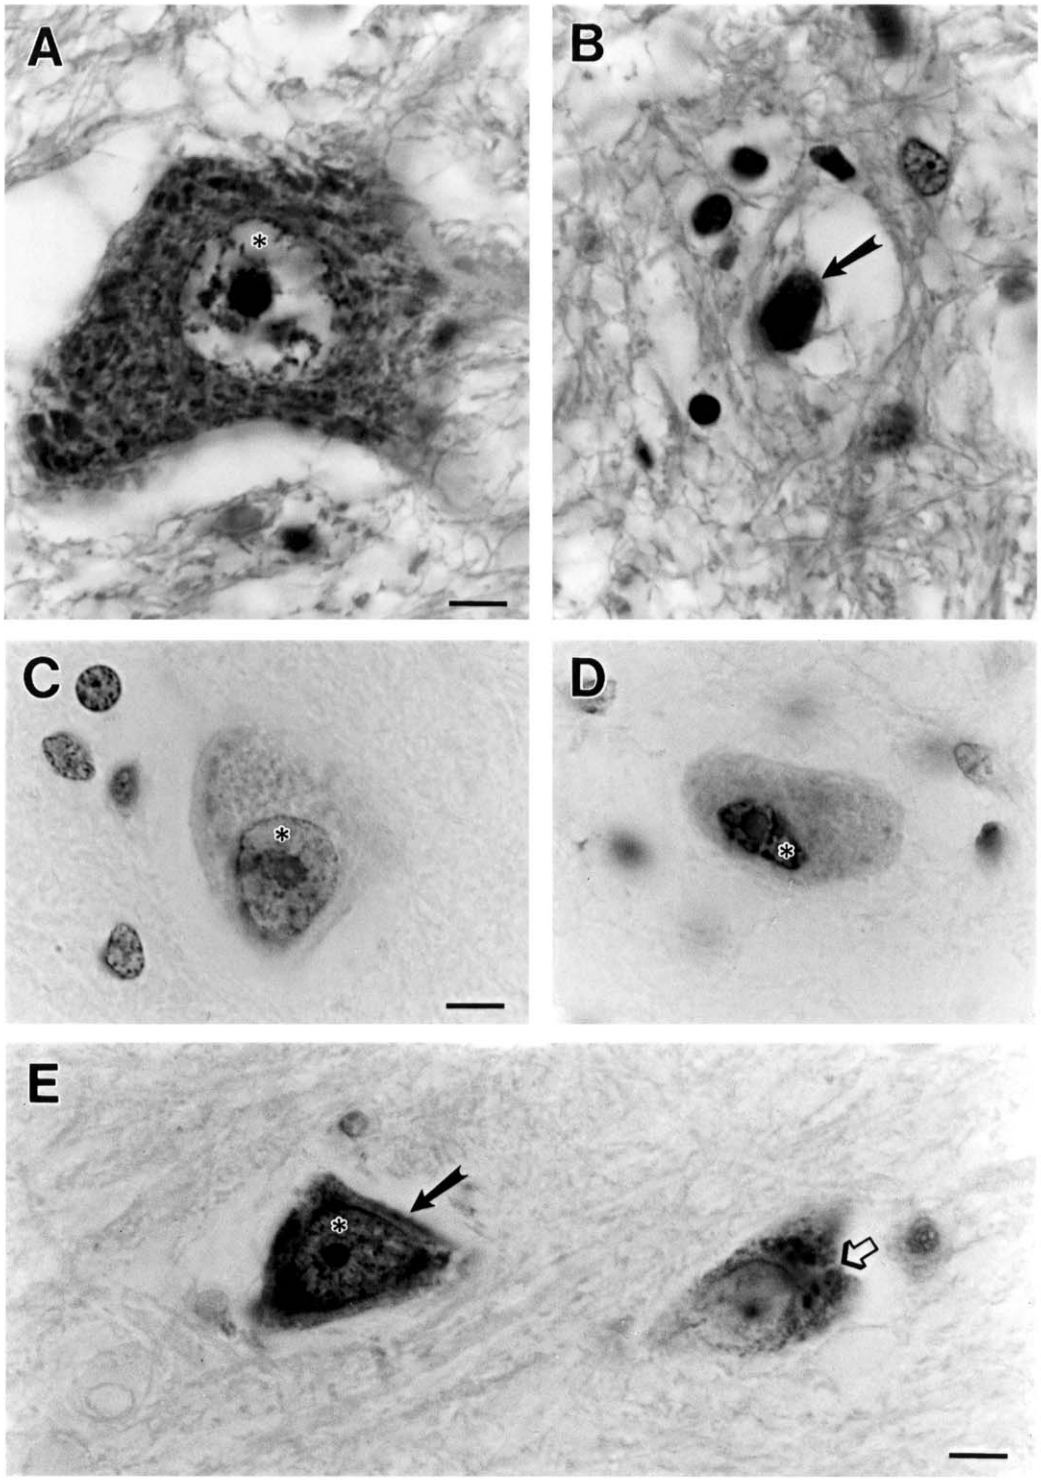

Figure 7 Motor neuron degeneration in ALS is a form of apoptosis that may be mediated by a p53-dependent mechanism. (A) Normal appearing spinal motor neuron with a large, multipolar cell body and a large nucleus (asterisk) containing a reticular network of chromatin and a large nucleolus. Scale bar = 7 μm (same for B). (B) Near end stage apoptotic motor neuron in ALS (arrow). The cell has shrunken to about 10% of normal size and has become highly condensed. (C and D) Nuclear DNA fragmentation (asterisk) occurs in motor neurons in patients with ALS as the nucleus condenses (asterisks) and the cell shrinks. Scale bar = 7 μm. (E) In individuals with ALS, p53 accumulates in the nuclei (asterisk) of motor neurons (arrow). The nearby neuron (open arrow) has an unlabeled nucleus for comparison. Scale bar = 10 μm. (See color insert in Volume 1).

understanding of motor neuron degeneration in ALS and perhaps other age-related neurodegenerative disorders in which chronic and progressive DNA damage may occur.

IV. NEURODEGENERATIVE DISEASES OF THE BASAL GANGLIA CAUSE MOVEMENT DISORDERS

The basal ganglia are subcortical brain structures that function in sensory–motor integration and in the planning and initiation of skeletal muscle movements. The striatum (caudate nucleus and putamen), globus pallidus (external and internal divisions), substantia nigra (pars compacta and reticulata), and subthalamic nucleus are the major components of the basal ganglia (Fig. 8). The basal ganglia do not control movement through direct connections with lower motor neurons, but rather the functions of the basal ganglia are executed by the frontal cortex through corticobulbar and corticospinal projections to brain stem and spinal motor neurons, respectively. The operation of the basal ganglia involves forebrain–diencephalon–midbrain circuitry loops. The different circuits within the basal ganglia utilize different neurotransmitters (Table V). The primary input to the basal ganglia originates from the neocortex and is directed to the striatum (Fig. 8). This corticostriatal projection uses the excitatory neurotransmitter glutamate. The primary output center of the basal ganglia is the globus pallidus, which conveys signals to back to the neocortex through the thalamus (Fig. 8). The pallidothalamic projection is inhibitory; in contrast, the thalamocortical projection is excitatory (Table V). Thus, the globus pallidus functions to inhibit the excitatory thalamic drive of neocortex. Somatic movements occur when thalamic neurons are released from tonic inhibition. This release occurs when corticostriatal projections excite striatal neurons that can phasically inhibit the neurons in the

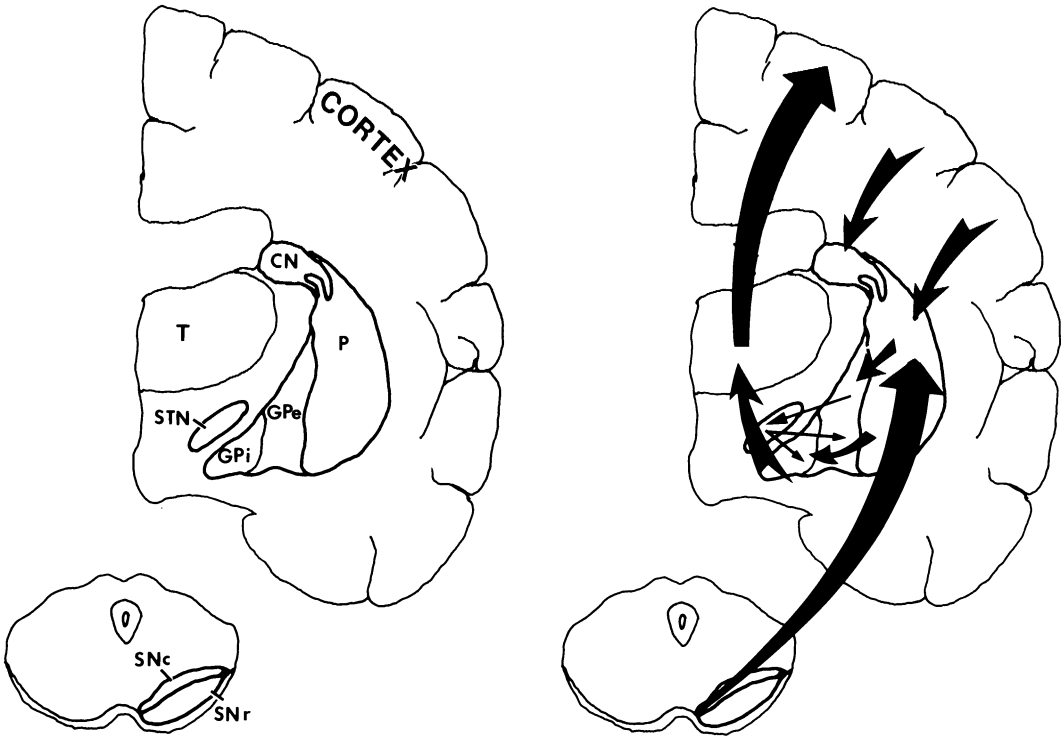

Figure 8 Basal ganglia circuits control movements. The basal ganglia comprise (left panel) the caudate nucleus (CN), putamen (P), globus pallidus external (GPe) and internal (GPi) divisions, the subthalamic nucleus (STN), and the substantia nigra compact (SNc) and reticular (SNr) divisions. The cerebral cortex and thalamus (T), although not part of the basal ganglia, participate in the connectivity loops (right panel). See Table V for connections. The major excitatory input to the striatum (the caudate nucleus and putamen) is from the cerebral cortex (right panel). The striatum in turn projects to the globus pallidus and the substantia nigra reticular division. Striatal activity is modulated by extensive dopaminergic input from the substantia nigra compacta. The major output of the basal ganglia is directed toward the thalamus, originating from GPi and SNr (not shown). The thalamic projection to the cerebral cortex (premotor and supplementary motor areas) drives the activity of the motor cortex, which executes somatic movements.

Table V
Primary Connections of the Basal Ganglia and Their Major Neurotransmitters[a]

Projection	Neurotransmitter
Neocortex to striatum (corticostriatal)	glutamate
Striatum to globus pallidus (striatopallidal)	GABA[b]–neuropeptides[c]
Globus pallidus externa to subthalamic nucleus (pallidosubthalamic)	GABA
Subthalamic nucleus to globus pallidus externa–interna (subthalamopallidal)	Glutamate
Subthalamic nucleus to substantia nigra reticulata (subthalamonigral)	Glutamate
Substantia nigra compacta to striatum (nigrostriatal)	Dopamine
Substantia nigra reticulata to thalamus (nigrothalamic)	GABA
Globus pallidus interna to thalamus (pallidothalamic)	GABA

globus pallidus that inhibit thalamic neurons. The resulting activation of thalamocortical projections excites the premotor and supplementary motor areas of frontal neocortex that activate the motor cortex, thereby facilitating movement.

There are two major circuits within the basal ganglia, designated as the direct and the indirect pathways. These two pathways counterbalance each another. The direct pathway is the striatal projection to the globus pallidus (internal segment) and the substantia nigra reticulata, which in turn project to the thalamus (Fig. 8). Activation of the direct pathway results in the activation of thalamocortical projections and the facilitation of movement. The substantia nigra dopaminergic neurons activate striatal neurons of the direct pathway, thus functioning to facilitate movement. The indirect pathway, in contrast, involves a loop with the subthalamic nucleus (Fig. 8), which changes the physiological outcome in the thalamus. In the indirect pathway, the striatum inhibits the globus pallidus (external segment), which functions to inhibit the subthalamic nucleus. The subthalamic nucleus projects back to the globus pallidus (both segments) and to the substantia nigra reticulata to activate these regions; the internal segment of the globus pallidus and the substantia nigra reticulata then inhibit the thalamus. Thus, activation of the indirect pathway decreases movement. The substantia nigra dopaminergic neurons inhibit striatal neurons of the indirect direct pathway, thus opposing the activation of the indirect pathway and functioning to facilitate movement.

Diseases of the basal ganglia can cause involuntary movements, lack of movement, or slowness of movement (Table III). In Parkinson's disease, degeneration of the dopaminergic neurons in the substantia nigra results in the loss of dopamine in the striatum. Parkinson's disease causes involuntary movements (tremors), lack of movement (akinesia), and slowness of movement (bradykinesia). Some of the neurological features of Parkinson's disease are thought to arise from the loss of dopamine inhibition of striatal neurons in the indirect pathway (Fig. 8), resulting in increased inhibition of the globus pallidus external segment and greater excitatory drive of the subthalamic nucleus on the globus pallidus interna and substantia nigra reticulata. Moreover, the loss of dopamine results in decreased activity of striatal neurons in the direct pathway, leading to increased pallidothalamic inhibition. In Huntington's disease, degeneration of subsets of the principal neurons in the striatum may lead to decreased activity of the globus pallidus internal segment via the indirect pathway (Fig. 8). This failure to suppress thalamocortical activity is thought to cause slow writhing movements of the extremities (athetosis) and abrupt movements of the limbs and facial muscles (chorea).

V. NEURONAL DEATH OCCURS IN DIFFERENT FORMS

Neurons can die in different ways (Fig. 9). The death of cells has been classified generally as two distinct types: apoptosis and necrosis. These two forms of cellular degeneration are classified differently because they are believed to differ structurally and biochemically. Apoptosis is generally regarded as physiological cell death and is considered to be an organized PCD that is mediated by active, intrinsic mechanisms through which certain molecular pathways are activated to initiate apoptosis (Table VI). In contrast, necrosis is cell death resulting from a failure to sustain homeostasis due to extrinsic insults to the cell (e.g., osmotic, thermal, toxic, traumatic). The process of cellular necrosis involves damage to the structural and functional integrity of the cell plasma membrane, a rapid influx of ions and H_2O, and, subsequently, dissolution

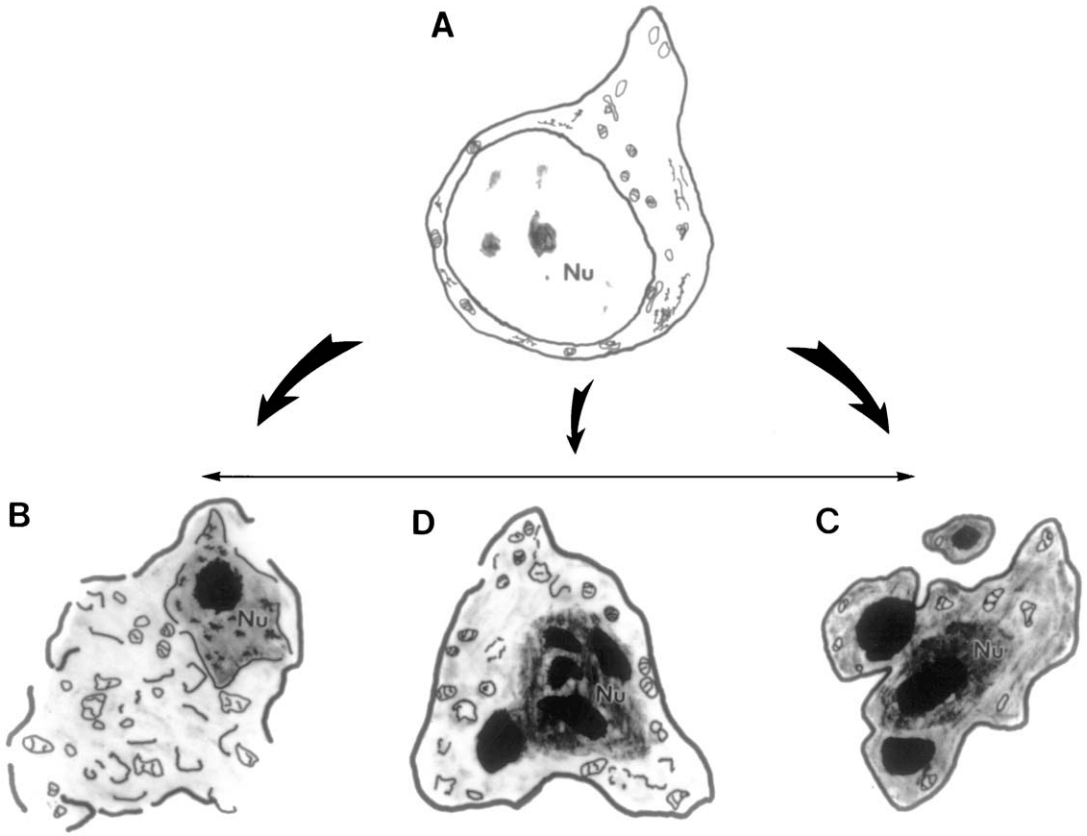

Figure 9 Neuronal cell death occurs as an apoptosis–necrosis continuum. According to the traditional binary scheme for cell death, a neuron (A) can die by either necrosis (B) or apoptosis (C). These forms of cell death were thought to be structurally distinct (representative images of cells are shown) and mutually exclusive. With cellular necrosis (B), which occurs as groups of cells, massive damage to organelles and the plasma membrane occurs with the release of cellular constituents. The nucleus (Nu) undergoes fragmentation, with the condensation of nuclear material being irregular and distinct from that occurring in apoptosis. In necrotic neurons the nucleolus can remain intact. In contrast, apoptosis (C) is an organized form of cell death that occurs generally as isolated cells within groups of cells. The nucleus containing the DNA is packaged into uniformly condensed masses (shown by the round or elliptical black structures), and the surrounding cytoplasm becomes shrunken and condensed (shown by the gray) with the organelles generally preserved until end stage apoptosis. Small fragments of cell cytoplasm surrounding packaged chromatin bud from the dying cell and are engulfed by glial cells. The concept of the apoptosis–necrosis continuum is based on the observation that neurons can die with a structure that is a hybrid of apoptosis and necrosis (D). The nuclear (Nu) and cytoplasmic changes are intermediate between those occurring in apoptosis and necrosis. The packaging of the chromatin occurs as large irregular masses in the nucleus. In the cytoplasm, some mitochondria remain intact whereas others are swollen.

of the cell. Thus, cellular necrosis is induced not by an intrinsic program within the cell per se (as in PCD) but by abrupt or slow homeostatic perturbations and departures from physiological conditions. It has been realized that an abnormal activation of PCD in brain and spinal cord neurons may also play a role in the disease process in humans with neurodegenerative disorders; therefore, deciphering of the contributions of the different types of cell death in degenerative diseases of the human CNS could help to develop treatments for these diseases. These treatments could possibly be drugs that inhibit the actions of key enzymes, ion channels in cell membranes, or numerous other proteins, as well as drugs (e.g., antioxidants) that block or inactivate the production of toxic chemicals (e.g., free oxygen radicals) that are generated during the process of neuronal death.

VI. PROGRAMMED CELL DEATH OCCURS NORMALLY DURING NERVOUS SYSTEM DEVELOPMENT

Naturally occurring apoptotic degeneration of neurons occurs normally in the developing nervous system (Fig. 10). Animals are born with excess numbers of

neurons. The elimination of these supernumerary neurons in the developing nervous system occurs by normal programmed neurodegeneration at specific times. This normal neurodegeneration is thought to be important for matching the size of neuronal groups to the size of their targets (other groups of neurons to which they are connected by axons and nerve terminal synapses) as well as to their own synaptic inputs from other regions. This developmental neuronal death (particularly of spinal and sympathetic ganglion neurons and motor neurons) is thought to be partially controlled by the supply of sustaining neurotrophic factors that are synthesized by the target axon-associated glial cells or by the input regions. Thus, an insufficient supply of neurotrophic molecules triggers an apoptotic process within interconnected groups of neurons by PCD.

Apoptosis is regulated by specific molecules within cells (Table VI). Several genes that regulate apoptosis were originally identified in a nematode worm. Homologous genes have been identified in mammalian cells. The molecular mechanisms for apoptosis involve the participation of at least three groups of proteins that are made from three different gene families. One set of proteins is the caspase family of cysteine-containing, aspartate-specific proteases (14 members have been identified to date). A second group includes the death-promoting and death-suppressing proteins in the *Bcl-2* family (e.g., *Bcl-2*, *Bcl-x_L*, *Bax*, *Bak*, *Bad*, *Boo*). A third group of proteins is designated as the inhibitor of apoptosis protein (IAP) family.

Caspases exist as dormant proenzymes in healthy cells and are activated through regulated proteolysis. These proteins function in the execution phase of apoptosis with "initiator" caspases activating "effector" caspases, which subsequently cleave a variety of proteins, thereby causing the molecular and structural changes of apoptosis. Once activated, caspases act on nuclear proteins, cytoskeletal proteins, or cytosolic proteins. Two different caspase cascades mediate PCD. One pathway involves the regulated release of cytochrome c from mitochondria that promotes the activation of caspase-9 through Apaf-1 and then caspase-3 activation. Another pathway is initiated by the activation of cell-surface death receptors, including Fas and tumor necrosis factor receptor, leading to caspase-8 activation, which in turn cleaves and activates downstream caspases such as caspase-3, -6, and -7.

Apoptosis regulation by the *bcl-2* protooncogene family is a very complex and exciting process (Table VI). Of these genes, *bcl-2* and *bcl-x_L* are antiapoptotic (death-suppressing), whereas *bax*, *bcl-x_S*, *bad*, *bak*, and *bik* are proapoptotic (death-promoting). Membership into the family of Bcl-2-related proteins is defined by homology domains within their amino acid sequences. These domains function in the interactions (i.e., binding) between members. Bcl-2 family members exist as monomers (single proteins) that form homodimers (two of the same proteins bound together), heterodimers (two different proteins bound together), and higher order multimers (more than two interacting proteins). For example, Bax forms homodimers or forms heterodimers with either Bcl-2 or Bcl-x_L. When Bax is present in excess, it antagonizes the antiapoptotic activity of Bcl-2. The formation of Bax homodimers promotes apoptosis, whereas Bax heterodimerization with either Bcl-2 or Bcl-x_L blocks apoptosis. Thus, the complex steady-state array of protein–protein interactions among members of the

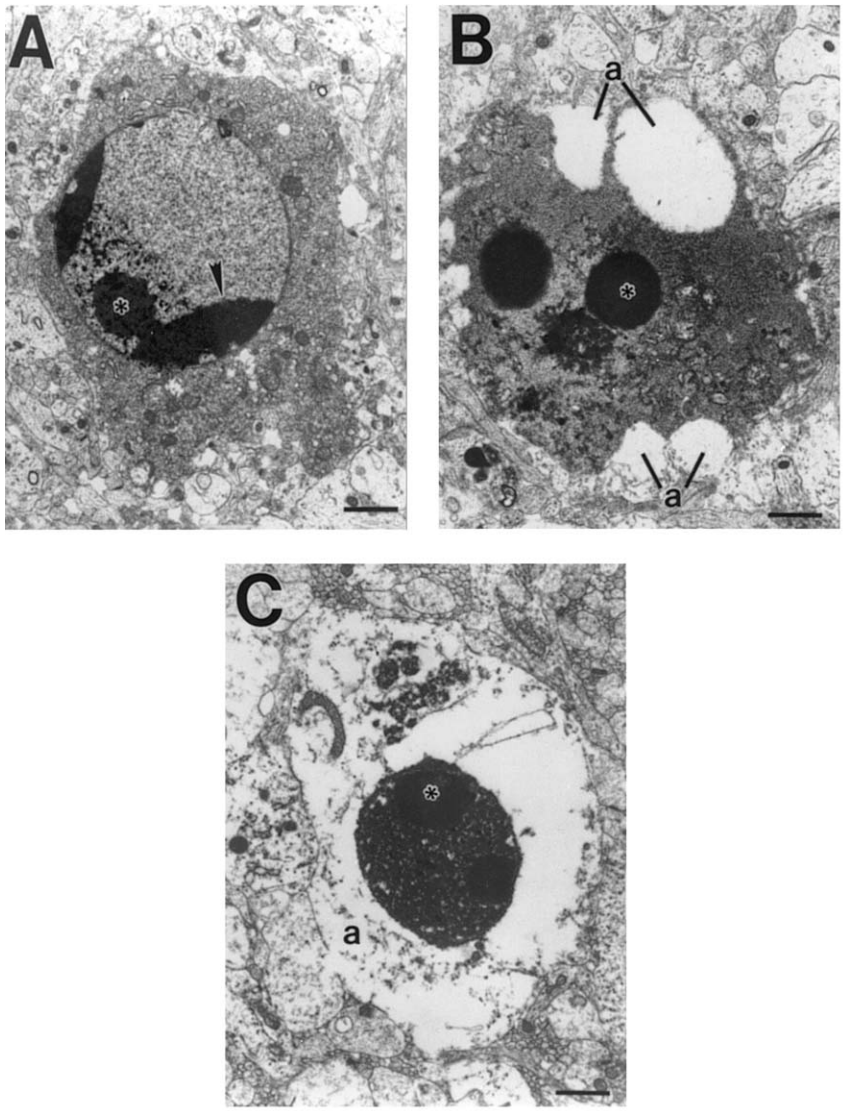

Figure 10 Neurodegeneration in the form of apoptosis is important for the normal development of the nervous system. By electron microscopy this naturally occurring programmed cell death has very characteristic features. (A) In the developing rat striatum, degenerating neurons in the early stages of apoptosis are characterized by chromatin condensation into crescentic caps (arrowhead) abutting the nuclear envelope and into round aggregates (asterisk). The surrounding cytoplasm condenses (as indicated by the uniformly dark staining), although most of the mitochondria remain intact. Scale bar = 2.5 μm. (B) As apoptosis progresses, major changes occur in the nucleus and cytoplasm. The chromatin packaging into dense round clumps (asterisk) becomes more advanced, and the integrity of the nuclear envelope is lost. The cytoplasm becomes more condensed and the mitochondria become damaged. Astrocytic processes (a) begin to surround the degenerating cell. Scale bar = 3.0 μm. (C) At end stage apoptosis, fragments of cells consist of round packages of chromatin (asterisk) surrounded by condensed cytoplasm. These apoptotic fragments are engulfed by astrocytic processes (a). Scale bar = 4.0 μm.

Bcl-2 family functions in dictating whether a cell lives or dies by apoptosis.

Cell death is also regulated by the IAP (inhibitor of apoptosis protein) family (Table VI). This family includes X-chromosome-linked IAP, IAP1, IAP2, and NAIP (neuronal apoptosis inhibitory protein). Survival motor neuron is another apoptosis inhibitory protein. The primary mechanism identified by which IAPs suppress apoptosis is the prevention of proteolytic processing of specific caspases. It appears that procaspase-9 is the major target of IAPs. However, IAPs do not prevent caspase-8-induced proteolytic activation of procaspase-3. IAPs can also block apoptosis by reciprocal interactions with the nuclear

transcription factor NFκB. NAIP is abnormal in infants and children with spinal muscular atrophy (Table II).

The regulation of PCD in the mammalian nervous system by caspases and *bcl-2* family members has been substantiated by using transgenic mouse technology and neuronal culture systems. In mice, deficiencies in the genes for caspase-3 and caspase-9 result in perinatal death and cerebral malformations, possibly caused by reduced PCD during brain development. Inhibition of caspase-1 and caspase-2 blocks the apoptosis of cultured dorsal root and sympathetic ganglion neurons when deprived of the neurotrophin nerve growth factor; furthermore, inhibition of caspase-1 arrests the PCD of motor neurons in cell culture resulting from neurotrophic factor deprivation and in the nervous system during the period of naturally occurring cell death. Mice that overexpress the *bcl-2* gene or have the *bax* gene eliminated fail to exhibit normal PCD of neurons in some nervous system regions, whereas *bcl-2*-deficient mice show progressive neurodegeneration after the period of PCD.

VII. GLUTAMATE RECEPTOR EXCITOTOXICITY KILLS NEURONS

Neurons communicate by neurotransmission at synapses (Fig. 2A). In the CNS, the amino acid glutamate is the major excitatory neurotransmitter that is packaged into small clear synaptic vesicles (Fig. 2A). Glutamate is released from nerve terminals into the synaptic cleft by regulated exocytosis of synaptic vesicles (Fig. 2B). Concentrations of glutamate at the synaptic cleft have been estimated to be approximately 1 m*M*, whereas the concentration of interstitial glutamate is about 1 μM. Glutamate can bind and activate several types of glutamate receptors (GluRs) on neurons (Table VII). These GluRs are classified broadly as either ion channel or metabotropic G-protein-coupled receptors. These classes of GluRs have distinct molecular compositions and distinct signal transduction mechanisms.

The ion channel GluRs are the *N*-methyl-D-aspartate (NMDA) receptors and the non-NMDA receptors. The non-NMDA GluRs are further divided into the α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA) and kainate (KA) receptors (Table VII). The ion channel GluRs all form monovalent cation (Na^+, K^+) conducting channels, but they have differences in their permeabilities to divalent cations (Ca^{2+}). The activation of ion channel GluRs directly changes the conductance of specific ions through the receptor–ion channel complex, thereby inducing membrane depolarization. Fast, short-lived (1–10 msec) excitatory postsynaptic currents in most neurons in the CNS are mediated by these receptors. These receptors are oligomers, most likely pentameric heterooligomers, of homologous subunits encoded by distinct genes. The NMDA receptor subunits are NR1, NR2A–NR2D, and NR3, the AMPA receptor subunits are GluR1–GluR4 (or GluRA–GluRD), and the kainate receptor subunits are GluR5–GluR7 and KA1–KA2.

The metabotropic GluRs (mGluRs) are G-protein-coupled receptors that are single proteins encoded by

Table VII
Molecular Classification of Glutamate Receptors

Ion channel (ionotropic) receptors			G protein-coupled (metabotropic) receptors		
NMDA	Non-NMDA		Group I	Group II	Group III
	AMPA	Kainate			
	Receptor subunits				
NR1	GluR1	GluR5	mGluR1	mGluR2	mGluR4
NR2A	GluR2	GluR6	mGluR5	mGluR3	mGluR6
NR2B	GluR3	GluR7			mGluR7
NR2C	GluR4	KA1			mGluR8
NR2D		KA2			
NR3					

single genes. The mGluRs do not form ion channels but are instead linked to signal transduction molecules within the plasma membrane. mGluRs have slower electrophysiological characteristics (latencies >100 msec) than ion channel GluRs. Group I mGluRs (mGluR1 and mGluR5) operate through activation of phospholipase C (PLC) by G_q proteins, phosphoinositide hydrolysis and generation of inositol 1,4,5-triphosphate and diacylglycerol, and subsequent mobilization of Ca^{2+} from nonmitochondrial intracellular stores. Group II mGluRs (mGluR2 and 3) and group III mGluRs (mGluR4 and 6–8) function by G_I- or G_o-protein-mediated inhibition of adenylyl cyclase and modulation of ion channel activity.

Although glutamate and GluR activation are critical for normal nervous system function, glutamate is toxic to neurons at abnormally high concentrations if the GluRs on neurons are excessively activated. This process is called excitotoxicity. The excessive stimulation of GluRs by glutamate or chemical analogs of glutamate produces abnormalities in intracellular ions, pH, protein phosphorylation, energy levels, and reactive oxygen species. Acute excitotoxicity causes degeneration in neuronal cultures of animal brain and spinal cord and after intracerebral delivery of GluR activators into the CNS of experimental animals. In addition, excitotoxicity participates in the mechanisms for neuronal degeneration in animal models of cerebral ischemia, as well as brain and spinal cord trauma, and in the neurotoxicity in humans resulting from consumption of mussels contaminated with the KA receptor activator domoic acid. Excitotoxicity is also suspected as a culprit in the nerve cell loss associated with AD, ALS, Huntington's disease, and Parkinson's disease.

The precise mechanisms for GluR-mediated excitotoxic degeneration of neurons are not understood. Both neuronal culture and animal model data are discordant with regard to whether excitotoxic neuronal death is apoptosis or necrosis. Activation of neuronal GluRs kills neurons by pathways that may involve alterations in cytosolic free Ca^{2+} homeostasis and activation of Ca^{2+}-sensitive proteases, protein kinases, endonucleases, lipases, and phospholipases. Excitotoxicity results in an activation of endonucleases (DNA-cleaving enzymes) and internucleosomal digestion of genomic DNA into 180–200 base pair fragments 12–48 hr after intracerebral injections of excitotoxins in rats. Internucleosomal fragmentation of DNA also occurs in cultures of cortical neurons, although others have not found internucleosomal DNA fragmentation in cell culture.

The structural changes that occur in neurons in the adult rat brain after an excitotoxic insult include swelling and vacuolation of the cell body and dendrites, fragmentation of the nucleus into irregular clumps of chromatin, and damage to membranous organelles including the Golgi apparatus, endoplasmic reticulum, and mitochondria. This damage is thought to be typical of cellular necrosis (Fig. 9). However, in the immature brain, excitotoxicity can cause neuronal death very similar to apoptosis.

VIII. NEURONAL DEGENERATION CAN OCCUR AS AN APOPTOSIS–NECROSIS CONTINUUM

We have developed the concept that neuronal degeneration is influenced by brain maturity and GluR subtype. We tested the hypothesis that GluR-mediated excitotoxicity in the brain induces neuronal death with characteristics that vary depending on the maturity of the brain at the time of the insult and the GluR subtype that is activated. In the newborn rat brain, excitotoxic activation of NMDA and non-NMDA GluRs (Table VII) causes neuronal death with phenotypes ranging from apoptosis to necrosis (Fig. 9). Three structurally different forms of dying neurons were identified initially: a classic apoptotic form, a vacuolated form, and a classic necrotic form. When the progression of excitotoxin-induced neuronal death in the newborn brain was evaluated, it was found that the vacuolated form is a precursor stage of apoptosis, which has many similarities to the PCD that occurs naturally in the developing brain. Thus, some neurons die as a hybrid of apoptosis and necrosis. In contrast, when the adult rat brain is exposed to excitotoxins, the degeneration of neurons caused by NMDA receptor activation is morphologically necrotic; however, the neuronal death produced by non-NMDA receptor activation (Table VII) is distinct from that caused by NMDA receptor stimulation. Non-NMDA receptor-mediated neuronal death in the adult brain has some cytoplasmic and nuclear features reminiscent of neuronal apoptosis in the excitotoxically injured newborn brain, although non-NMDA receptor excitotoxic neurodegeneration in the adult brain and naturally occurring apoptosis in the developing brain are very different structurally. Surprisingly, both NMDA and non-NMDA receptor-mediated excitotoxic neurodegeneration occur in the presence of apoptotic-like internucleosomal DNA fragmentation.

Our experiments using this animal model of excitotoxic degeneration of neurons led to the novel concept of an apoptosis–necrosis continuum for neuronal death in the CNS. We concluded that the excitotoxic death of neurons does not have to be strictly apoptotic or necrotic, according to a traditional binary classification of cell death (Fig. 9), but it can also occur as intermediate or hybrid forms of cell death with coexisting characteristics that lie along a structural continuum with apoptosis and necrosis at the extremes. This continuum is influenced by the subtype of GluR that is activated (Table VII); hence, excitotoxic neuronal death may not be identical in every neuron, possibly because of the high diversity in the expression, localization, and function of GluR subtypes and second messenger systems in the CNS. We also concluded that the structure of neuronal death is influenced by CNS maturity, because excitotoxic degeneration of adult neurons does not occur with apoptotic structural features that closely resemble those seen during naturally occurring cell death in the developing nervous system.

This new concept may be important for understanding how neuronal degeneration occurs in neurological disorders that affect the human brain and spinal cord (Table I) and, thus, may be important for future studies aimed at the prevention of neuronal loss in human neurodegenerative diseases. The clarification of the relationships between mechanisms of neuronal death (active or passive) and the resulting structure of dying neurons in human neurodegenerative disease is important, particularly when addressing hypotheses as to whether PCD and apoptosis are equivalent and whether apoptosis and necrosis are mutually exclusive forms of neuronal cell death. Furthermore, if brain maturity dictates how neurons die, then, in humans, neuronal degeneration in adults may be fundamentally different from neuronal degeneration in newborns or children. For example, mature neurons appear to be less capable than immature neurons of displaying an apoptotic structure after an excitotoxic insult. An injury that produces a hybrid of apoptosis and necrosis in the adult CNS is more likely to elicit primarily apoptosis in the immature CNS. We speculate that PCD mechanisms may be activated more readily after an injury to the immature brain than to the mature brain, because immature neurons are closer than mature neurons to the period of naturally occurring developmental PCD.

IX. APOPTOSIS MAY HAVE IMPORTANT CONTRIBUTIONS TO NEURODEGENERATIVE DISORDERS IN HUMANS

It has been discovered that the degeneration of neurons in ALS is a form of apoptosis (Fig. 7). Vulnerable brain and spinal cord regions in ALS (Table I) have abnormalities in the balance of Bcl-2, Bax, and Bak proteins and abnormalities in their interactions (Table IV). However, the initial molecular pathology and upstream signals for motor neurons to engage PCD mechanisms are not known, although we suspect DNA damage. Furthermore, it is still unknown whether the neuronal degeneration in other age-related neurological disorders such as AD, Parkinson's disease, and Huntington's disease is related causally to an abnormal activation of PCD pathways in selectively vulnerable neurons.

Much uncertainty also centers around the possible role of apoptosis in the nerve cell degeneration resulting from cerebral ischemia caused by heart failure, asphyxiation, and stroke. Historically, cellular degeneration resulting from these abnormalities has been considered a form of cellular necrosis, but it has been suggested that postischemic neurodegeneration is apoptosis possibly mediated by a PCD mechanism. However, the contribution of apoptosis to the selective degeneration of neurons after ischemia is not yet resolved.

X. ANIMAL MODELS OF NEURODEGENERATION ARE NECESSARY TO UNDERSTAND HOW NEURONS DIE

Animal models of neuronal degeneration are crucial for improving our understanding of the mechanisms and progressive stages of neuronal death. These models provide an experimental system to identify how nerve cells die in paradigms that mirror certain neuropathological and clinical features of a neurological disorder that occurs in humans (Tables I and VIII). With animal models, the process of nerve cell death can be studied at the structural, biochemical, and molecular levels, and then subsequently the model can be used to test new therapies to prevent the degeneration of neurons in a biologically relevant system.

A. Neuronal Degeneration in Models of Axotomy and Target Deprivation

Animal models of axotomy (axon cutting or transection) and target deprivation (target removal) provide

insight into the mechanisms of progressive neuronal degeneration and are relevant to acute and slow, chronic degenerative disorders that affect the human brain or spinal cord (Table VIII). The progression of axotomy–target deprivation-induced neuronal degeneration and the likelihood of subsequent neuronal death or survival are influenced by several variables, including whether the cell body of an axotomized neuron resides within the peripheral nervous system (PNS) or CNS, the age of the animal at the time of injury, the location of axonal trauma in relation to the cell body, and the animal species. In the immature brain and spinal cord, axotomized neurons often die rapidly. Axotomy-induced degeneration of motor neurons in the immature CNS appears to be apoptosis on the basis of structural evidence in mouse and chick and the finding that overexpression of the *bcl-2* gene reduces motor neuron death in newborn mice in response to facial nerve transection or sciatic nerve transection. In contrast, in the adult nervous system, axotomized neurons can recover or persist in some altered form or they can undergo apoptosis. The outcome depends upon the type of model. Thus, in general, neuronal apoptosis is induced more easily by axotomy in the immature or newborn CNS than in the mature or adult CNS. Differences in the fate of target-deprived neurons in the developing and adult CNS may be related to the extent of target deprivation and collateral connections of deprived neurons with other brain regions and related to the differential ability to activate a PCD pathway.

Interruption of specific axonal pathways by transection in rodents and nonhuman primates can be used as a model for some forms of neuronal degeneration and behavioral deficits found in humans with certain neurological disorders (Table VIII). The hippocampal formation and septum form a neural system in the brain that functions in learning and memory. This system is vulnerable in AD (Table I). These brain regions are interconnected by an axon pathway called the fimbria–fornix. Transection of the fimbria–fornix is a model of target deprivation–axotomy that results in degeneration of neurons in the basal forebrain cholinergic complex and partial removal of glutamate-utilizing synaptic inputs (deafferentation) to neurons in the lateral septal nucleus. By using this model in rats, we have shown that these neurons that are deprived of their target or of inputs undergo chronic atrophy rather than death. They shrink but survive in a sickly state. Thus, long-term damage occurs within the cell bodies and dendrites (the major synapse–receiving areas) of these neurons, including the formation of vacuolar pathology, but they do not die. This is encouraging because, if the process is reversible, therapeutic interventions could restore these neurons to a normal healthy condition.

This neuronal injury within the septal complex of rat brain after fimbria–fornix transection has some pathological similarities to neuronal damage caused by excitotoxic GluR activation (Table VII), suggesting a mechanistic overlap. This idea has been confirmed by experiments showing that a drug that blocks NMDA receptors reduces the neuronal damage in the septum after fimbria–fornix transection. This work shows that, following interruption of the fimbria–fornix, the neuronal damage that occurs within the septum is

Table VIII
Human Neurodegenerative Disorders and Animal Models

Neurological condition	Age of onset	Major vulnerable CNS regions	Animal model
Alzheimer's disease	Adult (mid to late life)	Neocortex, hippocampus, amygdala, basal forebrain	Axotomy/target deprivation, excitotoxicity, aging nonhuman primates, transgenic mice
Amyotrophic lateral sclerosis	Adult (midlife)	Motor neurons in spinal cord and brain stem, motor cortex	Axotomy–target deprivation, excitotoxicity, transgenic mice
Parkinson's disease	Adult (midlife)	Substantia nigra dopaminergic neurons	Target deprivation, excitotoxicity, MPTP poisoning, transgenic mice
Huntington's disease	Adult (midlife)	Striatum (caudate nucleus)	Excitotoxicity, metabolic toxins, transgenic mice
Spinal muscular atrophy	Infancy–childhood	Motor neurons in spinal cord and brain stem	Axotomy–target deprivation, transgenic mice
Cerebral ischemia	Any age	Cerebral cortex, striatum, cerebellum, thalamus	Global cerebral ischemia, focal cerebral ischemia (stroke), excitotoxicity, axotomy–target deprivation
CNS trauma	Any age	Cerebral cortex, striatum, cerebellum, thalamus, spinal cord	Contusion–compression injury, excitotoxicity, axotomy–target deprivation

partly caused by a sublethal excitotoxic process involving NMDA receptors. Although GluR activation has been implicated in a variety of neurodegenerative processes within the CNS, these experiments have identified important links between degenerative processes in neurons caused by axon transection, target deprivation, and deafferentation (removal of inputs) and those caused by excitotoxic mechanisms that may be relevant to the neurodegeneration in AD.

It was discovered that the neuronal degeneration in ALS has structural features of apoptosis and molecular characteristics of PCD. Because ALS is an adult-onset neurodegenerative disease, and because of the newly developed concept of the apoptosis–necrosis continuum, it is necessary to study the mechanisms of neuronal apoptosis in the CNS of adult animals. Therefore, models of *bona fide* neuronal apoptosis in the adult brain and spinal cord have been developed. In one model, the neocortex is damaged by unilaterally ablating the visual cortex in the rat. This model axotomizes and deprives thalamic relay neurons in the dorsal lateral geniculate nucleus of their neocortical target. In another model, the sciatic nerve is removed by avulsion. This model axotomizes and deprives motor neurons in the lumbar spinal cord of vital muscle- and Schwann-cell-derived survival factors.

By using these models of retrograde neuronal degeneration, it has been discovered that neuronal apoptosis occurs in association with the accumulation of functionally active mitochondria and oxidative (free radical) damage to the DNA in the cell nucleus. An important new theory of neuronal degeneration has been developed on the basis of these animal models of definitive neuronal apoptosis. Mitochondrial accumulation within the neuronal cell body and increased cytochrome c oxidase activity may result in overwhelming generation of reactive oxygen species within the vicinity of the neuronal nucleus, depletion of mitochondrial and cytosolic antioxidant mechanisms, subsequent oxidative damage to proteins and nucleic acids, and failure of DNA repair mechanisms. The mitochondria become progressively damaged, as evidenced by their swelling and lysis of the inner membrane that manifest concurrently with incipient condensation of the neuronal cytoplasm, supporting the hypothesis that apoptosis-initiating factors are sequestered within the mitochondrial intermembrane space, which upon their release activate an apoptotic cell death cascade. Damage to DNA then activates a p53-dependent form of PCD in injured neurons. At present, it is still not known whether this process truly mimics the condition in humans with a neurodegenerative disease, but this idea is being actively studied.

The process of axotomy-induced neuronal apoptosis is associated with hydroxyl radical damage to DNA. Hydroxyl radicals are products of the transition metal (e.g., iron) catalyzed, Haber–Weiss- and Fenton-type reactions that use superoxide and hydrogen peroxide as substrates, respectively. Among the reactive oxygen species, hydroxyl radicals are highly reactive and are thought to be genotoxic by interacting with DNA and producing DNA strand breaks and base modifications. Our experiments are very important because they show, for the first time, the formation of hydroxyl-radical-modified DNA during the progression of neuronal apoptosis in animal models that are relevant to both AD and ALS.

B. Neuronal Degeneration in Models of Cerebral Ischemia

An interruption in the normal supply of oxygen to the brain resulting from abnormal blood flow or low amounts of oxygen in the blood causes cerebral hypoxia–ischemia. If the entire brain is affected, as in heart failure or asphyxiation, the abnormality is called global cerebral hypoxia–ischemia. If only specific regions are affected as in stroke, the perturbation is called focal cerebral ischemia. The mechanisms by which cerebral ischemia produces irreversible neuronal death are still not fully understood. Interestingly, only certain regions of the brain are selectively damaged by global cerebral hypoxia–ischemia (Table I).

We have studied neuronal degeneration by using models of global ischemia in experimental animals. The degeneration of pyramidal neurons in the neocortex and hippocampus, Purkinje cells in the cerebellum, and medium spiny neurons in the striatum after global ischemia (Table I) pathologically is a form of cellular necrosis rather than apoptosis. We have observed patterns of DNA fragmentation, with a progression that is very consistent with acute damage by reactive oxygen species and subsequent neuronal necrosis. The degeneration of selectively vulnerable neurons after ischemia (Table I) evolves in association with damage to organelles that function in protein synthesis, posttranslational modification, and secretion. Disaggregation of polyribosomes and fragmentation or vesiculation of the endoplasmic reticulum and Golgi apparatus are prominent examples of this subcellular pathology that would likely alter protein

synthesis–processing capabilities. This degeneration of neurons after ischemia is structurally similar in the different brain regions, regardless of the severity of the ischemia and whether the degeneration occurs acutely ($\leq$ 24 hr) or is delayed (3–7 days). Thus, the acute and delayed neuronal deaths after cerebral ischemia are structurally, and perhaps mechanistically, identical. In several models of global cerebral ischemia, neuronal degeneration in selectively vulnerable regions is indistinguishable structurally from the neuronal death caused by excitotoxicity, and, specifically, it closely resembles the neuronal necrosis caused by NMDA GluR activation in the adult brain.

In the same animal models, apoptotic cell death occurs in some neuronal groups that are not typically regarded as selectively vulnerable to ischemia. For example, subsets of granule cells in the hippocampal dentate gyrus and cerebellar cortex and subsets of neurons in the thalamus undergo apoptosis. In addition, prominent apoptotic death of white matter oligodendrocytes can occur. It has been theorized that apoptosis in these groups of cells after global ischemia is a form of PCD caused by target deprivation and axonal degeneration in response to necrotic degeneration of selectively vulnerable populations of neurons (Table I). Thus, necrosis and apoptosis, occurring as secondary degeneration in remote or distant brain areas resulting from target deprivation, both contribute to the neurodegeneration after cerebral ischemia.

Interestingly, cell death in the different settings of naturally occurring and pathological neuronal degeneration may be mechanistically distinct, or some of the underlying mechanisms in these different settings of neuronal degeneration may be shared to varying degrees, but they differ in the rate at which the primary mechanisms of injury occur (e.g., how fast an oxidative stress occurs). For example, oxidative stress and free radical damage in neuronal death caused by target deprivation–axotomy evolve slowly, and the corresponding neuronal death is apoptosis; in contrast, if oxidative stress evolves rapidly, as in the death of striatal neurons after ischemia, then the neuronal death is necrosis.

An important, unresolved question regarding the pathobiology of neuronal degeneration is whether the absence of the classic apoptotic structure in vulnerable populations of neurons is sufficient evidence to exclude the possibility that PCD participates in the pathogenesis of neuronal degeneration. All forms of PCD may not occur via apoptosis. For example, the death of T cells during negative selection in mouse thymus and the death of intersegmental muscles during metamorphosis in the moth *Manduca sexta* both occur by PCD; however, these cell populations die with distinct structural and biochemical features. Thus, some cells can die by a PCD mechanism that is not associated with the structure of classic apoptosis. Clearly, much more work using animal and cell models is needed to answer this complex question as it may relate to neuronal degeneration in disorders of the human brain and spinal cord.

XI. THE FUTURE IS PROMISING FOR UNDERSTANDING THE CAUSES OF NEURODEGENERATIVE DISORDERS IN HUMANS AND IDENTIFYING TREATMENTS

Unfortunately, no effective treatments are available to prevent or cure any of these neurological disorders that affect humans. Molecular genetics studies are likely to identify additional gene mutations or deletions that are associated with progressive neurodegenerative disorders (Table II). Animal models of experimental neuropathology will remain critical for studying how nerve cells die in the brain and spinal cord. Neurons within the CNS can be damaged by neurotoxin exposure, by cutting nerves and white matter pathways, by reducing blood flow to the brain producing oxygen deprivation, by forcing brain cells to express mutant genes, and by deleting genes. These animal models of neuronal degeneration are relevant to several neurological disorders that affect humans, including Alzheimer's disease, ALS, and cerebral ischemia (Table VIII). A better understanding of the pathogenesis of neuronal degeneration in human diseases and in animal models that mirror this degeneration is critical for the future development of effective therapies for patients with Alzheimer's disease, ALS, and other conditions. A more complete understanding of the characteristics and mechanisms of neuronal death within the CNS, provided by animal models of injury and transgenic gene expression–deletion, is important for the subsequent development of effective pharmacological and biological treatments to prevent or limit neurodegeneration in human neuropathological conditions.

It is still generally believed that, once neurons die in the mature CNS of mammals, these neurons cannot be replaced by nearby neurons (unlike the liver for example) because the remaining neurons are postmitotic (i.e., after neurons have achieved their mature

state, they cannot enter back into the cell cycle and undergo cell division). However, nervous tissue grafting or stem cell implantation as a means for neuronal replacement is an experimental approach that offers some hope, though much work needs to be done to evaluate the feasibility and efficacy of this approach. Importantly, it remains to be shown whether the immature or adult CNS provides a permissive environment for the appropriate integration of exogenous or grafted cells into a functional neural system.

Neurofeedback

JAMES R. EVANS
University of South Carolina

GLOSSARY

amplitude Height of an EEG wave from baseline, reflecting the magnitude of voltage in the EEG.

artifact Contamination of an EEG wave by factors other than brain electrical activity, e.g., eye or other body movements, muscle electrical activity.

canned protocol A very specific neurofeedback treatment plan often applied in a rigid manner with clients.

electrode A small metallic conductor. These are placed on the scalp at points where EEG activity is to be detected and conducted to other processing equipment.

empirical Derived from experience and/or scientific experiment.

entrain To cause the interaction of one organismic rhythm with another, resulting in identical or related rhythms (frequencies) between the interactants.

filtered Having certain frequencies removed from the full EEG frequency spectrum. For example, frequencies above 32 Hz often are removed prior to further EEG analysis.

Fourier analysis A mathematical process, named after the nineteenth century French physicist, J. B. J. Fourier, enabling analysis of a complex waveform into simple sine waves. This permits the calculation of power (voltage) in a specific EEG frequency band(s) of interest.

frequency band A specified portion of a total frequency range, e.g., the 8.0–12.0 Hz portion of an entire 1.0 to 32.0 Hz EEG record.

Hz Abbreviation for hertz. A frequency unit of 1 cycle per second, named after the nineteenth century physicist, Heinrich Hertz.

international 10–20 electrode system A standardized system for locating EEG electrodes on the scalp, which corrects for individual differences in skull size.

phase A stage in anything that is cyclic in nature, e.g., an EEG wave. Two waves are synchronized if a given stage occurs simultaneously in each.

placebo effect Changes following a treatment that are due to the suggestion or expectancy of change.

Neurofeedback is a specific case of biofeedback in which the physiological process involved is the electrical activity of the brain. This article presents an overview of the field of neurofeedback.

I. INTRODUCTION

As is evident from other articles of this text, the twentieth century saw major advances in knowledge of the functioning of the human brain. Many such advances were associated with technological developments in computer science and brain imaging techniques, such as functional magnetic resonance imaging (fMRI), and with developments in psychopharmacological treatments in psychiatry. Similarly, twentieth century advances in the cognitive sciences have been associated with the development of effective cognitive and behavioral therapies for mental disorders and cognitive rehabilitation techniques for acquired brain damage. However, despite the many advances, treatment of psychiatric type disorders still primarily involves temporary control of the symptoms rather than permanent change in the underlying neurophysiology or actual cure. Pharmacological treatments have unwanted and often dangerous side effects,

whereas behavioral changes resulting from behavior modification procedures often fail to generalize to a sufficiently wide range of life situations, and cognitive rehabilitation has had limited success in many cases of traumatic brain injury. Furthermore, some neurophysiological diseases such as Alzheimer's disease have responded to treatment only marginally. Obviously, the need remains for new and/or improved treatment procedures for disorders now known to have neurophysiological bases (or correlates). Many alternative treatments have been proposed, with advocates of each claiming positive effects on neurophysiological function, e.g., biofeedback, chiropractic care, music therapy, meditation. This article is about one of the more recent ones: neurofeedback (NF) (sometimes referred to as neurotherapy or EEG biofeedback). Biofeedback may be defined generally as a research or clinical treatment technique in which electronic equipment presents a person with information about ongoing physiological processes that otherwise could not be monitored readily, thus allowing the person to learn through operant conditioning to self-regulate those processes. NF is a specific case of biofeedback in which the physiological process involved is the electrical activity of the brain.

Due in part to the newness of NF as a treatment modality, there is considerable controversy regarding which topics are of most importance to the field. Topics selected for inclusion in this article and many of the ideas presented are based on the author's 30 years of following developments in EEG biofeedback and several years of experience with NF in a part-time private practice in clinical psychology. The content also is based in part on the author's experiences in co-editing, with Andrew Abarbanel, the text *Introduction to Quantitative EEG and Neurofeedback*, and in part on the results of a survey questionnaire concerning the current status of NF returned to the author by 10 of today's leading NF practitioners. Hopefully, this article presents an accurate overview of the field of NF as it exists at the beginning of the twenty-first century. The author, however, assumes sole responsibility for the content, which may be perceived by some as neglecting certain important topics and misrepresenting or overemphasizing others.

A. Procedures and Premises

In the practice of clinical NF, a client requesting treatment first is evaluated to determine whether NF is an appropriate primary or adjunctive treatment modality. This involves considerations such as specific symptoms, likelihood of motivation and ability to persist in attempting to modify his or her EEG over the usual 20–50 sessions required for optimal results, use of prescribed (or illegal) pharmacological agents, and co-existing and contraindicative psychosocial, environmental, psychiatric, and/or general medical problems (e.g., certain types of seizures) for which a referral for mental health and/or medical treatment is needed. To obtain this information and other data that may be used for pre- and posttreatment comparisons in evaluating progress and outcome, practitioners often use structured interviews, behavior rating scales, and various standardized psychological tests such as continuous performance tests. Many NF practitioners also require an EEG assessment prior to beginning treatment. This most often involves a quantified (quantitative) EEG (QEEG) evaluation and comparison of obtained measures of wave frequency, amplitude, phase relationships, and coherence between scalp electrode sites to a lifespan database to determine which, if any, are abnormal and, hence, candidates for attempting normalization through NF.

Actual treatment begins once a client is considered acceptable for this type treatment and the EEG parameters to be modified are decided upon. An electrode (or more than one electrode in some applications) is placed at an appropriate scalp location, the EEG activity emanating from that location is filtered and amplified, and a feedback signal is presented to the client reflecting the current status of a selected feature (or features) of the ongoing EEG. The EEG activity actually eliciting the feedback varies with equipment. After filtration and amplification, some equipment provides a direct analogue or digital representation of the raw EEG in the feedback. Most often, however, the raw EEG signal is averaged over short periods of time (epochs) and a Fourier analysis is made for each epoch. It is these averaged and transformed data that are reflected by the feedback.

NF clinicians vary in their rationale for selecting a specific scalp electrode site(s) for training. Some train at sites from the international 10–20 electrode system where QEEG abnormalities were greatest for the client, whereas others regularly use specific sites identified through their clinical experience (or the experiences of others) to be the most effective for specific conditions, e.g., Cz for attention problems. Feedback usually is auditory (tones varying in pitch and/or volume) or visual (e.g., moving colored bars, puzzles, or animations are presented on a computer monitor). With most modern equipment, feedback

possibilities are nearly endless considering all the possible pitch, volume, and visual stimulus combinations. Various combinations usually are tried during early sessions until one considered acceptable to the client is agreed upon. Most often, feedback is given for desired changes in the amplitude of specific EEG frequency bands (or duration of specified frequency amplitudes) over the course of a training session, e.g., for changes in commonly used EEG frequencies such as δ (0.5–4 Hz), θ (4–8 Hz), α (8–12 Hz), sensorimotor rhythm (12–15 Hz) and/or β (>12 Hz bands). In some treatment protocols, feedback is provided to facilitate increased amplitude in one frequency band and simultaneous decreases in another, e.g., increase β–decrease θ. Although wave amplitude is the EEG characteristic presently involved most often in NF, degree of coherence, i.e., correlation and similarity of waveform morphology, phase lag, i.e., transmission time in milliseconds, between two (or more) scalp electrode sites, and various other EEG measures increasingly are being used. As with electrode site selection, there is considerable variability in the rationale for selecting a specific EEG feature for feedback. Some practitioners base selection on QEEG findings on the individual client, whereas others regularly use ''canned'' protocols based on clinical lore regarding what is effective for a given condition. Modern NF equipment also monitors EEG artifacts such as those caused by eye or other body movements or muscle tension (electromyogram or EMG) and inhibits feedback when such artifacts are above a level preset by the neurotherapist. Thus, feedback is provided only when the client's target EEG feature is changing above (or below) a desired threshold and artifacts are below a preset inhibit level. Typically, a cumulative score is kept of the percentage of time that the client received feedback during a session. Neurotherapists generally agree that, for optimal learning, thresholds and artifact inhibit levels should be set so that the client is able to meet all criteria and, thus, obtain feedback 70–80% of the time. As learning occurs, thresholds and inhibit levels may be made increasingly challenging. There is general agreement that training sessions should occur 2–3 times per week, especially during the earlier and middle portions of the total treatment.

The basic premises of NF, in many respects, are quite simple:

1. Functioning of the central nervous system is electrochemical in nature. It is commonly accepted that changes in neurochemistry can result in changes in behavior, perception, emotions, and cognition. It is logical to assume that changes in electrophysiology (i.e., EEG activity) also can result in such changes.
2. If an appropriately motivated person is provided immediate, accurate feedback regarding aspects of his or her ongoing brain electrical activity (EEG), he or she can learn to regulate it, i.e., operant conditioning of the EEG activity can occur.
3. If such operant learning is repeated a sufficient number of times, the electrophysiological changes will become quite stable.
4. Appropriate stable changes in brain electrophysiology can result in relatively permanent positive changes in perceptual, cognitive, and behavioral functioning across various settings and activities of daily life.

II. HISTORICAL NOTES

A. Early Beginnings

Until about 40 years ago, it was generally believed that brain electrophysiology was not under conscious control and could not be modified through learning. In fact, even today despite much evidence that EEG can be modified rather easily, there are some who assert that this occurs only through mediation by voluntary control of a skeletal muscle response, e.g., deep breathing. The birth of the field of neurofeedback (NF) commonly is reported to have occurred with a serendipitous discovery in the early 1960s. A University of Chicago physiological psychologist, Joe Kamiya, noted that some persons could consciously control bursts of α frequency EEG if asked to do so by simply observing their ongoing EEG tracings. This was quite a revolutionary idea at the time and led to a large amount of research and clinical work on EEG biofeedback through the 1970s.

Researchers and clinicians in both medicine and psychology claimed to have demonstrated that most persons not only can learn to self-regulate aspects of their EEG but that certain modifications (especially α-frequency amplitude and duration at certain scalp sites) are associated with major changes in consciousness, including perceived decreases in anxiety. For example, Tom Budzynski and Johan Stoyva published results of successful use of biofeedback to increase α levels in conjunction with systematic desensitization therapy for a phobic type condition. Barry Sterman

reported decreases in epileptic seizure activity, and Joel Lubar and M. N. Shouse published evidence of positive behavioral changes in a ''hyperkinetic'' child, with both of these being associated with training of the sensorimotor rhythm (SMR) and inhibiting θ activity at central scalp sites.

Under the leadership of Barbara Brown, a biofeedback research society was formed in 1969, and several books on biofeedback were published soon thereafter. However, during the 1970s there was increasing criticism of EEG biofeedback. For many it became associated with ''consciousness raising'' and other ''New Age'' movements of the time, and the claims of its advocates often were strongly attacked by researchers publishing in a few prestigious journals. For example, one especially influential article reported that biofeedback did not enable persons to increase α frequency amplitudes beyond those normally occurring when simply sitting in a dark room with eyes closed.

By the late 1970s the earlier promise of EEG biofeedback had faded. Although the larger field of biofeedback (e.g., temperature, heart rate, muscle tension feedback) continued to prosper to some degree, proponents and practitioners of EEG biofeedback were few. Joel and Judith Lubar at the University of Tennessee and Southeastern Biofeedback Institute pursued research and treatment with children having learning and attentional disorders, Lester Fehmi continued to use multi-EEG channel synchrony training to develop flexible attention, and Margaret Ayres reported major success using EEG biofeedback equipment of her own design with victims of head injury and stroke. Dale Walters and Alyce and Elmer Green continued to use and teach these procedures at the Menninger Institute in Kansas. During the early 1980s, Charles Stroebel and Adam Crane continued to perfect equipment for providing feedback of complex patterns of EEG activity.

B. Revival

A major turning point for NF came in the late 1980s largely due to several nearly simultaneous events: publications by Joel and Judith Lubar detailing successful treatment of attention deficit disorder with EEG biofeedback, a research publication by Eugene Peniston and Paul Kulkosky, and the development of high-quality, relatively low priced equipment for both QEEG evaluation and EEG biofeedback by companies such as Lexicor Medical Technology of Boulder, CO. The 1989 Peniston and Kulkosky research combined conventional treatment and relaxation and temperature biofeedback with NF in treating 10 male alcoholics and compared the results to those of a conventional treatment only control group. The finding of much better and more enduring results with the experimental group aroused strong interest in the potential of NF for treating this notoriously treatment-resistant group. During the 1990s, there was what some describe as an explosion of interest in NF that continues today. A few highlights will be mentioned briefly in the next few paragraphs.

Perhaps to shed an earlier negative image, the terms neurofeedback and neurotherapy largely replaced the term EEG biofeedback by the early 1990s, with the latter now referring primarily to research rather than clinical applications. Whereas scientific research activity in this area is growing but remains modest in extent, the clinical use of NF is spreading very rapidly, both nationally and internationally. It is estimated that approximately 1500 clinics and practitioners now use it as one of their treatment modalities. Some of the pioneers continue to expand their NF practices (e.g., Joel and Judith Lubar at Southeastern Biofeedback Institute and Margaret Ayers at Neuropathways), and there are many relative newcomers with large practices. Notable among the latter are Seigfried and Susan Othmer, who have trained many of today's practitioners and help new trainees establish practices throughout the country.

An early professional group, the Biofeedback Society of America, and its descendant and largest biofeedback association, the Association for Applied Psychophysiology and Biofeedback (AAPB), have always had members with interests in EEG biofeedback. However, until about the mid-1990s, many of these members apparently felt treated as ''second class citizens,'' perhaps related to the negative image EEG biofeedback had acquired during the 1970–1990 period and mainstream biofeedback's desire to avoid it. Partially as a result, a separate group was formed in 1992 and presently is known as the Society for Neuronal Regulation (SNR). Consisting of 450 members in 2001, it sponsors annual national conferences at which NF research and related developments are presented. At approximately the same time, AAPB changed its structure to allow for specialty interests, and in 1993 an EEG interest group was formed. This EEG Biofeedback Division within AAPB also has grown rapidly and now is well-accepted, as evidenced by the election of the NF pioneer Joel Lubar as the president of AAPB in 1996. In 1995 a journal devoted

entirely to NF-related topics, the *Journal of Neurotherapy*, was first published. It now has a circulation of 450 and is abstracted through the American Psychological Association's "Psychlit" service. The first text in the field, *Introduction to Quantitative EEG and Neurofeedback*, edited by this author and Andrew Abarbanel, was published by Academic Press in 1999. Several NF websites are operative, including that of SNR: www.snr-jnt.org. Although proper training and credentials continue to be controversial topics, more states are including biofeedback (and thus neurofeedback) as practice activities in licensing laws for professionals such as psychologists and counselors. Several groups provide intensive training seminars, and NF certification is available through the Biofeedback Certification Institute of America (BCIA).

III. SPECIFIC CLINICAL APPLICATIONS

As noted earlier, training of the amplitude of specific EEG frequencies presently is the most common NF application. This often involves simultaneous training for increasing the amplitude of one frequency and decreasing the amplitude of another. That is, some protocols train for changing amplitude ratios between two frequencies, e.g., lowering the θ:β ratio. Within the general area of frequency amplitude training, there are two often independent groups of NF practitioners: (1) those who emphasize training to increase the amplitude of higher (β) frequencies (and, in some protocols, decrease lower frequencies) and (2) those who train increases in the amplitude of lower frequencies (α, θ). The first group, typified by those who treat attention deficit disorder or seek to develop "peak performance," is interested in developing higher levels of arousal in presumably underaroused (or at least not optimally aroused) cortical areas. This is based on the fact that higher levels of brain activation are reflected in higher concentrations of high-frequency EEG. The second group typically is interested in "quieting" an overactive central nervous system and/or inducing an altered state of consciousness for therapeutic purposes. For example, training to increase the amplitude of the α frequency may be part of a relaxation training program, whereas the increasing θ (or α–θ) amplitude may be aimed at helping the client enter a state in which early childhood trauma may be reexperienced and resolved, with concomitant psychological reintegration.

A. Attention Deficit Disorder

Among NF practitioners there seems to be nearly universal agreement that this can be a highly effective treatment for many cases of attention deficit hyperactivity disorder (ADHD) in both children and adults. This may be especially true for cases of ADHD that involve cortical underarousal, and a growing body of research using brain imaging techniques such as functional magnetic resonance imaging (fMRI) and QEEG suggests that these may constitute the majority of cases. Relatedly, among the first and still most commonly used NF protocols for attention disorders is one designed to increase cortical activation (β or SMR amplitude) at frontal and/or central (e.g., Cz) scalp sites (often with simultaneous training of decreases in θ or α and θ amplitude). Joel and Judith Lubar pioneered this protocol, which in its original or slightly modified form continues to be considered highly effective. Some practitioners believe that NF can be effective as the sole treatment procedure, but most appear to advocate its use as a supplement to stimulant medication and/or psychological techniques such as family therapy, education about ADHD, and cognitive behavioral modification procedures. Indeed, some report past experiences in which a chaotic family situation seemed to prevent NF progress and refuse to treat children from highly dysfunctional families until that situation is addressed either before or during NF.

Whereas concurrent use of stimulant medication is often recommended and sometimes considered essential to enable the patient to attend sufficiently to the feedback stimuli during early sessions, there are frequent reports that less medication is needed as treatment progresses. In fact, some practitioners have reported that failure to adjust medications during treatment interferes with NF progress. In some cases the client reportedly has been able to cease the use of medication while remaining symptom-free.

The author's survey of highly experienced NF practitioners mentioned earlier found 42 NF treatment sessions (range = 25–60) to be the average number reported to be necessary for optimal results with attention deficit disorder without hyperactivity (slightly more when hyperactivity also was present). Many practitioners recommend having the client engaged in "challenge tasks" such as reading, writing, and listening during NF training, especially during later sessions. This is believed to facilitate the generalization of desired EEG changes to relevant real life situations. Ten-year (and more) follow-up of successfully treated clients has indicated that they remain symptom-free,

suggesting a permanent "cure." However, it also commonly is recommended that some clients return a few times annually for "tune-up" sessions to help reinforce the ability to appropriately self-regulate the EEG. All practitioners have encountered situations, in which the usual protocols for ADHD were ineffective. When this occurs, common recourses are to reevaluate the QEEG findings to determine whether other protocols might be more appropriate (e.g., training coherence between certain scalp sites, decreasing rather than increasing activation at specific sites) and checking further into the client's background to determine whether factors such as lack of motivation, use of illegal drugs, or family, psychiatric, or other medical problems are precluding progress (or are the true cause of the ADHD symptoms).

Although there are some vocal critics whose views range from considering NF with ADHD a promising but experimental procedure in need of more research to considering it a passing fad capitalizing on placebo effects, many case reports and a few small-scale studies involving control groups have supported the efficacy of NF for treatment of ADHD. A large multisite research study on NF and ADHD currently is in progress, and results should lend greater credibility to NF as a useful treatment. However, the definitive large-scale study incorporating double-blind procedures demanded by some NF critics remains to be done. Although ADHD is the disorder for which NF currently most often is used, several others will be discussed briefly in the following paragraphs.

B. Traumatic Brain Injury

Since the 1980s, Margaret Ayers has reported several studies successfully using NF to bring patients out of long-standing coma states and, in some instances, to help those with stroke and traumatic brain injury (TBI) return to premorbid levels of function. Several NF clinicians such as Daniel Hoffman and Steven Stockdale have published evidence that the majority of TBI clients undergoing NF treatment report improvement in cognitive functioning, headaches, and/or ability to relax along with significant normalization of EEG. Whereas these reports often have been considered incredible by mainline medicine, they seem less surprising in view of scientific evidence for nerve regeneration or neural reorganization and recovery of neurological function even in older adults. Given the fact that strokes, TBI, and other neurological disorders (depending on age, location of injury, etc.) can result in an almost infinite variety of EEG disturbances and behavioral disorders, it is not surprising that there is little consensus among NF clinicians regarding best treatment protocols. Some note the finding that excessive EEG slowing (as evidenced by abnormal increases in δ, θ, and/or low α frequency amplitude) occurs at sites of brain injury and, accordingly, train for increased amplitude of higher (SMR or β) frequencies and/or decreases in lower frequency amplitudes at those sites. Others note the intra- and interhemispheric disconnections of neural communication that often occur in brain injury from shear and strain forces on short- and long-distance nerve fibers (and other factors), resulting in abnormal EEG coherence among certain sites. These clinicians tend to emphasize training to normalize QEEG coherence measures. Certainly it would seem that the wide variety of EEG abnormalities resulting from TBI and neurological disease requires QEEG or traditional EEG assessment prior to selecting a NF protocol for those type disorders. Whereas some practitioners have reported obvious and significant improvements in TBI clients after as few as 2–5 sessions (even years posttrauma), the experienced therapists surveyed reported needing an average of 53 treatment sessions (range = 30–80) for optimal success. Whereas much more quality research obviously is needed, the many clinical reports of NF successes with certain clients point toward its promise as a major form of treatment for TBI and other neurological disorders.

C. Depression

Some interest in using NF for treating depression followed reports by Davidson in 1995 that depressed persons, and even those in remission, show greater α amplitude at left frontal regions than homologous right frontal areas. This was interpreted as evidence that decreased left frontal activation is correlated with negative affect and has led to attempts to use NF to decrease left frontal α amplitude and thus decrease abnormal differences in frontal EEG asymmetry (e.g., the research of Elsa and Rufus Baehr). Whereas the need for such treatment may seem questionable given the effectiveness of present antidepressant medications, it may contribute to greater understanding of the causes of mood disorders and appears to have none of the side effects associated with medications.

Interestingly, there are anecdotal reports that depressed persons successfully treated with NF have remained symptom-free after ceasing to take

antidepressant medications. In fact, there also are reports that some developed severe flulike symptoms in reaction to their medications during the course of NF treatment. NF researchers and clinicians working in this area note that it is not effective in all cases and emphasize the need for research to determine which mood disorders are responsive, whether successful treatment is specific to the use of the asymmetry reduction protocol (as compared to other potential NF protocols), and the degree to which NF alone may be effective with mood disorders or needs to be part of a more comprehensive treatment protocol involving psychotherapy and/or medication.

D. Dissociative Disorders

Dissociative disorders occur when there is a disruption in the usually unified aspects of consciousness such as memory, affect, perception, and sense of identity. One of the most severe of these disorders is dissociative identity disorder (DID), formerly referred to as multiple personality disorder. Some of the earliest work involving NF and dissociative disorders was done with clients suffering from posttraumatic stress disorder for whom one of the symptoms was dissociation. More recently, some researchers and clinicians have reported successful treatment of DID using NF. Researchers and clinicians who have published reports of their work in this area commonly use other techniques to supplement NF. For example, Carol Manchester required subjects to learn to control body temperature through temperature biofeedback prior to NF and to use various visualization techniques. Along with other NF practitioners who work with DID clients, Manchester trained subjects to increase amplitudes of lower frequency EEG. A rationale for this is that a lower state of arousal is facilitated, which enables one to access repressed memories of traumatic events (often related to childhood abuse). With sufficient NF practice, persons are believed to be able to more readily "connect and disconnect" to psychobiological responses they had to previous psychological trauma and eventually resolve them, with accompanying reintegration of their separate personalities. Some have speculated that the increase in amplitudes of lower (low α–θ) frequencies during NF sessions results in an EEG pattern characteristic of childhood when the trauma occurred and, therefore, enables recall of the trauma (i.e., state-dependent memory).

Thomas Brownback and Linda Mason use similar procedures in their protocol for the treatment of dissociation but have added other components. For example, they train to increase θ amplitude at 12 different scalp electrode sites, incorporate the training of frequencies other than θ at points in their protocol, and use imagery, breathing techniques, psychotherapy, and other methods to achieve the goal of increased attentional flexibility in their clients. The use of NF in the treatment of DID reportedly cuts the time necessary for reintegration of separate personalities by about one-half. Because the usual time required for such reintegration ranges from 3 to 5 years, the value of NF in the treatment of dissociative disorders is worthy of further investigation. However, research is needed to help determine the relative importance of the various components of these treatment "packages."

E. Miscellaneous Applications

As mentioned in an earlier section, it was a report of the successful use of a treatment protocol involving NF with a group of alcoholic clients that stimulated revival of interest in NF during the late 1980s. There continue to be reports of the successful use of that protocol and others involving NF with alcohol and drug addiction. However, to the author's knowledge, there have been no published reports of controlled research on this topic. As with NF treatment of dissociative disorders, most of the treatment protocols have included other procedures, and the relative contribution of NF to treatment success is unknown.

A rather large number of NF practitioners are claiming significant improvement in clients diagnosed with chronic fatigue syndrome and in many diagnosed with fibromyalgia. Such reports have gained considerable attention because these disorders have proven difficult to treat through traditional medical procedures. Several years ago it was often reported that chronic fatigue syndrome was characterized by abnormally high amplitude EEG slow waves, especially at frontal sites, and NF treatment was designed to increase activation (raise β amplitude) at those sites. More recently, however, there seems to be disagreement among even experienced practitioners, who report that other abnormalities are common in chronic fatigue syndrome, including generalized EEG slowing, generally low EEG amplitudes, and unusual variability of brain electrical activity.

Another area in which NF reportedly has been successful is specific learning disability. Most often the anecdotal reports and papers presented at NF

conferences involve the successful treatment of dyslexia (specific reading disability). Unlike the protocols for the disorders mentioned earlier, which primarily involve amplitude training of specific frequencies, protocols often mentioned in the successful treatment of reading disorders have involved phase and/or coherence training. Usually the training is designed to help the client learn to modify phase and/or coherence relationships between left posterior scalp sites or between those sites and left frontal sites, specifically between sites overlying Broca's and Wernicke's areas. Modification of such relationships involves modification of neural timing relationships between the sites involved rather than changing amplitudes at those sites. Because considerable research suggests that neural timing abnormalities may be the basic causes of dyslexia, it seems reasonable that NF of this type would have the potential to change timing relationships in a favorable manner and, thus, facilitate reading readiness.

At SNR conferences there have been reports of the effectiveness of NF with various sleep disorders. In fact, 6 of the 10 experienced researchers surveyed prior to the preparation of this article reported using NF to treat sleeping disorders. Interestingly, they reported fewer sessions needed for positive results than with any of the other disorders mentioned in the survey (range = 10–30 sessions).

A few practitioners have reported the successful treatment of violent individuals, including some diagnosed with intermittent explosive disorder. QEEG findings among persons convicted of violent acts often show excessive slow wave activity and other abnormalities at right frontal and/or right anterior temporal sites. NF training targeting those sites (and other sites when appropriate) appears to have some promise in the rehabilitation of violent offenders and perhaps in the prevention of violence in those showing such EEG patterns but who have not yet displayed episodes of violent behavior.

No discussion of the present status of NF would be complete without mention of its use in facilitating optimal or peak performance in nonclinical populations. Such performance enhancement training using NF is a rapidly growing branch of the field, with its own certification requirements and treatment protocols. Treatment is aimed at improving self-discipline, attentional focus, flexibility, sustained alertness, visualization skills, and various other functions. Actual treatment procedures vary widely, but many practitioners concentrate on increasing the amplitude of β or α frequency and increasing phase synchrony among multiple sites or between homologous right and left hemisphere sites. Consumers of these services range from professional athletes seeking a competitive edge to amateur golfers aspiring to achieve respectable scores to persons from all walks of life who simply seek to improve efficiency.

IV. MODELS OF EFFECTIVENESS

Within the field there are various opinions regarding the mechanisms through which NF treatment leads to remission of symptoms, improvement in performance, etc. Whereas some feel that at this point in time the field needs to demonstrate definitively that it truly is an effective treatment rather than being concerned with why, nevertheless, considerable effort has been put into speculation about dynamics. Greater mainstream acceptance is likely if a credible model of efficacy can be formulated to help account for the often incredible results reported. Some of the more popular models will be mentioned here.

A. Site–Frequency Specificity

One model assumes that specific perceptions, cognitive events, emotions, and behaviors are enabled, facilitated, hindered, or precluded by certain brain rhythms at or between specific brain sites. Abnormal EEG activity at or between sites is seen as an underlying factor in disordered behaviors that can be normalized with NF, resulting in positive behavioral change. One of the more common examples of this type reasoning is that excessive power in the θ and/or lower α frequency ranges at central or frontal cortical sites hinders sustained attention, and learning to decrease power at those frequencies while increasing power in higher frequencies will enable the development of attentional skills. Similarly, such site–frequency specific effects often are implied in NF training to increase power in α or θ frequency bands at posterior sites. For example, it generally is assumed (with some empirical support) that high-amplitude EEG in the α frequency range facilitates a subjective state of relaxed attention in many persons. Hence, NF training to increase α power is likely to be recommended for a client with generalized anxiety who also has abnormally low EEG α (or abnormally high β) amplitudes at posterior sites. This is the same type of reasoning mentioned in the previous section where high θ amplitude is believed to enable memories of childhood events and therefore is the goal of NF training in some cases of dissociative disorder. Advocates of this model naturally tend to place much

emphasis on prior QEEG or EEG findings in order to more accurately "pinpoint" the underlying abnormalities of brain rhythm needing to be addressed. They expect to see increasing normalization of the EEG accompanying decreases in behavioral symptoms. Those who support this model see the development of QEEG procedures involving much larger numbers of electrode channels than the 19 commonly used now as promising to provide a degree of resolution that will more accurately delineate the site–frequency abnormalities to be modified through NF.

B. The Self-Regulating Brain

A second model centers around the view of the central nervous system as a self-regulating system and postulates much more generalized, systemic effects of NF training. This seems to be the model implied when practitioners make statements such as, "NF lets the brain see what is possible and then the brain proceeds to optimize its own function." Seigfried and Susan Othmer and associates have developed this theme in some detail. If one proceeds from a view that rhythmicity regulates and facilitates communication within the central nervous system, it is reasonable to assume that EEG abnormalities or dysrhythmias are indicative of central nervous system disregulation. A dysrhythmic, disregulated brain may be considered a disorganized, unstable brain, giving rise to disorganized, unstable thoughts, moods, levels of arousal, and behaviors. As viewed by Othmer and associates, NF challenges the self-regulating function of the brain. That is, by challenging the brain out of its present homeostatic state (which may be an unhealthy state), a new and improved homeostatic state and greater stability of the brain's regulatory function are attained. With such attainment, not only will specific symptoms such as those for which a client may have sought help be attenuated but there will be generalized improvement in functioning because appropriate neuroregulation is basic to all behaviors. Those who emphasize this model tend to be less concerned about matching NF training to specific site–frequency abnormalities on the basis of the assumption that normalization of any one of them may have the same effect, i.e., assisting the self-regulating brain to improve its neuroregulatory function.

C. Other Models

Outside the field, the positive results reported for NF training often tend to be attributed to other factors not directly related to EEG changes. For example, it sometimes is noted that being provided with reinforcement one or more times per week for attending closely to relatively boring stimuli for increasingly long periods of time could explain results. In other words, operant conditioning is occurring but quite independently from the specific EEG features concurrently being trained. This view is disputed by some who cite evidence that the specific EEG changes being trained are strongly correlated with expected changes in behavior. Nevertheless, NF practitioners often report cases in which behavioral improvements have occurred without changes in the targeted EEG features. It also is common to dismiss NF results as being due to placebo effects. In fact, it has been said that NF approaches the "ultimate placebo" in that it involves expensive, sophisticated electronic equipment and esoteric jargon and purports to make direct changes in brain function. As with any treatment technique, placebo effects can be expected. However, NF practitioners strongly refute the notion that this is the only or primary reason for results. They defend their position by citing cases in which positive effects went beyond anticipated behavioral changes, cases in which there were initial, temporary negative effects of the treatment, and the commonly observed course of behavioral change in which initial positive changes are followed by a plateau or increase in symptoms prior to a gradual decrease in symptoms.

Finally, there is the view that it is a sense of self-efficacy and self-confidence that comes with successfully mastering one's brain wave activity that leads to increased self-regulation of behaviors. This, however, seems unlikely to be a major factor inasmuch as children with ADHD very often enjoy and master computer games with no obvious improvement in symptoms.

V. CURRENT ISSUES

Considering its rapidly growing popularity as a therapeutic procedure for a wide range of disorders, it is not surprising that there are many controversial issues surrounding NF. Some of the more frequently encountered ones are discussed next.

A. Need for Prior Diagnosis

As noted earlier, there is controversy within the field concerning the need for a thorough diagnostic

assessment prior to beginning NF. This relates especially to the need for a prior QEEG evaluation. Those who believe that NF's success depends on the training of specific sites and frequencies at which abnormalities exist insist upon prior QEEG data (usually in conjunction with a normative database). This is commensurate with the common medical practice of seeking specific underlying causes for specific disease conditions. In this model, the diagnostic data not only guide details of treatment but also can be used to evaluate treatment progress periodically in terms of normalization of the presumed underlying causes of the disorder (i.e., abnormal brain electrical activity). Advocates of the view that NF has more generalized effects, with positive results being mediated by facilitation of the brain's self-organizing ability, generally have little or no concern about prior QEEG data. Some attention may be given to site–frequency, but more in relation to ''canned protocols,'' which have been observed clinically to be the most effective for a given condition or syndrome. Proponents of the need for prior QEEG evaluation generally see their position as more defensible from a scientific point of view and fear that failure to require a thorough diagnostic workup will result in overlooking specific EEG differences underlying abnormal behaviors in many clients and failing to detect conditions that need referral for medical treatment. They emphasize that, even though QEEG assessments are expensive, all NF practitioners need these data and should either purchase and become trained in the correct use of QEEG equipment or contract with others who can provide these data that they consider essential. The ''canned protocol'' and general effects advocates often counter this with claims that they obtain equally positive results with no more side effects and at much less cost to their clients. However, they have not published scientific evidence for this. Certainly both sides should agree that it would be unethical and dangerous to initiate NF without some type of evaluation to help determine whether conditions exist that are known to be effectively treated with medication or other treatment modalities. Whether prior QEEG data is essential in this regard apparently remains to be determined.

B. Decreasing Treatment Time

NF practitioners are well aware of a need to shorten treatment time. The average 40–50 sessions now commonly employed limit the number of clients a practitioner can treat and the number who can afford treatment. It also brings criticism from cost-conscious insurance companies and from NF critics who may see it as a ''fleecing of the public.'' However, exactly how to shorten treatment time is controversial.

Some NF practitioners claim that they have found the ''answer'' to decreased treatment time for some given disorder in a specific site–frequency combination. Some have even obtained patents on their specific protocols. Some claim that factors such as speed of feedback (time between desired change in a specific EEG frequency and presentation of feedback) is critical and that providing an optimal time interval will speed treatment. Others emphasize differences in how accurately a feedback signal actually reflects a desired EEG change. For example, NF equipment that processes EEG signals digitally and in real time rather than by use of averaging techniques and the fast Fourier transform is said by some to allow increased accuracy of the match between raw EEG activity and feedback and, hence, facilitate faster learning and decreased treatment time.

Another frequently advocated way to decrease treatment time involves supplemental use of auditory–visual stimulation (AVS). It is well-known that exposure to a flashing light can entrain EEG activity to conform to the frequency of the flashes. This has led some NF practitioners to attempt to entrain EEG activity in a desired direction (e.g., increased β frequency) by presenting lights flashing at the desired frequency to their clients in conjunction with or prior to NF training. In some cases this has included simultaneously presented auditory stimulation of the same frequency and is referred to generally as AVS. An assumption often made is that such exposure may serve as a sort of prime to facilitate a client's learning to achieve voluntary control of a desired EEG frequency, i.e., elicitation of the particular frequency via AVS may enable the client to develop a ''sense'' of the state associated with the frequency and, thus, gain enhanced ability to achieve it again during NF. Some have tried variations such as using AVS that varies in frequency during the stimulation period, e.g., beginning at 13 Hz and gradually progressing to 20 Hz, or starting at 13 Hz, progressing to 20 Hz, and then returning to 13 Hz. Still others have used EEG-driven AVS in which equipment detects EEG peak frequency at a given electrode site and then continually adjusts the AVS stimulation up (or down) by some standard increment to entrain gradually higher or lower frequencies. Some of these latter procedures have been patented. There also have been attempts to

add rhythmic tactile stimulation to AVS, resulting in even broader multiple simultaneous sensory stimulation.

Although some research supports the contention that AVS can result in temporary EEG changes in targeted directions and several NF practitioners report being able to decrease the number of treatment sessions significantly by the use of AVS, there is controversy about its use. There have been isolated reports of seizures being induced by this method. However, this apparently is extremely unlikely in clients with no prior history of seizures, and its use has been approved for research by human subjects ethics committees in several major universities. A concern heard more often is that, like many medications, its effects are temporary, whereas NF results in enduring changes because the client is learning voluntary control of EEG rather than having changes imposed on it. Some critics of AVS see it as, at best, serving as an adjunct to NF in difficult cases in which initial learning of EEG control does not occur and/or during times of prolonged learning plateaus.

AVS has promise as a means of expediting NF progress. However, as with NF, there are a large number of variables needing to be investigated, e.g., the importance of color and intensity of the visual stimuli, sound wave features and intensity of the auditory stimuli, and the nature of presentation of stimuli [e.g., alternating between right and left eyes (and/or ears) or simultaneous].

C. Training Requirements

Few states regulate the practice of NF, yet it is being used with clients with a wide range of medical and psychological conditions. Many both inside and outside the field express alarm about potential dangers to the public when practitioners with minimal or no training in neurology or neuropsychology, or even general medicine or psychology, are treating persons with ADHD, depression, brain injury, and other conditions.

Sometimes this is without supervision from or collaboration with trained professionals who normally would treat such clients. Although BCIA certification requires considerable training and supervised experience, some consider it to be too little and advocate the establishment of one or more new certifying agencies with higher standards. Some suggest that two or three levels of certification should be established, with the PhD or MD degree and extensive neurofeedback training and experience required for the highest level. Opponents of higher standards sometimes note that undesirable side effects of NF are rare and that, although it may seem incredible (and threatening to established health care professionals), training beyond the bachelor's degree level is not necessary to practice the art of NF and higher standards would be unfair to lesser educated practitioners and to the many persons in need of NF treatment. Although most, if not all, groups currently providing NF training limit enrollment to those with master's level or higher degrees, the field has an unusually diverse group of professionals, including physicians, professional counselors, psychologists, physical therapists, chiropractors, social workers, and nurses. Whereas NF may be a very safe procedure and it may not be essential that its practitioners be knowledgeable about details of EEG dynamics, neuroanatomy, or psychiatric diagnoses, having rigorous certification standards likely would aid in gaining greater acceptance of the field by insurance carriers, other professions, and the general public.

D. Miscellaneous Issues

There is some controversy among NF practitioners about which site–frequency combinations should be used for specific syndromes. For example, even in the case of ADHD in which the increase β (or SMR)–decrease θ band amplitude protocol is used extensively, there are some who argue that decreasing θ is sufficient or that increasing only SMR (or β) or some narrower band within one or the other of those frequency bands is most efficient and speeds treatment. To the author's knowledge, however, these claims have not been supported by scientific research. An area of some disagreement among practitioners is whether the time of day of NF treatment needs to be matched to the individual client to conform to his or her unique biorhythms. This concern also has been voiced by some in regard to traditional medical treatments and seems worthy of further consideration. The importance of personality characteristics of the NF practitioner also is debated. It seems essential that he or she be empathic, patient, and highly skilled at motivating the client to put adequate effort into the task, e.g., knowing when to adjust EEG target and artifact thresholds to maintain an optimal reinforcement rate. These characteristics seem especially critical when working with children.

Criteria for when to terminate NF also are controversial. Some have advocated the cessation of treatment after only a few sessions if no desired changes in targeted EEG features are observed, whereas others recommend continuing through 50 or more sessions, trying various site–frequency combinations (or phase or coherence training) even if no EEG or behavioral changes are noted. The latter may cite cases in which a positive response occurred quite suddenly only after a very large number of sessions. There have been some attempts to provide specific guidelines for termination. Joel and Judith Lubar, for example, suggest termination when a client's learning curve plateaus for at least 2 weeks (or after a minimum of 25 sessions), there is approximation of normative age-based EEG criteria, and maintenance of a 50–70% reward level and 30–50% inhibit activity.

VI. FUTURE DIRECTIONS

The history of self-regulation of brain waves (neurofeedback) has had some wavelike characteristics itself. As noted earlier, the field rose rapidly in popularity and peaked in the early 1970s, followed by the trough of the late 1970s to mid-1980s. Now its popularity is rapidly rising, with no sign of cresting. This section includes speculation on whether NF's popularity will continue to rise until cresting and persisting at a level reflecting its true value or whether it will again crash (temporarily or permanently).

The scenario of steady growth and continuing popularity is likely if there are continuing reports of successful clinical use backed by credible research findings, favorable media coverage, and increasing acceptance by insurance carriers and managed care groups. A "crest and crash" scenario is likely if controlled research findings unfavorable to NF are published in prestigious journals and publicized in popular media outlets. Related to this, there is considerable concern among NF practitioners that laboratory research on NF will be so controlled as to be "sterile" in nature and preclude the positive results commonly reported by clinicians. Practitioners often state that it is the total treatment situation that yields positive results, i.e., client–therapist rapport, ongoing adjustment of electrode placement, as well as the EEG feature being trained. Many also fear that there will be bias in the large-scale, federally funded research being called for by some NF critics because researchers may be major stakeholders in the present health care system (e.g., drug companies, physicians) who stand to profit from continuation of the status quo. Relatedly, NF advocates often report a reflexive, negative response when the topic is mentioned to members of some other professions. Responses appear to range from skepticism to derision and often include automatic dismissal of claims of NF efficacy. Whether this situation stems from perceived threats to the health care status quo, perception of NF claims as incredible, lingering memories of early 1970s association of biofeedback with "flower children," and/or perceived lack of data to support claims, it impedes professional development of the field. Such attitudes by leading professionals in related fields and in university training programs need to be modified if the field of NF is to attract bright, young persons who could help insure its future development.

EEG biofeedback as a treatment method seemingly has "risen from the ashes" under the new title NF and is rapidly growing in popularity as a sole or adjunct treatment for an increasingly large number of disorders, many of which have been resistant to more traditional therapies. Whereas there are reports of near-miraculous results with minimal or no side effects, NF practitioners often express dismay that their results are dismissed by mainstream medicine, psychology, and education rather than embraced as evidence that treating abnormalities of the electrical aspects of the electrochemical functioning of the brain can be at least as effective as treating chemical imbalances. Considering the rapidly increasing scientific evidence for neural plasticity, central nervous system influence on immune system function, and a rhythmic basis for much transfer of information within the brain (time-binding theory), it does not seem unreasonable to expect that modification of aspects of central nervous system rhythms could have profound effects on health and learning rates. However, before becoming overly eager about the unique value of NF, advocates should consider that several other alternative medicine fields (e.g., chiropractic, nutrition) claim major and near-miraculous treatment successes for an equally wide range of disorders. Some of these, such as music therapy, also may be modifying basic central nervous system rhythms through entrainment or other means. If NF is to maintain its current popularity and grow in acceptance by other professions, it must be demonstrated through well-designed, nonbiased research to be not only an efficient treatment but a unique one that offers advantages beyond those of other available treatments.

Neuroglia, Overview

ANGUS M. BROWN and BRUCE R. RANSOM
University of Washington School of Medicine

GLOSSARY

astrocytes Neuroglial cells of diverse morphology and function located within the central nervous system.

enteric glia Neuroglial nonneuronal cells within the enteric nervous system.

microglia Neuroglial macrophage cells within the central nervous system.

neuroglia Nonneuronal cells located within the nervous system.

oligodendrocytes Neuroglial cells that myelinate axons within the central nervous system.

Schwann cells Neuroglial cells that myelinate axons within the peripheral nervous system.

This article provides an overview of glial cells, highlighting the distinct types of glial cells and describing their individual properties and functions, with a slant toward ongoing research in the authors' laboratory.

I. INTRODUCTION

Virchow initially described glial cells in 1846 as cellular elements that filled in the spaces between neurons but were distinct from neurons. Dieters further defined the description of glial cells in 1865 as cells that did not possess an axon. The concept that glial cells were a heterogeneous population of cells was realized by Golgi, who developed a technique of staining cells that allowed details of cellular morphology to be closely scrutinized. Golgi's studies indicated that glial cells had variation in their morphologies and led to subsequent subclassification of glial cells. Glial cells in fact outnumber neurons in a ratio of 10:1 and constitute 50% of the cellular volume of the central nervous system (CNS; not more than 50% because of their relatively smaller size compared to neurons).

The implication that glial cells act as a form of inert Styrofoam packing between neurons became an entrenched idea from these initial studies, and it is only within the last two decades that the true range and diversity of glial cell function have been fully realized. The impression of glial cells as inert entities with a purely supportive role in part may have arisen during the pioneering electrophysiological work in the 1930s to 1950s, when all interest was focused on cells that were electrically excitable and could fire action potentials. Because glia are incapable of firing action potentials, there was relatively little interest in them. It was not until the 1960s that the studies of Steven Kuffler suggested that glial cells, although incapable of firing action potentials, did indeed have specific roles in the nervous system. It is now realized that neurons cannot function as they should without normally functioning glial cells in close proximity. Under normal conditions there is a steady flow of information between neurons and glia. Glial cells are equally important under pathological conditions in the CNS.

They can contribute to the pathology, for example, by adding the excitotoxin glutamate to brain extracellular space (ECS) or potentially limit injury by minimizing ionic changes in ECS or providing energy substrate to neurons, which do not possess any internal energy stores. Thus, to understand pathological processes it is necessary to understand the glial reactions to the pathology. Current research on glial cells indicates that new properties and functions are still being assigned to them.

II. CLASSIFICATION

The classification of glial cells originally was based entirely on their morphological characteristics and dates back almost 150 years. Since then, additional techniques such as cell-specific proteins, electrophysiology, ultrastructural features, immunocytochemistry, and fluorescent imaging have been used to refine the classification of glia. Andreizen in 1893 first described two types of glial cells, fibrous and protoplasmic, a classification endorsed by Cajal in 1913. The initial characterization of glial cells was carried out by using light microscopy, but the advent of improved staining techniques at about the turn of the century accelerated the distinction of different cell types. It is now widely recognized that glial cells fall into the following categories: astrocytes, oligodendrocytes, and microglia in the CNS, Schwann cells in the PNS, and enteric glia in the gut. Astrocytes and oligodendrocytes are derived from neuroectoderm and are sometimes considered together as macroglia. The main functions of these cells can be categorized as follows: myelination of axons (oligodendrocytes in the CNS, Schwann cells in the PNS), maintenance of ionic and neurotransmitter stability of the brain's extracellular microenvironment (astrocytes), nurturing neurons (astrocytes), and acting as the CNS macrophages (microglia). Each cell type will be described in detail later in this article, however, a few brief words about the common features of glial cells are needed. One feature in which glial cells differ from neurons is their intercommunication. Neurons generally communicate at chemical synapses, where individual neurons use neurotransmitter molecules released into the synaptic cleft between the neurons as mediators of communication. Glial cells, especially astrocytes and oligodendrocytes, directly communicate with each other via gap junctions. Gap junctions are formed from protein molecules called connexins. These aggregate into transmembrane hexamers called connexons and fuse with connexons on the membranes of adjoining cells, forming large pores that allow the passage of substances up to 1 kDa in weight. In this way, glial cells can communicate directly and allow rapid intercellular transport.

III. ASTROCYTES

A. Anatomy

Astrocytes were originally described as filling the gaps between neurons. However, Golgi described in detail the morphological distinction between cell types in the CNS. Astrocytes can be divided into three groups: fibrous and protoplasmic astrocytes and radial glia. The latter cells project from the ventricular surface to the pial surface and are mainly prominent during early development. Fibrous astrocytes are located almost exclusively in white matter and have long, radially distributed processes that often terminate as end feet on capillaries. Protoplasmic astrocytes are located in gray matter and are characterized by short bushy processes; these processes also form vascular end feet. The three different types of astrocyte share common properties, including the synthesis of glial fibrillary acidic protein (GFAP). This protein is easily recognized in electron micrographs because it forms paired helical filaments, so-called intermediate filaments.

Astrocytes form connections with other astrocytes via gap junctions, and this allows intercellular communication that directly links the cytoplasm of the astrocytes. Neuronal communication, by comparison, is primarily mediated by chemical synapses. Gap junctions have a pore about 2 nm in diameter and couple astrocytes together into a syncitium, which allows the passage of all inorganic ions and small organic molecules up to 1 kDa. The use of dye injection into astrocytes allows an estimation of the extent to which the cells are coupled. The channels comprising gap junctions are large pores that extend from one cell across the extracellular space (ECS) into an adjacent cell. Each connexon hemichannel is composed of six symmetrical subunits (connexins). There are several different types of connexin, but the most common type in astrocytes is connexin 43. A gap junction is formed when a connexon from one cell aligns with a connexon from another cell. Gap junctions open and close abruptly, and the conductance varies between 50 and 150 pS depending on the type of connexin. Gap

junction openings are affected by transjunctional voltage and are decreased by increases in intracellular pH, Ca^{2+}, or octanol.

A striking feature of astrocyte morphology is the end feet surrounding capillaries. This morphology initially suggests that all substances in the blood must pass through astrocytes before being passed on to neural elements via the ECS. The astrocytic end feet do not represent a tight barrier, however, and substances that have passed the capillary endothelium (which is a tight barrier) can diffuse directly into brain extracellular space without passing through astrocytes. This notwithstanding, there is growing evidence that glucose and perhaps other blood-borne substances are taken up by astrocytes. Astrocytes possess glucose transporters, which would allow the movement of glucose from blood vessels directly into the capillaries. In the extreme, this would require that all neuronal nutrition be mediated via astrocytes (i.e., all glucose, the principal fuel of the brain, would go first to astrocytes). In actuality, some glucose undoubtedly bypasses the astrocytic end feet and diffuses directly to neurons, but astrocytes do provide fuel to neurons, probably in the form of lactate (see later discussion).

Astrocytes also seem to surround synapses and have been proposed as the main site of neurotransmitter uptake after synaptic activity. Astrocytes contain a variety of neurotransmitter transport mechanisms that are not found on neurons, in addition to enzyme systems that are capable of metabolizing neurotransmitters to more manageable inert compounds for transport back to neurons, where they are recycled back into the active neurotransmitter.

B. Function

Astrocytes share a common ECS with neurons, and virtually every neuron in the brain has a large percentage of its membrane immediately adjacent to astrocyte membrane. This situation lends itself to a role in regulating the ionic and/or chemical stability of extracellular fluid, which is necessary for normal neuronal function. In this capacity, it is true that astrocytes function to maintain constant ionic concentrations in the extracellular space by buffering K^+ and H^+, as well as by removing neurotransmitters. The membrane of astrocytes contains many transport and exchange mechanisms that allow the movement of ions into astrocytes. Astrocytes are the ideal cell type to buffer K^+ ions. K^+ accumulates extracellularly after neuronal activity, with the degree of activity determining the degree of K^+ elevation. It is thought that a single action potential can raise K^+ by as much as 1 m*M* in localized areas. After intense activity, $[K^+]_o$ can rise from a baseline level of 3 m*M* to about 12 m*M*, the so-called ceiling level. This ceiling level for $[K^+]_o$ is only breached with spreading depression and under pathological conditions such as trauma or ischemia, where concentrations of 60 m*M* or more may be recorded. There is some controversy as to how extracellular K^+ is removed or "buffered" during neural activity, but likely candidates include K^+ channels, Na^+ K^+ ATPase, and anion transporters such as the $Na^+K^+2Cl^-$ cotransporter. Once K^+ enters astrocytes, it can be dispersed via gap junctions to distant astrocytes and then released back into the ECS as levels return to normal (ultimately, of course, the neurons that released the K^+ in the first place must reaccumulate what was lost; see Fig. 1). Extracellular pH also changes with neural activity, and astrocytes have a unique transporter, the $Na^+HCO_3^-$ cotransporter, that helps to regulate this important ion level.

Astrocytic membranes contain neurotransmitter transporters. During neuronal activity synaptic neurotransmitters would rapidly build up if they were not sequestered intracellularly or metabolized

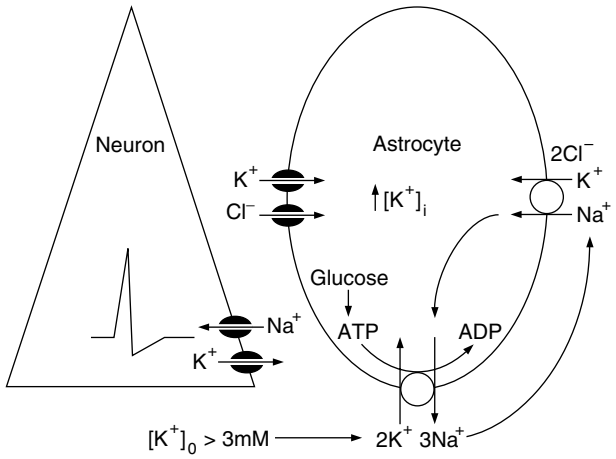

Figure 1 Schematic representation of mechanisms of K^+ uptake in astrocytes. K^+ released by active neurons is actively accumulated by astrocytes in three ways. The sodium pump and an anion transporter both take up K^+. The sodium pump relies directly on the availability of ATP, whereas the anion transporter is indirectly powered by the energy stored in the transmembrane Na^+ gradient. The presence of channels for Cl^- and K^+ allow Donnan forces to produce KCl influx. These mechanisms, along with K^+ spatial buffering (see text), prevent $[K^+]_o$ from exceeding $\sim$12 m*M*. Increases in $[K^+]_i$ are seen during neural activity as $[K^+]_o$ increases.

extracellularly. The most common excitatory CNS neurotransmitter is glutamate. Astrocytes take up ~90% of the glutamate released at synapses via two specific glutamate transporters called GLT1 and GLAST. The energy for this transport is provided by the transmembrane Na^+ gradient (see Fig. 2). Once inside the astrocyte the glutamate is converted to glutamine by the astrocyte-specific enzyme glutamine synthetase, resulting in the dephosphorylation of one molecule of ATP. The glutamine is shuttled out of the astrocyte and into the neuron by the glutamine transport protein, where it is converted back into glutamate by the enzyme glutaminase. Similar mechanisms exist for the uptake of the major inhibitory CNS neurotransmitter, GABA.

A major function of astrocytes is as an energy store. The full importance of this function is just being realized. Astrocytes are the only cells in the CNS that store glycogen, and as such astrocytes are the only cells in the CNS with energy stores. Glycogen is formed from glucose within astrocytes via the intermediary compounds glucose 6-phosphate, glucose 1-phosphate, and UDP-glucose in a reaction requiring ATP. Once glucose enters astrocytes it is immediately phosphorylated to glucose 6-phosphate, but the lack of the enzyme glucose-6-phosphatase, which converts glucose 6-phosphate to glucose, determines that glucose is not transported out of astrocytes. Glycogen is broken down to glucose by action of the enzyme glycogen phosphorylase. Thus, there is equilibrium between glucose and glycogen. In periods of high glucose the equilibrium favors the formation of glycogen (glycogenesis), and during periods of low glucose the equilibrium favors the breakdown of glycogen to glucose (glycogenolysis). It has been proposed that astrocytic glycogen can act as an energy source for neural elements in both gray and white matter during periods of energy deprivation.

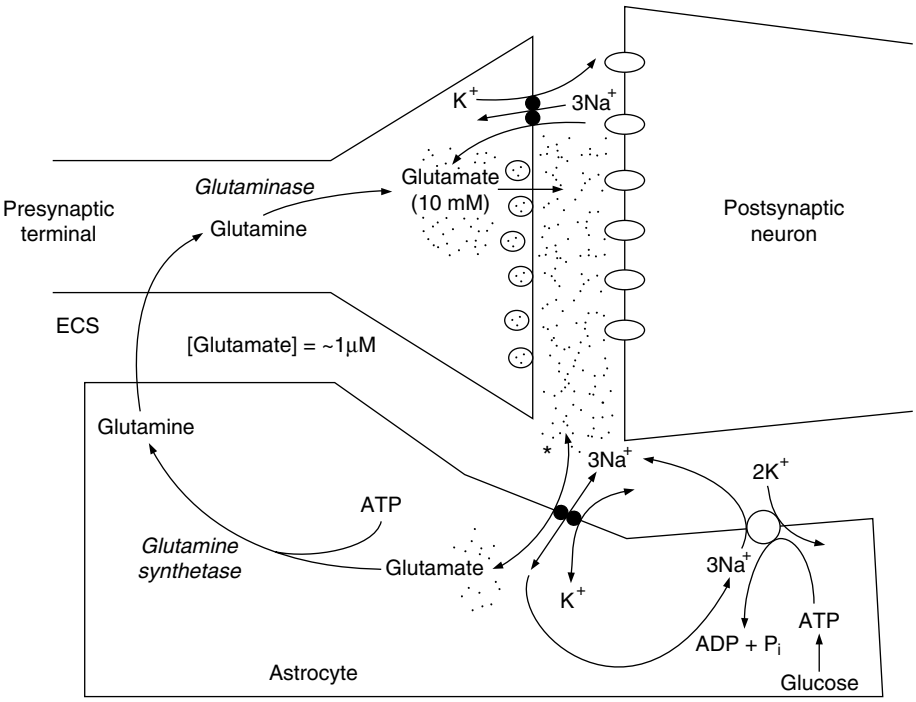

Figure 2 Scheme showing how astrocytes are involved in glutamate metabolism and uptake. Only astrocytes contain the enzyme glutamine synthetase, which converts glutamate to glutamine in an ATP-requiring reaction. Glutamine is transported to nearby presynaptic terminals, where it is converted to glutamate for synaptic release. Finally, the released glutamate is recaptured by astrocytes via a high-affinity glutamate uptake system. Although glutamate transporters are present in neurons, astrocytes are the most active in removing glutamate (see text). In the absence of the normal transmembrane Na^+ gradient maintained by the ATP-dependent Na^+ pump, the glutamate transporter ceases to remove glutamate and can run in reverse so that it pumps glutamate into the ECS.

Astrocytic glycogen is broken down to lactate, which is easily shuttled out of the astrocyte via the monocarboxylate transporter MCT1 and into the neuron–axon via the monocarboxylate transporter MCT2, where it is converted to pyruvate and incorporated into the citric acid cycle to yield ATP (see Fig. 3). Neurons in gray matter and axons in white matter are sustained by lactate as well as by glucose.

C. Lineage

There appear to be two separate pathways that result in the formation of astrocytes. The first pathway suggests that astrocytes are produced by immature cells of the ventricular zone but must temporarily pass via a radial glial cell intermediary. The other pathway proposes that astrocytes are direct descendants of immature cells in the germinal zones and do not pass via a radial cell intermediary stage. The first pathway results in response to epidermal growth factors and is separate from oligodendrocyte lineage. The second pathway shares a common progenitor with oligodendrocytes. The nature of astrocyte maturation seems to indicate that two separate pathways can produce the same cell, and although there are regional differences between astrocyte morphology, it is not known whether this is as a result of the maturation phase.

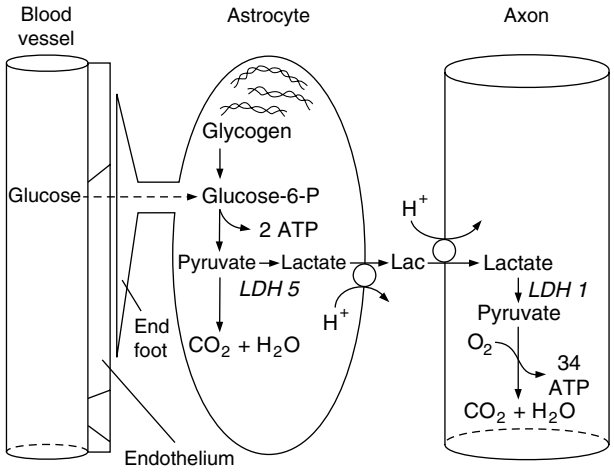

Figure 3 Schematic illustration of how astrocytic glycogen appears to fuel axons in the absence of glucose. Blood glucose first encounters astrocytic end feet as it is transported into the brain. In the absence of glucose, astrocytic glycogen is broken down into lactate, which is transported to the extracellular space via a monocarboxylate transporter (MCT). It is then taken up by a MCT in axons and is oxidatively metabolized to produce the energy needed to sustain excitability. LDH5 preferentially reduces pyruvate to lactate, whereas LDH1 preferentially oxidizes lactate to pyruvate. This scheme recognizes that astrocytes can subsist, at least transiently, on glycolytic energy metabolism, whereas axons require oxidative metabolism.

D. Physiology

The membrane of astrocytes contains a variety of neurotransmitter transporters, ion channels, and gap junctions. The neurotransmitter transporters act to clear the ECS of neurotransmitters, which accumulate during electrical activity. The continued presence of neurotransmitters in the ECS could lead to cell death by increased intracellular Ca^{2+}, e.g., glutamate. Alternatively, the sustained presence of GABA may lead to prolonged inhibition of cells. Astrocytes also contain a variety of ion channels. Although Na^+ channels are present, they are not present in sufficient density relative to K^+ channels to cause action potentials. Multiple K^+ channels are present and because astrocytes are almost exclusively permeable to K^+ at rest, they act as K^+ electrodes and the resting membrane potential is dictated almost exclusively by the transmembrane concentration of K^+ ions. As such, astrocytes are exquisitely sensitive to changes in extracellular K^+ concentration, and changes in this concentration due to increased neuronal activity are immediately sensed by astrocytes. Astrocytes also contain Ca^{2+} channels, but there has been controversy about whether Ca^{2+} channels are present *in vivo*. In cultured astrocytes and in astrocytes studied after having undergone trauma, Ca^{2+} channels have been shown to be present. However, one study could find no evidence of Ca^{2+} channels present *in vitro*, suggesting instead that increased intracellular Ca^{2+} occurred due to the activation of metabotropic glutamate receptors. These data suggested that the presence of Ca^{2+} channels in previous studies was due to up-regulation of Ca^{2+} channel expression induced by culture conditions or injury. However, technical limitations have made answering this question difficult. Patch clamp recordings suffer from the effects of space clamp induced by the gap junctional dissipation of current. However, a study using electrophysiological techniques and antibodies directed at Ca^{2+} channel subunits indicated that nifedipine-sensitive L-type Ca^{2+} channels are present on both astrocytes and axons in the adult rat optic nerve.

IV. SCHWANN CELLS

A. Anatomy

Schwann cells surround all axons in the peripheral nervous system either by forming channels that are contiguous with the axonal membrane or by wrapping myelin around the nerves. Peripheral nerves are composed of an outer epineurium, which is composed of blood vessels, connective tissue, and fibroblasts, a perineurium, which is composed of flattened cells surrounding the nerves, and the intrafascicular endoneurium, which contains supportive cells and the ECM that surrounds bundles of nerve fibers. The supporting cells include the Schwann cells that ensheath the axons, fibroblasts, and vascular elements. The perineurial cells form a diffusion barrier that isolates the endoneurium from the connective tissue of the surrounding epineurium.

B. Function

The function of Schwann cells is to provide myelin and a suitable environment for peripheral axons. Schwann cells can be divided into two classes: the ensheathing Schwann cell and the myelinating Schwann cell. It is the axons that determine whether a Schwann cell will become ensheathing or myelinating. This was shown by studies in which unmyelinated nerves were incubated with ensheathing Schwann cells, which subsequently differentiated into myelinating Schwann cells. Both types of Schwann cell originate from a common precursor, the neural crest cell, and they can be identified by expression of the calcium-binding protein S-100. The majority of ensheathing Schwann cells are associated with unmyelinated axons of DRG neurons and the myelinated efferent sympathetic axons of autonomic ganglia. There is a basal lamina surrounding each axon–Schwann cell unit, which provides both the structure and flexibility required for axonal function. In addition to this function, Schwann cells also form a myelin sheath around selected axons. This process occurs by separation of the axon from its neighbors, and a one-to-one relationship between axon and Schwann cell occurs. The Schwann cell envelops the axons during myelination, forming a very tight wrapping around the axon. The diameter of the myelin sheath is proportional to the diameter of the axon it myelinates, resulting in the optimal conduction velocity of the axon. The length of myelin provided by one Schwann cell is between 250 and 1000 μm and is separated from the adjacent segment by the node of Ranvier. The nodes are interspersed to give optimal conduction velocity. The node has a high density of Na^+ channels, which produces the upstroke of the action potential. The repolarizing K^+ channels are spread more evenly along the axons and can be found underneath the myelin. Schwann cells have a small cell body located at the midpoint of the length of the cell.

1. Regulation of Nerve Development

Schwann cells have been shown to regulate nerve development. In Erbb3– mice the survival of neuronal populations, including DRG neurons, depends on trophic factors released from Schwann cell progenitors and immature Schwann cells. Candidates for this function are glial cell line derived neurotrophic factor (GDNF) and a related compound, neurturin. GDNF mRNA is found in Schwann cells and it is essential for motorneuron survival. Neurotroph 3 (NT3) is a possible candidate. It is formed by Schwann cells at birth and promotes survival and differentiation of early sensory neurons. Thus, NT3 seems to support DRG neurons. Additionally, DHH may help form fibroblasts, and Schwann cell survival and MAC may support axonal architecture.

2. Repair of Axons

Schwann cells have been implicated in the repair of axons after injury. One of the major differences between peripheral and central axons is that the peripheral nerves will regenerate to a large degree whereas central axons seem unable to do so. This accounts for the devastating injury seen in patients whose central axons have been damaged, e.g., spinal cord trauma and multiple sclerosis. In the peripheral nervous system, cut axons can sprout and these sprouts elongate and reconnect with the correct targets. In the CNS, axons sprout but cannot advance to their original targets; thus, regeneration fails. In the peripheral nervous system the neurotrophins NGF, NT3, and BDNF show beneficial effects on the survival of axons, and these are also released from Schwann cells. More recent studies have indicated that peripheral nerves can be used in the regeneration of central axons. In the spinal cord, injection of Schwann cells into the site of injury is a promising strategy to aid regeneration.

C. Lineage

The majority of Schwann cells in the peripheral nervous system originate from neural crest cells, as do satellite cells, the other main type of glial cell in the PNS. The neural crest comprises a multipotent population of cells that arises from dorsal areas of the neural tube during development. The cells disperse through distant pathways in the mesenchyme and differentiate to form a variety of cell types. It has been shown that the progenitor neural crest cells can give rise to more than one cell type and that at some point in their differentiation the cells "decide" which way to differentiate. In order to understand this process of lineage choice, it is important to understand the effect of extrinsic signals on lineage outcome. In order for developing Schwann cells to survive, they must associate themselves with a developing peripheral nerve. This is likely to happen in the anterior parts of neural tube where both neural crest cells and peripheral axons are directed, and therefore they end up in the same place at the same time. These immature cells invade and ensheath bundles of developing axons, a process called radial sorting. They then differentiate into myelinating and nonmyelinating Schwann cells. It is not known whether the ultimate lineage of the cells is determined by the axons or whether the crest cells' lineage has already been decided prior to the meeting of cells and axons. There is evidence that the neural crest cell lineage is predetermined prior to meeting with the axons. Neural crest cells express the gene for the peripheral myelin protein P_o in small quantities prior to meeting the axon. However, once the cone is in contact with the axons, the expression of P_o is unregulated. Thus, expression of P_o may indicate cells that have entered Schwann cell lineage.

When do Schwann cell precursors give rise to Schwann cells? In rat sciatic nerve the phenotype of cells is determined between day E14 and birth. Cells from days E14 and E15 do not survive more than 20 hr in routine culture medium when removed from the nerve, but cells removed from nerves E17 and older survive. This suggests that at E14–E15 the nerve contains precursors, whereas at day E17 immature Schwann cells are present. To support this theory, nerves at day E16 contain both cell types.

Thus, it appears that Schwann cell development occurs by the following process. Neural crest cells form two main intermediates: the Schwann cell precursor found in rat nerves aged E14–E15 and the immature Schwann cells, which are present from E17 to birth. At birth the cells start to differentiate and form mature Schwann cells, of which there are two types: myelinating and nonmyelinating. It appears that the embryonic phase of development is controlled by a single signal, NRG-b. This substance is found in the membrane of axons, and it is likely that survival of Schwann cells is controlled by release of this substance from axons associated with the Schwann cells. High concentrations of NRG mRNA are found in the motor neurons of the ventral horn of the spinal cord and in DRG neurons, the two major sources of axons in the embryonic peripheral nerves.

Schwann cells, however, also provide support for peripheral neurons. Mice deficient in the NGR receptor ErbB3 have about 80% cell death by E18. This indicates mutual dependence between developing neurons and Schwann cells, in which the survival of the Schwann cell depends on NGF released from the axon and neuronal survival depends on an as yet unidentified precursor-derived signal.

D. Physiology

Until the advent of the patch clamp technique in the early 1980s, Schwann cells were thought to be electrically passive. This advance in technology revealed the possible presence of voltage-gated ion channels on Schwann cells. It has since been shown that Schwann cells from a variety of preparations express a wide range of ion channels, including Na^+ channels, K^+ channels, Cl^- channels, Ca^{2+}-dependent K^+ channels, and Ca^{2+} channels. The role of these channels in Schwann cells remains unclear, as the conventional role for Na^+ and K^+ channels, i.e., action potential conduction, obviously does not occur. It is thought that the role of the channels is more likely to be the maintenance of normal function of both the Schwann cell and the extracellular ionic milieu. K^+ channels may play a role in cell proliferation, as inhibition of K^+ current leads to a decrease in Schwann cell proliferation. Specifically, it is the TEA, 4-AP-sensitive, type 1 K^+ channel that appears to be involved in proliferation, as inhibition of the type 2 K^+ channel with dendrotoxin had no effect on proliferation. Ca^{2+} channels have been located on Schwann cells but their function remains unknown. To date it appears that only L- and T-types have been located in Schwann cells, but it is difficult to categorize these channels types without the use of antibodies directed at specific α_1-subunits. It appears, however, that Ca^{2+} channels are unregulated by neighboring DRG cells. Neuronal

activity in DRG cells results in the up-regulation of Ca^{2+} channels in cultured Schwann cells; presumably the DRG neurons release a diffusible factor that acts on Schwann cells.

Schwann cells have been implicated in Charcot–Marie–Tooth disease, a common inherited heterogeneous group of peripheral neuropathies. This disease is usually inherited as an autosomal dominant disorder, although recessively inherited forms do occur less commonly. Charcot–Marie–Tooth (CMT) disease is associated with severe demyelination of peripheral nerves, which results in greatly slowed conduction velocities in the nerves and results in muscle dysfunction and atrophy. It is a slowly progressive disease, and patients may ultimately become unable to walk. The most frequent form of the disease CMT1, designated CMT1A, is caused by abnormalities of one of several genes expressed in Schwann cells. The majority of cases have been shown to be associated with duplication in the p11–p12 region of chromosome 17, which contains the peripheral myelin protein 22 (PMP22) gene, which encodes one of the major PNS myelination proteins. A less common form of CMT1 (CMT1B) is caused by mutation in the protein zero gene (P0), which encodes the major PNS myelin structural protein. Point mutation in the early growth response gene 2 (EGR-2) of Knox 20, which is expressed in Schwann cells, has been implicated in the autosomal dominant form of CMT1. An X-linked form of CMT (CMTX) is caused by mutations in the connexin 32 gene, which is expressed in myelinating Schwann cells. CMT leads to axonal degeneration, which results in the clinical phenotype of the disease. This is analogous to the axonal dysfunction seen in the CNS in multiple sclerosis pathology.

V. OLIGODENDROCYTES

A. Anatomy

Oligodendrocytes are the cells in the CNS that manufacture and maintain myelin, and as such they play an analogous role to the Schwann cells in the PNS. Hortega characterized oligodendrocytes in the 1920s using silver carbonate impregnation techniques. Not only did Hortega offer the first detailed morphological description of these cells, he also implied their role in myelination. Whereas oligodendrocytes are classified as a single cellular entity, they display a great degree of polymorphism. They are distributed throughout the entire CNS but are most prominent in white matter areas. They tend to be lineated in one of three ways: (1) aligned in rows along nerve fascicles, (2) juxtaposed against neuronal somata, and (3) abutting blood vessels. On the basis of these lineations, Hortega classified oligodendrocytes as interfascicular, perineuronal, and perivascular. In addition to categorizing oligodendrocytes on the basis of lineation, Hortega classified oligodendrocytes into four groups on the basis of morphology. Type 1 oligodendrocytes have spherical somata from which numerous processes project toward nerve fibers. Type 2 oligodendrocytes are located exclusively in white matter areas and have a cuboid cell body shape, with fewer and thicker processes associated with nerve fibers. Type 3 oligodendrocytes have only three or four processes emerging from the somata extending toward nerve fibers. Type 4 oligodendrocytes occur near the entrance of nerves into the CNS and adhere directly to nerve fibers. Improved staining technology using intracellularly injected dyes has increased morphological resolution and provides a more detailed picture of oligodendrocytes. In addition to improved intracellular staining techniques, specific markers for oligodendrocytes have been developed, of which antimyelin basic protein is one of the most commonly used.

B. Function

The function of oligodendrocytes is to ensheath axons with myelin and to both support myelin production and ensure that it myelinates axons in the optimal fashion. Myelin is essential for action potential conduction and acts to increase the speed of action potential firing. Immature axons are premyelinated and separated into groups by primitive sheetlike glial processes from immature undifferentiated glial cells. This gives way to more organized wrapping of the axons with myelin by the oligodendrocytes. The myelin sheet extends from oligodendrocytes and is connected to the cell body via only a very thin process. During the process of myelination, the oligodendrocyte cell body remains stationary and the myelin sheet wraps around the axon. The myelin sheet is assembled at the local level as it sits close to the axon during the ensheathing process. There are several points to bear in mind about myelination. Oligodendrocytes myelinate more than one axon and can myelinate axons of different diameters. Despite a common cell body, myelin sheaths that myelinate large-diameter axons

are thicker than myelin sheaths myelinating small-diameter axons. At the time of myelination it appears that axons secrete molecules at the site of myelination that control the behavior of myelinating oligodendrocytes. The process is not fully understood, but it appears that there is an increase in the intramembranous particles (IMPs) on the protoplasmic side of the axon membrane. This occurs during the initiation of myelination and has been hypothesized to be the promoter of myelination.

Multiple sclerosis is a condition that occurs due to demyelination of central axons. The white matter lesions that define this disease are visible by T2-weighted MRI. The condition is due to an autoimmune inflammatory response that results in focal lesions in the CNS. The condition starts with an increase in the permeability of the blood–brain barrier in association with inflammation. The area of abnormality increases over a period of several weeks but then diminishes, leaving a scar that may be gliotic or may exhibit axon degeneration. Function decreases in tandem with the increasing lesion size, but then returns completely as the lesion diminishes. However, over time the attacks recur and function diminishes. Lesion sites have been shown to contain expanded extracellular space due to the loss of axons. This loss of axons results in dysfunction that can lead to limb paralysis and the eventual inability to walk. The potential for treating multiple sclerosis is determined by two main factors: remyelination of axons and replacement of dead axons. The first area is a subject of intense research, with stem cell transplants appearing to offer the best chance of success. Injection of immature oligodendrocytes into rat brain has indicated that they are capable of remyelination, but direction of this process remains a problem. Axon death can be countered by devising neuroprotective strategies for axons during acute attacks. In this it is similar to neuroprotective strategies during ischemic stroke. The advantage in the case of multiple sclerosis is that the attacks when axons die are clinically apparent, and thus therapy could be timed to coincide with attacks.

C. Lineage

Oligodendrocytes develop from migratory, proliferating progenitor cells called O-2A progenitors. These cells develop from neuroepithelial cells in the walls of the embryonic neural tube. Two markers are used to identify oligodendrocyte precursor cells: the chondroitin sulfate proteoglycan NG2 and platelet-derived growth factor α receptor (PDGFαR). PDGFαR-positive cells show a distribution similar to that of NG2+ cells. NG2+ cells are first detected in the developing ventral spinal cord at E14 and are found in the hindbrain and within the basal forebrain by E16. At birth NG2 cells are distributed widely in the CNS, indicating a rapid increase in cell distribution. From E17 to birth, all cells positive for NG2 also express PDGFαR, strongly suggesting that NG2+ cells are markers for oligodendrial precursors. *In vivo* NG2+ cells form oligodendrocytes, but in tissue culture these cells can also form astrocytes as well as oligodendrocytes. However, there is no evidence that this occurs *in vivo* and it may be an artifact of the culture conditions. It has also been shown that NG2+ cells persist in the mature CNS, indicating that not all of the NG2+ cells form oligodendrocytes but may have some additional function. However, the question remains whether these NG2+ cells are a separate cellular entity than oligodendrocytes. NG2+ cells in the mature CNS have a complex morphology, which is different from that of oligodendrocytes. They have highly irregular cell bodies from which fine branches radiate. In gray matter NG2+ cells lie closely apposed to neuronal cell bodies, whereas in white matter NG2+ cells are tightly packed between myelinated axons and have elongated cell bodies. These NG2+ cells are slowly dividing and have been implicated as having a role to play during remyelination. There are increased numbers of NG2+ cells at lesion sites, and there is limited evidence that these cells form new remyelinating oligodendrocytes. There is also evidence that separate progenitor cells may give rise to oligodendrocytes. These cells are characterized by the expression of plp/dm-20, and during development evidence exists that plp/dm-20 expressing cells differentiate into oligodendrocytes and that these plp/dm-20 precursors do not depend on PDGFαR to proliferate, as they do not appear to be precursors of PDGFαR progenitors.

D. Physiology

Despite having a common lineage with astrocytes, oligodendrocytes exhibit different ion channel distribution, most likely due to the different functional properties of each cell type. The mature oligodendrocyte expresses an inwardly rectifying K^+ channel, which constitutes the predominant ion channel in differentiated oligodendrocytes *in vitro*. This channel

has a conductance of 29 pS. Mature oligodendrocytes never express voltage-activated Na^+ channels, which are lost at an early stage of maturation. However, mature oligodendrocytes do express a tetrodotoxin-sensitive, voltage-independent Na^+ channel that is activated by acidification. Stepping of pH from 7.9 to 6.7 induces a large, slowly inactivating current that is potentiated by reducing ambient $[Ca^{2+}]_o$. A functional role for this channel has not been established.

VI. MICROGLIA

A. Anatomy

Microglia can be present in three states: resting, activated, and phagocytotic. The morphology of microglia differs from that of other glial cells in that it changes in response to the CNS perturbations. Thus, under normal conditions microglia are in the resting state, but they will become activated or phagocytotic in response to CNS injury and will invade the CNS. These changes in morphology are intimately linked with microglial function, as will be discussed later. The first selective stain for microglia was silver carbonate developed by Rio Hortega and, although unreliable, was the standard method for 50 years. The most reliable current histochemical staining method for identifying resting microglia uses the enzymes thiamine pyrophosphatase and nucleoside diphosphatase. Activated microglia can be distinguished from resting microglia in that they exhibit increased activity of enzymes that are absent from resting microglial cells. These enzymes include acid phosphatase, 5′-nucleotidase, oxidoreductase, nitric oxide synthase, lysosomal proteinases, plasminogen activator, lysozyme, purine nucleoside phosphorlyase, and elastase. However, these enzymes are not specific markers for activated microglia because they are found in other glial cells. Resting microglia can be distinguished both by their unique morphology and by their phenotype. Morphologically they have highly branched processes, a small amount of perinuclear cytoplasm, and a small, dense, and heterochromatic nucleus, and they can be positively distinguished as the only cells that express the CR3 complement receptor. At the ultrastructural level they are recognizable as true parenchymal constituents of the nervous system, i.e., they are located outside of the vascular basement membrane. Microglia are not a homogeneous cell population throughout the brain because their morphology varies with brain area. Specifically, in gray matter areas of the brain, resting microglia tend to be profusely ramified with processes extending in all directions, whereas resting microglia in white matter align to their cytoplasmic extensions in parallel but also at right angles to nerve fiber bundles.

B. Function

Microglia are the brain macrophages that respond to a variety of CNS injuries. There are three states of microglia: (1) resting, which are highly ramified cells, (2) activated microglia, which are cells responding to injury with morphological (enlarged cell bodies, contraction of processes) and immunophenotypic changes as well as proliferation, and (3) phagocytic microglia, which are full-blown brain macrophages with amoeboid morphology and expression of a number of immunomolecules. Activated microglia retract their processes followed by a rounding of the cell body. This is accompanied by increased expression of complement receptor 3. MHC class I and II antigens are upregulated on the microglial cell surface, which enables the microglia to interact with immunocompetent cells such as T-cells. Once activated, phagocytic microglia are able to remove debris. The phagocytic microglia invade the area of damage and appear over a period of days, depending on the nature, severity, and location of the CNS damage. However, the process of debris removal can take from days to many weeks. This is in contrast to damage in the PNS, where macrophages have cleared debris within 2 weeks. As well as having a role in acute CNS injury, microglia may also play a role in neurodegenerative diseases such as Alzheimer's disease and Parkinson's disease. These conditions are characterized by the selective loss of neurons in distinct areas of the brain, areas in which microglia are activated. In Alzheimer plaques containing amyloid-β protein, microglia are present in the center of these plaques. It has been shown that amyloid-β protein precursor can activate microglia, which may act to enhance their toxicity.

Microglia are also involved in CNS autoimmunity and are activated by inflammatory signals such as LPS and interferon. Microglia are involved in HIV encephalitis, and although it is not clear how HIV interacts with microglia, it is thought that the HIV virus enters the CNS parenchyma hidden in infected monocytes and may subsequently spread to microglia.

C. Lineage

The origin of microglial precursors is a controversial issue with two camps claiming distinct origins.

1. Microglial cells are of mesodermal origin.
2. Microglial cells originate from neuroepithelial cells.

The first view is supported by the majority of researchers, who believe that microglia derive either from monocytes that leave the blood and colonize the nervous parenchyma or from primitive hemipoietic cells (stem cells) that differentiate into microglia within the CNS. The evidence for each group can be summarized as follows. Evidence that microglial cells are of mesodermal origin is based on the fact that microglial cells and cells of monocytic lineage share common features, including the enzymes nucleoside diphosphatase, nonspecific esterase, and acid phosphatase. Additionally, both cell types contain vault particles and are labeled by several lectins. Antibodies have been developed that recognize both cell types in a variety of species. Ink- or carbon-labeled monocytes injected into the blood stream of newborn rats are incorporated into ramified microglia in adult animals, suggesting that microglia originate from monocytes that enter the nervous parenchyma via the blood stream. These findings together with the similarity of function of microglia and monocytic cells suggest a common origin. Less convincing evidence is that cells with morphological properties and patterns of membrane currents similar to those of microglia are derived from monocytes.

However, some authors maintain that at least some microglial cells are of neuroectodermal origin. Autoradiographic studies indicate that microglia are derived from glioblasts that also produce astrocytes, indicating that proliferating glioblasts form microglia. Microglial cells are found within the matrix cell layer during development, but these cells may be merely crossing the neuroepithelial layer after entering the nervous parenchyma and may not be derived from that area. Antibodies labeled against the protein lipocortin-1 label both microglia and neuroepithelial cells, and some of the antibodies that recognize microglial cells also label cells of neuroectodermal origin. Additionally, microglial cells can be produced in mouse neuroepithelial cell cultures thought to be devoid of mesenchymal precursors.

More recent data have shown that both microglia and astrocytes can derive from the same progenitor cell, suggesting either that some microglia are of neuroectodermal origin or that some astrocytes can be derived from mesenchymal cells, challenging the long-held view that astrocytes are of purely neuroectodermal origin. As such, the derivation of microglial cells has not been conclusively shown, but it is fair to say that

1. Microglial cells derive either directly from blood cells or are derived from cells of blood cell lineage.
2. During development microglial precursors invade the CNS.
3. Microglial precursor cells migrate within the CNS parenchyma to their final location.
4. Microglial cells resemble amoeboid microglia during migration but differentiate and become mature, ramified microglia once they reach their final location.

D. Physiology

In order for microglial cells to perform their task of responding to changes in CNS microenvironment, they must be able to sense changes in the extracellular microenvironment. This function can be achieved through the activation of ion channels. To date microglial cells have been shown to possess six types of K^+ channel, H^+ channel, Na^+ channels, Ca^{2+} channels, Ca^{2+}-release-activated Ca^{2+} channels, and voltage-dependent and voltage-independent Cl^- channels. However, the level of channel expression depends upon the state of the microglia, with activated microglia exhibiting different levels of channel expression than resting microglia. The inward rectifier K^+ channels are inhibited by G-protein activation and appear to be involved in regulating membrane potential, but so far no role has been suggested for delayed rectifier channels, although they may be involved in membrane repolarization and cell volume regulation . Both inward and outward rectifier channels are inhibited by increased intracellular Ca^{2+}, whereas, as expected, an increase in Ca^{2+} to 1 μM activates the Ca^{2+}-activated K^+ channel. Voltage-gated H^+ channels are expressed in phagocytic microglia. Their function is thought to be H^+ extrusion after phagocytic production of H^+. Increases in intracellular H^+ (decreased pH) and cell swelling activate this current, suggesting that it acts as a negative feedback mechanism to protect microglia from cytotoxic intracellular acidification and acidosis-induced swelling.

Na^+ channels are expressed in ramified microglia and have been proposed to play a role in membrane depolarization and regulation of morphological changes, although there is no firm evidence for this. L-type Ca^{2+} channels are present on microglia and are thought to be the pathway of increased intracellular Ca^{2+} by PrP and β-amyloid fragments. Capacitative Ca^{2+} currents were induced in rat microglia being perfused with IP3. However, although their existence has been shown, too little is known about them to compare them to known CRAC channels. However, it has been proposed that they play a part in microglial superoxide production. It is thought that functional Cl^- channels are required for changes in membrane potential and for the induction of microglial ramification, but not for maintenance of the shape. Microglia also contain a host of surface receptors, including AMPA receptors and thrombin receptors, although future research will no doubt uncover more receptor expression on microglia.

VII. ENTERIC GLIA

A. Anatomy

Enteric glia are different from other glial cells in that they are not located in the CNS but rather are located in the gut as part of the enteric nervous system (ENS). As such they are obviously distinct from glial cells in the central and peripheral nervous systems, but they do share common features that justify their inclusion in the family of neuroglia. The enteric nervous system is functionally different from the peripheral nervous system in that it is capable of mediating reflex activity without the input of the PNS or CNS. This has given rise to the concept that the gut is controlled by the activity of local isolated microcircuits located within the ENS. The structure of the ENS can be considered to resemble the CNS in certain respects. Nerve cell bodies and axons in the ENS are not surrounded by connective tissue as occurs in the PNS. This resemblance to the CNS suggests that support for ENS neurons comes from glial-like cells—the enteric glia. Morphologically, enteric glia differ from Schwann cells in that enteric glial cells are more irregularly shaped. In the myenteric plexus, the cell body projects long processes that end in small boutons that abut the basal lamina surrounding ganglia and interganglionic connectives. This enteric glial sheath is not complete and does not totally separate the myenteric plexus neurons from the extraganglionic connective tissue, thus allowing neurons to contact the periganglionic basal lamina directly.

B. Function

Enteric glial cells establish the perimeter of the myenteric plexus and partition myenteric ganglia into compartments. The surfaces of enteric glia are devoid of laminin and are only in contact with laminin where their end feet are in contact with the basal lamina. The enteric glial cells are packed with 10-nm intermediate filaments, and as such enteric glia are rich in glial fibrillary acidic protein (GFAP). GFAP-positive cells cannot be identified exclusively as enteric glial cells because PNS Schwann cells also express GFAP.

C. Lineage

As is the case with microglial cells, there are two possible origins for enteric glial cells; however, each theory has enteric glia originating in the neural crest. The first theory is that enteric glial cells migrate to the bowel within the original population of vagal and sacral crest-derived cells that also form enteric neurons. The second theory is that enteric glial cells enter the gut later in development. In order to investigate the first theory, portions of fetal gut were isolated before innervation by extrinsic nerves occurred. When these portions were grown *in vitro*, it was found that GFAP-positive cells developed, indicating that enteric glial precursors are present in the gut at the time when the explants were removed. Thus, cells capable of producing glial cells are present in the gut before extrinsic innervation arrives and proves that glial cells can be derived from the original wave of neural crest cells that colonize the gut. A similar type of study was carried out in which explants of the cells of presumptive ganglion cells were removed from ls/ls mice. In these mice, the terminal colon is aganglionic because it is not infiltrated by enteric glial precursors from the neural crest. However, this region is not denervated as extrinsic nerves grow into the region from the ganglia in more proximal regions. These nerves exhibit GFAP immunoreactivity. The mutation in ls/ls mice is due to the inability of the tissue to support inward migration of neural crest-derived neuroglial cells. Explants of ls/ls bowel give rise to cultures that contain neither neurons nor glia as these segments of gut are devoid of precursor cells. It appears that the supporting cells in

this area are derived from Schwann cells. Thus, glial components may be derived from separate lineages of cells, of which one is the crest-derived precursors that colonize the gut early and the other is the Schwann cell population that reaches the bowel later in development.

D. Physiology

Enteric glial cells possess a variety of surface receptors that can be used to distinguish them from nonmyelinating Schwann cells, with which they can be easily confused. These include reacting to the marker RAN-1, although it is only seen in cultured enteric glial cells, not *in situ*. The enzyme plasmalemmal 5′-nucleotidease is found on the surface of enteric glial cells but not on Schwann cells.

Neuroimaging

GIORGIO GANIS and STEPHEN M. KOSSLYN
Harvard University

GLOSSARY

brain activation Fast, transient biophysical and biochemical variations in neurons and, to some extent, in the glial cells that support them.

cerebral cortex Continuous sheet of tissue covering each hemisphere of the brain composed of billions of neurons and glial cells.

Gauss Unit of magnetic field strength. The preferred International System unit of field strength is the tesla (1 T = 10,000 G).

gray matter The gray tissue of the nervous system that contains a high proportion of nerve cell bodies.

hemodynamic response Variation of a vascular property, such as regional cerebral blood flow, in response to a change in neural activity.

sampling rate Rate at which physiological signals are sampled for subsequent analysis.

spatial resolution Precision with which physiological variables can be localized in space by a given neuroimaging technique.

voxel "Volume element" in a three-dimensional image.

white matter The white tissue of the nervous system consisting mainly of axons connecting nerve cells.

The ultimate goal of human neuroimaging is to monitor the living brain at all levels of structure and function, from neurotransmitter and receptor molecules to large networks of brain cells, with time scales ranging from milliseconds to minutes. Achievement of this goal would provide psychologists and neuroscientists with biological building blocks roughly similar to those that the human genome project provides geneticists. However, this analogy is misleading because the task of the neuroimager is probably more complicated than that of the geneticist. For instance, whereas the human genome contains an estimated 3×10^9 base pairs within at most approximately 10^5 genes, the human brain contains perhaps 10^{14} synapses on about 10^{11} neurons. In both the brain and genetic realms, it is important to realize that even perfect knowledge of biological building blocks would not automatically lead to knowledge of how the mechanisms function. Although knowledge of the structure of the brain tells us something about how it operates (just as knowledge about the structure of a lens tells one something about why people sometimes wear them in front of their eyes), further research will be required that specifically seeks to characterize how mental processes arise from neural tissue.

I. INTRODUCTION

The classical and most direct method of measuring neuronal activity in individual cells *in vivo* is by means of invasive electrical recordings in animals. In this method, tiny electrodes are placed into or near neurons, and the effects of different activities on the firing rate of the neurons are recorded. Although this method and its variants have provided a wealth of knowledge about how neurons operate, the invasive nature of intracranial electrical recording methods strictly limits their application to only special cases in humans (e.g., patients undergoing brain surgery). A host of noninvasive neuroimaging methods for

measuring brain activity in human beings has evolved. Herein, a brief overview is offered of the major human neuroimaging methods currently in use, emphasizing the strengths and limitations of each. Currently, there are two broad classes of noninvasive neuroimaging techniques to measure brain activity, which are the focus of this article: (1) direct methods that monitor electrical or magnetic fields *directly* linked to neural activity and (2) indirect methods that monitor metabolic and vascular changes associated with neural activity.

Note that in the literature the first category of methods often is not referred to as "neuroimaging." This is misleading not only because images can be produced on the basis of data obtained with electromagnetic measurements but also because research often integrates multiple methods, resulting in combined maps with high spatial and temporal resolution. In addition to neuroimaging techniques to monitor human brain activity, there are also techniques that provide structural information about the brain; these will be addressed only very briefly. Finally, techniques based on brain stimulation, such as transcranial magnetic stimulation, although important for cognitive neuroscientists, will not be discussed here because they are not neuroimaging techniques.

II. ELECTROENCEPHALOGRAPHY (EEG) AND MAGNETOENCEPHALOGRAPHY (MEG)

Noninvasive human electrophysiology was first accomplished in a systematic way with the electroencephalogram (EEG) in 1929 by the German psychiatrist Hans Berger, who recorded the α rhythm (10-Hz oscillations) from two electrodes placed on the front and back of his son's scalp. A variant of EEG is the event-related potential (ERP), in which changes in electrical activity immediately following the presentation of a stimulus or decision are recorded; ERPs are thus "time-locked," with changes being described relative to a particular event (hence the name, "event-related"). The first magnetic recordings of brain activity, using magnetoencephalography (MEG), were produced only much later in 1971.

Methods for recording EEG, ERP, and MEG provide information about the summed electrical events produced by individual brain cells. EEG and ERPs are recorded from electrodes placed on the scalp (although, very rarely, they can be recorded from within the brain in patients being prepared for surgical treatment of epilepsy). MEG and its time-locked derivative, event-related fields (ERFs, which are the magnetic analogs of ERPs), are recorded from arrays of superconducting quantum interference devices (SQUIDs). These detectors are so cold that tiny fluctuations in magnetic fields can induce slight currents, which can then be amplified and recorded.

A. Nature of the Signals

Signals that are recorded outside the head are very small, especially in the case of MEG. Consider that the magnetic field of the earth is about 0.5 G and that of the heart is 10^{-6} G. The α wave, a relatively large signal, is only 10^{-9} G, and most experimental effects are one-tenth of this or less. Indeed, a major expense of setting up a MEG, and to a lesser extent an EEG, system is the construction of an appropriate recording chamber to attenuate external interference.

At a cellular level, both electrical and magnetic activity originates from ionic current flowing across neuronal (and glial) membranes.

For a small brain volume, a single so-called "equivalent dipole" can be defined that approximates the locations where net local current flows either out from the volume (sources) or back into the volume (sinks). In general, an externally observable electrical or magnetic signal is produced if and only if (a) sources and sinks within the brain volume of interest are distributed in a non-radially symmetric manner, (b) the neurons are aligned somewhat systematically (so-called "open fields,") and (c) the neurons are activated synchronously. Thus, fields generated by brain regions in which the neurons have no consistent orientation (e.g., in the basal ganglia or thalamus) or are roughly radially symmetric ("closed fields," which is the case for many brain nuclei) generally contribute little to the EEG and MEG recorded from the scalp.

The gray matter of the neocortex is the main brain structure that meets all three constraints. The neocortex is a large, folded sheet a few millimeters thick composed of 70% pyramidal neurons oriented orthogonally to the cortical surface, with apical dendrites extending from the soma (cell body) to the sheet surface. When apical dendrites are activated near the soma by thalamic inputs, current enters the somatic region and exits the cell at sites near the cortical surface. This creates a source–sink configuration that is approximately dipolar and is oriented perpendicularly to the cortical sheet; a dipolar field of the opposite orientation is produced when apical dendrites near the cortical surface are activated. The sum of

post-synaptic activity in the apical dendrites of the hundreds of thousands of pyramidal neurons within a neocortical patch is considered to be the primary source of scalp-recorded EEG and MEG.

EEG and MEG provide differing but *complementary* views of underlying brain activity, and both therefore should be recorded simultaneously for the most complete picture of neural processing, timing, and localization. The complementary differences between EEG and MEG follow from differences in how electrical and magnetic signals depend on structural factors, such as head shape and the location and orientation of dipoles. Specifically, one difference stems from the fact that EEG recordings detect electrical current conducted through brain tissue and cerebrospinal fluid as differences in potential at the scalp. Electrical currents are greatly impeded and redirected by tissue boundaries (e.g., skull, skin, and cerebrospinal fluid) that differ substantially in conductivity. In contrast, MEG is virtually unaffected by these factors.

Two other differences must be understood within the context of the folded nature of the human neocortex. A crucial difference between EEG and MEG is that dipoles in any orientation (i.e., radial and tangential to the scalp) can modulate electrical potentials, whereas tangential (but not radial) components of the dipole are the principal contributors to the magnetic field outside the head. Another difference is that MEG detects primarily superficial sources, whereas EEG can sense deeper sources as well. This follows from the fact that magnetic field strength dissipates faster than electrical potentials with dipole depth; thus, SQUIDs can detect magnetic fields generated in large assemblies of neurons that are primarily near the outer surface of the brain.

In sum, MEG detects less brain activity than EEG, and all signals observable with MEG are also seen in EEG, but not vice versa. EEG provides a broader view of neocortical activity that includes both superficial and deep sources at many orientations relative to the scalp. In contrast, MEG reveals a more limited view of brain activity (perhaps half the generators in the human brain), being primarily selective to superficial and tangentially oriented dipoles, and, hence, detecting primarily activity originating in the sulci near the surface. Radial sources are essentially invisible to MEG. However, the electrical currents detected by EEG travel both over the cortex and over the scalp, and they are distorted by their passage through the skull (which has varying thickness at different places). In contrast, MEG is affected by none of these factors. Thus, at least in principle, MEG affords better spatial localization than EEG.

At first glance, it is counterintuitive that the lack of sensitivity of MEG to radial sources can be an advantage for the technique. However, given the extreme complexity of the recorded signals, resulting from the superposition of a large number of equivalent dipoles, the ability to rule out a subset of sources turns out to be very helpful. For example, MEG was able to resolve a localization controversy surrounding the early somatosensory potential N20 observed in EEG (the "N" means that it is a negative potential, and the "20" means that it occurs about 20 msec after a stimulus is presented). Because a magnetic N20 was observed, it could be inferred that the signal was generated by a tangential source in somatosensory cortex rather than by thalamic or radial neocortical sources alone because radial sources would have been absent from the MEG.

Although the main strength of EEG and MEG methods is to define the time course of neural information processing with high temporal resolution, it is important to localize the neural sources of EEG and MEG to specify the order in which each brain area contributes to the performance of a particular task. By present methods, in realistic situations EEG or MEG *alone* can often localize single dipolar sources to within 8–10 mm. The complementary nature of EEG and MEG sensitivity suggests that the most accurate localization should be achieved by taking into account both types of information simultaneously.

B. Analysis of EEG and MEG Data

In general, there are two major ways of interpreting EEG and MEG data; this dual approach can be understood to some extent by analogy to the wave and particle views in modern physics. One way is to consider EEG and MEG recordings as composed of discrete, relatively short-lasting neural events ("particles") triggered by specific events (plus "noise" not related to any event of interest). To enhance such neural events, the EEG or MEG can be time-locked to particular experimental events and averaged to yield ERPs or ERFs, respectively. Inferences from ERPs and ERFs are made primarily from their changes over time. In addition, the location of such changes often also provides useful data. The classical approach has been to define "components" in terms of their polarity [ERPs only: positive (P) and negative (N)], latency (milliseconds), scalp distribution, source location, and

function (i.e., modulation with specific experimental manipulations). For example, the P150 (or ERF M180) is a broadly distributed peak that is positive (hence the P) at the vertex around 150 msec. This event has been found to index early perceptual categorization of well-learned visual stimuli (i.e., words and faces), which seems to reflect activity in specific parts of the brain (the posterior fusiform gyrus and occipitotemporal sulcal regions).

A common assumption is that each ERP or ERF peak reflects one or more perceptual or cognitive processes and, therefore, is a neurophysiological index of those processes. To determine whether two experimental conditions engage the same or different processes, researchers evaluate whether both conditions evoke the same ERP or ERF component, and the degree of activation can be inferred from peak amplitude or area. More important, the time course of activation of these neural processes can then be inferred from the peak latency or the time when the conditions diverge.

Another way to analyze EEG and MEG recordings is to consider them as long stretches of data produced by a large ensemble of neuronal oscillators (''waves''). This view has led to analyses of the power (amplitude) of different frequencies of oscillations, which shift over time and when people are in different mental states. The first major success of this approach was to reveal that sleep involves different stages, as indicated by shifts in the power of the oscillations at different frequencies.

Hybrid approaches integrate the particle and wave methods by using ''wavelet filters'' to extract frequency information from the EEG while retaining temporal information. These approaches allow the detection of frequency changes occurring immediately after an event and have been used to discover EEG correlates of specific cognitive processes (e.g., linguistic processes).

The statistical analysis of EEG and ERPs is not trivial because of the large quantity of data acquired in most studies: for a typical experiment samples are recorded at thousands of time points from 100 or more spatial locations. Most investigators compare conditions of interest by performing tests based on the general linear model on data from a subset or all recording sites within various time windows. Similar to other neuroimaging techniques, the probability of finding an effect just by chance (so-called type I error) increases with the number of comparisons. The probability of a type I error is influenced by several factors, including the spatial and temporal correlations in the data. Although a few methods have been proposed to keep the overall probability of a type I error within acceptable limits, currently no universal solution exists.

C. Spatial Localization of EEG and MEG

The problem of determining the spatial location of the EEG and MEG sources, their orientation, and their strength from scalp recordings is often referred to as the ''inverse problem.'' The inverse problem is ill-posed (i.e., there is no unique solution): infinitely many distributions of dipoles are consistent with any set of EEG or MEG measurements. To resolve this ambiguity, additional constraints on the solution must be placed on quantitative models, including those specified by functional neuroanatomical data from other neuroimaging methods. A widely used approach assumes that EEG and MEG signals originate from a few focal, temporally uncorrelated sources and models the generators as some fixed number of discrete equivalent dipoles, where each represents activity within a specific brain volume. Although suitable for early sensory responses that are expected to be focal and recruit few brain areas, these assumptions are less appropriately applied to higher level cognitive activity or seizure-related processes. Cognitive functions often seem to involve widespread networks of somewhat synchronously active regions, and the spikes in partial epilepsy spread quickly across multiple regions.

Alternatively, the inverse problem can be reduced to an (linear) estimation of dipole strength everywhere across the entire folded cortical sheet (i.e., as a continuous dipole distribution) based on assumptions about the neocortical pyramidal cell origin of electromagnetic signals. Because the gray matter is the primary signal source, information about the geometry of the cortical surface, obtained by magnetic resonance imaging (discussed later), can be applied to greatly reduce the solution space of the inverse problem. The number of ''patches'' and corresponding equivalent dipoles that are needed to represent the cortical surface with sufficient precision, however, is much greater than the number of EEG or MEG sensors that can be placed as a practical matter. To circumvent this, a unique solution can be achieved by the further constraint of choosing the ''minimum-norm solution,'' which is the solution with the smallest overall activity (in absolute value); however, additional constraints from methods with high spatial resolution, such as functional magnetic resonance imaging,

are necessary to increase the likelihood that the unique solution is indeed also the correct one. Present methods for combining MEG with functional magnetic resonance imaging and structural magnetic resonance imaging can yield high-resolution spatiotemporal maps of human brain activity that are timed to within milliseconds of execution and localized to within millimeters. The combination of methods is a significant step in the direction of the ultimate goal of neuroimaging, as noted earlier.

D. Summary of Advantages and Disadvantages of EEG and MEG

To summarize, the chief strengths of EEG and MEG are the following. First, they are direct measures of the physiological activity of neural systems. Second, they are noninvasive. Third, electrical and magnetic monitoring of brain activity can reveal changes over very small delays (1 msec or less), which are crucially within the range of interneuronal communication time. EEG has an additional advantage of being one of the most inexpensive methods of neuroimaging; cost is actually a disadvantage of MEG, which is very expensive (at least 10 times more than EEG) in large part because of the cost of acquiring and maintaining the SQUIDs. The main disadvantage of both EEG and MEG is that they cannot indicate the location of activity on the surface of the brain very well (on the order of 10 mm) and are even worse at indicating activity in the neural structures located deep beneath the surface.

We now turn to methods that have properties complementary to EEG and MEG: good spatial resolution, but poor temporal resolution.

III. POSITRON EMISSION TOMOGRAPHY (PET), FUNCTIONAL MAGNETIC RESONANCE IMAGING (FMRI), AND OPTICAL IMAGING

The second broad class of neuroimaging methods is based on the measurement of metabolic and vascular changes that are associated with neural activity; these measures include oxygen and glucose consumption, cerebral blood flow, and cerebral blood oxygenation. The brain requires a continuous supply of glucose via the blood to meet its metabolic requirements; this is because only a little glucose is stored by the brain itself. Neural activity at a particular brain location leads to localized metabolic changes (such as those in glucose and oxygen consumption) and to vascular changes (such as those in regional cerebral blood flow, rCBF). These metabolic and vascular changes are referred to as "secondary changes," the challenge is to infer the nature of neural activity on the basis of such changes. This task is not trivial in part because multiple aspects of neural activity are reflected by single quantities; for instance, both synaptic inhibition and excitation produce similar increases in rCBF.

A. Nature of the Measured Changes

Numerous studies have shown that local glucose consumption and rCBF in the rat brain are highly correlated and that both in turn are highly correlated with underlying neural activity. Studies in humans using positron emission tomography (PET) have also shown close coupling between local glucose consumption and rCBF. Metabolic and vascular changes associated with neural activity appear to arise from synaptic processes rather than from action potentials in the cell bodies. Indeed, most of the increase in metabolism (deoxyglucose uptake) appears to occur not in the cell bodies but in the region occupied by synapses between axons and dendrites. Thus, of the three potential neural sites that contribute to metabolism, soma, axon, and synapses, the latter is the one that is the most highly correlated with the metabolic requirements of neurons. Furthermore, studies have shown that the increase in glucose metabolism is brought about by presynaptic, rather than postsynaptic activity (that is, activity of the "sending" neurons, not the "receiving" ones). This is an important observation because the source of EEG and MEG signals is thought to be primarily postsynaptic.

Work conducted to understand the energy-consuming processes taking place in axon terminals has shown that glucose consumption is correlated with the activity of the Na^+ pump, suggesting that this is the crucial event in the coupling between neural activity and energy consumption. If increased metabolic activity reflects presynaptic activity, then one would predict that both excitatory and inhibitory synaptic activity results in similar increases in energy needs. Consistent with this prediction, stimulation of excitatory and inhibitory afferents of the lateral superior olive within the brain stem auditory system of the cat brings about similar increases in deoxyglucose uptake. Note that, although increased excitatory and inhibitory presynaptic activity may produce identical local increases in deoxyglucose uptake, they will have opposite effects on the postsynaptic neurons being

driven. Thus, rCBF maps reflect a mixture of neurophysiological processes that require energy; such processes include excitatory and inhibitory synaptic activity as well as additional processes needed to regulate the extracellular environment. This observation should remind us that what is generally referred to as "brain activity" in the neuroimaging literature potentially reflects a mixture of many different energy-consuming phenomena.

B. PET

Although the exact mechanism by which synaptic processes cause metabolic and vascular changes is not well-understood, the empirical relationship between these parameters is very reliable. PET is one of the techniques that has exploited this empirical relationship to image neural activity of the human brain *in vivo*. In PET, participants are injected with (or in some cases breathe) a radioactively labeled compound (e.g., one containing ^{11}C, ^{15}O, ^{18}F, or ^{13}N). These compounds reach the brain about 20 sec after administration. When the isotope decays, it emits positrons that travel a short distance (a few millimeters on average, depending on the compound) until they encounter an electron; at this point they annihilate each other, producing two high-energy photons traveling 180° apart along a single line. The PET detectors (rings of "scintillation detectors" arrayed in parallel planes) record the near-simultaneous arrival of photons along a single line and employ the difference in arrival time to compute exactly where along the line the photons were produced. A three-dimensional image is then created on the basis of this information.

The relationship between local neural activity and regional glucose metabolism has been used in PET studies employing ^{18}F-fluorodeoxyglucose (^{18}F-DG), which is metabolized only partially (unlike glucose 6-phosphate), and more of it accumulates intracellularly when the local metabolic rate is greater. By employing ^{18}F-DG, it is possible to visualize brain regions containing neural populations that were metabolically active during the period between tracer injection and detection of the radioactive decay. Because of the long half-life of ^{18}F-DG (about 2 hr; recall that a half-life is the time required for one-half the radiation to decay), this technique has been employed to study phenomena with very slow time courses, such as sleep. To study faster phenomena, such as perception and attention, better temporal resolution is required. $H_2^{15}O$, with its half-life of about 2 min, became the most widely used tracer for these types of studies. The short half-life allows the administration of multiple experimental conditions in the same session. Because $H_2^{15}O$ accumulates locally, with linear increases relative to rCBF, it is possible to measure rCBF (which is tightly coupled with synaptic activity) without the need to measure the time course of radioactivity by arterial blood sampling.

1. Analysis of PET Data

Typical preprocessing stages in the analysis of PET data include the removal of global fluctuations in rCBF (i.e., changes in rCBF that occur over the entire brain), spatial smoothing (i.e., averaging of information from adjacent voxels to reduce the noise and increase the signal), and spatial normalization to correct for brain shape differences between individuals, after which statistical tests are applied, typically on a voxel-by-voxel basis. The simplest method consists of normalizing and subtracting two images acquired during the administration of two conditions and then looking for values significantly different from zero. What counts as "active," thus, depends on the statistical threshold used. Furthermore, the same issues regarding multiple comparisons described for the EEG and MEG techniques apply here. A commonly adopted approach consists of creating a "statistical parametric map" (SPM) from the single-voxel tests and computing corrected probability values for single voxels and clusters of voxels, such that the overall probability of obtaining significant differences by chance alone remains within acceptable limits. The resulting maps indicate the loci where one condition evoked more activation than another; these maps are sometimes overlaid onto high-resolution images of a standard brain obtained with magnetic resonance imaging.

2. Summary of Advantages and Disadvantages of PET

Currently, a major strength of PET for cognitive studies is that it can provide absolute measures of rCBF, which are much more difficult to obtain with other techniques. Such measures are particularly useful in individual differences studies that focus on the correlation between performance and brain activation. Another major strength of PET that is particularly important in the clinical domain is the possibility of mapping the distribution of particular receptors in the brain by using appropriate

"radio-ligands." These radioactive chemicals mimic various neurotransmitters and are lodged in receptors that typically accept such neurotransmitters. Thus, it is possible to map the distribution of receptors by noting where these chemicals come to reside after they are administered. The major disadvantages of PET are that it is very expensive (partly because the radioactive tracers need to be manufactured on the spot), is invasive, and has relatively poor temporal resolution (it requires at least 40 sec to obtain an image).

C. MRI

Advances in magnetic resonance imaging have made it possible to image with high resolution not only the structure of the human brain *in vivo* (including details of the white matter connecting various brain areas by means of diffusion-weighted MRI) but also *functional* changes. For a long time it was believed that local glucose consumption, local oxygen consumption, and rCBF were routinely coupled. The reasoning was that increased neural activity requires more glucose, more glucose requires more oxygen to be utilized, and more glucose and oxygen are delivered by more blood flow. These parameters are indeed strongly correlated *at rest*. However, rCBF and local glucose uptake increase much more than local oxygen consumption during physiological increases in neural activity, suggesting true uncoupling. At first glance this uncoupling between local oxygen consumption and rCBF might seem like a potential problem, but in fact it is another factor that can be used as an index of neural activity. Such uncoupling results in an increase in the concentration of oxygenated hemoglobin (HbO or oxy-Hb) and an apparent decrease in deoxygenated hemoglobin (Hb or deoxy-Hb) in neurally active areas relative to inactive areas. The most popular types of fMRI and optical imaging exploit the magnetic and optical properties of Hb and HbO.

1. Physical Foundations of MRI

Because fMRI is the neuroimaging technique most widely used today, we will describe some of its physical foundations in slightly more detail. According to quantum theory, electrons, protons, and neutrons possess a fundamental property referred to as "spin." We will consider a small group of protons, H^+. The spins of these protons can be thought of as magnetic moment vectors, which cause the protons to behave like tiny magnets with a north (n) and a south (s) pole. When the protons are placed in an external magnetic field with a north (N) and a south (S) pole, their spin vectors align themselves with the external field, just as a magnet would. For each proton there is a low-energy state in which the poles are aligned N-s-n-S and a high-energy state N-n-s-S (opposites attract and like signs repel; thus, more energy is required to keep the s-S and n-N poles aligned than when opposite poles are aligned). At room temperature, the number of spins in the lower energy level, $N+$, slightly outnumbers the number in the upper energy level, $N-$, depending on the molecular makeup of the substance. The difference between $N+$ and $N-$ is referred to as the "net magnetization" of the substance. The net magnetization vector is typically decomposed into two components: the *longitudinal magnetization*, in the direction of the external field, and the *transverse magnetization*, orthogonal to it. At equilibrium, the net magnetization vector lies along the axis of the imposed magnetic field and there is no transverse magnetization.

A crucial idea for magnetic resonance imaging is that the net magnetization vector can be moved by exposing the spin system to energy of a frequency equal to the energy difference between the spin states (e.g., by a radio frequency pulse). If enough energy is delivered to the system, it is possible to make the net magnetization vector orthogonal to that of the external magnetic field. Upon removal of the external energy source, the longitudinal magnetization returns to its equilibrium state, with a time constant labeled T_1. T_1 depends on the particular substance; for example, the T_1 of brain white matter is about 500 mse. The difference in T_1 between different types of tissues (such as gray versus white matter in the brain) is one of the main parameters used to construct structural MRI; these MRI images picture the physical structure of the brain, not its functioning.

While returning to equilibrium, the net magnetization vector will start to rotate about the axis of the external field. This is often depicted as a slow "wobble" or, more technically, *precession*. The precession of the net magnetization vector generates an electromagnetic signal that can be detected by an appropriate receiving coil. The precession occurs at a rate (the Larmor frequency) that depends on the properties of the material and is directly proportional to the strength of the applied field. Thus, if the strength of the applied magnetic field has a linear gradient of strength, then the precession rates at different spatial locations along the gradient will be different in predictable ways: the frequency of the electromagnetic signal received encodes the spatial location of its source.

To summarize so far: the key idea is that the net magnetization vector can be moved from the equilibrium position along the axis of the external field by applying a radio frequency pulse at the proper frequency, thus giving rise to a transverse magnetization component rotating around the axis of the external magnetic field. Such a component is the result of all of the spins precessing synchronously, thanks to the radio frequency pulse.

As soon as the pulse is turned off, the various spins begin to fall out of phase and the MRI signal begins to decay. This decay occurs for two reasons: intrinsic and extrinsic. The intrinsic factor is that the random configuration of the spins itself creates small inhomogeneities in the local magnetic field. The magnetic field is slightly stronger in regions where many spins line up with the field and slightly weaker in regions where many spins are in the opposite direction. These slight changes in the local magnetic field result in slight variations in the precession frequency, causing dephasing. The time constant that describes the return to equilibrium of the transverse magnetization is called T_2. T_2 depends on the molecular environment of the spins (it is about 70 msec for brain white matter). The extrinsic factor for dephasing is the slight inhomogeneities in the external magnetic field. Substances that possess paramagnetic properties (such as Hb) will distort the field, causing faster dephasing (the time constant in this case is referred to as T_2^*).

2. MRI Scanners

MRI scanners exploit the principles just described to create images of the human brain. In practice, an MRI scanner is composed of a magnet, usually a horizontal tube (referred to as the "bore") in which a person is placed, a radio transmitter, and a radio receiver. The radiofrequency pulses described earlier are transmitted by electrical coils located inside the magnet. Often, the same coils also receive the radiofrequency signals generated after the excitation radiofrequency pulse is turned off. The signals generated during this phase induce voltage changes in the receiver coil, which are then sent to suitable amplifiers. The image is reconstructed on the basis of these signals. The intensity of the MRI signal increases with field strength, which explains the trend toward building scanners with higher and higher field strengths: although most existing scanners have a field strength of 1.5 T, the number of 3- and 4-T scanners is rapidly increasing, with a handful of sites in the process of building 7-T scanners.

3. Blood Oxygenation Level-Dependent Contrast (BOLD)

The most popular type of fMRI, blood oxygenation level-dependent (BOLD) contrast, is based on the fact that Hb is paramagnetic whereas HbO is not. As described earlier, rCBF increases brought about by increased synaptic activity are not matched by corresponding increases in oxygen extraction. This causes an apparent decrease in Hb, which results in less rapid dephasing of protons (longer T_2^*). The final outcome is that a local increase in synaptic activity will result in an increased MRI signal. This phenomenon was first demonstrated in humans in 1992.

Although BOLD contrast is the predominant technique for functional mapping, other techniques have been developed. Among them, techniques to measure rCBF noninvasively by using arterial spin labeling (ASL) hold much promise. In essence, ASL techniques "label" arterial blood by changing the magnetic state of arterial water protons as they are carried up through the brain and then following the effect of labeled blood on the amplitude of the MRI signal. The advantages of ASL over BOLD are that, in theory, it should provide better localization of functional activation because of reduced sensitivity to intravenous signals, and that ASL signals are quantitatively related to CBF, which in turn is generally assumed to be tightly coupled with local neural activity. The main disadvantages of ASL relative to BOLD are that the ASL signal is 2–4 times smaller than the BOLD signal, and that ASL is limited in its maximum rate of image acquisition relative to BOLD imaging because of the time required for the tagged blood to flow into the portion of the brain being imaged.

The relationship between the BOLD signal, and the underlying activity is more complex than the well-established one between rCBF and neural activity. Thus, the issue of the extent to which the BOLD signal actually reflects neural events arises. Studies comparing the BOLD signal with rCBF (measured with PET $H_2^{15}O$) have found a linear relationship between PET and fMRI across sets of distributed regions. Animal studies have also provided evidence that BOLD, rCBF, and evoked potentials in response to visual stimuli at various frequencies are highly correlated, which is consistent with the hypothesis that the BOLD signal reflects neural events in a quantitative manner. However, exceptions to this relationship have also been found: in some cases, fMRI seemed more sensitive to activation in a number of cortical areas,

whereas PET seemed more sensitive to activation in deep nuclei.

Even without considering the spatial limitations of the imaging devices, the locus of the metabolic and especially of the vascular responses may not coincide with that of brain cell activity. The theoretical spatial resolution of the BOLD signal is limited by the size of the smallest vascular unit that can be modulated independently in response to neural activity. If synaptic activity only produced changes in the BOLD signal in large blood vessels, then the spatial resolution of BOLD would be very low. In theory, the smallest of such vascular units is the capillary. Based on the fact that capillary walls possess some contractile elements and that there are precapillary sphincters, the capillary recruitment hypothesis states that a major mechanism of blood flow regulation in the brain relies on the complete opening and closing of capillaries. This hypothesis is problematic, however, because under resting conditions all cerebral capillaries seem to be continuously perfused with plasma and most of them also contain moving red blood cells. From these considerations, we can infer that the spatial resolution of the hemodynamic response is at least 1 mm^3, the approximate size of arterioles feeding capillaries. Empirical work, noted shortly, suggests that in fact the spatial resolution of fMRI using BOLD may be a bit better than this.

One method researchers have used to assess empirically the spatial resolution of fMRI, and particularly that of the BOLD signal, has been to map anatomical structures with known functional properties. Activation in the lateral geniculate nucleus of the thalamus (LGN) during photic stimulation has been demonstrated by using BOLD contrast in a 4-T magnet. The LGN is a very small structure and is located near other structures (e.g., the hippocampus) that did not exhibit activation during this task. Although the BOLD signal in the LGN was smaller than that in the primary visual cortex (area V1), it had a similar time course. Furthermore, task-related activation in the pulvinar nucleus of the thalamus was also detected, and its activated location could be discriminated from that of the LGN. More recent work has also shown visual topography in the LGN. Furthermore, a study used high spatial resolution fMRI to map the activation in the ocular dominance columns (less than 1 mm thick) of area V1 during alternate visual stimulation of the left and right eyes. (Note that the success of this study indicates that the spatial resolution is better than 1 mm.)

Animal studies have also provided evidence regarding the spatial resolution of BOLD contrast. For example, stimulation of a rat's whiskers elicits BOLD signals with a spatial distribution that overlaps that of electrical activity in the rat whisker "barrel cortex." These results show empirically that the site of the BOLD activation is spatially very close to the sites of expected neural activity. Despite this convergent evidence, some findings also suggest that caution is warranted in the interpretation of the spatial location of fMRI foci based on BOLD contrast. Other work has compared BOLD signals with rCBF measured by PET during a visually cued sequential finger movement task. The results showed a general similarity in the pattern of activation, but in some cases they also showed a discrepancy between the precise location of foci detected with PET and fMRI (almost 1 cm average), perhaps due to the higher sensitivity of the BOLD contrast to signals coming from draining veins.

We have focused so far on the spatial resolution of fMRI, but the technique is also useful for its temporal resolution—especially in comparison with PET (which requires about 40 sec to obtain an image). The temporal resolution of fMRI depends not only on the sampling rates possible with current MRI hardware but also on the temporal characteristics intrinsic to the hemodynamic response (relative to that of the neural events that generate it). MRI sampling rates depend on the pulse sequences used. In practice, a whole-brain image can be obtained on the order of 1–2 sec with the commonly used gradient echo echoplanar imaging (EPI). Note that the MRI signal becomes smaller and smaller for sampling rates faster than about 3 sec because the magnetic spins do not have enough time to return to equilibrium. A clever method to get around this problem is to vary the onset of the trials relative to the sampling times. For example, if a voxel is sampled every 3 sec, half of the trials can be initiated in synchrony with the excitation pulses whereas the other half can be initiated 1.5 sec later. By combining the two trial types, one can achieve a temporal resolution that is twice the actual sampling rate. The temporal characteristics of the BOLD response have been well-characterized. The onset of detectable differences in the BOLD response, relative to the putative onset of neural activity, is about 2 sec; the BOLD response peaks between 6 and 9 sec and returns to baseline slightly more slowly after the cessation of neural activation. An initial undershoot, reaching a maximum around 1 sec after stimulus onset, has been observed in some studies, although the reliability and nature of this phenomenon are still under investigation. A more reliable post-undershoot in the BOLD

signal, peaking a few seconds after stimulus offset and lasting for about 20 sec, has also been observed.

The effective temporal resolution is affected by the variability of the parameters of the hemodynamic response (such as rise time) rather than by the absolute value of such parameters. For example, if the onset time is very large (e.g., several seconds) but the variance is very small (e.g., 100 msec), one can still determine relative latency shifts between conditions with accuracy. A few studies have addressed the issue of latency estimation variability within a region of interest. These studies measured the variability of a number of parameters such as the onset time and the time to peak of the hemodynamic response within specific regions of interest elicited by a brief sensory stimulus. Typically, the stability of the onset time and the time to peak in a given region are very high, especially within the same subject.

Several studies have shown large differences in the onset latency of the hemodynamic response in different brain regions. Variations in the delay of the BOLD response between 4 and 8 sec in visual and motor cortical areas are common. Such variations are too large to be accounted for by variations in neuronal activity latencies. Even longer delays, between 8 and 14 sec, can be observed in large vessels. Given the large spread of hemodynamic response latencies over space (several seconds), in general it is not possible to infer the temporal order of activation of two arbitrary regions (less than 1 sec for most cognitive tasks) from the absolute hemodynamic onset latencies. It is, however, possible to determine the *relative* timing of neural activation stages within a region of interest in response to two or more experimental manipulations. Although more problematic, it is also possible to determine the relative timing of neural activation stages between two regions of interest if these have comparable hemodynamic properties (e.g., striate cortex representation of the left and right hemifields). A few studies have shown that, within these limits, subsecond temporal resolution can be achieved.

4. Analyses of fMRI Data

A wide spectrum of methods for the analysis of fMRI data is currently in use. Not surprisingly, the range of techniques has expanded over the last few years. It is interesting to note that the analysis methods used most widely depend, to a large extent, on the availability of software packages. Often the software package that is the least difficult to use and the least expensive becomes the one used most widely, to a large extent independent of the soundness of the implemented algorithms. Although some preprocessing and artifact removal issues are specific to fMRI, the general statistical problems are similar to those encountered in the analysis of EEG, MEG, and PET data but are more difficult to solve because of the size of the data sets. A typical fMRI session produces tens of thousands of time series, one for each voxel. Typically $64 \times 64 \times 64 = 262{,}144$ voxels are monitored. Thus, the same kinds of type I error issues described for the previous techniques arise with fMRI. Many analysis techniques take advantage of the fact that the probability of obtaining clusters of active voxels decreases with cluster size (the actual probability depends on the detailed assumptions made).

The first fMRI paradigms were based on the same activation paradigms employed with PET, often referred to as blocked paradigms. These paradigms consist of administering the various conditions for several tens of seconds in a blocked manner. Analyses typically involve generating statistical maps of contrasts between images collected during the various conditions. Developments in the analysis of fMRI data have expanded the range of the paradigms available with fMRI. Such paradigms originated from researchers familiar with the ERP methodology and are thus referred to as event-related paradigms. Event-related paradigms essentially allow the presentation of trials in the various conditions in a mixed manner, thus eliminating several confounds inherent in the blocked paradigms, such as the effect of expectancy. The analytical methods used to analyze event-related paradigms usually rely on the assumption that the hemodynamic response is linear and time-invariant. That is, the methods assume that the response to stimuli A and B presented in close temporal succession can be estimated by summing the responses to stimuli A and B presented independently of each other. Results from several studies are consistent with the assumption that activation-induced hemodynamic responses behave in a roughly linear manner. For example, the hemodynamic response in the visual cortex is approximately linear, although the response to brief stimuli is greater than that predicted by a linear, time-invariant system. Despite such documented deviations from linearity, several studies have shown that useful results can be obtained by using the linearity assumption. For example, responses to visual stimuli delivered as rapidly as 1 per second can be resolved. Furthermore, reliable activation maps can be obtained with stimuli presented at an average rate of 2 per second, provided that the interval between stimuli

varies randomly. The possibility of using rapid presentation paradigms with fMRI is important in part because it has allowed the use of exactly the same paradigms typically employed with electromagnetic techniques, which has promoted the direct comparison of fMRI results with those obtained from EEG and MEG.

5. Summary of Advantages and Disadvantages of fMRI

To summarize, fMRI is the most common form of functional neuroimaging today for good reasons: in addition to its relatively good spatial and temporal resolution, it is also widely available (most hospitals have an MRI machine) and is relatively inexpensive, especially compared to PET. However, the technique is not ideal. First, it is very noisy; the shifting magnetic fields cause physical movements of the magnets, which, like a conventional loudspeaker, displace air and thus produce sound. Second, the hole in the bore is relatively narrow but very deep, which some people find uncomfortable. Third, the technique is very sensitive to motion. Although statistical methods have been designed to correct for the distortions produced by motion, this is still a major problem. Fourth, gradient echo EPI, the method most widely used for fast imaging, does not work well for areas adjacent to tissue–air interfaces.

D. Optical Imaging

Another way to obtain information about the functional state of neural tissue is to measure how light interacts with it. The most basic such method analyzes the light reflected by the exposed cortex during various functional states, a technique that has been mainly used in animal studies. This technique has provided *in vivo* high-resolution information, for example, of the functional organization of the visual cortex in cats and monkeys and of the whisker "barrel cortex" in rats. Because this technique requires drilling a hole in the skull and exposing the cortex, it is not generally suitable for human neuroimaging.

1. Near-Infrared Spectroscopy (NIRS)

The technique most widely used for noninvasive human optical imaging is near-infrared spectroscopy (NIRS). NIRS is possible because visible light can travel a significant distance through human tissue and still be detected. At wavelengths in the near-infrared region of the spectrum (700–900 nm), the optical penetration depth is several centimeters in biological tissues. Moreover, light absorption in this region is primarily due to HbO and Hb. Because different frequencies of light are absorbed differently by HbO and Hb, the concentrations of each can, in principle, be determined by measuring tissue absorption at multiple wavelengths. Thus, in NIRS, weak lasers shine light with the appropriate frequency from the scalp downward, and a set of photodetectors surrounds the location of the laser on the scalp. The photodetectors detect the amount of light transmitted at the different frequencies, and the amounts of HbO, Hb, and total hemoglobin ($HbT = HbO + Hb$) are calculated on this basis.

The average path photons travel from the source to the detectors is shaped roughly like a semicircle. The average depth reached by the photons is between 50 and 100% of the distance between the source and the detector. Thus, with a distance between source and detectors of about 4 cm, the average photon path encompasses gray matter in addition to other tissues. This observation illustrates two of the main limitations of optical imaging. The first is the maximum depth than can be probed with this technique, which is on the order of 2–3 cm. This means that subcortical nuclei and cortex lying deep in the sulci cannot be reached with optical imaging. The second limitation, related to spatial resolution, is caused by the various tissues interposed between the light sources, the gray matter, and the detectors. Of these layers, the most important is probably the cerebrospinal fluid, which produces "tunneling" phenomena—where light travels at a different rate through the fluid than though brain tissue, which complicates the interpretation of the optical signals.

a. Analysis of NIRS Data In general, the concentration of a chromophore (i.e., a light-absorbing molecule) in a volume of tissue can be determined by measuring the amount of light absorbed by the volume. All else being equal, an increase in the concentration of the chromophore results in an increase in the amount of light that is absorbed. The amount of absorption is quantified by the Lambert–Beer law, which assumes an infinitesimally small concentration of the chromophore and no scattering in the medium. Because biological tissues such as bone and white matter are highly scattering, a modified Lambert–Beer law has been used instead. This modified law introduces a factor to account for

scattering-related attenuation; furthermore, the distance between the source of the light and the detector is multiplied by an experimentally determined mean differential path length factor (DPF) that accounts for the longer path length of the photons in scattering media. It must be noted that this modified Lambert–Beer law works very well when changes in the concentration of the chromophores occur globally in the image volume, under the assumption of constant absorption along the photon pathlength. This assumption is not generally satisfied when changes in chromophore concentration occur only in a small volume within a larger sample, which is the typical situation encountered during focal brain activation. Once the time series of relative concentrations of Hb and HbO are calculated from the raw data and preprocessed (for example, by removing artifacts produced by the heart cycle and breathing), analysis essentially proceeds as it does for ERP data.

2. Diffuse Optical Tomography (DOT)

An important advance in optical imaging allows the computation of spatial variations in Hb and HbO by using multiple lasers and photodetectors. This approach produces an image of the pattern of activation over most of the cerebral cortex; this approach is referred to as diffuse optical tomography (DOT), and it affords continuous, real-time measurements of the spatial distribution of HbO, Hb, and HbT (total hemoglobin). Given that DOT can assess the same variable measured by the fMRI BOLD technique, in addition to other variables not measured by fMRI, the combination of these two techniques should be particularly productive. So far, only a handful of studies have compared the results obtained with fMRI and optical imaging techniques. These studies have shown reasonable consistency in the spatial localization of cortical activity between the two methods, although the spatial resolution of these optical imaging techniques remains to be systematically tested. The devices used to perform DOT are more complex than those required to perform NIRS with a single light source–detector pair because it is necessary to identify each source of light that reaches any detector. Thus, the sources must either be pulsed individually at distinctive frequencies or the light must be encoded in such a way that each source is specified. Furthermore, to resolve Hb and HbO within the sample volume, the volume must be probed with multiple wavelengths of light and the DOT system must be able to distinguish these signals at each wavelength. Even these DOT systems, however, are at least 10 times less expensive than an MRI or a PET scanner.

3. Analysis of DOT Data

With many sources and detectors arranged over the head, an image can be constructed by using ''back-projection algorithms.'' In these algorithms, each source–detector pair provides a ''projection'' of the underlying tissue in separate semicircle-shaped traces. These projections can then be combined to form an image of the spatial distribution of the tissue absorption and scattering coefficients. As for data from EEG and MEG, this is an ill-posed inverse problem in which many solutions are possible given any set of measurements. A number of current algorithms for image reconstruction are based on the ''photon diffusion equation,'' which is only accurate for highly scattering media. The nonscattering properties of the cerebrospinal fluid are known to introduce perturbations in photon migration. More recent algorithms are based on the more accurate radiative transport equation. By taking into account the anatomical and functional information provided by MRI, the accuracy of the inverse solution in the optical domain is likely to improve, just as it does in the case of EEG and MEG.

4. Fast Optical Signals

In addition to monitoring vascular changes, optical imaging also has the potential to monitor some aspects of brain function that are directly related to neural activity. *In vitro* studies have shown that light scattering in neural tissue changes with activation, probably because of changes in the refraction index of neural membranes. An increase in scattering causes photons to bounce around more times, thereby increasing the time they take to travel from the source to the detector (*time-of-flight* or *delay*). Note, however, that photon delay is also affected by tissue absorption, so that mathematical models are required to tease apart the scattering and absorption components. Studies have shown that fast task-related signals can be detected by measuring photon delay. The time course of these short-latency optical signals is comparable to that obtained with electrical event-related potentials. Although these findings await replication by other laboratories, they suggest that optical imaging is a very promising technique for noninvasive neuroimaging.

5. Summary of Advantages and Disadvantages of Optical Imaging

In sum, optical imaging techniques have the advantages of being relatively inexpensive, potentially having excellent temporal resolution, and having moderately good spatial resolution (probably comparable to PET). The major disadvantages are that they can record signals only from the cortex and only from regions that are not buried too deeply in sulci.

IV. FUTURE DIRECTIONS

Although ongoing incremental improvement of existing techniques will take us closer to the ultimate goal of neuroimaging, as described in the introduction, the most promising direction for functional neuroimaging is probably the combination of imaging techniques with complementary strengths that can, in principle, provide better spatial or temporal resolution than any one technique by itself. Combining techniques, however, is very challenging. On the one hand, different techniques often measure different aspects or consequences of neural activity. Thus, the combination of techniques must deal with the problem that each technique may register information not registered by the other and vice versa. In addition, the spatial localization of the same sources may be systematically different with different techniques. For example, as discussed earlier, MEG is thought to reflect postsynaptic activity, whereas fMRI reflects the indirect consequences of presynaptic activity; thus, it is conceivable that the locations of ''activation'' detected with the two techniques might not always coincide. On the other hand, the ability to obtain simultaneous measurements with two or more neuroimaging techniques sometimes is technically challenging or even impossible. For example, it is difficult to obtain good simultaneous EEG and fMRI measurements, and it is not currently possible to obtain simultaneous MEG and fMRI measurements.

Given the enormous advances in neuroimaging techniques over the past 15 years, we have every reason to be optimistic that current limitations will be surmounted as available techniques are refined and new techniques introduced. The end of the twentieth century was a watershed period for the study of the human brain, in large part because of the flowering of this technology.

Neuron

MARYANN E. MARTONE and MARK H. ELLISMAN
University of California, San Diego School of Medicine

GLOSSARY

action potential Term applied to the electrochemical signal caused by a rapid and reversible fluctuation in membrane potential used by the nerve cell for intracellular communication. Also known as a nerve impulse.

axon A cylindrical process extending from the nerve cell body specialized for conducting electrochemical signals away from neurons to their targets.

dendrite Name given to one or more tapering, typically branching processes extending from the nerve cell body that are specialized for receiving signals from other nerve cells and the environment.

neurotransmitter Any one of a number of small molecules that are released by a nerve cell at the synapse to pass signals between nerve cells and their targets.

synapse A term applied to the specialized junction between a nerve cell and its target where signals are passed from one cell to the next, usually in the form of chemical signals.

This article describes the major features of the neuron, the class of cell most closely identified with the functions of the nervous system. The major emphasis is on the structure of nerve cells and their basic physiology, along with their biochemical specializations.

I. INTRODUCTION

The neuron is a member of the class of cells most closely identified with the functions of the nervous system, namely, the transduction, processing, storage, and translation of environmental information into meaningful behaviors. The term neuron was coined by the German neuroanatomist Wilhelm Waldeyer in 1891. Neurons are unique among cells in their large size, complexity, and the diversity of their forms, which are closely related to the functions they subserve. The neuron is the fundamental anatomical building block of the neuronal circuits underlying behavior, but it is not the only cell type in the nervous system nor indeed the most numerous. That distinction belongs to a second class of cells called the neuroglia or simply glia. Although the focus of this article is the neuron, a neuron does not exist in isolation nor can it properly be described in the singular, because its interactions and associations with other neurons, glia, and target cells are integral to its function.

II. HISTORY OF THE NEURON

Most types of cell do not have a history.
Peters, Palay, and Webster (1991)

The challenge to neuroscientists imposed by the size and complexity of neuronal form is illustrated by the colorful and somewhat contentious history of the neuron concept. Once the concept of the cell as the unit of structure and function in all living things was established by Schleiden and Schwann in the early nineteenth century, scientists rapidly accepted that various tissues were made up of individual cells. Not so with nervous tissue, where nearly another 100 years would pass before the fact that neurons were distinct cellular entities, also known as the Neuron Doctrine,

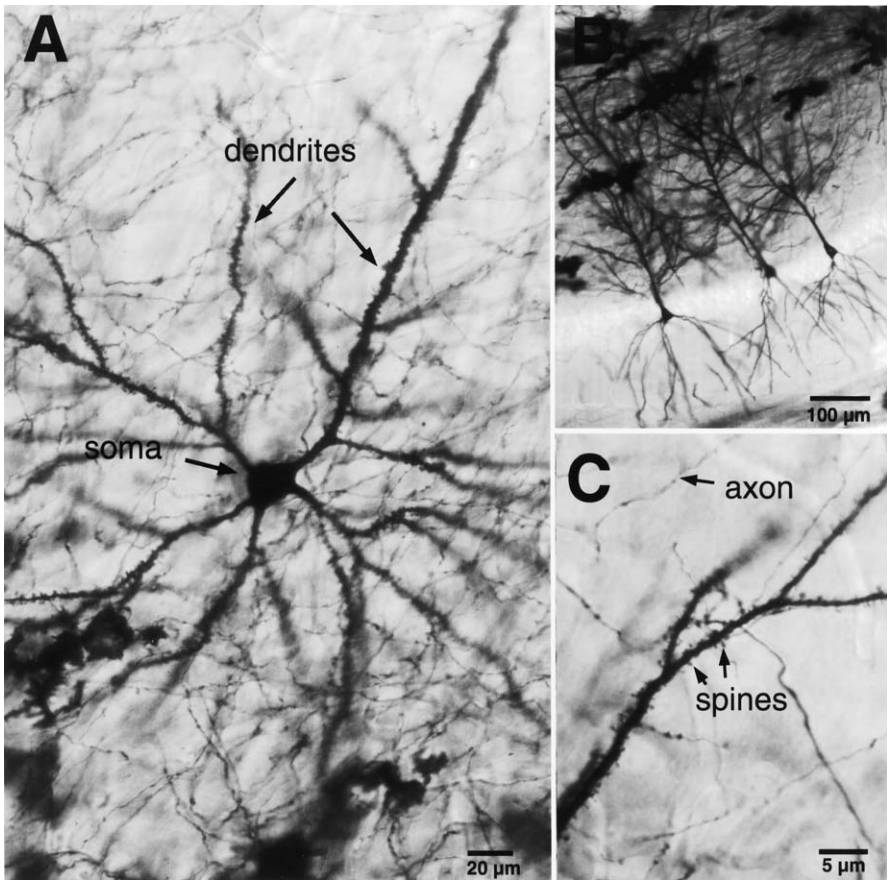

Figure 1 Neurons stained by Golgi impregnation. (A) Pyramidal neuron from the rat cerebral cortex. The plexus of fine fibers visible in the background is likely axon collaterals. (B) Three pyramidal neurons from the rat hippocampus. (C) Higher magnification view of a spiny dendrite showing the spiny protuberances from the dendritic shaft and varicose axons in the background.

would become universally accepted. Competing with the adherents of the Neuron Doctrine were the reticularists, who maintained that the nervous system comprises a syncitia of anastomosing filamentous processes in protoplasmic continuity with one another, much like a network of blood vessels. A leader of the reticularist school was the Italian neuroscientist Camillo Golgi, also famous for introducing the eponymous stain that was instrumental in elucidating the structure of the neuron, the Golgi reaction. Until the development of the Golgi reaction, most stains revealed only a complex jumble of fibrillar structures intertwined with corpuscular globules. The Golgi stain had the advantage of staining only a small number of neurons but revealing their entire form in glorious detail, including their far-reaching processes (Fig. 1). Ironically, the man most instrumental in putting forth the Neuron Doctrine, Santiago Ramon y Cajal, based most of his observations on material stained with the Golgi method developed by his competitor. The two scientists shared the Nobel prize in 1906.

With the development of biological electron microscopy in the 1950s, the limiting membrane of nerve cells and the separation between cells at points of contact were clearly visualized. However, whereas these early images from electron microscopy failed to reveal evidence for cytoplasmic connections between neurons at these arborized sites, more recently developed methods have revealed filamentous structures bridging the synaptic gap. This system, dubbed the transcellular filament system, may represent the constituents stained by the Golgi method, which Golgi interpreted as a network. Indeed, in the end, Golgi may have been partially right! Clearly it was correct to extend the cell doctrine to the nervous system and define the neuron. It appears that it was also correct to posit that a continuum of filamentous structures provides a reticular fabric for the nervous system and

that this is transcellular, especially at the synapses, which were at the heart of this controversy.

The establishment of the neuron doctrine did not mark the end of the evolving conception of the nerve cell. As our understanding of nerve cell physiology, biochemistry, and molecular biology has progressed, neuroscientists have had to create and modify models of information processing in the nervous system. For example, simple views of nerve cell processes as cables that either actively or passively propagated information in the form of electrical signals have given way to an increased emphasis on chemical signaling pathways and compartmentalization. The emphasis on molecular interactions has been fueled by advances in molecular genetics and methods for identifying and localizing the chemical constituents of nerve cells by using techniques such as immunocytochemistry. Thus, any review of the neuron represents a snapshot in time with an emphasis that is highly dependent upon the prevailing winds of scientific inquiry. However, regardless of the prevailing wind, any discussion of the neuron necessarily begins with its morphology.

III. STRUCTURE AND FUNCTION OF NERVE CELLS

A. Neurons Are Excitable Cells

Neurons are specialized to sense, transduce, process, store, and transmit information. Information is carried both within and between neurons in the form of electrical and chemical signals. Neurons are known as excitable cells, in that they are capable of altering their membrane potential to serve as a signaling mechanism. The membrane potential arises because the plasma membrane is not freely permeable to ions present in the intracellular and extracellular environment. The major ions used by nerve cells to carry signals are Na^+, K^+, Ca^{2+} and Cl^-. Ion channels specific for these ions are present in the plasma membrane. When they open, ions may pass into or out of the cell depending upon their concentration gradients, changing the membrane potential and also initiating second messenger cascades, activating enzymes, modifying the cytoskeleton, and regulating gene transcription. Ionic gradients are maintained by the action of electrogenic pumps, which actively pump ions into and out of the cell against their concentration gradients. These pumps are energy-dependent, that is, they require the hydrolysis of adenosine triphosphate (ATP) and are thus referred to as ATPases.

B. Neuronal Development

Embryologically, the nervous system derives from the thickening and infolding of the ectoderm, which also gives rise to the skin. Common progenitor cells give rise to both neurons and glia. Nerve cells retain many characteristics of epithelia, e.g., a polarized structure, little intracellular space, and the presence of numerous contacts between cells. The bulk of neurons in mammals are generated before birth, and once differentiated neurons are almost exclusively postmitotic. However, as with most well-established truths about the nervous system, this concept has had to be revised in light of evidence that nerve cells in some brain regions continue to be produced throughout the life of the organism, notably in the olfactory bulb and the dentate gyrus of the hippocampus. Work has also established that pluripotent stem cells are found in the brains and spinal cords of adult animals, which are capable of transforming into neurons and glia when given the proper signals.

C. Neurons Are Highly Polarized Cells

The structure of the nerve cell is well-suited for intracellular and intercellular information transfer. Neurons are highly polarized cells, with long processes that extend from the cell body to interact with other nerve cells, muscles, or glands (Figs. 1 and 2). Neurons are often classified according to the number of processes extending from their cell bodies as multipolar, bipolar, and monopolar. Neurons are the most morphologically diverse population of cells in an organism, varying widely in their size, form, and number of processes. The following will serve as a general description of the most common attributes of neurons, with a focus on vertebrate neurons. However, as with almost every aspect of the nervous system, exceptions to nearly every general statement can be found.

Two types of processes are distinguished in the typical nerve cell: dendrites and axons. These processes are sometimes referred to generically as neurites, particularly in developing neurons grown in culture and in invertebrates where many of the distinctions described in the following sections are less clear. Dendrites can be considered as extensions of the cell body specialized for receiving information from other nerve cells or the environment. The number of primary dendrites emanating from the cell body can vary from zero to many and is characteristic of a particular cell

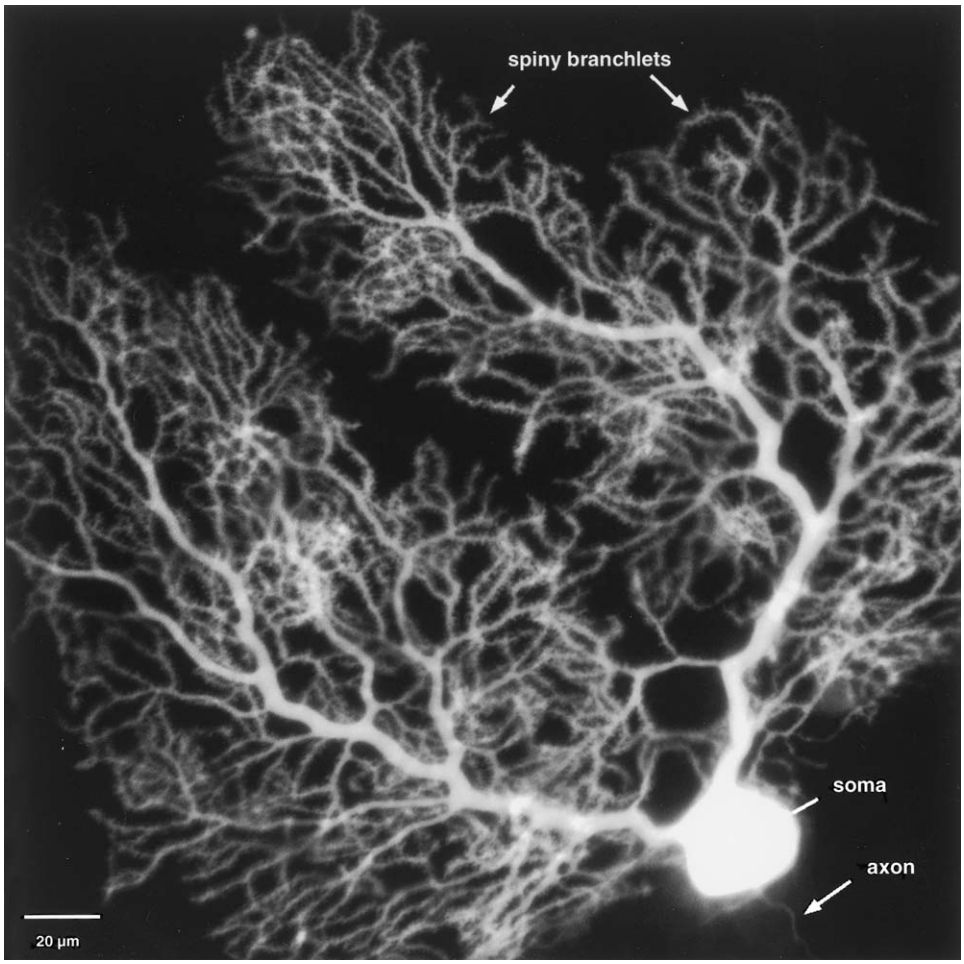

Figure 2 Purkinje neuron from the rat cerebellum stained by intracellular injection of the fluorescent dye lucifer yellow. The magnificent dendritic tree is revealed in its entirety. The fuzzy appearance of the finer caliber dendritic branches is due to the high density of dendritic spines (spiny branchlets). A single axon is visible emerging from the cell soma, although it is stained very faintly compared to the dendritic tree due to its small caliber.

type. The form of the dendritic tree can also be very distinctive, ranging from the simple morphologies of sensory cells to the magnificent tree of the Purkinje neuron (Fig. 2). The axon carries information away from the cell soma and transmits it to other neurons, muscles, and glands at a specialized cellular junction called the synapse. Information is conducted down the axon in the form of electrochemical signals known as action potentials. Transmission of signals to the next cell in the network usually involves the release of chemical neurotransmitters at the synaptic terminal, which interact with receptors in the target cell. The view that dendrites and axons are specialized for reception and transmission, respectively, was first proposed by Ramon y Cajal as the Law of Dynamic Polarization. However, examples where dendrites pass information between them (dendrodendritic transmission), signals are passed from the dendrite to the axon, and cells have no axons at all are numerous enough to suggest that this concept is only useful as a starting point for understanding neural circuits.

Since the time of Ramon y Cajal, neuroanatomists have spent considerable effort describing the morphology of nerve cells, from their overall form to their internal organization. The overall form has been studied by using techniques like the Golgi reaction (Fig. 1) and, more recently, by the injection of intracellular dyes, which reveal the pattern of the dendritic and axonal arbors of individual nerve cells (Fig. 2). The technique of intracellular dye injection is very powerful because it can be combined with intracellular recording in living tissue. By using this

method, neuroscientists have produced elegant studies correlating the form, chemical identity, and physiology of individual neurons. The form of a neuron is important in several ways in determining its functional properties. For example, the distribution and extent of the dendritic tree and axon will determine how a neuron fits into neural circuits. A neuron like the pyramidal cell of the cortex has dendrites that extend hundreds of microns and will receive different types of information compared to a cell such as the stellate cell, which has a much more limited dendritic field. Simple properties such as the diameter of the axon will affect the speed of neurotransmission, with larger caliber axons conducting faster than smaller caliber axons. Similarly, the diameter and branching pattern of dendrites along with the distribution of ion channels and other signal transduction molecules can affect the spread of a signal in the dendritic tree.

To develop and maintain their characteristic forms, neurons have well-developed cytoskeletons. The cytoskeleton is important not only for establishing and maintaining neuronal form but also for the transport of proteins and organelles throughout the neuron. The axons and dendrites of nerve cells can extend for hundreds or thousands of microns, necessitating an efficient mode of intracellular transport. The three major types of cytoskeletal elements found in all cell types, including neurons, are (1) microfilaments, e.g., actin, $\sim 7\,\mu m$ in diameter, (2) intermediate filaments, including neurofilaments, one of the neuron-specific classes of intermediate filaments, $\sim 10\,nm$ in diameter, and (3) microtubules, $\sim 25\,nm$ in diameter.

Although the morphology of a neuron is a good starting point for the discussion of neuronal diversity and function, the distinction between different types of neurons goes well beyond their unique morphology. Neurons are as heterogeneous in their biochemistry and physiology as they are in their morphology. Indeed, the nervous system by far displays the most molecular diversity of any tissue. The advent of immunocytochemical techniques to localize proteins and other small molecules and *in situ* hybridization to localize unique nucleic acid sequences has shown that different populations of neurons can be distinguished by their complement of neurochemical constituents. Such constituents include neurotransmitters, neurotransmitter receptors, ion channels, calcium-binding proteins, and neuropeptides. Even morphologically identical populations of cells can sometimes be divided into subclasses on the basis of their neurochemical signatures. Neurons are also distinguishable by their physiological properties, such as whether they excite or inhibit their targets, and by their pattern of firing. A major goal of modern neuroscience is to create an integrated view of nerve cells whereby the physiological properties of neurons can be understood in terms of their structural and biochemical specializations.

IV. PARTS OF THE NERVE CELL

Nerve cells are typically divided into several distinct functional domains (Fig. 3), each with its own unique set of structural and biochemical characteristics.

A. The Cell Body

The cell body of the neuron, also referred to as the soma or perikaryon, can range in size from 5 to $100\,\mu m$. The neuron cell body is like that of any other cell with the usual complement of organelles: a nucleus, usually with a prominent nucleolus, which contains the DNA of the cell, rough and smooth endoplasmic reticulum (RER and SER), free polyribosomes, a well-developed Golgi apparatus, mitochondria, and lysosomes (Fig. 4). Neurons are particularly rich in mitochondria, which produce cellular energy in the form of ATP, in part because the maintenance of the ionic gradients described earlier is an energy-dependent process. Cytoplasmic proteins are synthesized by free ribosomes in the cytoplasm, whereas those destined for insertion into membranes or for secretion are synthesized by ribosomes on the RER and further processed by the Golgi apparatus. In many neurons, the RER is arranged into parallel stacks close to the nucleus. These stacks stain prominently with a class of basic stains called Nissl stains, e.g., cresyl violet and toluidine blue, and for that reason are sometimes referred to as Nissl bodies (Fig. 4). An interesting feature of neurons is that they do not contain stores of glycogen, as do many types of cells. Thus, they are reliant on a constant supply of blood to meet their energy needs. However, astrocytes, the most numerous type of glia, do contain glycogen stores and are intimately associated with both neurons and blood vessels, suggesting that they provide some metabolic support to the neuron.

The cell body is the trophic center of the cell. It performs the bulk of protein synthesis for the neuron and contains the nucleus. *In situ* hybridization studies show that most mRNA species are confined to the cell soma. Dendrites and axons separated from their soma cannot survive and will eventually degenerate.

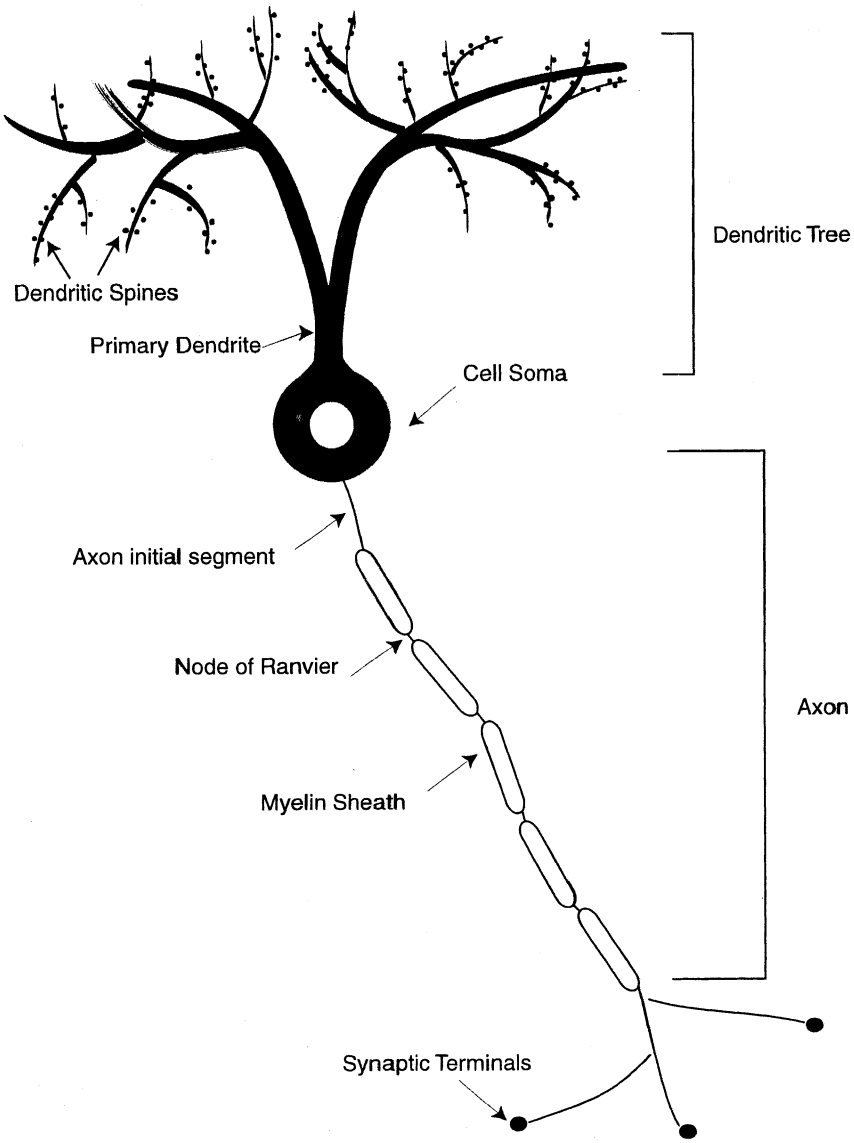

Figure 3 Schematic drawing of a neuron showing the major compartments and features.

However, neurons are also dependent for survival upon certain molecules, called growth factors, obtained from their targets via their axons and transported back to the cell soma. Especially during development, a neuron that fails to establish contacts with an appropriate target will degenerate.

When brain tissue is stained with a technique that identifies the cell bodies, e.g., a Nissl stain, the density of neuronal somata is very low compared to other tissues like muscle or skin. The bulk of nervous tissue is not composed of cell bodies in close apposition or extracellular space, but rather is composed of the intermingling of dendrites, axons, dendritic spines, and glial elements, which is called neuropil. Under the electron microscope, the neuropil appears as a dense conglomerate of small profiles (Figs. 4, 5, and 10).

B. Dendrites

One or more dendrites (Gr: "tree" or "branch") extend from the cell soma with a gradual tapering. Dendrites can extend for tens to hundreds of microns in length and can branch extensively, usually at acute angles and

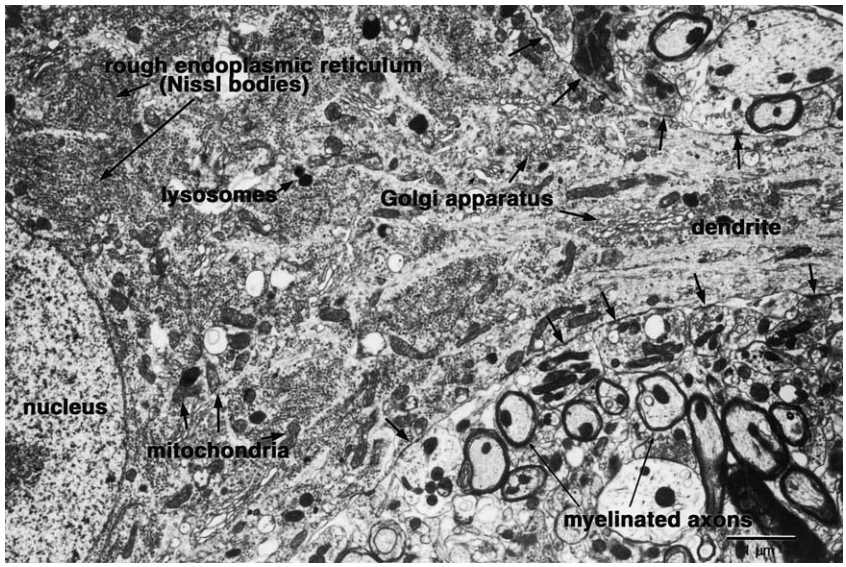

Figure 4 Electron micrograph of a motor neuron in the rat spinal cord showing the transition between the soma and a primary dendrite. The soma is the area surrounding the nucleus which gradually tapers into a dendrite. Numerous synaptic contacts onto the plasma membrane are visible (arrows). A group of myelinated axons is visible next to the soma.

with subsequent diminishment in dendritic diameter. There is often no clear morphological distinction between proximal dendrites and the soma; the same organelles, with the exception of the nucleus, are found in cell bodies and proximal dendrites, although the amounts of rough endoplasmic reticulum and Golgi apparatus diminish and eventually disappear from more distal dendrites (Fig. 4). In more distal dendrites, the only organelles found with regularity are mitochondria, the smooth endoplasmic reticulum, and multivesicular bodies (Fig. 5). The smooth endoplasmic reticulum is able to uptake, sequester, and release calcium, and dendrites express high levels of SER proteins involved in intracellular calcium regulation (Fig. 6). In some neurons, an expansion of the SER into cisterns closely apposed to the plasma membrane is seen. This expansion is very characteristic of Purkinje neurons and spinal motor neurons and is called the hypolemmal cisternae.

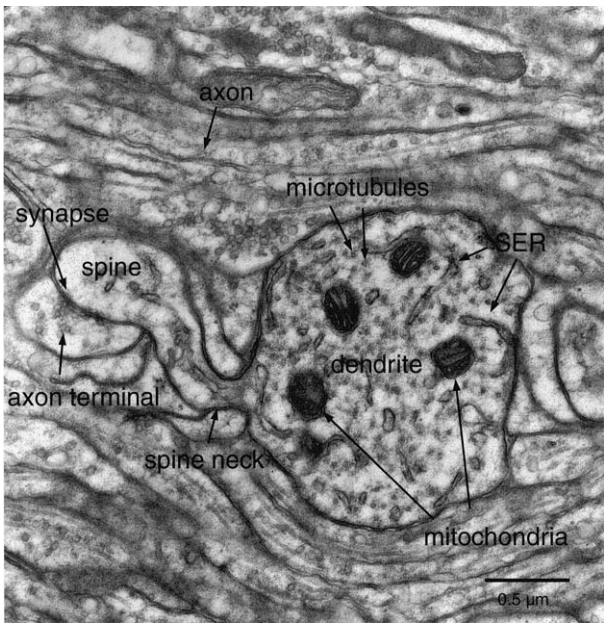

Figure 5 Electron micrograph of a cross section of a Purkinje cell dendrite in the chicken cerebellum with a single spine emerging from the dendritic shaft via a thin spiny neck. Small-caliber axons are visible coursing on either side of the dendrite.

Microtubules are the most prominent and abundant cytoskeletal element in dendrites and are aligned along the long axis of the dendrite, whereas intermediate filaments are less common. Although microtubules are found in the soma, axon, and dendrites, microtubules in each region are distinguished by the proteins associated with them. For example, dendrites are distinguished by high levels of MAP2 (microtubule-associated protein, type 2) compared to the soma and to axons. These microtubule-associated proteins appear to be important in determining the stability and arrangement of microtubules. Staining for MAP2 is often used as a method for identifying a neuronal process as a dendrite.

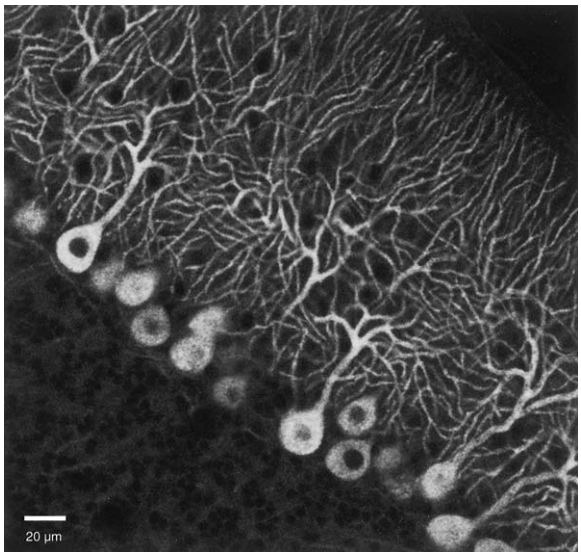

Figure 6 Purkinje neurons in the chicken cerebellum stained for the ryanodine receptor, a calcium channel located in the membranes of the smooth enodplasmic reticulum. When activated, the channel opens and releases calcium from stores inside the SER. Many other neurons are present in this brain region, but they do not stain for this particular protein.

Proteins and other constituents required for dendritic maintenance and functioning are transported into the dendrite from the soma by an active mechanism at the rate of about $\sim$20 mm/day. Whereas identifiable RER and the Golgi apparatus are almost never seen in distal dendrites, ultrastructural studies have shown that polyribosomes, some in close association with membranous cisterns, are found throughout the dendritic tree. Many of the polyribosomes are found near synaptic contacts. With the development of high-resolution *in situ* hybridization techniques, researchers discovered that a small number of mRNA species are also found localized in dendrites. These mRNAs are specifically targeted to dendrites by signal sequences contained within their 3′-untranslated regions and often encode proteins important for signal transduction. The most well-studied dendritic mRNA is that encoding the α form of calcium/calmodulin-dependent protein kinase II (CamKII), which is found in high levels in the dendrites of pyramidal neurons in the hippocampus. CaMKII is a multifunctional enzyme important in signal transduction at the synapse. Neurons grown in culture have been demonstrated to support protein synthesis in their dendrites, and some evidence exists that this also occurs *in vivo*. Researchers have hypothesized that these targeted mRNAs support protein synthesis that is activated in response to local activation of synapses and, thus, may be related to synaptic plasticity or the modulation of synaptic efficacy.

C. Dendritic Spines

Certain dendrites possess fingerlike extensions, 1–2 μm in length, called dendritic spines. In low magnification images, a high density of dendritic spines gives dendrites a fuzzy appearance (Figs. 1 and 2). Spiny protrusions are also found on the cell soma and on the axon initial segment, but the dendritic spines are more numerous and have received the most study. Neurons that have large numbers of spines on their dendrites are referred to as spiny neurons, whereas those with smooth dendrites or few dendritic spines are termed aspiny. Dendritic spines are one of the most intensively studied structures in the central nervous system because they receive the bulk of excitatory synaptic input and are thought to be key sites of synaptic plasticity, the process by which neurons are able to modify their properties in response to activity.

Dendritic spines vary widely in their size and morphology between classes of neurons and even within the same neuron (Fig. 7). The prototypical spine, seen in the hippocampus, neostriatum, cerebral cortex, and cerebellar cortex, consists of a thin stalk or neck, $\sim$100 nm in diameter, which arises from the main dendritic shaft, and a larger, rounder head. Dendritic spines can be distinguished from the main dendrite by the lack of mitochondria and microtubules, although some of the larger spines found in the olfactory bulb and hippocampal area CA3 contain both of these structures. Dendritic spines have very high concentrations of microfilaments, in particular filamentous actin. The majority of spines receive only a single synaptic contact onto the spine head, which usually uses the neurotransmitter glutamate. In the cerebral cortex and the neostriatum, about 20% of the spines receive a second synapse onto the spine neck, which is inhibitory or modulatory in action. The only other organelle seen with any regularity in the spine is the smooth endoplasmic reticulum, although coated and uncoated vesicles, multivesicular bodies, and single ribosomes have also been reported. Larger spines in the hippocampus, cerebral cortex, and neostriatum also contain a curious structure called the spine apparatus, consisting of lamellar plates of endoplasmic reticulum alternating with dense, filamentous material. The spine apparatus has

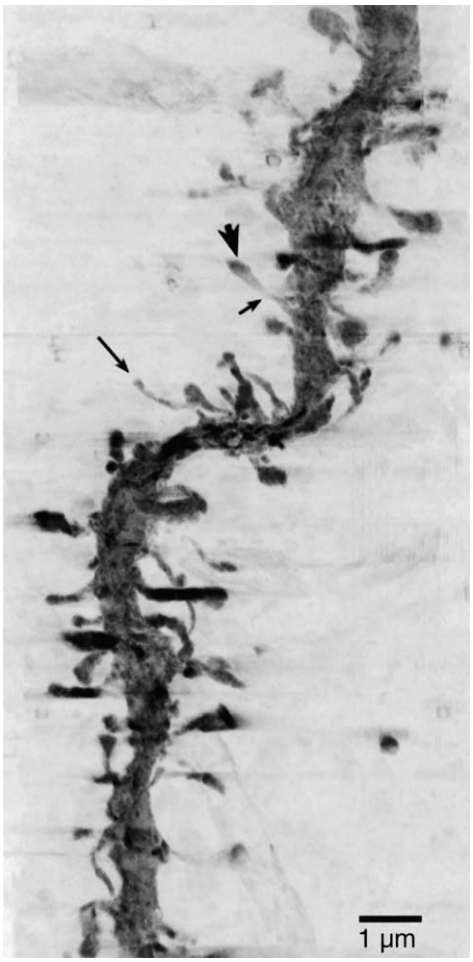

Figure 7 High-voltage electron micrograph of a spiny dendrite from the rat neostriatum showing the variation in size and shape of spines, even on a single dendrite. Spines can exhibit many morphologies, ranging from short stumpy spines to long thin spines without an obvious spine head (long thin arrow) to larger spines with an obvious head (short thick arrow) and neck (short thin arrow). The high-voltage electron microscope allows the microscopist to use much thicker sections than is possible in a conventional electron microscope. The thicker sections permit the viewing of dendritic spines in their entirety. The spiny dendrite was first injected with a fluorescent dye, which was then converted into a label that is visible under the electron microscope.

filamentous links with the postsynaptic site and may be involved in the shuttling of proteins to the synapse. As is the case with the SER in the dendritic shaft, proteins involved in the the uptake, storage, and release of intracellular calcium have been localized to the spine SER and spine apparatus. Release of calcium from these intracellular stores is thought to be an important signal transduction mechanism for synaptic transmission and may be involved in spine dynamics.

The most densely spiny cell in the CNS is the Purkinje neuron, which has been estimated to have upward of 150,000 spines per neuron. Precise counts of dendritic spines are difficult to obtain because they are too small to be resolved sufficiently in the light microscope, but they are too large to be contained completely within the thin sections typically employed for electron microscopy. To gain accurate spine counts, it is necessary to perform serial section reconstruction at the electron microscopic level or use high-voltage electron microscopy (Fig. 7). However, electron microscopic analysis is typically performed over a small portion of the entire dendritic tree, and the density of dendritic spines tends to vary over the length of the dendrite. Thus, a review of the literature can result in wildly disparate estimates of the total spine number on a given neuron type. Quantification of spine density is important because it gives an estimate of the total synaptic input to a given neuron.

Dendritic spines are labile structures in that neurons can change the size, shape, and number of their dendritic spines in response to developmental, environmental, pathological, and experimental influences. For example, researchers have shown that spine numbers are very sensitive to reproductive hormones such as estrogen. During the estrous cycle of the rat, the number of spines on a hippocampal pyramidal neuron can fluctuate by as much as 20%. Spine dynamics can be visualized directly by observing living neurons in culture or in brain slices. In these preparations, individual spines were observed to change their shape within seconds after a drug or electrical stimulus was applied to the culture dish. By using time lapse microscopy, researchers have observed new spines growing or established spines disappearing over the course of minutes.

The function of dendritic spines has been a matter of debate since their first description by Cajal. Their function clearly goes beyond simply increasing the surface area available for synaptic contact, because few synapses are established on the dendritic shafts of spiny neurons and only $\sim$10% of the total spine surface is taken up by a synaptic contact. Many theories have focused on their possible role in synaptic plasticity. One method by which neurons are thought to store information long term is by structural or biochemical modification of certain synapses. Because each spine usually receives only a single synapse, dendritic spines serve to isolate individual synapses. Rapid changes in spine shape could alter the signaling properties of a particular synapse, and the spine itself may serve as a local compartment whereby

modification of a given synapse can occur in isolation. Dendritic spines may also serve to protect the main dendrite from any negative effects associated with synaptic stimulation. As a consequence of synaptic activation, levels of calcium are raised inside the cell. These high concentrations of intracellular calcium are necessary for signal transduction but are also deleterious to the cell. Dendritic spines may allow local increases in intracellular calcium in the vicinity of the synapse while restricting its spread to other parts of the neuron.

D. The Axon

Axon is short for axis cylinder. Nerve cells may possess many dendrites but usually have only a single axon, which can be impressively long. Nerve cells projecting between the spinal cord and the brain and from the brain stem and spinal cord to muscles and glands can have axons over 1 m in length. At the other extreme, some small neurons seen in sensory systems have no axons, and these are termed amacrine cells. The main axon may give rise to many collateral branches, which typically branch off at obtuse angles. In some cases, a collateral can ramify within the dendritic field of the parent cell and nearby cells, which is known as a recurrent collateral, and examples of neurons synapsing upon themselves (autapses) have been described. Unlike dendrites, the diameter of the axon usually does not diminish with increasing distance from the cell soma. In a given brain region, neurons are typically classified into projection and intrinsic neurons, according to the trajectory of their axonal ramification. Projection neurons, also called principal, relay, or Golgi type I cells, have long axons and project outside of the region in which the parent cell resides. Intrinsic neurons, also called interneurons or Golgi type II cells, have shorter axons and ramify locally within a brain region. Interneurons tend to have inhibitory influences on their targets and are very important for shaping the spatial and temporal responses of principal neurons.

Axons can arise from either the cell body or primary dendrite, from a coned-shaped region termed the axon hillock. Unlike dendrites, where there is often a gradual changeover in cell constituents from the soma, there is an identifiable transition from soma to axon. The most proximal portion of the axon, which can be recognized in the electron microscope by its characteristic morphology, is referred to as the initial segment. Action potentials arise from the initial segment, which has an extremely high density of Na^+ channels. No rough endoplasmic reticulum, ribosomes, or Golgi apparatus extend into the axon much beyond the initial segment. Consistent with the lack of protein synthetic machinery, no protein synthesis is seen in axons. Initial segments can also be recognized in the electron microscope by bundles of microtubules aligned along the axon cylinder and by the presence of a fine, electron-dense fuzz lining the plasma membrane. As with dendrites, the smooth endoplasmic reticulum extends throughout the axon, where it is sometimes called the axoplasmic reticulum. Microtubules are also found throughout the axon, although in larger caliber axons, neurofilaments predominate. The microtubule-associated protein τ is concentrated in axons and can be used to identify a neurite as an axon in cell cultures.

Axons are almost totally reliant on the cell body for trophic support, and so axons separated from their somas will obligatorily undergo degeneration. This fact was exploited by early neuroanatomists, particularly in the 1950s and 1960s, for tracing axonal projections. A lesion was placed in an area containing cell bodies and then the brain was stained with silver-based stains specific for degenerating axons. By following the paths of degenerating axons, anatomists could infer the projection patterns of the lesioned neurons. Of course, any axons passing through the lesioned region damaged along with the cell bodies would also degenerate. In the modern anatomical age, degeneration-based methods have been largely replaced by the use of tracers that are injected into the brain, taken up by the cell body, and transported down the axon to their targets.

1. Axonal Transport

Axonal transport, the process by which protein complexes and membranous organelles are transported within axons, has been studied extensively. Axons are capable of bidirectional transport. Transport from the soma to the distal axon is known as anterograde transport, whereas transport from distal regions back to the soma is known as retrograde transport. Axonal transport is an energy-dependent process that involves microtubules and the microtubule-based motor proteins, the dyneins and kinesins. Several distinct components have been identified in axonal transport, which differ in their cargoes and the rate of transport. Small membrane-bound organelles such as clear-lumened vesicles and vesiculotubular structures are transported out of the cell soma in the fast component, capable of moving up to 100 mm/day.

Larger membrane-bound structures such as multivesicular bodies carry materials back to the cell body and are also transported by a fast mechanism. Mitochondria move independently of the anterograde and retrograde flows, and the axoplasmic reticulum is stationary relative to fast transport. Cytoskeletal and cytoplasmic proteins are transported much more slowly, on the order of 1–10 mm/day.

2. The Action Potential

Axons are able to transmit signals to their targets by the conduction of action potentials along their length. The action potential involves a sudden membrane depolarization followed by a rapid reversal. The ionic basis of the action potential was elucidated by Alan Hodgkin and Andrew Huxley in the 1940s and 1950s in pioneering studies using the giant axon of the squid. The main currents involved in generating the action potential are carried by Na^+ and K^+ ions. Na^+ is much more concentrated in the extracellular environment, whereas K^+ tends to be more concentrated inside the axon. The plasma membrane of axons contains ion channels permeable to Na^+ and K^+. These ion channels are known as voltage-gated channels in that the internal potential of the cell will determine whether the channel is open or closed. If the potential reaches a certain threshold value, the ion channel will undergo a conformational change that causes it to either open or close. The normal resting potential of a neuron is on the order of -60 to -70 mV, which is largely the result of a high concentration of K^+ ions inside the axon.

An action potential is initiated in the axon hillock when the synaptic signals received by the dendrites and soma are sufficient to raise the intracellular potential to the threshold potential of -55 mV. When this potential is reached, the Na^+ channels present in the axon initial segment will open. Na^+ ions rush into the cell, causing rapid reversal of the membrane potential from -90 to $+40$ mV. When the membrane potential reaches $+40$ mV, the Na^+ channels close and the voltage-gated K^+ channels open. K^+ ions move out of the axon, thereby repolarizing the membrane. As a result of this coordination of Na^+ and K^+ channels, the action potential is circumscribed in time and restricted in space to a local patch of membrane. However, some current spreads passively down the axon, driving the membrane potential toward threshold in an adjacent patch of membrane and the process is repeated. In this way, the action potential is propagated down the axon in an anterograde direction without a loss of amplitude. The action potential is prevented from traveling back toward the soma due to factors that make the preceding patch of membrane refractory to stimulation. Following the cessation of the action potential, Na^+/K^+ ATPases in the membrane remove Na^+ from the interior of the cell and uptake K^+ from the extracellular space, restoring the proper ionic balance. The speed of conduction in different axons varies tremendously from slow conduction (~ 0.5 m/sec) to very fast (80–120 m/sec). The speed of conduction of a given axon is directly proportional to the axon diameter and the density of ion channels in the membrane. Another major determinant of the speed of axon conduction is the presence or absence of the myelin sheath.

3. The Myelin Sheath

Fast-conducting axons in the vertebrate nervous system are wrapped in a thick, fatty coating called myelin, which is formed by glial cells. Myelin in the peripheral nervous system is formed by a type of glial cell known as the Schwann cell, whereas in the central nervous system, myelin is formed by the class of glia known as oligodendroglia or oligodendrocytes. Under the electron microscope, myelin appears as a series of concentric layers enveloping the axon (Fig. 8). These layers are actually the membrane of a single myelinating glial cell spiraled around the axon cylinder with the cytoplasm of the glial cell squeezed out. The dark staining is due to the fixation of the nerve cell with the heavy metal osmium tetroxide, which reacts primarily

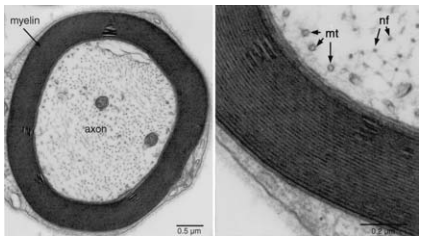

Figure 8 Electron micrograph of a myelinated nerve fiber in a rat peripheral nerve. (Left) Cross section of a myelinated axon showing the characteristic dense staining of the myelin sheath. Part of the cytoplasm of the Schwann cell forming the myelin sheath is also visible. (Right) Higher magnification view of the myelin sheath showing the concentric layers of the myelin sheath formed by the plasma membrane of the Schwann cell spiraling around the axon with the cytoplasm squeezed out. Some of the Schwann cell cytoplasm is visible around the outer layer of the myelin sheath. Microtubules (mt) and neurofilaments (nf) cut in cross section are clearly visible.

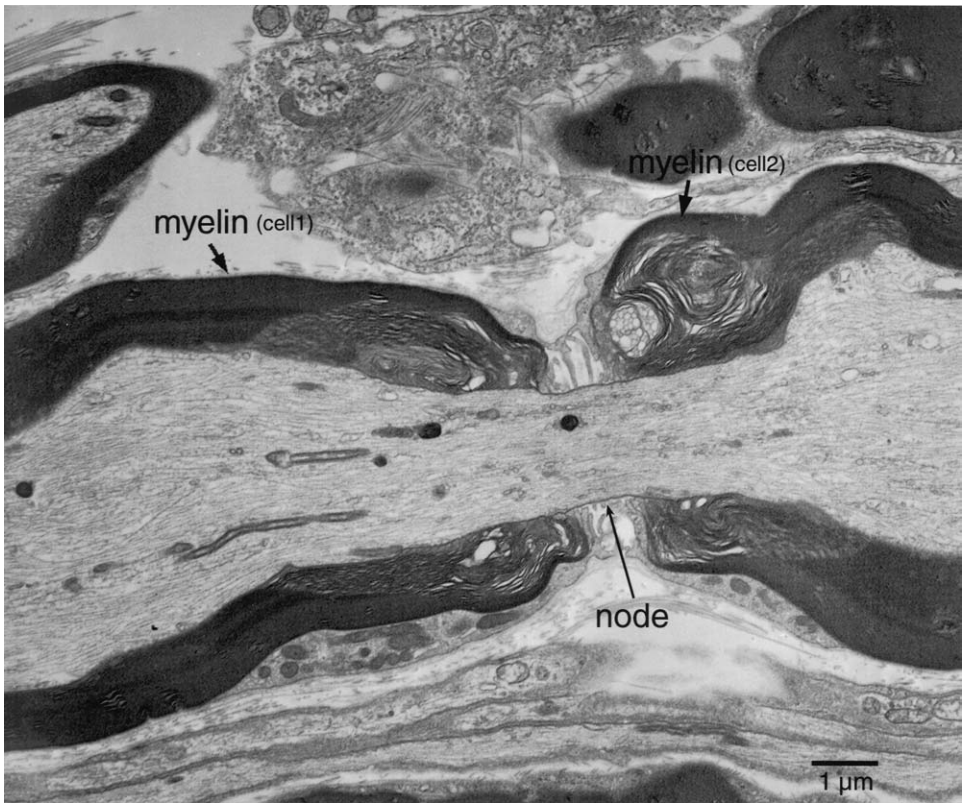

Figure 9 Electron micrograph of a node of Ranvier from a rat peripheral nerve. The nodal gap between the myelin formed by two adjacent Schwann cells is clearly visible.

with lipids and adds significantly more electron-scattering stain to these sites. In unstained tissue, the presence of myelin is what gives bundles of axons their macroscopic white, shiny appearance.

The presence of the myelin sheath tremendously increases the speed and efficiency of nerve conduction by improving the capacitive and resistive properties of the axon cable. The myelin sheath of these insulated axons is not continuous but is interrupted at regular intervals, 1–2 mm apart. The interruptions occur where the ensheathment of one glial cell ends and another begins (Fig. 9). The gaps in the myelin sheath were first described in the 1870s by the French neuroanatomist Louis-Antoine Ranvier, who also described myelin, and have been named nodes of Ranvier in his honor. Nodes of Ranvier have high concentrations of Na^+ and K^+ channels in the plasma membrane. The myelin sheath serves as an insulator to the axon, preventing the leakage of ions across the membrane in the internodal regions. Action potentials are generated only at the node, rather than continuously down the length of the axon. This form of axonal conduction is called saltatory conduction because the action potential jumps from node to node. Myelination is usually observed in axons $>1\,\mu m$ in diameter. Smaller axons in the peripheral nervous system are still ensheathed by Schwann cells, but no myelin is formed. In the central nervous system, small axons usually have no glial covering. The importance of the myelin sheath for normal nerve function is underscored by the devastating effects of demyelinating diseases, such as multiple sclerosis, which result in significant neurological impairments.

E. The Synapse

The term synapse (Gr: "fasten together") was first coined by the physiologist Charles Sherrington in the late nineteenth century. Synapses are specialized cellular junctions that are the site of intercellular communication between neurons and their targets. Two types of synapses are distinguished, chemical and electrical. Electrical synapses are also known as gap

junctions and are formed by proteins called connexins, which provide a low-resistance conduit between cells where ions and other small molecules can pass directly from cell to cell. Transmission through electrical synapses is very rapid and can provide a mechanism for synchronizing the firing of groups of connected neurons. Electrical synapses are more common between neurons in invertebrates but are found in vertebrates as well. Gap junctions are not unique to nerve cells but are also formed between glial cells and are found in other types of tissue. The most common form and best-studied synapse in the vertebrate nervous system is the chemical synapse, where signals are passed from one cell to the next through the agency of chemical neurotransmitters (Fig. 10). The neurotransmitter is released from small vesicles contained in the axon terminals of one cell (designated the presynaptic cell), diffuses across the extracellular space, and interacts with receptor proteins located in the postsynaptic cell. The postsynaptic cell is most commonly a neuron, but it can also be a muscle, gland, or organ. In fact, most of what is known about synaptic transmission is derived from studies of the neuromuscular junction, the synapse between motor neurons and the skeletal musculature, because this synapse is large and relatively accessible compared to synapses in the central nervous system.

Chemical synapses provide polarized, point-to-point zones of intercellular communication. Anatomically, synapses are difficult to identify conclusively at the light microscopic level without some sort of special stain, although Ramon y Cajal correctly identified the expansions at the axon terminal closely apposed to the dendrites and somata of other nerve cells as the point of intercellular communication. The anatomical correlate of the synapse was described definitively by Sanford Palay, George Palade, and others with the advent of biological electron microscopy starting in the 1950s (Fig. 10). Synapses can occur at the terminal end of axons, in which case they are called synaptic terminals or synaptic boutons, or they can occur along the length of the axon at local swellings. This type of synapse is very common in the mammalian nervous system and is called an *en passant* synapse. In myelinated axons, the *en passant* synapse occurs at the nodes of Ranvier. In the case of the terminal boutons, axons lose their myelin sheath prior to the terminal expansion.

The synapse and its associated specializations are most clearly visualized under the electron microscope (Fig. 10). Presynaptically, the synapse is characterized by the presence of a concentration of clear vesicles,

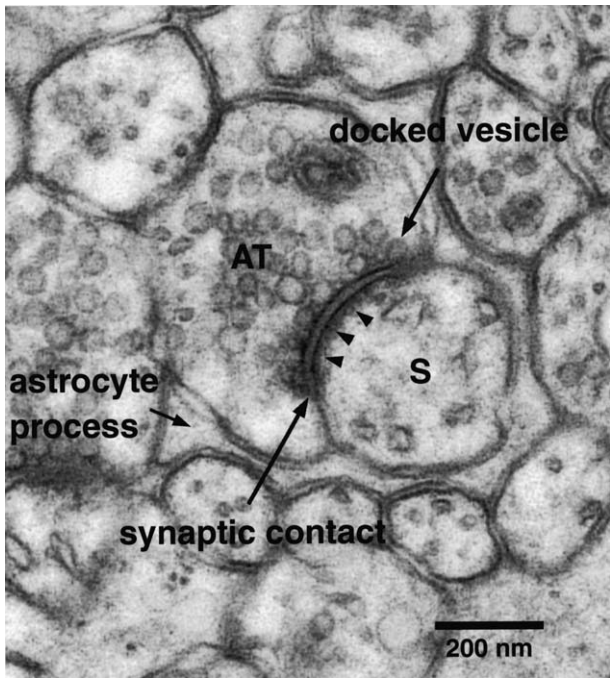

Figure 10 Electron micrograph of an asymmetrical synaptic contact onto a dendritic spine (S) in the rat cerebellum. The characteristic features of a synaptic contact are clearly visible, including the concentration of vesicles in the presynaptic axon terminal (AT), the widening of the extracellular cleft at the site of contact, and the presence of a prominent postsynaptic density (arrowheads). This synaptic complex is surrounded by an astrocytic process.

referred to as synaptic vesicles, $\sim$40 nm in diameter. These vesicles contain neurotransmitter molecules, which are released upon activation (see later discussion). Vesicles are clustered around presynaptic membrane specializations, consisting of a series of regularly spaced, electron-dense projections termed the active zone, believed to aid in the docking of vesicles for the release of neurotransmitter. More elaborate synaptic specializations can be seen in some synapses, such as the synaptic body of the vestibular hair cell and the ribbon class synapses found in several cell types. These specializations are thought to serve as a mechanism for conveying vesicles to docking sites. Other elements present in the presynaptic terminal include dense-core vesicles, mitochondria, microtubules, neurofilaments, and smooth endoplasmic reticulum.

The synaptic cleft, the intercellular gap across which the neurotransmitter diffuses, is also distinct. It tends to be wider than the average nonsynaptic distance between cells, on the order of $\sim$20–25 nm, and

contains electron-dense material. Fine filaments have been described spanning the cleft. Numerous cell adhesion molecules such as the NCAMs (neural cell adhesion molecules) and cadherins are found at the synapse, which serve to anchor the pre- and postsynaptic membranes. The adherence at the synapse is very strong and has been exploited in biochemical studies where intact synaptic complexes, or synaptosomes, can be recovered using cell fractionation techniques.

On the postsynaptic side, the major feature is the presence of a postsynaptic specialization consisting of electron-dense, filamentous material apposed to the postsynaptic membrane directly across the cleft from the active zone (Fig. 10). The electron dense material in the postsynaptic cell is called the postsynaptic density. In some types of synapses, especially those occurring in dendritic spines, the postsynaptic density is quite prominent, giving an asymmetrical appearance to the synapse. These synapses are often referred to as asymmetrical synapses and tend to be associated with excitatory synaptic transmission. Other synapses have much less prominent postsynaptic densities and are usually referred to as symmetrical synapses. Often, these synapses are associated with inhibitory synaptic transmission. These distinctions are not absolute and many synapses of intermediate morphology have been described. Asymmetrical and symmetrical synapses were first described by Edward Gray in the 1950s and are sometimes referred to as Gray's type I and type II synapses, respectively.

Much progress has been made to elucidate the composition of the postsynaptic membrane and density. In addition to neurotransmitter receptors, the postsynaptic membrane also contains proteins called cadherins as well as other adhesion molecules responsible for the tight adherence of pre- and postsynaptic membranes. Cytoskeletal proteins such as actin, tubulin, and fodrin are present in high abundance. Proteins involved in the anchoring of neurotransmitter receptors and ion channels to the cytoskeleton have also been identified. These proteins, also known as PDZ domain containing proteins, serve both to anchor neurotransmitter receptors and ion channels in the postsynaptic membrane and to link neurotransmitter receptors to downstream signaling proteins forming large macromolecular complexes. Other multifunctional signal transduction proteins such as CaM kinase II, DARP32, and protein kinase C may also be present in the postsynaptic density. Thus, the postsynaptic density serves to concentrate and organize signal transduction machinery at the synapse.

Synaptic complexes do not usually occur in isolation in the vertebrate nervous system but are closely associated with glial cells. In the central nervous system, the processes of astrocytes envelop or partially surround the presynaptic terminal and sometimes wrap around both the pre- and postsynaptic elements (Fig. 10). Astrocytes are the most numerous type of glial cell in the central nervous system. The extent of glial investiture of synapses varies across brain regions and even from synapse to synapse in a given brain region. Astrocytic processes are known to be able to take up certain neurotransmitters like glutamate from the extracellular environment and also to regulate the extracellular concentration of K^+ ions. Studies have suggested that glial cells are important for regulating synaptic transmission at glutamatergic synapses and for protecting against neurotoxic concentrations of glutamate in the extracellular space.

1. Synaptic Transmission

Chemical neurotransmission is a carefully regulated process. Synaptic transmission at the chemical synapse involves multiple steps and thus is slower than transmission through electrical synapses, but it provides the advantage of directionality and amplification of signal transmission. The major steps involved in the most rapid form of chemical synaptic transmission can be summarized as follows. Action potentials invade the synaptic terminal and open voltage-sensitive calcium channels present in the plasma membrane. Calcium triggers a series of molecular interactions ultimately causing vesicles in the vicinity of the vesicle docking area or active zone to fuse with the presynaptic membrane and release their contents into the synaptic cleft. This process is very fast, occurring on a submillisecond time scale. The neurotransmitter diffuses across the synaptic cleft and interacts with neurotransmitter receptors anchored to the postsynaptic membrane by cytoskeletal proteins in the postsynaptic density. Excess neurotransmitter either is broken down by enzymes located in the cleft, diffuses away from the synaptic site, or is taken up by the presynaptic cell through the action of transporter molecules present in the presynaptic membrane or surrounding glial cells. Lipids and specific proteins contained in the synaptic vesicle are then recycled from the plasma membrane using a clathrin-mediated mechanism, and in most systems the recycled vesicles are refilled with neurotransmitter and otherwise readied for another release cycle. A large number of proteins involved in vesicle docking, transmitter uptake and release, signal

transduction, and vesicle recycling have been identified. Unraveling of the molecular players in synaptic transmission is critical not only because synaptic transmission is fundamental to the functioning of the nervous system but also because many toxins and neuroactive drugs target proteins involved in this process.

The binding of a neurotransmitter to its receptor can result in several postsynaptic events occuring simultaneously. In some cases, the neurotransmitter receptor is an ion channel that allows Na^+ or Ca^{2+} into the cell (called ionotropic receptors). Ionotropic responses tend to be fast, occurring in the millisecond range. In other cases, the neurotransmitter activates a second messenger system like cyclic AMP or phosphoinositol breakdown (metabotropic receptors). The actions initiated via these metabotropic receptors are much slower than ionotropic response, occurring over seconds or even minutes. The result of neurotransmission can be either excitatory or inhibitory. Excitatory neurotransmission drives the postsynaptic neuron closer to firing an action potential, whereas negative neurotransmission drives the neuron farther from firing an action potential. Excitatory responses tend to involve intracellular increases of Na^+ or K^+ ions, resulting in membrane depolarization, whereas inhibitory responses usually involve increases of Cl^- ions, resulting in hyperpolarization. Beyond the voltage changes observed in the postsynaptic cell, a host of other signal transduction cascades are activated, usually in response to a rise in intracellular calcium. Calcium can activate various enzyme complexes such as protein kinases and proteases. Signals can be propagated to the nucleus to activate gene transcription. Several immediate early genes such as *c-fos* are turned on as a result of synaptic activation.

A variety of small molecules are now known to act as neurotransmitters. The prototypical fast excitatory neurotransmitter in the vertebrate nervous system is the amino acid glutamate, whereas the most common inhibitory neurotransmitter is γ-aminobutyric acid, usually referred to as GABA. Although these molecules are referred to as excitatory or inhibitory, in fact a neurotransmitter is neither excitatory or inhibitory, because its action depends upon the type of receptor present and the state of the postsynaptic cell. Other well-characterized neurotransmitters include acetylcholine, glycine, and the biogenic amine transmitters serotonin, dopamine, and norepinephrine. These molecules have all been identified as neurotransmitters on the basis of well-established criteria, such as their presence in presynaptic terminals and their interaction with specific receptors. Many other neuroactive substances are also released from the synapse along with recognized neurotransmitters, such as the fatty acid arachadonic acid, ATP, and even gases such as nitric oxide. Many of these act as neuromodulators, in that they modify the response of the cell to a neurotransmitter. These substances are not necessarily contained in synaptic vesicles but may be released directly from the terminal.

The brain contains a large number of neuroactive peptides, short chains of amino acids, such as the enkephalins, substance P, and neurotensin, which also function as neurotransmitters and neuromodulators. Neuropeptides are contained in vesicles in the terminal, but in the large dense-core vesicles and not the small clear vesicles seen in Fig. 10. Unlike other neurotransmitters that are synthesized locally in the axon terminal via specific enzymes, peptides are synthesized in the cell body, packaged in the vesicles via the Golgi apparatus, and transmitted to the terminal. Peptides interact with specific receptors that activate second messenger molecules and, thus, tend to be associated with slow synaptic transmission. They are often colocalized and coreleased from the synaptic terminal with one of the better characterized transmitters. However, exocitosis from dense-core vesicles does not occur at the presynaptic active zone but can occur anywhere in the nerve terminal or along the axon. Release from dense-core vesicles requires a higher concentration of Ca^{2+} than does release from clear vesicles and generally occurs when the nerve is firing at high frequency. Thus, although both fast and slow neurotransmitters may be contained in the same nerve terminal, they may be released under different circumstances.

2. Synaptic Arrangements and Integration

The most common site of synaptic contact on a neuron is on the dendrites or dendritic spines. These types of synapses are referred to as axodendritic or axospinous. In cells that possess dendritic spines, the vast majority of synapses occur onto the spine heads, whereas few synapses are observed onto the dendritic shaft. In fact, it has been estimated that over 90% of excitatory synaptic inputs in the brain occur onto dendritic spines. Synapses also occur onto the cell soma and axon initial segment. In general, those synapses that occur onto the cell soma, initial segment, and proximal dendrites tend to be inhibitory in nature. For example, in the cerebellum, hippocampus, and cortex, an inhibitory interneuron termed the basket cell forms

pericellular baskets surrounding the somata of projection neurons and establishing numerous inhibitory synaptic contacts. Inputs more distally and onto dendritic spines tend to be excitatory. In some areas of the brain, most notably the olfactory bulb, dendrites are capable of forming synapses onto other dendrites. These special arrangements are called dendrodendritic synapses because a dendrite is serving as both the pre- and the postsynaptic element. Reciprocal synapses, where each dendrite serves as both the pre- and the postsynaptic cell, have also been described.

Whether a neuron will initiate an action potential in response to synaptic activation will depend upon the spatial and temporal integration of excitatory and inhibitory activation over the whole cell. Excitatory and inhibitory influences are summed over the entire dendritic tree and cell body and integrated in the soma. If threshold is reached, an action potential is initiated in the axon hillock, the spike initiation zone. Previously, it was thought that ionic spread from dendrites to soma occurred exclusively through passive diffusion. However, several ion channels have been localized in the dendritic plasmalemma and some dendrites are known to possess the ability to fire action potentials.

Individual neurons vary widely in the number of synapses they receive, averaging approximately 1000 per neuron. Generally, if a neuron receives a large number of synapses, each synapse is relatively weak and the simultaneous activity of multiple synapses is necessary to excite the postsynaptic cell. An example of a cell that receives large numbers of weak synapses is the Purkinje cell found in the cerebellum, which receives up to 150,000 synapses onto its dendritic spines from the cerebellar granule cell. Each granule cell exerts relatively little influence on the Purkinje cell, and so multiple granule cells must be activated to cause the Purkinje cell to fire an action potential. In contrast, other types of synapses are very powerful, such as the synapse formed at the neuromuscular junction where every action potential in the nerve fiber results in a corresponding action potential in the muscle cell. Individual neurons can receive a mixture of strong and weak synapses. The strength of an individual synapse will be determined principally by the amount and duration of transmitter released upon stimulation and also its location on the postsynaptic cell. Those synapses occurring closer to the cell soma tend to exert a stronger postsynaptic effect than those occurring more distally.

The large number of synapses received by an individual nerve cell indicates that there can be a tremendous convergence of information at the cellular level. Divergence of information also occurs, because a single axon can synapse with many cells either through the *en passant* type along the course of the axon or by ramification of synaptic terminals. In several regions of the brain, a specialized arrangement called a glomerulus (L: "small ball") is seen. The glomerulus consists of a very large presynaptic bouton, which contacts multiple postsynaptic dendrites. In the cerebellar mossy fiber glomerulus, the presynaptic terminal can measure 10–20 μm in length and can contact up to 50 dendrites. Glomerular arrangements are also seen in the thalamus, olfactory bulb, and several other brain regions.

V. SUMMARY

Neurons are more than globes filled with talented molecules…

Harris and Kater (1994)

The morphology and general characteristics of neurons have been established through pain-staking investigation over the last 100 years. Our understanding of neurons has evolved over the same period from ill-defined corpuscular globules consisting of a lump of protoplasm containing a nucleus to the exquisitely detailed, highly compartmentalized, information processing cellular machines of today. The major challenge facing neurocytologists is the specification of the molecular machinery and the organization of functional domains used by the neuron to accomplish its daunting task. Modern neuroscientists have the advantage of access to powerful computers and algorithms for modeling the behavior of individual neurons and neuron ensembles. As our understanding of neurons, glia, and their interactions increases, further breakthroughs in understanding the functioning of the nervous system in health and disease can be expected.

Neuropeptides and Islet Function

BO AHRÉN
Lund University

GLOSSARY

exocytosis Extrusion of secretory vesicle from cell to extracellular space.

islet The endocrine pancreas, consisting of cell islets scattered throughout the pancreas and comprising several different types of endocrine cells.

neuropeptides Peptides localized to nerve terminals, released when the nerves are activated and functioning as neurotransmitters.

secretory granules Cellular vesicles storing the secretory product of the cell.

This article summarizes the present day knowledge of the islet neuropeptides, which are of relevance for the regulation of islet function. Normal islet function is of vital importance for glucose and lipid homeostasis, because a main function of the islets is to secrete an optimal amount of insulin and glucagon to regulate metabolism. Important factors for the regulation of islet function therefore are glucose and free fatty acids. Circulating hormones, mainly gut hormones, also are of importance for normal islet function, notably after food intake, as are the various peptide hormones produced within the pancreatic islets, which affect the secretory rate of the other islet hormones. In addition, the autonomic islet nerves are involved in the regulation of islet function, and the central nervous system therefore is able to adjust the secretory rates of the islet hormones for the optimization of metabolism under various conditions. Effectors for this action are the neurotransmitters in the islet nerves, which besides acetylcholine and norepinephrine also include several different neuropeptides.

I. ISLET ANATOMY

The pancreatic islets are scattered throughout the entire pancreas, and each islet mainly consists of four different endocrine cells synthesizing and secreting the four islet hormones: insulin (β cells), glucagon (α cells), somatostatin (δ cells), and pancreatic polypeptide (PP, F cells) (See Table I for a list of abbreviations used throughout the text.) Microanatomical studies have shown that the β cells usually form the central portion of the islet structure, whereas the other cells form a mantle zone surrounding the β cells. The afferent vessels to the islets first reach the centrally located β cells. Blood vessels then pass through the central portion of the islets to reach the mantle zone, from which they leave the islets in efferent vessels. In addition, the islets are densely innervated, and parasympathetic, sympathetic, sensory, and other

Table I
Abbreviation List

AA	Arachidonic acid
ADP	Adenosine diphosphate
ATP	Adenosine triphosphate
CALCA	Calcitonin complex gene A
CALCB	Calcitonin complex gene B
CALCP	Calcitonin complex pseudo-gene
cAMP	Cyclic adenosine monophosphate
CCK	Cholecystokinin
CCK_A	CCK receptor A
CCK_B	CCK receptor B
CGRP	Calcitonin gene-related peptide
CPON	C-terminal flanking peptide of NPY
CRLR	Calcitonin receptor-like receptor
CTR	Calcitonin receptor
DAG	Diacylglycerol
GalR1	Galanin receptor subtype 1
GalR2	Galanin receptor subtype 2
GalR3	Galanin receptor subtype 3
GIP	Gastric inhibitory peptide
GLP-1	Glucagon-like peptide-1
GMAP	Galanin message-associated polypeptide
GRP	Gastrin releasing peptide
IAPP	Islet amyloid polypeptide
IP_3	Inositol 1,4,5-triphosphate
NMB	Neuromedin B
NPY	Neuropeptide Y
PAC_1	PACAP receptor subtype 1
PACAP	Pituitary adenylate cyclase activating polypeptide
PHM	Peptide histidine methionine
PKA	Protein kinase A
PKC	Protein kinase C
PLA_2	Phospholipase A_2
PLC	Phospholipase C
PLD	Phospholipase D
PP	Pancreatic polypeptide
PRP	PACAP-related peptide
PYY	Peptide YY
RAMP	Receptor-activity-modifying protein
VIP	Vasoactive intestinal peptide
$VPAC_1$	VIP PACAP receptor subtype 1
$VPAC_2$	VIP PACAP receptor subtype 2

autonomic nerves innervate the islet endocrine cells. These nerves harbor the classical neurotransmitters, acetylcholine and norepinephrine, and a number of neuropeptides.

II. ISLET FUNCTION

A main function of the pancreatic islets is to secrete a sufficient amount of insulin and glucagon to keep the circulating glucose level within its normal range. The regulation between the islet hormones and circulating glucose is a closed circuit in which glucose stimulates insulin secretion but inhibits glucagon secretion, whereas insulin reduces circulating glucose but glucagon increases circulating glucose (Fig. 1). This allows insulin to be responsible for protection from hyperglycemia, which is of primary importance after food intake when glucose levels increase due to nutritional ingestion and glucose absorption. This effect of insulin is achieved by augmenting the uptake of glucose in a variety of tissues, mainly skeletal muscle cells and adipocytes. Conversely, reduction of the glucose concentration to hypoglycemic levels elicits a stimulation of glucagon secretion, allowing glucagon to increase glucose levels through a stimulated hepatic glycogenolysis, which eventually restores normal glucose concentrations. Therefore, glucagon protects from hypoglycemia. The islet nerves are involved in the optimization of this tight control of circulating glucose, allowing the brain to react to observed or anticipated changes in circulating glucose and eliciting islet hormone secretion to be inhibited or stimulated to adjust glucose concentrations (Fig. 1). Malfunction of this optimization of islet function may lead to disturbed control of circulating glucose, which may be manifested as glucose intolerance after food intake or inadequate glucose recovery after hypoglycemia. The islet nerves and their neuropeptides therefore might be involved both in the normal control of islet function and glucose homeostasis and in the development of malregulation of circulating glucose.

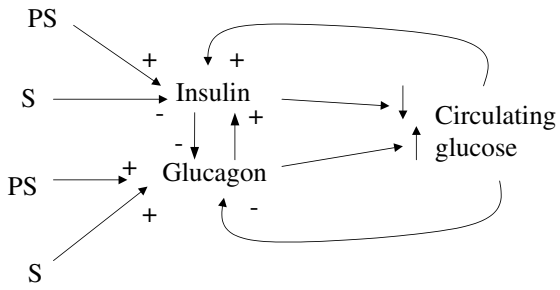

Figure 1 Schematic illustration of the influences of parasympathetic (PS) and sympathetic (S) nerves and glucose on insulin and glucagon secretion and influences of insulin and glucagon on the secretion of each other and on circulating glucose.

III. CELL BIOLOGY OF INSULIN SECRETION

The islet nerves and their neurotransmitters alter islet hormone secretion through surface-located receptors, which affect the cell biology of exocytosis of the islet hormones via signaling systems. Several transduction mechanisms are operative in β cells, transmitting signals for the stimulation or inhibition of insulin secretion. A primary mechanism underlying insulin secretion involves β cell metabolism of glucose, which increases the cytosolic ratio of ATP/ADP. This depolarizes the plasma membrane through the closure of ATP-regulated K^+ channels, which causes the opening of voltage-sensitive Ca^{2+} channels and the uptake of extracellular Ca^{2+} to raise the cytosolic concentration of Ca^{2+}. Another signaling pathway is initiated by phosphoinositide hydrolysis using phospholipase C (PLC) and phospholipase D (PLD), which produces diacylglycerol (DAG) and activates protein kinase C (PKC). PLC also induces the formation of inositol 1,4,5-triphosphate (IP_3), which stimulates the liberation of Ca^{2+} from intracellular storage sites. A third pathway involves the activation of adenylate cyclase, which produces cyclic AMP and activates protein kinase A (PKA). Finally, a fourth pathway involves the activation of phospholipase A_2 (PLA_2), which generates arachidonic acid (AA). These second messengers (cytosolic Ca^{2+}, PKC, PKA, and AA) then activate the exocytotic machinery, which releases insulin. The neurotransmitters affecting insulin secretion may execute their actions either by affecting any of these signaling mechanisms or by directly affecting the final exocytosis of insulin-storing granules. The mechanism of action of the neurotransmitters is different for each receptor activated.

IV. RELEVANCE OF THE AUTONOMIC INNERVATION OF THE PANCREATIC ISLET

The brain controls islet function through the autonomic nerves. Both parasympathetic and sympathetic nerves form a dense innervation of each islet, enabling release of their neurotransmitters in close apposition to the individual islet endocrine cells. A dense parasympathetic innervation has been verified by light and electron microscopy after staining sections with cholinesterase. Furthermore, histochemical data have shown a 10-fold higher concentration of choline acetyltransferase in islet tissue than in pancreatic tissue as a whole, which illustrates the high density of islet innervation. The parasympathetic nerve fibers innervating the islets originate in the intrapancreatic ganglia. These ganglia are in turn controlled by the preganglionic fibers, which emanate mainly from the dorsal motor nucleus of the vagus. The preganglionic fibers traverse through the vagus, both as part of the bulbar outflow tract and the hepatic and gastric branches of the vagus. They enter the pancreas along the vessels and terminate at intrapancreatic ganglia, from which the postganglionic nerves originate. These in turn penetrate the islets to terminate in close proximity to the endocrine cells. Activation of the parasympathetic nerves has been undertaken experimentally by electrical activation of the vagus, which stimulates the secretion of both insulin and glucagon. Therefore, the brain exhibits a potent autonomic system to stimulate the secretion of the two main glucoregulatory hormones from the islets.

Parasympathetic activation of islet hormone secretion is of importance in two conditions. First, it is involved in the cephalic phase of insulin secretion during food intake. This is the rapid and early increase in insulin secretion that is seen during the first 3–4 min after the initiation of food intake before any nutrient has reached the circulation to affect islet function. This phase is triggered by sensory mechanisms involving afferent pathways activated by olfactory, visual, gustatory, and oropharyngeal mechanical receptors. The afferent pathways are then integrated centrally, eliciting stimulation of the efferent pathways activating the secretion of insulin. A cephalic phase regulation of insulin secretion has been verified by demonstrations of insulin secretion (1) during sham feeding, i.e., feeding without food actually entering the gastrointestinal tract, (2) during imaginary food ingestion under hypnosis, (3) after the sight, smell, and expectation of food, and (4) after the ingestion of nonmetabolizable food. Furthermore, this early insulin response during food intake is also apparent when blood sampling is rapidly undertaken after food ingestion when an increase in circulating insulin is already evident before any significant increase in postabsorptive glycemia. Experimental studies have shown that the cephalic phase of insulin secretion is activated through the stimulation of oral taste receptors. It has also been demonstrated that the central integrative circuit is localized to the ventromedial hypothalamus and to the dorsal motor nucleus of the vagus and that the effector pathway is mediated by parasympathetic neurons within the vagus nerves. Consequently, the cephalic phase of insulin secretion is

abolished by vagotomy and by ganglionic blockade. Even though this cephalic phase of insulin secretion during food intake is short-lived and in magnitude corresponds to only 1–3% of the total insulin secretion after intake of a meal, it is of major importance for glucose tolerance after feeding. Thus, prevention or inhibition of the cephalic phase of insulin secretion results in glucose intolerance, and a brief insulin administration during inhibition of the cephalic phase restores glucose tolerance.

Another important function of the parasympathetic nerves is to stimulate glucagon secretion during hypoglycemia, which provides a mechanism for the recovery of circulating glucose. The protection against hypoglycemia is also achieved by other mechanisms, for example, the secretion of adrenaline and cortisol from the adrenals as well as direct stimulation of the release of glucose from the liver, but the primary involvement of glucagon in this respect has been established. The glucagon response to hypoglycemia is due to direct stimulation of glucagon secretion by the low glucose level and by the reduced intraislet concentration of insulin, and several studies have shown that the autonomic nerves also contribute to a major degree. Thus, ganglionic blockade is associated with more than 75% inhibition of the glucagon response to hypoglycemia in conjunction with lowered responses of markers for parasympathetic activation, as demonstrated both in humans and in experimental animals. In summary, the parasympathetic nerves are known to innervate the pancreatic islets, to stimulate insulin and glucagon secretion, and to be of importance for the cephalic phase of early insulin secretion during food intake and for the stimulated glucagon response to hypoglycemia.

The pancreatic islets are also innervated extensively by the sympathetic nerves, as demonstrated by fluorescence microscopy, electron microscopic studies, and immunocytochemistry. The islet sympathetic nerves are postganglionic with most nerve cell bodies located in the celiac ganglion or in the paravertebral sympathetic ganglia. The preganglionic nerve fibers originate from nerve cell bodies in the hypothalamus and leave the spinal cord at the level of C8–L3, whereafter the fibers traverse the lesser and greater splanchnic nerves to reach the paravertebral or celiac ganglia. From the ganglia, the nerves pass within the mixed autonomic nerves, which enter the pancreas along its vessels, although preganglionic sympathetic nerve fibers may also directly enter the pancreas. Activation of the sympathetic nerves has been undertaken by electrical activation of either the splanchnic nerves or the mixed autonomic nerves entering the pancreas after atropinization. This results in the inhibition of insulin secretion and stimulation of glucagon secretion. This activation is of marked importance during various forms of stresses or physical exercise, when hyperglycemia is achieved by the sympathetically induced inhibition of insulin secretion and stimulation of glucagon secretion. Therefore, the hyperglycemia and increased glucose turnover associated with these conditions are executed to a large degree by the islet sympathetic nerves.

In addition to innervation by parasympathetic and sympathetic nerves, the islets are also innervated by sensory nerves whose nerve terminals harbor the sensory neuropeptides, mainly calcitonin gene-related peptide (CGRP). These sensory islet nerves have been shown to innervate in particular the peripheral portions of the islets, although occasional nerve fibers are also found in the central part. The fibers leave the pancreas along the sympathetic fibers within the splanchnic nerves to reach the spinal cord. The role of the islet sensory nerves is not known. Rodents treated with capsaicin, which results in deafferentation of small unmyelinated C-fibers and leads to sensory denervation in conjunction with a substantial reduction in the number of islet CGRP nerves, have been shown to exhibit increased insulin secretion and glucose elimination. This suggests that the sensory nerves inhibit insulin secretion. This is in line with several studies under a variety of experimental conditions, demonstrating that exogenous administration of CGRP inhibits insulin secretion. Hence, it is possible that islet sensory nerves have an efferent function through the local liberation of CGRP, which inhibits insulin secretion, although the physiological role of this effect is not known.

V. EVIDENCE FOR NONCHOLINERGIC, NONADRENERGIC NEURAL ISLET EFFECTS

Because evidence for parasympathetic innervation of the islets is based on the localization of cholinesterase and because exogenous administration of acetylcholine or other muscarinic agonists mimics the stimulatory effects of vagus nerve activation on insulin and glucagon secretion, it may be anticipated that the parasympathetic effects on islet function are mediated by cholinergic mechanisms. However, several studies have shown that noncholinergic mechanisms also contribute to these effects, because it has been

demonstrated that vagally induced islet hormone secretion is not always sensitive to inhibition by muscarinic antagonism by atropine. For example, vagally induced insulin secretion in the pig pancreas is resistant to atropine, although it is inhibited by ganglionic blockade, and, furthermore, glucagon secretion during vagal nerve activation in the dog is resistant to atropine. In regard to sympathetically induced actions on insulin secretion, evidence exists that these are mediated by the classical neurotransmitter, norepinephrine. Thus, norepinephrine is both localized to islet sympathetic nerve terminals and released from the pancreas during electrical activation of these nerves. Furthermore, upon exogenous administration, norepinephrine inhibits glucose-stimulated insulin secretion. However, evidence also exists for the contribution of nonadrenergic mechanisms for sympathetically induced islet effects. Thus, combined and complete α_2- and β-adrenoceptor blockade by yohimbine and propranolol does not counteract the inhibition of basal insulin secretion induced by electrical sympathetic activation, as demonstrated in dogs. Furthermore, exogenous administration of norepinephrine does not mimic the inhibition of sympathetic nerve activation of basal insulin secretion. Moreover, immunoneutralization of one of the neuropeptides in the sympathetic nerves, galanin, prevents exercise stress from inhibiting glucose-stimulated insulin secretion, as demonstrated in mice. Therefore, these studies suggest that both noncholinergic and nonadrenergic mechanisms contribute to the islet actions of parasympathetic and sympathetic nerves. These actions, as the action of the sensory nerves, may be mediated by the neuropeptides localized to the islet nerve terminals.

VI. ISLET LOCALIZATION OF NEUROPEPTIDES

Immunocytochemistry has revealed three neuropeptides to presumably parasympathetic nerve terminals in pancreatic ganglia and in islets: gastrin releasing peptide (GRP), vasoactive intestinal peptide (VIP), and pituitary adenylate cyclase activating polypeptide (PACAP). These neuropeptides are released from the pancreas upon electrical vagal activation and they stimulate both insulin and glucagon secretion, as demonstrated in a number of studies *in vivo* as well as *in vitro*. From both a morphological and a functional point of view, they are therefore candidates to contribute to islet hormone secretion induced by vagal nerve activation. Similarly, two neuropeptides may mediate the nonadrenergic contribution to the inhibitory action of sympathetic nerve stimulation on insulin secretion: galanin and neuropeptide Y (NPY). These two neuropeptides are localized to the islet sympathetic nerve terminals and to nerve cell bodies in the celiac ganglion. Furthermore, galanin and NPY are also released from the pancreas upon electrical activation of the sympathetic nerves and inhibit insulin secretion, as demonstrated both *in vivo* and *in vitro*. In addition, CGRP has been shown to be localized to islet nerves that are sensitive to capsaicin and, therefore, presumably sensory nerve terminals. Finally, cholecystokinin (CCK), which was originally described as a gut hormone, also is localized to islet nerves. The nature of these latter nerves has, however, not yet been identified, and therefore they are referred to as "other" nerves. Hence, at least seven neuropeptides seem to be involved in the local regulation of islet function. Table II summarizes these neuropeptides, their presumed

Table II

Islet Neuropeptides, Islet Neuropeptide Receptors, Their Main Signaling Pathways, and Their Effects on Insulin and Glucagon Secretion

Neuropeptide	Receptor	Main signaling pathway	Effect on insulin secretion	Effect on glucagon secretion
GRP	GRPR	PLC–PLD	Stimulation	Stimulation
VIP	$VPAC_2$	cAMP	Stimulation	Stimulation
PACAP	PAC_1	cAMP	Stimulation	Stimulation
	$VPAC_2$	cAMP		
Galanin	GalR1	K^+–Ca^{2+}	Inhibition	Stimulation
NPY	Y1	K^+–Ca^{2+}, cAMP	Inhibition	Stimulation
CGRP	CRLR–RAMP	K^+–Ca^{2+}, cAMP	Inhibition	Stimulation
CCK	CCK_A	PLC–PLA_2	Stimulation	Stimulation

receptors and signaling pathways when affecting islet hormone secretion, and their islet effects.

VII. ISLET NEUROPEPTIDES

A. Gastrin Releasing Peptide (GRP)

GRP is the mammalian homolog of the amphibian peptide bombesin. Bombesin is a 14-amino acid peptide that was initially isolated from the skin of the frog *Bombina bombina* in 1971 by Anastasi and collaborators. Three different families of bombesin-like peptides exist in amphibians (bombesins, ranatensins, and phyllolitorins). These peptides are localized to myoepithelial poison glands that are under adrenergic control and therefore likely function in defence against predators. During the 1970s it became evident that bombesin-like peptides also exist in mammals, and in 1979 a mammalian homolog to bombesin was isolated from the porcine gastrointestinal tract by Dr. McDonald in the laboratory of Professor Mutt in Stockholm. Because this peptide was found to stimulate gastrin release from a porcine stomach model, it was called GRP. A few years later, a second bombesin-like peptide was isolated in mammals and called neuromedin B (NMB). These two peptides show a resemblance to different bombesin families. Thus, whereas GRP is structurally related to bombesin, NMB is structurally related to the ranatensins. GRP consists of a 27-amino acid residue that is α-amidated at its C-terminal methionine. The peptide was highly conserved during evolution, and the human and porcine forms of the peptide differ in only two residues (Fig. 2). The gene for GRP is located on chromosome 18q21 and consists of three exons (Fig. 2). The first exon encodes for the signal peptide and for the first 23 N-terminally located amino acids of GRP, whereas the second exon encodes for the remaining amino acids in GRP and for the first 74 amino acids in a C-terminal extension peptide of GRP. Finally, the third exon encodes for the remaining 21 amino acid residues in this long extension peptide. Due to alternative donor and acceptor sites in the second intron, three different GRP mRNAs are formed by differential splicing. These three GRP mRNAs therefore arise from the same gene and they code for three different proGRPs; however, all consist of 125 residues and differ only in their C-terminal parts. The proform of GRP contains, besides GRP (=proGRP$_{1–27}$), the C-terminal extension peptide of GRP (=proGRP$_{31–125}$). This extension peptide contains a 95-amino acid residue, but the

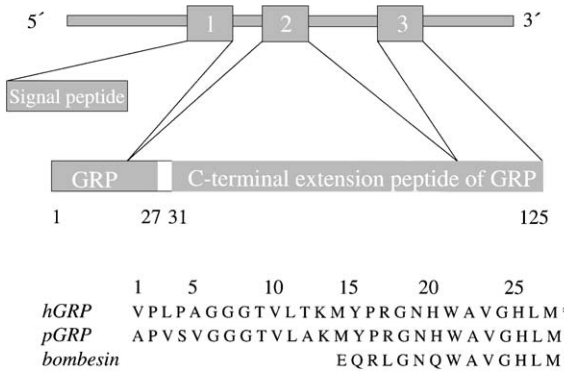

Figure 2 Schematic representation of the GRP gene and proGRP. The first exon encodes for the signal peptide and the N-terminal portion of the sequence of GRP, exon 2 encodes for the remaining portion of the GRP sequence and the major, N-terminal portion of the C-terminal extension peptide of GRP, and exon 3 encodes for the remaining sequence of this extension peptide. At the bottom of figure are the amino acid sequences of human and porcine GRP and bombesin. * indicates a C-terminal NH_2 group. The amino acids in this and the other figures are abbreviated according to the one-letter system: A, Ala; C, Cys; D, Asp; E, Glu; F, Phe; G, Gly; H, His; I Ile; K, Lys; L, Leu; M, Met; N, Asn; P, Pro; Q, Gln; R, Arg; S, Ser; T, Thr; V, Val; W, Trp; Y, Tyr.

amino acids are different depending on which mRNA is translated. This is in contrast to the GRP sequence, which is identical in all three GRP gene-derived mRNAs. proGRP$_{31–125}$ is posttranslationally modified to several different smaller peptides. GRP itself is also posttranslationally modified, and the major molecular forms in various tissues are GRP14, i.e., GRP27$_{1–14}$, and GRP27. The NMB gene is located on chromosome 15 and encodes for a 76-residue proNMB, which is processed to NMB (10 and 22 residues) and a 17-residue C-terminal extension peptide of NMB. It is thought that the GRP and NMB genes developed during evolution by duplication of the bombesin gene.

GRP is widely distributed in mammalian tissues, with the highest concentrations in the lung, central nervous system, and gut. In the peripheral nervous system, GRP is involved in the regulation of a variety of physiological processes, such as exocrine and endocrine secretions and smooth muscle contractions, and GRP is a powerful trophic agent as well. GRP is also localized to the brain with particular density in the hypothalamus, and centrally the peptide has been shown to be involved in the control of food intake and behavior. In the pancreas, GRP is localized to nerves with particular density in the ganglia, and GRP has also been shown to be released from the isolated pig pancreas when the attached vagal nerve is activated.

Furthermore, when GRP is exogenously added to different experimental models, both *in vivo* and *in vitro*, and to both the intact pancreas and isolated islets, the peptide efficiently stimulates both insulin and glucagon secretion. Because the pancreatic density of GRP localization is highest in the ganglia, it is possible that the peptide exerts actions both locally in the islets and also through ganglionic activation. Experimental support for such a notion was presented because ganglionic blockade inhibited the insulin response to exogenously added GRP in mice. Therefore, morphological and functional evidence suggests that GRP is a pancreatic parasympathetic neurotransmitter, the effect of which may contribute to islet actions of parasympathetic nerve stimulation, and this may be achieved both by a direct islet action and by an indirect ganglionic action.

The bombesin-like peptides, like GRP, are known to bind to G-protein-coupled receptors that are of the seven transmembrane domain type. Three receptors for the bombesin-like peptides have been cloned in mammals: the GRP receptor, the NMB receptor, and the bombesin receptor subtype 3. It is also possible, although not yet demonstrated, that bombesin receptor subtypes 2 and 4 might exist in mammals. However, in contrast to the GRP and NMB receptors, no endogenous ligand for these receptors has been found in mammals. The genes for both the GRP receptor and the bombesin receptor subtype 3 are localized to the X chromosome, whereas the gene for the NMB receptor is localized to chromosome 6. The chromosomal site for the GRP receptor is chromosome Xp21.2-p21.3, and this gene contains three exons. The receptor consists of 384 amino acids and shows a high degree of conservation during evolution, with homology between species of approximately 90%. Interestingly, the GRP receptor shows 60% homology with the NMB receptor. It has not yet been established whether the GRP receptors are expressed in the islet endocrine cells, although it is known that the islets are equipped with specific GRP binding sites. In islets, activation by GRP has been shown to be coupled mainly to PLC and PLD, and the islet action of GRP therefore is related to changes in cytoplasmic Ca^{2+}, formation of DAG, and activation of PKC. Studies have also demonstrated that GRP induces typical patterns of oscillation in cytosolic Ca^{2+}, which is due to both dynamic release of Ca^{2+} from intracellular stores and passage of Ca^{2+} through plasma membrane Ca^{2+} channels.

The relative importance of GRP for islet function has not yet been established. One study has used a specific GRP receptor antagonist, *N*-acetyl-$GRP_{20–26}$-amide, which is a fragment of GRP in which methionine has been deleted from position 27, to examine the potential involvement of GRP in islet function in mice. This antagonist has been used to inhibit the actions of GRP in a number of experimental systems and has also been shown to inhibit insulin secretion stimulated by exogenously added GRP in mice. However, the antagonist did not reduce islet hormone secretion induced by autonomic nerve activation, which suggests either that GRP does not contribute to islet function during autonomic nerve activation or that this antagonist is not a suitable tool for examining this contribution *in vivo*.

Another approach to the study of the physiological impact of GRP and GRP-related peptides is the use of receptor-deficient mice. Dr. Wada and collaborators in Japan have used genetic targeting to develop mice with deletion of either the bombesin receptor subtype 3 or the GRP receptor. Studies presented so far indicate that the mice with bombesin receptor subtype 3 deleted develop obesity. However, until the endogenous ligand for this receptor in mammals is found, the physiological relevance of this finding is not known. Furthermore, the GRP-receptor-deficient mice show impaired insulin response to gastric administration of glucose and to autonomic nerve activation, which suggests that GRP is involved in the parasympathetic regulation of islet function through activation of the GRP receptors. This would imply that GRP physiologically contributes to parasympathetically mediated insulin secretion during food intake, which supports a role for this neuropeptide in the regulation of islet function through the activation of GRP receptors.

B. Vasoactive Intestinal Peptide (VIP)

VIP was originally isolated from the porcine small intestine in the early 1970s by Dr. Said in the laboratory of Professor Mutt. The peptide has been shown to consist of a 28-amino acid residue with a C-terminal α-amidation. It shows structural similarities to the so-called glucagon family of peptides, i.e., glucagon, gastric inhibitory peptide (GIP), glucagon-like peptide-1 (GLP-1), and secretin. There is a high degree of identity in the VIP sequence between different species. For example, human, porcine, and rat VIPs are identical, differing from guinea pig VIP in only two amino acids. The human gene coding for VIP is located on chromosome 6q24 and contains seven

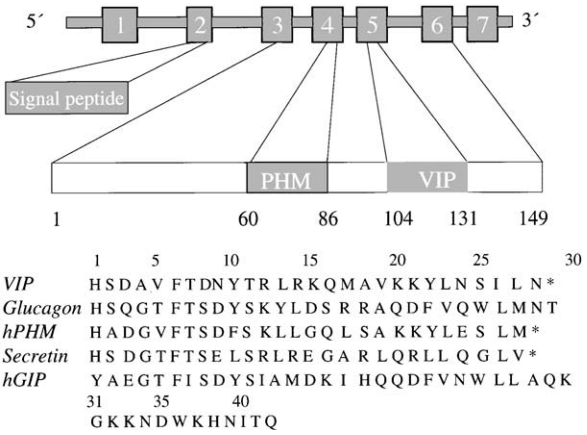

Figure 3 Schematic representation of the VIP gene and proVIP. The first exon is non-encoding, exon 2 encodes the signal peptide, exons 3–6 encode the proVIP sequence, and exon 7 is non-encoding. At the bottom of the figure are the amino acid sequences of VIP, glucagon, human PHM, secretin, and human GIP. * indicates a C-terminal NH_2 group.

exons. It encodes, besides for VIP, for peptide histidine methionine (PHM). This is a 27-residue peptide showing a high degree of homology to VIP because 15 of the amino acids are identical. VIP is encoded in exon 5, whereas PHM is encoded in exon 4 of the gene. Exon 2 encodes the signal peptide, which contains 21 residues, and proVIP is encoded in exons 3–6, which contains 149 residues, of which PHM is equivalent to $proVIP_{60–86}$ and VIP is equivalent to $proVIP_{104–131}$ (Fig. 3).

VIP is a neuropeptide exhibiting widespread distribution in the body. Thus, VIP nerves are localized to both the central nervous system and the respiratory, gastrointestinal, and genitourinary systems. In these systems, a variety of actions of VIP have been reported, such as relaxation of smooth muscle cells and stimulation of exocrine and endocrine secretions. A notably powerful action of VIP is its relaxation of smooth muscles in vessels, leading to vasodilatation. In the 1970s, it was also demonstrated that VIP occurs in the pancreas. Initially, the peptide was assumed to be an endocrine peptide in the islets, but it is now established that VIP is exclusively a neuropeptide localized to nerve terminals in the islets, ganglia, and exocrine pancreatic tissue. A neural VIP network surrounding the islets has also been demonstrated in both humans and experimental animals, suggesting important contributions of VIP to islet function. VIP may be involved in the local regulation of islet blood flow, because the peptide is a powerful vasodilatory agent and also has been demonstrated to increase islet blood flow upon exogenous administration. VIP may also be involved in the local regulation of islet hormone secretion. Thus, VIP is released from the pancreas when the vagal nerves are activated, and, furthermore, VIP is a powerful stimulator of both insulin and glucagon secretion under a number of conditions.

Two different VIP binding receptors have been cloned. They both show affinity for PACAP and are called the $VPAC_1$ and $VPAC_2$ receptors, respectively. They are both of the seven transmembranous domain type and they are G-protein-coupled. The $VPAC_1$ receptor consists of 460 residues and the $VPAC_2$ receptor consists of 438 residues. $VPAC_1$ is encoded by chromosome 3p22, whereas $VPAC_2$ is encoded by chromosome 7q36.3. Both of these genes consist of 13 exons. Activation of the VIP receptors is followed by activation of adenylate cyclase with the formation of cAMP, as has been demonstrated in islet cells. Cyclic AMP in turn activates PKA, which enhances exocytosis. Hence, the stimulation of insulin and glucagon secretion by VIP seems to be a classical cAMP–PKA-mediated process.

The relative contribution of VIP to islet function has not been established. Changing the VIP structure by substituting methionine in position 17 for leucine and inserting a 4-chloro substitution on phenylalanine in position 6 results in a VIP antagonist, [4-Cl-D-Phe^6, Leu^{17}]VIP, which inhibits islet hormone secretion after exogenous administration of VIP. However, this antagonist was without effect on the insulin or glucagon response to autonomic nerve activation in an *in vivo* study of the mouse. Therefore, further studies are required to examine the role of VIP in the regulation of islet function.

The VIP gene product, PHM, may also be of potential importance in the regulation of islet function, because this peptide, like VIP, stimulates insulin and glucagon secretion. However, much less is known about this peptide. For example, the receptors mediating its actions and its signaling pathways have not been established.

C. Pituitary Adenylate Cyclase Activating Polypeptide (PACAP)

PACAP was originally extracted from the pituitary gland in 1989 by Dr. Arimura and collaborators. Two forms of PACAP exist consisting of 27 and 38 amino acids, respectively, and PACAP, like VIP, belongs to the glucagon superfamily of peptides. In fact, PACAP

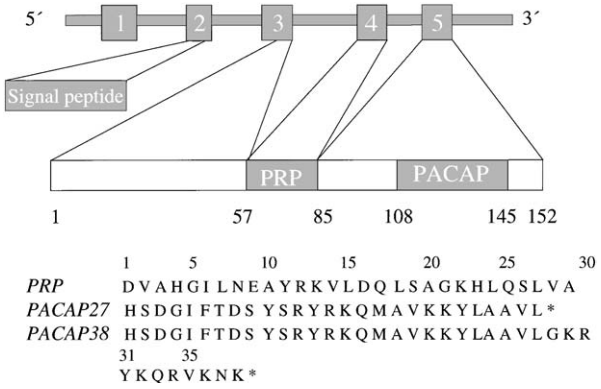

Figure 4 Schematic representation of the PACAP gene and proPACAP. The first exon is non-encoding, exon 2 encodes the signal peptide, and exons 3–5 encode the proPACAP sequence. At the bottom of the figure are the amino acid sequences of PACAP27, PACAP38, and PRP (PACAP–related peptide). * indicates a C-terminal NH_2 group.

shows 68% identity to VIP. The gene for PACAP is located on chromosome 18p11 and consists of five exons. The entire PACAP sequence is included in the fifth exon. Transcription and translation of the second exon yield a 24-residue signal peptide, whereas the fifth exon encodes the PACAP precursor, which is 152 residues long. PACAP38 is equivalent to proPACAP$_{108–145}$ (Fig. 4). PACAP27 is then cleaved from PACAP38, consisting of its 27 N-terminal amino acids (PACAP38$_{1–27}$). In various tissues, including the pancreas, the main PACAP form is PACAP38. In addition, a PACAP-related peptide (PRP) is formed from proPACAP$_{57–85}$. Although this peptide, like PACAP, is distributed in a variety of organs and its structure shows a 44% resemblance to PHM, its function is still not known.

Like VIP, PACAP is also distributed ubiquitously and occurs mainly in nerves in the central nervous system, the lungs, and the gastrointestinal tract. PACAP has been demonstrated to exert a multitude of effects in these organs, such as relaxation of smooth muscle cells and stimulation of secretion from the pituitary and adrenal glands. In the central nervous system, a neurotrophic action of the peptide has also been reported. The neuropeptide is located in islet nerve terminals and in pancreatic ganglia, and because it is released from the pancreas during electrical activation of the vagal nerves, it is thought to be mainly a parasympathetic neuropeptide. It has, however, also been reported that PACAP is a neurotransmitter in sensory nerves. Finally, in one study PACAP has also been reported to be expressed not only in pancreatic nerves but also in islet β cells, although this has not been confirmed in other studies.

Like parasympathetic nerve activation, PACAP potently stimulates the secretion of both insulin and glucagon, which has been demonstrated both *in vivo* and *in vitro* in a number of experimental conditions. Like VIP, PACAP stimulates insulin secretion in a glucose-dependent manner accompanied by increased action of adenylate cyclase with increased formation of cAMP and activation of PKA. PACAP also exerts, however, other signaling actions in insulin producing tissues, like an increase in the cytoplasmic concentrations of both Ca^{2+} and Na^{+} and a distal effect on the exocytosis machinery. It is possible that the potency of PACAP to stimulate insulin secretion, which exceeds that of VIP, is due to the diversity of signaling actions induced by PACAP in islet β cells.

The close relation between PACAP and VIP is evidenced by the structural similarity of the peptides and by the affinity of both peptides to the $VPAC_1$ and $VPAC_2$ receptors. However, the findings that PACAP is more potent in stimulating insulin secretion than VIP and that signaling pathways other than the cAMP–PKA pathway also seem to be activated by PACAP suggest the existence of a third PACAP receptor, which is specific for PACAP. Such a receptor has also been cloned and named the PAC_1 receptor, and it is, like the two VPAC receptors, of the seven transmembranous domain type and G-protein-coupled. The PAC_1 receptor gene is located on chromosome 7p15-p14, and the receptor consists of 525 amino acids. The PAC_1 receptor is further divided into eight subtypes, all resulting from alternative splicing. The function of this splicing is not known, although different affinities for various PACAP forms have been documented for the different splice variants. In pancreatic islets, the occurrence of PAC_1 and $VPAC_2$ receptors has been verified.

The functional relevance of the PACAP nerves for islet function has started to emerge. One study used a PACAP antagonist, the 22 C-terminally located residues in PACAP27, i.e., PACAP$_{6–27}$, and administered it to mice. It was first demonstrated that the antagonist indeed is a PACAP antagonist, because insulin secretion stimulated by exogenously administered PACAP27 was inhibited by the antagonist. It was also found that the antagonist was without effect on the insulin response to exogenous VIP, suggesting that the antagonist is specific for PAC_1 receptors. When this antagonist was administered to mice challenged with a gastric administration of glucose, the resulting insulin response was impaired. This suggests that PACAP is

involved in the neural mediation of the insulin response to food intake. Similar results were also shown in a mouse model from which the PAC_1 receptor had been deleted. The model was developed by Dr. Brabet and collaborators in Montpellier by genetic targeting, and a gastric challenge with glucose was found to display a reduced insulin response in these mice compared to wild-type controls. Furthermore, studies undertaken in isolated islets have demonstrated that specific PACAP antisera not only reduce the insulin response to PACAP but also reduce the insulin response to glucose alone. Because this was not observed in islets that had been cultured for 48 hr and therefore were devoid of any remaining PACAP in surviving islet nerve terminals, it is likely that the insulinotropic response to glucose is dependent on release of PACAP and intact PACAP receptors. Similar results with reduced glucose-stimulated insulin secretion were also reported in the PAC_1-receptor-deleted mouse model. Hence, PACAP seems to be an islet neuropeptide of importance for islet function, notably after activation by glucose and postprandially.

D. Galanin

Galanin was isolated from the porcine gastrointestinal tract by Dr. Tatemoto in the laboratory of Professor Mutt in 1983. It was given its name by its glycine C-terminus and alanine N-terminus. It is a highly conserved peptide consisting of 29 amino acids in most species and C-terminally amidated. However, the human form of galanin consists of a 30-amino acid residue that is not C-terminally amidated. Whereas the C-terminal amino acid of galanin in the pig is alanine, it is threonine in rat galanin and serine in human galanin. Nevertheless, the name galanin has been retained for the peptide in rats and humans. The human galanin gene is located on chromosome 11q13.3-q13.5 and consists of six exons. The first exon is noncoding, whereas the coding region for progalanin consists of five exons (Fig. 5). Progalanin is a 123-residue peptide, which includes the signal peptide (23 amino acids), galanin (30 amino acids), and galanin message-associated peptide (GMAP, 61 amino acids). Posttranslational modifications yield the 91-amino acid progalanin consisting of galanin and GMAP. The N-terminal amino acids 1–13 in the galanin molecule are encoded in exon 3 and the remaining 17 amino acids in exon 4, which is of interest because it is the N-terminal end that is biologically active.

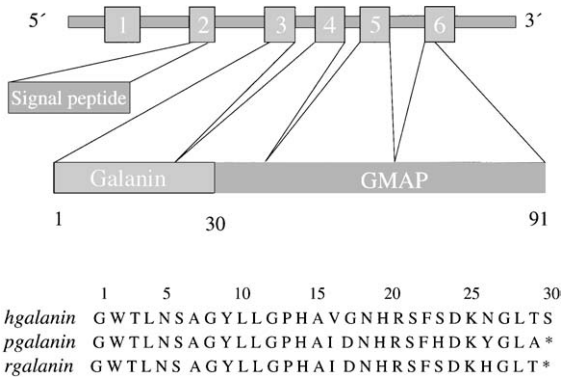

Figure 5 Schematic representation of the galanin gene and progalanin. The first exon is non-encoding, exon 2 encodes the signal peptide, exons 3–5 encode for the sequence corresponding to galanin, and exons 5 and 6 encode for the sequence corresponding to GMAP (galanin message-associated peptide). At the bottom of the figure are the amino acid sequences of human (h), porcine (p), and rat (r) galanin. * indicates a C-terminal NH_2 group.

Galanin is widely distributed in the peripheral nervous system, in both the sympathetic and parasympathetic nerves. It exerts a wide spectrum of actions, such as stimulatory or inhibitory influences on smooth muscle cells depending on location and inhibition of secretion of gastrointestinal hormones and gastric acid. Galanin is also widely distributed in the central nervous system with major localization to the nuclei of the septum–basal forebrain complex, the hypothalamus, and the dorsal raphe nucleus. Centrally, a main function of galanin is its stimulation of feeding, as has been demonstrated in rats. In the pancreas, a dense galanin innervation of the islets was first demonstrated in dogs. These nerves were found to be sympathetic, because galanin is colocalized with tyrosine hydroxylase in nerve terminals and because galanin occurs in nerve cell bodies in the celiac ganglion. In other species, islets are innervated by galanin nerves, although with a lesser density than in the dog. Galanin has been demonstrated to potently inhibit insulin secretion and to stimulate glucagon secretion in a number of experimental systems both *in vivo* and *in vitro*. The potential effect of GMAP on insulin secretion has also been examined in one study in isolated islets. However, the peptide had no influence over a wide dose range and at different glucose concentrations.

Three galanin receptors have been cloned and called GalR1, GalR2, and GalR3, respectively. They are all encoded by different genes located on different chromosomes (GalR1 on 18q23, GalR2 on 17q25.3, and

GalR3 on 22q13.1), and they are all G-protein-coupled receptors. The structural organization of the genes encoding for GalR2 and GalR3 are conserved during evolution, suggesting a common evolutionary origin, whereas the structure of the GalR1 gene is unique among the G-protein-coupled receptors, the relevance of which is not yet known. It is this galanin receptor subtype, GalR1, that has been shown to be expressed in insulin producing cells. Whereas the structure of the GalR1 gene is different between species, the structure of the receptor itself shows high conservation during evolution, and human (349 amino acids) and mouse (348 amino acids) GalR1 displays 93% identity. The powerful inhibitory influence of galanin in rodent islets has been shown to be accompanied by a complex signaling mechanism involving hyperpolarization due to the opening of K^+ channels and a concomitant reduction in the cytosolic concentration of Ca^{2+}, although reduced formation of cAMP and inhibition of the exocytotic mechanism by a direct effect on the exocytosis machinery may also contribute.

Functional studies have indicated that galanin contributes to the sympathetically induced inhibition of insulin secretion. Thus, it has been demonstrated that galanin is released from the dog pancreas during sympathetic nerve activation and that the amount of galanin released under these conditions is sufficient to mimic the inhibition of insulin secretion induced by sympathetic nerve stimulation. The physiology of galanin has also been studied in a physiological model of swimming mice, in which swimming for 2 min is accompanied by a 50% inhibition of glucose-stimulated insulin secretion as a sign of the stress associated with the physical exercise. When galanin was immunoneutralized in these mice by pretreatment with a high-titer galanin antiserum, the impairment of glucose-stimulated insulin secretion during the swimming was abolished. This suggests that galanin released from the sympathetic nerves during the swimming contributes to the inhibition of insulin secretion. Studies to conclusively establish this remain to be performed, however. One approach might be the use of selective GalR1 antagonists, a few of which have been reported, like galantide. Another approach would be the use of galanin- or GalR1-deficient mice. It must be emphasized, however, that species differences seem to be of particular relevance regarding the role of galanin in islet function. For example, whereas it is established that extensive galanin innervation exists in dog islets, there is only scanty innervation in rat or human islets. Furthermore, whereas potent inhibition by galanin of insulin secretion has been reported in dogs, no such effect is evident in humans. In addition, in the pig galanin has been shown to stimulate, not inhibit, insulin secretion. Therefore, the involvement of galanin in islet physiology remains to be established.

E. Neuropeptide Y (NPY)

NPY was isolated from the porcine brain by using an assay developed by Dr. Tatemoto and Professor Mutt in 1982 to detect C-terminally α-amidated peptides. Because the isolated peptide was found to consist of tyrosine in both its N- and C-terminal ends, it was named NPY. The peptide consists of a 36-amino acid residue and shows a high structural homology to peptides YY (PYY) and PP. The human NPY gene is located on chromosome 7p15.11, consists of four exons, and encodes for the 29-residue signal peptide and the 68-residue proNPY. proNPY is further processed to NPY at its N-terminal end and to the 30-residue peptide, CPON (C-terminal flanking peptide of NPY), at its C-terminal end (Fig. 6). Both NPY and CPON are highly conserved between species. Thus, NPY in humans and rats has an identical sequence, differing from porcine NPY in only one amino acid (position 17 is a lysine residue instead of methionine). Furthermore, human and rat CPON shows only two amino acid differences (position 19 being arginine and position 28 being serine in rat CPON).

NPY is a widely distributed neuropeptide both in the brain and in peripheral tissues, with primary localization to adrenergic neurons. In the central nervous system, localization to both the cerebral cortex and the forebrain has been reported, and a particularly high content of NPY has been observed in specific nuclei in the hypothalamus, mainly in the paraventricular nucleus and the arcuate nucleus. In these locations, the peptide seems to be of major importance for the regulation of feeding behavior and energy balance, and it is of great importance that its expression is inhibited by leptin. In the peripheral nervous system, NPY exists in almost all organs, particularly in perivascular adrenergic nerve fibers, and a major function of the neuropeptide is its involvement in the local regulation of blood flow. NPY also affects smooth muscle contractions in other locations and may be involved in the regulation of the gastrointestinal tract and the genitourinary system.

In the pancreas, NPY containing neurons are richly distributed around vessels in the exocrine portion of

Figure 6 Schematic representation of the NPY gene and proNPY. Exons 1 and 2 encode the signal peptide and exons 2–4 encode the proNPY. At the bottom of the figure are the amino acid sequences of human VIP, human PP, human PYY, and human CPON. * indicates a C-terminal NH_2 group.

the islets, and NPY nerves also innervate the islets. Because NPY is colocalized with tyrosine hydroxylase both in islet nerves as well as in nerve cell bodies in the celiac ganglion, it is supposed that NPY is an islet sympathetic neuropeptide. This is supported by findings that chemical sympathectomy by 6-hydroxydopamine substantially reduces the pancreatic NPY innervation in islets. However, NPY has also been shown to be colocalized with VIP in islet nerves in the pig, suggesting that nonadrenergic NPY nerves might also exist. In addition, under some conditions, as in insulin resistance, islet β cells also seem to express NPY. NPY therefore might function both as a sympathetic and as a parasympathetic neuropeptide and as a local autocrine islet peptide. A main function is, however, the role of NPY as a sympathetic neurotransmitter.

NPY has been shown to inhibit glucose-stimulated insulin secretion, i.e., to exert a sympathetic-like effect, in several studies both *in vivo* and *in vitro*. Six different NPY receptors have been cloned (Y1, Y2, Y3, Y4, Y5, and Y6 receptors). Some of these receptors show affinity for PYY and/or PP. These receptors are all of the seven transmembranous domain, G-protein-coupled type but show differences in localization and characteristics with regard to the spectra of affinity for the peptides in the NPY–PP–PYY family. In insulin producing cells, most evidence shows that it is the Y1 receptor subtype that mediates islet actions of NPY. Thus, analogs of PYY that are specific for Y1 receptors mimic the effects of NPY, and a specific Y1 receptor antagonist prevents NPY from inhibiting insulin secretion. The gene for the human Y1 receptor is located at chromosome 4q31.3-32, and the full-length receptor consists of a 384-amino acid residue. The human and mouse forms of the receptor show 93% identity, suggesting a high degree of conservation of the Y1 receptor during evolution. Studies have indicated that two different isoforms of the Y1 receptor exist, called the Y1α and Y1β receptors, respectively. They show a high degree of identity, differing in only seven amino acids, and they are encoded by the same gene and are generated by alternative splicing. The Y1β receptor seems, however, to be expressed mainly during embryogenesis and therefore might not be of relevance after birth.

The mechanism underlying the inhibition by NPY of glucose-stimulated insulin secretion is not fully established but seems to involve inhibition of adenylate cyclase with reduced formation of cAMP. However, distal mechanisms in relation to the formation of cAMP also seem to be involved because insulin secretion stimulated by a cAMP analog is inhibited by NPY, as demonstrated in a perfused rat pancreas model. The physiological importance of NPY for islet function remains to be established. One study has demonstrated that immunoneutralization of NPY in isolated islets leads to increased insulin secretion, which would suggest a physiological inhibitory effect of islet NPY on insulin secretion. However, it is not clear whether this is exerted through its neural

localization or through its expression in islet β cells, which occurs under some conditions. Furthermore, results from studies using a Y1-receptor-specific antagonist or NPY-deficient mice have found no effect on glucose and insulin levels, and the NPY-deficient mice do not develop diabetes or other abnormalities in glucose homeostasis. However, the issue of whether NPY contributes to sympthetically induced regulation of islet function has not been examined in these mice. Therefore, the role of NPY in the regulation of islet function remains to be established.

F. Calcitonin Gene-Related Polypeptide (CGRP)

The localization of the 37-amino acid peptide CGRP to islet nerves was first reported by Rosenfeld and collaborators in 1983 and later confirmed in other laboratories. CGRP was originally described in a medullary thyroid carcinoma cell line, where it was found to be encoded in the same gene as calcitonin. This gene is called the calcitonin complex gene A (CALCA), is located on chromosome 11p15.2-p15.1, and consists of six exons. This gene encodes for two different mRNAs, one being translated to preprocalcitonin and the other to preproCGRP. The N-terminal portions of procalcitonin and proCGRP, consisting of 75 amino acids, are identical in the two prohormones and encoded in exon 3. The remaining part of the 141-amino acid preprocalcitonin is encoded in exon 4, whereas the rest of the 128-amino acid preproCGRP is encoded in exon 5 (Fig. 7). Hence, by alternative splicing, CALCA will be transcribed and translated to either procalcitonin or proCGRP. This alternative splicing has turned out to be tissue-specific. Later, an additional gene that also encodes for CGRP was described and named calcitonin complex gene B (CALCB). This gene is located at chromosome 11p12-14.2 and encodes for a form of CGRP, which is called β-CGRP and shows a high degree of similarity to the α-CGRP that is encoded in CALCA. In addition, two other genes have been grouped together with CALCA and CALCB to a calcitonin gene family. These other genes are the calcitonin complex pseudogene (CALCP), the function of which is yet unknown, and the islet amyloid polypeptide (IAPP) gene, located at chromosome 12p13.2-12.1 and encoding for IAPP. CGRP consists of 37 amino acids with a high degree of identity between species. The two forms of CGRP, α and β, differ in three amino acids in humans and in one amino acid in rats. CGRP is also structurally related to IAPP, calcitonin, and adrenomedullin. CGRP has been demonstrated to be a ubiquitously distributed neuropeptide with localization in both the central nervous system and peripherally. It seems to be mainly localized to sensory nerves. A multitude of biological

Figure 7 Schematic representation of the calcitonin complex gene A (CALCA) and proCGRP. The first exon is non-encoding, exon 2 encodes the signal peptide, exon 3 encodes the N-terminal extension peptide of proCGRP, which is identical to the corresponding N-terminal extension peptide of procalcitonin, exon 4 encodes for the remaining portion of procalcitonin, exon 5 encodes the remaining portion of proCGRP, and exon 6 is noncoding. At the bottom of the figure are the amino acid sequences of human α- and β-CGRP, human IAPP, and human calcitonin. * indicates a C-terminal NH_2 group.

actions of CGRP have been demonstrated in a variety of experimental conditions, and these include the induction of vasodilatation, increase in tissue blood flow, activation of adrenergic nerve outflow, inhibition of gastric acid and thyroid hormone secretion, and stimulation of exocrine pancreatic secretion.

CGRP nerves are also localized to the pancreas, where they are scattered throughout the parenchyma with particular density along small blood vessels and within the islets. Exogenous administration of the peptide under various experimental conditions leads to the inhibition of insulin secretion and stimulation of glucagon secretion. The physiological relevance of the CGRP nerves has been studied in animals treated with capsaicin, which destroys C-fibers and is followed by marked reduction of the CGRP nerves in the pancreatic islets. In capsaicin-treated mice, the glucagon response to neuroglycopenia induced by the glucose analog, 2-deoxyglucose (2-DG) is inhibited and the glucose recovery from insulin-induced hypoglycemia is impaired, suggesting a stimulatory role of the sensory fibers on glucagon secretion. Furthermore, insulin secretion is augmented after capsaicin, suggesting a tonic inhibitory influence of the sensory nerves on the β cells. These studies therefore suggest a physiological importance for CGRP nerves in the regulation of both insulin and glucagon secretion.

CGRP acts through the calcitonin receptor-like receptor (CRLR) or the calcitonin receptor (CTR). Both of these receptors show affinity for IAPP, calcitonin, and adrenomedullin. Three different receptor-activity-modifying proteins (RAMPs) seem to govern the specificity of the receptors for these ligands. For example, elegant studies by Sexton and collaborators in Melbourne have shown that the RAMP1-transported CRLR is a CGRP receptor, whereas RAMP2- or RAMP3-transported CRLR is an adrenomedullin receptor. They also demonstrated that IAPP binding is more related to RAMP-transported CTR. These findings suggest an interesting mode of regulation of cellular activity. Of particular interest for islet physiology is the relation between CGRP and IAPP, both in terms of sequence similarity and in terms of similarities in receptors activated by the peptides. IAPP is a β-cell peptide with a potential role in diabetes pathophysiology because it both inhibits insulin secretion and forms amyloid fibrils, which are common in islets of subjects with type 2 diabetes. It should also be emphasized that, in some species, CGRP seems to be expressed in the islet endocrine cells. Thus, in rat islets, CGRP is found in the D cells. The role of islet cellular CGRP is not known.

G. Cholecystokinin (CCK)

It has been demonstrated that nerve fibers that are not strictly related to the sympathetic, parasympathetic, or sensory nervous system innervate the endocrine pancreas. These nerve fibers have been shown to harbor different neurotransmitters from the other types of autonomic nerve terminals. For example, nitric oxide synthase and cholecystokinin (CCK) have been localized to these nerve terminals, suggesting that nitric oxide and CCK are islet neurotransmitters. CCK was initially demonstrated in 1928 by Ivy and Oldberg as a gut hormone released into the circulation, stimulating gall bladder contraction. It is known today that the peptide is produced in the intestinal I cells, which are situated mainly along the mucosa of the duodenum and the proximal jejunum. Besides its main actions to stimulate gall bladder contraction and exocrine pancreatic secretion, CCK also inhibits gastric emptying and intestinal motility. During the 1970s and 1980s it was demonstrated that CCK is a neuropeptide with localization to both central and peripheral neurons. An interesting central action of CCK is inhibition of food intake. In 1980 it was reported by Dr. Rehfeld and collaborators in Copenhagen that CCK is a neuropeptide in pancreatic islets. The human gene for CCK is located on chromosome 3q12-3pter and consists of three exons. It encodes for a proCCK with a 115-amino acid residue including the 20-amino acid signal peptide, which is posttranslationally modified to generate several different forms of CCK (Fig. 8). The

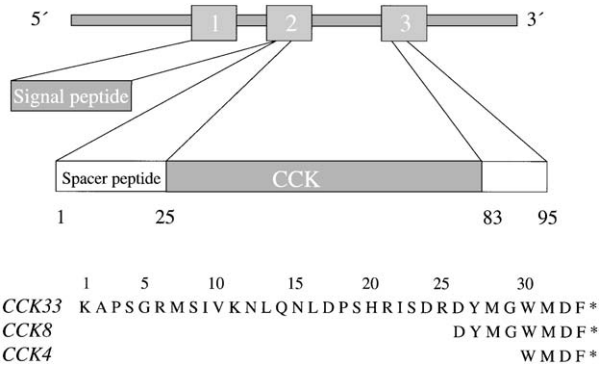

Figure 8 Schematic representation of the CCK gene. The first exon and the 5′-end of the second exon encode the signal peptide. Exon 2 also encodes a 20-amino acid spacer peptide in proCCK and, together with the 5′-end of exon 3, the remaining portion of proCCK. At the bottom of the figure are the amino acid sequences of CCK33 ($CCK58_{26–58}$), CCK8 ($CCK58_{51–58}$), and CCK4 ($CCK58_{55–58}$). * indicates a C-terminal NH_2 group. Observe that the Y residue in position 27 (in both CCK33 and CCK8) is sulfated.

initial translational product is CCK83, which is further processed by the removal of a 25-amino acid spacer peptide at its N-terminal end, yielding CCK58, the initial stable product of the gene. CCK58 is further processed by N-terminal truncation to CCK variants with 39, 33, 25, 22, 18, 12, 8, 7, 5, and 4 residues, respectively. The processing mechanisms and the function of all of these intermediates or CCK forms are still not established. However, CCK33 and CCK8 appear to be the main forms of CCK in circulation, whereas in the neurons most evidence favors the smaller CCK forms, like CCK4, as the main products that therefore probably function as neurotransmitters. The processing of proCCK in the nerves has not been examined in such detail as in the gut, although it has been revealed that it is the same CCK gene that is expressed in nerve cell bodies as in the I cells.

In the pancreatic islets, CCK has been shown to potently stimulate insulin secretion, and this has been demonstrated under a variety of experimental conditions. This action may be of physiological importance after food intake, when the circulating levels of CCK are increased. It is unlikely, however, that CCK is of physiological importance after food intake, because the circulating levels of CCK achieved after food intake are lower than those required for stimulation of insulin secretion and because inhibition of CCK release or action does not affect meal-induced insulin secretion in humans. Therefore, the main function of CCK in relation to the pancreatic islets is probably as a neurotransmitter. However, the role of these "other" nerves in the regulation of insulin secretion, particularly in relation to the influence of the three main branches, is not known. CCK has also been shown to stimulate glucagon secretion, although this has not been studied in such great detail as its effects on insulin secretion.

Two different types of CCK receptors have been described, both of which are of the G-protein-coupled, seven transmembranous domain type linked to the activation of PLC. The CCK_A receptor gene is located on chromosome 4p15.1-p15.2, whereas the CCK_B receptor gene is located on chromosome 11p15.4-p15.5. The CCK_A receptor type consists of 428 amino acids and is expressed in the gall bladder smooth muscle cells, pancreatic acinar cells, gastrointestinal muscular cells, and various parts of the brain. This receptor type shows an almost 1000-fold higher affinity for CCK than for gastrin. The CCK_B receptor type consists of 447 amino acids and is expressed in the cerebral cortex and other brain areas, gastric parietal cells, ECL cells, and gastrointestinal muscular cells. This receptor type shows equal affinity for CCK and gastrin. In the islets, most studies favor the CCK_A receptor subtype as the one that mediates the actions of CCK.

The insulinotropic activation of CCK is mainly mediated by PLC, which stimulates the hydrolysis of phosphoinositides. Phosphoinositide hydrolysis in turn yields the formation of IP_3, releasing Ca^{2+} from intracellular Ca^{2+} stores to increase the cytosolic concentration of Ca^{2+}. Consequently, CCK increases the cytosolic concentration of Ca^{2+} independently from the uptake of extracellular Ca^{2+}, which is accompanied by rapid stimulation of exocytosis and insulin secretion. CCK has also been shown to stimulate the generation of arachidonic acid (AA) through the activation of PLA_2. AA in turn stimulates the exocytosis of insulin through several mechanisms. In contrast, CCK does not seem to increase the islet formation of cAMP. The combined action by CCK to release Ca^{2+} from intracellular stores to increase the cytosolic concentration of Ca^{2+} and to stimulate the formation of AA and activate PKC seems to contribute to the insulinotropic action after activation of the CCK_A receptors.

VIII. CONCLUSION

It is known that the pancreatic islets are innervated by the autonomic nerves. The net effects of activation of the nerves on islet hormone secretion, the presumed neurotransmitters mediating these effects, and the putative receptors and their signaling pathways have also been established. In particular, several neuropeptides have been localized to islet nerve terminals, and their actions on islet hormone secretion have been documented under a variety of experimental conditions. Studies are now required to establish the physiology and pathophysiology of the islet nerves and their neurotransmitters, particularly concerning the possible involvement of the nerves in the pathophysiology of glucose intolerance, type 2 diabetes, and obesity.

Neuropharmacology

EDWARD A. WORKMAN

Lakeshore Mental Health Institute and University of Tennessee Medical Center, Knoxville

GLOSSARY

anti-convulsant An agent designed to reduce nervous system irritability and reactivity by changing sodium or calcium channel activity.

antidepressant An agent designed to treat depressed mood by altering metabolism and the transmission of neurotransmitters such as serotonin or norepinephrine.

anti-psychotic An agent designed to treat psychotic thought processes (e.g., cognitive disorganization, paranoid thinking) by altering the metabolism of dopamine, among other neurotransmitters.

bipolar disorder A major psychiatric disorder presumptively caused by a neurotransmitter imbalance, resulting in impairment of judgment and dramatic swings in mood from highly energized irritability to despair.

dementia Any one of the usually progressive, organic brain disorders characterized by disorganized thinking, severe memory dysfunction, and eventual functional debility.

dependence The process wherein an individual persistently uses a deleterious substance in order to avoid withdrawal effects (which are aversive) in the face of tolerance, which requires the use of progressively larger amounts of the substance to achieve the desired pleasurable effect.

depression A psychiatric disorder caused by aberrant metabolism of one or more neurotransmitters, resulting in persistent blue mood, low energy, slowing of cognitive tempo, and difficulty maintaining functional status.

drug Any externally administered agent that induces some biological response.

dyssomnia A disorder characterized by difficulty initiating or maintaining a normal pattern of sleep and waking.

neuroleptic An old term referring to pharmacologic agents designed to treat psychosis by inhibiting dopamine neurotransmission.

neuron A highly specialized type of tissue that has the capability to conduct electrical impulses via changes in sodium and calcium channels, thus allowing for communication from one site to another.

neurotransmitter A biochemical substance, usually a protein or a protein containing compound, that transmits information from one part of the nervous system to another.

schizophrenia The brain disease presumptively caused by aberrant dopamine neurotransmission with an onset usually in early young adulthood, characterized by cognitive disorganization, severe deficits in social functioning, and, often, delusions and hallucinations.

seizure A paroxysmal burst of electrical activity in the brain that lacks organization and focus, usually resulting in involuntary movements.

Neuropharmacology is the medical science field that examines the effects of pharmacologic agents (i.e., drugs) on the nervous system. Although the field is quite broad, encompassing both animal and human studies and both basic ''bench'' science and clinical science, the focus of this article is on the latter. Our perspective throughout this article is on those pharmacologic agents that are used to treat disease processes in the human nervous system. This group of diseases is also rather broad and falls under the purview of multiple medical fields, including psychiatry, neuropsychiatry, and neurology. The emphasis here, thus, is on clinical neuropharmacology or what

could be termed ''neuropsychopharmacology.'' The organization of the article is designed to reflect the emphasis on clinical neuropharmacology. By following a concise and simplified but, hopefully, reasonably inclusive discussion of the basic principles of neuroscience that underlie neuropharmacology, the reader will be oriented to the basic pathological processes encountered in psychiatry and neurology. The section on psychiatric disorders will review mood and thought disorders, the neurotransmitter imbalances thought to produce them, and the drug therapies that contemporary psychiatrists use to treat them. Neuropsychiatric disorders within our coverage include sleep disorders, cognitive deficit disorders, traumatic brain injury, and chemical dependence disorders. Finally, we will review the pharmacologic basis and treatment of neurological disorders, including seizure disorders, movement disorders, and headaches. This organization rather clearly reflects the clinical emphasis of the article. There is, of course, an enormous body of knowledge and literature on the basic science aspects of neuropharmacology. It is, however, beyond the scope of this article, and the reader who is interested in exploring that field is referred to the Suggested Reading section at the end of the article.

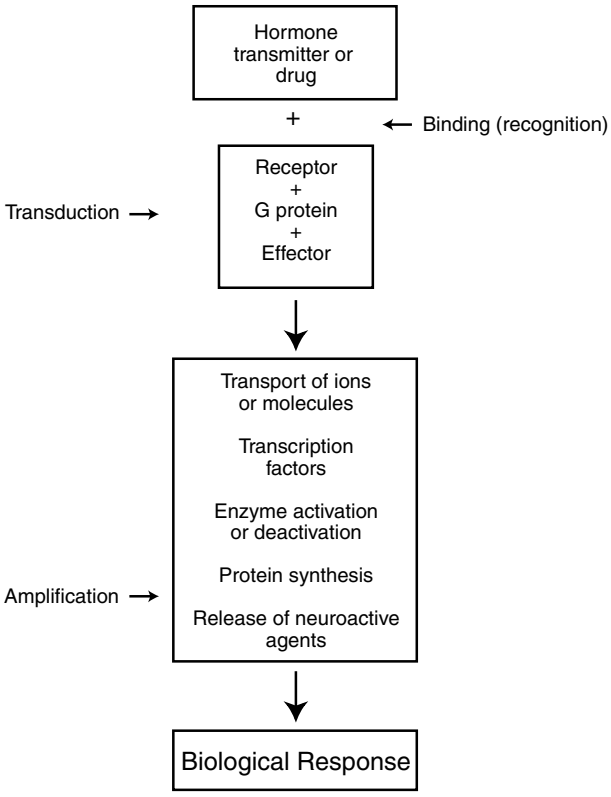

Figure 1 Model for receptor–ligand interaction.

I. BASIC PRINCIPLES AND THEORETICAL MODELS IN NEUROPHARMACOLOGY

Neuropharmacology depends upon many fields for its underlying structural basis. Cellular biology, molecular biology, biochemistry, and branches of neuroscience from neuroanatomy to neurophysiology all have made, and continue to make, substantial contributions to this field. For the sake of simplicity and conceptual economy, we will focus on that small set of models that provides the basic concepts for understanding how diseases develop in the nervous system and how drugs can treat these diseases.

Perhaps the most fundamental process in neuropharmacology is shown in Fig. 1. This figure portrays a neuroactive agent interacting with a receptor, eventually resulting in a specific biological response. In the natural state, neuroactive agents can include hormones, enzymes, or neurotransmitters. In the clinical setting, the neuroactive agent is a drug, a concept that is ubiquitous in its usage but frequently confused in its meaning. In this article we will use the term drug to include any externally administered neuroactive agent that results in a biological response (of any kind).

As can be seen in Fig. 1, the neuroactive agent interacts with (e.g., binds with) a receptor, which is a protein structure that is produced in the cell body of the neuron (nerve cell) and then embedded into its membrane surface. The binding of the neuroactive agent (NA) and receptor involves recognition of one for the other due to structural compatabilities. In other words, due to their specific molecular structures, a given NA will bind with some types of receptors but not others. This is the concept of transmitter–receptor specificity and forms a fundamental structural basis of neuropharmacology. In other words, a specific type of NA (e.g., the neurotransmitter, serotonin) naturally interacts with some specific types of receptors (e.g., serotonin type 2 and 3 receptors) but not others (e.g., adrenergic β1 and 2 receptors).

Once bound, the NA–receptor unit experiences changes in its inherent protein structure, allowing it to then bind to an intracellular G protein (e.g., adenylyl cyclase, phospholipase C). The NA–receptor–G-protein complex, once created, spontaneously experiences further structural changes (called changes

in conformation) that trigger interaction of the complex with an intracellular enzyme. This process is called transduction, because chemical energy is transduced from the structure of the NA to the NA–receptor–G-protein–enzyme complex, and results in the manufacture of what is called a second messenger molecule. Second messenger molecules include cyclic adenosine monophosphate (cAMP) and phosphatidylinositol (PI); first messengers are the neuroactive agents themselves. These second messengers comprise an effector system, which can yield effects in other parts of the neuron.

The second messenger system is extremely complex and remains under intense investigation at present. However, we do know that the second messenger molecules interact with additional intracellular enzymes to accomplish various biological effects. The processes involved include the following: (1) opening ion channels (e.g., Ca^{2+} ion channels) at the cell membrane, resulting in changes in intracellular concentrations of various agents and, thus, changes in the reactivity of the neuron itself; (2) inducing the neuron to produce various biochemical agents (e.g., neurotransmitters, hormones, and enzymes) by interacting with mRNA and altering the neuron's DNA instructions; and (3) up- or down-regulating the number and density of various receptors in the neuronal membrane via production or destruction of receptors and their structural components. Through these processes, naturally occurring NAs have their biological effects. By understanding how these processes take place, drugs can be designed that mimic the effects of natural NAs, and therein lies the basis of neuropharmacology. Drugs are developed or discovered for the purposes of mimicking or modulating a naturally occurring process that, for some reason, no longer occurs or does so in an inadequate manner (i.e., a disease or disorder).

II. NEUROTRANSMITTERS

The known number of neurotransmitters occurring naturally in the human nervous system appears to grow progressively as our investigational tools become more sensitive and sophisticated. Currently, Table I represents a reasonable articulation of the known human neurotransmitters; the reader should be aware that, in another decade, this table will be, perhaps substantially, larger and will likely include a number of surprises as our knowledge base grows.

Literally, a book chapter could be written about each of the categories of neurotransmitters in Table I. However, the clinical focus of this article dictates that we restrict our discussion to those neurotransmitters that currently have utility in clinical medicine. Although intense research effort is being applied to evaluating the clinical significance of many, if not all, of the neurotransmitters in the table, our focus here will be on the amine category.

A. Serotonin

Serotonin, or 5-hydroxytryptamine (5HT), is perhaps the most widely known neurotransmitter in a popular sense. The reason for this is the massive press given to the drug Prozac, a NA that results in an increase in the amount of serotonin available around neurons, a feat accomplished by inhibiting the destruction of serotonin. Serotonin or 5HT was originally discovered in the gastrointestinal mucosa in the 1940s. Its chemical structure is very similar to the amino acid tryptophan, which is, in fact, the dietary precursor of 5HT itself. 5HT is found in virtually all vertebrate organisms, as well as in many invertebrates such as wasps, scorpions, and ocean crustaceans. It is also found in abundance in several plant species, including bananas and pineapples. Although a neurotransmitter of major importance, 5HT is distributed throughout the body. Interestingly, approximately 90% of the total 5HT in the human body is in the gastrointestinal tract, 8% is in blood platelets (where it is involved in the clotting process), and only 2% is in the central nervous system.

5HT is synthesized in the terminal end of the neuron and transported to synaptic vesicles (cystlike structures that exist at the neuronal cell membrane), from which it is released into the synapse for interaction with receptors in adjacent neurons. Once released freely into the synaptic space, molecules of 5HT will either stimulate receptors in other neurons or they will interact with autoreceptors from their original neuron (the neuron that produced them). Interaction with adjacent neurons results in neurotransmission of a nature specific to the type of adjacent neuron. Interaction with autoreceptors results in an important process called re-uptake. Neurotransmitter re-uptake results in a decrease in the amount of the neurotransmitter (in this case 5HT) that is available in the synaptic space. Through re-uptake, the 5HT neuron can exert modulatory control over the amount of serotonergic neurotransmission generated from that neuron: net transmission can be reduced through the

Table I
Neurotransmitters in the Brain

Amines	Serotonin (5HT)

	Met-enkephalin
	Leu-enkephalin
	Kyotorphin

production of more autoreceptors, which, in turn, trap and destroy free 5HT molecules in the synapse. By increasing the density of autoreceptors, the neuron reduces the amount of 5HT that can exert its effect in the synapse. On the other hand, the nerve cell can increase serotonergic transmission by reducing production of autoreceptors, thereby destroying less 5HT and thus increasing the net amount of serotonergic neurotransmission.

5HT is synthesized from the amino acid tryptophan. Tryptophan is hydroxylated to L-5-hydroxytryptophan, which is, in turn, decarboxylated to the serotonin molecule itself. In addition to the preceding mechanisms at the neuron's disposal for regulating serotonergic neurotransmission, it can also modulate the production of 5HT via the regulation of the activation state of the enzyme, tryptophan hydroxylase. Once synthesized, 5HT is involved in a wide variety of behavioral processes, including hunger and food intake, mood regulation, aggressive behavior and its control, sleep architecture, and anxiety and its regulation.

Two decades of research have yielded a listing of the clinical conditions that have been shown to be influenced by altered serotonergic neurotransmission. Although surely not exhaustive, the list underscores the importance of serotonergic neurotransmission processes and documents the wide-ranging distribution of 5HT systems. The disorders include mood disorders, anxiety disorders, eating disorders, migraine headaches, neuro-degenerative processes and aging, obsessive compulsive disorder, substance abuse, pain sensitivity (chronic pain), posttraumatic stress disorder, schizophrenia, sexual dysfunction, and sleep disorders.

B. The Catecholamines: Dopamine, Norepinephrine, and Epinephrine

The catecholamines, including dopamine (DA), norepinephrine (NE), and epinephrine (EPI), belong to a group of neurotransmitters called monoamines. These molecules contain a single amine ($-NH_2$) group, a catechol nucleus (consisting of a benzene ring with two hydroxyl groups), and a side chain consisting of an ethylamine or a closely related derivative. EPI was originally called adrenaline and NE was called noradrenaline, as both were initially found in the adrenal gland. Retaining these original names, neurotransmission via EPI and NE is still termed adrenergic and noradrenergic, respectively.

Catecholamine neurotransmitters were first discovered by Walter Cannon and his associates in the 1920s. In their classic experiments involving nervous system arousal, the researchers discovered that these substances (then called sympathins) were released whenever sympathetic nerves were stimulated. Thus, they recognized that catecholamines were involved in nervous system arousal and stimulatory states.

All three of the preceding catecholamines are synthesized from the amino acid tyrosine as derived dietary proteins. Tyrosine is hydroxlated (via tyrosine hydroxylase) to DOPA, which is then decarboxylated to dopamine. Dopamine can then be transported to the synaptic space and released for use in dopaminergic neurotransmission, or it can be further metabolized within the neuron. In the latter case, dopamine (DA) is β-hyroxylated to norepinephrine (NE), which can, likewise, be transported and released for neurotransmission or further metabolized. If further metabolized, NE is methylated to epinephrine (EPI). Thus, DA can be used by the neuron as a neurotransmitter or as a precursor substrate for the production of two other neurotransmitters, NE and EPI.

As was the case with the 5HT neuron, the DA neuron can control the amount of neurotransmission via its production of autoreceptors, thereby controlling re-uptake of the catecholamines. Additionally, the DA neuron has modulatory control over DA, NE, and EPI neurotransmission via its control over the rate-limiting enzyme, tyrosine hydroxylase. Production of NE and EPI is modulated by regulation of the intraneuronal enzymes dopamine β-hydroxylase and phenylethanolamine *N*-methyltransferase, respectively. Further, the catecholamines (as well as 5HT) can be destroyed in the synaptic space by an enzyme called monoamine oxidase (MAO); thus, neuronal production and release of MAO into the synaptic space are yet other mechanisms whereby neurotransmission can be modulated by the neuron.

Once synthesized and released into the synaptic space, the catecholamines serve multiple functions throughout the human nervous system, particularly the brain itself. Although it is usually an arousal-inducing neurotransmitter, DA neurotransmission varies in function depending upon the neuroanatomic system involved. In the nigrostriatal system (with fiber tracts running from the substantia nigra to and from the basal ganglia), for example, DA transmission controls motor behavior and its fine control. In the mesolimbic system (where fiber tracts traverse the brain stem and the nucleus accumbens), DA transmission is involved in cognitive and affective processing and emotional regulation. When involved in the mesocortical system (with fibers traversing the tegmentum and the frontal lobes), dopaminergic neurotransmission plays a role in attention, arousal, and motivation. In the tuberoinfundibular pathway (with fibers running to and from the hypothalamus and the tegmentum), DA is involved in the regulation of prolaction secretion (and, relatedly, bone mineral metabolism), fertility, and sexual function. In the median forebrain bundle and neuronal fibers connecting to the hypothalamus, DA appears to be intimately involved in processes of reward, pleasure, and motivation.

NE is involved in the regulation of arousal throughout the nervous system. EPI is involved with a relatively small number of neuron systems and primarily has very rapid short-lived and localized effects. Thus, NE has more substantive neuropharmacologic significance and will be the focus of this section. Centrally, adrenergic neurotransmission (via NE and, to a lesser extent, EPI) is involved in myriad processes including activation, arousal, attention–concentration, hunger, and feeding behavior. Peripherally, adrenergic transmission is involved in cardiac function, blood pressure regulation, and muscle tone, among other processes.

C. Acetylcholine

The neuroactivity of acetylcholine (ACh) has been characterized since the early 1920s, and the molecule was first discovered in the mid-1800s. It was, thus, the first neurotransmitter to be identified and has been the focus of a massive amount of research over the past century.

ACh is synthesized in cholinergic neurons from the precursors acetyl coenzyme A and dietary choline via the catalyst choline acetyltransferase. Several mechanisms regulate the production of ACh, including (1) feedback inhibition wherein increasing amounts of ACh in the nerve terminal ''feed back'' to the producing neuron to inhibit the activity of choline acetyltransferase, thus reducing further ACh production, (2) the availability of dietary choline, and (3) neuronal activity wherein ACh is depleted in the nerve terminal, thus stimulating the accelerated production of ACh. In addition to these regulatory mechanisms, ACh activity is also modulated by the presence of enzymes that hydrolytically break down ACh. These enzymes are called acetylcholinesterases and, as will be seen later, are the targets of various pharmacologic agents.

Once synthesized, ACh is found to be widely dispersed throughout the body, particularly in the brain and spinal motor neurons. In the central nervous system, ACh is heavily involved in the striatal complex (e.g., the caudate–putamen region and the nucleus accumbens) where it is, perhaps, the most important

motor system neurotransmitter. In the substantia nigra region, ACh is a cofactor in dopaminergic neurotransmission. The basal forebrain region represents a major ACh neurotransmission area, with cholinergic fiber projections traversing the area from the medial septal nucleus to the limbic cortex and hippocampus with involvement in memory, cognitive processing, and emotional functions. In the diencephalon, cholinergic neurons and their projections are involved in a variety of neuroendocrine functions, whereas the cholinergic fibers in the medulla innervate the cerebellar cortex and motor components of some cranial nerves. In the peripheral nervous system in spinal and cranial motor neurons, ACh is involved in the movement of limbs, head, trunk, eyes, face, tongue, and jaw. In the parasympathetic nervous system, ACh functions as a neurotransmitter in connections between ganglionic fibers and smooth muscle tissue in virtually all systems. In the sympathetic nervous system, ACh is involved in neurotransmission to sweat glands.

ACh is, thus, widely dispersed and nearly ubiquitously involved as a neurotransmitter. It has been demonstrated to function as a regulator of aggressive behavior, sensory processes, learning and memory, sleep and arousal, eating behavior, digestion, and sexual behavior. In the 1970s, several laboratories demonstrated that ACh neurotransmission tended to decline with age and that cholinergic neurotransmission activity was particularly deficient in the brains of patients with Alzheimer's dementia. As will be seen in subsequent sections, these findings have become the focus of an important area of research in neuropharmacology.

D. Amino Acid Neurotransmitters: GABA, Glutamate, Glycine, and Aspartate

Although the catecholamines ACh and serotonin have extremely important neurotransmitter roles in brain function, the amino acid neurotransmitters are more common by far and exist in substantially higher nervous system concentrations. Despite their ubiquitous distribution in mammals, these neurotransmitters have proven more difficult to study than any others. Nevertheless, there is a growing body of literature regarding their characteristics and roles.

γ-Aminobutyric acid (GABA) was originally synthesized in the 1880s and for years was thought to be exclusively a product of plant metabolism. In the 1950s, however, it was found to be a constituent of mammalian tissue and was determined to exist in large quantities in the brain and spinal cord. Over the past several decades, much evidence points to GABA's role as an inhibitory neurotransmitter. GABA is synthesized in GABAergic neurons by the conversion of L-glutamate via the catalytic enzyme, glutamate decarboxylase (GAD). GABA synthesis is regulated primarily by the presence and concentration of GAD and its cofactor, pyridoxal phosphate (a form of vitamin B_6), within the neuron. Following its synthesis and release into the synaptic space, GABA interacts with postsynaptic receptors to exert inhibitory effects; GABA thus is a neurotransmitter that serves to dampen or depress the effects of other neuron systems. Although there is more active research than conclusive evidence about the inhibitory effects of GABA, it is thought to be involved in the regulation of anxiety and relaxation states and overall motor tone. A growing body of research is also implicating GABA in seizure disorder development. The inhibitory effects of GABA appear to involve one of two processes, both of which result in making the affected target neuron more difficult to stimulate: hyperpolarization and depolarization. Hyperpolarization appears to be more the more common GABAergic mechanism in central cortical neurons, whereas depolarization predominates in spinal cord neurons.

Another inhibitory amino acid neurotransmitter is glycine, the amino acid with the simplest structure. Found in all mammalian proteins and tissues, glycine is synthesized primarily via hydroxymethylation from serine. Once synthesized, glycine functions as an inhibitory neurotransmitter in the spinal cord and, to a lesser extent, in the brain. In the brain, glycine's role primarily appears to involve the inhibition of neuronal activity in the striatum, substantia nigra, and cerebellum. Pharmacologically, research is still ongoing regarding the drugs that can affect this neurotransmitter, but it is well-characterized in many of its actions due to its inhibition by the poison strychnine. Observation of strychnine effects has led to an understanding of the various regulatory functions of glycine, including relaxation of muscles of facial expression and mastication, limb and trunk movement, relaxation of respiratory and cardiac muscles, as well as vascular wall musculature, and regulation of various visual, auditory, cutaneous, and vestibular functions.

Two amino acids function as excitatory neurotransmitters: glutamate and aspartate. Both are nonessential amino acids, can, thus, be synthesized in the body, and do not require a dietary source. Glutamate is

synthesized primarily as a byproduct of glucose metabolism (the Kreb's cycle) via a transamination reaction. Once synthesized, glutamate can, interestingly, serve as the precursor for GABA, or it can function as an excitatory neurotransmitter in the spinal cord and, literally, throughout the brain in virtually every region. It appears to be involved in learning, memory, and the regulation of neuronal oxygenation states and is, thus, purported to be important in the regulation of neuronal damage following strokes and heart attacks. Although aspartate is known to be excitatory, it is less well-characterized as a neurotransmitter, and most of the research on this agent is in the early investigatory stages.

E. Histamine

The final neurotransmitter upon which we will focus here is histamine. Like serotonin and the catecholamines, histamine is a biologically active amine derived from amino acid precursors. It is formed by the decarboxylation of the amino acid histidine and is degraded via methylation to type B monoamine oxidase. Histamine, although heavily involved in the regulation of allergic and inflammatory reactions, has been found to be a neurotransmitter that is involved in a wide variety of behavioral processes. It is involved in the regulation of ingestive behavior (eating and drinking), sleep and arousal, sexual behavior, pain tolerance, learning and memory, and blood pressure.

III. NEURO-RECEPTORS: THE OTHER SIDE OF NEUROTRANSMISSION

Receptors in the nervous system are essentially glycoprotein-based recognition sites for neurotransmitters. When interacting with a given receptor, a neurotransmitter can be a full or partial agonist, which stimulates maximal or submaximal effect, respectively, or an antagonist, which blocks the usual effect of stimulating the receptor. A neurotransmitter can also be an inverse agonist at a receptor, stimulating the receptor to have the opposite effect that it usually has when stimulated by an agonist (inverse agonists do not block receptors, they stimulate them). Chronic interaction between an agonist neurotransmitter and its receptor typically results in down-regulation (decreased production and distribution) of the receptors; chronic antagonism results in up-regulation (increased production and distribution) of receptors. In this manner, transmitter–receptor interactions serve as a negative feedback loop based, self-regulatory system for the control of net neurotransmission processes.

Table II
Neurotransmitter Families

Adrenergic receptors	α 1a, 1b, 1c, 1d, 2a, 2b, 2c, 2d
	β 1, 2, 3
Dopaminergic receptors	D1, D2, D3, D4, D5
GABA receptors	GABA-A, GABA-B1A, B1γ B2, GABA-C
Glutaminergic receptors	NMDA, AMPA, kainate, MGLUr-1–7
Histamine receptors	H1, 2, 3
Cholinergic receptors	
	Muscarinic: M1–5
	Nicotinic: muscle, neuronal
Opioid receptors	μ, γ, κ
Serotonergic receptors	5HT-1A, 1B, 1D, 1E, 1F, 5HT-2A, 2B, 2C, 5HT-3, 4, 5, 6, 7

Table II lists the currently known neurotransmitter receptors. As can be seen, most receptors have multiple subtypes, a fact that became apparent during the past decade and has added to the complexity of neuropharmacologic processes.

Adrenergic receptors are G-protein-coupled receptors for catecholamines. Two primary subtypes exist, α and β. α adrenergic receptors are located in blood vessels, smooth muscle sites, and throughout the nervous system. α-1 receptors are postsynaptic receptors and are characterized by high sensitivity to the agonists phenylephrine and methoxamine and to the antagonists prazosin and phenoxybenzamine. α-2 receptors are primarily presynaptic and are activated by clonidine and α-methylnorepinephrine and antagonized by yohimbine, rauwolscine, and idazoxan. Subtypes of both α-1 and α-2 receptors have been found and characterized by their differential responsiveness to various agonists and antagonists. β adrenergic receptors are found in the heart, blood vessels, and other smooth muscle sites, as well as in nervous system tissue. β-1 and β-2 receptors differ in their reactivity to EPI (NE and EPI are equally potent in β-1 activation, whereas EPI is far more active than NE in β-2) and localization. β-3 receptors are atypical and have been found to exist in adipose tissue as well as in several types of gastrointestinal cells. Stimulation of these receptors results in lipolysis and thermogenesis.

Dopaminergic receptors, like adrenergic receptors, are G-protein-coupled receptors. The first group of DA receptors, found in the 1970s, consisted of D-1 and D-2. Currently five subtypes of DA receptors have been found and characterized, D1–5. It is likely that many more exist. Although receptors of the D-1 family exist in wide distribution in mammalian nervous tissue, they are particularly densely located in the mesostriatal regions of the brain. They are, thus, heavily involved in neuromotor functions. Interestingly, the D-5 receptor is considered to be a part of the D-1 receptor family and is found primarily in the thalamohippocampal regions of the brain.

The D-2 family of dopaminergic receptors was an early focus of research because of its affinity for the antipsychotic drugs, such as thorazine (formerly called neuroleptics). D-2 receptors are found in a variety of locations in addition to the mesostriatal region, including the mesolimbic and mesocortical areas. D-2 receptors are also located in a chemical trigger zone of the medulla, where stimulation with apomorphine induced nausea and vomiting. The highest density of D-2 receptors appears to be in the caudate–putamen, nucleus accumbens, and substantia nigra regions. Classic antipsychotic agents, such as thorazine, mesoridazine, and haloperidol, are antagonists for the D-2 and, to a lesser extent, the D-1 receptor systems. Thus, the effects of these agents are not restricted to emotional and cognitive processes but also affect neuromuscular function. D-3 and D-4 receptors differ from the D-1 and D-2 families on the basis of their different localizations and affinities for agonists and antagonists. D-3 receptors appear to be particularly dense in the limbic regions of the brain and are thought to represent an additional site of action of antipsychotic agents. D-4 receptors, first characterized and cloned in the early 1990s, are thought to be sites of action of the atypical anti-psychotic, clozapine.

Multiple serotonin (5HT) receptors have been discovered since the mid-1980s. 5HT-1 receptors were the identified first, and currently five subtypes of this receptor are known, designated 1A, 1B, 1D, 1E, and 1F. The 5HT-1A subtype is the best characterized and is activated by the agonists buspirone and gepirone (both azapirone derivatives). These receptors are quite dense in the hippocampus, raphe nucleus, amygdala, and cortical regions and have been implicated in the regulation of feeding, temperature, and anxiety–arousal. Perhaps the most important role of the 5HT-1 receptor involves its function as a postsynaptic auto receptor, wherein it detects the presence of 5HT in the synapse and blocks further release of 5HT. In this manner, it functions as the regulator of 5HT synthesis in neurons. Additional 5HT-1 subtypes have been characterized on the basis of their differential interactions with agonists and antagonists, but their functions remain elusive.

The 5HT-2 receptor family has three currently known subtypes, A, B, and C. 5HT-2A receptors are densely distributed in the hippocampus and cortical and neocortical regions of the brain. The B subtype is found in the cortex as well as the gastrointestinal tract, accounting for the side effects (see later discussion) of the serotonergic antidepressants. The C subtype is distributed primarily in the hippocampus and medulla. The 5 HT-2 receptor is stimulated to action by the agonists α-methyl-5HT (a 5HT analog), the phenylalkylamines, and lysergic acid diethylamide (LSD). Methylchlorophenylpiperzine (m-CPP), a metabolite of the antidepressant trazodone, is a partial agonist at the 5HT-2 sites. Antagonists include ketanserin, ritanserin, mesulergine, and quinolone. Ordinarily, chronic administration of these antagonists would be expected to result in an up-regulation of 5HT-2 receptors; however, the 5HT-2 system exhibits a paradoxical characteristic wherein chronic antagonism results in down-regulation. As such, it is possible that what were originally thought to be antagonists are actually inverse agonists. These findings underscore the fluid and evolving nature of the knowledge base of neuropharmacology.

5HT-3 receptors have been found to be densely located in the brain stem and the area postrema. At both locations they appear to be involved in the regulation of nausea and vomiting. Unlike most other receptor families, they are not G-protein-coupled but are operated through a gated channel in the neuronal membrane.

The 5HT-3 receptor is structurally and functionally more similar to the nicotinic cholinergic receptor family than the other 5HT receptors. This receptor is activated by methyl-5HT and antagonized by ondansetron, granisetron, metoclopromide, and MDL72222, a derivative of cocaine. It is thought that 5HT-3 antagonists exert an antiemetic effect by blocking the effect of 5HT on the gastrointestinal tract and by blocking the release of 5HT from the vagus nerve (which triggers emesis by the brain stem's vomiting control center).

ACh receptors are of two subtypes, muscarinic and nicotinic. Nicotinic ACh receptors are always excitatory and transmit nerve impulses very rapidly, on the order of milliseconds. They are blocked by tubocurarine, the active agent in the paralytic poison curare,

hexamethonium, mecamylamine, and gallamine. Nicotinic receptor agonists include nicotine itself, decamethonium, and succinylcholine. Nicotinic ACh receptors are distributed throughout muscle and nerve tissue and are particularly important in striated muscle and sympathetic and parasympathetic neurons.

Muscarinic ACh receptors can be either excitatory or inhibitory and have a long latency of action (on the order of 100 msec). They are antagonized by atropine or scopolamine and activated by muscarine, pilocarpine, and oxotremorine. Muscarinic receptors are also widely distributed, particularly in parasympathetic neurons that subserve cardiac and smooth muscle at sites throughout the mammalian system. However, most of the central nervous system cholinergic activity takes place via muscarinic receptors in the neocortex, hippocampus, striatum, and thalamus. Four subtypes have been found, M1–4, that vary in their localization and, to some extent, the agents by which they are activated or antagonized. For example, M1 receptors are heavily distributed in the striatum on dopaminergic terminals of the nigrostriatal system; stimulation of these receptors by ACh results in the release of dopamine. In the septal–hippocampal pathways, M1 receptors, upon simulation, release ACh, which in turn inhibits the release of the excitatory neurotransmitters, glutamate and aspartate. ACh receptors are, thus, involved in diverse regulatory functions involving other families of neurotransmitters, in addition to having their own roles in neuromuscular and cortical transmission.

Now that we have explored the basic principles and models that underlie neuropharmacology, we will turn our attention to the clinical significance of this information. The remainder of this article will focus on the disorders of brain chemistry to which neuropharmacology applies its knowledge base.

IV. PSYCHIATRIC DISORDERS

A. Mood Disorders

Contemporary biological psychiatry strongly emphasizes the neurobiology of mood and thought disorders as the area upon which it focuses its diagnostic and treatment armamentarium. Although psychiatry deals with a wide variety of disorders, most psychiatrists spend the majority of their time diagnosing and treating major depression, bipolar disorder, schizophrenia, and anxiety spectrum disorders. Although the exact neurobiological mechanisms for these disorders are yet to be fully elucidated, reasonable theoretical models for their development have been articulated and are well-accepted in the medical community.

Major depression is a severe mood disorder characterized by blue mood, extreme sadness, loss of interests, low energy, and cognitive slowing, among other symptoms lasting for at least several weeks (DSM-IV). Unlike simple "bad moods," major depression is a painful, debilitating, and sometimes, in the case of suicidally depressed patients, life-threatening. Approximately 15% of the population can expect to suffer from severe major depressive illness at some point in their lives, and 1 in 50 of these people will require hospitalization. Even those not requiring inpatient treatment will experience an increase in their cardiac mortality and morbidity rate, increased likelihood of depressive recurrences, and some degree of functional debility during their depressive episode.

In the "monoamine hypothesis of depression," depressive symptoms are thought to be due, at least in part, to a deficiency in neurotranmission involving one or more of the neurotransmitters serotonin, norepinephrine, or dopamine. This deficiency can be the result of genetics or the individual's interactions with a highly stressful environment, as is the case with most psychiatric disorders.

The first suggestion of a biochemical basis for major depression came from early work in the 1950s, when a drug, iproniazid, that affected monoamine re-uptake (as a side effect) was used to treat tuberculosis and found to improve the mood of the patients. This led to the development of a class of drugs called monoamine oxidase inhibitors (MAOIs). These drugs exerted antidepressant effects by inhibiting the MAOs in the neuronal synapses that destroyed the monoamines 5HT, NE, and DA, thus increasing the synaptic concentration of these neurotransmitters. MAOIs include two groups: the hydrazines, iproniazid, isocarboxazid, and phenelzine, and the nonhydrazine tranylcypromine. These agents result in the nonselective increase in synaptic NE, EPI, 5HT, and DA and their effects are irreversible. Although highly efficacious in the treatment of major depression, these agents fell into disuse due, in part, to their requiring a special tyramine-free diet to avoid a malignant hypertensive crisis (tyramines are found in common foods such as cheeses and red wine and, when ingested along with MAOIs, they produce the release of supranormal amounts of NE, causing a rise in blood pressure). Additionally, MAOIs interact with a variety of other pharmacologic agents, including alcohol, opiates, barbiturates, and aspirin, altering the body's ability

to metabolize them and resulting in a prolongation and enhancement of their effects.

Two subtypes of MAO have been identified: MAO-A and MAO-B. The former appears to be most active in deaminating 5HT, NE, EPI, and DA, whereas the latter deaminates DA, tyramine, and phenylethylamine. Agents that are selective for MAO-A are under investigation as antidepressants and include moclobemide, clorgyline, and cimoxatone. Theoretically, such agents should not exhibit a side effect profile as problematic as that of the original MAOIs. Nevertheless, the MAOIs are still in use, but only as third and fourth line agents with the most treatment-resistant cases of major depression.

Following development of the MAOIs, apparently safer antidepressants were developed that specifically blocked the re-uptake pumps for 5HT, NE, or DA, thus increasing the amount of neurotransmitter available in the synapse. These were the tricyclic antidepressants (TCAs), and they were the first efficacious, widely used and marketed agents for the treatment of major depression. These agents had a three-ring structure, hence their name. The most well-known of these include imipramine, amitriptyline, desipramine, and nortriptyline. Desipramine almost exclusively blocked the re-uptake pump (autoreceptor) for NE; the others had mixed effects, blocking the re-uptake autoreceptors for both 5HT and NE. The TCAs were essentially of equal effectiveness as antidepressants but differed in their side effect profiles. Unfortunately, all of the TCAs were highly nonspecific in their target effects. In addition to blocking re-uptake pumps in their targeted synapses, they all had additional untoward effects including the blockade of ACh and histamine receptors. The former resulted in dry mucous membranes (eyes and mouth), changes in vision, confusion (particularly in the elderly), constipation, and urinary difficulties. The latter resulted in increased appetite (especially for carbohydrates), weight gain, and sedation. Additionally, TCAs also have antagonistic effects on the α-1 receptor, resulting in blood pressure decrements (particularly upon standing), and possess the ability to prolong the QT interval on EKG due to their sometimes altering a susceptible patient's cardiac rhythm. The latter requires clearance with a normal EKG prior to starting TCA therapy in older patients. Although they were highly effective in the treatment of major depression, TCA side effects frequently resulted in poor compliance and lack of full patient satisfaction.

In order to provide an alternative to TCAs, a new class of antidepressants was developed in the 1980s. These were the selective serotonin re-uptake inhibitors (SSRIs). The first of these was fluoxetine (Prozac), an SSRI that was shown to be as efficacious as the TCAs but without the troublesome side effects of ACh and histamine receptor blockade. SSRIs exert their antidepressant effect by inhibiting the serotonergic re-uptake pump in the presynaptic 5HT neuron, thus blocking the destruction of 5HT. This, in turn, results in an increase in 5HT in the synapse, an increase in serotonergic neurotransmission, and down-regulation of the 5HT-1A receptors. These processes occur in multiple cortical pathways that are thought to be deficient in serotonergic neurotransmission in major depression: the frontal cortex, basal ganglia, hippocampus, and raphe nucleus.

Since the development and success of Prozac (fluoxetine), four additional SSRIs have been developed and marketed: sertraline (Zoloft), paroxetine (Paxil), fluvoxamine (Luvox, which was actually developed for obsessive compulsive disorder), and citalopram (Celexa). All have the same mechanism of action, and all have been used successfully in both depressive and anxiety spectrum disorders (e.g., panic disorder, obsessive compulsive disorder, and posttraumatic stress disorder). Their use in both anxiety and depressive disorders has called into question the differences (or lack thereof) in the underlying neurobiological mechanisms of these disorders, and this represents an intense area of investigation at present.

Although the various SSRIs all inhibit the presynaptic re-uptake pump, they also affect other serotonergic receptors to varying degrees. When they stimulate (agonize) 5HT-2 receptors, the result can be agitation, anxiety, sexual dysfunction (particularly anorgasmia), and insomnia. They also can stimulate 5HT-3 receptors; in some patients, as would be predicted by the foregoing discussion, this results in nausea, dyspepsia, and diarrhea. 5HT-3 receptor agonist effects have also been used to explain the side effect of headaches. The SSRIs, in general, also interact with a liver enzyme system called the cytochrome P450 system and its isoenzymes 1A2, 2D6, 2C19, and 3A4. This mitochondrial system functions to metabolize a wide variety of drugs (e.g., carbamazepine, theophyllin), and its inhibition can result in an increase in the serum level (and, sometimes, the toxicity) of these drugs. The various SSRIs differ in the degree to which they inhibit a given p450 isoenzyme (e.g., fluoxetine has a high impact on 2D6 and 2C19, but less on 1A2; paroxetine has a high impact on 2D6, but a low impact on 1A2), so care must be taken

for the patient to avoid problematic drug interactions with the SSRIs (e.g., opiate analgesics).

Since the development of SSRIs, several atypical antidepressants have been developed and marketed for major depression. Venlafaxine (Effexor) is a dual-channel agent that inhibits the re-uptake of 5HT, NE, and DA. Interestingly, venlafaxine only inhibits the re-uptake of 5HT at a low dose; at moderate doses both 5HT and NE re-uptake is blocked. At high doses, re-uptake of 5HT, NE, and DA is blocked. At low doses, as would be predicted, it has the same side effects as SSRIs; at medium to high doses, it can, in some individuals, cause hypertension, insomnia, agitation, and headache. It should be noted that venlafaxine has some, albeit low level, interactivity with all of the known P450 isoenzymes.

Trazodone is an antidepressant that was actually developed in the early 1980s. It is unique in its structure and mechanism: it antagonizes 5HT-2 receptors and functions as a 5HT re-uptake inhibitor simultaneously. It also blocks α-1 and histamine receptors, resulting in some side effects reminiscent of TCAs. More recently, the trazodone cogener nefazodone (Serzone) was developed. Nefazodone, like trazodone, antagonizes 5HT-2 receptors and blocks 5HT re-uptake, but, in addition, it blocks re-uptake of NE. This agent has been particularly useful in major depression associated with anxiety, agitation, or insomnia and appears to have fewer sexual side effects than SSRIs. Unfortunately, both trazodone and nefazodone produce a metabolite, mCPP, that results in dizziness and lightheadness in a relatively small percentage of patients.

Bupropion (Wellbutrin) is an atypical antidepressant that blocks the re-uptake of NE and DA. It is used widely in those cases of major depression where the level of deenergization is a major problem. The enhancement of noradrenergic and dopaminergic neurotransmission likely results in increased feelings of energy. Also, it is virtually without sexual or gastrointestinal side effects and is often used in cases where these have been problematic.

Finally, mirtazapine (Remeron) is an atypical antidepressant with an extremely unusual receptor profile. It blocks α-2 receptors on noradrenergic and serotonergic neurons, resulting in an increase in available NE and 5HT. Simultaneously, it blocks 5HT-2 and 5HT-3 receptors, minimizing the side effects (mentioned earlier) associated with stimulation of these receptors and, thus, avoiding sexual and GI side effects. It also blocks the histamine receptor, which likely counteracts the noradrenergic propensity for increased anxiety. Unfortunately, this action can also sedate and cause weight gain.

Currently, a wide variety of antidepressant agents are available to the clinician. A great deal of work is currently ongoing that attempts to match agent(s) to the specific subtype of major depression (e.g., agitated–anxious, deenergized, comorbid with pain) to be treated. However, selection is usually based upon the fact that the various agents vary somewhat in their side effects.

Another type of mood disorder often encountered by psychiatrists is bipolar affective disorder (BPAD) (DSM-IV). This is a serious mood disorder that occurs in about 1% of the population and is characterized by severe mood swings—from agitated, uncontrollable excitement (or, alternatively, hostility and irritability) to abject depression and back, often accompanied by psychotic delusions (usually of grandeur, wherein the patient believes himself or herself to be a celebrity or some other prominent person, or paranoia, wherein he or she believes that others are trying to harm him or her in some way). Various subtypes of BPAD include the classic syndrome of mood cycling from manic excitement to depression, cycling from mania to euthymia, and rapid cycling from one state to another in a matter of a few days. Ordinarily, the mood swings of BPAD patients last for many days or weeks, and their behavior during these intervals can cause serious problems in their relationships, careers, and financial well-being. Etiologically, the specific mechanism of BPAD is not elucidated, but there is clearly a genetic component (the disorder tends to be heritable) and manic episodes tend to be stimulated by stress. It is thought that aberrations in the noradrenergic and serotonergic systems are responsible for manic excitement, and it has been shown that antidepressants, particularly TCAs, can stimulate a manic episode. Thus, a complex balance of noradrenergic and serotonergic neurotransmission systems may be dysfunctional in BPAD. Further, it is thought that the psychosis that sometimes accompanies acute BPAD episodes is related to excess dopaminergic transmission. The responsiveness of BPAD to specific medication therapies underscores these theoretical assertions.

The first pharmacotherapy for BPAD was lithium carbonate. A simple salt of the element lithium, which was used in the nineteenth century for gout and arthritis, this agent's therapeutic potential was discovered in the late 1940s, but was not approved for use in the United States until the 1970s due to its toxicity in overdose. Almost immediately upon approval it

became the most widely used treatment for BPAD and was shown to be highly effective in the stabilization and long-term treatment of manic illness. Although its precise mechanism of action is not known, lithium has been shown to (1) block the neuron's ability to recycle inositol phosphate and thus synthesize inositol from glucose (this reduces the firing rate of affected neurons and dampens their overall sensitivity) and (2) modulate both serotonergic and noradrenergic neuronal systems. Lithium enhances the effect of 5HT itself and elevates the brain concentrations of tryptophan (a 5HT precursor) and 5HT. Regarding its noradrenergic effects, lithium increases the re-uptake of NE and also reduces its release. Both of these actions result in a net decrease in noradrenergic neurotransmission activity, which likely accounts for its calming effect on patients with manic excitement. Furthermore, these effects, in the face of the clear efficacy of lithium as a treatment for BPAD, suggest that the etiological basis of BPAD involves neuronal hyperexcitability and inadequate serotonergic activity combined with excessive noradrenergic activity.

Despite the efficacy of lithium therapy in BPAD, the agent is not without problems and complications. First, lithium, unlike the vast majority of other psychotropic agents, is metabolized by the kidneys rather than the liver. This means that it can interact with a variety of other renally metabolized agents, including the ubiquitous nonsteroidal anti-inflammatories, most diuretics, some antibiotics, and the popular angiotensin converting enzyme (ACE) inhibitor antihypertensives. Lithium effectiveness, furthermore, requires that the patient attain a serum lithium level between 0.8 and 1.2 mmol/liter; steady state (attained after 4 days of dosing) serum levels under these limits are usually ineffectual, whereas levels over 1.5 mmol/liter result in progressive toxicity. Both lithium's interaction profile and its tight therapeutic range require that the serum level be periodically monitored. Close clinical monitoring of patients in lithium therapy is necessitated by an array of potential side effects on the thyroid, gastrointestinal, cardiac, and dermatologic systems.

Due to the obvious complexities in the clinical use of lithium, other pharmacologic agents have become increasingly more popular in the treatment of BPAD. These belong to the general group of anticonvulsants, including carbamazepine (Tegretol), valproic acid (Depakote), and, more recently, lamotrigine (Lamictal) and gabapentin (Neurontin). Originally developed for the treatment of various seizure disorders, these agents serve as mood stabilizers at least in some subgroups of BPAD patients. Although, as with lithium, the precise mechanisms of action of anticonvulsants on BPAD are not clear, a partial picture is emerging. Valproic acid exerts an effect on the GABA system, thus stimulating inhibitory brain pathways. It also appears to modulate dopaminergic neurotransmission. Carbamazepine modulates the activity of several neurotransmitters, including 5HT, NE, and DA, via sodium channel dampening of each neuron system's excitability. Less is known about the mechanisms of lamotrigine and gabapentin, but both apparently act by effecting a decrease in neuronal excitability, presumptively in the 5HT, NE, and DA systems.

B. Schizophrenia

Schizophrenia is, without doubt, the most severe and devastating of all the psychiatric disorders. It occurs in approximately 1% of the population, has its onset in the early adult or late teen years, and has a clear heritable component (it occurs more often in individuals with affected family members). The most often encountered subtypes of schizophrenia are paranoid schizophrenia and disorganized schizophrenia. In the former, the individual is plagued by delusions of being persecuted by others, sometimes one's family or even by strangers. Sometimes the delusions are accompanied by hallucinations of voices that threaten or give commands to the affected patient. In disorganized schizophrenia, the patient may or may not have delusions and hallucinations, but most prominently suffers from loose associations, inability to process and follow a logical train of thought, and frequently, extreme social withdrawal and lack of appropriate social interaction skills. The etiology of schizophrenia is complex and multifactorial, but it clearly involves biochemical brain aberrations including excessive dopaminergic activity in the mesolimbic and mesocortical brain pathways. The former appears to produce the positive (or outwardly manifested) symptoms of schizophrenia, such as delusions and hallucinations. It is thought that the dopaminergic aberrations in the latter pathways produce the negative (or the absence of normality) symptoms of the disease, such as disorganization and social withdrawal.

Early drug treatment of schizophrenia involved the use of so-called neuroleptics, including phenothiazines (chlorpromazine or Thorazine, thioridazine or Mellaril, and trifluoperazine or Stelazine). Later more potent and presumptively less sedating antipsychotics

were developed, including the butyrophenones Haloperidol and Droperidol. All of these agents block D2 receptors. In the mesolimbic and mesocortical systems, this is desirable and efficacious. However, blockade of D2 receptors in the nigrostriatal and tuberoinfundibular regions results in side effects such as motor dyscontrol (e.g., extrapyramidal symptoms, tardive dyskinesia) and hyper-prolactinemia (resulting in breast secretions and sexual dysfunction).

In order to avoid the side effects associated with mass D2 blockade at multiple indiscriminate sites, research efforts have resulted in the development of a new class of antipsychotic agents called serotonin dopamine antagonists (SDAs) or atypical antipsychotics. These agents include Clozapine (the first of its class), Olanzapine, Risperidone, and Quetiapine. Ongoing research suggests that these agents (1) have more specificity for the mesolimbic and mesocortial D2 receptors, (2) have less specificity for striatal and infundibular D2 receptors, and (3) antagonize 5HT-2A receptors, which is thought to increase dopamine availability at striatal and other sites. Continuing clinical use of these agents does, in fact, suggest that they have less propensity for producing the side effects associated with typical antipsychotics or neuroleptics, while being at least equally as effective in treating positive symptoms of schizophrenia. Perhaps of equal importance is the growing body of evidence that these agents may be more effective than the typicals agents for the negative symptoms of schizophrenia.

V. NEUROPSYCHIATRIC DISORDERS

In this section, we will explore the pharmacologic basis and treatment of several disorders that span the realms of psychiatry and neurology. The disorders that we will address include cognitive deficit syndromes (e.g., dementias), sleep disorders, and chemical dependence disorders.

A. Dementias

Dementias involve cognitive deterioration (e.g., memory decrements and deficits in attention and concentration) and confusion that progress as a function of age. The most common and most widely studied dementia is Alzheimer's disease (AD). This condition remains a focus of extensive contemporary research, and its etiology is far from clear. However, research has indicated several likely etiologic factors, including the abnormal deposition of amyloid plaques around neurons and neuron bundles (neuritic plaques), which form neurofibrillary tangles, and the depletion of ACh particularly in the cortex and hippocampus. Also, it has been shown that M2 and nicotinic ACh receptors are reduced in patients with AD. The latter body of research has led to pharmacologic treatments designed to treat the cholinergic deficits in AD. Perhaps the most widely used agent of this genre is tetrahyroaminoacridine (Tacrine). This is a high-affinity, noncovalent inhibitor of acetylcholinesterase that, by reduction of the enzyme that inhibits ACh activity, increases net cholinergic activity in the brain. Other acetylcholinesterase inhibitors in clinical use are velnacrine, donepezil, and metrifonate. All have the same basic mechanism but differ in their affinities for acetylcholinesterase and metabolism and, therefore, their side effects. A summary of the research has shown that, although not all studies demonstrate effectiveness, the bulk of the evidence indicates that these agents can improve the behavioral and cognitive functions of AD patients to varying degrees.

B. Sleep Disorders

Sleep disorders are rather common in the general population and include (1) dyssomnias, (2) parasomnias, and (3) sleep dysfunction secondary to other neurological, general medical, or psychiatric disorders. Dyssomnias are by far the most common sleep disorders and represent conditions wherein the patient has difficulty either initiating or maintaining sleep; some have both syndromes. Both are characterized by chronic irritability, feelings of tiredness, excessive daytime sleepiness, poor concentration, and, in some cases, significant memory impairment. Etiological factors are widely variable and include recent significant stressors, poor sleep hygiene, and disturbances in circadian rhythm. The former is primarily an excessive arousal reaction to stress, which can be treated pharmacologically with arousal modulating agents. Trazodone has long been used to reduce nocturnal arousal and normalize sleep architecture. More recently, Nefazodone has been used similarly and shown to improve sleep architecture. The benzodiazepines (e.g., Lorazepam and Valium) have long been used to induce and maintain sleep but have fallen into disfavor of late due to the potential for producing dependence and dysfunction in memory and rapid eye movement (REM) sleep with prolonged use. The non-benzodiazepine hypnotic, Zolpidem, has seen heavy clinical use

in the past decade and has been shown to induce and maintain sleep without dependence or changes in cognition and sleep staging.

Poor sleep hygiene, although frequently treated pharmacologically with agents such as those listed previously, is best treated by changing the patient's sleep habits. For example, avoiding the intake of caffeine in the 4–5 hr prior to sleep and going to bed only when sleepy (or for sex) (to avoid associating the bed and bedroom with insomnia) have both been shown to be effective in some patients. Circadian rhythm disturbances are common in specific occupational groups such as factory shift workers, nurses, and others with periodic changes from day to night shift work. Pharmacologic induction of sleep is often used on a temporary basis with such patients, but attaining a stable and consistent work schedule has been shown to be preferable "treatment."

Parasomnias are relatively uncommon sleep disorders and involve unusual behaviors, movements, and sensations during sleep. Often, the patient will experience jerking or myoclonus of the lower extremities, sometimes called restless legs syndrome. Repetitive, rhythmic movements of the head, neck, and limb affect another small subgroup of patients; some patients will find themselves awakened by their walking about while asleep. Although detailed sleep studies are usually necessary to design an individualized treatment program for parasomnia patients, many are helped pharmacologically by the administration of sedating antidepressants such as trazodone and nefazodone. Those with problematic nocturnal muscle movements are responsive to the high-potency, highly sedating, and skeletal muscle relaxing benzodiazepine, Clonazepam. This agent, which is also classified as an anticonvulsant, appears to act by very significantly reducing cognitive arousal as well as by reducing nocturnal skeletal muscle tone.

Sleep dysfunction due to other general medical or psychiatric conditions is most often due to pharmacologic side effects. For example, the SSRIs, venlafaxine, and bupropion often cause sufficient arousal to result in difficulty initiating sleep and, thus, require very slow titration from low doses as the patient becomes accustomed to their effects. Prednisone and theophylline, both widely used for inflammation and respiratory dysfunction, respectively, are well-known for their tendency to disrupt sleep and inhibit its onset. Medical and psychiatric conditions that commonly cause sleep dysfunction include hyperthyroidism, chronic obstructive pulmonary disease (COPD), Parkinson's disease, degenerative arthritis, depressive spectrum disorders, bipolar affective disorder (BPAD), and various anxiety disorders (e.g., panic disorder, generalized anxiety disorder). In the case of general medical disorder induced sleep disorders, pharmacologic treatment with sedation antidepressants or with Zolpidem is often effective. With psychiatric disorders, effective treatment of the disorder itself usually results in the resolution of the secondary sleep disorder.

C. Chemical Dependence Disorders

Chemical dependencies are characterized in DSM-IV and other sources by intense and consuming substance preoccupation, intoxication, tolerance, withdrawal, and, most importantly, significant impairment of social and occupational functioning due to the substance's use. One of the major problems in developing empirically based treatment for these disorders is that, despite the present consensus criteria for their diagnosis, there is rather astounding conceptual confusion around the concepts of addiction, dependence, and abuse of various substances. Related to this conceptual confusion is the difficulty in making a firm and reliable chemical dependence diagnosis, even when done by well-trained professionals.

Regardless of the conceptual confusion around issues of what constitutes abuse vs dependence and despite the difficulties in making a diagnosis in the complex behavioral arena of chemical dependence, psychiatrists frequently encounter patients with substance use that seriously impairs their ability to function. The most common substance dependencies seen by psychiatrists include opiate, stimulant (e.g., cocaine and amphetamine), and alcohol dependence.

Opiates are narcotic analgesics whose primary action is pain reduction. Secondary actions involve the production of an intense state of euphoria and relaxation, the basis of their dependence induction. For hundreds if not thousands of years, the sole opiate ingested was opium, from which the term opiate was derived. In the early 1800s, the active ingredient, morphine, was synthesized, and in 1874, the morphine molecule was altered to synthesize the highly dependence inducing agent, heroin. Morphine and its derivatives cause their CNS effects via interaction (as agonists) with the opiate receptors: μ, γ and κ (σ receptors were once thought to be opiate receptors, but this theory is no longer considered tenable). μ receptors are heavily distributed in the cerebral cortex, thalamus,

hippocampus, locus coeruleus, amygdala, caudate, putamen, and the dorsal portion of the spinal cord. This receptor is involved in the production of both analgesic and euphoric states. γ receptors are distributed similarly to μ receptors, but more restrictively. Their primary locations are in the neocortex, striatum, and substantia nigra, with the expected involvement in cognitive processes and motor integration. The κ receptor binds ketocyclazocine, an opiate analog molecule that produces hallucinations and dysphoric mood states; thus, it is thought to have a possible role in psychiatric disorders, but presently this is far from clear. Opiate interactions with κ receptors are involved in GI motility, food and water intake, thermoregulation, and pain perception.

Natural opiate-like neurotransmitters, called endogenous opioids or endorphins, exist throughout the nervous system and function as agonists with the preceding opiate receptors. The currently known and characterized endogenous opioids include the enkephalins met-enkephalin and leu-enkephalin, β-endorphin, and dynorphin. These agents have multiple precursors that may also have the ability to interact with opiate receptors.

Opioid effects in the nervous system are highly complex and involve interactions with other neurotransmitter systems. For example, opioid interactions with μ receptors in the brain stem result in the stimulation of GABA activity, with resultant inhibition of sensory processes in the spinal cord. Enkephalins in the caudate are localized with and probably modulate the activity of the neurotransmitter glutamate. It behaves similarly in the raphe nucleus and area postrema with 5HT. Dynorphin in the arcuate and supraoptic nuclear regions interacts with and modulates tyrosine hyroxylase and thereby influences the catecholamines. Research is ongoing in attempts to more fully characterize how opiates interact with their own receptors and with other neurotransmitter systems to produce analgesia, euphoria, and dependence states.

Despite the at best partial picture of the actions of opiates, pharmacologic methods have been developed to treat opiate dependence. The earliest treatment protocols involved an attempt to substitute agents that do not have the problematic effects of opiates. For example, methadone therapy involves the controlled administration of methadone, a synthetic narcotic analgesic similar in effect to morphine. The theory was that methadone would reduce narcotic craving, making the patient more amenable to rehabilitation. In reality, methadone is cross-dependent with morphine and heroin, and one chemical dependence is basically substituted for another, albeit a more "controlled" and clinically administered dependence in the case of methadone.

Detoxification under clinical supervision is another pharmacologic treatment protocol for opiate dependence. In this model, the symptoms of opiate withdrawal are modulated and minimized via pharmacotherapy. Clonidine, for example, is an α-2 agonist that results in the inhibition of excess arousal generated by withdrawal. It thus decreases the syndrome of sweats, myospasm, and stomach cramping. Benzodiazepines, in systematic tapered regimens, also have found usefulness in minimizing the arousal of withdrawal.

Finally, a more recent treatment option involves the use of narcotic antagonists following detoxification. These agents include naloxone, naltrexone, and cyclazocine and function to block the euphoric effects of opiates. Naltrexone is a μ receptor specific antagonist, has a relatively long duration, and has few side effects; thus, it is the most commonly used agent. When one takes naltrexone, the ingestion of heroin or other opiates has no euphoric effect, thus reducing the motivation for their ingestion. Unfortunately, the opiate-dependent patient can simply stop taking the antagonist agents for several days to re-instate the euphorigenic potential of opiates.

Alcohol is the most widely used substance that results in chemical dependence and appears to interact with GABA receptors at multiple sites. This results in reduced skeletal muscle tone, decreased arousal and anxiety, and impaired cognitive and sensory processes. Chronic alcohol use also appears to result in down-regulation of the dopaminergic system and a reduction in NE synthesis and level, possibly resulting in another avenue of decreased arousal and anxiety. Although the withdrawal symptoms of alcohol dependence are effectively treated with benzodiazepine in a taper down protocol, alcohol dependence treatment itself has not generated a literature showing clear efficacy. Disulfiram (Antabuse) is sometimes used to prevent alcoholics from consuming alcohol due to the fact that it produces toxicity when combined with consumed alcohol. This agent irreversibly inhibits the action of aldehyde dehyrogenase, an enzyme that converts acetaldehyde (a major metabolite of alcohol) to acetate (which is readily excreted). Thus, consumption of alcohol while on disulfiram results in a buildup of acetaldehyde, which results in a highly unpleasant state including tachycardia, flushing of the face, nausea and vomiting, dizziness, and shortness of

breath. This provides a form of "aversion" therapy wherein alcohol use, instead of resulting in a pleasant relaxed state, results in a highly noxious state. Unfortunately, many if not most alcohol patients learn quickly that all they need do is stop taking disulfiram so that they can drink alcohol with "impunity." Another pharmacologic treatment of alcoholism is naltrexone, the μ antagonist used to treat opiate dependence. Naltrexone is used on the theory that its blockade of μ receptors may block "brain reward" centers that are stimulated with alcohol and, thus, reduce the alcoholic's propensity for alcohol consumption. Unfortunately, there is no unequivocal evidence for its efficacy, particularly in the face of the ability of the alcoholic patient to terminate its use to enhance the pleasure producing effects of alcohol, as is the case with disulfiram.

Stimulants are drugs that produce increased alertness, arousal, and excitement, as well as euphoria. The most commonly abused stimulants are amphetamine and cocaine. Amphetamine blocks the re-uptake of DA and NE (and possibly 5HT) throughout cortical regions and is also a potent stimulator of DA release from neurons. It, thus, increases the amount of DA available and then blocks the neuron's ability to regulate DA along with NE and possibly 5HT. Cocaine is an alkaloid stimulant that exerts its stimulatory action by blocking the re-uptake of DA, NE, and 5HT. Both amphetamine and cocaine can produce chemical dependence syndromes. Stimulant dependence is often treated pharmacologically with dopamine agonists and antidepressants.

Bromocriptine is a D2 receptor agonist that has been used on the theory that stimulant "craving" and withdrawal are due to DA depletion; a D2 agonist would, thus, replete synaptic DA levels. Unfortunately, this treatment has not been shown to be clearly efficacious. Fluoxetine has also been used on the assumption that its arousal inducing properties (although serotonergic rather than dopaminergic in nature) would replace the "need" for the stimulant. Buproprion, an antidepressant that has both noradrenergic and dopaminergic properties, has been used in the treatment of amphetamine and cocaine dependence, but there is no consistent evidence of its efficacy.

While on the subject of chemical dependence, the reader is likely aware that there is currently much discussion of dependence upon the mild stimulants, nicotine and caffeine. Although there is clear evidence that smoking is a health risk factor in a variety of illnesses and excess caffeine consumption may be similarly implicated in some gastrointestinal illnesses, their status as dependence inducing agents is far less clear than the media and public health authorities would suggest. Some researchers have argued strongly against the use of a dependence model to explain nicotine use, citing evidence that, despite allusions to the similarity of heroin and nicotine in the press and public health statements, there is, in fact, little similarity when one examines the impact the use of the respective substances has on immediate functional status. Other researchers have demonstrated that cocaine and amphetamine result in a dramatic ($>50\%$) lowering of the threshold for brain reward stimulation in the dopaminergic reward centers of the brain, providing a marker for their dependence inducting capabilities; agents such as caffeine and nicotine result in substantially smaller and similar (to each other) effects ($<30\%$ brain reward stimulation threshold lowering), strongly suggesting that the two sets of pharmacologic agents are quite different in their effect on brain pleasure centers and, thus, possibly their dependence inducing ability.

Despite the conceptual and definitional problems in the literature, many people want to stop smoking and there have been neuropharmacologic treatments designed to assist. The most common involve nicotine gum and the nicotine transdermal patch. The former provides oral nicotine via chewing, whereas the latter provides nicotine secreted through the skin in a progressive taper down dosage form. Both are based on the assumption that people benefit from the ingestion of nicotine (nicotine stimulates ACh receptors and this can release DA into the synapse, likely resulting in an alteration of arousal state), and replacement in an oral or transdermal form replaces that obtained from smoking. Unfortunately, only about 10% of patients report that these methods help them quit smoking, and several studies have shown that the presence or absence of nicotine in delivery devices has little, if any, effect on reports of withdrawal symptoms. The low success rate of nicotine replacement clearly indicates that smoking involves factors in addition to attaining the pharmacological effects of nicotine.

Another pharmacologic strategy for smoking cessation involves the attempt to replace a state of high arousal and evidence that many smokers become depressed when they cease the use of nicotine and may, thus, be self-treating depressive symptoms with nicotine. This treatment involves the antidepressant bupropion, marketed for smoking cessation as Zyban. As the reader recalls, bupropion has both noradrenergic and dopaminergic properties, and it is one of the most

arousing of the antidepressants available. Unfortunately, there is no conclusive data on its efficacy in smoking cessation.

VI. NEUROLOGICAL DISORDERS

The final section of this article focuses on several disorders that have traditionally fallen under the purview of neurology. These include seizure disorders, movement disorders, and headaches.

A. Seizure Disorders

Seizure disorders involve episodic abnormal discharges of groups of neurons in the central nervous system. Their etiology lies in the paroxysmal stimulation of neuronal firing, and this is modulated by sodium channel current states, GABAergic activity in affected neurons, and calcium channel current states. The classification of these disorders is nearly a field unto itself, and a full discussion of this issue is beyond the scope of this article. In general, seizures can be viewed as falling into three categories based upon clinical manifestations and localization vs generalization of symptoms: tonic–clonic generalized, tonic–clonic partial, and absence.

Tonic–clonic seizures can involve generalized convulsive activity (involving the entire body) or partial convulsive activity, wherein one arm or one leg, for example, exhibits convulsive activity. Most anticonvulsants are used for both types of seizures, but the drugs of choice vary according to type. In generalized tonic–clonic seizures, the current drugs of choice are valproic acid (discussed in the section of BPAD) and topiramate, despite their pending FDA approval status for these purposes. Carbamazepine, phenytoin, phenobarbital, primidone, and lamotrigine are also used with generalized seizures. The drugs of choice for partial tonic–clonic seizures are carbamazepine, phenytoin, and valproic acid. Also used are phenobarbital, primidone, gabapentin, lamotrigine, felbamate, topiramate, tiagabine, and vigabatrin.

Absence seizures involve the absence of typical convulsive activity and instead, are characterized by episodic periods of the absence of normal awareness and arousal. The patient reports an episode where he or she "lost touch" or "just went away." Observers typically only notice that the individual appears not to pay attention to what was going on in the environment. When an EEG study is made during such an episode, it shows typical seizure-like brain wave activity despite the lack of muscle system involvement. The drugs of choice for the treatment of absence seizures include ethosuximide and valproic acid. Other drugs include clonazepan (a benzodiazepine), and lamotrigine.

The definitive picture of the mechanism of anticonvulsants, like antidepressants and antipsychotics, is not fully clear. However, it is known that most, if not all, serve to modulate neuronal activity by altering sodium channel activity, calcium channel activity, and GABAergic activity in neuron groups that are associated with a given type of seizure. Some agents, such as phenytoin and carbamazepine, primarily have their effect on sodium channels where they block activity by binding to and inactivating the channel. Phenobarbitol interacts primarily with the GABA system and facilitates the opening of chloride channels in response to GABA, thus serving to inhibit affected neurons. Phenobarbitol also interacts with glutamate by interfering with its excitatory actions on relevant neuron groups. Topiramate blocks sodium channels, enhances GABA inhibitory effects, and antagonizes glutamate. Ethosuximide has its effect by inhibiting calcium channel activity in the thalamic regions, where the synchronous firing of neuron groups appears to summate into absence seizures. Two of the newest anticonvulsants are vigabatrin and tiagabine. Both of these agents have their effects by enhancing GABA activity, which, as the reader knows, is inhibitory. Vigabatrin binds to and inactivates GABA transaminase, the enzyme responsible for degrading GABA. Tiagabine blocks the re-uptake of GABA, much as the antidepressants do with 5HT and NE, thus increasing the availability, concentration, and duration of the inhibitory actions of GABA.

B. Movement Disorders

Movement disorders involve abnormal, insufficient, or excessive motor activity. Most of the movement disorders involve stiffness, rigidity, bradykinesia (slow movements), tremors, tics, gait difficulties, and loss of control of movements. The most common movement disorder in neurology is Parkinson's disease, which is by far the most studied and well-understood. Other conditions include Tourette's syndrome, tremors, and myoclonus. Parkinson's disease is characterized by resting tremor (a tremor that worsens at rest, compared to during activity), cogwheel rigidity (rigidity that, in the arms, can be felt with movement showing stiffness, then giving way, then restiffening), slowing of

movements, and, finally, the absence of movement (for example, the classic loss of facial expression due to the inability to move the facial muscles). The disease usually starts on one side and remains most severe on that side. Also, its final stage involves a severe dementia that is similar in presentation to that of Alzheimer's disease described earlier.

Parkinson's disease involves etiologically obscure degeneration of the nigrostriatal pathway, a dopaminergic neuron system that originates in the substantia nigra and terminates in the striatum. The nigrostriatal pathway synthesizes and stores a large amount of DA. As the reader recalls, DA is synthesized from tyrosine, which is converted to L-dihyroxyphenylalanine (L-DOPA) by the enzyme tyrosine hyroxylase. L-DOPA is then converted to DA by decarboxylation via dopa decarboxylase. DA actions are regulated by its re-uptake and degradation by the enzymes MAO and catechol-*O*-methyltransferase (COMT). Although Parkinson's clearly involves the dopaminergic system, the ACh, 5HT, and GABA systems have also been implicated in its etiology.

The treatment of Parkinson's disease has focused upon symptomatic relief in reducing the motor symptoms of the disease by targeting various points in the synthesis of DA described earlier. The most common strategy has been to replace DA by giving the patient L-DOPA, the DA precursor. Another strategy has been to treat with either carbidopa or benserazide, which are both peripheral dopa decarboxylase inhibitors. Most often, the two agents are administered together for maximal effect. Both agents obviously focus on directly combating the loss of DA with the degeneration of the nigrostriatal system in the disease. Another strategy has involved the administration of DA receptor agonists, such as bromocriptine, pergolide, and lisuride, in hopes of enhancing dopaminergic activity. Selegeline, an inhibitor of the B subtype of MAO, which thus blocks the destruction of DA, has been used with some success. More recently, two new agents, entacapone and tolcapone, have also been used with some success. Both agents inhibit COMT at multiple metabolic sites, thus dramatically increasing the availability of DA. Unfortunately, none of the anti-Parkinson agents have done any more than delay the worsening of the disease, because the primary lesion involves the large and important dopaminergic motor system in the brain and its progressive degeneration cannot be stopped by simply replacing DA or slowing its degradation. As with many if not most of the diseases in this article, a real cure awaits much more research in the neurobiology of the diseases for which neuropharmacology offers therapeutic protocols.

C. Headaches

The next disorder we will focus upon involves headaches. Headache is ubiquitous and is always one of the top five reasons why people visit doctors. Headaches are classified by various schemes, but, most simply, they can be viewed as involving migraine headache, tension headache, cluster headache, and trigeminal neuralgia. Migraine headache in its various manifestations can involve unilateral or bilateral headache that is usually associated with a prodrome (preceding the headache) or codrome (occurring with the headache) of nausea, vomiting, photosensitivity–photophobia, and alterations in mood. Its etiology is not fully known, but it is now thought to involve excessive serotonergic activity due to histamine-induced release of 5HT from mast cells in the vertebrobasilar arterial system. In this model, the excessive serotonergic activity results in alternating constrictions and relaxation of vascular structures, which, with repetition, result in vasospasm. The vasospasm is thought to be the primary mechanism of the headaches themselves.

Historically, a wide variety of agents have been used to treat migraines, but ergotamine and dihydroergotomine have been, until recently, the mainstays of migraine treatment. Both agents inhibit NE re-uptake at sympathetic nerve endings, thereby causing vasoconstriction. The treatment rationale was that "forced" vasoconstriction would stop the process of sequential vasorelaxation and vasoconstriction that results in vasospasm. Other agents used in the treatment of migraine, especially in the chronic preventive rather than acute abortive treatment, have included tricyclic antidepressants, SSRIs, neuroleptic antipsychotics, β-adrenergic antagonists, anticonvulsants, and nonsteroidal anti-inflammatories (NSAIDS). Aside from NSAIDS, where the rationale was simply to stop the vascular inflammatory process thought to be involved in the initiation and maintenance of migraine, the rationale for the use of many of these agents was sometimes obscure and based more on clinical lore and clinician observation of efficacy than on empirical investigation.

Methysergide, a serotonin antagonist, was shown to be efficacious in the 1970s but was plagued by a variety of side effects, including a uncommon but severe syndrome of posterior mediastinal and cardiac fibrosis. As the serotonergic basis of migraine became more

substantiated in the 1990s, a new class of antimigraine abortive agent emerged, the 5HT-1 receptor agonist. The 5HT-1 receptor is a presynaptic autoreceptor that functions as a re-uptake pump. A 5HT-1 agonist thus stimulates the 5HT re-uptake pump, making less 5HT available. In the case of migraine, this is thought to stop the serotonergically mediated vasospasm process. The currently available 5HT-1 agonists include sumatriptan, naratriptan, and zolmitriptan. Sumatriptan is a 5HT-1 agonist that is structurally similar to 5HT itself and interacts with the 5HT-1 site without the usual effects of 5HT. Naratriptan is essentially identical in function to sumatriptan. Zolmitriptan is a selective agonist of the 5HT-1B and 5HT-1D receptor family and is thought to stimulate re-uptake without the side effects associated with blocking the 5HT-1 site in a more generalized manner.

Tension headache is characterized by a band of muscle tension in the frontal, temporal, and occipital regions of the scalp, locations where most people experience tension due to stress and anxiety. Pharmacologic treatment of these common headaches is usually reserved for those with extremely severe and intractable conditions. NSAIDS are commonly used for their straightforward analgesic effects. Additionally, tricyclic antidepressants as well as SSRIs have become more commonly used with severe tension headache on the assumption of an underlying mood or anxiety disorder. In some cases, antispasmodic agents such as isometheptene (combined with the anticonstrictives dihloralphenazone and acetaminophen with the trade names Midrin and Isopap) and baclofen have been used with some success.

Cluster headaches are cyclical headaches that literally occur in clusters (of daily headaches for several days), often in cycles varying with seasonal changes. They usually awaken the patient after 1–2 hr of sleep. The etiology is unknown, but several neuropharmacologic agents have been used in their treatment, including lithium carbonate (on the theory that the cyclical headaches are akin to mood cycling) and methysergide (on the theory that cluster headaches are a migraine variant with serotonergic etiology).

Trigeminal neuralgia is a syndrome of head pain due to blood vessel or inflammatory impingement upon the trigeminal nerve root. The syndrome is viewed as a type of seizure-like involvement of that specific nerve root due to excessive mechanical stimulation via impingement. The mainstay of treatment is and remains carbamazepine, as this agent modulates the sodium channel activity of the trigeminal nerve root and decreases its firing rate, thus reducing painful sensations. The other agent used in the treatment of trigeminal neuralgia is phenytoin, with a mechanism essentially identical to that of carbamazepine.

D. Chronic Pain Syndromes

Related to the subject of headache is a vast array of disorders subsumed under the concept of chronic pain syndrome (CPS). CPS can involve any severe pain in virtually any area of the body that has lasted for 6 months or longer. The pain can stem from muscle, joint, or skeletal tissue, called musculoskeletal pain, or it can be generated by damaged nerve tissue, called neuropathic pain.

Musculoskeletal CPS can involve a single joint, i.e., arthritis, a single muscle or set of muscles, i.e., myofascial pain, or multiple sites, such as in the syndrome fibromyalgia, wherein at least 11 specific body sites have pain and tenderness. The mainstay of musculoskeletal CPS treatment involves NSAIDs, as described previously. The basic theory is that musculoskeletal pain, at least partially, involves inflammation of the target tissue. NSAIDs, thus, attack inflammation as a pain generator. A second set of pharmacologic agents used widely in musculoskeletal CPS includes the antispasmodics. Two such agents, cyclobenzaprine and chlorzoxazone, both widely used, inhibit the activity of polysynaptic reflexes at the neuromuscular junction. As such, they reduce skeletal muscle tone. Another second line agent is baclofen, a much more powerful antispasmodic. Baclofen acts by stimulating the GABA receptor in neuromuscular regions and, therefore, increases the inhibition of muscle activity. There is also some evidence that baclofen has an inhibitory effect on substance P, a major transmitter of painful sensory processes.

Neuropathic CPS involves pain stemming from damage to nerve tissue. The pain generator can be a single large nerve or set of nerves (as in polyneuropathy), or it can involve networks of small nerve structures, as in what was formerly called reflex sympathetic dystrophy (now called complex regional pain syndrome or CRPS). The etiologic agent in neuropathic pain syndrome can vary widely, ranging from diabetes (high blood glucose can damage nerve fibers), to impingement of nerve fibers by other structures (tumors, ruptured vertebral disks), to direct trauma to a nerve or nerve networks (projective wounds, crush injuries, or displaced fractures that tear nerve tissue).

Despite the varied etiology and nature of neuropathic CPS, one commonality is its treatment. Anticonvulsants, as described earlier, are the mainstay of its treatment. The theory is that anticonvulsants reduce nerve fiber reactivity and, thus, reduce the transmission of pain impulses. Nerve blocks with anesthetic agents such as Lidocaine (which reduces nerve impulse activity by modulating sodium channels) are also often used in trying to modulate neuropathic pain.

Regardless of etiology or type, CPS is often a challenge to treat pharmacologically. Often physicians must resort to the use of opiate narcotic analgesics to control pain. Although chemical dependence among CPS patients is not nearly as common as once thought, care must be taken to avoid side effects, abuse, or dependence upon narcotics in the CPS population. The complexity of pain management is such that a new field of medicine has emerged, pain medicine, dedicated to diagnosing and appropriately treating pain in all its forms. This author, who is a member of the American Academy of Pain Medicine, believes that this new field will surely generate a plethora of new neuropharmacological approaches to pain control in the future.

VII. SUMMARY

This article has explored neuropharmacology from the standpoint of the most important clinical conditions in the fields of psychiatry, neuropsychiatry, and neurology. Neuropharmacology contributes to these fields by bringing to bear the models of receptor–ligand interactions as one basis for the diseases upon which they focus. These models yield neuropharmacologic agents that can alter aberrant neurophysiological and neurochemical processes. Although many of the diseases upon which this article focused are not fully elucidated in terms of mechanism, ongoing neuropharmacologic research, by developing and testing more receptor-selective drugs, is slowly providing a means for piecing together their etiologies. Through a cyclical process, whereby neuropharmacologic agents are suggested by receptor models of disease, the receptor models are refined on the basis of the effects of the agents, and new agents are, thus, developed on the basis of receptor model refinements. Many of the diseases about which we know little in the year 2002 may be more treatable and possibly even "cured" in the years to come.

Neuroplasticity, Developmental

DAPHNE BAVELIER
University of Rochester

HELEN NEVILLE
University of Oregon

GLOSSARY

altered experience Experience that is atypical for the organism, such as deprivation of input or exposure to stimulation outside the range normally encountered by the organism.

compensatory plasticity Changes in behavior and brain organization resulting from altered experience.

sensitive–critical period Developmental time period during which experience can significantly alter the organism's behavioral performance and related aspects of brain structure and/or function.

synaptogenesis–neurogenesis Generation of new synapses and new neurons.

The term neuroplasticity is generally used to refer to the capacity of the nervous system to modify its organization. Such changes may occur as a consequence of many different events, including normal development and maturation of the organism, the acquisition of new skills (learning), damage to the nervous system, and sensory deprivation. Studies to date of the molecular and cellular events underlying neural plasticity in such different conditions have revealed a limited set of mechanisms available to induce changes in the organization of the neural networks of the brain. Such reports raise the hypothesis and the hope that the diverse phenomena referred as neuroplasticity will be elucidated in the not-too-distant future. However, whereas there is evidence to suggest that there is considerable overlap in the cellular and molecular mechanisms that mediate neuroplasticity, we are still left with the challenge of understanding why a second language can be difficult for adults to learn, why children born with only one cerebral hemisphere fair so well compared to individuals who lose a hemisphere in adulthood, or why some skills are easier to learn than others. Studies of changes in behavior as a result of development or learning suggest more specificity than might have been predicted from the reports of a limited repertoire of cellular or molecular changes. Our goals are to qualify the specificity of plastic changes, characterize the parameters that determine this specificity, and elucidate its neural mechanisms. Although there is no agreed upon way to divide up the field of neural plasticity, the little data currently available suggest a greater potential for plastic changes during development than adulthood. Even if some of the mechanisms of neuroplasticity are similar or even identical during developmental and adult plasticity, the fact that these mechanisms operate on nervous systems that are structurally and physiologically different is likely to result in quantitative and/or qualitative differences in neuroplasticity in immature and mature organisms. For example, the number of synapses is 50% greater in the immature human brain than in the adult brain. This redundant connectivity

exists at different times in different brain regions and almost certainly constrains the nature and extent of modifications that can occur. Accordingly, studies of animals indicate considerable variability and specificity in the types of plastic changes that can occur from system to system as a function of age. In view of these differences between developmental and adult plasticity, we focus on developmental plasticity in this article. This article starts by reviewing neural events during human brain development. It then turns to within-modality plasticity and reviews the effects of altered visual experience during development on the cerebral organization for vision. Between-modality plasticity is discussed next by considering the evidence for reorganization across modalities in humans, including tactile and auditory skills in the blind and visual abilities in the deaf. Finally, plasticity within the language system is considered.

I. HUMAN BRAIN DEVELOPMENT: SIMILARITIES AND DIFFERENCES BETWEEN HUMAN AND NONHUMAN PRIMATES

The observation that the programs that govern development are remarkably conserved throughout phylogeny has led to the wide acceptance that human brain development goes through stages of development similar to those described for nonhuman primates. Whereas the earliest stages of development show limited room for plastic changes, plasticity naturally mediates the later stages of development as early experience in part controls the modulation of the connectivity between neurons. In most species, including humans, the pattern of connectivity that emerges as a result of early prenatal stages of development is only a rough sketch of the final wiring. Postnatally, the pattern of connectivity is refined through progressive and regressive events during which axons, dendrites, synapses, and possibly neurons show exuberant growth and major loss, leading to remodeling of the neural circuitry. The extensive changes in connectivity observed during that stage of development are believed to be limited to certain time periods. Reshaping of the connectivity during this period of time appears to be mediated by mechanisms similar to those observed at other ages, particularly activity-dependent mechanisms that are modulated by experience. However, the amplitude of the changes may be considerably greater in the immature system.

A. Role of Experience in Development

The role of sensory experience during sensitive periods has been documented in numerous animal studies. Experience in part controls the selection of axons, dendrites, synapses, and neurons that will form the functional neural circuits. For example, during the sensitive period for ocular dominance, visual deprivation induced by monocular eyelid suture results in shrinkage of the ocular dominance columns serving the closed eye. Outside the sensitive period, visual deprivation has little effect on the pattern of ocular dominance. There is good agreement in the literature that experience affects the organization of local circuits rather than major pathways because the main topographical and columnar organization of the cortex has already been achieved by the time most sensitive periods have been reported to occur. Experience has also been implicated in the onset of sensitive periods. In cats, rearing in the dark results in delayed onset of the sensitive period for ocular dominance formation. Similar observations of the role of experience have been made in the auditory systems of songbirds and humans. For example, the maturation of an early auditory evoked response displays an extended time course of development after cochlear implantation in congenitally deaf children. In this case, the number of years of auditory experience, rather than chronological age per se, was predictive of the maturational time course, even in individuals implanted during adulthood. Whereas this result indicates that this early auditory response retains its capacity to mature throughout life, most systems typically exhibit limits on the period of time when experience leads to normal maturation. Kittens raised with both eyes sutured at the age of 1.5–16 months show significantly reduced contrast sensitivity, human babies with bilateral cataracts show little recovery if operated on after 2 years of age, and children exposed to a natural language for the first time around puberty fail to master that language.

Evidence indicates that some sensitive periods are mediated, at least in part, by changes in the sensitivity of the *N*-methyl-D-aspartate (NMDA) receptors; in particular, these receptors require stronger input for learning to proceed as a sensitive period unfolds. This change in sensitivity occurs over time but also appears to be modulated by experience. For example, the visual cortex of older, binocularly deprived cats exhibits the same large NMDA component in their response to light as younger kittens

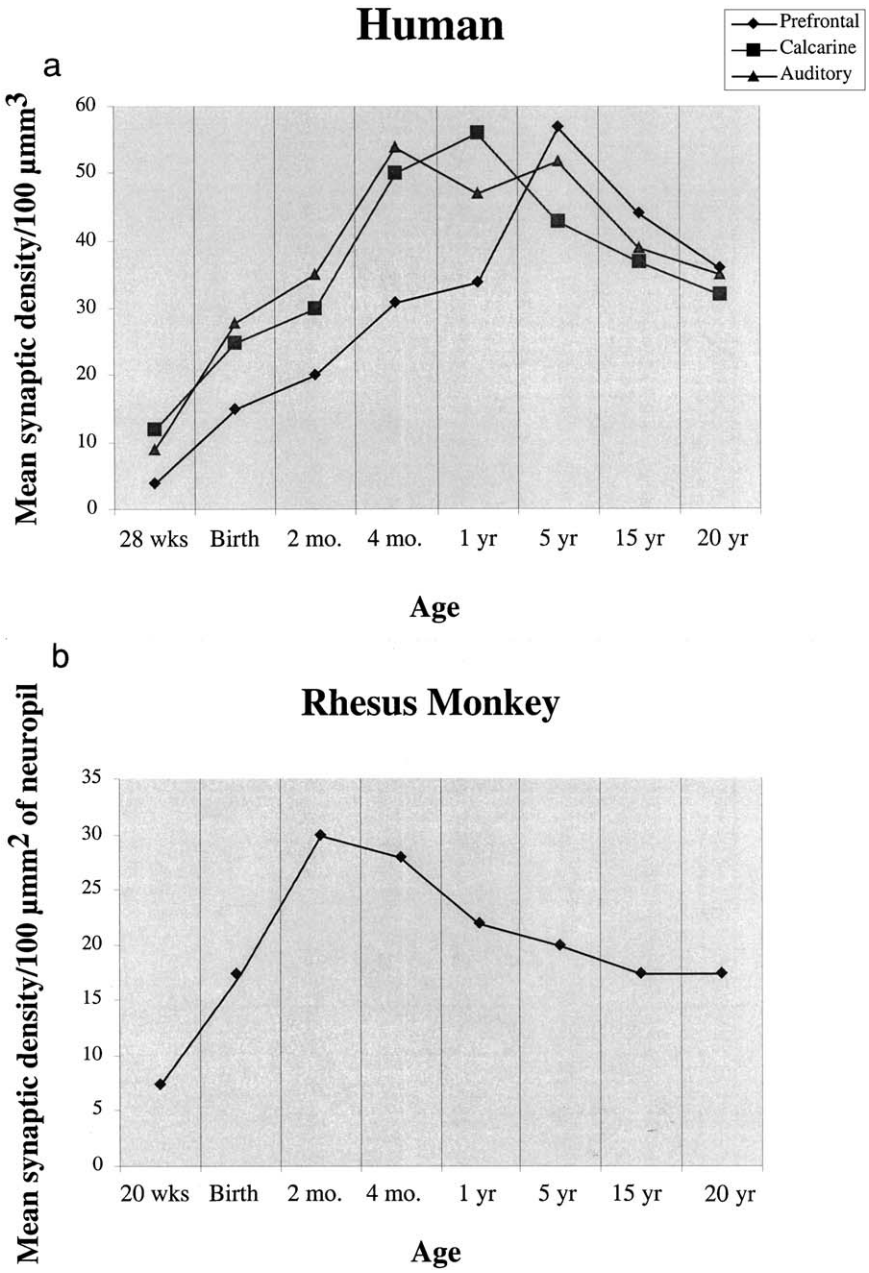

Figure 1 (a) Mean synaptic density in synapses/100 μm^3 in visual, auditory, and prefrontal cortices at various ages during human development. The data suggest regional differences in synaptogenesis [adapted from Huttenlocher and Dabholkar (1997)]. (b) In contrast, the mean synaptic density in synapses/100 μm^2 of neuropil was found to be comparable across visual, somatosensory, motor, and prefrontal cortices during development in monkeys [adapted from Rakic, Bourgeois (1986)].

that have had a similar amount of exposure to light, indicating that visual experience affects this change. Thus, the maturational status of the brain is affected by both chronological age and experience, illustrating the inextricable roles of nature and nurture during the course of development.

B. Mechanisms of Plastic Changes during Development and Learning

Although little is known about the factors that control the duration and timing of sensitive periods,

it is commonly believed that they are closely related to synaptogenesis, i.e., the phase of overproduction of synapses observed during cortical development. Studies of nonhuman primate development have indicated that about 35% of axons–neurons are lost from the peak of development to adulthood and that the onset of this loss co-occurs with the period of synaptogenesis. Similar studies conducted on human brain tissue also document periods of overproduction of synapses. Researchers have used electron microscopy to map out the synaptic remodeling that occurs during human development. They have compared synaptogenesis and synapse elimination within several different brain areas. In primary visual cortex, a burst in synaptogenesis occurs at about 3–4 months of age with maximum density reached at 4 months. In contrast, synaptogenesis in the middle prefrontal cortex takes longer, reaching maximum synaptic density at about 3.5 years of age. Furthermore, the same researchers have shown that the time course for synapse elimination occurs significantly later in the middle frontal gyrus (until 20 years of age) than in the primary visual cortex (converged on adult levels by age 4 years; see Fig. 1). These findings suggest that brain areas differ in their rate of development. The anatomical measures of synapse proliferation in the human brain describe developmental time courses similar to those observed in physiological studies using positron emission tomography (PET) with fluorodeoxyglucose (FDG), a technique that traces glucose metabolism. These studies show a rapid rise in cerebral metabolism during infancy, perhaps reflecting the burst of synaptogenesis described in the structural studies. This is followed by a decrease in brain glucose metabolism later in childhood, with a timing sequence similar to that observed for the loss of synapses. In the metabolic studies, increased glucose metabolism is observed in primary sensory and motor cortices, the hippocampal region, and the cingulate cortex before other cortical regions; one of the latest structures to show increased glucose metabolism is the prefrontal cortex. These structural and physiological findings support the view of different maturational timetables for distinct brain structures, with primary cortices developing before higher association cortices in humans.

The proposal that cortical maturation occurs earliest in sensory–motor cortices, then in brain areas mediating language, and last in frontal areas mediating complex social or planning behavior is tantalizing, because this sequence mimics in part the time course of sensory, motor, and cognitive development in the child. There is, however, much debate about the link between synaptogenesis and behavioral stages. First, whereas the findings in humans suggest a different time course of synaptogenesis for different brain systems, detailed studies by researchers have reported the concurrent onset of synaptogenesis across different brain areas in macaque monkeys. Although this may indicate different constraints during development across species, the source of this difference may be due to the technical difficulties encountered when working with human tissue and/or to the compressed rate of maturation in nonhuman primates. Furthermore, and more importantly, it is unclear whether synaptogenesis should be considered as a reliable marker of cortical maturation. The few studies of cortical development that consider the development of the connectivity of separate cortical layers within a region establish that synaptogenesis can only be part of the story. For example, detailed studies of the establishment of local connectivity in human V1 indicate that the development of intralaminar connections within intermediate layers of V1 overlaps with the period during which the overall synaptic density of V1 has been described to decrease. Clearly, an undifferentiated measure of synaptic density cannot be used as the sole marker of cortical maturation. Only by characterizing the development of different subsets of projections can one hope to link the emergence of cortical circuits with the maturation of behavioral functions.

So far, we have considered plasticity mediated by changes in connectivity as axons, dendrites, or synapses form or disappear; however, plastic changes may also be mediated by the generation of new neurons. The preeminent view has been that neurogenesis, or the period of time during which new neurons are generated, is restricted to a short period of development between embryonic days 42 and 120 in humans. This view has been challenged on two grounds. Reanalysis of the longitudinal data set of human brains collected by Conel has led some to propose that there is a 2-fold increase in the number of neurons between 15 months and 6 years of age. Although methodological considerations prevent a firm conclusion on these grounds, there is now agreed-upon evidence that neurogenesis can occur in adult primates, including humans. Neurogenesis has been documented in the human dentate gyrus as well as in the association cortices of nonhuman primates, opening new perspectives on neuroplasticity.

C. Summary

There is common agreement that experience plays a critical role in shaping the organization of the brain. We have seen that a number of brain systems show sensitivity to experience only during limited time periods, called sensitive periods. This is a time period during which experience may profoundly and durably alter the organization of that system. In contrast, other systems display life-long sensitivity to experience. There is ample evidence that similar molecular and cellular mechanisms are at play to mediate these different kinds of plastic changes. Why then does plasticity during sensitive periods appear to be more pervasive than at other stages of life? Though there is no clear answer to that question, a few hints are available. First, there appear to be molecular and cellular differences between the immature and later stages of life. For example, the NMDA receptor that mediates learning in adults is also found in young animals but in a form that facilitates learning and plastic changes. The NMDA receptor in young animals is triggered more easily and leads to larger neuronal responses than in adults; these properties suggest that learning is likely to happen more readily in young animals. It has also been proposed that these properties may be especially suited to maintain synapses in regions that do not receive well-correlated inputs, in effect keeping the multipotentiality of the young cortex. This view is supported by computational models of development, which illustrate that the redundancy of the connectivity at the onset of sensitive periods may allow for easier learning and adaptation than what can be achieved once the architecture of the brain has committed to a given pattern of organization. Thus, even if some of the mechanisms are similar or even identical between developmental and adult plasticity, the fact that these mechanisms operate on nervous systems that are structurally and physiologically different may account for the observation that plastic changes in development often become irreversible, whereas plastic changes in adults often are reversible provided adequate training.

II. WITHIN-MODALITY PLASTICITY

This section will focus on early changes in visual experience, such as strabismus, and how they affect the development of visual functions and, ultimately, their organization in the adult brain. We review evidence that suggests that, because different visual functions have different developmental timetables, the period of time during which optimal plasticity is observed is specific to each visual function. The relationship between developmental events and plastic changes is first considered by reviewing fast-developing visual functions such as orientation selectivity or stereopsis. Functions with a more protracted period of development are then considered. A major consequence of these differences in developmental time course is that the timing and nature of the experience that leads to plastic changes differ for different visual functions.

A. Development and Plastic Changes in Orientation, Motion, and Stereopsis

There is abundant evidence that the development of most visual functions in humans proceeds at a fast pace during the first 2 years of life, with different maturational schedules for different functions, such as orientation, motion, and stereopsis.

Although the human newborn is able to perform gross discriminations of orientation, it is commonly accepted that orientation selectivity appears around 3 weeks of age in human babies. Most human babies can distinguish gratings of different orientation at around 6 weeks of age, and this skill appears to be mature by 12 weeks of age. Orientation selectivity is largely mediated by the organization of thalamic projections in layer 4 of the primary visual cortex. In humans, as in other primates, these projections are among the first part of the visual cortical pathway to develop, showing a largely mature pattern of organization just before birth. In accordance with the principle that early developing thalamocortical pathways show little sensitivity to experience, it has proven very difficult to alter orientation columns at the level of layer 4 in animal studies. In one study, kittens reared in a striped environment showed an over-representation of the rearing orientation as measured by optical imaging; however, orientations that had never been shown were still represented, suggesting that visual experience can only partially alter orientation maps. Thus, orientation selectivity, which develops very early, can only be partially affected by experience.

Less is known about the development and plasticity of the motion pathways. The connectivity in V1 layer 4B is believed to control the maturation of motion perception because this layer projects heavily to MT–MST, the cortical area specialized for motion processing. This connectivity appears to be mature at 8 weeks in human babies. Whereas this provides adequate

timing for the onset of motion direction discrimination in babies, little is known about the developmental timetable of the motion complex MT–MST, which mediates motion discrimination in adults. Studies that probe the developmental time course of motion pathways have often relied on the analysis of motion tracking. Newborns can easily track a slowly moving target. However, at that age, pursuit is not entirely smooth but, rather, saccadic. It is only at 2 months of age that babies exhibit the smooth pursuit typical of adults. Research shows that this ability is impaired by early altered experience such as strabismus. This may result from alterations in the development of the cortical MT–MST complex or of the subcortical pathways involved in the control of eye movements. An animal model of motion processing after early strabismus indicates modifications in the visual pathway as early as V1. Further research is needed, however, to map out the plasticity of the different brain mechanisms that mediate motion perception.

The onset of stereopsis has been reported around 10 weeks in humans; most babies display stereo depth perception capabilities around 21 weeks and a rather mature pattern of stereovision at 26 weeks. This sequence of events is rather well-matched with what is known about the maturation of the brain architecture that mediates stereopsis. The development of stereopsis is one of the most studied models of visual plasticity. Computation of stereo information requires the preservation of eye of origin information, and it is widely accepted that this cannot be achieved before the initially overlapping connections from the two eyes become anatomically segregated to form ocular dominance columns (ODC). In a seminal study, researchers showed that visual experience plays a key role in ODC formation by establishing that monocular eyelid suture results in the shrinkage of the ODC serving the closed eye. Work on cats suggests two distinct mechanisms at play for plastic changes in ODC: (i) a competitive activity-dependent mechanism controlling the competition between left and right eye input that is affected by unilateral deprivation and (ii) an absolute activity-dependent process that controls the sensitivity of the visual pathway to visual information and that is triggered as soon as the eye receives a patterned input. Accordingly, the abnormal pattern of ODC after binocular deprivation indicates that visual experience is important for normal development, and the greater abnormalities noted after monocular deprivation stress the central role of interocular competition in the formation of ODC.

Early medical conditions in humans such as strabismus or cataracts result in deficits similar to those noted in animal studies. In particular, greater abnormalities in visual functions are noted after monocular congenital cataracts than after bilateral ones. This effect is so potent that it has become normal practice to recommend the patching of the good eye for 50–90% of the time in patients operated for unilateral cataracts to encourage the use of the previously deprived eye. Additionally, visual deprivation has dramatic effects on stereopsis. Children treated for congenital cataracts display little measurable stereopsis, a finding consistent with observations in animal models of a loss of neurons tuned to binocular disparity and a reduction in cells that respond to both eyes after deprivation by lid suture. Interestingly, these individuals (who still have strabismus in adulthood) report deficits of binocular integration and complain of visual suppression or interference between contours in the image. Again, this finding is in line with the animal literature. The strong binocular facilitation observed when moving bars of similar orientation are presented simultaneously to corresponding locations in the two eyes is significantly reduced or even turns into suppression in cats with strabismus, providing a possible neural basis for the visual suppression reported in strabismic humans.

In accordance with the developmental timetable of stereopsis, the percentage of human infants demonstrating stereopsis in a control group and in a group with early strabismus was comparable until about 4 months of age. During the following months, the proportion of normal infants demonstrating stereopsis increased whereas that of infants with strabismus decreased. These data suggest that the neural substrate that mediates stereopsis is present and functional at the onset of the sensitive period for stereopsis but is subsequently lost because of abnormal visual experience.

The finding of a restricted period of time during which stereopsis can be altered or corrected in humans is consistent with animal studies showing that the effect of experience on ODC is restricted to a sensitive period. Little effect of experience is noted on the pattern of ODC when deprivation occurs after that period, although some deprivation-induced changes can be shown in cortical cell physiology. In humans, normal ODCs have been reported in an individual who developed a convergent squint after 2 years of age, suggesting that the sensitive period for ODC may be over by that time. Similarly, individuals who developed cataracts late (after 6 years) show evidence of

binocular functions when tested with displays that appropriately correct for their low acuity and the presence of strabismus. Thus, as in animal studies, the time course of the ODC development in humans appears to be tightly coupled to the sensitive period for stereopsis. Although it was first thought that the end of the sensitive period for stereopsis corresponded to the time of full development of the ODC, it is now clear that the period of development of ODC corresponds to the most sensitive part of the sensitive period, but that the sensitive period extends beyond the full formation of ODC. This may explain some of the variability reported in humans for the oldest age at which corrective surgery for cataracts and/or strabismus is successful.

B. Protracted Visual Functions: Opening New Doors to Plastic Changes

Though so far we have concentrated on visual functions that have a short and well-defined maturational time course, other visual functions, such as visual acuity, long-range orientation integration, or orientation toward peripheral space, seem to have a protracted time course of development and a much longer period of sensitivity to altered visual experience.

Grating acuity or the capacity to discriminate sinusoidal gratings from noise is extremely low at birth; it develops rapidly during the first 6 months of life, but then continues to improve very slowly until about 6 years of age. Although adultlike performance is achieved around that age, it is not until about 10 years of age that visual acuity is no longer sensitive to altered visual experience. Early visual deprivation such as cataracts or strabismus results in enduring loss of visual acuity. Researchers have shown that tests of visual acuity just after corrective surgery indicate acuity within the range of newborns, even when deprivation lasted up to 9 months. Within an hour, the acuity of the treated eye was shown to improve dramatically to the level of a normal 6-month-old infant. These results highlight the triggering role of patterned visual input in the development of visual acuity. The timing of that patterned input is critical, however. Although the grating acuity of children treated within their first year for cataracts or strabismus continues to improve with age, it does not keep pace with normal development and falls below normal limits as development proceeds. Whereas this effect is quite similar for unilateral and bilateral deprivation, the effects of early unilateral deprivation appear to be more drastic later in life than those of bilateral deprivation. For example, acuity as measured by the ability to recognize or match letters (e.g., Snellen chart) is much worse after unilateral cataracts than bilateral cataracts. Additionally, the outcome after bilateral cataracts shows little sensitivity to the duration of deprivation. In contrast, whereas there is no effect of deprivation duration after unilateral cataracts if operated early (before 6 weeks of age), deprivation duration affects the outcome of recovery in cases of unilateral cataracts treated after 6 weeks. By this age, uneven competition between the two eyes appears to limit recovery. Accordingly, the patching strategy adopted after surgery has been found to be a major determinant of treatment outcome. These findings support the view that plastic changes in visual acuity are mediated by at least two separate mechanisms with different time courses. One mechanism is driven by the absolute amount of patterned input to which the visual system has access; this mechanism is present at the onset of development and probably throughout development. The other mechanism, which emerges only later in life, appears to be driven by the competition between the two eyes and quickly becomes the main predictor of recovery.

Another skill with a protracted time course of development is the capacity to integrate long-range spatial information. For example, the detection of contours that are defined solely on the basis of long-range orientation domain correlation has been found to improve throughout childhood, reaching adult levels around 14 years of age (Fig. 2). This skill requires the integration of visual information across space and is believed to rely in part on the integrity of long-range horizontal connections in layers 2 and 3 of the visual cortex. This skill is also jeopardized by alterations of visual experience such as in amblyopia. Little is known at this time about the time frame during which visual deprivation affects that skill, but its protracted period of development suggests that it may be influenced by altered visual experience throughout childhood.

A similarly protracted visual function is the ability to orient to peripheral information. Whereas the ability to detect large, bright peripheral events is present in the newborn, the automatic ability of adults to detect pinpoints of light at the far edge of the visual field develops slowly, reaching adult levels by 12–14 years of age. In accordance with its slow developmental time course, this skill is altered when deprivation occurs not only early in life but also at 6 years of age.

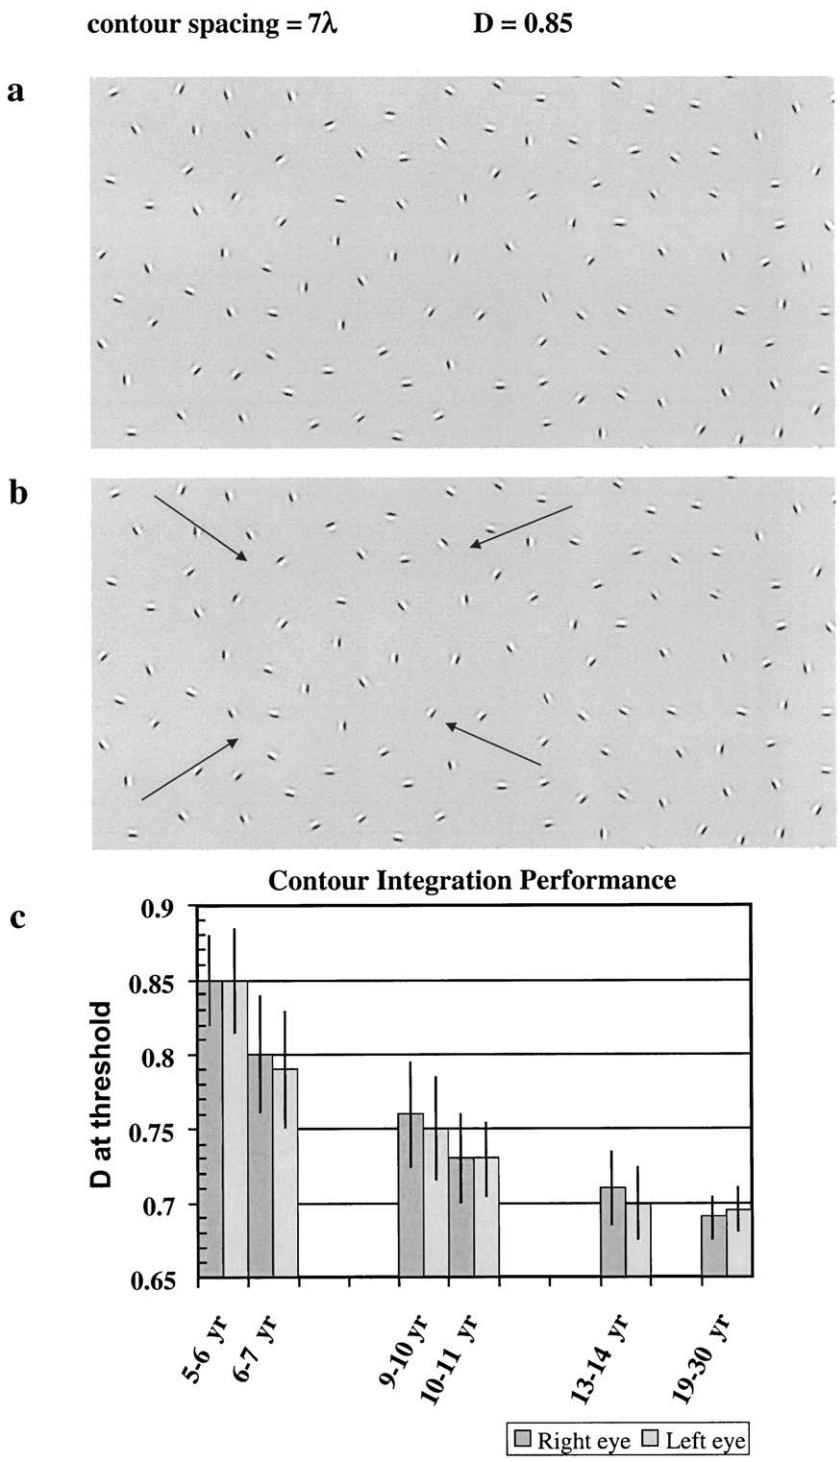

Figure 2 (a) Examples of stimuli used to study visual–spatial integration of long-range orientation. Subjects were presented with displays like the one in (a) and asked to delineate the elements that form a contour [answer given in (b)]. The difficulty of the task was manipulated by varying the spacing and numbers of elements used. (b) The contour present in (a) is indicated by arrows. (c) The developmental time course of this skill appears to be protracted, with adult performance only seen at 13–14 years of age. Reprinted from Kovacs, Kozma *et al.* (1999), Late maturation of visual spatial integration in humans. *Proc. Natl. Acad. Sci. USA* **96**(21), 12204–12209, copyright 1999, National Academy of Sciences, USA.

C. Summary

Studies of visual plasticity in humans suggest constraints in human developmental plasticity similar to those unveiled by animal studies. (i) Visual experience during sensitive periods plays a central role. As a result, functions that have a protracted sensitive period have more opportunity to be altered by experience. (ii) There is a close correspondence between the onset of the sensitive period for a skill and the development of the neural circuitry that mediates that skill. (iii) There are different developmental time windows for different visual functions. As a result, altered visual experience affects various visual functions and systems differently, preventing gross generalization from system to system and indicating the need for separate studies of each of these systems.

III. BETWEEN-MODALITY PLASTICITY

Whereas anecdotal evidence of better audition after early blindness or better vision after early deafness exists, the available data are quite mixed. The long-held belief that multisensory integration is a necessary step in optimal development led investigators to focus initially on the disabilities caused by early blindness or deafness. For example, a number of studies, mostly from the 1970s and the early 1980s, document deficient spatial abilities in the blind and deficient visual perception in the deaf. The realization of the adaptability of the brain led investigators to carefully review this issue. It is now evident that when the etiology and characteristics of the population tested are carefully controlled and the task is appropriately chosen not to rely on encoding strategies that are not available to the deprived subjects, convincing evidence of compensatory plasticity can be established.

The mechanism at play in compensatory plasticity is still a question of debate. Whereas within-sensory modality changes appear to be mediated by local changes within a limited set of cortical areas, between-modality reorganization is often thought to imply more drastic modifications of connectivity across areas. Most animal models of cross-modal plasticity have surgically forced the input of one modality to be rerouted to the primary cortex of another modality. For example, researchers have shown that, when retinal inputs are rewired to innervate the auditory thalamus and, therefore, to project to the auditory cortex in ferrets, cells in the primary auditory cortex exhibited sensitivity to visual stimulation and a substantial degree of orientation selectivity and can be used to mediate visual orientation behavior. Studies of cross-modal plasticity in animal models suggest that, at least early in development, cortical areas can change their functional specificity depending on which inputs they receive. Can such cross-modal rewiring be observed in humans? There is very little evidence to date on the question of whether compensatory plasticity, in the absence of surgically induced rewiring, can occur in primary cortices in humans or animals. However, there is converging evidence that secondary and association cortices can compensate for the loss of one modality. This rewiring is believed to involve the stabilization of early multisensory corticocortical connections that exist in the newborn but are eliminated in the presence of normal input. For example, researchers have shown that the associative cortical area 19, which is predominantly visual in normal animals, becomes more sensitive to tactile information in monkeys deprived of vision early in life. In the absence of competition from visual inputs, early transient connections may remain and recruit the visual cortex for tactile and/or auditory processing. Evidence supporting this view in humans is reviewed next.

A. Effects of Congenital Blindness on Touch

A number of studies have confirmed the functional participation of visual areas during somatosensory tasks in early blind individuals. By using PET, researchers compared tactile discrimination in early blind Braille readers and control subjects. Blind subjects revealed the activation of visual cortical areas, whereas these regions were deactivated in controls. The functional relevance of visual areas in tactile discrimination was further established in a transcranial magnetic stimulation experiment. Transient stimulation of the occipital cortex induced errors on a tactile task in early blind subjects but had no effect on the sighted controls. It is worth noting that not all aspects of somatosensory processing recruit visual areas in blind subjects. For example, simple tactile stimuli that did not require discrimination produced little activation in the visual areas of blind subjects. This finding is in agreement with the hypothesis that different neurocognitive systems and subsystems exhibit different sensitivities to altered experiences.

B. Effects of Congenital Blindness on Audition

The few studies that have addressed the accuracy of sound localization in the blind report a mixed pattern of results. Whereas impaired performance in blind individuals has been reported, other studies report no change or enhancement in the blind. A closer look suggests that, whereas distance perception may be hindered in congenitally blind subjects, sound localization is either similar or enhanced in blind subjects. In particular, pointing accuracy was comparable in the blind and sighted for binaural targets and enhanced in the early blind for the localization of monaural cues. Unlike sighted subjects, which systematically failed to correctly localize the monaural sounds on the side of the obstructed ear, half of the blind subjects were able to do so quite accurately, suggesting that early blind individuals may use monaural cues more efficiently than sighted subjects. This point is further supported by the work of researchers who have studied auditory localization abilities in blind humans. Event-related potentials (ERPs) were recorded as congenitally blind adults and sighted controls attended to either central or peripheral sound sources in order to detect a rare noise burst at either the 0° or the 90° loudspeaker (on different blocks). Behavioral data revealed a higher spatial resolution in the blind when attending to the periphery. Gradients of ERP amplitudes suggested a sharper auditory spatial attention focus in the blind compared to the sighted when attending to the periphery. This result suggests that the representation of peripheral space may be more altered by early sensory experience than that of central space.

C. Effects of Congenital Deafness on Vision

Studies of visual functions after early genetic deafness indicate enhanced visual processing, at least for visual motion, visual attention, and peripheral vision. For example, deaf adults are better than hearing controls at detecting the onset or the direction of motion of a peripheral stimulus. They are also faster at switching visual attention toward a near-periphery target in the presence of distractors located at the fixation point. Electrophysiological recordings while subjects monitored moving stimuli have indicated larger visually evoked responses for deaf than hearing adults over occipital and temporal sites. These group differences were especially marked for peripheral stimuli. In an fMRI study, the effects of visual attention on motion processing were compared in deaf and hearing individuals. When participants monitored the peripheral visual field, greater recruitment of the motion-selective area MT was observed in deaf than in hearing participants, whereas the two groups were comparable when attending to the central visual field (Fig. 3). Further analysis suggested that changes in peripheral attention in the deaf are mediated through the modulation of the connections between earlier sensory areas and the posterior parietal cortex, which is one of the main centers of attention.

The functions altered in the deaf, i.e., motion, visual attention, and peripheral processing, share the property of being mediated predominantly by the dorsal visual pathway that projects from V1 to the motion area (MT–MST) and the parietal cortex. To test the specificity of dorsal pathway enhancement after early deafness, motion processing was compared to color processing. It is commonly accepted that, whereas motion processing is primarily mediated by the dorsal pathway, color is primarily mediated by the ventral pathway projecting from V1 to IT. Electrophysiological recordings while subjects monitored either high-spatial-frequency colored gratings (color) or low-spatial-frequency, gray scale, moving gratings (motion) were compared in deaf and hearing persons. Several specific group differences occurred in the amplitude and distribution of early sensory responses recorded over anterior and temporal regions. Deaf subjects displayed significantly greater amplitudes than hearing subjects, but this effect occurred only for moving stimuli not for color stimuli (Fig. 4). Further, whereas in hearing subjects, color stimuli elicited larger responses than did motion stimuli, in deaf subjects responses to motion stimuli were as large as those to color stimuli. These data suggest that larger changes in motion than color processing occur after early deafness. Taken together, the available data suggest that there is considerable specificity in the aspects of visual processing that are altered in congenitally deaf individuals.

Because many genetically deaf individuals learn American Sign Language (ASL) as a first language, some of the changes reported could have been due to deafness or to the acquisition of a signed language. Signing has been shown to affect performance on tasks that require visuospatial transformations and are likely to recruit the dorsal pathway. Deaf native signers are both faster and more accurate than controls on tasks of mental rotation or when identifying objects presented from a noncanonical viewpoint. This effect is not specific to auditory deprivation; hearing native

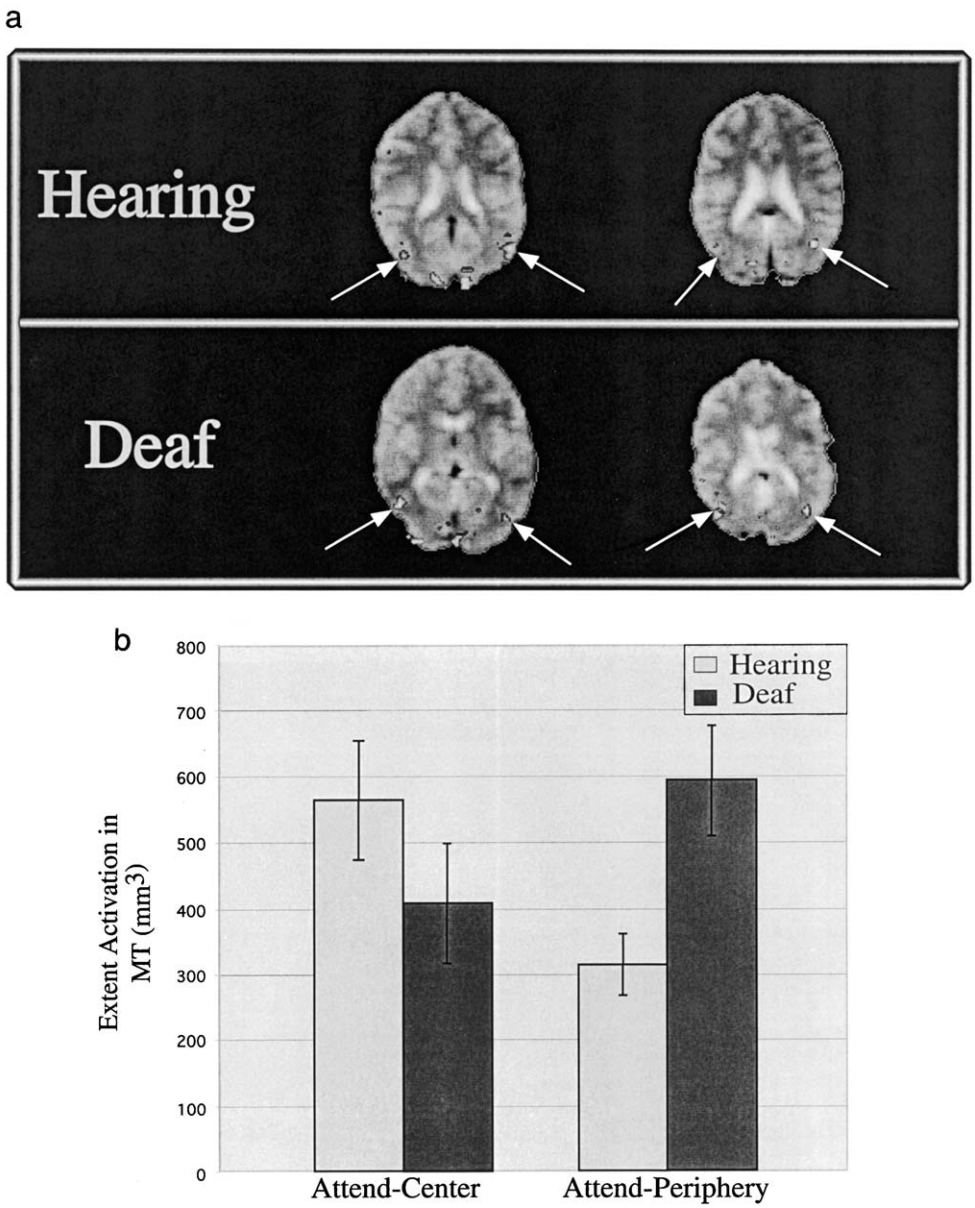

Figure 3 Extent of activation in MT–MST in deaf and hearing individuals as they monitored moving stimuli for luminance changes in either the center or the near periphery of the visual field. Enhanced recruitment of MT is observed for the peripheral condition in the deaf.

signers also exhibit better mental rotation performance than nonsigners. Researchers have also shown that deaf and hearing signers are faster at generating mental images than hearing nonsigners. This work establishes that familiarity with ASL results in behavioral enhancement in a number of visuospatial tasks that are likely to recruit structures in the dorsal pathway. Acquisition of ASL has also been linked with brain reorganization for motion processing. The few studies on that topic have reported a left hemisphere advantage for motion processing in native signers, whereas hearing nonsigners displayed a tendency for a right hemisphere advantage. Interestingly, the studies available indicate that the lateralization pattern for motion processing is guided by sign language acquisition, whereas the enhancement of motion processing in the visual periphery is specific to deafness. This research illustrates the specificity of the plastic changes as a function of the nature of altered experience.

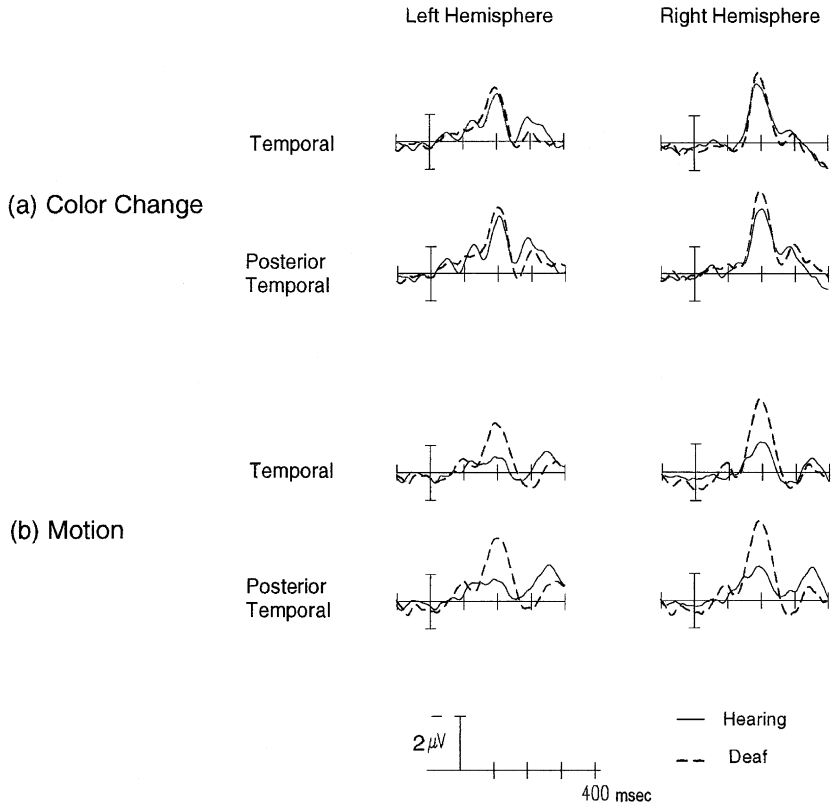

Figure 4 ERPs elicited by (a) color change and (b) motion in normally hearing and congenitally deaf adults. Recordings are from temporal and posterior temporal regions of the left and right hemispheres. Reprinted from Neville and Bavelier (1999), In "The New Cognitive Neurosciences," 2nd ed., M.S. Gazzaniga, (Ed.), pp. 83–98, with permission of MIT Press.

D. Summary

The existing literature suggests that, across auditory and visual modalities, the representation of peripheral space is more altered by early sensory experience than is the representation of central space. Close examination of the behavioral data for blind cats indicates a similar effect, i.e., a larger advantage in sound localization for blind cats at peripheral locations. Importantly, the available studies indicate that not all aspects of the remaining senses are altered after early blindness or deafness. Rather, different neurocognitive systems and subsystems exhibit different sensitivities to altered experience.

IV. PLASTICITY WITHIN THE LANGUAGE SYSTEM

It is reasonable to assume that the rules and principles that govern the development of the sensory systems also guide the development of language-relevant brain systems. Next, we briefly review facts about the normal development of language and the capacity for plasticity in the language system after altered experience and brain lesions.

A. Facts about the Normal Development of Language

Developmental studies indicate several milestones during language acquisition. By 12 weeks, most infants produce vowellike sounds called cooing. By 20 weeks, vocalizations begin to include more consonant sounds, a stage termed babbling. Whereas initially these vocalizations are very different from the sounds of the language environment, they come to resemble the syllables of the surrounding language by 8 months of age. Isolated words are produced around 1 year; these usually include common nouns that describe everyday objects or frequent social words such as hello. Sometime during the second year, vocabulary size

begins to grow at a dramatic pace and short, 2-word sentences appear. These sentences, although very brief, already display considerable structural information. Thus, young learners of English typically say "Daddy eat" or "eat pizza," showing sensitivity to the subject–object distinction. Between 3 and 5 years of age, patterns of grammatical development occur, including syntactic and morphological developments such as over-regularization (goed vs went), question formation, negation, and passive. The finding that these milestones are shared in all learners all over the world supports the proposal that language learning has a significant biological basis.

Indeed, several reports indicate that the milestones of language development are extremely robust in the presence of significant variations in experience. For example, the same stages of language development are observed across variations in the mother's speech. Children that are carried on their mother's backs and seldom talked to show the same milestones of language development as children raised in a more nurturing environment. Similarly, deaf children acquiring a visuospatial language also exhibit the same milestones. This is not to say that language experience does not guide language development. It is clear that the language environment determines which kind of language is learned. But a striking feature of language development (like visual development) is that the effects of experience are constrained by the age of the learner. For example, learners exposed to language late in life (whether second-language learners or individuals deprived of language exposure early in life) do not display the same level of proficiency as early learners. Thus, as in other domains, this research indicates that the effect of experiential influences during language development are constrained by the maturational status of the learner.

A few studies have begun to chart the changes in brain organization as children acquire their primary language and to ask whether different maturational constraints may exist for different types of processing as has been reported earlier for most sensory domains. One of the best-documented dichotomies in language processing is that between lexical–semantic information and grammatical information. For example, nouns and verbs (e.g., table, run) that convey semantic information elicit a different pattern of brain activity (as measured by ERPs) than do function words that convey grammatical relationships (e.g., within, out, the) in normal, right-handed, monolingual adults. Similarly, sentences that are semantically nonsensical (but grammatically intact) elicit a different pattern of ERPs than do sentences that contain a violation of syntactic structure (but that leave the meaning intact). These results are consistent with several other types of evidence that imply two separate systems within language, one for lexical–semantic and one for grammatical processing. Specifically, the studies available indicate a greater role for more posterior temporal–parietal systems in the left hemisphere for lexical–semantic processing; frontal–temporal systems within the left hemisphere are implicated for grammatical processing. How does this functional specialization arise during development? ERPs for open- and closed-class words have been compared in infants and young children from 20 to 42 months of age (Fig. 5). All children understood and produced both the open- and closed-class words presented. At age 20 months, ERPs in response to open- and closed-class words did not differ. However, both types of words elicited ERPs that differed from those elicited by unknown and backward words. These data suggest that in the earliest stages of language development, when children are typically speaking in single-word utterances or beginning to put two words together, open- and closed-class words elicit similar patterns of brain activity. At 28–30 months of age, when children typically begin to speak in short phrases, ERPs for open- and closed-class words elicited different patterns of brain activity. However, the more mature left hemisphere asymmetry for closed-class words was still not observed. By 3 years of age, most children speak in sentences and use closed-class words appropriately to specify grammatical relations, so that like adults, ERPs from 3-year-olds displayed a left hemisphere asymmetry to closed-class words. The results across the three groups are consistent with the hypotheses that, initially, open- and closed-class words are processed by similar brain systems and that these systems become progressively more specialized with increasing language experience.

B. Plasticity in the Language System after Altered Language Experience

1. Delayed Exposure to Language

How is language learning affected by delayed exposure to a language? Many investigators have studied this question by comparing individuals who learned a second language at different times in development. English–Korean speakers who came to the United States and were immersed in English at varying ages have been studied. Their data clearly establish a steady decrease in performance as a function of age at first

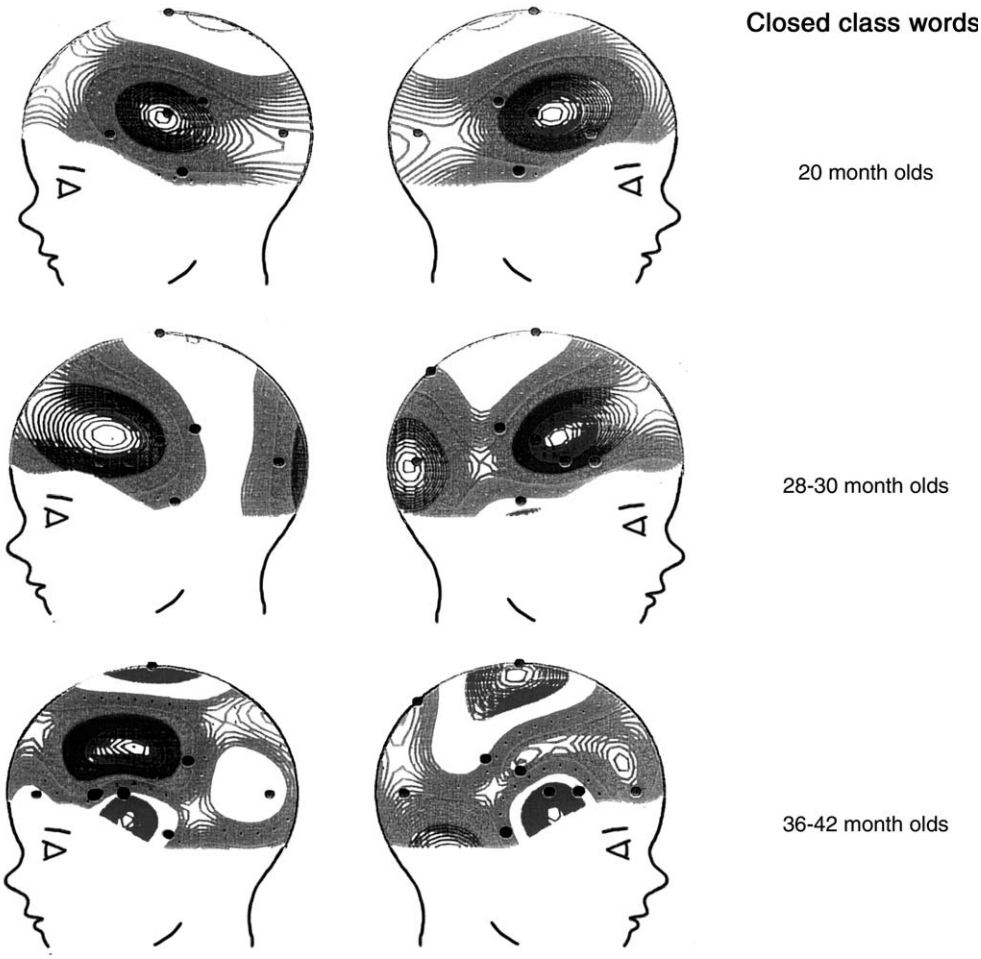

Figure 5 Current source density (CSD) analyses of neural activity in response to closed-class words at 200 msec. The CSDs illustrate sinks, i.e., activity flowing into the head (purple), and sources, i.e., activity flowing out of the head (orange), at three age groups. Top: At 20 months the CSD shows sinks over both the left and right hemispheres. Middle: At 28–30 months the CSD show sinks that are bilateral but slightly more prominent over the right than the left hemisphere. Bottom: At 36–42 months the CSD shows a sink over left anterior regions. Reprinted from Neville and Bavelier (1999), In "The New Cognitive Neurosciences," 2nd ed., M.S. Gazzaniga, (Ed.), pp. 83–98, with permission of MIT Press.

exposure (Fig. 6). The effect of age of exposure was especially striking for those aspects of language that rely on grammatical processing. Interestingly, duration of exposure cannot compensate for this effect; thus, a 14-year-old who has been immersed in English for only 4 years is more likely to show a good command of English intricacies than a 50-year-old who has been immersed in English for the last 25 years. It has been argued that the difference in late learners of a second language is due to competition from their extensive knowledge of a first language rather than their late start in learning. The observation of parallel results in deaf adults exposed at varying ages to their first and unique language (American Sign Language) suggests, however, that age of exposure is the key factor in this pattern of results. As in second language learners, late learners of American Sign Language (ASL) had particular problems with the ASL equivalent of morphemes and syntactically complex sentences.

The available results suggest that aspects of semantic and grammatical processing differ markedly in the degree to which they depend upon language input. Specifically, grammatical processing appears to be more vulnerable to delays in language experience. In Chinese–English bilingual speakers, delays of as long as 16 years in exposure to English had very little effect on the organization of the brain systems active in lexical–semantic processing. In contrast, delays of only 4 years had significant effects on those aspects of brain organization linked to grammatical processing. Further evidence on this point was provided by ERP

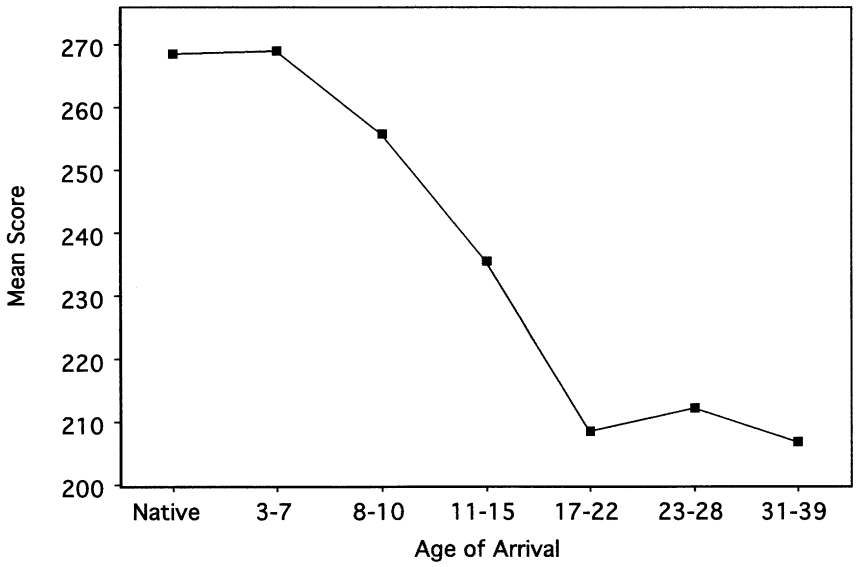

Figure 6 Total score on a test of English grammar in relation to age of arrival in the United States. These data show that the participants' performance declines as the age of exposure to the language is delayed. Reprinted from Johnson and Newport (1989), *Cog. Psych.* **21,** 60–99, with permission of Academic Press and Erlbaum Inc.

studies of English sentence processing by congenitally deaf individuals who learned English late and as a second language (ASL was the first language of these subjects). Deaf subjects displayed ERP responses to nouns and semantically anomalous sentences in written English that were indistinguishable from those of normal hearing subjects who learned English as a first language. These data are consistent with the hypothesis that some aspects of lexical–semantic processing are largely unaffected by the many differences in language experience between normally hearing and congenitally deaf individuals. By contrast, deaf subjects displayed aberrant ERP responses to grammatical information like that presented in function words in English. Specifically, they did not display the specialization of the anterior regions of the left hemisphere characteristic of native, hearing–speaking learners (Fig. 7). These data suggest that the systems that mediate the processing of grammatical information are more modifiable and more vulnerable in response to altered language experience than are those associated with lexical–semantic processing.

2. Visuospatial Languages

We have employed ERP and fMRI techniques to further pursue the preceding hypothesis and also to obtain evidence on the question of whether the strongly biased role of the left hemisphere in language occurs independently of the structure and modality of the language acquired first. ERPs recorded from native signers in response to open- and closed-class signs in ASL sentences displayed timing and anterior–posterior distributions similar to those observed in native speakers processing English. However, whereas in native speakers of English responses to closed-class English words were greatest over anterior regions of the left hemisphere, in native signers closed–class ASL signs elicited activity that was bilateral and that extended posteriorly to include parietal regions of both the left and right hemispheres. These results imply that the acquisition of a language that relies on spatial contrasts and the perception of motion may result in increased recruitment of right hemisphere regions into the language system. Both hearing and deaf native signers displayed this effect. However, hearing people who acquired ASL in their late teens did not show this effect, suggesting there may be a limited time (sensitive) period when this type of organization for grammatical processing can develop. By contrast the response to semantic information was not affected by age of acquisition of ASL, in keeping with the results from studies of English that suggest these different subsystems within language display different degrees of sensitivity to altered experience.

In an fMRI study comparing sentence processing in English and ASL, researchers observed evidence for biological constraints and effects of experience on the

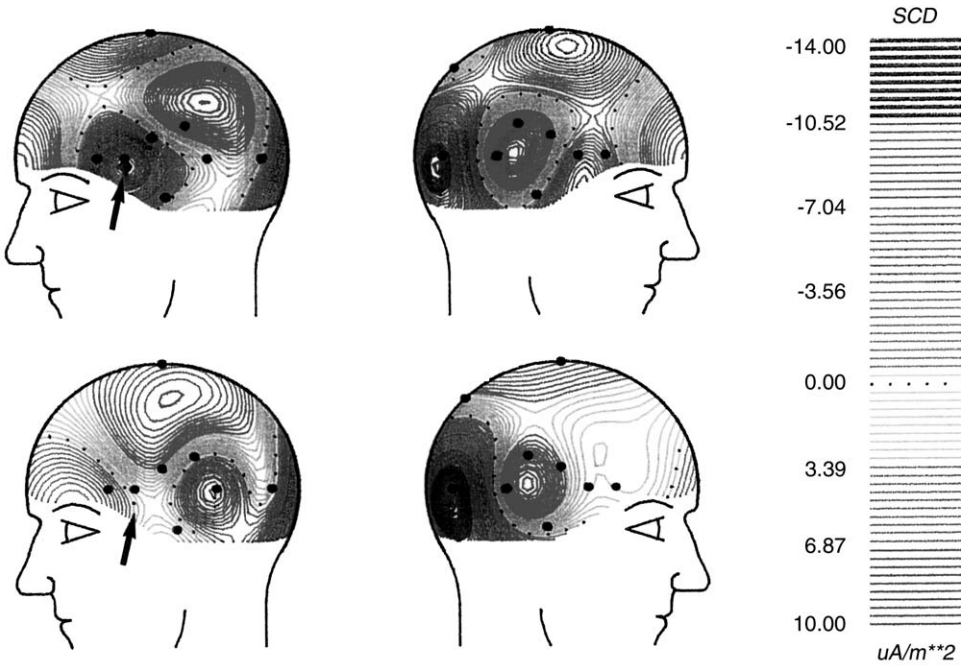

Figure 7 Distribution of current flow for the N280 peak elicited by closed-class words in English. Maps in the top row show the prominent response in the left hemisphere of hearing subjects (blue, marked by arrow). Bottom row maps display results from congenitally deaf individuals who lack the response (arrow). Reprinted from Neville, Mills, and Lawson (1992), *Cerebral Cortex* **2,** 244–258, with permission of Oxford University Press.

mature organization of the language systems of the brain. When hearing adults read English (their first language), there is robust activation within the left (but not the right) hemisphere and in particular within the inferior frontal (Broca's) region. When deaf people read English (their second language, learned late and imperfectly), there is no activation of these regions observed within the left hemisphere. Is the lack of left hemisphere activation in the deaf linked to the lack of auditory experience with language or to incomplete acquisition of the grammar of the language? ASL is not sound-based but displays each of the characteristics of all formal languages, including complex grammar (that makes extensive use of spatial location and hand motion). Studies of the same deaf subjects when viewing sentences in their native ASL clearly showed activation within the same inferior frontal region of the left hemisphere that is active when native speakers of English process English. These data suggest that there is a strong biological bias for these neural systems to mediate grammatical language regardless of the structure and modality of the language acquired. However, if the language is not acquired within the appropriate time window, this strong bias is not expressed. Biological constraints and language experience interact epigenetically as has been described for the other systems mentioned earlier.

The fMRI data also indicate a robust role for the right hemisphere in processing ASL. These results suggest that the nature of the language input shapes the organization of the language systems of the brain. Further research is necessary to specify the different times in human development when particular types of input are required for optimal development of the many systems and subsystems important in language processing.

C. Plasticity in the Language System after Brain Lesions

Studies of cerebral organization for language in the adult imply a greater role for perisylvian regions within the left hemisphere in language processing. This overall pattern appears ubiquitous in adults, and many investigators have suggested that the central role of the left hemisphere in language processing is strongly genetically determined. Certainly the fact that most individuals, regardless of the language they learn, display left hemisphere dominance for language in-

dicates that this aspect of neural development is strongly biased. Nonetheless, it is likely that language-relevant aspects of cerebral organization are dependent on and modified by language experience.

Some investigators have studied this question by assessing the language skills of children with left or right hemisphere lesions. Unlike what is observed in adults after lesions, children with left hemisphere damage (LHD) do not necessarily show poor verbal IQ and those with right hemisphere damage (RHD) poor pictorial IQ. Upon close examination, some language deficits can be observed after LHD. Most common problems include weak fluency, poor scores in formulating sentences giving oral directions or recalling sentences, and difficulties in written language particularly with spelling and production. They also show delays in language development, such as delays in prelinguistic development like babbling or in vocabulary acquisition. However, these children do not display the typical symptoms of aphasia reported in LHD adults. Although there are sizeable individual differences in the verbal IQs of children with LHD, overall they show receptive skills within normal limits and no major impairment in clinical evaluations; most are able to read and can create connected discourse. The interpretation of these findings is, however, complicated by the large interindividual variability in language performance found in that population, by the fact that most of these children function in the range of mental retardation (allowing confounding between intellectual functioning and language functioning), and by the mixing of children whose lesions occurred at different times.

A more recent study that included only children with early focal brain injuries indicates that language-relevant aspects of cerebral organization are dependent on and modified by early experience. First, this study confirms that LHD in children does not lead to the pattern of aphasia observed in adults. In fact, the early stages of language development (10–17 months) were more likely to be delayed by RHD than by LHD. Second, frontal damage was associated with greater delays in the emergence of expressive grammar that occurs around 2 years of age; however, unlike in adults, this effect was as severe after RHD as after LHD. Finally, damage to the left temporal lobe (but not the right one) led to delays in word production and the emergence of grammar. Although this disadvantage could be observed until 6 years of age, it was not detectable after 6 years of age, suggesting that significant compensatory plasticity had occurred by that age (although it is unclear whether differences would still be observed with finer tests of language abilities). These data are consistent with the proposal that the early stages of language development are represented more bilaterally and that the left hemisphere specialization for language is expressed only slowly over the course of development.

The striking result of lesion studies, however, is that the outcomes of a left hemisphere lesion are much better in infancy than in adulthood. The finding that plasticity for language decreases between birth and adulthood is consistent with the findings described earlier showing that the age of the learner affects language acquisition. It is likely that, as in other systems, nature and nurture continue to conspire during development to shape the functional organization of the brain for language. A series of studies on the development of object recognition in monkeys provides new clues for the understanding of the relative roles of nature and nurture in the development of slowly maturing functions like language. In the adult monkey, object recognition is mediated by the inferior temporal cortex including, area TE. After bilateral lesions of TE, adult monkeys are unable to perform tests of object recognition. However, bilateral removal of TE in infant monkeys leads to performance that is only slightly below that of age-matched controls. Thus, as is the case for language, the outcome of a lesion is dramatically different in adults and in infants. By lesioning other areas in TE-lesioned infants, the researchers showed that object recognition in these individuals is mediated by the recruitment of a large network of other cortical areas, which normally mediate other visual tasks or multisensory information. Further studies suggest that this reorganization is possible in infants because of the existence of early diffuse anatomical connections that disappear during development under normal circumstances, but that in the lesioned case are maintained and recruit the cortical areas they contact for their functional purpose. This research illustrates how the biological endowment of the infant, such as the pattern of redundant connections, constrains development. But it also shows how experience shapes the path of development by controlling the selective loss of some and not other connections. From what we know of biology, it is very likely that, throughout development, the genetic material provides the learner with a brain architecture that constrains the possible path of development, but experience, by altering the existing architecture, in its turn influences the next set of possible genetic instructions.

V. SUMMARY AND CONCLUSIONS

The results from the language studies taken as a whole point to different developmental time courses and developmental vulnerabilities of aspects of grammatical and semantic–lexical processing. Thus, they provide support for conceptions of language that distinguish these subprocesses within language. Similarly, following auditory deprivation, processes associated with the dorsal visual pathway were altered more than functions associated with the ventral pathway, providing support for conceptions of visual system organization that distinguish functions along these lines. A general hypothesis that may account for the different patterns of plasticity within both vision and language is that systems employing fundamentally different learning mechanisms display different patterns of developmental plasticity. It may be that systems that display experience-dependent changes throughout life, including the topography of sensory maps, lexical acquisition (i.e., object–word associations), and the establishment of form, face, and object representations (i.e., ventral pathway functions), rely upon very general, associative learning mechanisms that permit learning and adaptation. By contrast, systems that are important for computing dynamically shifting relations between locations, objects, and events (including the dorsal visual pathway and the systems of the brain that mediate grammar) appear to be dependent on and modifiable by experience primarily during more limited periods in development. This could account for both the greater developmental deficits and enhancements of dorsal pathway function following various developmental anomalies and the greater effects of early altered language experience on grammatical functions. Further research is necessary to characterize systems that become constrained in this way and those that can be modified throughout life. This type of developmental evidence can contribute to fundamental descriptions of the architecture of different cognitive systems. Additionally, in the long run, they may contribute to the design of educational and habilitative programs for both normally and abnormally developing children.

Neuropsychological Assessment

AARON P. NELSON* and MEGHAN M. SEARL†
*Harvard Medical School * and Boston University †*

GLOSSARY

baseline examination The first in a series of neuropsychological assessments, the results of which are compared with those of subsequent assessments in order to detect changes in neuropsychological status over time.

battery A selection of specific neuropsychological tests intended for use in the context of an assessment.

diagnosis An identification or label denoting that an individual suffers from a specific illness or condition; the art or act of identifying a disease from its signs and symptoms.

differential diagnosis A list of possible conditions in order of likelihood that could potentially account for a patient's symptoms, findings, and results of examination.

dominant hemisphere The hemisphere of the brain that subserves language functions in an individual.

lesion An area of abnormal brain tissue resulting from injury, disease, or anomalous development.

lesion method The process of inferring a causal brain–behavior relationship based on cognitive or behavioral dysfunction following a specific brain lesion.

limbic system A network of structures deep in the brain important for memory and emotion. Major components relevant to memory functioning include the hippocampus and amygdala.

localization Identification of a specific brain area or network subserving a particular cognitive or behavioral function.

neuropsychological test A standardized procedure designed to elicit a behavioral sample, usually related to a particular cognitive function, that can be used to guide inferences about the integrity of brain function.

process approach A hypothesis-driven method of neuropsychological assessment that tailors the selection of tests to the particular patient, uses test behavior and performance during the examination to inform the subsequent course of the assessment, and incorporates qualitative aspects of testing performance into the process of analysis and diagnostic formulation.

prognosis The anticipated future course of a patient's illness or condition.

psychometric method A means of scientifically quantifying human cognitive abilities, originally designed for the purpose of investigating individual differences.

psychophysics The science of measuring basic perceptual functions; a branch of psychology concerned with the effect of physical processes on mental processes.

reliability The consistency with which a test yields the same results on repeated occasions.

validity The accuracy with which an assessment instrument measures the function it was intended to measure.

Neuropsychology is the science of human behavior based on the function of the brain. Clinical neuropsychology is an applied discipline that uses principles of brain–behavior relationships to evaluate and diagnose abnormality in the realm of behavior and cognition. This process of evaluation and diagnosis, termed "neuropsychological assessment," involves obtaining information about an individual's history and current functioning as well as administering a variety of behavioral measures designed to probe specific cognitive functions. A clinical neuropsychologist analyzes and integrates information collected during the assessment process with the aim of providing diagnostic clarification or helping to guide treatment planning.

I. HISTORICAL DEVELOPMENT

From the dawn of self-reflective thinking, humans have wondered about the source of mental activity. The solution to this puzzle was largely relegated to superstition, faith, and philosophy. The 137th Psalm (sixth century B.C.E.) may constitute one of the earliest recorded descriptions of a neurobehavioral syndrome: "If I forget thee, O Jerusalem, let my right hand forget her cunning. If I do not remember thee, let my tongue cleave to the roof of my mouth; if I prefer not Jerusalem above my chief joy." The author appears to be depicting the major sequelae of a left hemisphere stroke: right hemiparesis (weakness) and aphasia (inability to speak). We can glimpse the first stirrings of a science in the writings of Hippocrates, who posited that the brain was the organ of intellect. However, it was not until the time of Flourens in the 1800s that the first studies of brain function were conducted.

Clinical neuropsychology traces its roots to the confluence of three major tributaries of psychological science: psychophysics, the psychometric method, and the lesion method in behavioral neuroanatomy. New methodologies for viewing the brain, both structurally and functionally, continue to illuminate the everyday miracles of thought, memory, and emotion. The integration of clinical work with experimental discoveries has reached a new zenith in cross-fertilization of both endeavors. The phenomenal growth of clinical neuropsychology over the past three decades owes much to contemporaneous work in clinical neuroscience.

Although it is not possible to pinpoint the date of its establishment as a discipline, Arthur Benton points out that clinical neuropsychology lacked the usual trappings of a coherent specialty prior to 1960. There were no professional organizations, journals, or training programs. In its earliest form neuropsychology was practiced in medical settings in association with departments of neurology and neurosurgery. Psychologists with expertise in psychological measurement and a special interest in the behavioral effects of brain injury designed tests to assess various abilities in their patients.

Although theories of brain function can be traced back to the writings of the ancients, the term *neuropsychology* came into use only relatively recently. The ancient Egyptians originally localized the seat of human thought to the heart. This notion remained largely unchallenged until some 3000 years later when a Greek student of Pythagoras proposed that the brain was responsible for sensation and thought and advanced the notion that specific aspects of mental function were represented in specific regions of the brain. This approach to thinking about the brain was later termed localization and became the center of great controversy 2000 years later. Hippocrates, writing in the fourth century BC, claimed the brain as the organ of intellect, sensation, and emotion. Furthermore, he posited that mental illness was rooted in abnormal brain function. Along this line, he advanced the hypothesis that epilepsy was not the result of demonic possession, but rather an organic ailment.

Beginning in the middle of the nineteenth century, psychophysics comprised a refined approach to the precise measurement of various human attributes. Galton's studies of individual differences in sensory and psychomotor responses epitomized this approach, as did the early work of Ebbinghaus on "individual memory curves of retention." At the beginning of the twentieth century, Binet and others introduced the revolutionary concept of measurable intelligence, a notion that continues to have a profound and controversial impact on human society. The psychometric method was employed to design and construct measurement methods possessing validity and reliability, which are crucial underpinnings of all psychological and neuropsychological tests. The lesion method has its origins in early case reports of brain–behavior effects in injury and illness. The famous case of Phineas Gage (1848) described a railroad worker who survived a catastrophic injury in which an iron spike was blasted through his head, essentially disconnecting the anterior portion of his brain. The resulting pattern of spared and affected functions in Gage gave rise to an early understanding of the functional role of the frontal lobes in human behavior. The pioneering work of Paul Broca, a French neurologist who described his patient "Tan" (1861), was instrumental in unveiling the role of the dominant hemispheres in human language function. More recently, in the 1950s, Scoville and Milner's studies of patient HM shed new light on the role of the limbic system in anterograde memory function.

The advent of World War I saw the first period in history when modern American medicine had to cope with the tragedy of "industrial" warfare. Legions of combatants returned from Europe with life-altering brain injuries. Assessing the cognitive consequences of such injuries spurred the growth of early assessment methodologies. The aftermath of World War II marked the establishment of modern clinical psychology, with an emphasis on the special skill of psychological testing. Measurement of intelligence was the

venue in which early testing applications were most significant.

The earliest codification of neuropsychological examination methods can be attributed to Dr. Ralph Reitan. A pioneering neuropsychologist, Reitan and his colleagues assembled a battery of test measures in which specific patterns of scores were linked to the dysfunction of associated brain regions. Later approaches diverged from reliance on a set battery of tests and instead used a more dynamic method, the "process" approach to neuropsychological assessment, developed by Dr. Edith Kaplan in her work at the Boston V.A. Hospital. This technique entails ongoing *in situ* hypothesis testing in which particular attention is paid to the qualitative aspects of a patient's test response. Although quantitative data are also important, the patient's route to solving a particular cognitive problem often reveals an underlying process that can be reflective of spared and affected brain regions. In contemporary practice, both of these methods rely on a vast body of knowledge about characteristic syndromes that are known to be associated with underlying disease states.

The current practice of clinical neuropsychology concerns itself with the assessment of cognitive functions, through the use of test instruments, for the purpose of understanding the functional integrity of the brain. By relying on knowledge of brain–behavior relationships and characteristic syndromes, the results of assessment are useful for the diagnosis and treatment of brain-related injuries and illness.

II. FUNDAMENTAL ASSUMPTIONS

The study of clinical neuropsychology is firmly rooted in the larger field of neuroscience and, therefore, rests on the assumption that the nervous system impacts behavior and cognition. Conversely, inferences can be made about the integrity of the brain based on observable behavior. The ability to make accurate and meaningful inferences is predicated on a thorough understanding of two streams of knowledge: (a) the neural infrastructure underlying normal human cognition and behavior and (b) the characteristic profiles of neurocognitive and neurobehavioral syndromes.

Observable behavior is frequently the most sensitive manifestation of brain pathology. Such behavior can range from a person's manner of dress to his or her performance on a specific neuropsychological test. A competent neuropsychologist will sample multiple domains of behavior. Observable behavior, including "test behavior," reflects an interaction between the domains of person and environment. Variables from each domain must be considered in order to arrive at an understanding of the clinical significance of a given behavior.

Individual tests used in neuropsychological practice focus on measurement of particular cognitive processes. In order to be useful, each test must be constructed according to sound psychometric principles and possess adequate validity and reliability. In addition, there must be appropriate normative data with which to compare a single patient's performance. It is the responsibility of the neuropsychologist to have a comprehensive understanding of test construction and proper usage so that it may be applied appropriately in relevant clinical circumstances. This includes choosing tests with normative data derived from subjects of similar age, education, and nationality to the patient currently being tested.

The interpretation of test results depends on an understanding of the component processes involved in any given test response. For example, the ability to name an object depends on multiple processes that are mediated by different brain systems. A person must first orient and attend to the stimulus. Second, the stimulus must be accurately registered at the level of visual perception. Third, the neural pathway that links the visual percept to meaningful recognition must be intact. Fourth, the ability to assign a phonemic/lexical label to the object must be intact. Finally, the person must be able to convey a response through speech. Because a complex cognitive process, such as naming a simple object, can be undermined by perturbation at any point along the route between these processes, a neuropsychologist must understand the component processes involved in each behavior. By examining the patient's function in multiple domains with multiple measures, the neuropsychologist can determine which processes and associated neural circuits are functioning abnormally.

Performance on a single test is not sufficient to make a diagnostic inference. A common misconception is that a poor score on a particular test denotes an impairment in the domain that the test is nominally designed to assess. For example, if a patient performs poorly on a memory test, this does not necessarily signify an impairment in memory, but could indicate difficulties with attention or language. A neuropsychologist will evaluate a profile of test results in a dynamic, interactive fashion in order to arrive at a diagnostic formulation.

Neuropsychological testing is simply one means of obtaining a sample of behavior. A neuropsychologist

must proceed with caution in using test data to predict behavior. The testing environment is, by necessity, contrived to promote a standard approach to test administration. This contrivance constitutes a challenge in understanding how test performance corresponds to "real-life" behavior. For example, a patient who complains of difficulty with concentration and memory at work may perform quite normally in the context of the quiet, distraction-free consultation room. Discrepancy between test behavior and real-life behavior is the source of ongoing challenge for the design of an ecologically valid assessment environment.

III. CLINICAL APPLICATIONS

In its infancy, neuropsychological testing was used primarily as a means of localizing the site of a lesion in the brain. Developments in the field of neuroimaging have obviated the need to depend exclusively on neuropsychology in this role. In contemporary clinical practice, neuropsychology is primarily devoted to diagnostic formulation, entailing the identification and description of cognitive and behavioral syndromes. Hand in hand with advanced imaging techniques and other diagnostic methodologies, the evolution of a true behavioral neuroscience has been ongoing.

Clinicians often refer patients for neuropsychological assessment when there is a question about diagnosis. Neuropsychological assessment can be useful in describing the nature of cognitive or behavioral deterioration and can help clarify the pathology underlying such a process. For example, neuropsychologists often see elderly individuals who have been referred for the evaluation of a possible neurodegenerative illness, such as Alzheimer's disease. Through an analysis of a variety of behaviors, neuropsychologists can often clarify the diagnosis and, in so doing, help guide decisions about appropriate treatment and provide information concerning prognosis. It is often difficult to arrive at a definitive diagnosis; in these cases, a neuropsychologist can assist in narrowing the *differential diagnosis*. Serial follow-up examinations can further clarify the diagnosis by tracking the course of cognitive symptoms across time.

Neuropsychological test data can be useful for establishing a baseline of cognitive functioning against which to calibrate the degree of change in patients with a known history of neurological disease, injury, or developmental abnormality affecting cerebral functions. This involves both tracking decline in the context of illness and also measuring treatment gains. With rich quantitative and qualitative data, neuropsychologists are in a unique position to evaluate the efficacy of treatment interventions (e.g., pharmacotherapy, electroconvulsive therapy, neurosurgery) by establishing a patient's baseline performance and reevaluating following initiation of therapy.

Neuropsychological assessment can delineate the potential impact of brain pathology on venues of real-life functioning, ranging from the most rudimentary human activities (bathing and dressing) to work life and the complexities of intimate relationships. Neuropsychologists can provide an explanatory context for a patient's cognitive, social, or behavioral difficulties. In addition, in the case of progressive disease, neuropsychologists can provide education about how the patient's changing condition will impact day-to-day functioning differently over time. It is not unusual for an otherwise sensitive spouse to blame an affected husband or wife for a particular behavior, which had been assumed to be under voluntary control. Learning that the behavior is part and parcel of a disease process dramatically alters this attribution and allows both patient and spouse to work together on the problem.

Because of its knowledge base in behavioral neuroscience, neuropsychology has an important role in treatment planning, Neuropsychologists make specific and detailed recommendations for rehabilitation in cases of brain injury, tumor, and stroke and are central to the planning process for patients and families confronting dementing illnesses.

Neuropsychological consultation is frequently critical in cases involving the adjudication of criminal or civil matters. Neuropsychologists with special training and experience in forensics play an important role in the determination of competency in matters ranging from criminal responsibility to guardianship.

IV. APPROACH TO NEUROPSYCHOLOGICAL ASSESSMENT

Two major approaches to neuropsychological assessment have emerged during the last century.

A. Fixed Battery Approach

The fixed battery approach to neuropsychological assessment was developed primarily by Ralph Reitan and his colleagues. As the name suggests, practitioners of this approach typically utilize a standard set of tests in the context of assessment and do not vary this battery, if possible. The battery is designed to assess each major cognitive domain and therefore ensures a

comprehensive assessment of every patient. A clear advantage of this approach is the ability to detect deficits that are unsuspected or not otherwise evident. Another advantage is that practitioners of this approach become very familiar with the subtleties of the battery and develop a greater sensitivity to slight variations in the performance of component tasks. Disadvantages of this approach include inefficiency (i.e., a time-consuming battery is administered in all cases, including those for whom more focused assessment would be sufficient) and lack of flexibility. Some have also criticized the fixed battery approach for insufficient assessment of key functions, including memory.

B. Flexible Battery or Process Approach

The other major approach to neuropsychological assessment is the Boston Process approach, primarily developed by Edith Kaplan and her colleagues. This type of approach proceeds in a hypothesis-driven manner and uses the patient's test performance to guide and inform an evolving and dynamic assessment strategy. The process-oriented evaluation is individually tailored to each patient and uses specific tests for the purpose of answering particular questions. As answers to these questions emerge during the evaluation, the neuropsychologist moves through a series of decision points, probing particular cognitive functions as needed. Tests are administered in a standardized fashion but can also be modified to test the limits of cognitive function and to produce richer qualitative data. As with the administration of tests, the data can be viewed from both a qualitative and a quantitative perspective. Task performance is analyzed across multiple measures to parse out component processes and identify specific cognitive defects.

V. CLINICAL METHOD

Clinical neuropsychological assessment comprises a series of procedures during which information is elicited and analyzed in the service of diagnosis and treatment planning. This process is illustrated in Fig. 1. While test administration is the most time-consuming component of the process, it is often the case that some of the most valuable information emerges while discussing a patient's history and current life situation. The information obtained during the initial interview is important for differential diagnosis and frequently guides the remainder of the assessment.

A. Referral Question and Chief Complaint

The first task of a neuropsychological assessment is to clarify the reason for referral. Patients are typically referred for neuropsychological assessment by other clinicians involved in their care, often for assistance in diagnosis and treatment planning. After the referral question is ascertained, the patient is seen and a chief complaint is elicited, including a clear description of the onset and course of the complaint (e.g., symptoms, concerns) as well as information regarding the medical and social context in which the problem(s) emerged. The patient's overall understanding of the rationale for the consultation and appreciation of his/her current circumstances is also sought.

B. History

Information is obtained from a variety of sources, including the patient's self-report, observations of family members or close friends, medical records, and prior evaluations from academic or work situations. Information is obtained regarding (1) past medical history, including illnesses, injuries, surgeries, medications, hospitalizations, substance abuse, and relevant family medical history, (2) past psychiatric history, including hospitalizations, medications, and outpatient treatment, (3) developmental background, including circumstances of gestation, birth and delivery, acquisition of developmental milestones, and early socialization skills, (4) social development, including major autobiographical events and relationships (a three-generation genogram is highly useful in gaining relevant family information), (5) educational background, including early school experiences and academic performance during high school, college, postgraduate study, and other educational and technical training (the presence of a learning disability should be assessed) (6) vocational history, including work performance, work satisfaction, and relationships with supervisors and co-workers, and (7) recreational interests and hobbies.

C. Behavioral Observations

Physical appearance is inspected, including symmetry of anatomical features, facial expression, manner of dress, and attention to personal hygiene. The patient is asked specific questions regarding unusual sensory or motor symptoms. Affect and mood are assessed with respect to range and modulation of felt and expressed

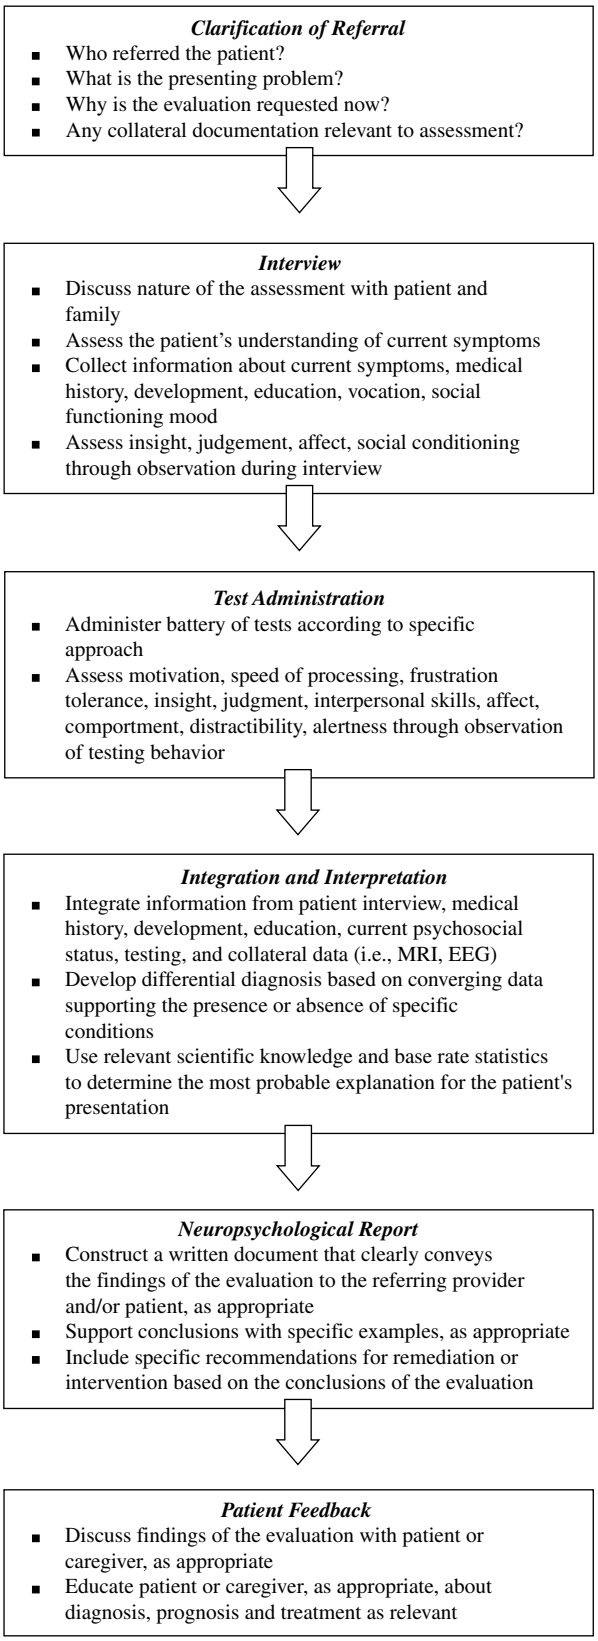

Figure 1 Schematic of neuropsychological evaluation.

emotions and their congruence with concurrent ideation and the contemporaneous situation. Interpersonal comportment is assessed in the context of the interview. Specifically, attention is paid to whether the patient's behavior reflects a normal awareness of self and other in the interaction. Whether the patient is motivated and complies with examination requests, instructions, and test procedures. An appreciation of the patient's level of motivation to participate in the evaluation and comply with examination instructions is crucial to assessing the validity of the test data. General level of *arousal* or *alertness* is determined by observing the patient's degree of drowsiness, tendency to yawn or fall asleep during the interview, level of interpersonal engagement, and speed of response in conversation. Environmental and diurnal factors can modify arousal, and an attempt should be made to assess whether this is relevant in the case of a particular patient by inquiring about the consistency of arousal level and any fluctuations that the patient or caregiver has observed.

D. Examination

A sufficiently broad range of neuropsychological functions is evaluated using tests and other assessment techniques. The major domains to be surveyed include general intellectual ability, attention, executive functioning and comportment, memory, language, visuospatial abilities, motor functioning, and mood/personality. As a prelude to test administration, it is imperative to establish the integrity of sensation and perception because impairments in these areas can invalidate the results of examination. For example, it would be incorrect to conclude that a patient has a receptive language impairment when, in fact, there is a primary hearing deficit.

Significant impairment of sensory function (auditory, visual, kinesthetic) is usually obvious and may indicate a need for specialized assessment procedures. However, when there is no obvious impairment, it is the responsibility of a neuropsychologist to inquire about all sensory modalities, particularly with regard to visual, auditory, and kinesthetic function. Vision can also be examined with tests of acuity, tracking, scanning, depth perception, color perception, and attention–neglect for visual field quadrants. Simple auditory function can be assessed by finger rub stimuli to each ear. Unusual or abnormal gustatory and olfactory experiences should be sought through direct questioning. Kinesthetic perception is assessed with tests of graphesthesia and stereognosis. Double simultaneous stimulation can be

used in auditory, visual, and kinesthetic modalities to determine whether hemiextinction occurs. Once it is clear that basic sensory and perceptual functions are intact, neuropsychological tests can be administered in a standard manner.

E. Diagnostic Formulation

Data from the history, observation, and testing of the patient are analyzed collectively to produce a concise understanding of the patient's symptoms and neuropsychological diagnosis. A configuration of abilities and limitations is developed and used both diagnostically and as a framework through which to address the goals of treatment. When possible, the diagnostic formulation should identify the neuropathological factors that give rise to the patient's clinical presentation, including underlying anatomy and disease process.

F. Recommendations and Feedback

Consultation concludes with the process of feedback, through which the findings of the evaluation and treatment recommendations are reviewed with relevant individuals (i.e., referring physician, the patient, family, treatment team members). A variety of treatment plans may be advised, including neurological evaluation, psychiatric consultation, psychotherapy, cognitive–behavioral remediation, and vocational guidance. Recommendations should be pragmatic and individually tailored to each patient's specific needs. Strategies for optimizing performance in personal, educational, occupational, and relational spheres are identified and discussed in lay language that the patient and family member can understand. When possible, the clinician outlines concrete strategies to facilitate the remediation of identified problems. Further clinical evaluations and other neurodiagnostic procedures are suggested, when appropriate, in order to provide more information relevant to differential diagnosis, response to treatment, and functional status over time. Appropriate neuropsychological follow-up is also arranged, when indicated.

VI. DOMAINS OF NEUROPSYCHOLOGICAL FUNCTION

The fractionation of neuropsychological functions into specific domains is a somewhat arbitrary organizational contrivance. In reality, there is considerable overlap within and between cognitive domains. For example, working memory shares much common ground with aspects of attention and language.

A. General Intellectual Ability

Determination of an individual's level of intellectual functioning is a fundamental component of the neuropsychological assessment. Once established, general level of intelligence serves as a point of reference from which to evaluate performance in other domains. Intelligence encompasses a broad range of capacities, many of which are not directly assessed in the traditional clinical setting. The estimate of general intellectual ability is based on both formal assessment methods and a survey of demographic factors and life accomplishments. Formal measures of general intellectual function typically assess a broad range of functions through multiple subtests (e.g., *WAIS-III*, *WASI*, *WISC-III*), and yield an "intelligence quotient" as well as other derived index scores. Other test instruments obtain high correlations with IQ measures and have been used to estimate overall intellectual ability (e.g., Ravens Progressive Matrices, Shipley Institute of Living Scale). In cases of known or suspected impairment, premorbid ability can also be surmised from performance on measures presumed less sensitive to cerebral dysfunction (e.g., vocabulary). Single-word reading tests (e.g., *AmNART*) have been used to estimate baseline verbal intelligence in patients with early degenerative conditions. In addition, so-called "best performance methods" can be used. This method assumes that the patient's highest level of performance can be used to set a reference point for optimal baseline ability (Table I).

Demographic variables, including level of education and professional achievement, avocational interests and pursuits, and socioeconomic status, can also be used to gauge an individual's current or premorbid general intellectual ability. Relationships among these variables are complex, and particular care must be exercised in the evaluation of patients from diverse sociocultural backgrounds. It is important to consider real-world accomplishments in the unique context of the individual, with attention to environmental factors that influence opportunity and achievement.

B. Attention and Executive Function

1. Attention

Many cognitive capacities are inherently predicated on a fundamental ability to attend to the surrounding

Table I
General Intellectual Ability

Test name	Description
Wechsler Intelligence Scales	The *Wechsler Adult Intelligence Scale-III* (*WAIS-III*) is composed of 13 individual subtests. Administration of all subtests generates three Intellectual Quotients (IQs): Full-Scale IQ, Verbal IQ and Performance IQ, and four different performance indices: Verbal Comprehension Index, Perceptual Organization Index, Working Memory Index, and Processing Speed Index.
	The *Wechsler Abbreviated Scale of Intelligence* (*WASI*) is designed to be a short and reliable measure of intelligence that produces VIQ, PIQ, and FSIQ scores that are similar to those obtained with the *WAIS-III*.
	The *Wechsler Intelligence Scale for Children* (*WISC-III*) is used for testing children and adolescents ranging in age from 6 to 17.
	The *Wechsler Preschool and Primary Scale of Intelligence* (*WPPSI*) is used for testing children ranging in age from 4 to 6.5 years.
American National Adult Reading Test (*AmNART*)	The *AmNART* is a measure of recognition vocabulary requiring oral reading of 45 phonetically "irregular" words. It is used to estimate premorbid baseline intellectual ability in patients with known or suspected dementia. Similar measures include the *NART*, *NART-Revised*, and *ANART*. Errors consist of word mispronunciations.
Shipley Institute of Living Scale	The *Shipley ILS* consists of a multiple-choice measure of vocabulary (knowledge of synonyms) and a measure of verbal reasoning (providing the missing member of an established logical pattern). The two components are scored together to estimate a *WAIS-R FSIQ* score. Errors consist of incorrect responses to the task involving choosing a synonym for the target word and providing no response or responding with an incorrect continuation of the logical pattern.
Raven's Standard and Colored Progressive Matrices	These are standardized measures of nonverbal analogical reasoning widely used both within and outside the U.S. as a "culture fair" measure of general intellectual ability. Both tests require the patient to demonstrate an understanding of the logic underlying visual patterns by selecting the missing component of the pattern from a series of choices. The *Standard Matrices* contain 60 black and white items ranging from simple to extremely difficult, while the *Colored Matrices* consist of 36 colored items that span a limited range of complexity. Errors consist of incorrect identification of the missing component of the visual pattern.

environment. For example, an individual cannot effectively name an object if the object is not first attended to and visually processed. Because attention is a prerequisite for other aspects of cognitive function, disruption of attention can generally skew the results of a neuropsychological assessment. Early assessment of attention is vital for informing the scope of the examination and the analysis of test data (Table II).

Attention is a general term that encompasses a number of different component processes. *Attention span* refers to the number of unrelated "bits" of information that can be held on line at a given moment in time. Assessment of attention span is typically accomplished through the recall of progressively longer series of information bits, such as numbers (digit span) or spatial locations (spatial span). *Sustained attention*, also called *vigilance*, refers to the capacity to maintain active attention over time. The most common method of assessing vigilance utilizes a target detection paradigm. Here the patient is instructed to respond to an infrequently occurring target stimulus. For example, on a measure of auditory vigilance, the patient hears a series of letters of the alphabet and must signal by pressing a response key each time a particular target is read (see *CPT*, *PASAT*). *Selective attention* is similar to sustained attention but requires a response only to a particular class of stimuli, but not other stimuli. *Set-shifting* refers to the capacity to relinquish an existing procedural strategy in favor of a new response, based on recognition of a change in reward contingencies. It is typically measured with tasks requiring the patient to shift focus among stimulus features of test display (see *Trailmaking A and B, Wisconsin Card Sorting Test, Luria Graphomotor Sequences*). *Resistance to interference*, also called *response inhibition*, refers to the ability to sustain a given response, even in the face of a salient distraction designed to undermine the target response.

This is assessed with tasks requiring the patient to inhibit overlearned responses or other distractions that could undermine a desired response (see *Stroop Interference Test*, *Trailmaking Test*).

2. Executive Functioning

Executive functions require the capacity to process information in a planful, organized, and contextually appropriate manner. Formal tests of executive function assess a number of different capacities, including some functions mentioned earlier (*set-shifting*, *overcoming interference*, *response inhibition*), and also *planning*, *perseverence*, *initiation*, *reasoning*, and *abstraction*. *Planning* involves thinking several steps ahead of one's current circumstances for the purpose of informing and altering a course of action. Tests measuring planning ability often require a person to determine the correct series of steps needed to successfully reach a particular goal (see *Tower of Hanoi*, *Tower of London*). *Perseverence* is the ability to sustain a particular course of action, even in the absence of an external prompt. Measurement of perseverance often begins with both examiner and subject performing the same task, but involves the subject continuing the task even after the examiner has stopped (see *Luria Motor Sequences*, *Verbal and Design Fluency*). *Initiation* refers to the ability to spontaneously commence an action in the absence of a direct prompt from the external environment. This function is measured with the presentation of a task followed by a period of time during which the subject is expected to respond independently (see *Verbal Fluency*, *Go-No-Go*). *Reasoning* involves using a system of logic to solve a particular problem or task. This can be measured in a variety of ways, including the use of visual puzzles and verbal analogies (see *Raven's Progressive Matrices*, *Shipley Institute of Living Scale-Abstraction*, *WAIS-III Comprehension*). *Abstraction* is the ability to articulate shared attributes of dissimilar objects (see *WAIS-III Similarities*, *Wisconsin Card Sorting Test*) (Table II).

C. Comportment, Insight, and Judgment

Although few tests probe these functions in a formal manner, they are important components of neuropsychological function and are frequently disturbed in cases of neurological and neuropsychiatric illness. *Comportment* refers to the ability to behave in a contextually appropriate manner. Disturbances often manifest as socially inappropriate behaviors that suggest an insensitivity to accepted cultural norms. Examples might include making offensive comments, crossing interpersonal boundaries, interrupting during conversation, or failing to attend to personal hygiene. In the context of neuropsychological assessment, *insight* involves an accurate perception of one's mental and physical condition as well as appreciation of the impact of one's behavior on others. Cognitively impaired individuals often lack one or both of these components of insight. *Judgment* involves the capacity to perceive and assess one's environment accurately and to make decisions that reflect a sensitivity to preserving the safety and integrity of oneself, one's resources, and one's environment.

A neuropsychologist can assess these functions informally through naturalistic observation, reports from individuals familiar with the patient, and by inquiring about any accidents or legal infractions involving the patient. Formal measures of these functions exist primarily in the form of questionnaires that quantify the degree to which the patient manifests disturbances in these general areas. The *Frontal Lobe Personality Scale* (*FLOPS*) comprises 46 descriptions of various behaviors that are characteristic of patients with frontal lobe damage. Each behavior is assigned a severity rating by the patient and by a family member, and the overall severity rating is thought to reflect the degree of behavioral disturbance present. The *Neuropsychiatric Inventory* (*NPI*) is another self-report rating scale that is completed by a family member or caregiver. Both the extent of the patient's behavior and the degree of subsequent familial distress are rated.

D. Learning and Memory

The assessment of learning and memory function is perhaps the most complex endeavor of the neuropsychological examination. *Working memory* involves holding a stimulus or set of stimuli in mind in order to either produce it after a delay (i.e., looking up a telephone number and remembering it until it is successfully dialed) or use it in a mental procedure involving manipulation of information (i.e., carrying out mental arithmetic). The simpler aspect of working memory, also called *maintenance* of information, can be tested by requiring a subject to hold information in mind and reproduce it after a short delay (see *Digit Span Forwards*). The more complex components of working memory can be tested in a number of ways, all of which involve on line maintenance *and*

Table II
Attention and Executive Functioning

Function	Test	Description
Attention span	*Digit Span*	The examiner reads increasingly long strings of numbers aloud. The examinee must repeat the numbers aloud in the same order, first forward and then in the reverse order.
	Spatial Span	The examiner taps a series of blocks in fixed locations. The examinee must repeat this series in the same order and then in the reverse order.
Sustained attention and vigilance	*Auditory and Visual Continuous Performance Test* (*CPT*)	Basic auditory vigilance is tested by having the patient listen to a series of letters read serially and responding to a single target letter or series of letter configurations. Visual vigilance can be tested by showing a series of single numbers on a computer screen and requires responding to a target stimulus, but not to non-target stimuli.
	Paced Auditory Serial Addition Test (*PASAT*)	The patient hears a tape recorded voice reading numbers at various rates, ranging from every 2.4 seconds to every 1.2 seconds. The objective of the task is to sum the last two numbers heard and voice the sum aloud (e.g., if the numbers from the tape were "5, 2, 8, 4," the patients responses would be the following (in italics): "5, 2, *7*, 8, *10*, 4, *12*," etc.). The process of voicing the sum aloud serves as interference, which must be overcome in order to attend to the following number. In total, 60 numbers are read in each of the four trials and every subsequent trial is faster than the one preceding it.
Set-shifting	*Trail Making Test A and B*	This measures visual scanning, visuomotor tracking, and response set flexibility. Trails A involves connecting consecutively numbered circles, from 1 to 25. Trails B requires the patient to continually shift set, alternating between letters and numbers (i.e., 1, A, 2, B, etc.). Both tasks must be performed as quickly as possible and without lifting the writing utensil from the paper.
	Wisconsin Card Sorting Test	A measure of nonverbal concept formation, response set flexibility, sustained attention, and ability to integrate corrective feedback. The patient must sort cards according to underlying principles (color, form, number), which must be deduced and which are shifted at set intervals.
	Luria Graphomotor Sequencing	Involves using a pencil to copy a series of patterns (i.e., m-n-m-n, peaks and plateaus, and multiple loops) without lifting the pencil. Errors consist of failing to alternate (i.e., m-n-m-m-m-m).
	Luria Motor Sequences	Involves performing repeated sequences of hand movements. Errors consist of failure to maintain the order of movements within each sequence.
Response inhibition	*Stroop Color-Word Interference Test*	Composed of three parts that require (1) reading a series of black and white color words (red, blue, green), (2) identifying the color of red, blue, and green "Xs," and (3) identifying the ink color of incongruent color words (i.e., the correct response to the word "red" printed in blue ink would be "blue"). In all conditions the patient is asked to perform as quickly as possible.
	Motor Go-No-Go	Involves responding to a target signal (one loud knock) by lifting a finger, but not to a second signal (two loud knocks). The tendency to respond to the second signal must be inhibited. The examiner produces a series of one or two knocks and observes the patient's responses. Each hand is tested separately.
Planning	*Tower of London*	Involves ordering three or four colored beads within a set of constraints. Only one bead may be moved at a time, and beads moved from their initial placement may not be returned. Similar tests include *Tower of Hanoi* and *Tower of Toronto*.
Perseverance	*Verbal and Design Fluency*	Letters: the examinee must recite as many words as possible that start with a particular letter, with the exception of proper nouns, numbers, and more than one iteration of the same root word. This is repeated with three different letters in total. Categories: the examinee must recite as many words as possible from a particular category. This is repeated with three different categories in total. Design: the examinee must create as many unique designs as possible by connecting lines between dots laid out in a grid.

manipulation of information (see *Tests of Mental Control*, *WAIS-III Letter–Number Sequencing*, *WAIS-III Arithmetic*, *PASAT*). Memory is assessed with respect to modality of presentation (auditory vs visual), material (linguistic vs figural), and locus of reference (personal vs nonpersonal). Also important is the time of initial exposure, namely, whether information was learned before the onset of brain damage (retrograde memory, see *Boston Retrograde Memory Test, Transient Events Test*) or after (anterograde memory, see *WMS-III*, *RAVLT*, *Bushke SRT*, *Three Words–Three Shapes*, *Warrington RMT*). The evaluation of memory should include measures that allow the dissociation of the component processes entailed in the acquisition and later recall of information, namely, encoding, consolidation, and retrieval. To this end, measures are used to assess performance with respect to length of the interval between exposure to information and demand for recall (immediate vs short vs long delay) and extent of facilitation required to demonstrate retention (free recall vs cued recall vs recognition). The assessment of retrograde memory function poses a special problem insofar as it is difficult to know with certainty what information was previously registered in the remote memory of a particular patient. Although there are a number of formal tests that can be used for this purpose (e.g., *Boston Remote Memory Battery*, *Transient Events Test*), we also assess this aspect of memory function by asking for personal information that presumably is or had been well-known at one time by the patient (i.e., names of family members, places of prior employment). In these instances it is helpful to obtain confirmation of the accuracy of this information from family members or friends, if possible. (See Table III).

E. Language

Language is the medium through which much of the neuropsychological examination is accomplished. Language function is assessed both opportunistically, as during the interview, and via formal test instruments (Table IV). Conversational speech is observed with respect to fluency, articulation, and prosody. The patient's capacity to respond to interview questions and test instructions provides an informal index of receptive language ability or comprehension. Visual confrontation naming is carefully assessed so that word-finding problems and paraphasic errors may be elicited. Repetition is measured with phrases of varying length and phonemic complexity. Auditory comprehension is evaluated by asking the patient questions that range in length and grammatical complexity. Reading measures include identification of individual letters, common words, irregularly spelled words, and nonwords, as well as measures of reading speed and comprehension. Spelling can be assessed in both visual and auditory modalities. A narrative handwriting sample can be obtained by instructing the patient to describe a standard stimulus scene.

F. Visuospatial Functions

After the integrity of basic visual acuity is established, the spatial distribution of visual attention is evaluated. The presence of visual neglect is assessed through the use of tasks that require scanning across all quadrants of visual space. Assessment of left–right orientation involves directing patients to point to specific body parts, either on themselves or the examiner. Topographical orientation can be tested by instructing the patient to indicate well-known locales on a blank map. Graphic reproduction of designs and assembly of patterns using sticks, blocks, or other media are used to assess visual organization and constructional abilities. Facial recognition represents a special component perceptual process and can be measured using Benton's *Facial Recognition Test*. The *Judgement of Line Orientation Test* assesses perceptual accuracy in judging the angular displacement of lines. Warrington's *Visual Object Space Perception Battery* is an example of a collection of measures, designed to assess various aspects of perceptual function. (See Table V).

G. Motor Functions

Naturalistic observations of the patient's gait and upper and lower extremity coordination are an important part of the motor examination. Hand preference should be assessed either through direct inquiry or a formal handedness questionnaire. (Table VI) Motor speed, dexterity, and programming are tested with timed tasks, some of which involve the repetition of a specific motor act (e.g., finger tapping, peg placement) and others involve more complex motor movements (e.g., finger sequencing, sequential hand positions). Manual grasp strength can be assessed with a hand dynamometer.

H. Affect, Mood, and Psychological Functioning

Standardized measures of mood, personality, and psychopathology can be used to assess the contribution

Table III
Learning and Memory

Function	Test	Description
	Tests of Mental Control	The examinee is asked to recite familiar sequences such as the alphabet, days of the week, months of the year, and numbers from 1 to 20 as quickly as possible. The examinee then must recite all sequences, except the alphabet, in reverse order. Serial subtractions involve subtracting a particular number until a predetermined point is reached.
Working memory[a]	*WAIS-III Letter–Number Sequencing*	The patient hears a series of alternating numbers and letters and is required to reconfigure them so that all of the numbers are recited first, in ascending order, and then letters in alphabetical order.
	WAIS-III Arithmetic	Involves mental calculation of aurally presented arithmetic problems of increasing difficulty.
	Boston Retrograde Memory Test	Involves showing a series of black and white photos of famous persons from the 1920s to the 1980s. If the patient cannot spontaneously generate the correct name, the examiner can give a semantic cue (i.e., "he was a singer in the 1920s"), and then a phonemic cue (i.e., first name). This test assumes that the patient has been exposed to the information in the first place.
Retrograde memory	*Transient Events Test* (*TET*)	This is a measure of memory for popular news events from the 1950s through the 1990s. Items were selected by way of the *New York Times* index according to the criteria that they were mentioned at least 250 times during a particular year and less than five times over the subsequent two years. Hence, all items were of transient notoriety thereby minimizing confounding effects of overexposure. Free recall and recognition are tested.
	Wechsler Memory Scale (*WMS-III*)	This is a composite battery of tests assessing orientation, attention, learning, and memory for verbal and visual information across immediate and delayed intervals. It yields a series of index scores.
	Rey Auditory Verbal Learning Test	This measure of verbal encoding, learning, and retention involves drilling the examinee on a series of 15 unrelated words over five successive trials. Learning is followed by an interference trial, immediate recall, and 30-minute delayed recall and recognition. Various comparisons yield information regarding sensitivity to proactive and retroactive interference and rate of forgetting.
Anterograde memory	*Bushke Selective Reminding Test*	This is a special type of list-learning test that is most helpful in cases where encoding is intact, but where there is a question of impairment at the level of consolidation or storage. A list of 12 words is read and the patient must repeat as many words as possible. However, different from the previous list-learning tasks, the examiner then reads only the words that the patient did not recall. This continues across six trials and each time, the patient must try to recite as many words as possible, but only hears the words not recalled on the preceding trial. There are immediate and delayed recall trials followed by visual multiple choice recognition paradigms.
	Three Words Three Shapes Memory Test	The patient is instructed to copy three words and three shapes after which incidental recall is tested. The patient is drilled on the words and shapes until criterion is reached and recall is tested after intervals of 5, 15, and 30 minutes. Recognition is tested using distracter shapes and words.
	Warrington Recognition Memory Test	Involves the visual presentation of single words and faces at the rate of one every three seconds. The patient is instructed to read each word silently and make and report a judgment regarding his association (pleasant or unpleasant) to it. Immediately afterward, the patient is shown a pair of words, each containing a target word and a distracter, with the instruction to identify the one presented previously. Memory for faces is tested in the same way.

[a] See also *Digit Span* forward and *PASAT* tests in Table II.

Table IV
Language Function

Test name	Description
Boston Diagnostic Aphasia Examination (BDAE)	This comprises measures that assess all aspects of expressive and receptive language function, including naming, comprehension, repetition, reading, writing, praxis, and prosody.
Boston Naming Test	One component of the *BDAE*, this measure of confrontation naming is often administered independently. It consists of a series of 60 black and white line drawings of objects. Naming difficulty increases as the objects progress from high-frequency to low-frequency words. Stimulus cues are provided in the event of perceptual difficulty. Phonemic cues are used to distinguish between retrieval difficulties and lack of knowledge of a particular object name.
Nelson Denny Reading Test	This test contains two multiple choice measures that assess vocabulary and reading comprehension. Reading speed is also computed. Reading comprehension can be scored on the basis of both a standard and an extended length of time.
Wide Range Achievement Test-III (*WRAT-3*)	This standardized battery of acquired scholastic skills includes measures of spelling, written arithmetic, and single-word reading.
Woodcock–Johnson Tests of Achievement Revised	Selected subjects such as dictation, writing fluency, writing sample, proofing, word attack, and reading comprehension provide measures of reading encoding, comprehension, and written language abilities. This is another useful measure in the assessment of language-based learning disabilities.

Table V
Visuospatial Functioning

Test name	Description
Benton Facial Recognition Test	This task is composed of two parts. The first involves matching a target face with one of six faces. The target stimulus is always identical to the correct answer. The second part of the task involves choosing the three photographs, out of the array of six, that contain the same face as the target photograph. Increasing use of camera angle and shadow contribute to the progressive difficulty of the task.
Benton Line Orientation Test	This task involves judging the spatial orientation of sets of line segments by comparing them to a grid composed of 11 radii. It is sensitive to visuoperceptual deficits associated with posterior right hemisphere lesions.
Visual Object Space Perception Battery	This battery contains eight individual tests that each probe a specific component of object or space perception. Individual subtests are untimed and can be given in isolation or within the context of the full battery. Normative data are based on healthy control subjects as well as patients with right and left-hemisphere lesions.
Visual Cancellation	The objective of this task is to circle each instance of a target letter or symbol from among a field of similar stimuli. There are a total of 60 targets evenly distributed among the four quadrants of the 8-1/2 $\times$ 11 inch page. Errors of omission involve failing to respond to the target stimulus. Errors of comission involve responding to stimuli other than the target stimulus.
Hooper Visual Organization Test	This task involves examining line drawings of objects that have been broken into fragments and rotated. The objective is to mentally reorganize each set of fragments and subsequently identify the corresponding coherent whole.
Complex Figure Drawing	This task involves copying a complex line drawing, usually the Rey-Osterreith complex figure or Taylor complex figure. Ability to reproduce the gestalt as well as the internal details of the design facilitate the detection of various perceptual deficits. Significant distortion of or failure to copy one side of the figure can indicate the presence of hemispatial neglect.

Table VI
Motor Functioning

Test name	Description
Finger oscillation test	Finger tapping speed is measured by having the patient tap a key as quickly as possible over a period of ten seconds, using the index finger. Each hand is tested a number of times and trial totals are averaged. Poor performance consists of slow tapping speed. Unilateral motor weakness can be assessed by comparing tapping speeds of each hand. Bilateral weakness is assessed through comparison with age-matched norms.
Hand dynamometer	Grip strength is measured in each hand by having the patient squeeze a pressure-calibrated instrument. Unilateral motor weakness can be assessed by comparing performance with each hand. Bilateral weakness is assessed through comparison with age-matched norms.
Grooved pegboard	Measures of fine motor speed and dexterity, entailing placement of pegs in a pegboard, are obtained with each hand separately. Poor performance consists of difficulty grasping and manipulating the pegs, resulting in slowed performance.
Reitan-Klove Sensory-Perceptual Examination	Collection of measures of tactile, auditory, and visual perception using unilateral and double simultaneous stimulation. Finger tip number writing, visual fields, and tactile finger recognition are tested.

of psychiatric illness to the patient's presentation and diagnosis (Table VII). However, it is important to understand that many neurological illnesses can cause disorders of affect and mood. In addition, certain neurological illnesses can produce symptoms that overlap with particular psychiatric disorders. Therefore, neuropsychologists must have a thorough understanding of the psychiatric profiles associated with various neurobehavioral syndromes and proceed with caution when evaluating psychiatric symptoms in the presence of neurological or medical illness.

I. Dementia Screening Tools

Because detection of age-related cognitive impairments and dementia plays a significant role in neuropsychological evaluation, a number of specific screening tools have been developed (Table VIII). Many of these measures are designed to quickly assess gross level of functioning in major cognitive domains and can be administered in a matter of minutes (see *Blessed Dementia Scale*, *MMSE*). The *Mattis Dementia Rating Scale* is a more comprehensive set of items designed to stage severity of impairment in patients with known dementia.

VII. CONCLUSIONS

Although clinical neuropsychology is a relatively new discipline, it traces its roots back to the ancients who wondered about the "seat of the soul" and the source of human thought. Drawing from the earliest studies of brain–behavior relationships in patients with naturally acquired lesions and the accumulating body of

Table VII
Psychological Functioning and Mood

Test name	Description
Beck Depression Inventory	This instrument is used to assess depression severity based on self-reported ratings of a number of different relevant symptoms. Higher scores indicate greater severity of symptoms.
Beck Anxiety Inventory	This instrument is used to assess anxiety severity based on self-reported ratings of a variety of somatic, cognitive, and psychological symptoms of anxiety. Higher scores indicate greater severity of symptoms.
Minnesota Multiphasic Personality Inventory-2 (*MMPI-2*)	This series of 537 true/false questions load on to a number of different subscales that correspond to various personality traits or types of psychopathology. Scores on each subscale are standardized. Combinations of high and low scores on individual subscales correspond differentially to the presence or absence of various psychopathologies. Careful interpretation of subscale scores is crucial to the accurate use of this measure.

Table VIII
Dementia Screening Tools

Test name	Description
Blessed Dementia Scale	Consists of two parts: (1) a rating scale of activities of daily living to be completed by a caregiver or other independent rater and (2) a brief screening measure of orientation, concentration, and memory. Higher scores indicate greater severity of dementia.
Mini Mental Status Exam (MMSE)	This is a set of brief tasks that can be administered at the bedside and used to screen for obvious cognitive impairment. Includes items that assess attention, orientation, language, memory, and construction. Lower scores indicate greater severity of dementia.
Mattis Dementia Rating Scale (DRS)	This scale assesses a wide range of neuropsychological domains, including attention, initiation and perseverance, construction, conceptualization, and memory. It is used for grading and tracking the overall degree of dementia. Lower scores indicate greater severity of dementia.

literature in cognitive neuroscience, neuropsychologists have created a diverse collection of test instruments and other assessment methods which permit the precise measurement of specific components of human thinking. Together with a comprehensive knowledge of neuropathologic syndromes, the results of neuropsychological examination provide both descriptive and diagnostic information regarding the condition of the brain. As in all venues of medicine, diagnostic precision is a prerequisite for sound therapy. Because of its relative newness as a clinical discipline, several applied paradigms currently exist and there is some debate regarding preferred methods. Neuropsychologists in the 21st century face the challenge of establishing and promulgating an approach to assessment and treatment that unifies clinical practice and embraces the need for progressively refined normative information suited to diverse patient populations.

Neuropsychological Assessment, Pediatric

LAWRENCE C. HARTLAGE
Augusta Neuropsychology Center, Georgia

GLOSSARY

attention deficit hyperactivity disorder Condition presumably reflecting delayed maturation of a given brain area, characterized by poor attention, concentration, and possibly impulse control relative to those expected for the child's age.

cortex Area on the lateral surface of the brain involved with higher mental functions.

dyslexia Generic name for poor reading ability. Specific dyslexia is related to dysfunction in the area of the supramarginal angular gyrus of the dominant cerebral hemisphere. Dyslexia may also represent a manifestation of generalized language disorder, reflecting dysfunction of broader areas of the dominant cerebral hemisphere.

frontal lobes Involved with impulse control, planning, and executive function. Maturation rate is quite slow, typically not reaching maturity until the teenage years in girls and later in boys.

neurobehavioral Behavioral functions (e.g., monitoring behavior, judgment, impulse control) dependent on or subserved by the (central) nervous system.

neurocognitive Cognitive functions (e.g., memory, intelligence) dependent on or subserved by the (central) nervous system.

psychometric Measurements of psychological functions with objective, calibrations, such as intelligence quotient or learning levels, corrected for age.

Pediatric neuropsychological assessment deals with the evaluation of brain–behavior relationships in a pediatric population. Such assessment measures the developmental status and functional integrity of given brain areas and systems by utilizing tests and measurement procedures based on psychometric principles of psychological science.

I. BACKGROUND

Neuropsychological assessment grew from infancy to maturity in the half century between 1950 and 2000. Originally developed with a primary focus on the assessment of neurocognitive correlates of neurological disorders in adults, by the 1970s neuropsychological assessment had expanded to encompass neurodevelopmental phenomena among children. Pediatric neuropsychological assessment in its early years was characterized by the use of measurement concepts and instruments found to be of value with adults, and early practitioners were often individuals sophisticated in the physiological bases of adult cognitive dysfunction with little clinical experience with or knowledge of a pediatric population.

Growing awareness and interest in brain–behavior relationships in children, typified by such issues as minimal brain dysfunction or attention deficit hypotheses to account for comparatively poorer performance by some children in academic and social milieus, generated government support during the Great Society era of a number of training programs designed to incorporate pediatric neuropsychological assessment into both health care and academic settings. The increasing involvement of individuals with a background in child development and the problems unique to a pediatric population heightened recognition that

conceptual models typical of brain–behavior relationships in adults were not necessarily applicable to children. This recognition has led to three decades of research and development involving issues of unique relevance to pediatric neuropsychological assessment.

II. CONCEPTUAL ISSUES IN PEDIATRIC NEUROPSYCHOLOGICAL ASSESSMENT

Neuropsychological assessment of a pediatric population differs in a number of respects from such assessment of an adult population. Whereas a primary feature of adult neuropsychological assessment is that it is based on the loss or impairment of a previously acquired function, child neuropsychological assessment is concerned with a comparable function that may be slowed in development, limited in its extent of development, or totally precluded from development. A critical feature in this respect involves the age at which insult to the central nervous system is sustained and, to a lesser but interactive extent, the brain area or functional system sustaining insult. For more than 100 years it has been documented that, in an adult, damage to a specific brain area (i.e., in the dominant cerebral hemisphere foot of third frontal convolution) may produce loss of the ability to speak (i.e., Broca's type aphasia). However, damage to the same area in a very young child may produce no apparent problems in the development of expressive speech due to the recruitment of intact areas of the nondominant cerebral hemisphere to subserve this function. Neuropsychological assessment of such children, however, may reveal impairment of the functions typically subserved by cortical areas that have been recruited to accommodate the mechanisms of expressive speech. Interestingly, there appears to be an upper age level, somewhere around 8 years of age, after when such contralateral recruitment no longer occurs or occurs to a substantially attenuated extent.

Obviously the diagnosis of an ability (e.g., expressive speech) that has been acquired and then lost is much easier than that of the impaired emergence or slowed rate of development of a skill not within the individual's prior repertoire. Accordingly, neuropsychological assessment of pediatric age populations requires considerable knowledge of the expected ages at which neurodevelopmental phenomena affecting cognitive and behavioral adjustment may be expected to occur, as well as the normal sequence of stages through which such development occurs.

This age specificity constitutes perhaps the most important difference between neuropsychological assessment in pediatric as opposed to adult populations. In the adult population the span of a decade—say between 30 and 40 years of age—produces relatively little change in neurological maturation or organization, and level of performance on most diagnostic measures can, for the most part, be interpreted in the same way for a younger vs an older individual in this age range, with little differentiation between genders except on measures of strength. Conversely, the difference in neuropsychological repertoire between a 2 year-old and a 7-year-old is at once remarkable and striking, reflecting the phenomenal changes in neurological organization occurring during this 5-year period. Accordingly, pediatric neuropsychological assessment needs to consider and take into account the emerging states of central nervous system structures and functions subserving given abilities measured by assessment and be prepared to incorporate such considerations into a diagnostic profile.

In a typical 2-year-old, receptive language is usually reflected in the ability to recognize a few words of command and to match pictures of a few familiar objects to the spoken word (e.g., cat, cup, chair) associated with such objects. By age 7 years, brain maturation has occurred to an extent sufficient to permit the recognition of abstract symbols representing letters of the alphabet and words composed of such symbols. Conceptually, this age may also include understanding of bigger–smaller, pretty–ugly, and alike–different at varying levels generally corresponding to younger vs earlier stages of this 5-year range. Obviously, pediatric neuropsychological assessment needs to be based on an understanding and appreciation of such development to permit understanding of whether a given child's performance on given tests suggests dysfunction in the central nervous system. An example of the interaction between developmental level and specific neurocognitive function may help to provide an illustration of the interdependence of development and central nervous system, normally vs abnormally.

Consider a specific function mediated by the central nervous system, expressive language. Expressive language at a 5-year-old level in an 8-year-old child of normal intellectual ability may be indicative of brain dysfunction involving frontal areas of the dominant cerebral hemisphere, whereas such expressive language functions in an 8-year-old of borderline intellectual ability may represent nothing more remarkable than a manifestation of intellectual function.

More complex functions mediated by the central nervous system in children are encountered with considerably greater frequency than single problems such as expressive language, which may ultimately depend on a single location in the brain (i.e., foot of the second frontal convolution). A diagnostic question frequently presenting for pediatric neuropsychological assessment involves that of reading difficulty. Obviously, before the possible central nervous system components of such a problem can be assessed, the pediatric neuropsychologist must rule out or at least consider the potential effects of such factors as poor educational instruction, mismatch between educational instructional procedure and the child's learning style, possible language barriers, sensory problems involving sight or hearing, impaired motivation, genetic factors, emotional problems, or health factors including medication use that might be operative. Next, the evaluation of the child's reading problem needs to proceed along anatomical parameters. Is there a specific word blindness that might implicate brain areas in the supramarginal–angular gyrus area of the dominant cerebral hemisphere? Does the problem involve associational deficits corresponding with frontal lobe functions? Can the child actually perceive and recognize words but have difficulty translating this into an appropriate response? Is there dysfunction among functions mediated by the arcuate fasciculus?

III. DEVELOPMENTAL ASYMMETRY AND ASYNCHRONICITY

In right-handed individuals and approximately 94% of left-handed individuals, the left cerebral cortex is specialized for language functions and sequential information processing, whereas the right hemisphere is specialized for spatial functions and wholistic or intuitive information processing. Just as children demonstrate growth spurts or uneven patterns of physical growth, the evolutionary functions of given brain areas tend to show asymmetric, nonlinear growth patterns in what some child development specialists have referred to as brain growth periodization. A child may show delayed language production with accelerated motor skills and then demonstrate accelerated language growth corresponding to dominant hemisphere growth acceleration. The importance of this asymmetry and asynchronicity in pediatric neuropsychological assessment is obvious: over-reaction to such false positive indices of abnormality leads to over-diagnosis of abnormality, whereas failure to account for these phenomena may miss important clues to emerging problems and the opportunity for timely intervention. Over-diagnosis of the presentation of normal variations in central nervous system developmental symmetry and synchronicity can lead to unnecessary parental concern, initiation of costly and unnecessary interventions and treatment, and even precipitate spurious lawsuits for damages when none have occurred. Conversely, under-diagnosis can produce problems resulting from lack of timely intervention, whether from early stages of arteriovenous malformations or neoplasms or from language delays wherein critical periods for intervention may be missed. Issues of asymmetry and asynchronicity tend to be more pronounced during younger ages when brain growth is most rapid and tend to become less critical as children approach the end of the pediatric period and segue into young adulthood. However, at this stage the evolution of anterior cortical brain areas—heavily influenced by gender differences as previously noted—begins to represent an increasingly important facet of pediatric neuropsychological assessment. Factors such as impulse control, consideration of alternatives and consequences, monitoring and self-evaluation of responses, and executive functions become progressively important foci of pediatric neuropsychological assessment. Adolescents with delayed frontal maturation may present on examination with findings of abilities spuriously depressed due to impulsive responding or failure to consider attenuators. Knowledgeable and sophisticated examiners recognize the possible effects of such determinants and will structure the examination to detect such possible confounds and correct for their impact on findings.

A. Clinical Manifestations of Developmental Asymmetries

For many years, it has been documented that depressed dominant (almost always left) cerebral hemisphere development will lower verbal IQ and depressed nondominant hemisphere development will lower performance IQ. Similarly, developmental tasks such as acquisition of reading skills or expressive language are primarily dependent upon dominant hemisphere maturation (in the posterior and anterior portions, respectively). Thus, the measurement of developmental phenomena relevant to the acquisition of such academic pursuits as learning to read and spell or to recognize and reproduce images of given objects

depends on the developmental status of cortically mediated functions, which in turn are dependent on the development of given cortical areas. Neuropsychological assessment of pediatric age patient is an important adjunct and contributes to the understanding of skill development (or lack of development) of a number of functions central to the acquisition of educational mastery at given age levels.

IV. DIAGNOSIS OF NEUROPSYCHOLOGICAL DISORDERS

Although a wide range of classification procedures have been developed for neuropsychological disorders in a pediatric age population, a relevant dichotomization may segregate such disorders into those representing conditions whose treatment is typically relegated to medical specialists vs those conditions whose alleviation or remediation is more commonly within the domain of educational–behavioral interventions.

A. Disorders Involving Medical Intervention

1. Neoplasms

Perhaps primary among such disorders would be neoplasms or tumors, because early detection and intervention can have crucial implications. Whereas primary brain tumors do not typically occur with high frequency in a pediatric population, neuropsychological assessment can detect them at an early stage, frequently before the child would be referred for computerized tomography or other radiological procedures. This is due to the fact that neuropsychological assessment measures *functional* processes, such as interaction of functional systems of the brain, whereas X-ray procedures do not reflect abnormalities until some structural alteration of the brain is manifested. It is not uncommon for changes in rate of development to become manifested before structural changes (e.g., tumor growth) in the brain are suspected. Whereas surgical intervention would not be based solely on neuropsychological findings, such findings can and often do serve as a first documentation that neoplastic growth is occurring. For more than a quarter of a century, it has been recognized that neuropsychological assessment can provide accurate information concerning location, size, and growth velocity of neoplasms, information that can be applied to make inferences concerning the specific nature of the tumor. Other conditions, such as arteriovenous malformations or epileptogenic seizure foci, are similarly amenable to neuropsychological evaluation.

2. Traumatic Brain Injury

A very frequent occurrence among children of all ages involves traumatic brain injury. Such injuries can occur at various levels, classified as severe (e.g., extended coma, multiple potential residua), moderate (briefer coma, typically fewer physical developmental residua), or mild (brief or no loss of consciousness). Most common causes involve automotive injuries, falls, and sports injuries. The large majority of traumatic brain injuries in the pediatric age population are typically mild concussive incidents with little or only brief loss of consciousness. Diagnosis of such injuries by standard imaging (CAT or MRI scan) or electroencephalographic (EEG) procedures are often not productive, because such procedures are not particularly sensitive to such injuries. That such injuries are important to diagnose and can have serious consequences is, unfortunately, not widely recognized. Neuropsychological examination is consensually recognized as the most definitive approach for determining whether neurocognitive, neurobehavioral, or both types of problems have resulted. Whereas some 80–85% of mild concussive disorders tend to show recovery without treatment, a second mild blow to the head shortly following an initial mild concussion can produce coma and death. Further, among 15–20% of children who do not make spontaneous recovery, impairments may range from social inappropriateness, depression, irritability, learning difficulty, and intellectual slowing to increased risk of delinquency. Even among many of those children who appear to have made a spontaneous recovery, long-term follow-up has shown mild residual neuropsychological deficits, especially as a result of automotive injuries or repeated very mild blows to the head such as are experienced among children involved in football, soccer, and boxing. Research on both former soccer players and former boxers has found the degree of neuropsychological deficit to be directly related to the amount of time involved in participation in the sport, with a similar but somewhat weaker correlation found between such deficits and time involved in participation for football players.

Neuropsychological assessment of these children is important for a number of reasons. Primarily, it can identify those children at risk for "second impact"

injuries, and aid in the prevention of such potentially serious or even fatal injuries. It can also provide the basis for understanding changes in personality or school performance that might ordinarily be referred to a mental health professional or educational therapist for treatment. It can provide guidelines for parents concerning substrates of learning or behavioral difficulties, with guidelines for management and longer term planning. In cases of liability, such as in automotive injuries, neuropsychological assessment can provide definitive documentation concerning the nature and extent of brain injuries related to or resulting from the given incident, and the likely effect(s), if any, of that injury on the child's longer term educational and personal–social adjustment and eventual vocational potential.

3. Chemical Exposure

Although not widely recognized, neurotoxic chemical exposure is not uncommon among children and exerts considerably more adverse and deleterious effects than among adults. Particularly among younger children, whose brains are growing rapidly, the metabolism of neurotoxic substances like lead takes place faster than with adults. Further, the comparatively smaller size of children makes them especially vulnerable: a serving of mercury-contaminated fish may realistically be expected to have a greater effect on a 25-lb child than on a 150-lb adult. Further, whereas the adult brain typically has established patterns of speech, language, memory, and problem-solving, insult to these systems by neurotoxic exposure represents a subtractive process that is not likely to obliterate an entire system. Conversely, among children, especially younger ones who do not yet have fully developed systems of receptive or expressive language, social behavior, or judgment, insult to the central nervous can interfere with or even prevent the development of such functional systems in the brain. Neuropsychological assessment often provides the first documentation that an interruption of central nervous system development has occurred, thus leading to specific definitive testing for blood (urine, hair, bone) samples to determine the specific neurotoxins to which the child has been exposed. Once such a determination has been made, neuropsychological assessment can ascertain how much damage has occurred to specific functions, such as short-term memory, attention, and concentration, and establish educational, behavioral, and related goals and expectancies on the basis of remaining intact functional systems. Finally, neuropsychological assessment at intervals over an extended time can monitor response to treatment and identify emerging manifestations of neuropsychological deficits relative to the given age expectancies.

This listing by no means exhausts the range of neuropsychological assessment applications to medically determinable phenomena, but it does represent illustrative elaborations of how such assessment may relate to three types of medical problems.

B. Disorders Involving Educational–Behavioral Intervention

It is noteworthy that the medical phenomena just described, as well as a wide range of other medical phenomena with neuropsychological substrates (e.g., HIV–AIDS, sickle cell anemia, hypoxic episodes, and degenerative disorders, genetic and metabolic disorders), may profit from educational modifications to accommodate neuropsychological anomalies associated with the disorder, as well behavioral intervention in the form of counseling for educators and parents concerning reasonable expectations and the need for behavioral support in form of behavioral modification or supportive therapy intervention.

1. Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) represents a manifestation of neuropsychological disorders estimated to occur in approximately 5% (or more, depending on source) of school-aged children. Boys are referred approximately 3–4 times more frequently than girls. Neuropsychological assessment is indicated for determining the exact nature of the disorder: (1) classic (hyperactive, restless, distractible); (2) inattentive (absent-mindedness without hyperactivity); and (3) temporal lobe (aggressive, memory problems). Whereas SPECT imaging can document the physiological basis of these types of ADHD, neuropsychological assessment is method of choice for documenting the presence and type of disorder and recommended intervention approaches.

2. Learning Disabilities

Learning disabilities are found in some 5% (or more, depending on source) of school-aged children. In most states, a learning disability is documented by a 15-point or greater (i.e., 1 standard deviation or more), difference between ability as measured by individual

IQ test and school achievement, as measured by standardized individual achievement testing measuring basic skills such as reading, arithmetic, and spelling. Although arithmetic disorders are not particularly rare, language-related learning disabilities exert by far the greater impediment to learning and are the most frequent learning disorders noted. Language learning disorders can be of two generic types.

a. Language Learning Disabilities Language learning disability, reflecting generalized neurodevelopmental asymmetry involving the dominant cerebral hemisphere, is the more common type of learning disability seen for neuropsychological evaluation. The learning problem may involve recognition–decoding problems related to more posterior brain structures (e.g., angular gyrus), associative problems involving the accurate fasiculus–temporal lobe areas, expressive functions more related to frontal cortical areas, or any combination of these problems. Typically, problems are manifested to some extent in all three functional systems.

b. Specific Development Dyslexia Specific developmental dyslexia was first described in the late nineteenth century as congenital word blindness and is usually related to dysgenesis in the area of the supramarginal and angular gyri of dominant cerebral hemisphere. Anatomic differences in brain morphology have been demonstrated upon autopsy of individuals with this type of dyslexia. Tending to occur approximately 4:1 in boys over girls, there appears to be a genetic pattern. This problem may occur in individuals at any intellectual level and, in fact, is often not detected until around the 4th grade level due to ingenious subterfuges and compensatory mechanisms employed by individuals with this specific reading disorder. Whereas some cases of this disorder occasionally may be detected by school psychometric testing, the definitive diagnosis is dependent on neuropsychological assessment.

V. CONCLUSION

Neuropsychological assessment of pediatric age patients is an important component of documentation of the presence of a disorder subserved by the central nervous system, of a nature that may present as a psychiatric disorder, stubbornness, failure to apply oneself to learning, or related behavioral or cognitive problems. By relating the maladaptive or dysfunctional behavior (or misbehavior) to its cortical substrates, neuropsychological assessment provides diagnostic explanatory information that can represent a major source of understanding of the disorder, as well as provides rationale for the development of appropriate treatment and intervention.

The precise nature of the measurements involved, when compared with the more clinical measures used in neurological or neurosurgical evaluation, provide highly quantifiable and reliable data that can be compared to normative expectancies, used to measure responsiveness to a given drug or dosage of a given drug affecting the central nervous system, tracked over time to assess improvement or decline, or used to predict ecological phenomena such as potential to perform certain tasks. In this regard, neuropsychological assessment can be used for determining whether a child may be safely cleared to return to a sport activity, expected to perform at a given expectancy level for an academic task, or to expect success in a given curriculum focus or pedagogic procedure.

Neurotransmitters

JAMES H. SCHWARTZ
Columbia University

GLOSSARY

biosynthetic pathway A series of enzymatic reactions by which a substance is made.

cholinergic Denotes a neuron that uses acetylcholine as transmitter.

cholinoceptive Denotes a target cell with a receptor for acetylcholine.

endoplasmic reticulum Polyprotein precursors of neuropeptides (and other secreted proteins) are translated from messenger RNA on polyribosomes attached to the cytoplasmic surface of the endoplasmic reticulum, a series of membranous tubules. The nascent polypeptide chain is extruded into the lumen of these tubules, processed, and then sent to the Golgi apparatus in transport vesicles.

Golgi apparatus A complex structure consisting of a series of tubules arrayed in stacks. Its primary function is to process newly synthesized proteins and package them for transport to the external cell membrane.

receptors for neurotransmitters As a rule are transmembrane proteins located on the postsynaptic surface of a target cell. Ionotropic receptors form a channel for the passage of ions when they bind the transmitter. Metabotropic receptors interact with second messenger systems when the transmitter is bound, often through a G-protein. The receptors for some messengers (e.g., NO and arachidonic acid) are enzymes or factors within the target cell.

Chemical synaptic transmission is mediated by the release of one or more substances from a nerve terminal. About 100 neurotransmitters have been identified. These belong to two categories: neuropeptides and small molecules. Neurotransmitters produce their action by binding to receptors in target cells.

I. INTRODUCTION

A neuron's key function is to communicate with other neurons or with target cells (gland or muscle). Communication is mediated either electrically or chemically. Electrical synapses are rather stereotyped. In contrast, chemical transmission, which involves the slow to rapid release of one or more of over 100 possible transmitter substances, is quite complex. This complexity, which also includes the time and amount of transmitter released, is the basis of synaptic plasticity. Synaptic plasticity, in turn, is the basis of higher mental function, for example, learning and memory. Electrical transmission essentially is instantaneous because the necessary cytoplasmic connection between the neuron and its target cell is continuous. In contrast, in chemical transmission, the target cell is situated at some distance from the signaling neuron, causing synaptic delay. For a transmitter released from the signaling neuron to act successfully as a chemical messenger, it must bind to an appropriate receptor in the target cell. Typically the separation is not much greater than the distance between two adjacent

neurons (the synaptic cleft is about 200 μm across), but occasionally the separation can be much greater.

Chemical transmission is a specialized form of secretion. In simple organisms and during embryogenesis, communication between cells is mediated only by peptide growth factors. These are hormones that are secreted by one cell and diffuse to relatively distant targets. Neurotransmitters can be categorized into two groups: neuropeptides and small molecules (classical transmitters). Each group uses a distinct set of molecular mechanisms that are familiar from general cell biology: neuropeptides are synthesized, processed, and packaged within vesicles of the *secretory* pathway. In contrast, small-molecule neurotransmitters are made in the cytoplasm and pumped into vesicles derived from the *lysosomal* pathway.

It is important to realize that neurons are constructed according to the general polarized plan of epithelial cells. Toward the end of the nineteenth century, Santiago Ramón y Cajal discussed the building plan of neurons in terms of functional polarity. He pointed out that a typical nerve cell has a receiving end (dendrites), a cell body (soma), and a transmitting end (axon). This corresponds to the basal-to-apical blueprint of a typical epithelial cell. In neurons, most of the Golgi apparatus is situated between the cell's nucleus and the axon hillock. Membranous vesicles filled with newly synthesized secretory products are transported from the *trans* face of the Golgi apparatus to the axon and from there to nerve terminals for release.

II. FOUR CRITERIA DEFINE A NEUROTRANSMITTER

The ideas defining a neurotransmitter have changed over the past century as a consequence of growing knowledge of cell biology, pharmacology, and electrophysiology. As late as 1940, there was debate about whether chemical transmission plays any role in synaptic transmission. Some investigators, John C. Eccles among them, believed that all synaptic signals were electrical. By midcentury, however, everyone agreed that there are two forms of transmission, chemical and electrical. Eccles had changed his mind to become one of the foremost investigators of the physiology of synapses.

Most influential was a simple experiment performed by Otto Loewi in 1921. It was known that the heartbeat is slowed when the vagus nerve is stimulated. In order to prove that a diffusable substance is released upon stimulation, Loewi bathed two frog hearts in a physiological saline solution. Both hearts beat at a normal rate. Then he stimulated the vagus nerve to one of the hearts. That heart slowed, as expected. But the heart with the unstimulated vagus also slowed, indicating that a substance, which Loewi called *Vagusstoffe*, was released into the bath to slow the other heart. Soon afterward, *Vagusstoffe* was identified as acetylcholine (ACh), a substance previously found in high concentrations in nervous systems. Long afterward, Loewi told the story about how this influential experiment occurred to him in dreams on two successive nights. In an autobiographical sketch, he tells how the design for the experiment came to him on the first night but was forgotten when he awoke. On the next night, he made sure he had pencil and paper ready and successfully noted the protocol of the dream experiment.

Two of the four criteria used today for deciding whether a substance is in fact a neurotransmitter are suggested by Loewi's experiment: (1) the substance must be synthesized by the neuron, and (2) the substance must be concentrated in nerve terminals and released when the neuron is stimulated. The amount of transmitter released should, of course, be sufficient to affect the postsynaptic neuron or target cell. The third criterion is pharmacological: (3) the putative transmitter must mimic the action of the substance released from the neuron when applied to the target cell in reasonable concentrations.

The last requirement reflects an important aspect of synaptic transmission: (4) mechanisms must exist for removing the putative transmitter from its target. Removal of the released transmitter is a requirement for transmitting a meaningful message. Failure to remove the transmitter would result either in a persistently activated postsynaptic element or, more commonly, a block of transmission because of postsynaptic receptor desensitization.

III. THERE ARE MORE THAN 100 DIFFERENT NEUROTRANSMITTERS

The classification of transmitters into neuropeptides and small molecules is based on how the transmitter is made. Typically neuropeptides are synthesized on polyribosomes that attach to the endoplasmic reticulum during translation. Characteristically, a polyprotein, while it is translated from messenger RNA, is extruded into the lumen of the endoplasmic reticulum and is then transported to the Golgi apparatus. During

its passage through the major membrane systems of the cell, the polyprotein is cut into peptides, which ultimately are packaged into secretory vesicles. Some of these peptides had been identified earlier as hormones in other tissues, notably the gut (for example, gastrin), or as neurosecretory products (for example, oxytocin, vasopressin, somatostatin, and thyrotropin-releasing hormone). A partial list of neuropeptides is presented in Table I.

In contrast, small-molecule neurotransmitters are synthesized in the neuron's cytoplasm, usually in short enzymatic pathways much like intermediates of metabolism (Table II). There are three types of small-molecule neurotransmitters. The first is amine transmitters, which are amines or molecules derived from amines in a few enzymatic steps. This group includes (1) ACh, (2) biogenic amines, and (3) various amino acids. Because these molecules were discovered first historically, they are often referred to as classical neurotransmitters. Loewi's experiment with acetylcholine (1921) has already been mentioned; the pharmacology of norepinephrine (NE) and related amines was being studied contemporaneously by Henry H. Dale. By the middle of the twentieth century, ideas about neurotransmitters were based almost entirely on experiments with these two small-molecule transmitters.

Table I
Some Families of Peptide Neurotransmitters

Family	Neurotransmitter
Opioid	Opiocortins, enkephalins, dynorphin, FMRFamide
Secretin	Secretin, glucagon, vasoactive intestinal peptide, gastric inhibitory peptide, growth hormone releasing factor, peptide histidine isoleucineamide
Tachykinins	Substance P, substance K (neurokinin A), neurokinin B
Neurohypophyseal	Vasopressin, oxytocin, neurophysins
Pancreatic polypeptide related	Pancreatic polypeptide, NPY
Gastrin	Gastrin, cholecytokinin
Others	
Calcitonin gene-related peptide(CGRP)	
Calcitonin	
Galanin	
Cholecytokinin (CCK)	

Table II
Small-Molecule Neurotransmitters and Their Neuron-Specific Enzymes

Transmitter	Enzyme
Amine	
Acetylcholine	Cholineacetyl transferase
Biogenic amine	
Dopamine	Tyrosine hydroxylase
Norepinephrine	Tyrosine hydroxylase
	Dopamine β-hydroxylase
Epinephrine	Tyrosine hydroxylase
	Dopamine β-hydroxylase
	Phentolamine-*N* methyltransferase
Indoleamine	
Serotonin	Tryptophan hydroxylase
Amino acid	
Glutamate	
GABA	Glutamic acid decarboxylase
Glycine	
Membrane soluble	
Nitric oxide	Nitric oxide synthase
Arachidonic acid	

Another group of small-molecule transmitters, the purines, is derived from adenosine triphosphate (ATP). Like the amine transmitters, ATP is not made within the tubules of the endoplasmic reticulum or in the stacks of the Golgi apparatus, but in mitochondria. How then do the amine transmitters and ATP get into vesicles, typically in rather high concentrations (0.01–0.5 *M*)? The answer is that membranes of vesicles contain special pumps that effectively transport small-molecule transmitters into the lumen of the vesicle. Because all transmitter vesicles contain ATP, when a transmitter is released, ATP and its catabolites, adenosine and AMP, are also released. Finally, the most recent substances to be recognized as transmitters are molecules that are membrane-soluble. Thus, nitric oxide (NO) and arachidonic acid pass from one neuron to another.

IV. NEUROPEPTIDE TRANSMITTERS

Neuroactive peptides, typically 3–15 amino acid residues in length, are processed from precursor

polyproteins that contain about 200 residues. In many precursor polyproteins there are multiple copies of a single neuropeptide sequence. These can be cut from the polyprotein so that several copies of the same peptide are produced, thereby amplifying the concentration of the peptide transmitter released. A polyprotein also can contain the amino acid sequences of several different neuropeptides. These, when cut from the precursor, will all reside in the same vesicle. As a consequence, a set of neuropeptides, usually with synergistic action, is released at the same synapse from a single vesicle.

Differential processing of a polyprotein precursor can result in the production of different neuropeptides. Thus, for example, bulky glycosylation, which takes place during the passage of the nascent polypeptide through the endoplasmic reticulum and Golgi, can block proteolytic cleavage at specific sites in the precursor and result in different sets of neuropeptides. Differential processing occurs with pro-opiomelanocortin (POMC), a precursor of one of the three distinct opioid genes. In the hypothalamus, β-endorphin and α-melanocyte-stimulating hormone (α-MSH) are formed; in the anterior pituitary, POMC yields corticotropin.

The proteases responsible for processing polyproteins into neuropeptides are present within the endoplasmic reticulum and Golgi apparatus. These enzymes are related to the well-known digestive proteases, trypsin, chymotrypsin, and pepsin, which are synthesized in the endoplasmic reticulum and packaged in secretory granules of the pancreas. Trypsin and chymotrypsin are called serine proteases because the hydroxyl group of a serine residue in the enzyme's catalytic site participates in the proteolytic reaction. The other major families of proteases are related to pepsin, a thiol peptidase, and carboxyprotease, proteases that contain a zinc ion at their catalytic center. Common sites of cleavage in the polyprotein are between an amino acid residue X and a pair of dibasic residues (for example, X-Lys-Lys or X-Arg-Lys) or between X and a single basic residue.

The great diversity of neuropeptides prevents a comprehensive description of each of the approximately 100 peptides known or even of particular peptide families. The opiate family is representative, however. There are three distinct genes that encode three different polypeptide precursors: opiocortin, enkephalin, and dynorphin. Proteolytic processing of each polyprotein precursor gives rise to peptides with narcotic properties, all of which contain the amino acid sequence, Tyr-Gly-Gly-Phe. Because the three genes are similar, it is thought that they all stem from a single ancestral gene. Even so, in humans the three opioid genes are each situated on different chromosomes.

The synthesis and processing of peptide neurotransmitters take place exclusively in the cell body of neurons. Secretory vesicles containing neuropeptides, which are similar to secretory granules in other cells, bud off from the Golgi apparatus. These large vesicles (60–175 nm in diameter) appear dense-cored in the electron microscope because their contents stain with osmium salts and, therefore, are electron-dense. The vesicles are moved out of the cell body and along the axon to nerve terminals by the process of fast axoplasmic transport. Once they bud off the Golgi apparatus, the vesicles cannot be refilled, nor is there any mechanism for new synthesis of the peptide. Consequently, once the contents of a vesicle are released, the vesicle membrane cannot be reused: the release of neuropeptides thus is a one-time-only situation.

Release of neuropeptides occurs by exocytosis, which, like secretion, is triggered by a rise in intracellular Ca^{2+} ion concentration. The Ca^{2+} ion concentration, which is increased when the neuron is stimulated, must rise throughout the nerve terminal. Typically, the neuron must be stimulated for a relatively long period of time to elevate the concentration of Ca^{2+}. There are no specialized sites at which these large vesicles undergo exocytosis. Because exocytosis can occur throughout the nerve terminal, neuropeptides are released over a large target area.

Thus, transmission with neuropeptides is slow in onset, covers a broad target area, and is long-lasting. The action of neuropeptides is long-lasting first because the binding constants of postsynaptic receptors tend to be quite low (therefore, a low concentration of the peptide is effective) and, second, because the chief mechanism for removing the peptides is diffusion, which tends to be quite slow with molecules the size of these peptides (see later discussion).

Another important reason why the actions of neuropeptides are slow and long-lasting is because the postsynaptic effects of the peptides are produced by second messenger cascades. Unlike the opening or closing of ionotropic receptors, which results from rapid allosteric changes in the conformation of a channel protein, actions involving second messengers typically require a series of discrete molecular steps to bring about a physiological change. Almost all postsynaptic receptors for neuropeptides are metabotropic seven-transmembrane-spanning proteins that are coupled to G-proteins. Each neuropeptide usually has

more than one receptor. Thus, there are three for opioids (δ, κ, and μ), all cloned. Morphine and related drugs produce narcosis (relief of pain), sleepiness, euphoria, and constipation.

An important technique for demonstrating the second criterion for a neurotransmitter—its presence in a neuron's terminals—is immunocytochemistry. Neuropeptides are excellent antigens for raising antibodies. Specific antibodies are useful for locating immunoreactivity in tissue sections of nervous tissue. For example, an antipeptide antibody can be raised by immunizing a rabbit. That antibody can be applied to a tissue section, where it binds strongly to the components in the cell containing the antigen. Once bound, the antibody can be located by applying a second antibody against the immunoglobulin of the rabbit antipeptide antibody, say, goat antirabbit antibody. These secondary antibodies are available commercially labeled with fluorescent dyes (e.g., fluoroscein and rhodamine), which permits the localization of neuropeptides by fluorescence (light) microscopy. Immunocytochemistry with the electron microscope is made possible by using antibodies linked to colloidal gold particles, which are electron-dense. These particles can be made with different diameters. Therefore, it is possible to detect two different antibodies simultaneously on the same tissue section, with each antibody being tagged with gold particles of different size. In the light microscope, neuropeptide immunoreactivity typically is intense over the cell bodies and terminals of neurons. In the electron microscope, it is easy to show that vesicles are the subcellular organelles that are most heavily labeled.

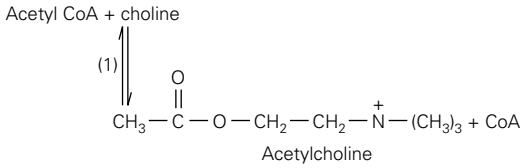
V. SMALL-MOLECULE NEUROTRANSMITTERS

Unlike neuropeptides, small-molecule neurotransmitters are synthesized in cytoplasm throughout the neuron. Thus, they can be made in nerve terminals as well as in the cell body. Small-molecule neurotransmitters are not synthesized within the major membrane system of the cell: the endoplasmic reticulum, the Golgi apparatus, or any of the vesicles that are derived from the Golgi apparatus. Rather, they are produced in short enzymatic pathways that branch off of the major pathway of intermediary metabolism. Typically, one enzyme in the biosynthetic pathway is expressed only by neurons that make use of that particular neurotransmitter (Table II). The presence of that enzyme in a neuron can be used as a biochemical criterion for that particular transmitter. In effect, it is evidence for the first neurotransmitter criterion, that the substance is synthesized by the neuron.

A. Amines

1. Acetylcholine (ACh)

ACh is formed in a single enzymatic step. The enzyme, choline acetyltransferase, catalyzes the esterification of choline by acetyl-CoA.



The transferase is specific to cholinergic neurons and is not expressed in any other cell type. (The term cholinergic is used to denote a cell that releases ACh as a neurotransmitter. Similarly, glutaminergic, dopaminergic, and serotonergic indicate that a neuron releases glutamate, dopamine, or serotonin, respectively. If a cell responds to ACh, that cell is called cholinoceptive, a term used infrequently for the other neurotransmitters; e.g., "dopaminoceptive" is unusual.) The formation of ACh is limited by the supply of choline. Choline is not made in nervous tissue, but must be obtained through the cerebrospinal fluid from dietary sources or recaptured from the synaptic cleft from the ACh released and hydrolyzed by the enzyme acetylcholinesterase (see later discussion).

There are two general classes of acetylcholine receptors (AChR): nicotinic, responding to the alkaloid nicotine, and muscarinic, responding to the mushroom poison, muscarine. ACh is excitatory at the neuromuscular junction, where it binds to postsynaptic nicotinic AChRs. As we saw with Loewi's experiment, it is an inhibitory (parasympathetic) transmitter to the heart through muscarinic AChRs. In the periphery, ACh is also the transmitter for all preganglionic neurons of the autonomic nervous system. In the brain, there are many cholinergic systems, for example, cholinergic neurons in the nucleus basalis have widespread projections to the cerebral cortex.

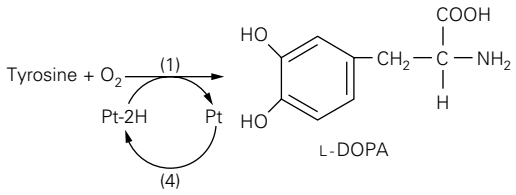
Nicotinic AChRs are *ionotropic*, meaning that, when they bind ACh, they open up to pass ions from the extracellular space into the postsynaptic neuron. Muscarinic AChRs are *metabotropic*. These receptors activate various second messenger pathways to

produce biochemical changes within the postsynaptic neuron. Thus, as with other neurotransmitters, ACh can excite or inhibit depending on the postsynaptic receptor.

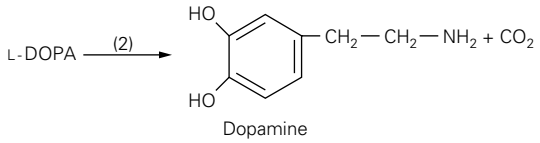
2. Biogenic Amines

The biogenic amine transmitters include the catecholamines [dopamine, norepinephrine (NE), and epinephrine], the indoleamine serotonin (5-hydroxytryptamine, 5-HT), and the imidazole histamine. Synthesis of the catecholamines and 5-HT is catalyzed by a set of enzymes that are similar in structure and mechanism. Because of amino acid sequence similarity, these enzymes are believed to come from a common ancestral molecule. The first enzymes in the synthesis of catecholamines and 5-HT are oxidases that require a pterin (tetrahydrobiopterin, THB) cofactor. These enzymes are specific and rate-limiting.

a. Dopamine For the synthesis of catecholamines, the essential amino acid L-tyrosine is converted to L-dihydrophenylalanine (L-DOPA).

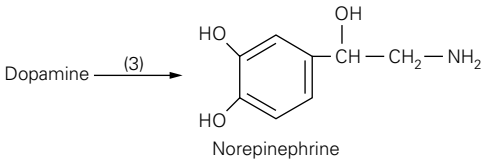


Tyrosine must be supplied in the diet and taken up by neurons. Next, L-DOPA is decarboxylated by amino acid decarboxylase to the transmitter, dopamine.



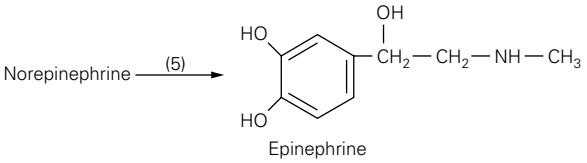
There are five types of dopamine receptors, all of which are metabotropic. Dopaminergic neurons are abundant in the substantia nigra and the ventral tegmental area; dopamine cells project to the basal ganglia, hypothalamus, and the limbic system to regulate voluntary movement, thinking, and planning. Dopamine plays an important role in the reward system and in addiction.

b. Norepinephrine NE is produced by the introduction of a hydroxyl group into the carbon chain of dopamine by dopamine β-hydroxylase.



NE is present in neurons of the locus ceruleus, which have widespread projections to the cerebral cortex, cerebellum, and spinal cord. NE is the transmitter used by the postganglionic neurons of the sympathetic nervous system.

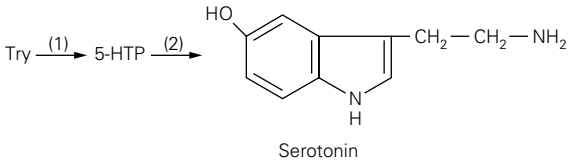
c. Epinephrine In the adrenal medulla, NE is converted to epinephrine by methylation. This reaction is catalyzed by phentolamine-*N*-methyltransferase and requires *S*-adenosylmethionine as a methyl donor.



Only a few neurons in the central nervous system use epinephrine. These are located together with noradrenergic cells in the medulla oblongata, solitary tract nucleus, and medial longitudinal fascicle.

As we have seen, the synthesis of epinephrine is carried out in four enzymatic steps, the first two being common to dopamine, NE, and epinephrine, the first three being common to NE, and epinephrine, and the last needed only for the synthesis of epinephrine. Why are NE and epinephrine not made in dopaminergic neurons? The particular neurotransmitter produced is determined by the absence of the next enzyme. Thus, no products past dopamine are produced in dopaminergic neurons because dopamine β-hydroxylase is absent. Similarly, epinephrine is not produced in neurons that lack the methyltransferase.

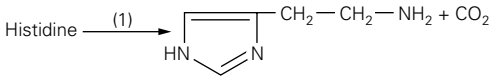
d. Serotonin (5-HT), an Indoleamine The essential amino acid L-tryptophan is oxidized to 5-hydroxytryptophan (5-HTP) by tryptophan hydroxylase, an enzyme homologous to tyrosine hydroxylase. The amino acid decarboxylase that operates in the catecholamine pathway also decarboxylates 5-HTP to serotonin.



Serotonin

About 13 5-HT receptors have been characterized. Only one is ionotropic. Transmission with 5-HT is critical for sleep, mood, sexual behavior, and aggressive behavior.

e. Histamine Histamine is formed by decarboxylation of the amino acid L-histamine catalyzed by histidine decarboxylase.



Histamine

There are only about 100,000 neurons in the brain that are histaminergic; they are situated in the posterior hypothalamus and have widespread projections. Three types of histamine receptors have been identified, all metabotropic. Central histaminergic neurons control appetite and regulate the secretion of pituitary hormones. In the periphery, histamine is familiar as a hormone that is important in the inflammatory reaction and in the activity of exocrine glands, for example, in the secretion of acidic gastric juice.

B. Amino Acids

1. L-Glutamate

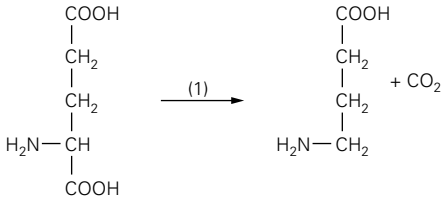
This common amino acid is synthesized from α-ketoglutarate by transamination or by the hydrolysis of glutamine. At least half of all of the synapses in the brain are glutaminergic, and most of these are excitatory. Five types of excitatory glutamate receptors have been identified. These are all ionotropic and have been classified by their sensitivity to various glutamate agonists. An important example is the NMDA (*N*-methyl-D-aspartate) receptor. This receptor permits the passage of Ca^{2+} as well as Na^{+} and K^{+} ions only when the neuron is significantly depolarized. The NMDA receptor is thought to play a key role in learning and memory. Other receptors for glutamate are metabotrophic and mediate modulatory synaptic actions.

Under certain pathological conditions such as stroke or injury, large amounts of glutamate are released into the brain, which activate these glutamate receptors and cause neuronal death. This process is called excitotoxicity and is a significant way in which brain tissue is damaged during a stroke. Many neurons that are excited by glutamate are also excited by L-aspartate when it is applied. L-Aspartate fulfills all of the criteria of a neurotransmitter except one: it is not released from presynaptic neurons.

Released glutamate is removed from the synaptic cleft by a specific uptake mechanism in the membrane of glutaminergic neurons and surrounding glial cells. These transporters pump the transmitter molecules in against a concentration gradient and, therefore, require the energy of ATP. In glial cells, the glutamate is converted to glutamine by the enzyme glutamine synthase. The glutamine is then transported into neurons to be hydrolyzed back to glutamate.

2. GABA

γ-Amino butyric acid (GABA) is the chief inhibitory neurotransmitter in the brain. It is formed from glutamate by decarboxylation with glutamic acid decarboxylase (GAD) using pyridoxal phosphate as a cofactor.



Glutamate GABA

Antibodies against GAD are used to identify GABAergic neurons.

3. Glycine

Glycine is synthesized from serine. It is the major inhibitory neurotransmitter in the spinal cord and retina. Receptors for GABA and glycine allow the influx of Cl^{-} ions, which hyperpolarizes the postsynaptic cells.

C. Purines

ATP is present in high concentrations in transmitter vesicles, both for neuropeptides and for small-molecule transmitters. ATP is synthesized in mitochondria

and is abundant in cytoplasm: it gets pumped into vesicles. Because it is present in vesicles, it is routinely coreleased with neurotransmitters. In some postsynaptic cells, there are receptors that respond to ATP, adenosine, or AMP where they modulate the transmission of other neurotransmitters. Thus, they can inhibit by activating autoreceptors. Receptors are present in the vas deferens, gut, smooth muscle, and neurons of the dorsal horn of the spinal cord. There are two classes of purine receptors, P1 and P2. P1 receptors are sensitive to adenosine and AMP and are all metabotropic. P2 receptors respond to ATP and AMP; a few of these are ionotropic.

Purinergic transmission illustrates an important aspect of chemical synaptic transmission. The abundant release of a substance is necessary, but not sufficient evidence that the substance is a transmitter, even though that substance has been shown to act as a transmitter elsewhere in the body. A postsynaptic receptor must also be present. A substance is not a neurotransmitter if it is released into an area that lacks a receptor for it. It may seem improbable that this occurs frequently, but ATP is actually released at all synapses.

VI. THE SYNAPTIC MESSAGE IS ENCODED IN THE POSTSYNAPTIC RECEPTOR

It is important to appreciate the nature of the information being sent during synaptic transmission. Release of a neurotransmitter is triggered when a neuron is depolarized with the consequent influx of Ca^{2+} ion. The particular transmitter substance released does not determine the type of action in the target cell. That is determined entirely by the postsynaptic receptor. Thus, whereas the release of transmitter is permissive, the receptor is determining. All transmitters have more than one type of receptor. As we have seen, ACh activates a variety of ionotropic receptors, all of which are excitatory. Its metabotropic receptors can be inhibitory, like those that Loewi studied in the heart, or excitatory, as those in the gut, bladder, bronchi, and iris. Thus, the actions of ACh can be excitatory or inhibitory. Another example is glutamate. In the hippocampus, glutamate activates two types of ionotropic receptors, the NMDA and the non-NMDA [AMPA (α-amino-3-hydroxy-5-methylisoxazoleproprionic acid), quisqualate, and kainate] receptors, and a metabotropic receptor. At normal resting potentials, the dendritic spines of a hippocampal neuron are briefly depolarized by a pulse of glutamate, because non-NMDA receptors respond but NMDA receptors do not. When the dendrites are depolarized for a longer time, the NMDA receptors are activated, causing prolonged Ca^{2+} entry and inducing a series of molecular changes within the dendrite. These changes enhance the responsiveness of the synapse, which can persist for many hours. This phenomenon is called long-term potentiation (LTP).

VII. SYNAPTIC VESICLES

Our thinking about neurotransmission was strongly influenced by two important discoveries made at midcentury. By using electrophysiological techniques to study nicotinic cholinergic transmission (primarily at the neuromuscular junction), Bernard Katz and his co-worker discovered that transmission is quantized. The postsynaptic responses (excitatory postsynaptic potentials, EPSPs) occur in discrete units of strength, presumably because the presynaptic component of the synapse releases ACh in specific units of about 3000 molecules. Thus, depending on the intensity of stimulation, it was estimated that 3000, 6000, 9000, etc. molecules of the neurotransmitter are released. At the same time, Eduardo De Robertis, using the electron microscope, examined the fine structure of synapses. He observed that nerve endings typically have a cluster of small (0.50 nm in diameter) vesicles crowded over a thickened membrane specialization. This observation prompted the idea that guided subsequent research on synaptic transmission. Katz proposed that his quantum is the amount of ACh contained in a single small vesicle when it is emptied into the synaptic cleft. Depending on the intensity with which the neuron is stimulated, one or more vesicles would participate in transmission.

Unlike the larger secretory granules that carry neuropeptides, the small vesicles appear clear or electron-lucent in electron micrographs. Examination of presynaptic elements that release small-molecule neurotransmitters other than ACh reveals a similar morphology. Synaptic vesicles can be isolated intact using differential ultracentrifugation. One convenient preparation, developed independently by both Victor Whittaker and De Robertis, is called synaptosomes. Nervous tissue is gently ground in a glass–glass tissue grinder. During this procedure, a large proportion of nerve endings are twisted off their axons to become closed spheres. These spheres contain the presynaptic components of synapses (with frequent contamination of some of the postsynaptic elements). After these

synaptosomes are isolated, they can be broken by osmotic shock to release the small vesicles. By using this technique, the content of ACh in one synaptic vesicle was by biochemical assay found to match the amount of neurotransmitter present in a quantum estimated electrophysiologically.

Unlike the neuropeptides, small-molecule transmitters are not synthesized and processed within membranes of the endoplasmic reticulum. Rather, they are made in the cytoplasm of nerve terminals (as well as in the cell body, axon, and dendrites). Their concentration in vesicles (0.1–0.5 *M*) is much greater than that in cytoplasm. Therefore, these transmitters must be taken up against considerable concentration gradients. For this purpose, there are at least four different types of active transport systems in vesicle membranes that pump in potential transmitters. These systems are ATPase pumps that use the energy of ATP to create proton gradients (the contents of the vesicles are acidic) to trap the positively charged amine molecules within the vesicle.

The membranes of some large, dense-cored vesicles also contain pumps for small-molecule transmitters. Therefore, these vesicles can contain both neuropeptides and small-molecule neurotransmitters. In addition some neurons contain both large vesicles and small vesicles. As a result, both types of transmitter can be released from the same neuron. The discovery of this phenomenon (called coexistence or cotransmission) caused considerable astonishment when it was first discovered in the 1970s. Neurobiologists were surprised because the discovery of cotransmission appeared to disobey a law called Dale's principle. In 1935, Dale suggested that all parts of a neuron would make the same neurotransmitter (because of the "unity of biochemistry"). Later this idea became much more stringent. Dale's principle became "one neuron, one neurotransmitter substance." Because we now understand how peptides and small-molecule transmitters are packaged into vesicles, we should not be troubled that a small-molecule transmitter can be packaged in both small synaptic vesicles and in large, dense-cored vesicles but that neuropeptides exist only in the large vesicles.

The two types of neurotransmitters can be released differentially. As discussed earlier, large dense-cored vesicles undergo exocytosis when the concentration of Ca^{2+} ion is elevated throughout the terminal. This condition occurs during sustained stimulation. If the large vesicles contain a small-molecule transmitter as well as a neuropeptide, both transmitters will be coreleased. As might be expected from evolutionary considerations, two coreleased transmitters usually have synergistic actions on target cells. As an example, motor neurons release calcitonin gene-related peptide (CGRP) together with ACh. ACh causes the ionotropic AChRs to open and produce muscle contraction, and CGRP stimulates adenylyl cyclase to initiate cAMP-dependent protein phosphorylation within the muscle fiber that both enhances the force of contraction and activates energy metabolism.

Small synaptic vesicles, which are derived from early endosomes, exclusively package small-molecule transmitter substances. Their membranes contain special proteins (synaptotagmin, synaptophysin, synaptobrevin) that are required for the rapid membrane fusion that these vesicles undergo during exocytosis. These constituents belong to families of proteins that mediate the interaction of membranes in all cells, such as the budding off of transport vesicles from the endoplasmic reticulum, their fusion with the Golgi apparatus, and vesicles shuttling between the Golgi stacks and between the Golgi and the plasma membrane. Characteristic of the small synaptic vesicles is their ability to fuse with the synaptic plate membrane specialization to open and release their contents into the synaptic cleft. Exocytosis takes place at specialized docking sites, which are arrayed regularly along the synaptic plate. As first described by Rodolfo Llínas, just adjacent to each docking site is a specialized Ca^{2+} ion channel. Depolarization produced by brief stimulation will result in the rapid influx of Ca^{2+} ions near the docking site, rapidly raising the local concentration high enough to cause membrane fusion.

In summary, the cell biology of the two vesicle types to a large extent determines the physiology of the synaptic transmissions that they mediate. Small synaptic vesicles discharge rapidly after the neuron has been briefly depolarized. Only small-molecule transmitters are released. Because the synthesis of these transmitters can take place in nerve terminals, synaptic vesicles can be used many times and new transmitter can be pumped into the recycled vesicle. This results in rapid and repeated transmission. In contrast, the large vesicles require relatively prolonged stimulation to be released. There are no specialized proteins in their membrane, so exocytosis occurs anywhere in the nerve terminal. Release is sustained, because the built-up Ca^{2+} ion concentration remains elevated for relatively long periods of time throughout the terminal. Large vesicles can release both neuropeptides and small-molecule transmitters. Once used, however, these vesicles cannot be used again because there is no mechanism for refilling with neuropeptides at nerve terminals. Thus, transmission is slow and long-lasting.

After the work of Katz and De Robertis it became almost axiomatic that a substance must be packaged in vesicles and released at nerve terminals in order to be a true neurotransmitter. Whereas it is prudent to keep this axiom in mind, more recent discoveries indicate that this traditional view must be expanded. Exocytosis is not the only mechanism by which small-molecule neurotransmitters can be released. Thus, dopamine (in the substantia nigra) and GABA (in the retina) can be released from nerve cell bodies. Release occurs by reversal of transporter pumps. If this nonexocytotic release affects a nearby target cell, the process must be called neurotransmission.

VIII. MEMBRANE-SOLUBLE MESSENGERS

Another type of nonvesicular neurotransmission is mediated by small molecules that are membrane-soluble. The best studied are the gas nitric oxide (NO) and the fatty acid arachidonate and its metabolites. These molecules diffuse through membranes and do not need vesicles to be released. Both NO and arachidonic acid have long been known to play important physiological roles in tissues other than the nervous system: NO primarily as a regulator of contractility of blood vessels and arachidonate in inflammation. NO is formed by the oxidation of arginine catalyzed by the enzyme nitric oxide synthase and an electron donor (FAD, NADPH, or THB) as cofactor. The aminoacid citrulline is produced.

Arachidonic acid is released from membrane phospholipids by the receptor-mediated activation of phopholipase A_2 through a G-protein. The fatty acid released is then metabolized through two general pathways: (1) lipoxygenase, of which there are several (5-, 8-, 12-, 15-), and (2) cyclo-oxygenase. Metabolites from both of these pathways have been shown to be active in other tissues. Thus far, only 5-, 8-, and 12-lipoxygenase products have been implicated in synaptic transmission.

It has been proposed that both NO and arachidonic acid act as retrograde messengers. Thus, in LTP, glutamate released from the presynaptic neuron would, in addition to depolarizing the postsynaptic cell, also activate the synthesis of membrane-soluble messengers, which then would diffuse back to the presynaptic element to enhance further release of glutamates.

IX. REMOVAL OF TRANSMITTERS

There are three ways by which transmitters are removed from the synaptic cleft: (1) enzymatic degradation, (2) specific uptake by neurons and glia, and (3) diffusion.

A. Enzymatic

Removal of ACh is primarily enzymatic. Acetylcholinesterase is anchored extracellularly to the postsynaptic membrane near the AChRs and hydrolyzes the transmitter to acetate and choline. The enzyme is so effective that on average an ACh molecule binds only once to a receptor. Thus, hydrolysis of ACh serves to punctuate the message; it also is a conservation mechanism (see later discussion).

Both small-molecule and peptide transmitters are degraded by enzymes, but these do not play an important role in synaptic transmission. A clinically important example is monoamine oxidase (MAO), which is located in the outer membrane of mitochondria. MAO catalyzes the oxidative deamination of catecholamines to the corresponding aldehyde. Another nonspecific degradative enzyme is catechol-*O*-methyltransferase (COMT), which is present in the blood. The transferase inactivates catechols by methylating one of the ring hydroxyl groups. Unlike acetylcholinesterase, these enzymes are not located strategically at synapses, and they operate over a long time relative to synaptic transmission. Nevertheless, physiologically they are important because they ultimately contribute to the regulation of the amount of transmitters in the brain. Regulation of transmitter concentration is thought to be important in some psychiatric conditions, for example, aggression and depression.

B. Specific Uptake

As described earlier, choline is not synthesized in nervous tissue. The choline produced by the hydrolysis of ACh by acetylcholinesterase is taken back up into the presynaptic neuron by a transport mechanism specific to cholinergic neurons and is used for the resynthesis of transmitter. As also described previously for glutamate, the small-molecule neurotransmitters are taken up by high-affinity transporter mechanisms. Uptake by means of specific transport is the most

important way classical transmitter molecules are removed from the synaptic cleft. Neuropeptides are not taken back up into the neuron and are removed by diffusion and by cleavage by extracellular peptidases.

C. Diffusion

Some transmitter is removed by diffusion. With small molecules this process is relatively fast; with peptides, on the other hand, the slow speed of diffusion contributes to the long-lasting quality of peptidergic transmission.

Nociceptors

LORNE M. MENDELL
State University of New York, Stony Brook

GLOSSARY

Aδ-fiber A sensory neuron whose axon in the peripheral nerve is lightly myelinated. These axons have the lowest conduction velocity among myelinated axons.

allodynia The pain elicited by a normally nonpainful stimulus after inflammation or damage to peripheral or central neurons.

C-fiber A sensory neuron whose axon in the peripheral nerve is unmyelinated. These axons are the slowest conducting in the peripheral nerves.

dorsal horn The region of spinal cord gray matter in which nociceptive neurons terminate. This region is generally divided into laminae (laminae I–V). Lamina I is also known as the marginal zone, lamina II as the substantia gelatinosa, and laminae III–V, as nucleus proprius.

dorsal root ganglion The location of cell bodies of sensory neurons innervating the body. A corresponding ganglion for the face is the trigeminal or gasserian ganglion.

dorsal root ganglion cell A sensory neuron consisting of a cell body in the dorsal root ganglion, a peripheral process innervating the peripheral tissues (skin, muscle, etc.), and a central process projecting into the spinal cord to synapse on postsynaptic neurons.

hyperalgesia The increase in perceived intensity of a normally painful stimulus after injury.

nociceptor A class of sensory neuron responding selectively to tissue damage in its receptive field.

sensitization A process that decreases the stimulus intensity required for a nociceptive response or that increases the magnitude of the nociceptive response elicited by a given nociceptive stimulus.

Nociceptors belong to a specialized class of sensory fibers that transmit information concerning stimuli that are potentially damaging to the organism; they generally elicit a response of pain. This article discusses the properties of this important class of neuron, specifically its specialized physiology, anatomy, and biochemistry. In addition to acutely signaling the presence of a potentially damaging stimulus, nociceptors can exhibit significant plasticity in response to injury in their receptive field, and this will be discussed in the context of persistent or chronic pain.

I. INTRODUCTION

Nociceptors are sensory fibers that respond to stimuli that are potentially damaging to the organism. In practice this can mean a variety of stimuli, ranging from intense pressure, extremes of temperature, to inflammation. Impulse activity in nociceptors activates central circuits that can lead to what is subjectively referred to as *pain*. It is necessary to specify "can lead" because neural systems originating in the midbrain and medulla and projecting to the spinal cord can suppress this input at the level of the spinal cord or medulla where impulses from nociceptors first

activate neurons in the central nervous system. Other more complex mechanisms at the thalamic and cortical levels also can affect the perception of the input from nociceptors. Thus, a stimulus that elicits pain under some circumstances does not always do so. Conversely, as will be discussed later, stimuli that usually do not elicit a report of pain can do so under certain conditions.

Effective nociceptive inputs instigate removal of the affected area from the source of the potentially damaging stimulus and help to protect the injured area from further damage, i.e., to promote healing of the tissue. Removal of the affected area can occur via a combination of segmental reflex mechanisms (e.g., via a flexor reflex) as well as more conscious behavior. However, in many cases the precipitating event can also result in persistent changes in the nociceptors that outlast the initiating event. Remarkably, changes can also occur in sensory neurons normally responding only to nonnociceptive stimuli, such that they can elicit nociceptive reactions. In some cases these changes are adaptive, e.g., keeping the skin cool after sunburn or immobilizing a limb after muscle damage. However, in other cases the changes can last well beyond the time when it is useful, and this chronic pain can be extremely maladaptive, e.g., in postherpetic neuralgia.

It could be anticipated that afferent fibers transmitting nociceptive information from the periphery would be among the smallest because of early findings that the stimulation of peripheral nerves in humans elicited reports of pain only when the electrical stimuli were sufficiently intense to activate small myelinated (Aδ) or unmyelinated (C) fibers. However, early work using either direct or indirect methods to monitor the electrophysiological responses of small-diameter fibers yielded only scattered reports of small fibers activated selectively by intense stimuli. This raised the possibility that nociceptive stimuli were coded primarily by increased frequency of firing in primary afferent fibers also responding to innocuous stimuli, in effect the possibility that discharge *pattern* in afferent fibers is the prime neural representation of noxious vs nonnoxious stimuli. The development of techniques to record reliably from small-diameter fibers in peripheral nerves by Perl and his associates led to a clear demonstration of several classes of small myelinated and unmyelinated fibers innervating receptors that respond exclusively to stimuli that are potentially damaging to the organism. Nociceptors have been found in skin, muscle, joints, and viscera (see Section III). It is activation of these fibers rather than specific impulse discharge patterns in fibers also responding to innocuous stimuli that signals the occurrence of a stimulus that is nociceptive. This is true under normal conditions; however, after certain injuries or under certain pathological conditions, fibers normally responding to gentle stimulation can elicit pain (allodynia; see Section VIII).

Although nociceptors are restricted largely to sensory neurons with small axons, not all sensory neurons with small axons are nociceptors. A group of sensory neurons with Aδ-axons innervates sense organs in the skin known as Down hairs (D-hairs) that are exquisitely sensitive to innocuous mechanical stimulation. Unmyelinated C-fibers can also innervate receptors responding to innocuous mechanical or thermal stimulation. Conversely, cells with Aβ-axons innervating high-threshold mechanoreceptors have been reported. These Aβ-nociceptors tend to be among the more slowly conducting Aβ-fibers.

II. UNIQUE ANATOMICAL AND BIOCHEMICAL PROPERTIES OF NOCICEPTORS

Although the cell bodies of nociceptors and low-threshold mechanoreceptors are located in the sensory ganglia [the dorsal root ganglion (DRG)] or similar structures for cranial nerves (e.g., the gasserian ganglion of the trigeminal nerve), they exhibit numerous differences in their projections and in their chemistry that determine their properties as nociceptors (Fig. 1). All of these contribute to the basic characteristics of nociceptors and nociceptive pathways, including their high threshold and their ability to be sensitized after certain types of stimuli.

From the early functional studies indicating that axons of nociceptors are among the smallest in peripheral nerves, it was believed that the cell bodies of nociceptive afferents would be among the smallest, and this has been confirmed with correlative electrophysiological and anatomical studies of individual sensory neurons. However, there is considerable scatter in soma size for axons of a particular group (e.g., Aδ-axons), making soma size somewhat less reliable as an indicator of nociceptive vs nonnociceptive neurons than axon size. Nonetheless, many workers have considered a soma diameter of 30 μm to be a dividing line below which the population is highly enriched in nociceptors.

Various markers have been found to correlate with cell size, and thus putatively to correspond to cells with nociceptive and nonnociceptive function. Many investigators have divided the dorsal root ganglion cell

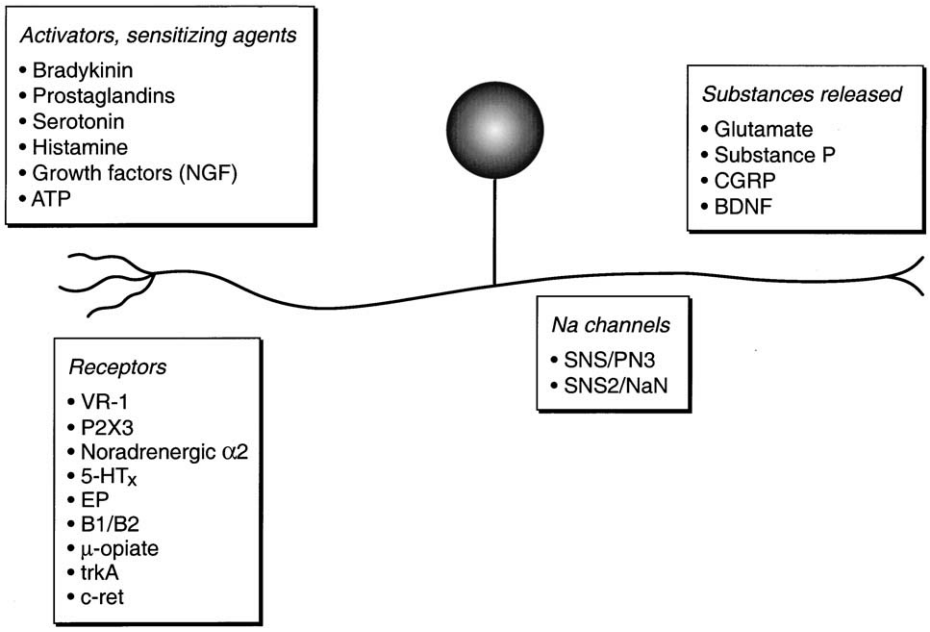

Figure 1 Chemical specialization of nociceptive sensory neurons that distinguishes them from nonnociceptive afferents. These specializations are divided into activators and sensitizing agents, receptors, Na channels, and released substances. In the latter group, glutamate is not unique to nociceptive afferents, but as discussed in the text it activates specialized glutamate receptors that result in the unique central action of nociceptors.

population into small dark and large light cells on the basis of their appearance in Nissl-stained sections. The large light cells stain with RT-97, an antibody against the phosphorylated form of the 200-kDa neurofilament subunit, whereas the small dark ones do not. Cells staining with RT-97 are believed to have myelinated axons ranging over the entire size spectrum (Aβ and Aδ).

A number of biochemical labels are present only in small somata and, thus, presumptively those that are nociceptors. These markers include the lectin IB4, the enzyme fluoride-resistant acid phosphatase (FRAP), trkA (the high-affinity receptor for NGF), c-ret (the receptor for glial-derived neurotrophic factor, GDNF), and various peptides such as substance P (SP), calcitonin gene-related peptide (CGRP), and somatostatin. However, none of these markers is present in the entire population of small cells, and some such as CGRP are also present to some degree in larger cells. Thus, the population of small DRG neurons is quite varied in its expression of these and other markers. Loss of specific functional capacity when a specific gene is eliminated, i.e., in "knockout" mice, suggests that the expression of some of these markers corresponds to specific psychophysical modalities, e.g., substance P expression relates to the ability to sense very intense thermal stimuli.

Although small DRG cells are highly varied in their expression of FRAP, substance P, etc., some of these markers tend to be frequently coexpressed, whereas others are coexpressed very infrequently. For example, c-ret, IB-4, and FRAP tend to be coexpressed and these cells do not express peptides. Another group of cells expresses trkA as well as peptides such as CGRP and/or substance P. The population of cells coexpressing markers in these different groups is relatively small. The trkA/peptide-expressing cells include some with small myelinated and some with unmyelinated axons, whereas the IB4/c-ret/FRAP-expressing neurons have largely, if not exclusively, unmyelinated axons.

Nociceptive neurons are also unique in their projection into the central nervous system. Numerous evaluations of their termination sites, including the location of peptide-expressing terminals as well as the transport of various materials such as horseradish peroxidase (HRP) in physiologically identified nociceptive afferents impaled at the dorsal root entry zone, have demonstrated that they terminate largely though not exclusively in the most superficial laminae of the dorsal horn. Small myelinated nociceptive afferents terminate in lamina I (also known as the marginal zone) and lamina V (the deepest part of the nucleus proprius), whereas unmyelinated afferents terminate in lamina II.

Many workers have subdivided lamina II into inner and outer portions (lamina II_o and lamina II_i). The IB4/c-ret/FRAP-expressing neurons terminate largely in lamina II_i, whereas the peptide-containing neurons terminate in laminae II_o and I. Physiological evidence suggests that cells in lamina II_i respond almost exclusively to nonnoxious stimulation. This would indicate that the afferent population projecting into this zone responds to nonnociceptive stimuli. However, many IB4-expressing neurons express the receptor for capsaicin (VR1), which would suggest that they are responsive to noxious heat and chemical stimulation, specifically protons. This apparent discrepancy remains to be resolved, but it is important to recall that, in this as in other studies, the recordings from central neurons were made in reduced preparations where their properties may be distorted.

III. PHYSIOLOGICAL PROPERTIES OF NOCICEPTORS IN DIFFERENT TISSUES

A. Skin

Nociceptors innervating the skin can be differentiated into two major groups on the basis of the conduction velocity of the axon transmitting impulse discharge from the skin to the spinal cord. These are the small myelinated Aδ-fibers and unmyelinated C-fibers. Two groups of Aδ-nociceptive afferents have been described. Both discharge in response to high-intensity, potentially noxious mechanical stimuli but can be distinguished on the basis of their response to noxious heat. One group with a high thermal threshold ($>53^{\circ}$C) exhibits a long response latency to heat stimuli and tends to sensitize in response to successive thermal stimuli. These are known as type I AMH (A mechanoheat) receptors, but because of their high thermal threshold this response is often ignored; thus, they are denoted as high-threshold mechanoreceptors (HTMs). The other group, known as type II AMH fibers, has a lower heat threshold (46°C), tends to respond quickly, and desensitizes in response to repeated stimuli. Some of these fibers exhibit sensitivity to chemical stimuli. Nociceptors innervated by C-fibers also exhibit responses to noxious mechanical and thermal stimuli (threshold averaging about 46°C) and often to chemical stimuli such as lowered pH and bradykinin. These sensory neurons are often referred to as polymodal nociceptors.

Many investigators have identified a population of small-diameter afferent fibers whose terminations in the skin can be identified by electrical stimulation but that exhibit no response to peripheral stimuli of any known modality. These "silent" nociceptors (presumably nociceptors whose sensitivity can be brought to a detectable level by sensitizing stimuli) represent an extreme of the spectrum of nociceptive thresholds in normal skin.

B. Muscle

Muscle afferent fibers innervating endings activated by potentially damaging (nociceptive) stimuli also transmit their impulses to the spinal cord via small myelinated and unmyelinated afferents. These fibers are generally identified by the Roman numeral system in keeping with D.P.C. Lloyd's original classification of muscle afferents (I–IV). Thus, the small myelinated afferents are known as group III (equivalent in fiber diameter to Aδ-fibers) and unmyelinated afferents are known as group IV (equivalent to C-fibers). These small fibers innervate receptors in muscle whose adequate stimulus is best described as squeezing the muscle (normally quite painful). Those with group III axons tend to be activated at lower stimulus intensity than those with group IV axons. Many of these receptors can also be excited by chemical stimuli such as bradykinin or 5-HT. These substances are released when the muscle is under stress due to ischemia, lactic acid buildup (lowered pH), etc. Some of these receptors also exhibit responses to noxious temperature ($>43^{\circ}$C). Thus, nociceptors in muscle resemble those in skin in responding to one or more modalities of stimulation.

C. Visceral Afferents

Many visceral organs (heart, veins, lungs, colon, ureter, bladder, etc.) are innervated by small-diameter afferent fibers that selectively respond to intense mechanical stimuli and also to irritant chemical stimulation such as bradykinin, capsaicin, and serotonin.

D. Joint Receptors

Nociceptors are innervated by group III and IV afferents (as described in the section on muscle afferents) and are defined as being activated only when the joint moves outside its normal physiological range. Most of these afferents can also be activated by

various chemical agents such as bradykinin, prostaglandins, and serotonin.

E. Cornea

The cornea occupies an important place in studies of nociception because the early histology indicated exclusively free nerve endings, whereas contemporaneous psychophysical studies indicated that gentle stimulation elicited nonnociceptive responses. This challenged the dogma originating at the end of the nineteenth century that free nerve endings are associated exclusively with nociceptors and pain. Studies of the physiological properties of fibers innervating the cornea indicate the presence of polymodal nociceptive afferents with Aδ- or C-fibers responding to mechanical, thermal, and chemical stimuli. The mechanical threshold of polymodal nociceptors is slightly lower than that of mechanosensory units. Thermal threshold is about 39°C. Chemical sensitivity can be demonstrated for protons, bradykinin, prostaglandin, and serotonin. A third type of unit known as a mechanoheat unit that exhibits a higher mechanical threshold than the others has also been described. Such units can develop chemical sensitivity after repeated thermal stimulation. Recent psychophysical studies of corneal sensation suggest that gentle stimulation elicits unpleasant if not frankly painful sensations, in line with the adequate stimulus of the afferent fibers innervating this tissue.

F. General Comments

Although nociceptive afferents are not a uniform or homogeneous population, certain general conclusions emerge. First, they transmit via small-diameter, slowly conducting axons. Second, they tend to transmit information about more than a single modality. Third, the spectrum of stimuli that activate these nociceptive afferents is remarkably similar from tissue to tissue. Finally, as was only touched upon in the foregoing brief description, the properties of these receptors are not static; they can be influenced by the state of their termination site and by preceding activity.

IV. THE CONTRIBUTION OF NOCICEPTORS TO THE SUBJECTIVE PERCEPTION OF PAIN

Evidence in favor of the role of physiologically described nociceptors in mediating pain sensation has been obtained for thermal nociceptive responses using several different approaches. An important contribution has come from comparison of the physiological responses of nociceptors in primates with the results of psychophysical experiments in human subjects. There is general correspondence between changes in the intensity of the subjective response and changes in the firing rate of the nociceptive afferents. In the case of a long-lasting thermal stimulus, the response of nociceptors indicates that C-fiber nociceptors mediate the initial component of the subjective response, whereas Aδ-fiber nociceptors (type I AMH) mediate the maintained response. The finding of severely reduced nociceptive responses in humans congenitally lacking unmyelinated fibers supports a crucial role for unmyelinated fibers in thermal nociception. Furthermore, pain is reported by subjects with conduction block of myelinated fibers in the nerve supplying the tested area.

One of the important implications of the nociceptor hypothesis, i.e., that pain is the response to activation of a special group of peripheral afferent fibers responding exclusively to damage in the periphery, is that selective activation of such fibers in peripheral nerves should elicit pain referred to the receptive field of the fiber. In human subjects, stimulation through a microelectrode recording activity from a single or a small number of C-fiber nociceptors results in a report of pain from a projected field (i.e., the region of skin to which the pain produced by the electrical stimulus is referred) close to the receptive field of the recorded fiber(s). The differences are within the uncertainty in the ability to localize nociceptive stimuli. It is difficult to be certain that only a single C-fiber is being activated under these conditions. However, the agreement of stimulus modality and receptive field location of the recorded fiber(s) with the projected field from the stimulation suggests that the electrical nerve stimulus activates the same fiber(s) is/are driven by the nociceptive stimulus used to test the adequate stimulus of the recorded fiber(s).

It should not be concluded from the findings under the experimental conditions described earlier that impulses in nociceptive fibers always elicit the same central effects. In the 1960s, the *gate theory* of Melzack and Wall described a physiological mechanism by which the spinal actions elicited by impulses in small-diameter afferent fibers depended on the balance of ongoing activity in small and large fibers. Specifically, segmental inputs in large-diameter afferents were proposed to attenuate the synaptic effects evoked by small-diameter afferents. More recently, descending

systems have been identified that also elicit such inhibitory effects. These fibers activate spinal interneurons that release the opiate agonist enkephalin. This transmitter activates opiate receptors on terminals of sensory neurons and this reduces Ca entry into the terminals and, thus, transmitter release. Because opiate receptors are expressed primarily on terminals of small-diameter nociceptive afferents, this is a specific action on nociceptive afferent fibers resulting in presynaptic inhibition of transmitter release.

V. MEMBRANE PROPERTIES

Nociceptors exhibit specialized electrical properties that set them apart from low-threshold mechanoreceptors, whose cell bodies also are located in sensory ganglia. At a descriptive level, the action potentials in nociceptors recorded intrasomatically have consistently different shapes, suggestive of the contribution of different ion channels (Fig. 2). Specifically, the spike in nociceptors tends to be larger and broader than spikes in low-threshold mechanoreceptors. A shoulder is often observed on the descending limb of the spike. Spikes in these cells also exhibit a longer lasting after-hyperpolarization. It has been suggested that the differences in spike properties between nociceptors and nonnociceptors are caused by a reduced delayed rectifier, leading to a larger upstroke and a larger Ca channel conductance. This would account for both the shoulder and the longer postspike after-hyperpolarization (AHP), the latter mediated by an enhanced Ca-mediated K conductance. These differences in spike configuration have been useful in studies carried out in dissociated cell culture where other criteria to classify nociceptors (e.g., response threshold) are unavailable.

Nociceptors also have a unique complement of Na channels that distinguishes them from nonnociceptors. Na channels are highly differentiated and can be classified in part on the basis of their sensitivity to the neurotoxin tetrodotoxin (TTX). Some Na channels can be blocked by TTX concentrations in the nanomolar range, whereas others are insensitive to TTX concentrations as high as 10 μM. Several sensory-neuron-specific Na channels have been identified, including the TTX-sensitive channel called PN1 and the TTX-insensitive channels called SNS/PN3 and SNS2/NaN. These Na channels have been cloned, and the expression of SNS/PN3 and SNS/NaN has been found to be restricted to small somata, i.e., putative nociceptors. In agreement with these studies, the somatic spike of nociceptors recorded *in vivo* is resistant to TTX, in contrast to the somatic impulses in low-threshold afferents that are blocked by TTX. However, axonal spikes in both classes of afferents can be blocked by TTX. Thus, the membrane of individual DRG cells is not necessarily homogeneous with respect to Na channel expression. Significantly, there is also evidence for TTX-resistant Na channels in the peripheral terminals of nociceptive neurons. Thus, any physiological role for TTX-resistant channels obtained from studies of the cell body can be applied to generation of the impulse in the sensory terminals (see Section VIII.A on peripheral sensitization).

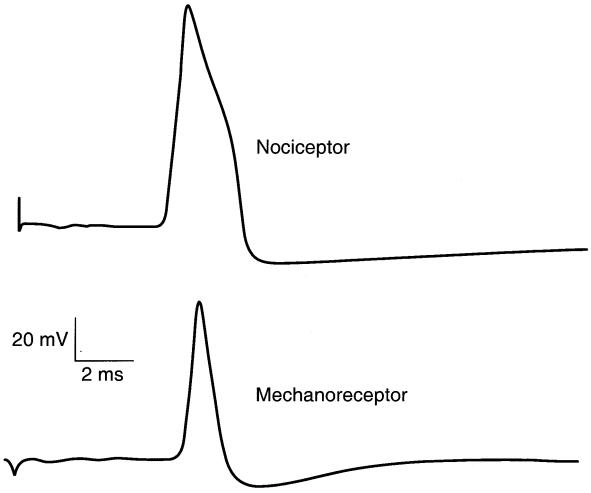

Figure 2 Examples of action potentials recorded intracellularly from the soma of a nociceptor and a low-threshold mechanoreceptor. Note the difference in spike configuration. Adapted from Traub, R. J. and Mendell, L. M. (1988). *J. Neurophysiol.* **59,** 41–55, with permission. Further details are given in the text.

VI. CENTRAL TRANSMITTER ACTION

Glutamate is the major transmitter released onto spinal neurons by nociceptive afferents. It activates AMPA–kainate receptors on central neurons to produce rapid EPSPs that excite them. This system is responsible for the rapid, nonpersisting pain acting as a signal to the organism to remove the stimulated tissue from the potentially damaging stimulus.

Cells in the superficial dorsal horn also express another glutamate receptor known as the *N*-methyl-D-aspartate (NMDA) receptor, whose activation can lead to long-lasting activity and extensive metabolic changes in these cells, resulting in persistent pain.

Activation of these receptors is facilitated by corelease of peptides, particularly substance P, from terminals of the afferent fibers in response to intense activity. Substance P elicits a long, slow depolarization of its target cells via activation of tachykinin (NK1) receptors. This depolarization acts to remove the block of postsynaptic NMDA receptors that occurs in the presence of extracellular Mg at normal resting potentials. The details of pre- and postsynaptic changes in central neurons as a consequence of activation of NMDA receptors as well as the interaction between these neural elements in eliciting these long-term changes are presently not completely characterized. Not all nociceptive afferents may be able to elicit long-term changes in this manner because many IB4/c-ret/FRAP-expressing nociceptive afferents are not peptidergic.

VII. TRANSDUCTION MECHANISMS

The availability of molecules eliciting pain has provided important evidence concerning the transduction of noxious stimuli. An extract from hot peppers known as capsaicin is a powerful stimulant of nociceptors and, when administered to human subjects, it evokes the sensation of noxious heat. The receptor for this molecule, VR1, a member of the TRP receptor family, has been cloned and has been found to be expressed in small sensory neurons coexpressing other markers characteristic of nociceptors. When VR1 is expressed in oocytes, they exhibit sensitivity to noxious heat and other stimuli that activate nociceptors, such as protons (low pH). The response of VR1 to heat can be enhanced when the pH of the surrounding medium is reduced, corresponding to the reduced threshold to heat observed behaviorally during inflammatory conditions when pH naturally falls. Thus, this receptor is a logical candidate to be an important participant in the transduction of these nociceptive stimuli. No corresponding molecule for high-threshold mechanoreceptors has been definitively identified.

ATP and its associated receptor family (the P2X family) have also been implicated in peripheral nociceptive events. Damaged cells release ATP, and the fraction of the cytosol that elicits pain when applied to blisters is rich in ATP. In rats, a member of the P2X receptor family, P2X3, is expressed exclusively in sensory neurons, and evidence suggests that its expression is confined to nociceptors. Together these findings suggest that ATP could be an important agent for evoking pain when tissue is damaged.

VIII. SENSITIZATION

Nociceptive pathways are subject to sensitization as a consequence of their previous activation. Elucidation of the mechanisms underlying these changes is exceedingly important in achieving an understanding of nociceptive physiology and pathology. Two important terms used in describing these changes are *hyperalgesia* and *allodynia* (Fig. 3). Hyperalgesia refers to the increase in perceived intensity of a normally painful stimulus after damage to the stimulated region. Allodynia refers to the pain elicited by a normally innocuous stimulus as a consequence of injury. In terms of sensory pathways, hyperalgesia can be thought of as an increased activation of normally nociceptive pathways, whereas allodynia can be considered as a nociceptive response to the activation of normally nonnociceptive pathways. It is now clear that these sensitization processes involve both peripheral and central mechanisms.

A. Peripheral Sensitization

Peripheral sensitization of nociceptive afferents is measured electrophysiologically as a reduction in response threshold to a nociceptive stimulus as well as an increased discharge in response to a given

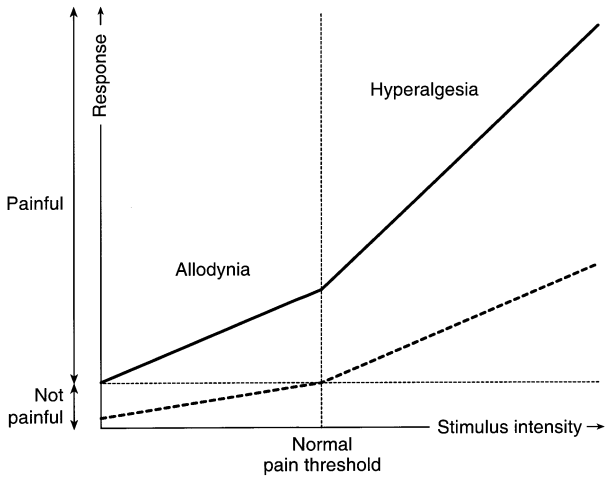

Figure 3 Graphical representation of two components of sensitization. Stimulus–response function before sensitization is shown with the dark dashed line; after sensitization the response increases so that in this example all stimuli elicit the report of pain. Allodynia refers to the painful response to a previously nonpainful stimulus; hyperalgesia refers to the exaggerated response to a normally painful stimulus. The dashed horizontal and vertical lines are provided to give thresholds.

suprathreshold stimulus. Damage to peripheral tissue generally results in sensitization of peripheral nociceptors, although a given stimulus does not sensitize all types of nociceptive responses (e.g., to noxious heat or to high-intensity mechanical stimulation) equally. Similarly, sensitization is not elicited equally well by noxious mechanical and heat stimulation. There are other complications in classifying sensitization responses, e.g., whether it is *primary hyperalgesia* (sensitization in a region that overlaps the region of injury) or *secondary hyperalgesia* (sensitization in a region outside the region of primary injury). Primary heat hyperalgesia after a burn injury involves sensitization of the response of nociceptors to noxious thermal stimuli. Primary mechanical hyperalgesia after a burn injury does not involve peripheral sensitization to mechanical stimuli, and so central changes (i.e., central sensitization; see the following section) are believed to be responsible. However, sensitization of the response of mechanical nociceptors does occur and is believed to account for the mechanical hyperalgesia after chemical sensitization. In summary, there is substantial evidence that both thermal and mechanical responses of nociceptors can be sensitized by natural stimuli.

It is now clear that peripheral sensitization after inflammation involves very complex mechanisms in the periphery resulting from the release of numerous substances in the periphery. There are two major sources of these substances. The first of these are peptides such as substance P and/or CGRP released from the nerve terminals themselves due to a local axon reflex and/or impulses elicited in the spinal terminals of the sensory axons and conducted antidromically, the dorsal root reflex. These peptides evoke several effects in the periphery, notably vasodilatation and neurogenic extravasation (leakage of large molecules from capillaries into the skin). In parallel with these changes is the release into the skin of numerous substances, which have been demonstrated to induce activation and/or sensitization of nocieceptive afferents. These include bradykinin, prostaglandin E2 (PGE2), serotonin, histamine, and nerve growth factor (NGF), each of which is a consequence of a different component of the inflammatory response. Together, this mixture of substances has been referred to as the "inflammatory soup." Numerous cell types in the skin such as macrophages, mast cells, and Schwann cells have been shown to be sources of these substances. It has also been demonstrated that certain cytokines such as TNFα and IL-1β are important precursors to the up-regulation of these substances. Expression of so many substances leading to hyperalgesia suggests that it is a highly adaptive response to inflammatory injury, whereby an inflamed limb is protected to promote the healing process.

The mechanism by which these substances sensitize nociceptive afferents is not presently well-defined. In the case of sensitization to noxious heat, there is evidence that some sensitizing agents, e.g., NGF and PGE2, can acutely enhance the response to capsaicin, suggesting a direct effect on the transduction process mediated by the VR1 receptor believed to mediate the response to noxious heat, at least in part. Attention has been focused on second messenger signaling pathways that elicit sensitization or more definitively on antagonists of these pathways that block the sensitization elicited by endogenously released agents (Fig. 4). For example, activation of the adenylyl cyclase/cyclic AMP/PKA intracellular signaling pathway by forskolin, a specific activator of this pathway, can result in acute sensitization of the response to PGE2. However, the situation is undoubtedly more complex because activators and inhibitors of another signaling pathway involving the molecule PKC can also affect peripheral sensitization to noxious heat.

TTX-resistant sodium channels are also believed to participate in the peripheral sensitization produced by inflammation. These channels are expressed preferentially in nociceptive afferents and their terminals (see previous discussion), and molecules such as PGE2, bradykinin, serotonin, and NGF that elicit inflammatory hyperalgesia selectively enhance the current produced by these channels via intracellular messengers such as PKA and PKC (Fig. 4). This would be expected to decrease the threshold for activation of nociceptive afferents and increase the discharge in response to a given level of depolarization, because TTX-resistant Na channels have a more rapid recovery from inactivation, rendering them more appropriate for steady discharge than TTX-sensitive channels.

In summary, these studies indicate that peripheral sensitization can involve the action of the sensitizing agents on the transduction process (e.g., via VR1), the cell's excitability, and possibly the spike-encoding process (via the TTX-insensitive Na channel).

B. Central Sensitization

It is apparent that not all sensitization in response to injury can be accounted for by changes in the threshold of peripheral nociceptors. Furthermore, under some conditions, preventing afferent impulses from reaching

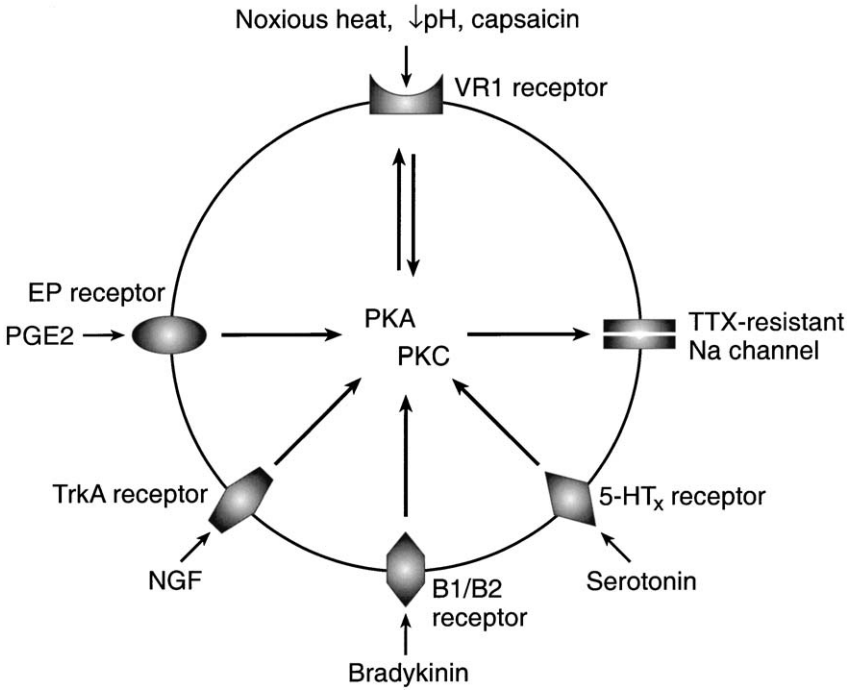

Figure 4 A sensory terminal illustrating the receptors and channels as well as some elements of signaling pathways (PKA and PKC) that may be involved in sensitization. Sensitizing molecules PGE2, NGF, bradykinin, and serotonin act on their receptors to affect the VR1 receptor and the TTX-insensitive Na channel via intracellular signaling. Sensitization of VR1 should result in an increased response to noxious heat and protons as well as capsaicin. Sensitization of TTX-resistant Na channel results in a reduced threshold for steady impulse discharge.

the spinal cord can abolish sensitization. This suggests that some of the changes underlying sensitization must take place central to the peripheral nerve. One mechanism may involve the dorsal root reflex conducted antidromically in sensory nerve fibers from their terminals in the spinal cord, but there is evidence that exclusively central mechanisms also contribute.

It has been recognized for many years that small-diameter afferent fibers differ qualitatively from large ones in the central effects that they exert. Specifically, successive volleys in large-diameter fibers elicit constant central effects, whereas the response to volleys in small-diameter afferent fibers, particularly unmyelinated fibers, can increase in frequency and duration if the peripheral stimuli occur at a high enough rate (at least once per 4 sec in the cat). This progressive increase in the central discharge of cells in the spinal cord has been referred to as *windup* and represents one component of the more comprehensive phenomenon known as central sensitization. Other components are much longer lasting and are thought to require metabolic changes in postsynaptic cells that are induced by the activation of NMDA and metabotropic glutamate receptors. They also lead to changes in gene expression in postsynaptic cells, e.g., *c-fos*, and additionally to a wider zone of postsynaptic cells being activated due to structural changes. The possibility exists that these changes also lead retrogradely to changes in transmitter release from presynaptic terminals via signaling molecules such as nitric oxide.

IX. DEVELOPMENT OF NOCICEPTORS

Sensory neurons are known to be overproduced during development, and in the immediate prenatal period many DRG cells undergo programmed cell death (apoptosis). There is considerable evidence that sensory neurons compete for a trophic substance in the periphery, and those that fail to obtain adequate levels of such a substance are the ones that do not survive. In the case of nociceptive neurons the trophic substance is nerve growth factor (NGF), and small-diameter neurons express the high-affinity receptor trkA for NGF. If NGF is experimentally depleted, fewer than normal nociceptors survive. In the rat the dependence of nociceptors on NGF for survival lasts until about postnatal day 2.

Nociceptors continue to require NGF beyond postnatal day 2 for at least some functions. Their response to noxious heat is substantially reduced if NGF levels are decreased by chronic treatment with an NGF antibody or with an immunoadhesin molecule, trkA–IgG, that binds endogenous NGF. Another indication of trophic support of nociceptors by NGF emerges from the restoration of function when it is provided to axotomized nociceptors. For example, the TTX-resistant Na current and the SNS/PN3 channel both decline in nociceptor somata after peripheral axotomy, and these can be partially restored by the administration of NGF to the cut proximal nerve stump. Similar findings have been made with regard to SP and CGRP expression in these nociceptors.

The dependence of certain nociceptive functions on NGF in postnatal animals implies that nociceptors continue to express the trkA receptor. However, it has been demonstrated in rats that as the animal develops into a young adult, some nociceptors cease expressing trkA and begin to express the receptor c-ret, for which glial-derived neurotrophic factor (GDNF), a member of the TGF-β superfamily, is a ligand.

In the prenatal rat nociceptive afferents, at least those associated with unmyelinated fibers, exhibit responses to skin stimulation similar to those in the adult even before their central terminals penetrate into the spinal cord gray matter. These afferents send their collaterals into the spinal cord at embryonic day 18–19 (E18–E19), which is somewhat later than cells that will become the large nonnociceptive afferents (E15–E16). The biochemical markers associated with nociceptive afferents begin to be expressed during this prenatal period. The spinal terminals of small-diameter afferent fibers are restricted to the superficial laminae of the dorsal horn from the time of their arrival into the cord, as they are in the adult. However, in the first postnatal week, C-fiber volleys are unable to elicit discharges in dorsal horn neurons. After postnatal day 10, activation of C-fibers elicits the same responses as in adult cord, specifically the windup indicative of the rapid component of central sensitization, and activation of immediate early genes, i.e., *c-fos*. Thus, in the rat the nociceptive system activated by C-fibers is not an effective sensory system until the second postnatal week.

X. PLASTICITY OF NOCICEPTORS

One of the hallmarks of nociceptors and the nociceptive pathway is their susceptibility to change in response to various alterations in their environment (Fig. 5). Inflammation in the periphery can result in a diminished threshold to noxious stimuli. In part this reflects the action of various substances in the "inflammatory soup" (see Section VIII.A). However, there are also changes in properties of the nociceptor itself, such that it responds differently to components of the inflammatory soup. For example, the response of individual nociceptive afferents to capsaicin can be enhanced if NGF or PGE2, known to sensitize individual nociceptors, is applied to the neuron. Thus, sensitization at the level of the periphery is thought to represent a change in the sensitivity of the receptor itself, in this case quite possibly a change in the phosphorylation state of the capsaicin receptor (i.e., VR1).

A second locus at which nociceptors exhibit plasticity is the cell body. Inflammation in the periphery results in up-regulation of substance P and CGRP as well as the neurotrophin brain-derived neurotrophic factor (BDNF) in nociceptors. The enhanced level of these substances is believed to result in a more intense driving of the postsynaptic cells on which these nociceptors terminate. The peptides act to prolong the depolarization, thereby relieving the Mg block of postsynaptic NMDA receptors and enabling these cells to be more intensely activated. BDNF directly increases the NMDA-receptor-mediated responses and thereby enhances the response of nociceptive neurons of the dorsal horn that are known to express NMDA receptors.

After peripheral inflammation, some large-diameter afferents that are activated by innocuous stimuli can undergo a phenotypic switch and display characteristics of nociceptors, specifically the expression of substance P in their somata. Release of this peptide could result in intensification of the discharge of some central neurons that they activate. Activation of cells in lamina II by large-diameter afferents can be enhanced under these conditions. These changes could contribute to the allodynia that is often reported after inflammatory injury.

Nociceptive afferents also display considerable plasticity when their axons are cut in the periphery. The level of some peptides (CGRP, SP) decreases, whereas the level of others (e.g., neuropeptide Y and GAP43) increases. This is thought to reflect, at least in part, the changing metabolic priorities of these neurons from a transmission mode to a regeneration mode. Similar changes occur in nociceptors of aged animals, and this has been shown to reflect diminished neurotrophic support from the periphery, e.g., a

Nociceptor Plasticity in Different States

Inflammation	Axotomy	Aging
Increase in NGF/trkA signaling (and in other peripheral sensitizing agents, e.g., PGE2)	Decrease in trkA expression	Decrease in NGF/trkA signaling
Increased levels of SP, CGRP in soma	Reduced levels of SP and CGRP in soma	Reduced levels of SP and CGRP in soma
Increased levels of BDNF in soma	No change in BDNF level in soma	Increase in GDNF/c-ret signaling
	Accumulation of Na channels at neuroma	
	Upregulation of adrenergic receptors	

Figure 5 Nociceptor plasticity in different states. Note the difference between the effects of inflammation and axotomy and the similarity between the effects of axotomy and aging.

diminished level of NGF. However, peripheral levels of GDNF are higher in aged animals, indicating increased trophic support of certain nociceptive functions, i.e., those associated with the IB4/FRAP population of nociceptors.

Afferents that have undergone damage to their axon exhibit other important changes that contribute to very painful conditions after peripheral nerve injury, e.g., causalgia and reflex sympathetic dystrophy. The pain associated with these syndromes is related at least partially to alterations in the expression of channels in the nociceptor membrane. The proximal stump of a cut nerve forms a tangle of nerve fibers referred to as a neuroma. This region becomes very sensitive to mechanical stimuli. This is believed to result from the increased level and duration of firing produced in response to mechanical stimulation by the presence of an increased density of Na channels in the membrane of the growing tip and in preterminal demyelinated segments.

It has long been recognized that the sympathetic nervous system can interact with nociceptive afferents and that certain pain states can be exacerbated by increased sympathetic outflow or diminished by a reduction in sympathetic outflow. These effects are particularly evident in conditions where peripheral nerve damage has taken place, e.g., conditions such as causalgia or reflex sympathetic dystrophy. An increase in responsiveness to adrenergic transmitters is also observed in the terminals of injured nerve fibers with α-adrenergic transmission being the major contributor to this action. For example, after partial lesions of mixed peripheral nerves, intact nociceptive afferents running in the same nerve developed increased expression of α_2-adrenergic receptors and an increased sensitivity to agonists of this receptor.

Together these studies demonstrate that nociceptive afferents are not fixed in their properties. Conditions known to result in changes in nociceptive processing generally are accompanied by changes in the properties of the afferents that contribute to the observed changes. A complete understanding of these changes is required to devise strategies to reduce the undesirable persistence of pain after certain types of injury.

XI. CONCLUSIONS

The wealth of data that is now available on the properties of nociceptors indicates that these afferent fibers have unique properties beyond their fundamental one that distinguishes them from other sensory afferents as nociceptors, namely, the ability to respond only to stimuli that are potentially damaging to the organism. They express a unique blend of receptors and transmitter molecules, resulting in an ability to undergo sensitization peripherally and to induce central sensitization. They follow a different developmental timetable than nonnociceptive afferents, and they exhibit greater plasticity than nonnociceptive afferents. They activate unique populations of neurons in the central nervous system, and the inputs that they provide to the CNS are subject to modification by impulses in fibers descending from the medulla. These

properties provide a significant targets for therapeutic intervention, a fortunate opportunity given the debilitating consequences of persistent pain. Although central targets certainly exist for a therapeutic approach, the nociceptor itself and neurons to which it projects would appear to be a particularly suitable focus for intervention because of their relative isolation as well as the chemical uniqueness referred to earlier.

Some important new approaches are already in progress. For example, it is known that the action of substance P released by nociceptive afferents is terminated by re-uptake into spinal neurons. This knowledge has been used to design a cytotoxin, substance P–saporin, whose uptake kills the cell. This treatment that kills certain populations of spinal neurons has been found to diminish inflammatory and neuropathic thermal hyperalgesia and mechanical allodynia with no loss of response to acute mild nociceptive stimuli. It is thus clear that continued exploration of the detailed molecular properties of nociceptors and their peripheral and central projections should be highly profitable from both the scientific and therapeutic points of view.

Norepinephrine

CANDICE DROUIN and JEAN-POL TASSIN
Collège de France, Paris

GLOSSARY

attention Condition of selective awareness governing the extent and quality of the One's communication with one's environment, although not necessarily held under voluntary control. The psychologist William James held that attention made humans perceive, conceive, distinguish, and remember.

electroencephalogram (EEG) The electrical changes taking place within the healthy human brain can be recorded from electrodes attached to the scalp. Such recording enables observation of the minute patterns of voltage fluctuation that take place as the brain cells process information and relay messages.

event-related potentials (ERPs) Consistent patterns that accompany the perception and evaluation of sensory information and that can be recorded on an electroencephalogram. These changes extend over the period of 0.5 sec or so immediately following the onset of the signal concerned. ERPs are composed of a relatively consistent pattern of positive and negative electrical peaks that vary systematically when the properties of the signal that elicits them change. The succession of the different ERP components constitutes a convenient and meaningful indicator of the various aspects of information processing being carried out on the signal. For example, a novel sound produces a prominent negative component about 100 msec (P100) after the sound is heard. A modulation can, however, occur. Indeed, if an individual who is hearing different voices speaking simultaneously in each ear is told to listen for a particular word spoken by one voice only, all words spoken by the "attended" voice elicit a larger P100 than those spoken by the other voice. Only the designated word elicits a later prominent, electrically positive component, occurring about 300 msec (P300) after it is spoken.

habituation Basic mechanism whereby response to novelty wanes with repeated and regular presentation of the same signal, which may be described as a progressive loss of behavioral responsiveness to a stimulus as its lack of adaptive significance, is discovered. Naturally, if the signals have special significance for the individual, they will continue to be attended and responded to, even though they may be, repetitive. For loud or bright stimuli, habituation may take place, but only very slowly.

locus ceruleus Group of neurons situated in the brain stem of vertebrates containing the largest number of noradrenergic cell bodies in the central nervous system of mammals. The term ceruleus (blue) was attributed because the high concentration of the pigment, neuromelanin, in noradrenergic neurons made this nucleus appear as a blue spot under the fourth ventricle in human brain sections.

neuromodulator Refers to neurotransmitters that do not directly convey neuronal information by classical synaptic transmission but rather exert a diffuse modulatory action on information processing. Monoamines (especially serotonin, norepinephrine, and dopamine) exerting their effects via divergent projections through metabotropic rather than ionotropic receptors are considered to be neuromodulators, as opposed to GABA, glycine, and excitatory amino acids.

stress Concept that arose from observations of the endocrinologist Hans Seyle that a large number of damaging or potentially damaging stimuli led to similar physiological reactions. Sympathoadrenal activation is an essential component of the physiological response to stress. Various stimuli, aversive or considered as a challenge to the organism, increase heart rate and plasma epinephrine, norepinephrine, and corticosteroid levels.

vigilance Sustained attention, referring to the state in which attention must be maintained over time. Often this is to be found in some form of "watch-keeping" activity when an observer or listener continuously has to monitor a situation in which significant, but usually infrequent and unpredictable, events may occur. Among the factors that influence vigilance performance, the most important is the frequency with which task-relevant events occur.

Norepinephrine (NE), one of the first neurotransmitters discovered, is commonly associated with the rapid behavioral and physiological response to stress, the *fight or flight* response, related to the secretion of corticosteroids by the adrenal cortex and the release of epinephrine and NE by the adrenal medulla. Present in the brain, NE plays the role of a neurotransmitter in the sympathetic ganglia and that of a hormone following its secretion by the adrenal medulla. In the central nervous system, NE is considered as a neuromodulator. There is now general agreement about the concept of specific neurons that modulate information processing rather than convey sensory or motor signals. In any representation of the primary pathways responsible for the processing of sensory stimuli or motor outputs, it is notable that these pathways include neurons releasing γ-aminobutyric acid (GABA) and excitatory amino acids, possibly acetylcholine, whereas monoaminergic (i.e., noradrenergic, dopaminergic, or serotonergic) cells do not appear to be involved. NE therefore is one neuromodulator among others that, due to its multiple modes of action, is implicated in a wide variety of functions, such as the regulation of blood pressure, sleep–wake cycle, anxiety, pain, or cognitive processes. In this article, we will focus on the actions of NE in the central nervous system; however, general information concerning NE synthesis or adrenergic receptors also applies to the periphery.

I. DISCOVERY OF NOREPINEPHRINE

NE was discovered together with epinephrine in the peripheral nervous system. Initially, a substance that increased the heart rate and was released in the blood following the stimulation of the sympathetic ganglion was characterized by a German physiologist, Otto Loewi. This substance, named *Accelerans* by Otto Loewi and later *sympathine* by Walter Cannon, was finally identified as epinephrine. NE was first considered as an inactive precursor of epinephrine, but Ulf von Euler demonstrated in 1940 that NE was also involved in the sympathetic response in mammals. In 1954, Marthe Vogt further extended the role of NE as a neurotransmitter in the central nervous system.

II. ANATOMY OF NORADRENERGIC NEURONS

Taking advantage of the fluorescent properties of amines after condensation with aldehydes, histochemistry was developed by Erankö in 1955 and applied to brain structure by Falck and Hillarp in 1962. Thanks to this technique, noradrenergic pathways are probably the best characterized in the peripheral and central nervous systems. The noradrenergic cells in the central nervous system are localized in the most posterior part of the brain in two sets of neurons (Fig. 1). First, the locus ceruleus (LC, cell group A6) and adjacent nuclei (A5 and A7) are in the upper pons. Second, the medullary nuclei (cell groups Al and A2) innervate forebrain areas as the hypothalamus, amygdala, septum, and piriform cortex via the ventral NE bundle and play a role in the control of vegetative functions and endocrine regulations. Because this article's main subject is the brain, we will focus on the LC, the major source of central noradrenergic innervation, with the medullary nuclei functions being mainly peripheral. The anatomical, as well as physiological, characteristics of the LC cells have been studied most in the rat, cat, and primate. The most obvious species difference is that LC neurons are essentially noradrenergic in rats and primates and that, in contrast, NE-containing neurons are interspersed with non-noradrenergic neurons in the LC of other species including cat.

A. Locus Ceruleus Efferent Fibers Innervate Many Target Structures

A striking feature of the LC is the extreme divergence of its projections, partly due to an intense collateralization of the axons. Indeed, a few neurons (20,000 in humans and 1,500 in rats) provide extensive innervation of the brain from the olfactory tubercle to the spinal cord (Fig. 1).

Projections of the LC are organized in two ascending fiber systems: first, the dorsal NE bundle innervating the amygdala, olfactory tubercle, septum, bed nucleus of the stria terminals, hippocampus, entire neocortex, habenula, ventral and anterior thalamus, and hypothalamus, and second, the rostral limb of the dorsal periventricular pathway. Projections also include descending fibers to the cerebellum, medulla oblongata, and spinal cord. A certain topographical organization is observed because neurons from the ventral part of the LC preferentially project to the spinal cord, cerebellum, and hypothalamus, whereas neurons from the dorsal part project to the cortex and hippocampus. A functional organization was also observed concerning the projections to somatosensory structures. Studies employing double-fluorescent

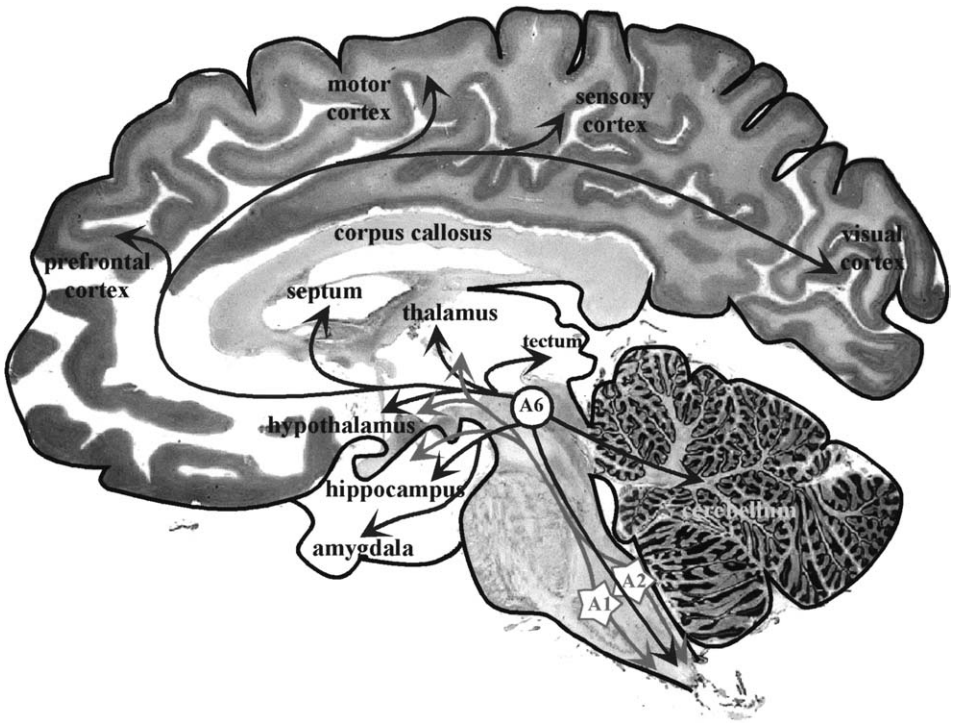

Figure 1 Noradrenergic pathways in the human brain. Sagittal human brain section containing the main projection sites of noradrenergic neurons. A6: Noradrenergic nucleus corresponding to the locus ceruleus. It widely projects to the anterior part of the brain and also to the cerebellum and spinal cord. A1–A2: Medullary noradrenergic nuclei, projecting essentially to the hippocampus, thalamus, and hypothalamus.

retrograde labeling strategies revealed that single LC neurons preferentially collateralize to different sites that process the same sensory information.

B. Coexisting Neurotransmitters in Central Noradrenergic Neurons

Some distinction between noradrenergic neurons is also possible in the function of the neuropeptides they coexpress. Up to 14 different neuropeptides are expressed in the human LC, but the most abundant are galanine and neuropeptide Y (NPY). Galanine is expressed in 80% of LC neurons projecting to the hypothalamus, medial thalamus, cerebral cortex, hippocampus, and spinal cord. NPY is present in approximately 20–40% of the LC neurons, very few of which project to the hypothalamus, instead projecting to the thalamus, cortical areas, ventral hippocampus, and spinal cord. Whereas corelease of NE and NPY was observed in the peripheral nervous system, it was never demonstrated in the brain and the function of such a release is not clearly established. Galanine inhibits LC neuron firing and NPY depresses the inhibitory postsynaptic potential induced by NE in pontine slices, which suggests that NPY and galanine exert inhibitory control on noradrenergic activity.

III. BIOCHEMISTRY OF NE

NE synthesis starts in the cytosol and ends in synaptic vesicles, where it is stored at extremely high concentrations (100 m*M* in vesicles versus a few micromolar in the cytosol). The release of NE from synaptic vesicles is triggered by the arrival of an action potential. Its removal from the extracellular space is due to very efficient re-uptake (about 80% of the NE released is re-uptaken in the synaptic terminals). NE essentially is finally metabolized by a monoamine oxidase (MAO) into dihydroxyphenylglycol (DHPG). A small amount of NE is re-uptaken in nonneuronal cells and metabolized by catechol-*O*-methyltransferase (COMT) (Fig. 2).

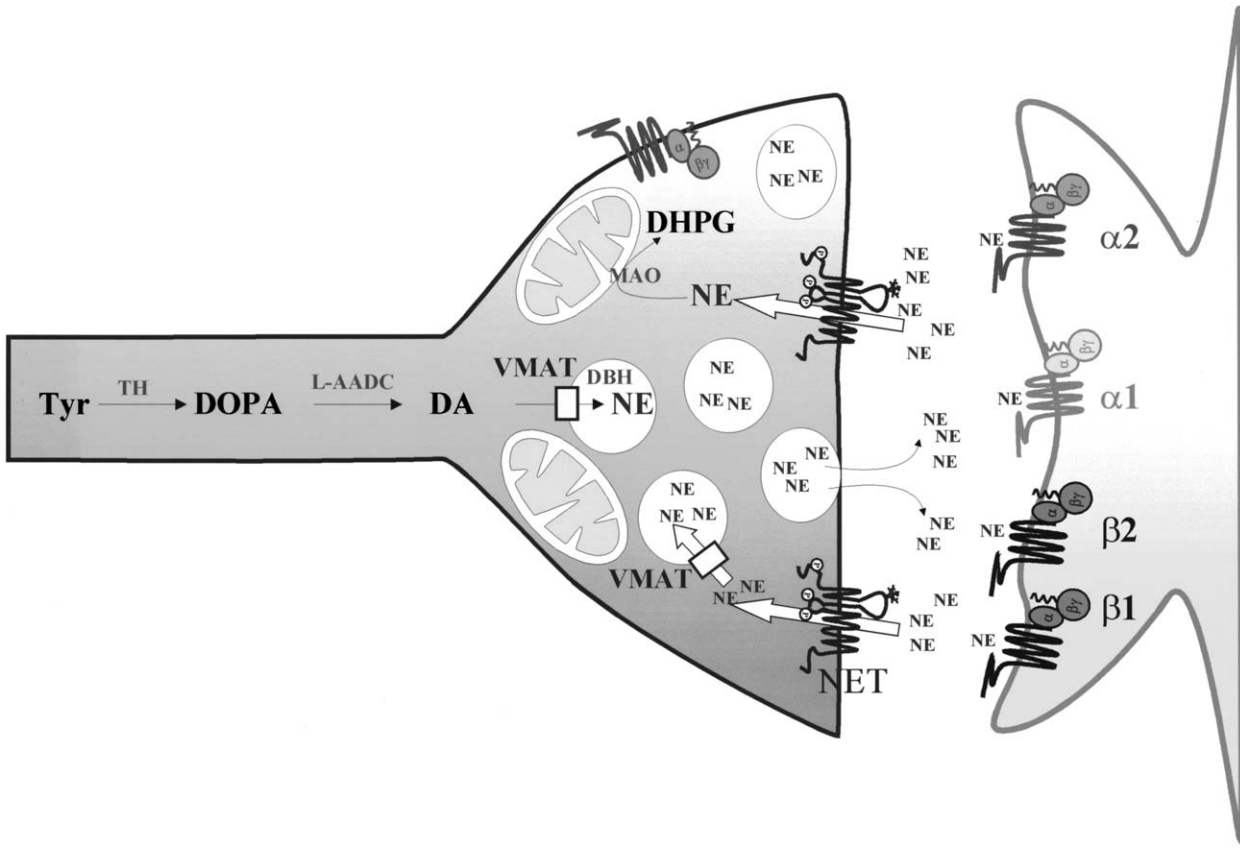

Figure 2 Noradrenergic synapse. NE is synthetized from the amino acid tyrosine (Tyr) via three enzymes, tyrosine hydroxylase (TH), L-aromatic amino acid decarboxylase (L-AADC), and dopamine-β-hydroxylase (DBH). NE and dopamine (DA) are transported in vesicles through the vesicular monoamine transporter (VMAT). After release from synaptic vesicles, NE is re-uptaken by the NE transporter (NET) and further metabolized by the monoamine oxidase (MAO) into dihydrophenylglycol (DHPG). DOPA: dihydroxyphenylalanine.

A. NE Synthesis and Storage

NE is synthesized from the amino acid tyrosine. Four enzymes are necessary (Fig. 3). The first, tyrosine hydroxylase (TH), converts tyrosine to L-dihydroxyphenylalanine (L-DOPA). This enzyme is rate-limiting for the synthesis of both NE and dopamine. It requires a reduced pteridine (Pt-2H) cofactor, regenerated from pteridine (Pt) by another enzyme, pteridine reductase, which is not specific to neurons. TH is subject to multiple controls. Short-term regulation includes activation of TH in response to increased nerve traffic and negative feedback control through end-product (i.e., dopamine and NE) inhibition. Short-term activation of TH involves phosphorylation at four sites corresponding to serine residues 8, 19, 31, and 40 in the rat sequence. In particular, the phosphorylation of serine 40 increases the dissociation rate between TH and its endogenous inhibitor. Long-term regulation involving the production of new TH enzyme occurs at the level of transcription and translation in response to various stimuli via three main second messengers: cyclic AMP, diacylglycerol, and calcium. Nerve growth factor and cell–cell contacts are important during development to promote and maintain the catecholaminergic phenotype, and neurotransmitters and glucocorticoids mediate the activation of TH in response to environmental changes such as stress and exposure to certain drugs such as reserpine, nicotine, or cocaine.

L-DOPA is decarboxylated by a nonspecific L-aromatic amino acid decarboxylase to give dopamine and carbon dioxide. Dopamine is then transported into vesicles by the vesicular monoamine transporter (VMAT) using the proton electrochemical gradient across the vesicle membrane.

Finally, dopamine β-hydroxylase (DBH), which is localized in a membrane-bound (77-kDa) or soluble

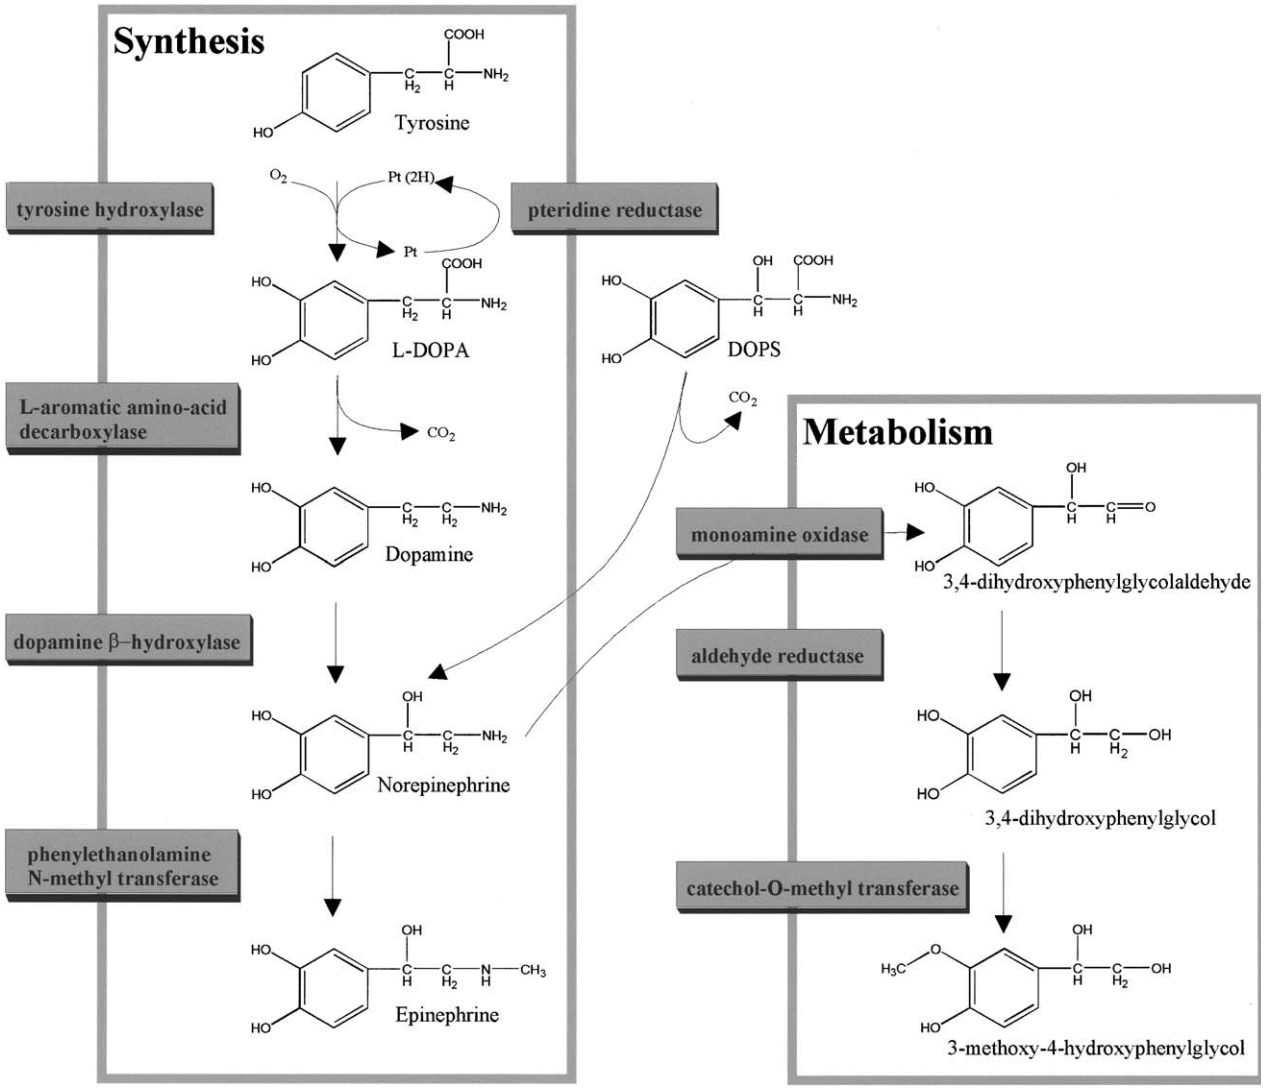

Figure 3 NE synthesis and metabolism. NE is synthetized from the amino acid tyrosine. Tyrosine is transformed into L-dihydroxyphenylalanine (L-DOPA), together with the oxidation of a cofactor, reduced pteridine (Pt-2H). Pteridine is regenerated by pteridine reductase. L-DOPA is decarboxylated by the L-aromatic amino acid decarboxylase to form dopamine. Dopamine is converted to NE by dopamine-β-hydroxylase. In adrenergic cells, phenylethanolamine-*N*-methyltransferase methylates NE to form epinephrine. In the case of dopamine-β-hydroxylase defiency, NE can be synthesized from dihydroxyphenylserine (DOPS), which is decarboxylated by the L-aromatic amino acid decarboxylase to form NE. NE is metabolized by monoamine oxidase into dihydroxyphenylglycolaldehyde, which is immediately reduced to dihydroxyphenylglycol (DHPG). Dihydroxyphenylglycol is methylated by catechol-*O*-methyl transferase to form methoxyhydroxyphenylglycol (MHPG).

form (73-kDa) in the synaptic vesicles, converts dopamine to NE. Both forms of DBH arise from a single translational product. The 77-kDa form has an uncleaved signal sequence. DBH gene expression is activated by a subset of conditions that elevate TH gene expression, but DBH gene expression often requires more severe and more prolonged treatment than TH. In the adrenal medulla and also in sparse neurons located in the central nervous system, a fifth enzyme, phenylethanolamine-*N*-methyltransferase, methylates NE to form epinephrine.

B. Noradrenaline Re-uptake and Metabolism

Re-uptake of released NE into presynaptic nerve terminals is responsible for the rapid termination of

neurotransmission in noradrenergic synapses. Transport of NE by the neuronal NE transporter (NET) is dependent on extracellular Na^+ and Cl^-. cDNAs of a series of neurotransmitter transporters have been cloned, and the NET has been shown to be a member of the superfamily of structurally related Na^+- and Cl^--dependent transporters for monoamines (dopamine, serotonin, and NE) and certain amino acids such as GABA and glycine. Transporters of this family are structurally characterized by 12 transmembrane domains, intracellular amino and carboxy termini, and a large second extracellular loop (Fig. 4). Three consensus sequences for phosphorylation by protein kinase C are found: one in the second intracellular loop and two in the carboxy-terminal end. Phosphorylation of NET by protein kinase C results in down-regulation of NE transport, presumably corresponding to a diminution of the number of transporters expressed to the membrane. NET is one of the different pharmacological targets of several psychotropic substances, such as tricyclic antidepressants and psychostimulants (amphetamine and cocaine) (Fig. 8).

Following re-uptake, monoamine oxidase (MAO) is essential in the neuronal degradation of NE (Fig. 3). Two isoforms of MAO were described, MAO-A and MAO-B. MAO-A is predominant in noradrenergic neurons, whereas MAO-B is found in serotonergic cells. MAO is located on the outer membrane of mitochondria where it uses the FAD cofactor to convert NE into dihydroxyphenylglycolaldehyde, which is reduced into dihydroxyphenylglycol (DHPG). DHPG is further metabolized into methoxyhydroxyphenylglycol (MHPG) outside neurons.

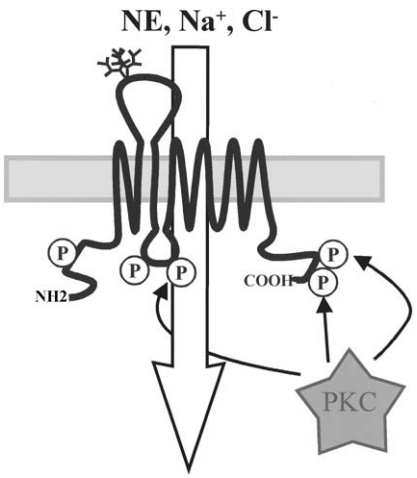

Figure 4 NE transporter. NE transporter is a 12-transmembrane-domain protein with intracellular amino and carboxy termini, a large glycosylated second extracellular loop, and five sites of phosphorylation (P), three of which are consensus sites for protein kinase C (PKC). NE is cotransported with sodium (Na^+) and chloride (Cl^-).

IV. CONTROL OF NORADRENERGIC NEURON FIRING

A. Organization of Afferents to the LC

The organization of afferents to LC has been a subject of controversy for a long time. Early retrograde tracing studies (using the horseradish peroxidase–diaminobenzidine technique) led to the conclusion that LC receives afferents from more than 30 regions (including the dorsal prefrontal cortex, amygdala, ventral tegmental area, raphe nucleus, contralateral LC and deep cerebellar nuclei, and dorsal horn of the spinal cord). However, more recent experiments using new tracers allowing more focal injections restricted the source of afferents to only two structures: the nucleus paragigantocellularis (PGi) and the nucleus prepositus hypoglossi (PrH) in the medulla oblongata. Anterograde analysis further confirmed that the ventral tegmental area, the dorsal horn of the spinal cord, the rostral solitary tractus, and the prefrontal cortex do not project to the LC but to adjacent structures.

Electrophysiological studies did not confirm, however, that PGi and PrH are the sole sources of afferents to the LC. First, the destruction of both PGi and PrH does not prevent LC responses to sensory stimuli. Second, it remains that stimulation of the ventral tegmental area, prefrontal cortex, and raphe nucleus alters LC firing, a finding suggesting that their projections to structures adjacent to the LC might be implicated.

The answer to this paradox came from light and electronic microscopic analyses, which revealed that many LC neurons extend their dendrites to pericerulear regions (rostromedial and caudal juxtaependymal regions). These pericerulear regions are sometimes denoted as the shell of the LC and distinguished from the core of the LC that represents the LC proper. These shell dendrites are selectively targeted by a number of extrinsic afferent inputs that do not project appreciably into the LC core.

Although it is not the primary LC afferent, PGi remains an important afferent to the LC and is a key sympathoexcitatory region in the brain. There are

widespread afferents to the PGi from diverse brain areas. The PGi may be an integrative pathway for activating the LC by a variety of mechanisms because it is involved in the control of arterial blood pressure, cardiopulmonary reflexes, and sympathetic function. It has been suggested that the peripheral sympathetic nervous system is activated in parallel with the LC by projections to both areas from the PGi.

B. Neurochemical Regulation of LC Neuron Firing

Immunohistochemical methods have shown that many neurotransmitters may contribute to the regulation of LC–NE neuron activity. Most of them are found in neurons of the two major LC afferents, the PGi and the PrH. These include epinephrine, excitatory amino acids, enkephalin, corticotropin releasing factor (CRF), substance P, serotonin (5-HT), and γ-aminobutyric acid (GABA). Adrenergic innervation of the LC derives from the PGi and may mediate part of the postactivation inhibition in LC responses to footshocks. GABA innervation arises from the PrH, the PGi, and other nuclei. The LC receives a rich enkephalinergic innervation, a large percentage of which arises from the PGi and PrH, and LC neurons are particularly invested with μ-opiate receptors. CRF innervation of the LC is noteworthy because the LC–NE system is sensitive to most stressors (see Section IV.C). CRF is presumed to play a crucial role in eliciting the coordinated set of endocrine, autonomic, and behavioral events that constitute the stress response. This peptide was initially characterized as the hypothalamic hormone inducing adrenocorticotropin release, but CRF is now considered as a neurotransmitter that, among others, stimulates the LC in response to hypotensive stress. CRF seems to originate from the PGi and the hypothalamus.

LC neurons also carry α2-adrenergic autoreceptors, allowing inhibitory feedback via recurrent collaterals. Intracellular studies have demonstrated that the stimulation of α2-adrenergic receptors inhibits firing by opening an inwardly rectifying potassium channel via a G-protein. The injection of clonidine, an α2-adrenergic agonist that suppresses LC neuron activity, is often used as a tool to characterize NE–LC neurons. These cells also contain many μ-opiate receptors, whose similarly activation results in an inhibition of the firing by a mechanism identical to that of α2-adrenergic receptors. In particular, μ-opiate and α2-adrenergic receptors share the same potassium channels.

Several inputs to the pericerulear region exert an excitatory influence on LC discharge, suggesting that these projections may be glutamatergic. Other transmitter receptors were identified on these distal dendrites, including CRF receptor, met-enkephalin, and μ-opiate receptors.

C. Electrotonic Coupling in LC Neurons

In some cases, LC neurons can exhibit synchronized activities. This property does not require classical synaptic transmission, but rather requires gap junctions that are located on pericerulear dendrites allowing communication between neurons with distant cell bodies. Electrical and dye couplings between LC neurons are often found in rats younger than 10 days old, whereas such a coupling is difficult to demonstrate in adults.

D. *In Vivo* Responsiveness of LC Neurons

1. Spontaneous Activity

The spontaneous discharge of LC neurons varies with the stage of sleep–wake cycle, 2 Hz during waking, lower during slow-wave sleep (from $\sim$1.5 Hz in stage 2 to $\sim$0.2 Hz in stage 4), and virtually absent during paradoxical sleep ($\sim$0.02 Hz). Rate of discharge also varies during different kinds of waking behavior, suggesting that LC activity is correlated with the state of arousal even during waking. Typically, LC neurons exhibit relatively little activity during low-vigilance behavior, such as grooming and food consumption, whereas their activity increases during exploratory behavior.

2. Responsiveness to Sensory Stimuli

LC neurons also exhibit phasic responses of short latencies (15–50 msec) to sensory stimuli in every modality (auditory, visual, somatosensory, and olfactory). These responses consist of a brief excitation followed by an inhibition lasting for several hundred milliseconds.

The responsiveness of LC varies between species. In rats, any of a variety of intense stimuli evokes LC responses in a majority of sensory trials. However, the response habituates with repetitive stimulus

presentation. In monkeys, LC is influenced less strongly by intense stimuli, but again, when responses occur, they fade after the first few trials. Intense conspicuous stimuli that interrupt behavior and elicit an orientating response reliably induce a LC response. Similarly, in complex behavioral tasks such as the *oddball*, where target cues are presented in a semirandom fashion with nontarget cues, target stimuli, even nonintense, are sufficient to induce a LC response (Fig. 5).

In cats, when the animal is well-habituated to its environment and is in a quiet waking state, LC neurons often display very little response to previously presented neutral stimuli. The presentation of novel or noxious stimuli will, in contrast, elicit a burst of unit activity (see the following section).

More generally, it can be considered that *tonic activity* of noradrenergic LC neurons is highly correlated with changing degree of alertness, whereas LC neurons respond *phasically* to behaviorally significant stimuli.

3. Responsiveness to Stressful Stimuli

Stressful stimuli such as confrontation with a dog (for cats), footshock, cold environment, loud noise, and immobilization reliably stimulate LC activity, an excitation usually accompanied by a sympathetic activation. This has led to the proposal of the LC as a central analog of peripheral sympathetic ganglia.

Physiological stress (hypotensive challenge, bladder distension, colon distension, and sciatic nerve stimulation) also reliably stimulates LC neurons even in nonnoxious magnitudes. Some of these effects are mediated via CRF release within the LC (for example, hypotensive stress as previously mentioned), but this is not the rule and different stresses act through different mechanisms.

Whereas chronic presentation of a nonnoxious stimulus results in the diminution of the LC response, chronic stress often results in sensitized noradrenergic activation by a subsequent stress. This noradrenergic

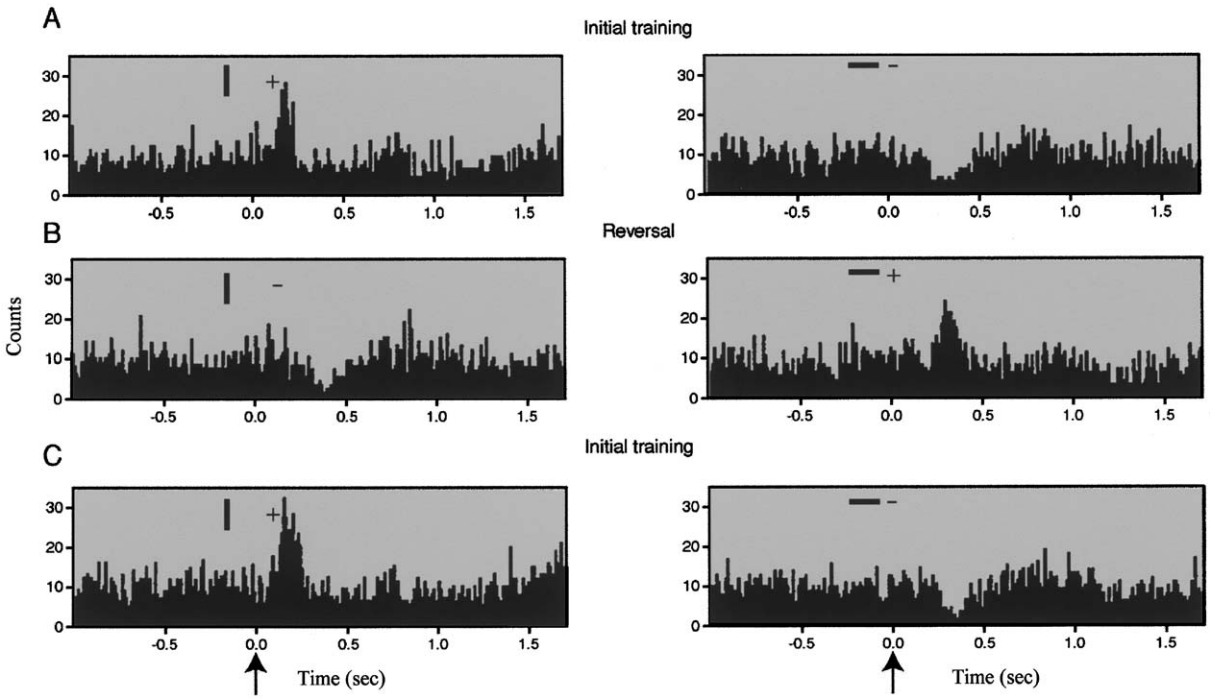

Figure 5 Noradrenergic neuron responses during the *odd ball* task. In the *odd ball* task, either vertical or horizontal bars are presented to monkeys. The activity of their noradrenergic neurons is shown here in a peristimulus histogram, which means that all recorded responses were added, with time zero corresponding to stimulus presentation (arrows). In A, vertical bars are presented in 10% of the trials and the animal response is rewarded (+). Horizontal bars are presented in 90% of the trials and are not rewarded (−). In B, the rule is reversed. Horizontal bars are presented 10% of the time and rewarded (+), whereas vertical bars are presented 90% of the time and not rewarded (−). In C, the initial rule is back. LC neuron firing is specifically increased by the presentation of the rewarding stimulus. From Aston-Jones, G., *et al.* (1999). Attention. In *Fundamental Neuroscience*, Academic Press, San Diego.

sensitization parallels an increased behavioral response.

V. IMPACT OF NE ON TARGET STRUCTURES

A. The Variety of Noradrenergic Receptors

Adrenoreceptors are membrane-bound, G-protein-coupled receptors located throughout the body on neuronal and nonneuronal tissues, where they mediate a diverse range of responses to NE and epinephrine. They share the common features of an extracellular amino terminus, seven transmembrane domains, and an intracellular carboxy terminus.

1. Adrenoreceptor Classification

The adrenoreceptor family was initially divided into two subtypes, the α- and β-adrenoreceptors, as first proposed in 1948 by Raymond Ahlquist, an American pharmacologist. A quarter of a century later, the α-adrenoreceptors were further subdivided by Langer according to their anatomical location, with α-adrenoreceptors located on sympathetic nerve terminals designated as α2-adrenoreceptors and those located postsynaptically designated as α1-adrenoreceptors. This anatomical classification rapidly gave way to the identification of pharmacological differences between α-adrenoreceptors, notably, the ability of yohimbine and rauwolscine to act as α2-adrenoreceptor antagonists. Subsequent studies using pharmacological and molecular biological techniques have further subdivided the α–adrenoreceptor family; three subtypes within each group have now been cloned and pharmacologically characterized. The αl-adrenoreceptor subtypes have been classified as the α1A-, α1B-, and α1D-adrenoreceptors, and the α2-adrenoreceptors have been classified as α2A-, α2B-, and α2C-adrenoreceptors (see Fig. 6).

a. α1-Adrenergic Receptors Subdivision of the αl-adrenoreceptors has been facilitated by both pharmacological and molecular biological techniques. The initial classification of α1-adrenoreceptors as α1A and α1B subtypes was determined from differences in the binding characteristics of the competitive antagonist WB 4101 and a site-directed alkylating agent, chloroethylclonidine (CEC). In addition, three different cDNAs, which coded for α1 subtypes, were isolated. These have since been characterized and are believed to code for three functional α1-adrenoreceptors: the α1A and α1B subtypes as described earlier and a third subtype, the α1D. A putative α1L-adrenoreceptor shows characteristics similar to those of the α1A- and α1D-adrenoreceptors, but the gene has not been identified.

The α1-adrenoreceptors mediate their response via the Gq/l1 mechanism. All of the subtypes are coupled to phospholipase C, and activation of the receptor results in the production of inositol triphosphate (IP_3) and diacylglycerol (DAG). The production of these second messengers results in the activation of both

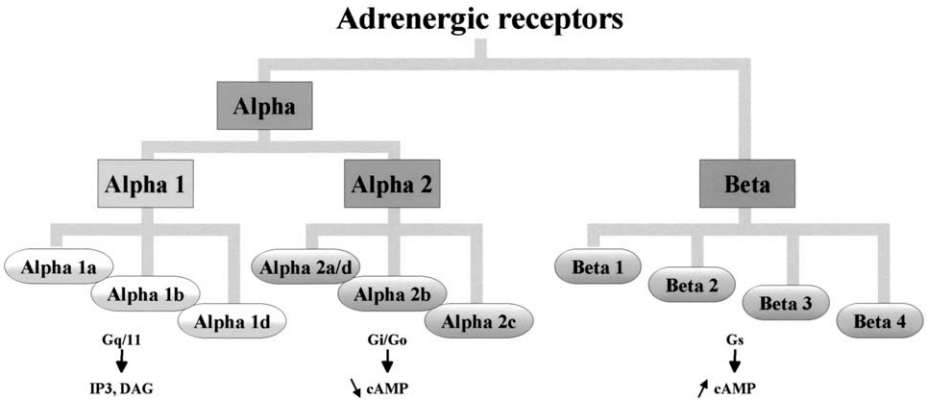

Figure 6 Adrenergic receptor classification. Adrenergic receptors are divided into α1-, α2-, and β-adrenoreceptors. These categories are further subdivided into subtypes, for which genes have been identified. α1-Adrenorecptors are coupled to the G-protein Gq/11, which activates the phospholipase C, producing inositol triphosphate (IP3) and diacylglycerol (DAG). α2-Adrenoreceptors are coupled to the G-protein G_i/G_o Which inhibits cyclic adenosine monophosphate (cAMP) production by adenylyl cyclase. β-Adrenoreceptors are coupled to the G-protein G_s, which stimulates adenylyl cyclase production of cAMP.

voltage-dependent and -independent calcium channels, as well as protein kinase C and phospholipase A2 and D stimulation, arachidonic acid release, and cyclic AMP formation.

The α1-adrenoreceptors are located in both the central and peripheral nervous systems. In the CNS, they are predominantly located postsynaptically where they mediate an excitatory response and are particularly concentrated in the anterior cerebral cortex and thalamus. Peripheral α1-adrenoreceptors are located on both vascular and nonvascular smooth muscle, where their activation results in contraction. On the vascular smooth muscles, the α1-adrenoreceptors are located intrasynaptically where they mediate the response to endogenous neurotransmitter release. They are also located in the heart, where they mediate a positive ionotropic effect, and in the liver, where they activate glycogen phosphorylation.

b. α2-Adrenergic Receptors The α2-adrenoreceptors are located on both pre- and postsynaptic neurons, where they mediate an inhibitory role on the central and peripheral nervous systems. The heterogeneous nature of the α2-adrenoreceptor was first determined from the different pharmacological profiles of the receptor between species, and subsequent studies have revealed the presence of different subtypes within the same tissue. Thus, on the basis of radioligand binding profiles, amino acid sequence, and chromosomal location, four distinct subtypes of α2-adrenoreceptor have been characterized. These α2-adrenoreceptor subtypes, α2A, α2B, α2C, and α2D, are found in a variety of species and tissues and have been characterized by using tissue and cell lines expressing only one subtype. The α2D subtype exhibits a distinct pharmacological profile, but from the sequence homology it is believed to be a species variation of the α2A subtype and is not recognized as separate.

α2-Adrenoreceptors mediate their functions through a variety of G-proteins including G_i and G_o. All of the subtypes have been shown to be negatively coupled to adenylyl cyclase and to mediate an inhibitory effect through the inhibition of cyclic AMP production. In addition, evidence now links the α2-adrenoreceptors to the stimulation of Ca^{2+} influx and also the activation of K^+ channels, phospholipase A2, and Na^+–H^+ exchange.

α2-Adrenoreceptors are found in both the central and peripheral nervous systems, located either pre- or postsynaptically. In the CNS, this receptor can regulate neurotransmitter release as an autoreceptor when located on noradrenergic nerve terminals or as a heteroreceptor when bound on nonnoradrenergic nerve terminals. This role in regulating the release of both NE and serotonin has stimulated the investigation and development of α2-antagonists such as idazoxan in order to cure mental depression.

c. β-Adrenergic Receptors The β-adrenoreceptors were first subdivided into β1- and β2-adrenoreceptors following comparison of the rank order of potency of various adrenergic agonists. The β1-adrenoreceptor is predominant in the heart and adipose tissue and displays equal affinity for epinephrine and NE. In contrast, the β2-adrenoreceptor is predominant on vascular, uterine, and airway smooth muscle and exhibits a higher selectivity for NE than epinephrine.

The classification of β-adrenoreceptors is not limited to β1- and β2-adrenoreceptors. Characterization of β-adrenoreceptor-mediated responses resulted in evidence for further atypical subtypes, β3 and β4, which are insensitive to typical β-adrenergic antagonists. The β4-adrenoreceptor is localized in the cardiac tissue.

The β1-adrenoreceptor is positively coupled to the adenylyl cyclase via activation of G_s. β2- and β3-adrenoreceptors are also coupled to G_s, but their activation can result in either the stimulation or inhibition of adenylyl cyclase. Activation of the β4-adrenergic receptor results in increased cyclic AMP and the stimulation of cyclic-AMP-pendent protein kinase. There is also evidence to suggest that β-adrenoreceptors are linked to voltage-gated Ca^{2+} channels.

The β1- and β2-adrenorecetors have distinct patterns of distribution in the CNS, as determined by using *in situ* hybridization. In the rat, β1-adrenoreceptors are found in high densities in the striatum, although there is an almost complete absence of noradrenergic innervation in that structure, whereas the highest brain concentration of β2-adrenoreceptors is found in the cerebellum.

2. Adrenoreceptor Desensitization and Resensitization

A regulatory feature shared by many of the members of the superfamily of G-protein-coupled receptors is that of desensitization. In response to prolonged or repeated agonist exposure, dampening of the signal transduction process is observed. Desensitization represents the summation of several different processes, including receptor phosphorylation, receptor

sequestration, enhanced degradation of intracellular messengers, and degradation of receptor protein.

Rapid receptor desensitization appears to be mediated by uncoupling of the receptor from its respective G-protein, a consequence of receptor phosphorylation. This mechanism has been studied particularly for the β2-adrenoreceptor, which is phosphorylated on serine and threonine sites by PKA or PKC (Fig. 7A).

β2-Adrenoreceptors are also phosphorylated by β-adrenergic receptor kinase (β-ARK), a member of the G-protein-coupled receptor kinase (GRK) family (Fig. 7B). GRKs are kinases specialized in receptor desensitization. After phosphorylation by GRKs, receptors are recognized by cytosolic proteins from the arrestin family, and binding of arrestin proteins blocks the activation of the G-protein. Once uncoupled from the G-protein, the receptor function can only be restored by receptor dephosphorylation. The extent and duration of receptor desensitization depend not only on the activity of GRKs but also on the activity of the G-protein-coupled receptor phosphatases (GRP). β2-Adrenergic receptor uncoupling is rapidly followed by sequestration into an intracellular compartment distinct from the plasma membrane. The low pH in these endocytosis vesicles induces a conformational change in the receptor, allowing dephosphorylation by GRP. Once dephosphorylated, the receptors are recycled back to the plasma membrane.

Although it has been studied particularly for β-adrenergic receptors, desensitization also occurs for α-adrenergic receptors; β1-adrenergic and α2-adrenergic receptor desensitization has been proposed as a mechanism of action of chronic antidepressant treatment.

B. Several Cellular Targets

The hormonal function of NE raised the question of whether NE had a classical synaptic transmission in the brain. Early studies on the noradrenergic nerve terminals concluded that they do not make synaptic contacts. But more recent data obtained from the cerebral cortex, diencephalon, and cerebellum indicated that noradrenergic nerve terminals exhibit conventional synapses. Both synaptic and paracrine modes of transmission are likely to coexist. Additionally, NE also participates in neuroastrocytic transmission. Cultured glial cells express both α- and β-adrenergic receptors. Brain β2-adrenergic receptors are bound on astrocyte membranes rather than on neurons, and contacts between noradrenergic nerve terminals and astrocytic processes bearing β-adrenergic receptors have been observed. Stimulation of these receptors was shown to increase glycogenolysis and induce NGF release. α1-Adrenergic receptors are observed more frequently on neuronal cells (Fig. 8) but are also present on astrocytes, and their stimulation was found to reduce dye coupling in striatal astrocytes.

C. Postsynaptic Effect of NE and LC Stimulation

1. Effect on Neuronal Discharge

The postsynaptic effects of NE have been studied in several target structures of the LC, such as the neocortex, hippocampus, and thalamus. The impact of LC on the electrophysiological activity of its target neurons was assessed by *in vivo* or *in vitro* application of noradrenergic agonists or antagonists and by *in vivo* LC activation.

Numerous studies have been conducted on the spontaneous and sensory-evoked responses of the neocortical neurons, indicating that NE application or LC stimulation is particularly efficient to enhance the responsiveness of these neurons to sensory stimulation. Indeed, NE does not change the amplitude of evoked potentials but reduces the spontaneous activity of neocortical target cells via both excitatory and inhibitory inputs. Altogether, NE seems to enhance the signal-to-noise ratio of sensory-evoked responses, thus making salient new features of the environment. More recently, noradrenergic activation was found to "gate" inputs to target neurons, which means that subthreshold synaptic inputs become suprathreshold in the presence of NE.

Similarly, facilitory NE effects were demonstrated on various types of synaptically elicited activity in the hippocampus. In addition to these effects, there have been numerous demonstrations of NE enhancement of long-term potentiation in CA3 and the dentate gyrus.

2. Effects on Electroencephalograms (EEG)

Activation of LC neurons by local application of cholinergic agonists induces a desynchronization of cortical EEG, characterized by a shift to high-frequency, low-amplitude activity. This desynchronization is generally considered as an index of sensory

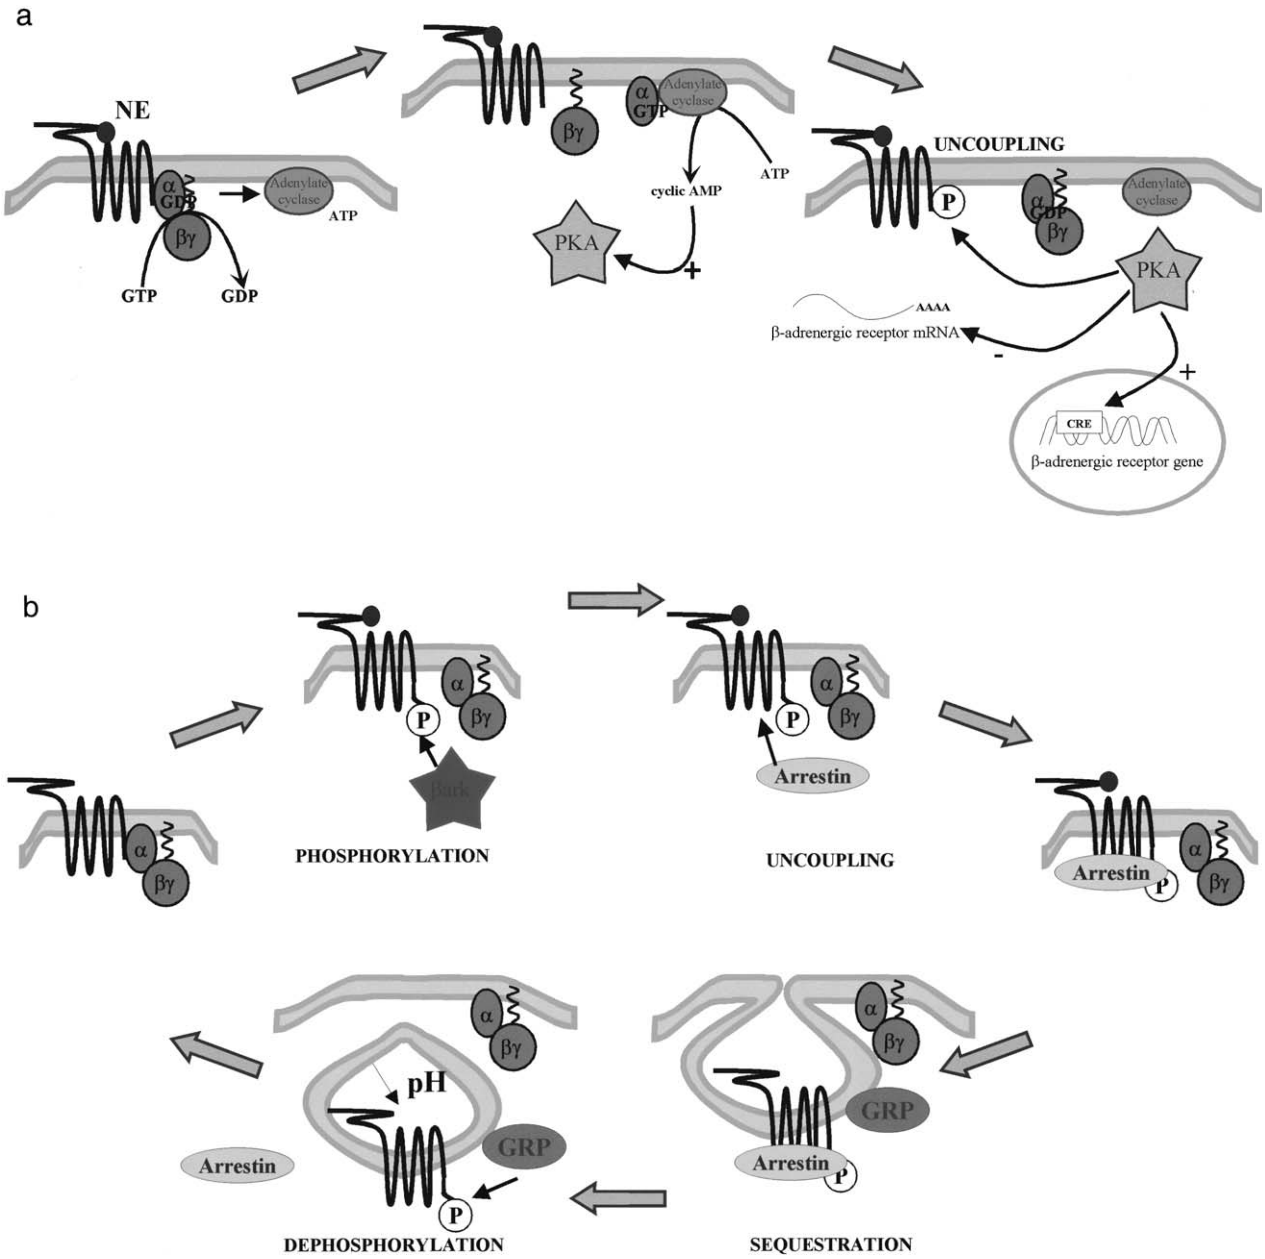

Figure 7 β-Adrenergic receptor desensitization. (A) β-Adrenergic stimulation by NE results in the activation of adenylyl cyclase and the transformation of adenosine triphosphate (ATP) into cyclic adenosine monophosphate (cAMP). cAMP stimulates protein kinase A (PKA). Activated PKA phosphorylates the β-adrenergic receptor, which results in the uncoupling of the receptor from the G-protein. PKA also destabilizes the receptor mRNA and activates the transcription of its gene via the promoter cAMP-responsive element (CRE). Abbreviations: GTP, guanosine triphosphate; GDP, guanosine diphosphate. (B) Stimulated β-adrenergic receptor can also be phosphorylated by the β-adrenergic receptor kinase (β-ARK). A cytosolic protein, arrestin, binds to the phosphorylated receptor, provoking the uncoupling of the receptor from the G-protein and its sequestration in a clathrin-coated vesicle. Following its internalization, the receptor conformation adapts to the low pH maintained in the vesicle. Arrestin separates from the receptor, allowing its dephosphorylation by the G-protein-coupled receptor phosphatase (GRP) present in the membrane and its reexpression to the cell surface.

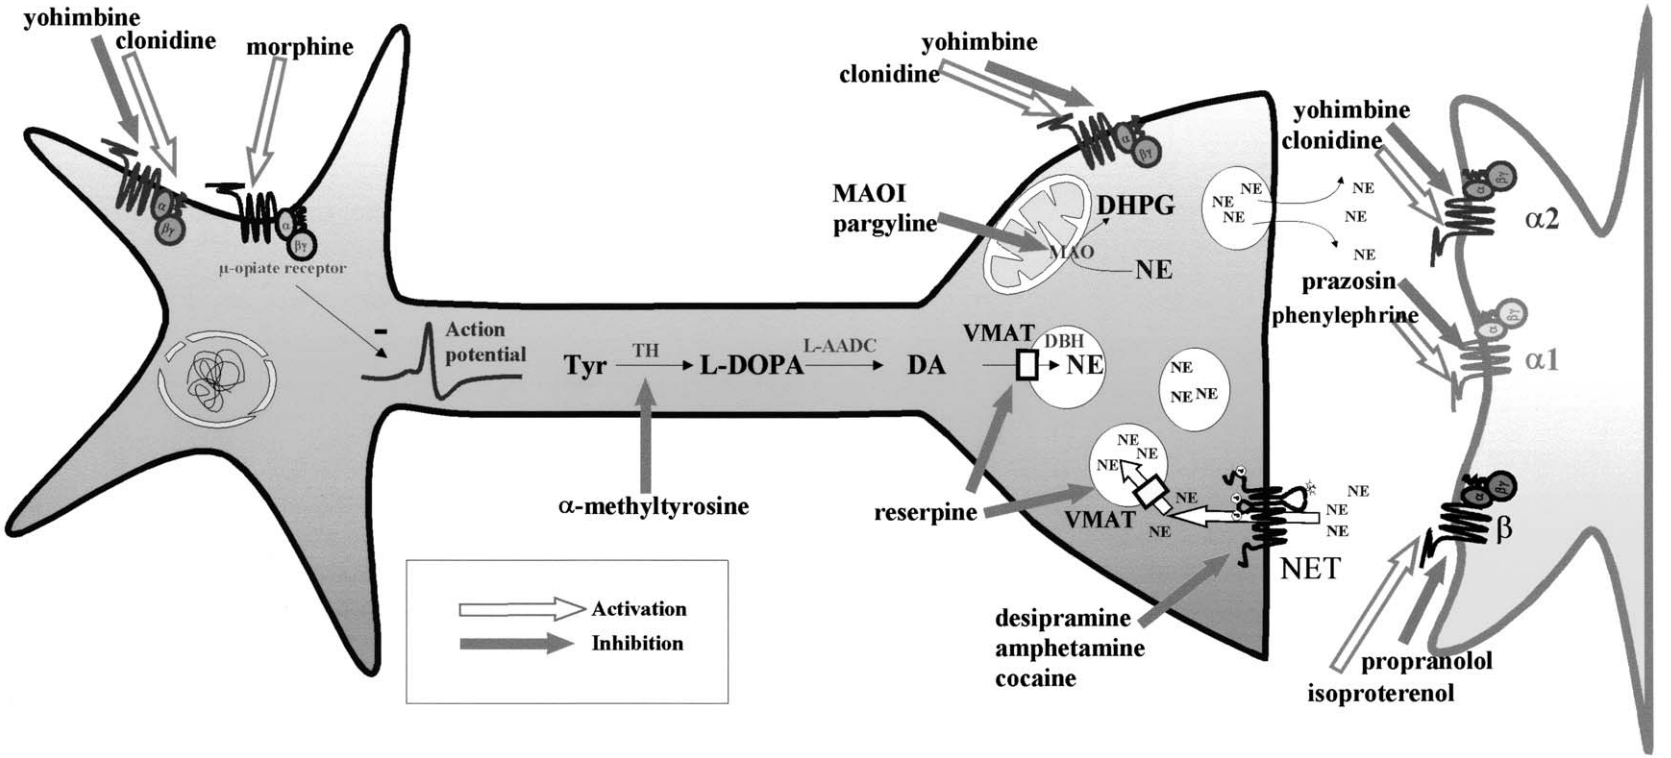

Figure 8 NE pharmacology. Several pharmacological agents are able to modify the noradrenergic transmission. α-Methyltyrosine inhibits tyrosine hydroxylase (TH). Reserpine provokes the release of NE from the synaptic vesicles. Desipramine and cocaine inhibit NE re-uptake by the NE transporter (NET). Amphetamine promotes reverse transport through the NET. Pargyline and many antidepressants (called MAOI for monoamine oxidase inhibitors) block the degradation of NE by monoamine oxidase (MAO). Prazosin, yohimbine, and propranolol (among others) inhibit the action of NE on α1-, α2-, and β-adrenergic receptors, respectively. Phenylephrine, clonidine, and isoproterenol stimulate α1-, α2-, and β-adrenergic receptors, respectively. The action of clonidine or yohimbine on α2-adrenergic autoreceptors also results in the inhibition or activation, respectively, of noradrenergic neuron firing and NE release. Finally, morphine inhibits noradrenergic neuron firing via somatodendritic μ-opiate receptors.

perception. Conversely, LC inactivation by local or peripheral clonidine administration induces a shift in neocortical EEG to low-frequency, large-amplitude activity. Whereas LC innervates the cerebral cortex, the influence of LC on cortical EEG at least partly results from the stimulation of β-adrenergic receptors in the medial septum–diagonal band of Broca, a region that receives dense noradrenergic innervation from the LC.

Long-latency components of event-related potentials include the positive potentials recorded approximately 300 msec (P300) after the occurrence of novel or attention-eliciting events. These P300-like potentials are often considered as electrophysiological correlates of human cognition. Although the electrolytic destruction of LC cells disrupts P300 potentials, this effect is not observed following specific 6-hydroxydopamine chemical destruction of noradrenergic ascending fibers. It is, therefore, possible that non-noradrenergic cells located in or passing through the LC may act in synergy with noradrenergic neurons.

VI. NE IMPACT ON PHYSIOLOGY AND BEHAVIOR

The impact of NE on physiology and behavior was studied in animals by several approaches, including the administration of noradrenergic agonists and antagonists, the stimulation or lesion of noradrenergic neurons, and, more recently, the disruption of genes implicated in noradrenergic transmission. As the widespread distribution of LC innervation through the brain may indicate, NE is implicated in a great variety of physiological and behavioral responses. Most of these responses, including increased heart rate and blood pressure, increased vigilance, hyperarousal, and enhancement of memory storage, are elicited when animals are submitted to unusual or stressful situations.

A. Pharmacological Studies

The effects of noradrenergic agonists and antagonists have been known for several decades, and many are now used clinically. Their major effects are observed at the periphery on the cardiovascular system, interfering with the NE released from sympathetic neurons. Due to their multiple sites of action, systemic administration of these agents sometimes led to difficulties of interpretation, and drugs had to be administered locally in brain structures.

1. α2-Adrenoreceptors

The effects of systemic administration of an α2-adrenergic agonist, such as clonidine, or antagonist, such as yohimbine or idazoxan, are mainly due to their action on autoreceptors, leading to inhibition or activation of noradrenergic neuronal activity, respectively. These effects also implicate the action of NE on postsynaptic adrenergic receptors.

Moderate inhibition of α2-adrenoreceptor by low systemic doses of yohimbine or idazoxan, which increase noradrenergic neuron firing, stimulates locomotion and exploratory behavior toward novel and unexpected objects and exerts a variety of positive effects on learning, such as an increase in food-rewarded operant responding, a reduction in the delay to learn a task when rules are changed during learning, and alleviation of forgetting after a 4-week posttraining delay. At low and moderate doses, idazoxan and yohimbine dose dependently potentiate the amphetamine-induced hyperlocomotion. At high doses, they inhibit locomotion, exploratory behavior, and learning and increase neophobia, suggesting that excessive stimulation of LC neurons may have negative effects. Indeed, exploratory behavior, measured by the time an animal spends investigating objects in a novel environment, has been shown to be sensitive to prior exposure to stressors. At high doses, idazoxan and yohimbine elicit stresslike decreases in exploratory behavior. The α2-adrenergic agonist clonidine antagonizes the restraint-induced decrease in exploratory behavior and the reduction in exploratory head dipping and locomotor activity produced by high doses of yohimbine. Clonidine totally eliminates the preference for novel objects and reduces amphetamine-induced hyperlocomotion.

Feeding behavior is stimulated by low levels of clonidine and decreased by further production of NE. The anorectic action of amphetamine is reversed by centrally administered clonidine.

Clonidine and dexmedetomidine (a highly specific α2-adrenergic agonist) treatments also cause sedation mainly by increasing the time spent in non-REM sleep. These hypnotic effects are not mediated solely by changes in noradrenergic transmission, but are strongly associated with a decrease in serotonergic neurotransmission and diminished by stimulation of 5-HT2 receptors. Similarly, yohimbine produces a dose-dependent anticonflict effect by increasing

serotonergic transmission. Noradrenergic effects on sedation and aggressive behavior seem to be mediated via α2-adrenergic heteroreceptors located on serotonergic neurons.

Finally, phentolamine, a non-subtype-specific α-adrenergic antagonist, inhibits NE facilitation of substantia nigral self-stimulation behavior, but propranolol, a β-adrenergic antagonist, does not.

2. α1-Adrenoreceptors

Intraventricular administration of terazosin, a nonspecific α1-adrenergic antagonist, produces a dose-dependent suppression of locomotor activity, whereas β1- and β2-adrenergic antagonists have a smaller or no inhibitory effect. This activity-reducing effect is not due to sedation or motor coordination impairment and may have a motivational or sensory gating component. On the contrary, administration of NPY or phenylephrine, an α1-adrenergic agonist, into the prefrontal cortex increases locomotion and exploratory behavior. NPY effects are blocked by prazosin, an α1-adrenergic antagonist analog to terazosin, suggesting that NE modulation of locomotor and exploratory behaviors involves the α1-adrenoreceptor located in the prefrontal cortex. Alternatively, electrophysiological studies have established that α1-adrenergic receptors in the dorsal raphe nucleus exert a tonic excitatory action on serotonergic neurons, which may also be implicated.

Prazosin and corynanthine, another α1-adrenergic antagonist, dose dependently attenuate amphetamine-induced hyperlocomotion. In contrast, the selective α1-adrenergic agonist, ST 587, potentiates the locomotor effect of amphetamine. It was found that blockade of α1-adrenergic receptors in the prefrontal cortex inhibits not only the amphetamine-induced locomotor hyperactivity but also, as measured by microdialysis, the functional release of dopamine in subcortical structures. Such a finding is one piece of evidence of the existence of functional coupling between cortical noradrenergic and subcortical dopaminergic systems.

Intraventricular terazosin, an α1-adrenergic antagonist, also produces hypothermia and a reduced respiratory rate suggestive of reduced sympathetic outflow.

3. β-Adrenoreceptors

Evidence indicates that NE modulates memory storage through the activation of β-adrenoreceptors in the amygdala and hippocampus. In newborn rats, propranolol, a β-adrenergic antagonist, injected immediately following training in a classical conditioning test impairs memory in a dose-dependent manner. Isoproterenol, β-adrenergic agonist, injected immediately after training also impairs memory performance. In adults, LC stimulation enhances memory retention in a food-rewarded maze task. This enhancement is blocked by propranolol. β-Adrenergic antagonists increase working memory errors induced by NMDA receptor antagonist administration in the hippocampus, whereas α-adrenergic antagonist administration in the hippocampus has no effect on working memory. However, the enhancing effect on memory retention of amygdala β-adrenergic activation by clenbuterol is attenuated by coadministration of prazosin, an α1-adrenergic antagonist.

β-Adrenergic receptors also participate in maternal behavior. Activation of β-adrenergic receptors in the olfactory bulb of the sheep is required to establish olfactory recognition of the lamb. Propranolol administration in the olfactory bulb before parturition prevents ewes from recognizing their lambs. Propranolol treatment increases maternal onset latencies in new mother rats with brief maternal experience, whereas isoproterenol reduces these latencies.

Like α-adrenergic receptors, β-adrenergic receptors are implicated in novelty-elicited behaviors. Propranolol totally eliminates the preference for holes with novel objects while having no effect on total time spent investigating the holes. Propranolol administration in the basolateral nucleus of the amygdala reduces neophobia for food in animals highly responsive to novelty.

Systemic propranolol prevents restraint-induced changes in behavior in mice. Intraventricular isoproterenol administration produces an increase in defensive withdrawal, which is inhibited by propranolol. Finally, blockade of β1-adrenergic receptor in the CNS by betaxolol mimicks the inhibitory effect of stress on swimming and locomotion and increases grooming behavior.

B. LC Stimulation

Electrical stimulation of the LC produces a series of behavioral responses similar to those observed in naturally occurring or experimentally induced fear. Such behaviors are also elicited by the administration of α2-adrenergic antagonists that stimulate LC firing via their action on autoreceptors.

LC activation can also produce potent antinociception by reducing the response of neurons of the dorsal horn of the spinal cord through the stimulation of α2-adrenergic receptors.

C. Lesions of NE Neurons

Lesions of NE neurons can be achieved by different methods, including excitotoxic lesion of the locus ceruleus, local administration of 6-hydroxydopamine in the main LC projection pathway, or systemic administration of DSP-4. Although easy to use because of the possibility of a systemic injection, DSP-4 is not a suitable tool because it only induces a 70% loss in tissue NE and makes interpretations difficult when no behavioral deficit is observed.

In the rat, nearly complete depletion of NE (>99%) in the forebrain can be achieved by injecting 6-hydroxydopamine, a neurotoxin selective of the catecholaminergic neurons locally into the trajectory of the LC axons, i.e., the dorsal noradrenergic bundle (DNAB). Such a lesion has no effect on eating, drinking, or spontaneous locomotor behavior but affects responses to novelty and the acquisition of conditioned behavior. DNAB lesions impair appetitive and aversive conditioning whenever the rat has to learn a behavior in response to the discriminative stimulus, but only when the lesion occurred before the acquisition of the task. Tasks in which a simple behavioral response is required, such as conditioned taste aversion, are resistant to DNAB lesion. DNAB lesion also spares behavioral tasks in which the animal has to refer to distal cues, as in contextual aversive conditioning or spatial learning in a Morris maze. Taken together, these results suggest that DNAB-lesioned animals are only impaired in tasks requiring a high level of arousal and focused attention to local cues. Additionally, DNAB lesions have been shown to exert anxiolytic effects in anxiogenic behavioral test situations.

D. Knockout and Transgenic Mice

Several genes coding for adrenergic receptors or proteins implicated in the synthesis or metabolism of NE have been deleted from mice with the knockout technique. Most of the initial studies have focused on the cardiovascular functions of these knockout mice, and only few behavioral experiments performed on these animals have yet been described.

1. Dopamine β-Hydroxylase (DBH) Knockout Mice

Most DBH−/− mice die *in utero*. However, survival can be enhanced by perinatal administration of dihydroxyphenylserine (DOPS), a direct precursor of NE (see Fig. 3). DBH−/− mice have impaired adaptation to cold and have elevated basal metabolic rates without abnormalities in thyroid hormone levels. A deficit in maternal behavior in DBH−/− females may also exist. The results of cross-fostering between DBH−/− females and DBH+/− females suggest that an important interaction mediated by NE occurs between the dam and the neonate during the first 24 hr for establishing maternal behavior.

The results of behavioral tests indicate that NE plays an important role in motor learning and performance and in the retention of several behaviors. Restoration of NE with DOPS eliminates the motor deficits and improves fertility in males, indicating that these differences are due to the physiological absence of NE rather than lasting developmental defects secondary to NE deficiency. More recently, it was found that DBH−/− mice exhibit altered ethanol-induced behavioral and physiological responses. DBH−/− mice exhibit a reduced ethanol preference in a two-bottle choice paradigm and delayed extinction in the ethanol-conditioned test aversion. They are hypersensitive to the sedative and hypothermic effects of systemic alcohol administration. Interestingly, NPY−/− mice show increased consumption and less sensitivity to the hypnotic effects of ethanol, whereas NPY-overexpressing mice decrease their consumption of ethanol. This suggests that NPY, which, as previously mentioned, is colocalized with NE in LC cells (see Section II.B), counterbalances NE effect.

2. NE Transporter Knockout Mice

Although such animals have been already obtained and seem to survive at normal Mendelian ratios, data concerning their phenotypes are scarce. There is no doubt that mice lacking the NE transporter will be an interesting tool to use to approach the different roles of NE, especially if one considers that NET is a major target site for most antidepressants and psychostimulants. Recent data indeed indicate that mice lacking NET are hypersensitive to behavioral effects of psychostimulants.

3. α2-Adrenergic Receptor Transgenic Mice

Mice with the deletion of α2A-, α2B-, or α2C-adrenergic receptor genes, as well as point mutation

of the α2A gene and a 3-fold overexpression of the α2C gene, have been generated and facilitated the assignment of different functions of α2-adrenergic receptors to specific subtypes because subtype-specific agonists and antagonists were lacking. Studies with these mice indicate that most of the classical physiological functions mediated by the α2-adrenergic receptors, such as hypotension, sedation, analgesia, and hypothermia, are mediated by the α2A subtype. The α2B subtype, the principal mediator of the hypertensive response to α2-agonists, appears to play a role in salt-induced hypertension and may be important in developmental processes.

The α2C subtype appears to be involved in many central nervous system processes, such as the startle reflex, stress response, and locomotion. In particular, α2C-knockout mice show an increased locomotor response to amphetamine, whereas mice overexpressing the α2C gene show decreased activity in response to the drug. In an isolation-induced aggression paradigm, α2C knockout mice present decreased attack latency, whereas mice overexpressing the α2C gene increase attack latency. α2C overexpression increases and lack of α2C-adrenergic receptor decreases the immobility of mice in the forced swimming test, i.e., α2C-adrenergic receptor expression appears to promote the development of behavioral despair. α2C-adrenergic receptor is also involved in spatial learning. In the Morris water maze, α2C-adrenoreceptor overexpressing mice develop an ineffective thigmotaxic search pattern characterized by swimming close to the pool walls during both spatial and nonspatial water maze training, whereas their swimming pattern is normal when no cognitive component is required. In the T-maze delayed alternation task, α2C-knockout mice present lower performance than wild-type mice due to a higher number of perseverative errors.

Both α2A and α2C subtypes are important in the presynaptic inhibition of NE release and appear to have distinct regulatory roles. However, simultaneous disruption of both α2A and α2C genes leads to far more severe deficits than the single disruption of either of these genes.

4. α1-Adrenergic Receptor Knockout Mice

Only data on α1B-adrenergic receptor knockout mice were published at that time. The mutants have no apparent phenotype changes except a decreased phenylephrine-induced blood pressure response. However, interestingly, experiments have indicated that these knockout mice exhibit locomotor responses to psychostimulants, such as cocaine or amphetamine, that are dramatically decreased when compared to those obtained with wild-type congeners. Because it has been claimed that psychostimulants exert their behavioral effects through an increase in subcortical dopaminergic transmission, such data suggest, as previously mentioned, the presence of coupling between noradrenergic and subcortical dopaminergic systems. In other words, it cannot be excluded that psychostimulants exert some of their behavioral effects through the noradrenergic stimulation of α1B-adrenergic receptors.

5. β-Adrenergic Receptor Knockout Mice

Ninety percent of β1-adrenoreceptor (−/−) mice die *in utero* between days 10.5 and 18.5 of gestation. Surviving mice appear normal and are fertile. β2-adrenoreceptor(−/−) knockout mice are normal and fertile. Physiological responses (blood pressure and heart rate) of the mice to β-adrenergic agonists and antagonists were tested and confirmed their absence of effects. Behavioral experiments have not been reported yet.

VII. CLINICAL IMPLICATIONS OF CENTRAL NORADRENERGIC SYSTEMS

Several agonists and antagonists of noradrenergic receptors are currently used in the pharmacopea to interact with different diseases related to NE in the peripheral nervous system. For example, inhalation of β2-adrenergic receptor-selective compounds has long been established as an effective therapy for asthma and other bronchospastic condition, and β-blockers are used in the treatment of angina pectoris and cardiac arrythmias. They are both used as a treatment for acute congestive heart failure or for long-term management of patients who survive myocardial infarction. In addition, β-adrenoreceptor antagonists have been used as effective antihypertensive drugs for several decades. α-Adrenoreceptor ligands, such as α1-adrenoreceptor antagonists and α2-agonists, are also widely employed as antihypertensive agents.

It must be recalled, however, that brain noradrenergic neurons are protected from peripheral NE by the blood–brain barrier and that several peripheral noradrenergic agents have been developed in such a way that they do not pass through this barrier. Consequences of central or peripheral noradrenergic

system dysfunctions therefore have to be considered separately. For instance, because of the widespread projections of the central noradrenergic system and the numerous functions NE plays in the brain, it can be anticipated that any dysfunction of central noradrenergic neurons may induce a series of different neurological and psychiatric diseases.

A. Parkinson's Disease

Besides the cardinal signs of tremor, bradykinesia, rigidity, and postural instability, patients suffering from Parkinson's disease (PD) may also present many other neurological symptoms and signs, including cognitive, sensory, and autonomic disturbances. The implication of NE in PD is based on the observation that PD is associated with the degeneration of not only dopaminergic neurons located in the substantia nigra but also NE–LC cells. This LC alteration results in a drastic diminution of NE levels in brain areas such as the prefrontal cortex and also in the peripheral system. As for dopaminergic neurons, noradrenergic neurons contain neuromelanin, a pigment that results from oxidative catabolism of catecholamines and that may sensitize noradrenergic cells to oxidative stress. It should be noted, however, that noradrenergic medullary nuclei remain unchanged.

The role of NE in PD is not as clear as it is for dopamine. One possibility is that the depletion of noradrenergic cells is responsible for secondary symptoms of PD such as depression, dementia, or deregulation of endocrine function. This hypothesis is supported by the fact that NE loss is significantly higher for PD patients that also suffer from dementia. Another possibility has been raised by experiments on MPTP-treated monkeys. MPTP is a neurotoxin whose injection results in the degeneration of dopaminergic cells and the development of Parkinson-like symptoms, which may be followed by a partial recovery. Bilateral LC lesions, which do not induce any particular motor deficits in normal monkeys, strongly aggravate the symptoms in MPTP-treated monkeys and delay their recovery.

B. Psychiatry

Studies about the role of NE in psychiatric disorders often rely on the measurement of plasma or urinary levels of NE and its neuronal metabolites (MHPG and DHPG), which represents the most direct method available to measure noradrenergic activity in living human subjects. However, the variations in these levels more probably correspond to NE released by the sympathetic system rather than to NE released in the brain. Alternative methods have been considered (MAO activity of platelets, platelet density of α2-adrenergic receptors, growth hormone release in response to clonidine), but results are still contaminated by noradrenergic activity at the periphery. The limitation of such approaches has always led to debate. Central noradrenergic activity can easily be measured in animals, but animal models of psychiatric disorders are subject to controversy. The most convincing arguments often arise from the pharmacological properties of psychotropic drugs and, conversely, the psychotropic effects of noradrenergic agents.

1. Anxiety: Panic Disorders and Posttraumatic Stress Disorder (PTSD)

Anxiety is phenomenologically similar to states of fear, with the difference that fear is related to real threat, whereas anxiety is an excessive response when little or no real danger is present. There is considerable evidence for a relationship between noradrenergic brain systems and behaviors associated with stress and anxiety. In animals, behaviors that are characteristically observed in situations of stress and fear are associated with an increase in activation of LC–NE systems. Similarly, in healthy human subjects, many studies found significant correlations between states of anxiety and plasma or urinary levels of MHPG. Conversely, stimulating NE transmission induces fear reactions. Infusion of NE into the hypothalamus of cats results in defensive–aggressive behaviors such as hissing, growling, and ear retraction. Stimulation of LC in monkeys induces behavior seen in the wild when the animal is threatened. Panic attacks are induced by yohimbine, an α2-adrenergic antagonist that increases LC firing, in approximately 60–70% of patients with panic disorders.

In animals, chronic stress is associated with a sensitization of both behavioral and NE responses after reexposure to a subsequent stress. This stress sensitization might be relevant to the neurobiology of disorders such as panic disorders or PTSD, in which patients have had a history of previous exposure to stress. This suggests that panic disorders and PTSD may result from abnormally high LC activity. Indeed, some studies have demonstrated increased urinary NE and blunted growth hormone response to clonidine in

both patients with panic disorders and those with PTSD. Studies on other anxiety disorders, such as generalized anxiety disorder and obsessive–compulsive disorder, do not support an important role for NE brain systems.

Finally, the therapeutic efficacy of tricyclic drugs or monoamine oxidase inhibitors, usually considered as antidepressants, may result from their actions on the noradrenergic system. Benzodiazepines that are highly efficient in reducing panic disorders also reduce LC firing.

2. Depression

In 1965, Joseph Schildkraut initially proposed the hypothesis that noradrenergic systems would play a role in depression and be the major site of action of antidepressant drugs. Although more recent data clearly indicate that other neurotransmissions, such as serotonergic and dopaminergic ones, are also implicated, the role of noradrenergic systems nevertheless remains prominent. For example, in bipolar patients, urinary MHPG levels are lower during the depressed phase and higher during the manic phase than during periods of euthymia. Furthermore, unipolar and bipolar depressive patients demonstrate greater increases in plasma NE after moving to an upright position than do controls. Finally, post mortem studies have reported higher β-receptor densities in the brains of suicide victims than in controls.

Since the demonstration that most antidepressants decrease β1-adrenergic receptor transduction in the cerebral cortex of the rat, this parameter has generally been considered as a biochemical correlate of therapeutic activity. This observation is noteworthy not only because it seems to be a common consequence of chronic treatments with most antidepressants whatever their mechanism but also because its development parallels clinical improvements. Indeed, in animal studies, down-regulation of βl-adrenergic receptors only appears following 10–20 days of chronic treatment, a delay that corresponds to clinical observations. Not all antidepressants, however, induce desensitization of β-adrenergic receptors. A reactivation of serotonin transmission, which can be obtained by some antidepressants such as SSRIs (specific serotonin re-uptake inhibitors), can hamper the development of β-adrenergic receptor desensitization even when noradrenergic transmission is also reactivated. The lack of a response by β-adrenergic receptors has been proposed to be due to past receptor events at the level of phosphorylations mediated by PKA and PKC.

β-Adrenergic receptors are not the only receptors desensitized by antidepressants. A serotonin receptor subtype, 5-HT2, is also frequently affected. This should not imply, however, that an up-regulation of β1-adrenergic or 5-HT2 receptors is responsible for the disease and that, consequently, down-regulation of these receptors is the goal to achieve. These observations rather suggest that both types of receptors, β1-adrenergic and 5-HT2, are very sensitive to any modification of their respective neurotransmissions and that an activation of the latter occurs following chronic treatment with antidepressants. According to that view, a deactivation of serotonergic and/or noradrenergic neurons is probably the main biochemical characteristic of depression.

It can be added that tricyclic antidepressants are generally considered to have better clinical therapeutic efficacy than SSRIs in major depression. Both groups share the property of inhibiting the re-uptake of NE and serotonin, but tricyclic antidepressants are, in contrast to SSRIs, potent cholinergic and αl-adrenergic receptor antagonists. Although α1-adrenergic antagonism may represent an adverse side effect because of its hypotensive action, it cannot be excluded that the blockade of central α1-adrenergic receptors at least partly explains the better clinical efficacy of tricyclics.

3. Schizophrenia

Since the early 1970s, the dopamine hypothesis has been at the forefront of explanations for the pathogenesis of schizophrenia. This was founded on the fact that classical neuroleptics are potent dopaminergic antagonists. However, estimation of NE and its metabolite MHPG post mortem and in cerebrospinal fluid has produced more consistent findings than similar studies on dopaminergic systems.

Moreover, psychophysiological abnormalities observed in schizophrenic patients, such as dysfunction in smooth pursuit eye movement (smooth pursuit being replaced by stepwise pursuit or spiky pursuit) or in skin conductance responses to novel sensory stimuli (absence of response or failure of its habituation), which may reflect under- or overarousal, are also observed as a consequence of noradrenergic system sub- or supersensitivity.

The interest in noradrenergic systems was renewed with the apparition of atypical antipsychotic agents such as clozapine. Clozapine is one of the first agents demonstrating superior efficacy compared with classical neuroleptics (particularly on negative symptoms)

and, perhaps because it has a relatively low affinity for dopaminergic receptors of the D2 subtype, is devoid of extrapyramidal side effects. It has also been found that chronic clozapine treatment increases plasma DHPG levels in a manner that is correlated with clinical improvement. This study is in agreement with experiments in rats showing that chronic clozapine increases the firing rate of LC neurons. Like other atypical neuroleptics, clozapine is a potent αl-adrenergic receptor antagonist. If we assume, as previously mentioned, that the coupling between noradrenergic and dopaminergic systems is due to the stimulation of α1-adrenergic receptors, it may explain that blockade of the latter can moderate the increased dopaminergic subcortical activity generally considered as one of the main biochemical features of schizophrenia. Finally, clonidine, an α2-adrenergic agonist that decreases LC neuron firing, shows a strong therapeutic effect on positive symptoms in acute treatment but is not used because tolerance develops rapidly with chronic medication and provokes a rebound exacerbation of the symptoms after withdrawal.

4. Attention Deficit Hyperactivity Disorder

Attention deficit hyperactivity disorder (ADHD) is a childhood psychiatric disorder characterized by inattention, impulsivity, and overactivity. Children with ADHD have difficulty completing tasks, they make careless mistakes, do not listen, lose things, and avoid tasks that require concentration, and they are forgetful and disorganized. The behavioral deficits ADHD are estimated to be present in 3–5% of all school-aged children and are believed to arise in early childhood. The neurotransmitter systems most commonly implicated in the pathophysiology of ADHD are the catecholamines, dopamine and NE. Virtually all medications that are effective in the treatment of ADHD, in particular psychostimulants such as methylphenidate, affect catecholamine transmission, and medications that do not interact with catecholamine transmission are rarely effective in the treatment of ADHD, thus indicating the possibility of a biological etiology. A relatively early model has postulated that a noradrenergic dysfunction in the LC produces the deficits in vigilance and sustained attention observed in children with ADHD. However, although studies employing peripheral measures to assess catecholaminergic function in ADHD are plentiful, they are highly inconsistent in their findings. Urinary MHPG levels, for example, were either higher, not changed, or lower in children with ADHD than in normal controls.

The prefrontal cortex and the basal ganglia play prominent roles in a complex neural system that serves to regulate motor function and behavior via working memory. There are different indications suggesting that working memory in the prefrontal cortex is under the control of the stimulation of D1-dopaminergic receptor subtype, whereas activation of cortical α1-adrenergic receptors inhibits the effects of D1-receptor stimulation. Complex interactions between prefrontocortical Dl, D2, and α1-adrenergic receptors have been demonstrated, and it cannot be excluded that ADHD corresponds to some dysfunction of these interactions, which, in turn, are responsible for the expression of subcortical functions.

5. Pharmacodependence

Although multiple lines of research have implicated the mesolimbic dopaminergic system in drug reward, the role of noradrenergic systems in pharmacodependence processes should not, however, be overlooked. Indeed, virtually all classes of abused drugs affect LC discharge characteristics at doses that are in the range of those abused by humans. These include hallucinogens, psychostimulants, opiates, alcohol, nicotine, and benzodiazepines. Much of the work on the LC concerning substance abuse has focused on physical dependence and withdrawal symptoms. This is due to the fact that α2-adrenergic agonists such as clonidine, which suppresses LC activity, partly alleviate withdrawal symptoms for several dependence-producing substances. Indeed, the cessation of drug use in chronic opiate abusers produces a severe withdrawal syndrome that is highly aversive. Although increased NE in the brain has long been implicated in opiate withdrawal, it was not clear whether noradrenergic systems were involved until studies, performed in the rat, were completed to indicate that the noradrenergic inputs to the bed nucleus of the stria terminalis arising from noradrenergic cell groups of the caudal medulla are critically involved in the aversiveness of opiate withdrawal.

As mentioned earlier, LC receives a prominent enkephalinergic input associated with a high density of opioid receptors in that region. Opioid antagonists have no effect on LC activity by themselves, but produce a dramatic long-lasting excitation in rats that have chronically received opiates. It is this effect that has been the basis for rationalizing the use of clonidine, which inhibits LC discharge, in the treatment of opiate withdrawal.

The case of nicotine is also interesting because it produces a potent activation of LC neurons when administered systemically. Surprisingly, evidence indicates that this effect of nicotine is not mediated in the LC, or even initiated in the brain, but results from nicotine activation of primary sensory C-fiber afferents. In addition to increasing LC discharge, nicotine induces an increase in the frequency of burst activity, suggesting that the net effect of nicotine is to elicit more NE release in targets and produce short-lasting periods of enhanced arousal.

Dopaminergic systems are, however, more generally considered as the main targets of drugs of abuse than noradrenergic ones because it is believed that psychostimulants, such as amphetamine and cocaine, or opiates, such as morphine and heroin, cause addiction in humans and induce locomotor hyperactivity in rodents through increased release of dopamine in a subcortical structure, the nucleus accumbens. Nevertheless, as noted earlier, experiments performed on rats have indicated that prazosin, an α1-adrenergic antagonist, could hamper the locomotor hyperactivity induced by D-amphetamine. Similarly, we have previously mentioned that mice lacking the α1B-adrenergic receptor were considerably less sensitive to the locomotor effects of amphetamine and cocaine than their corresponding controls. This suggests that, in addition to its role in drug withdrawal, NE, via the stimulation of α1B-adrenergic receptors, may enhance the release of subcortical dopamine and, therefore, amplify the rewarding effects of drugs of abuse. Such a role for NE may provide some new insight into the problem concerning the great variability in the sensitivity to drugs of abuse observed in humans and animals. Indeed, because LC cells are extremely sensitive to environmental stimuli, small genetic or epigenetic variations in the reactivity of noradrenergic neurons to environmental cues may affect the activation of mesencephalic dopaminergic neurons and, more generally, the sensitivity to drugs of abuse.

VIII. CONCLUSION

Several theories have been proposed to describe LC functions, ranging from notions of reinforcement and arousal to the mediation of anxiety or the control of selective attention. Because there is a good chance that most of these theories, although different, originate from the same observations, it seems wise to restrict this conclusion to a brief description of experimental data that have reached general agreement. On an anatomical point, LC cells send widely ramifying axons, which innervate diffuse forebrain structures such as the cerebral cortex and the hippocampus. The electrophysiological data and also neurochemical indices indicate that LC neurons stop firing during REM, are especially active during high states of arousal, and exhibit phasic responses to novel or intense stimuli. Finally, the release of NE in terminal regions enhances the signal-to-noise ratios of event-related action potentials.

From these data, it follows that LC neurons improve the processing of external events, whether these events are novel or salient because of previous conditioning, making them even more salient. Although this article was devoted to NE in the central nervous system, it must be noted that interactions with the periphery do exist, and, as proposed by Gary Aston-Jones, whereas the "activation of the peripheral sympathetics system prepares the animal physically for adaptive phasic responses to urgent stimuli, … parallel activation of LC increases attention and vigilance, preparing the animal cognitively for adaptive responses to such stimuli." Indeed, LC activity participates in the mechanism, which effectively focuses attention on salient stimuli in threatening or demanding situations. It can be considered, therefore, that LC cells do not mediate anxiety or stress per se, but rather a state of arousal leading to attentional and cognitive change. Any over- or underactivation of these LC cells will induce exaggerated or attenuated responses, leading to diseases such as panic attacks or depression. Finally, it must be recalled that noradrenergic systems interact with other neuromodulatory neurons, especially serotonergic and dopaminergic, and that there is little doubt that malfunction of the former will have consequences on the functions controlled by the latter.

Number Processing and Arithmetic

KAREN WYNN
Yale University

GLOSSARY

acalculia Severe deficit in arithmetical calculation abilities, often resulting from a brain lesion or degenerative neurological disorder.

cardinality The total number of items in a set.

counting Determining the number of items in a set by engaging in a serial process that satisfies the counting principles.

enumeration Determining the number of items in a set by any means including, but not limited to, counting.

individuation To determine the boundaries of a specific individual and maintain a representation of that entity as a distinct unit.

subitization A process of rapidly determining how many items are in a display; applies over small numbers only.

The formal system of mathematics is arguably one of the greatest and most beautiful of human achievements. Mathematics captures and describes many aspects of the physical world, yet it is an abstract logical system that is unconstrained by physical reality. How is it that the human mind is able to grasp an understanding of such abstract knowledge? How are we able to determine the numbers of things in our world? How does the human mind represent number concepts, and how does it operate on these representations to perform basic numerical computations, including arithmetic? These questions form the central focus of this article. Empirical findings suggest that some understanding of number is part of the inherent structure of the human mind. Evidence from comparative psychology and cognitive neuroscience suggests that we may be born with an evolved mental mechanism for number, which we share with a number, of animal species; specific brain structures are responsible for our sense of magnitude and our ability to engage in basic numerical thought.

I. SOME ABILITIES OF NORMAL HUMAN ADULTS

A. Linguistic Counting

One obvious means we have for determining the numerosity of a set is to purposefully count the members of a set, to apply our list of number words to items in the set. Psychologists Rochel Gelman and Randy Gallistel, in their classic book *The Child's Understanding of Number*, outlined the functional principles required of any and all counting procedures. The Stable-Order Principle specifies that the number labels must be used in a consistent order across all counts. The One-to-One Correspondence Principle specifies that one and only one number label must be applied to each item to be counted, and the Cardinality Principle specifies that the number label applied to the final item in a count serves to represent the total number, or cardinality, of the set of items counted. Furthermore, the Order-Irrelevance Principle states that the same answer will be obtained regardless of the order in which the items in the set are counted. Finally, the Abstraction Principle states that any items can be

counted; items need not be homogeneous to be grouped into a single count.

To engage in this procedure clearly requires having learned both the counting routine and the number words of one's language. But there is evidence that our ability to determine number is not entirely language-dependent. Human adults possess other cognitive processes that will also yield numerical representations.

B. Subitization and Estimation

1. Subitization

It has been known for a long time that human adults can identify small numbers of objects precisely without having to consciously count them. If someone places a small handful of up to three or four coins onto a table, one would have the experience of immediately being able to tell how many there were, without counting. This ability is known as subitization and has been studied experimentally since the 1940s. There are two experimental findings that typify the subitization phenomenon: (1) If varying numbers of items are visually presented very briefly (say, 200 msec) to adult subjects whose task is to indicate the number of the items, subjects tend to show virtually perfect performance for numbers up to three or four items, with performance error increasing linearly with numbers beyond this range. (2) If visual displays containing varying numbers of items are presented to subjects whose task is to respond *as accurately as possible* with the number of items, subjects show very little increase in reaction time as the number of items in the display increases from zero to three or four, and then show a much steeper linear increase with additional items (see Fig. 1). Note that the first measure in essence holds reaction time constant (by presenting all stimuli equally briefly) and measures the effect of number on accuracy, whereas the second measure holds accuracy constant (by asking subjects to be as accurate as possible) and measures the effect of number on reaction time. Thus, there is a trade-off between accuracy and reaction time for numbers above the subitization range, typically at about four items and higher, but little trade-off between the two for numbers within the subitizing range.

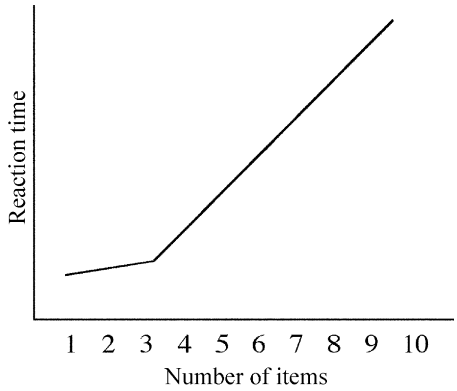

Figure 1 Typical reaction-time function for subitization.

2. Estimation

Adults' ability to determine number without conscious counting is not limited to small set sizes. We can estimate the number of items in a display containing many elements, for example, the number of black dots on a page filled with dots. In such situations, whereas the exact number estimated may be quite off the actual number, adults quite reliably give much higher estimates when presented with, say, 2000 dots than when presented with, say, 500 dots. Moreover, adults are good at representing both the absolute and relative frequencies of many different kinds of items: visual entities, sounds, events, number of words in a list that begin with the letter r, and so on. This is true even when subjects have no knowledge, when presented with the stimuli, that the task will involve subsequently giving a numerical judgment.

3. Theories of the Cognitive Processes Underlying Subitization and Estimation

What is the nature of each of these abilities to determine and represent number? There have been different proposals as to the underlying nature of the subitization process. One early proposal was that subitization is a visual pattern-recognition process, in which subjects are not actually determining the number of items present in a display but are recognizing distinct patterns that typify displays of a given number. For example, two points define a line and three points in random configuration typically define a triangle. Subjects could very quickly recognize such patterns and simply associate each pattern with its corresponding numerosity. This would explain the relatively flat reaction time slope for numbers in the one to three range; the different patterns (point, line, triangle) associated with these numbers are all recognizable in about the same amount of time. However, as

the number of items increases to four or more, the number of possible configurations for a given number increases exponentially, and the variety of configurations for displays of different numbers begin to overlap each other much more heavily, so that pattern recognition would break down at about this number, precisely where the subitization reaction-time data show a sharp "elbow." In this proposal, subitization (which ends at about three items) and estimation (which begins at around four and more items) are inherently distinct processes. However, this theory has largely fallen out of favor, primarily because data show that subitization effects are obtained even when subjects could not be identifying each number with a unique perceptual pattern (for example, when all points are arranged collinearly or when objects are not simple dots but complex household items each with a unique contour, making the overall contour of even a one- or two-item display complex and variable rather than linear).

A very different possibility is that subitization is a rapid and automatic serial enumeration process: subjects are determining the number of items per se in the displays through some form of unconscious counting. One specific model of such a counting process is the accumulator mechanism. This model will be described in greater detail later. Briefly, in the accumulator model, numerosities are represented by magnitudes, so that the counting process is akin to filling a bucket with a burst of water, one burst for each item to be counted. The final fullness level of the bucket represents the total number of the items counted. Evidence favoring the view that subitization is some form of serial counting process is that the reaction time curve is not flat for the numbers one to three but shows a shallow slope even across this range indicating some "cost" to each additional item in terms of processing time—a hallmark of serial processing.

How does this theory account for the subitization "elbow" in reaction times and for the decrease in accuracy with larger numbers? In this theory, there is variability in the counting process, an error term that is additive with each item counted (the bursts of water are not all identical in amount). Thus, with larger counts there will be more variance in the final fullness level. This means that larger numbers will be more difficult to discriminate than smaller numbers, leading to a decrease in accuracy as number increases. Whereas the mean fullness levels for, say, five and six will be as far apart as the mean fullness levels for two and three, the normal distributions of the fullness levels for the former will overlap more than those for the latter. In order for subjects to maintain near-perfect accuracy in subitization tasks for numbers large enough that their fullness values are not reliably discriminable, subjects will have to resort to other measures, such as consciously counting the items. When consciously counting, one must serially attend to each item in the display, such that there is a constant increase in processing time required for each added item to be counted, thus explaining the linear increase in reaction time (RT) for numbers four and higher. In this proposal, both subitization and estimation reflect the *same* enumeration process at work: because of the additive nature of the variance, this automatic enumeration process enables highly reliable discrimination and fast reaction time for very small numbers of items (i.e., subitization) but enables only approximate, "ballpark" identification of larger numbers (estimation).

Further evidence suggests that there may be additional processes involved in subitization as well. Lana Trick and Zenon Pylyshyn have suggested that subitization may be based in part on certain encapsulated processes within visual cognition. Specifically, they propose that the visual system comes equipped with a small number (three or four) of pointers or "fingers," which pick out selected objects in the visual field. Each pointer is assigned to an object the visual system wishes to track and indexes the current location of the object, updating the location as required (as the object moves, for example, or over brief occlusions and successive saccades). These fingers are assigned in parallel during the early preattentive stages of visual processing. In order to determine the numerosity of a group of items, one must first individuate the items, keeping track of the items to be counted and mentally keeping separate the already-counted items from the to-be-counted items. After individuating each item, one must operate over each item serially, for example, assigning a number word (if one is engaged in verbal counting) for each item or incrementing an accumulator with one increment for each item (the accumulator model). If there are specialized processes within the visual field for rapidly and in parallel individuating three to four items in a display, then this will enable the serial enumeration operation to commence significantly earlier, considerably speeding up—and rendering more error-free—the process for displays containing at most three or four items. In displays containing larger numbers of items, some of the items will be individuated "for free" by these preattentive pointers within the visual system, but the remainder of the items will need to be individuated serially themselves,

lengthening the time course of the process and also increasing the likelihood of error.

Evidence for such a component within the visual system comes from numerous sources. First, when subjects are presented with displays in which serial attentional processes are required to individuate the items to be enumerated (for example, displays containing items with overlapping contours such as concentric circles or containing distractor items from which the target items do not "pop out" but must be searched for serially), the subitization function disappears: there is a linear increase in reaction time for each added number of items, even in going from one to two items. Moreover, neuropsychological data obtained by Stanislas Dehaene and Laurent Cohen showed a clear dissociation between enumeration within the subitizing range and enumeration beyond this range. Their subjects were brain-lesioned human adults who were severely simultagnosic, that is, who showed significant deficits in serial visual exploration but whose parallel preattentive visual processes were largely intact. By hypothesis, these patients should not be hindered in subitizing, if subitizing is dependent on parallel, preattentive visual processes. However, they should show severe deficits in their ability to engage in serial counting processes, those hypothesized to be required for numerosities of four or more. All patients showed an intact ability to accurately quantify smaller numbers, one, two, and sometimes three, but showed significantly impaired ability to enumerate larger sets of items, showing that subitization can be preserved even when counting is impaired.

C. Calculation

Humans are able to do much more than simply determine numbers of entities; we are able to determine, for example, whether two values are equal or whether one is greater or less than the other, and we can perform numerical computations, determining the sum, difference, or product of two numbers, for example. Some of these computations may be supported by an accumulator-type representation. One finding in studies of adults' calculation performance is that, when subjects have to state, as rapidly as possible, which of two presented numbers is larger, reaction time decreases as the proportionate difference between the two numbers increases; this is known as the Distance Effect. For example, subjects are much faster to respond that 5 is greater than 4 than they are to respond that 15 is greater than 14. But they respond about equally quickly to the comparison between 4 and 6 and that between 12 and 18. This effect fits well with predictions of the accumulator mechanism. In the accumulator, numbers with a smaller proportionate difference will have more confusable magnitude representations and, thus, comparison will be slowed, and when the proportionate difference becomes so small that the magnitudes cannot be reliably distinguished, other processes will have to be recruited to complete the comparison (for example, rapidly mentally counting up the number word list or mentally scanning a number line to determine which number comes first).

However, there are many aspects of our arithmetical competence that cannot be attributed to an accumulator-like magnitude representation of number. For example, our ability to compute the correct answers to precise arithmetical problems involving large numbers clearly cannot rest (at least not solely) on the representations generated by something like an accumulator mechanism, because such representations are much too approximate to support the precise results of our computations with numbers above 3 or 4. Human adults can quite rapidly, and with relatively low error rates, state the answer to the question, "What is the sum of 32 and 24?" These abilities clearly rest on additional cognitive structures and involve a different kind of numerical representation.

There is abundant evidence that numerical calculation is a specific ability unto itself, dissociable from language abilities, general memory function, and general reasoning ability. For example, neuropsychologist Brian Butterworth presented the case of Monsieur Van, who, due to the onset of Alzheimer's disease, had very poor general reasoning abilities, showing an inability to engage in even relatively basic problem-solving strategies. Moreover, he failed on Piaget's typical number-conservation task, in which two rows containing equal numbers of elements are arranged in one-to-one correspondence before the subject. Once the subject agrees that the two rows are equal in number, the experimenter spreads out one of the rows and asks if they still have the same number. Even 6-year-old children will typically answer correctly, unlike Monsieur Van. However, when presented with a wide range of calculation, estimation, and comparison problems, he performed quite well. Contrast this case with that of Butterworth's patient Signora Gaddi, who had very good general reasoning abilities but was unable to reason about or perform even the simplest computations on numbers higher

than four. Butterworth has further case studies of (1) amnesics able to perform normally on number computation tasks, even in the face of drastically impaired short-term memory spans, suggesting that special memory systems may exist for arithmetical facts, and (2) patients with certain kinds of brain damage, who, while retaining their normal long-term memories and short-term memory capacity, lose all of their stored number facts.

There is some evidence that the brain stores well-learned numerical facts (such as those in the addition and multiplication tables, for example) separately from procedures for performing numerical operations such as addition, multiplication, and division and even that distinct numerical operation procedures are stored separately from each other. That is, arithmetical calculation appears to be not just one, but rather several distinct (albeit related) systems. Signore Tiziano, a patient studied by Lisa Girelli and Margarete Delazer, suffered a stroke that affected his left parietal lobe; subsequently, he became unable to perform subtraction procedures correctly, while retaining his proficiency with other arithmetical operations. Or consider the patient of Alphonse Caramazza and Michael McCloskey, who became unable to follow the standard procedure for multiplication but could still perform long division correctly. Such patients, and others like them, were still able to retrieve memorized number facts (such as the addition and multiplication tables). Their problems were at the *procedural* level; they were unable to identify the appropriate sequence of operations and often unable to correctly relate the different numbers in the problem to each other. Conversely, patients like Dr. Constable exist, studied by Elizabeth Warrington, who show the opposite pattern of abilities: Dr. Constable, following a stroke, was unable to recall even basic number facts such as $5+7$ (he had to work out the problems, often by counting up or down) but was well able to instantiate the correct procedures and sequence of operations for carrying out all of the arithmetical operations. Moreover, he could quickly give very good *approximate* answers to questions (such as "$5+7$ is approximately 13") before working them out to obtain the precise answers.

II. A NEUROPSYCHOLOGICAL MODEL OF NUMBER PROCESSING

A. Description of the Model

The abilities, performance patterns, and dissociations described in Section I, together with other findings relating to how human adults represent and process number, led the French cognitive neuroscientist Stanislas Dehaene to develop a cognitive neuropsychological model of number processing that is the dominant model today. In this model, our number knowledge consists of three distinct representational systems. Each of these systems represents numbers in a very different format from the others and so supports different aspects of our numerical knowledge and abilities. Each is localized in a different brain region (see Fig. 2).

A *verbal word* representational system is located in the classical language-specific areas within the left hemisphere only (such as the left inferior frontal and superior and middle temporal gyri) and is responsible for the recognition and processing of spoken or written number words. This system represents numbers as syntactically organized sequences of words (employing

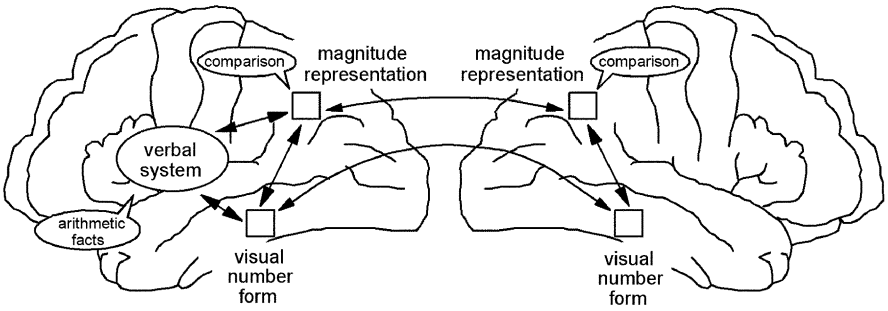

Figure 2 Stanislas Dehaene's triple-code model of number processing (courtesy of *Mathematical Cognition*).

the syntactic rules governing the number naming system of the language) and operates over phonological representations of the number words. This system also stores well-learned arithmetical facts, such as the memorized facts from addition and multiplication tables (subtraction and division facts are not memorized by rote and so are *not* hypothesized to be stored within this system). Finally, this system is heavily implicated in precise mental arithmetic such as multidigit calculations, which involve both retrieval of stored verbal facts and visuospatial representations of numbers.

A *visual Arabic numeral* representational system, located in the left occipitotemporal region of both hemispheres, underlies the recognition of Arabic digits and numerals. This system represents numbers in their Arabic numeral format as strings of digits.

Finally, an *analogical magnitude* representational system, located in the inferior parietal cortex regions of both hemispheres, employs representations that inherently embody the magnitude of a given numerical quantity, representations such as those given by the accumulator mechanism, for example. It is only within this third system that information about what we think of as the meaning or sense of a number—its quantity, magnitude, or size—is represented. Thus, comparison and relational information, such as that one number is smaller or larger than another, is only available within this system. This system also supports approximate, as opposed to precise, arithmetic calculations; such calculations depend on a sense of the magnitudes the values being operated on and the outcome value.

Connections exist (a) between the verbal, Arabic numeral, and magnitude systems within the left hemisphere, (b) between the visual and magnitude systems within the right hemisphere (recall that the verbal system exists solely in the left hemisphere), and (c) across the two hemispheric components of the visual system and of the magnitude system. These connections enable access to multiple kinds of information about a number that has been accessed through one of the systems. For example, the connections between the Arabic numeral code and the magnitude code mean that, when we see an Arabic numeral, say seven, we can then access its magnitude and so perform operations over the magnitudes and/or make magnitude judgments, such as which of two numerals represents the larger or smaller number.

There is considerable neuropsychological evidence, from case studies of brain-damaged patients as well as from studies of normal adults, that these systems are both anatomically and functionally distinct.

B. Evidence from Brain-Damaged Patients

First, consider patients with major left-hemisphere lesions. As one would expect given that language faculties reside in the left hemisphere, such damage is highly associated with severe problems in understanding and speaking language. But patients with this kind of damage can also be acalculic, showing profound deficits in their ability to deal with numbers: an inability to understand number words or relate them to each other and an inability to perform relatively simple arithmetical calculations such as adding $9+7$. However, in the face of this extreme impairment, nonverbal digit recognition, magnitude judgments, and some arithmetical operation abilities may still be functioning relatively normally. For example, one patient, NAU, who had suffered a major lesion of the posterior left hemisphere, had great difficulty reading number words and moreover was unable to solve even such simple arithmetic problems as $2+2$! However, when presented with digits, he could indicate where they should fall on the number line by pointing to roughly the correct location, showing that his digit recognition was preserved and that he was able to access the approximate magnitude of the number represented by the digit. Moreover, and most interestingly, whereas he was unable to give the correct answer to a problem such as $2+2$ and unable to state accurately the truth or falsity of arithmetical statements such as $2+2=5$ or $2+2=3$, he *was* able to state the falsity of statements such as $2+2=9$! Moreover, when presented with two digits, he could immediately say which of the two was larger. He had also apparently retained the approximate, but not the exact, magnitude values of numbers, stating (for example) that there are about 6 or 10 eggs in a dozen, about 350 days in a year, and about 50 min in 1 hr. In sum, NAU was able to identify and operate over the approximate magnitudes of the digits and obtain the approximate magnitudes of the solutions to simple arithmetic problems. In contrast to such effects of damage to the left hemisphere, damage to the right hemisphere has little or no effect on number processing.

Consider now lesions to the inferior parietal cortex. According to the model, such patients can be expected to have a preserved ability to call up memorized arithmetic facts and to correctly read and recognize number words and Arabic digits, but to have no sense of the meanings of these numbers and no understanding of numerical magnitudes and magnitudinal relationships. Again, numerous cases fit this description.

Mr. M., who had a lesion to the inferior parietal cortex, was unable to subtract (saying, for example, that $3-2=2$) and had great difficulty in saying which of two digits was larger. He was also unable to generate the solution to what number lies midway between two given numbers; not only were his responses wrong, they were frequently ridiculous, for example, he replied that the number that lies midway between 10 and 20 is 30 or 25. In essense, Mr. M. had lost all sense of the meanings of numbers. However, he was well able to read number words and digits and to generate answers to addition and multiplication problems learned by rote in school, such as that $3 \times 9=27$.

Finally, split-brain patients present an interesting test of the model. Because all three numerical codes are present in the left hemisphere, numerical tasks presented to the left hemisphere should show normal performance. However, because the right hemisphere lacks the verbal number system, numerical tasks presented selectively to the right hemisphere should show the same pattern of results as that for patients with left-hemisphere lesions. Indeed, this is the case: larger–smaller comparisons are performed by split-brain patients equally well (and on a par with the performance of normal controls) whether presented to the left or right hemisphere. In contrast, performance on mental calculation tasks equals performance by control subjects when the tasks are presented to the left hemisphere but is severely impaired when the tasks are presented to the right hemisphere.

C. Evidence from Normal Adults

In studies of normal adults, researchers Elizabeth Spelke and Stanislas Dehaene and their colleagues have found evidence that precise arithmetic facts are stored in a language-specific format, whereas approximate number facts and knowledge appear to be language-independent. In several experiments, bilingual subjects were trained on precise number facts (e.g., they had to choose which of two answers was the correct sum to an addition problem when given the correct answer versus a distractor answer very close in magnitude to the correct answer) and on approximate number facts (e.g., they had to choose the correct sum when given the choice between the correct answer and an answer that was much farther off from the correct sum, such that an idea of the approximate result would be sufficient to rule out the latter). After training, subjects were tested on these facts in the language in which the facts were trained and in the subjects' other language. The acquisition of the exact number facts did not transfer to the untrained language, whereas acquisition of the approximate number facts did: performance was equally good in both the trained and untrained language for the approximate facts. Thus, precise number facts appear to be stored in the same language in which they are learned, whereas approximate number facts, which engage subjects' magnitude sense of number, are represented in a language-independent format.

Brain-imaging experiments on normal adults also show that these two systems engage distinct brain regions. Several fMRI studies examined the brain structures recruited while subjects were engaged in precise number calculations and compared them with those structures activated during the processing of approximate number calculations. In accordance with the model, both left and right parietal lobes (along with some additional areas associated with visuospatial and analogical mental transformations) showed greater activation for approximate than for exact calculation. In contrast, the left inferior frontal lobe showed greater activation for exact calculation than for approximate.

The preceding sources of evidence all suggest that number processing rests on a variety of different mechanisms: some visuospatial, some highly language-dependent, and some involving a sense of numerical magnitude. Clearly, the visual and verbal representational systems for number are acquired—we are not born knowing the number words of our language or the Arabic numeral system. But where does our magnitude sense of number come from? If it is truly independent of language, we might see evidence of this component of numerical understanding in prelinguistic and nonlinguistic subjects, such as human infants and nonhuman animals. Before turning to empirical evidence addressing this question, however, let us look at this component of number knowledge in closer detail, in particular, the mental structures that underlie our sense of numerical magnitude.

III. MAGNITUDE REPRESENTATIONS OF NUMBER: THE ACCUMULATOR MODEL

A. Description of the Model

The accumulator model, briefly described in Section I, was originally developed by comparative

psychologists Warren Meck and Russell Church to account for a variety of numerical abilities that they found in rats. Meck and Church noticed a number of similarities in rats' ability to determine number and their ability to measure temporal duration. To account for these similarities, they proposed that a single mechanism underlies both abilities and expanded an existing model for measurement of temporal intervals so as to incorporate a counting component. Their proposed accumulator mechanism works as follows: a *pacemaker* puts out pulses of energy at a constant rate, which can be passed into an *accumulator* by the closing of a *mode switch*. In its timing mode, the switch closes at the beginning of the temporal interval being timed and remains closed for its duration, passing energy into the accumulator continuously at a constant rate. Thus, the amount of energy in the accumulator varies in direct proportion to the length of the timed duration. The fullness of the accumulator after timing of some duration can be compared with fullness values previously stored in memory to determine whether the just-timed duration is longer, shorter, or the same as a duration associated with some event. In its counting mode, when an entity is experienced that is to be counted, the switch closes for a brief, fixed interval and then opens again. Thus, when counting, the accumulator fills up in equal-sized increments, one increment for each entity counted, and its final fullness value varies in direct proportion to the number of entities so counted (see Fig. 3). Note that there will be differences in the exact fullness of the accumulator on different counts of the same number of items, resulting from inherent variability in the rate at which the pacemaker is generating pulses and in the amount of time the switch closes for each increment. This variability is normally distributed around a mean fullness value for each number, and the variance increases in proportion to the numerosity represented. This mechanism contains numerous accumulators and switches, so that the animal can count different sets of events and measure several durations simultaneously.

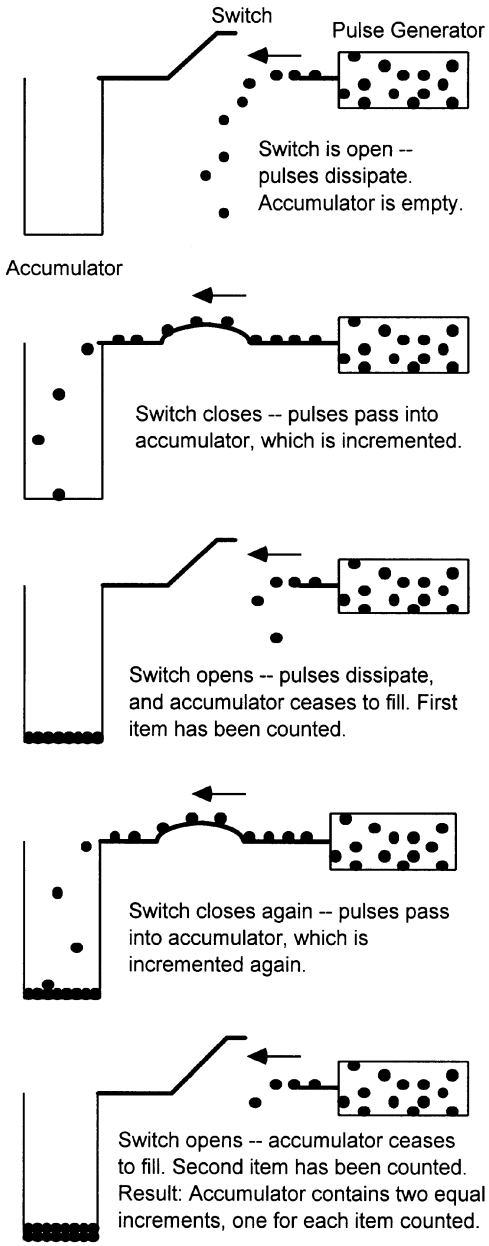

Figure 3 Schematic diagram of the states of the Meck and Church accumulator mechanism as it enumerates two items. The resulting fullness level of the accumulator is the mental representation for two (courtesy of *Current Directions in Psychological Science*).

B. Evidence for Similarity between Counting and Timing Processes in Animals

Evidence for functional similarity between rats' timing processes and their counting processes comes from several experiments. First of all, methamphetamine increases rats' perceptions of duration and numerosity by exactly the same factor, suggesting that the same mechanism is affected in both cases. This effect could be explained in the model by the drug causing an increase in the rate of pulse generation by the pacemaker, leading to a proportionate increase in the final value of the accumulator regardless of the mode in which it was operating. Second, both numerical and duration discriminations transfer to novel stimuli equally strongly when rats trained on auditory stimuli

were then tested on mixed auditory and cutaneous stimuli. Finally, an experiment tested the following prediction: If the animal's decision is based on a comparison of the final value of the accumulator with a previously stored value of the accumulator, then one might expect there to be transfer from making an evaluation on the basis of the output of the timing process to making an evaluation on the basis of the output of the counting process, so long as the final output value of the accumulator in the two cases was identical. For example, a count that yielded the same final fullness value in the accumulator as for a previously trained duration might be responded to as if it were that duration. This prediction was confirmed: when rats were trained to respond to a specific duration of continuous sound, they immediately generalized their response when presented with a certain number of 1-sec sound segments that had been calculated by the experimenters to fill up the accumulator to the same level as that for the duration on which the rats had been initially trained. Transfer was equally strong from number to duration. Meck and Church concluded that the same mechanism underlies both counting and timing processes in rats.

C. Predictions of the Model

A number of consequences fall out as predictions of the accumulator by virtue of the inherent structure and functioning of the model.

1. It predicts that animals (including human infants) should be able to discriminate different numbers of entities on the basis of number per se, not nonnumerical properties of arrays such as light–dark contrast, configuration, contour complexity, physical magnitude (size, volume, height, etc.), and so on. The accumulator is a mechanism that determines numbers of individual entities; it takes as input discrete *individuals*, not perceptual information. Moreover, because there is nothing inherent in the structure of the accumulator to restrict the kinds of idividuals it can count, we would expect infants and animals to be able to determine numbers of different kinds of entities. From an evolutionary standpoint, there are many kinds of entities it would be advantageous to be able to enumerate; thus, we might expect that a mechanism that evolved specifically for the task of determining the discrete number of things and that has no structural limitations on the kinds of input it can take, beyond the requirement of *discrete inividuals*, should be able to count different kinds of things.

2. Because of the fact that variance in the fullness of the accumulator increases with numerosity, with larger numbers representation of these numbers becomes more rough and approximate. As a result, discriminability for a given numerical difference should decrease as number increases. Because the variance is additive, the discriminability of two values should rest more on their proportionate difference than on their absolute difference; thus, animals and infants should be able to discriminate larger numbers, provided their proportionate difference is sufficient.

3. Because the representations have a structure in which the magnitudinal relations between different numbers are inherently embodied, we might expect animals and infants to possess procedures for extracting such information, that is, we would expect them to be able to use these representations in numerically meaningful ways.

The following section examines how these predictions bear out in empirical studies of numerical abilities in infants and animals. To preview, a review of the findings shows considerable evidence that this aspect of numerical understanding may form part of the inherent structure of the mind: a sense of numerical magnitude appears to be present early on in infancy and is evident in a wide range of animal species.

IV. NUMERICAL ABILITIES IN INFANTS AND ANIMALS

A. Sensitivity to Number per se

Animals can discriminate numerosities of simultaneously presented objects. For example, a raccoon was successfully taught, when presented with an array of three to five Plexiglas boxes each containing from one to five items, to choose the box containing three items; nonnumerical cues such as size, stimulus density, odor, and location of target box were controlled. Chimpanzees have been trained to pick out the correct Arabic number symbol when presented with arrays of zero to six physical objects. In all of these studies, results generalized to novel items without additional training.

In a particularly compelling study, Irene Pepperberg trained Alex, an African gray parrot, to speak the appropriate number word when presented with up to five objects. Most interestingly, because Alex had also been taught to "name" different kinds of objects, he could be asked to identify the number of a subset of items of the display. For example, when presented with

a tray with two corks and three keys randomly scattered over it, Alex could successfully answer all three of the questions, how many (correct answer: five), how many cork (two), and how many key (three). Here, he had to selectively attend to different aspects of the same display based on the question asked. Again, results generalized to items not previously presented to the parrot for numerical evaluation. The flexibility of this controlled focus of selective attention suggests a general concept of number accessible to higher level central processes.

In addition, many different species of animals are able to keep track of a number of sequentially occurring events. In a popular experimental paradigm, rats are trained to press a certain number of times on a particular lever before pressing a single time on a second lever for a reward; penalties of varying degrees are imposed upon the rats for pressing the second lever too early. Rats can learn this task with at least as many as 24 presses required. That their response is based on number of presses rather than on elapsed time is clear: when rats are trained to press for a certain amount of time, they continue to press for a certain extra *proportion* of the trained time on each trial in order to ensure that they have satisfied the criterion for reward, but when trained to press a certain number of times, they press a certain extra *constant number* of presses independent of the required number. Similar abilities have been shown in pigeons with a somewhat different task.

Rats have also been trained to turn down the third, fourth, or fifth left-hand tunnel in a maze and, once trained, did so even when the distance between the tunnels was varied from trial to trial and a corner had to be turned before the rewarded tunnel was reached. The rats could not simply have been running for a fixed length of time before turning left or responding to some level of fatigue. They had to have encoded the numerosity of the tunnels on the left in order to succeed at the task. Birds show similar abilities. In one experiment, canaries were successfully trained to select an object on the basis of its ordinal position in an array. Ten cubicles were spaced along a runway, and the canaries had to walk along the runway and choose the cubicle containing, say, the fifth aspirin in the series. Which cubicle contained the relevant aspirin was varied from trial to trial, ruling out any regularity of distance from the starting point. To control for the possibility that the birds might use rhythm as the basis of their judgments, the number of aspirins per cubicle ranged from zero to two, and the distance between cubicles varied from trial to trial. Given this, the birds must have been succeeding on the basis of the ordinal position of the aspirin.

The preceding review shows that a wide range of animal species are sensitive to number; they can discriminate different numbers of entities even when nonnumerical cues such as size, color, odor, length of run (and therefore amount of fatigue), density, and spacing, are controlled. They are also able to determine numbers of many different kinds of entities: physical objects, self-generated actions, sounds, and cutaneous stimuli.

Although the experimental evidence with human infants is less extensive than that with animals, the evidence does suggest that infants have similar abilities. Many habituation studies have found that infants (from a few days old to over 1 year of age, depending on the study) can discriminate number: when repeatedly presented with (''habituated to'') displays containing a given number of items, infants' interest will decrease and their looking time at each display will drop. They will subsequently look longer at a display containing a new number of items than at a new display containing the same, habituated number of items. In a study by Prentice Starkey, Elizabeth Spelke, and Rochel Gelman, for example, 7-month-old infants were habituated to visual displays of either two or three randomly arranged objects. The displays were constructed of photographs of various household objects that were different in each picture, for example, one picture might consist of an orange and a glove and the next might include a key chain and a banana. Following habituation, the infants were shown test pictures of two and three items containing new objects not seen in the habituation pictures. Infants looked significantly longer at test pictures containing the number of items that differed from what they had been habituated to, indicating that they discriminated between the two numbers.

In an intriguing series of experiments by Erik van Loosbroek and Ad Smitsman, infants of 5, 8, and 13 months were habituated to displays of two, three, or four moving ''objects'' displayed on a video screen. Each ''object'' was constructed by randomly filling in a certain proportion of the rectangles defined by a 16-by-16 grid. Stimuli were constructed at three different levels of density by specifying a higher or lower proportion of the grid to be filled in. The objects' paths of motion occasionally intersected so that one object overlapped another. Thus, a static view of the display would not guarantee correct number information: the number of objects could only be determined by watching the display in motion over time.

Nonetheless, infants of all ages tested discriminated two from three and even three from four, and the older two groups of infants also distinguished four from five.

Some of these results have come under question due to research findings by Melissa Clearfield and Kelly Mix. In several experiments, they found that infants were sensitive to the *contour length* of a display—the sum total of the contours of the individual items in a display. When infants were habituated to displays of a single number and contour length and then in testing presented with new displays containing alternately (a) the habituated contour length but a new number of items and (b) a new contour length but the habituated number of items, infants looked longer at the second kind of test trial, suggesting that the new contour length was of greater interest than the new number. This raises the possibility that, in previous experiments in which infants discriminated numbers of objects, they might have been doing so on the basis of contour length and not number per se, as the contour length of a display tends to covary with the number of items in that display.

However, there are reasons to doubt that all of infants' putative number-discrimination abilities can be accounted for by this explanation. There are now several studies in which infants have successfully discriminated number even when perceptual factors such as contour length and visual area were strictly controlled. In a study conducted by Paul Bloom, Wen-Chi Chiang, and the author, we found that 5-month-old infants could determine how many *groups* of objects were present in a display, independent of the number of individual objects themselves. Half the infants were habituated to two groups of three objects each moving on a computer screen, and the remaining infants were habituated to four groups of three objects each. Infants subsequently discriminated between two groups each containing four objects and four groups each containing two objects; in both habituation groups, infants preferred the test display containing the new number of *groups* of objects. Note that both test displays contained the same total number of objects—eight—and thus were equated on many perceptual dimensions such as density, area covered, and contour length of the display. Similarly, experiments examining infants' ability to discriminate relatively large numbers of objects have also controlled strictly for contour length, area, density, etc. of displays and have found successful numerical discrimination in infants under these conditions.

Like many nonhuman animal species, human infants are able to enumerate different kinds of entities. Not only can they identify the number of visual objects in displays, they can also determine numbers of physical actions, such as the jumps of a puppet. This has been shown in several studies conducted by Tanya Sharon and the author. A sequence of actions differs from a display of visual objects in several respects. Objects exist continuously through time and are separated from each other in two-dimensional (in the case of photographs or pictures) or three-dimensional space. Sequential actions, on the other hand, have a momentary existence, are separated from each other in one-dimensional time, and may or may not occur at precisely the same location in space. Perhaps most importantly, one has perceptual access to the entire collection of objects at once, whereas one has perceptual access to just one element at a time in a collection of sequential actions and cannot anticipate the final element.

In one set of experiments, 6-month-old infants were habituated to a puppet jumping; for half of the infants it jumped two times and for the other half three times. Upon completion of the jump sequence, infants' looking time at the now-motionless puppet was measured. Following habituation, infants received test trials in which the puppet jumped two times and trials in which it jumped three times. The jump sequences were structured to control strictly for the tempo and overall duration of jump sequences. We found that infants looked significantly longer at the puppet following a new number of jumps than following the old number of jumps. Thus, infants were able to identify the individual jumps in the sequence and to enumerate them. Subsequent experiments showed that infants could also enumerate heterogeneous action sequences composed of several distinct kinds of actions.

Additional studies show that infants are able to determine the number of other kinds of entities as well. One study (described earlier) showed that 5-month-olds can enumerate collective entities; they attended to how many groups of items were present in a display. Finally, some studies have found that infants can determine numbers of sounds; however, other researchers have obtained conflicting data, so that further research is required to clarify this issue.

B. Discriminability and Set Size

The finding that, as numerosity increases, discriminability of a give numerical difference decreases is a

robust effect, found within animals, human infants, and human adults. In an experiment in which rats were required to discriminate two from three and three from four sounds, all three subjects successfully discriminated two from three, but only two learned to discriminate three from four. Similarly, in an experiment requiring squirrel monkeys to pick out the smaller of two simultaneously presented arrays of objects, subjects were able to distinguish six from seven and seven from eight, but only one subject was able to distinguish eight from nine. Discrimination of adjacent numbers by human infants is also stronger with smaller numerosities. Two studies obtained results in which infants discriminated two from three but not four from six; in another study, infants discriminated two objects from three reliably, discriminated three from four only in certain situations, and did not discriminate four from five. In yet another study, three different ages of infants discriminated two objects from three and three from four, but only the oldest age groups (8- and 13-month-olds) discriminated four from five. These results, though obtained with a very different methodology, parallel the finding that human adults also show an effect of set size, even within the subitization range, when asked to rapidly identify the numerosity of an array; the identification of numbers is both faster and more error-free the smaller the number.

However, both animals and human infants are able to represent approximate values of larger numbers and to discriminate two numbers when the *proportion* by which they differ is sufficiently large. When rats are trained to press a lever a minimum required number of times in order to obtain a reward, the variance of their response increases with the required number, but they are nonetheless able to perform this task even with numbers as high as 50 (the largest tested). Human infants can discriminate 8 items from 16 and 16 from 32, with nonnumerical factors such as area, density, and contour length controlled.

C. Computational Capacities

There is more to numerical knowledge than the ability to distinguish different numbers. The ability to distinguish numbers does not entail an ability to reason about those numbers, to determine, for example, that five is larger than three or that two is composed of one and one. To determine such relationships, the animal or infant must not only be able to construct mental representations of the relevant numbers but be able to manipulate these representations in numerically meaningful ways. There is empirical evidence that infants and animals can determine the results of certain numerical operations on small numbers of physical objects.

Studies in the author's lab have investigated human infants' numerical reasoning capacities. In one experiment, 5-month-old infants were divided into two groups. Those in the "$1+1$" group were shown a single item being placed into an empty display area. Then a small screen rotated up, hiding the item from view, and the experimenter brought a second identical item into the display area in clear view of the infant. The experimenter then placed the second item out of the infant's sight behind the screen (this sequence of events is shown in the top portion of Fig. 4). Thus, infants could see the nature of the arithmetical operation being performed but could not see the result of the operation. The screen was then dropped to reveal an outcome of either one (the impossible outcome) or two (the possible outcome) objects. Infants in the "$2-1$" group were similarly presented with a sequence of events depicting a subtraction of one item from two items (shown in the bottom portion of Fig. 4). Again, after this sequence of events was concluded, the screen rotated downward to reveal either one (now the possible outcome) or two (impossible outcome) items in the display case.

Infants' looking time at the display was recorded when the screen dropped. The prediction was that infants would be surprised by an apparently impossible result. Thus, the two groups should show significantly different looking patterns; infants in the $1+1$ group should look longer when the result is one than when it is two, in comparison to the $2-1$ group, which should show the reverse pattern. (A pair of pretest trials, in which infants were simply shown displays of one and two items, revealed that infants in the two groups did not differ in their baseline looking patterns at one and two items.) This was, in fact, the pattern of results obtained; infants in the two groups differed significantly in their patterns of looking in the test trials. Infants in the $1+1$ group looked longer when the addition appeared to result in a single item than when it resulted in two items, whereas infants in the $2-1$ group looked longer when the subtraction appeared to result in two items than when it resulted in a single item. To ensure that infants were determining the exact result of the operation (that is, that they were expecting two objects in the $1+1$ situation and one object in the $2-1$ situation) rather than simply

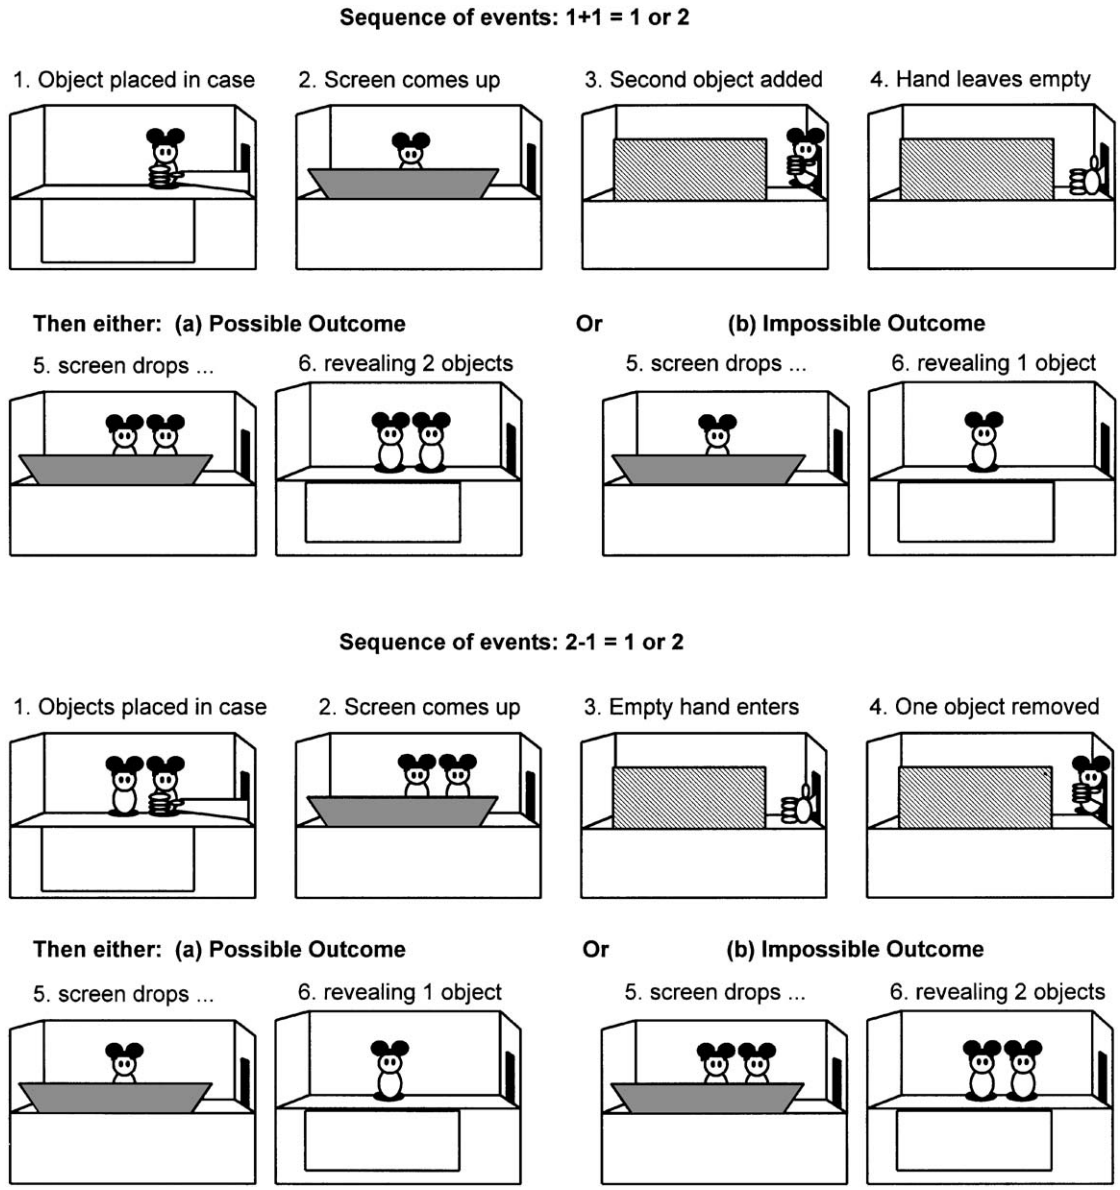

Figure 4 Sequence of events shown to infants in Wynn (1992) (courtesy of *Nature*).

expecting the number to have been changed in some way as a result of the operation without having expectations as to precisely what the result should be, another experiment was conducted. Here, infants were shown an addition of 1 + 1, with outcomes of two and three objects. In this case, both outcomes are different from the initial number of objects (one) placed in the display. Thus, if infants only expect *some change* to obtain as a result of the addition, they will not be surprised by either outcome. However, if they are computing the precise nature of the numerical change, they will be expecting two objects behind the screen and will look longer at the incorrect result of three objects. (A pretest condition showed that infants looked equally long at two and three objects.) This was the pattern of results obtained: infants looked longer when the addition appeared to result in three items than in two items.

The studies reviewed previously and others like them show that infants as young as 5 months of age are sensitive to the numerical relationships between small numbers and are able to determine the results of simple numerical operations. Similar abilities have also been shown in somewhat older infants by a task that

required them to perform motor actions based on their numerical expectations. In this study 18- to 35-month-olds saw from one to five identically colored ping-pong balls placed into an opaque box and then saw an experimenter either add or remove a small number of balls. They then were allowed to reach into the box to retrieve the objects. The box was constructed so that infants could not see into the box as they were reaching into it, so that each reach into it allowed contact with, and removal of, only one object at a time. Thus, the number of reaches into the box that the infants made indicated how many items they believed the box to contain. Even the 18-month-olds showed a knowledge of how many objects the box contained when small numbers were involved.

Some nonhuman species are also able to compute results of certain numerical operations. The most conclusive evidence comes from studies conducted by Sarah Boysen and Gary Berntson, who taught a female chimpanzee to associate the Arabic numerals 0–4 with their respective numerosities. Without further training, she was able to choose the numeral representing the sum of oranges hidden in any two of the three possible hiding places in her pen. Most impressive of all, when the sets of oranges in the hiding places were replaced with Arabic numerals (one card with an Arabic numeral printed on it hidden in each of any two hiding places), she was immediately able to choose the Arabic numeral representing the sum of the two found numerals. That is, without training, she was able to operate over two symbols representing numerosities in such a way as to arrive at the symbol representing their sum. In another study, free-range wild rhesus monkeys were given a version of the $1+1$ addition situation described earlier for human infants. When shown one eggplant and then another eggplant placed in a box out of sight, the moneys looked significantly longer when only one eggplant was revealed than when two were, despite showing no preference in a control situation for looking at one eggplant over two.

Suggestive findings have been obtained with other species as well. Rats appear to anticipate when they are approaching the required number of presses when they must press a required minimum number of times on a lever to obtain a reward. Rats will frequently check for the reward before they have given the required number of presses in situations when there is no penalty for checking for the reward too early and, upon finding no reward, will return to the lever to increase their number of presses. Interestingly, the greater their number of presses before pausing to check for the reward, the smaller their number of additional presses upon returning to the lever. That is, they appear to know how close they are to the needed number, not only whether they have or have not reached that number yet. Finally, in one study, rats were trained to press a lever on the left when presented with either two sounds or two light flashes and a lever on the right when presented with four sounds or four light flashes. Following training, rats were presented with two sound–light flash pairings (a sound accompanied by a simultaneous light flash, followed by another sound accompanied by a light flash). In this situation, rats pressed the right-hand lever, showing that they had computed that there were four stimuli altogether. They were either adding the number of sounds to the number of light flashes or enumerating the stimuli independently of their kind.

D. Summary

As shown in the preceding review, both human infants and nonhuman animals are sensitive to number. They can determine numbers of fundamentally different kinds of items—objects, actions, collections—and can do so for items presented simultaneously as well as those presented sequentially. Moreover, animals and infants have procedures for computing the numerical relationships that hold between different numbers, which entails that their representations for these numbers have a structure that allows for the extraction of such information. These findings suggest the existence of an unlearned capacity for numerical representation and reasoning that spans these different species and is operational quite early on in life.

V. CONCLUSIONS

Evidence from cognitive neuropsychology suggests that our number processing and arithmetical capacities comprise a set of dissociable systems: verbal knowledge of number and stored precise number facts, procedural knowledge for numerical computations, visual knowledge of Arabic numerals, and a magnitude sense of numbers. Evidence from comparative and developmental psychology suggests that both human infants and nonhuman animals share one of these component systems: a magnitude sense of number that supports enumeration, numerical comparison, and numerical computation operations. Language and learning appear to play key roles in the

formation of the other components; in particular, evidence suggests that we may store learned numerical facts in the specific natural human language in which they are learned. Much more remains to be learned about (a) how these systems interrelate, (b) precisely how we build onto the initial sense of numerical magnitude, and (c) how we obtain genuinely new mathematical knowledge.

Object Perception

PEPPER WILLIAMS
University of Massachusetts, Boston

GLOSSARY

primitives The fundamental elements, or basic building blocks, of a representation. These can range from simple spots of light of varying intensity to complex three-dimensional volumes with varying aspect ratios, degrees of curvature, cross-section shapes, etc.

representation A thing that stands for another thing. In other words, a representation can be used in place of its representee to carry the same meaning. For example, France is represented by a flag with red, white, and blue horizontal stripes; the United Nations can fly this flag in front of its headquarters to indicate that this country is a member of the institution.

structural description A form of representation that uses relatively complex primitives, usually corresponding to object parts, and specifies the relationships between parts explicitly.

view A form of representation that uses relatively simple primitives and does not specify relations between them explicitly.

Object perception refers to the process of identifying an external stimulus from the image cast by the object onto the retina. This ability is remarkable because of the fact that an object's image can change radically when it is viewed under different circumstances, for example, from different viewpoints and distances. Furthermore, before perception of a single object can even begin, the object of interest must be separated from other objects in the background and foreground of the scene. Some theories propose that the visual system constructs a *structural description* of to-be-perceived objects, in which the shapes of and relations between the object's parts are explicitly represented. Other models posit simpler representations in which parts and relations are specified only implicitly in a view of the object; these models then specify processes for matching perceived to encoded views. Neither type of theory is universally accepted, but the theoretical debate has inspired, and in turn been constrained by, a great deal of interesting neurophysiological and behavioral research.

I. OBJECT CONSTANCY

Consider the objects in Figs. 1A and 1B. Call them SOGI and DUVA, respectively. Although you have never seen these objects before, you should have little difficulty perceiving that the images in Figs. 1C–1I are of the SOGI, not the DUVA. The ability to treat different two-dimensional (2D) images as the same three-dimensional (3D) shape is known as *object constancy*, and the acheivement of object constancy is the fundamental goal of object perception. As is the case with most fundamental cognitive processes, we generally take this ability for granted, but also as with many other cognitive processes, the mechanisms that allow us to perceive objects are far from simple.

One way to appreciate the difficulties inherent in achieving object constancy is to consider what we would have to do to progam a computer to recognize objects. To a computer, the images in Fig. 1 are nothing more than collections of numbers that specify the intensity of each small dot, or *pixel*, in each image. To teach the computer to associate the collection of pixels in Fig. 1A with the label SOGI and the pixels in Fig. 1B with the label DUVA is a simple matter of

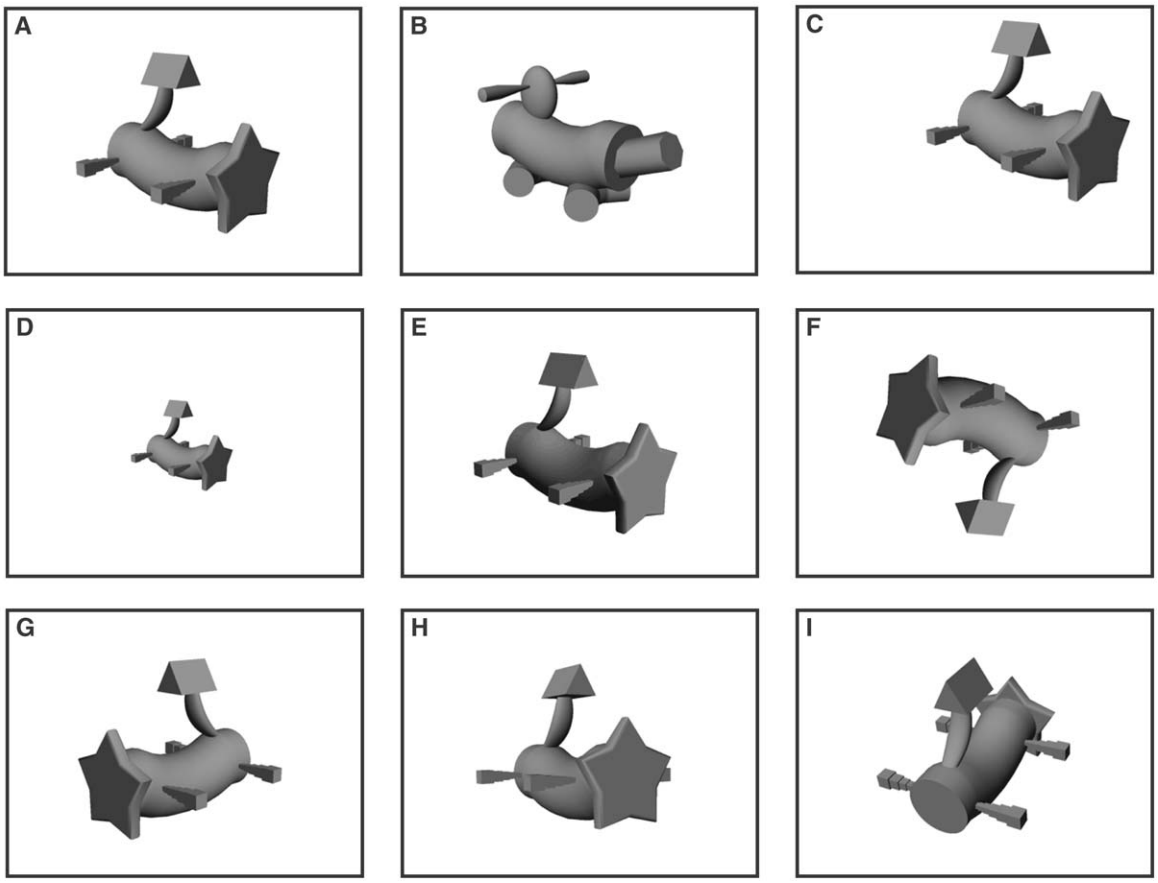

Figure 1 (A) and (B) show two novel objects under similar viewing conditions. (C)–(I) show how the former object would look under different viewing conditions. More specifically, the images illustrate (C) a translation (caused by the observer shifting his or her gaze or the object moving in the picture plane), (D) a size change (caused by the observer moving backward or the object moving away from the observer in depth), (E) a shift in lighting direction, (F) a shift in picture plane orientation (caused by the object turning upside down or the observer standing on his or her head), (G) a mirror reflection, and (H–I) viewpoint shifts (caused by the object rotating in depth or the observer moving around the object). Each of these changes to viewing conditions introduces significant alterations to the image delivered to the retina, and the human object perception system must somehow compensate for these alterations in order to successfully identify the object.

storing the pixel values and labels of both images in memory. When one or the other image is encountered again, the new pixel values can be compared to those of the previously seen images. If the new values match those of Fig. 1A, the SOGI label is retrieved, whereas if the values match those of Fig. 1B, the DUVA label is retrieved. But what will happen when the images in Figs. 1C–1I are presented to the computer? The collections of pixels in these images are identical to neither the learned SOGI nor the learned DUVA image, so our simple pixel comparison process will fail to produce a perfect match with either remembered image.

The human visual system faces the same conundrum: the raw input for vision is a set of firing rates of receptor cells (rods and cones) in the retina, roughly analogous to the set of pixel values that serve as input to the computer. If an object was always seen under the same viewing conditions, its image would always produce the same retinal firing rates and object perception would be straightforward. But Figs. 1C–1I illustrate several different ways in which alterations in viewing conditions produce different retinal input from the same object. Somehow, the visual system must find a way to compensate for these changes to the retinal image so that the perception of the object remains constant. Let us consider each of these forms of object constancy in turn.

In Fig. 1C, the image of the SOGI has been moved, or *translated*, relative to the bounding rectangle. If one's gaze is fixed at the center of the rectangle, the

pattern of retinal activity will be almost completely different for this image than for Fig. 1A. The visual system usually elicits eye movements that bring the image of a to-be-recognized object onto the fovea, a process that effectively compensates for image translations. However, common experience and psychophysical experiments indicate that objects can be recognized before being foveated: even when pictures of objects are shown experimentally for less than 0.3 sec, precluding eye movements, translations produce a minimal, if any, decrease in recognition accuracy or time. Therefore, some other compensation mechanism besides eye movements must also be at work.

In Fig. 1D, the image of the SOGI has been shrunk to one half its size in Fig. 1A. Although actual, physical size is an important characteristic of every object, the size of an image on the retina is determined jointly by the size of the object and the viewing distance (when viewed from certain distances, a tennis ball, a basketball, and the moon may all produce the same retinal size despite wide variations in physical size). To use object size as a cue for identity, then, depth cues would have to be consulted to determine object distance. Whereas this strategy may sometimes be utilized, the images in Figs. 1A and 1D contain no depth cues, yet we have a strong predilection to perceive them as the same object (and thus the same size), demonstrating that the visual system often somehow ignores retinal size when computing object identity. As with translations, most psychophysical studies that have investigated the issue have found little if any effect of object size on recognition fluency.

Fig. 1E shows what would happen if the light source were moved from above and to the left of the SOGI, as it is in Fig. 1A, to a position above and to the right of the object. Although one might not even notice this change if it was not explicitly pointed out, almost all of the pixels in the interior of the objects are different in the two images. For example, in Fig. 1A, the side of the SOGI's prism-shaped "head" is brighter (i.e., the pixel values here are more intense, and retinal receptor cells will fire at higher response rates to this surface) than the front of the star-shaped part, whereas in Fig. 1E this relationship is reversed. Because humans and other diurnal animals evolved under conditions in which the angle of their only light source (the sun) was constantly changing throughout every day, compensation for lighting direction may have been an important factor in the evolution of object perception.

Fig. 1F shows what the SOGI would look like if the observer were to stand on his or her head or if the SOGI were to be flipped upside down: the image's orientation has been shifted 180° in the picture plane relative to Fig. 1A. Because humans usually stand on their feet and many objects have a normal upright position (the trunks of trees and wheels of cars almost always touch the ground), orientation often provides a diagnostic cue for recognition. Psychophysics studies discussed later show that, although we can identify upturned trees and cars with high accuracy, the time taken to recognize such misoriented objects varies with the amount of misorientation, indicating that the visual system may take advantage of this orientation diagnosticity by representing objects in their canonical positions.

Fig. 1G is a mirror image of Fig. 1A. Although the amount of pixel shifting is about the same between mirror reflections as between upright and upside down images, reflections cause very small (if any) decreases in performance in psychophysical experiments, whereas, as noted earlier, turning of an image upside down typically leads to a substantial impairment in recognition time. Explanations for this combination of results feature prominently in many theories of object recognition.

Fig. 1H shows what the SOGI would look like if the observer moved slightly to the left relative to the vantage point from which the object was seen in Fig. 1A, or if the object rotated to its right. Fig. 1I shows the result of a larger change in viewpoint. Note that, unlike all of the other image transformations discussed here, changes in viewpoint may cause different parts and surfaces of the object to become visible or invisible and, at the least, lead to changes in the projection of the 3D surfaces onto the 2D retinal image. For example, the front surface of the star-shaped part of the SOGI covers a larger amount of the image (relative to other surfaces in the object) in Fig. 1H compared to Fig. 1A and then becomes completely invisible in Fig. 1I. In this way, the image changes introduced by viewpoint shifts are more radical than those caused by the other transformations discussed earlier. Thus, compensation for viewpoint shifts seems to be a computationally more demanding problem, and the most crucial measure of any object perception theory is usually taken to be how well it can account for humans' ability to achieve viewpoint constancy.

II. PRECURSORS TO OBJECT PERCEPTION

The pictures in Fig. 1 each show a single object isolated against a uniform white background. Object perception

is a difficult enough computational problem in this context, but in the real world we face the additional challenge of perceiving an object of interest amid a cluttered foreground and background of other objects, as illustrated in Fig. 2. In order to deal effectively with the enormous amount of information entering through the eyes, the visual system employs a divide-and-conquer strategy. First, the information coded initially as raw receptor firing rates is recoded in terms of various types of elementary features. The features are then analyzed to determine which combinations form single objects, and collections of features are pieced together to form representations of various aspects of the scene, including the object we want to identify. This section briefly describes some of what we know about the breakdown of visual information into features and the later regrouping of these features.

A. Breaking Down the Image

The process of breaking the visual field down into constituent features begins before visual information has even left the eye. Whereas receptor cells simply fire action potentials more rapidly the brighter the light that hits them, ganglion cells, the neurons whose axons leave the eye through the optic nerve, respond to particular *patterns* of light over a small patch of the retina. More specifically, most ganglion cells exhibit *center-surround* receptive fields, firing most rapidly either to a small spot of light surrounded by darkness (an on-center receptive field) or to a small spot of darkness surrounded by light (an off-center receptive field).

By the time visual information has reached the primary visual cortex (also known as striate cortex and area V1), it has been recoded again. Here, neurons called simple cells respond most strongly to stationary bars (rather than spots) of light surrounded by darkness (or to dark bars surrounded by light). Furthermore, each of these neurons responds best to a bar in a particular orientation. A second type of neuron in V1, the complex cell, also responds to oriented bars but is tolerant of small shifts in location of the bars. In addition to bars, simple and complex cells also respond to the borders between regions of light and darkness. One prominent place where such borders occur is at the edges of objects, so that simple and complex cells can be considered edge detectors (see Figs. 4A and 4B). Oriented edges are thought to be some of the most important features coded by early visual processes.

Other types of elementary features thought to be coded in the primary and secondary visual cortex include color, line size, line curvature, edge corners and intersections, motion direction, and distance in 3D space. Each feature can be thought of as being coded in a topologically organized feature map, which holds information about which parts of the visual field contain the feature. Early visual cortical areas contain a large number of such feature maps, e.g., one map for right-tilting lines, one for horizontal lines, and one each for the colors blue, green, and red. For example, a pencil rolling across a desktop might engender activity on the yellow color, vertical line orientation, and rightward motion feature maps. By splitting up the information in this way, the visual system is able to process each type of elementary feature separately, but at the same time.

Figure 2 Unlike the situation shown in Fig. 1, real-world object perception almost always requires that the to-be-perceived object be separated from other elements in the visual field, as illustrated here. For example, the coffee mug is partially occluded by the plate and salad bowl and itself occludes parts of the tabletop, fruit bowl, and an apple. To deal with this complexity, the visual system breaks the image into constituent features such as edges and color patches, decides which features belong together and which belong in separate groups, and then recombines feature subsets to form representations of single objects.

B. Building Up Objects

Once the visual image has been parsed into its constituent features, the visual system must put different features together to form representations of individual objects. Scientists working in the Gestaltist tradition, a school of psychology that began in mid-twentieth century Germany, have proposed a number of principles that appear to guide this process of

perceptual organization. For example, the principle of good continuation states that, other things being equal, lines or edges that form straight or smoothly curving contours should be grouped together. Thus, in Fig. 2, the lines forming the back edge of the table are combined into a group even though they are separated by the occluding salt and pepper shakers. Other Gestalt principles include proximity (elements close to each other should be grouped together), common fate (elements moving in the same direction should be grouped together), and connectedness (elements connected by other elements should be grouped together).

Whereas Gestalt psychologists have worked to provide intuitive heuristics for *which* elements should be grouped together, another group of cognitive scientists have worked on the problem of *how* elements are combined. The key concept in this tradition is that of visual attention, and the metaphor of a spotlight is often used to describe the role of attention in feature combination. The attentional spotlight illuminates a circumscribed portion of the visual field and combines the various features present in that portion of the image into a multidimensional representation, which can then be identified by the object perception processes discussed later. Because attentional capacity is limited, we are only able to analyze in detail a relatively small portion of an image at a time. Therefore, the attentional spotlight must move from place to place in a serial fashion in order to completely analyze an image, even though all individual features are detected in parallel.

Object perception theories generally make the simplifying assumption that all of the features of a to-be-perceived object are eventually (possibly after several shifts of the attentional spotlight) combined together into a single representation, which can then be compared to representations in memory to determine the object's identity. However, research on a phenomenon termed "change blindness" indicates that this assumption may not be valid. Consider the image in Fig. 3. Is the scene depicted here exactly the same as the one in Fig. 2 (examine the two figures before reading on)? Not quite: the handle of the pepper shaker is missing from the second figure. Behavioral studies using a number of different paradigms have converged on the conclusion that subtle changes such as this one often go unnoticed, especially when visual attention is not focused on the region of the visual field where the change occurs. Even changes to a single, isolated object that is clearly the focus of attention can be missed if the object is obscured from view for a short period of time. These findings imply that our initial representations of objects may not be as complete as we intuitively believe them to be. Object perception theories may need to be altered to take this imprecision into account.

Figure 3 This image is similar, but not exactly the same, as the one in Fig. 2 (see the text for a description of the change). The fact that experimental participants are poor at detecting such changes indicates that our representations of perceived objects are not as complete as we intuitively believe them to be.

III. THEORIES OF OBJECT PERCEPTION

Object perception begins with retinal receptors firing in response to light rays that have bounced off the to-be-perceived object and into the eye. The pattern of firing rates over the millions of receptor cells *represents* the object, in that this particular pattern of firing will result whenever the object is seen from this viewpoint and distance, under these lighting conditions, etc. However, as described in Section I, this representation changes drastically when the object rotates, the lighting direction changes, the observer moves toward or away from the object, etc.

Theories of object perception seek to explain how the visual system compensates for such changes to viewing circumstances, transforming the ever-changing retinal representation into a stable representation of an object. The low-level visual processes described in Section II, which organize the retinal output into collections of elementary features, begin this transformation, but theorists disagree on how these feature assemblies are used to ultimately produce object constancy. No single model enjoys universal support, so that rather than catalog the numerous theories that have been proposed, more general distinctions between classes of theories are described next.

A. Recovery of 3D Structure

The goal of object perception is to treat different 2D views of a 3D object similarly. One intuitive way to do this is to recover the 3D structure of the object from the 2D image. If the visual system can construct an accurate 3D model of the to-be-recognized object, the problem of object constancy is automatically solved, because such a model would constitute a *viewpoint-invariant* representation—the same model would be constructed for a given object regardless of viewing conditions, so that all retinal images would result in an identical representation.

David Marr, whose theoretical work has driven much of the research in object perception, felt that the derivation of a precise, viewpoint-invariant 3D model is a fundamental step in the achievement of object constancy, and most vision scientists have agreed with this ideal. But for most objects, it is not feasible for the visual system to construct a complete 3D model from any one view of the object. For example, the structure of the back of a house is unknowable when the house is viewed from the front. Similarly, it is impossible to know whether or not the SOGI has a fourth "arm" from the view in Fig. 1A (Fig. 1I indicates that the fourth arm does in fact exist).

A more realistic goal is to represent the 3D structure of the portion of the object that can be seen from a given viewpoint. In such a system, small shifts in viewpoint (such as that from Figs. 1A to 1H) would be likely to lead to the same *structural description* and thus would cause no trouble for the visual system. Large viewpoint shifts may result in a completely different structural description, and when these shifts occur, object constancy is expected to be violated (i.e., object perception should be error-prone and/or slow under such conditions).

Despite the elegance of the structure-recovery approach, it is important to understand that limited object constancy is theoretically attainable without referring to a 3D structural description. A representation of the 2D image of an object—such a representation is referred to as *view-based*—can serve as the basis for object perception as long as perceived views can be accurately matched to encoded views. The latter part of this statement is crucial: the success of view-based models depends on the ability to specify processes that select the proper encoded representation when presented with a novel view of an object. Thus, whereas the focus of structural description theorists has been on how to construct an informationally rich representation of an object, the focus of view-based theorists has been on specifying computational procedures that achieve object constancy using less sophisticated representations but more complex matching processes.

B. Specification of Primitives and Relations

A second way in which various object perception models differ is in the elementary units, or *primitives*, that make up object representations. Again, Marr set the agenda by proposing a different set of primitives for each of the four stages in his object perception theory. In this framework, the image initially is represented by pixel intensity values, then the contours of the object are represented by oriented line segments, then the "2.5D" structure of the object is represented by surface patches, and finally the 3D structure is represented by a collection of volumetric primitives called generalized cylinders (which include such shapes as bricks, pyramids, and tubes).

Representations made up of simple primitives such as pixel intensity values have the advantage of describing an object with great precision. For example, in Fig. 4A, we see a close-up of the image pixels in a portion of Fig. 1A. A great deal of information is derivable from this simple representation, e.g., the various surfaces making up the object's "head" and "neck," the amount of light reflected by the surfaces, the precise curve of the neck, and the fact that the head is above the neck. Though not explicitly stated, these details nevertheless are implicit in the collection of pixel intensity values.

If we transform this representation into one using more sophisticated primitives, such as the oriented line segments illustrated in Fig. 4B, we lose some information but gain the advantage of explicitly representing certain properties of the object. Here, the oriented lines explicitly specify the boundary between the object and the background but do not code anything about surface lightness either explicitly or implicitly. In Fig. 4C, we see a further transformation from contours to a structural description with high-level primitives. Here, we explicitly represent the facts that there are two distinct parts and that one has the shape of a curved tube, whereas the other is wedge-shaped. But now we have lost the information about exactly how much the neck is curved.

Along with the set of primitives, an object perception model must also specify how the relationships between primitives are coded in a representation. Structural descriptions generally use high-level primitives (e.g., generalized cylinders) and specify relations

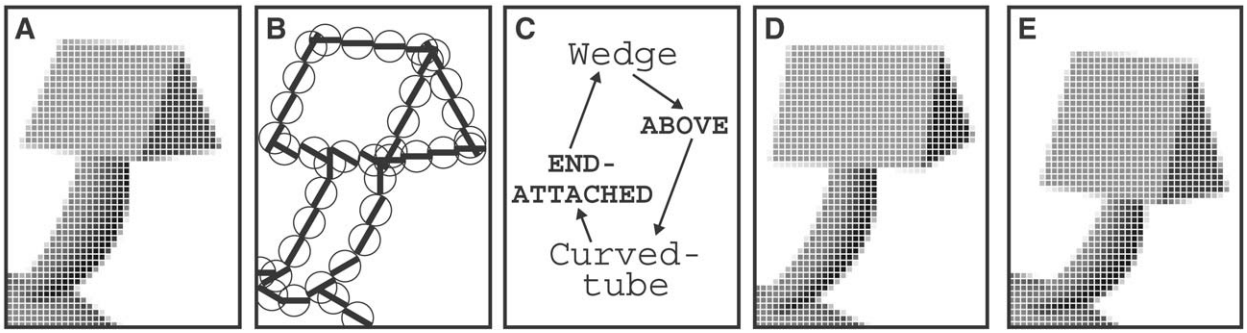

Figure 4 (A)–(C) illustrate three representations of a portion of the SOGI object using increasingly complex primitives. (A) simply includes the pixel intensity values of the image, (B) codes the orientations of the object's edges, and (C) is a structural description that explicitly denotes the shapes and relations between the two parts of the object. The latter representation is stable across the viewpoint shift that produces the image in (D) but is not sensitive enough to represent the difference between the objects depicted in (A) and (E).

explicitly—for example, the representation in Fig. 4C makes explicit the fact that the wedge is ABOVE the curved tube. Indeed, explicit specification of the relations between primitives is, for many theorists, the defining property of a structural description. View-based theories, on the other hand, generally use low-level primitives and represent relations between them only implicitly. That is, Fig. 4A includes the information that the head is above the neck only because the gray pixels of the head part have X-coordinates that are smaller than the coordinates of the pixels composing the neck part.

C. Structural Descriptions vs Views

By representing an object in terms of a limited number of high-level primitives and by explicitly specifying the qualitative relations between parts, structural descriptions are *stable* across many changes in viewing circumstances. For example, Fig. 4D shows the same object as Fig. 4A from a new viewpoint. Whereas the image (and thus any view-based representation) has changed, the same structural description should be generated. As noted earlier, such stable representations automatically solve the object constancy problem. To understand the downside of structural descriptions, consider Fig. 4E. Here, we see an image that is clearly of a different object but that also corresponds to the structural description in Fig. 4C. This example illustrates that structural descriptions may not be *sensitive* to distinctions in object structure that define the difference between two objects.

Another way to understand this trade-off is in terms of the information preserved and discarded in structural descriptions and view-based representations. As noted earlier, some information about an object that is implicitly captured in a view, e.g., the precise angle of the apex of the wedge-shaped part in Fig. 4A, is discarded in the process of forming a structural description. Throwing away this information boosts the stability of the representation, because when the object is rotated in depth, the angle may appear to change (as it does in Fig. 4D). The problem is that sometimes the discarded information is necessary for a representation to be sensitive enough to distinguish two different objects (Figs. 4A and 4E).

Marr recognized the difficulty of simultaneously achieving stability and sensitivity and proposed as a solution a hierarchical series of structural descriptions, each one more sensitive but less stable than the last. For example, in a famous illustration he showed a human form represented at the highest level by a collection of six tubes of various sizes and aspect ratios (one for the head, one for the trunk, and two each for the arms and legs). At a lower level, an arm is represented as two tubes (one for the upper arm and one for the lower arm) connected at an obtuse angle. At a still lower level the lower arm includes two parts, one for the hand and another for the portion above the wrist, and at the lowest level the shape of the fingers presumably is represented in enough detail to distinguish between the hands of different people. When an object simply needs to be classified as human, the highest level representation can be used, providing stability across different human forms, whereas when a particular person must be identified, lower level representations come into play.

As is the case for other aspects of Marr's theory, hierarchical structural descriptions are intuitively

elegant but implementationally impractical. As an alternative, many theorists have proposed that the visual system computes and encodes both a structural description and a view-based representation for each object encountered. As we will see later, both neurophysiological and psychophysical studies indicate that object perception sometimes appears to be regulated by views and sometimes by structural descriptions, consistent with the dual-system approach. Nevertheless, stalwart theorists of both persuasions continue to develop models that attempt to explain all of these results using a single form of representation. Whereas they may someday be forced into accepting dichotomous representations, single-system theories tend to generate more testable predictions, so it would be imprudent to abandon these efforts at this time.

IV. NEUROPHYSIOLOGY OF OBJECT PERCEPTION

One way to study the nature of the processes and representations used in object perception is to examine the neural tissue of the visual system directly. Several means are available to do this: scientists may record from single neurons or selectively lesion brain areas in laboratory animals; they may work with human patients who have sustained damage to selective brain regions; or they may use functional brain imaging techniques to isolate the portions of normally functioning human visual systems that are engaged while performing various tasks. This section describes some of what we have learned about object perception via these methods.

A. Feature Analysis in Inferior Temporal Cortex

As noted earlier, the pattern of receptor firing rates on the retina constitutes the initial representation of an object. In a like manner, the center-surround ganglion cells and simple and complex cells in V1 can be considered increasingly complex object representations, with each cell coding for a particular feature (e.g., an edge tilted at a particular orientation) of the object. How are objects represented in later visual cortical areas?

Axons from neurons in V1 project to several other cortical areas, including (logically enough) areas V2 and V3. From here, visual processing separates into two streams. One, commonly referred to as the ''where'' pathway, flows dorsally, ending in the posterior parietal lobe, and determines the spatial locations and/or functional aspects of visual stimuli. The second stream, which flows ventrally toward the inferior temporal lobe, is responsible for determining object identity. The present discussion is confined to this latter ''what'' pathway, because we have defined object perception as the process of recognizing the identity of an object.

Relatively little is known about the function of areas V2 and V3, in part because, whereas V1 is easily exposed by surgically removing portions of the skulls of laboratory animals, V2 and V3 are hidden in folds of the occipital cortex. It is possible that these areas, as well as area V4, to which neurons from V2 and V3 project, provide the medium for further stages of representation in the ventral processing stream. We know more about the functional characteristics of cells in the inferior temporal lobe (area IT), which receives input from V3 and V4 and is the last purely visual processing area in the ventral stream. Researchers recording from single cells in various parts of IT have found neurons that respond best to complicated patterns of light. For example, one study found a neuron that responded with a rapid firing rate to a plastic model of a pineapple (Fig. 5A). Further investigation revealed that the neuron responded equally well to the leaves of the pineapple isolated from the rest of the object (Fig. 5B), and the researchers eventually established that the neuron's most rapid firing rate occurred in response to an eight-pointed star (Fig. 5C). This type of neuron was dubbed the ''elaborate cell,'' suggesting a more complicated building block for representations of whole objects, itself constructed from sets of complex cells in earlier visual areas.

Other studies have found neurons in IT that respond best to whole objects, most notably faces. Some neurons are remarkably selective, consistently responding at their fastest rate only when a particular familiar face is presented (e.g., the face of one of the experimenters). These findings seem, on the surface, to support the concept of ''grandmother cells,'' single neurons that are each responsible for signalling the presence of a single object, for example, one's grandmother. However, several considerations indicate that this notion is almost certainly misguided. Whereas a particular neuron might respond best to a particular face, it will also respond fairly well to other faces. Furthermore, most face-selective cells in IT (as well as most elaborate cells) respond best when the image of the face is of a particular pose (e.g., profile or full frontal), is in a particular orientation (most cells

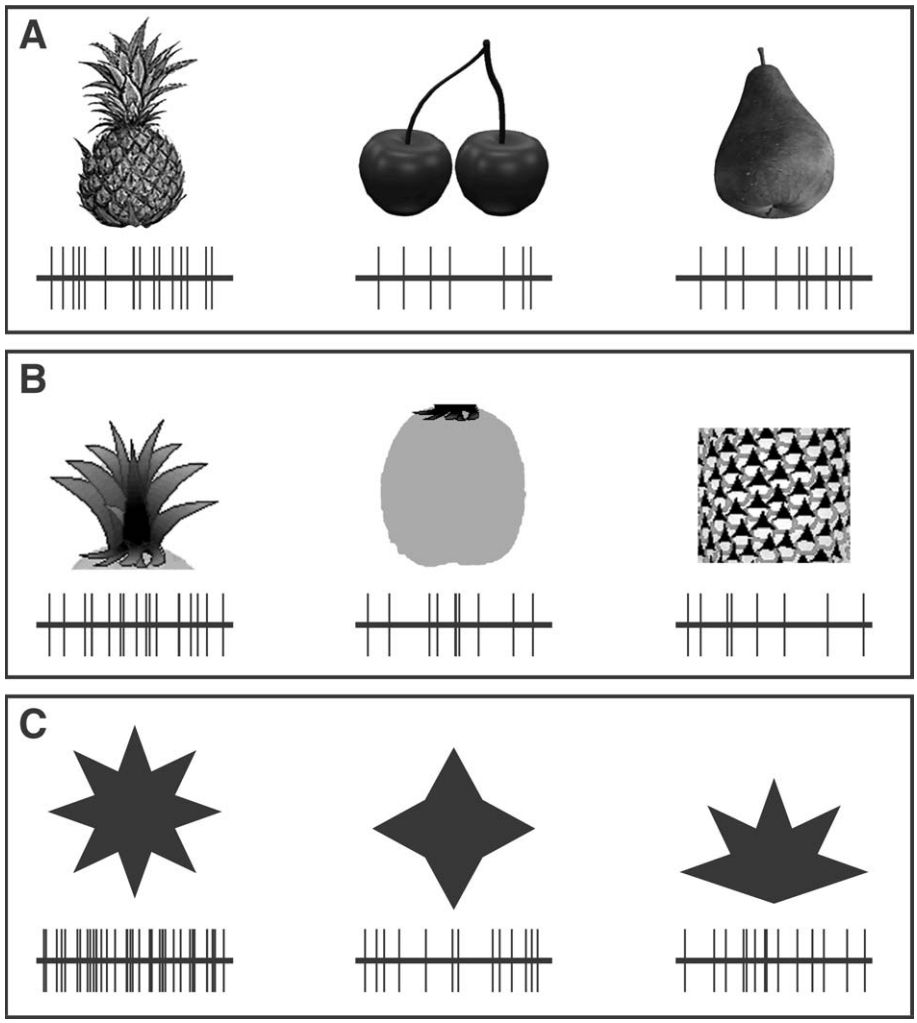

Figure 5 Schematic results from single-cell recording studies of neurons in cortical area IT. The vertical lines below each image show action potentials generated by the neuron while the image is shown to the animal subject (this figure illustrates the results of a study using macaque monkeys as subjects). Faster firing rates presumably indicate a greater preference by the cell for a given image. Results shown in (A) indicate that the cell responds better to an image of a pineapple than to other fruits. (B) indicates that the cell appears to be responding to the leafy part of the pineapple, not to the shape or texture of the bottom portion. Finally, (C) shows that the cell responds best of all to an eight-sided star shape.

respond best to upright faces, although some respond better to misoriented views), and takes up a particular retinal size (corresponding to a certain viewing distance). Thus, a neuron that responds better to grandmother's than auntie's face when they are presented from the front, tilted 30°, and viewed from 2 m, might reverse its preference if the faces were shown in profile, upright, and viewed from 10 m. The pattern of responses over a large number of IT neurons, rather than single cells, must be considered for object identity to be determined.

Because the majority of IT cells that have been found to respond best to a particular object also respond best when the object is seen from a particular orientation, view, and distance, the single-cell recording literature would seem, on the surface, to support view-based over structural description theories. That is, if area IT is the site of high-level object representations and neurons in IT show viewpoint-dependent responses, one might conclude that high-level representations are view-based. Again, though, patterns of responses over a population of neurons, rather than single neurons alone, represent objects, and it is possible that an appropriately selected population of IT neurons might respond to objects in a viewpoint-invariant manner. Furthermore, some single neurons

do respond to objects across a wide range of views, and the response properties of other neurons are completely unknown (indeed, in most studies only a relatively small proportion of neurons are found to selectively respond to any one object). At present, we can conclude that single-cell recording studies are more consistent with view-based than with structural description theories, but it is entirely possible that future studies may reveal evidence for structural descriptions (or some sort of currently unimagined hybrid representation) in area IT.

Before we leave the topic of single-cell recording, another feature of the receptive fields of IT cells should be noted: the receptive field size (the area of the retina to which a neuron responds) is greatly expanded for these cells compared to simple and complex cells in V1. V1 neurons, in turn, have larger receptive fields than retinal ganglion cells; more generally, there is a trend for receptive field sizes to increase as information gets farther along in the ventral processing stream. A natural consequence of this trend is the effective solution to translation constancy. Whereas a particular simple cell "looking" for a 45° oriented edge will only respond if SOGI's head falls within a small area, an IT cell that responds best to the SOGI as a whole will fire regardless of where in the visual field the object is located. However, it is important to note that, whereas the large receptive fields of IT cells indicate that translation constancy has been achieved by this point in processing, we do not yet know exactly *how* these cells come to respond to objects in any part of the visual field.

B. Neuropsychology of Object and Face Perception

In addition to using animal models, as described in the last subsection, it is also possible to examine the neurophysiological underpinnings of object perception with the help of humans who have sustained damage to visual areas of their brains. *Agnosia* is the general term for patients who have lost the ability to visually recognize objects. Such patients retain normal visual acuity and memory—they can see objects and remember object labels (as well as their structural and functional properties)—but they cannot retrieve an object's name from its image. Even more remarkably, patients with *associative* forms of agnosia may be able to produce excellent drawings of objects from memory, but fail to name their own drawings when shown them later.

Associative agnosic patients show myriad patterns of spared and impaired object perception abilities. Patients with *alexia* are unable to recognize letters, but recognition of many other objects appears normal. *Prosopagnosia* is a selective inability to identify individual humans from their faces with, again, many other types of objects remaining recognizable. Other patients have category-specific agnosias, only showing difficulty naming fruits and vegetables, animals, or some other class of objects. Still other patients show even more idiosyncratic deficits, for example, one well-known patient is excellent (by some tests, better than normal) at recognizing people by their faces but is severely agnosic for all other object classes.

The dissociation evidenced in the agnosia literature between the perception of faces and other objects (a number of patients showing impaired face recognition abilities with relatively intact object recognition, along with at least one patient showing the opposite pattern of abilities and disabilities) is especially interesting to object perception theorists. All faces have the same basic parts in similar relations to each other, so that it would be difficult to craft a structural description that could distinguish different faces from each other. Thus, a number of researchers have drawn the inference that faces are perceived by a visual subsystem that uses view-based representations and is damaged in prosopagnosic patients, whereas other objects are perceived by a structural-description-based subsystem that is relatively spared in prosopagnosia.

Several neuroimaging laboratories using techniques such as functional magnetic resonance imaging (fMRI) have showed that greater cellular activity is generated in a particular portion of IT cortex (more specifically, the anterior fusiform gyrus) when humans view pictures of faces than when pictures of other objects are viewed. The tantalizing conclusion is that this is the area of the brain where view-based representations of faces are processed and/or encoded and that selective injury to this area results in prosopagnosia. This hypothesis will be evaluated in greater detail later after we have considered behavioral evidence concerning the different forms of processing inherent in the perception of faces and other types of objects.

V. BEHAVIORAL STUDIES OF OBJECT PERCEPTION

The previous section described research by physiological psychologists and neuroscientists on how

different neurons and different parts of the brain contribute to the process of object perception. Other cognitive scientists have studied object perception through behavioral experiments on human subjects with normally functioning visual systems. In these studies, subjects are asked to perform a task on a selected set of stimuli, for example, naming pictures of common objects. Some aspect of the stimuli (e.g., the viewpoint from which each stimulus is pictured) or the task (e.g., the duration of time that the stimulus remains on the screen) is varied, and subjects' responses are recorded. By examining the relationship between the manipulated variable and responses, we can indirectly learn something about how the brain is processing the stimuli in order to perform the task.

A. Effects of Image Transformations

One important set of behavioral studies involves psychophysical experiments, where psychological responses to variations in a physical property of object stimuli are recorded. The basic logic of these experiments is that, if a certain stimulus dimension is encoded in the representations used for object perception, then transformations to stimuli along this dimension should cause impairments of performance (i.e., increased response times and/or increased error rates) in object perception tasks.

To take a well-known and oft-replicated example, many researchers have shown subjects pictures of common objects in different orientations, ranging from the object's canonical upright position to an upside down orientation. Example stimuli and the typical pattern of results from these experiments are shown in Fig. 6. In the initial block of trials, subjects usually require more time to recognize an object the farther it is rotated from its upright orientation. However, there is often a small dip in the response time function at 180° (the upside down position), as shown in the graph. Another important feature of these studies' results is that, if the experimental trials are repeated, subjects take considerably less time to recognize the objects in misoriented orientations—the slope of the response time function decreases with practice.

These findings indicate that something about objects' canonical orientations is encoded in the representations used for object perception. This conclusion helps to constrain both view-based and structural description theories. The fact that response time varies with degree of misorientation is explained in many

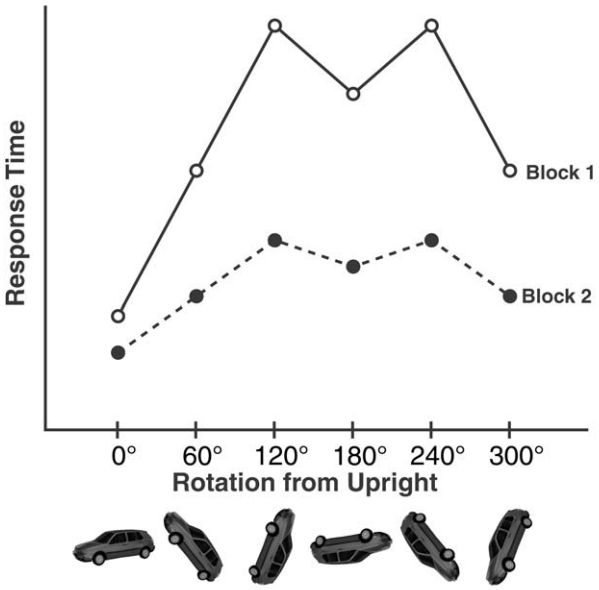

Figure 6 Schematic results from psychophysical experiments in which common objects, such as the car shown at bottom, are presented in various orientations and must be named as quickly as possible by subjects. Three results are evident in the graph: (1) naming response time generally increases as the object is rotated away (either clockwise or counterclockwise) from its canonical upright orientation; (2) there is a small dip in the response time function at 180°; and (3) the slope of this function is reduced if the stimuli are seen again in a second block of trials.

view-based theories as a consequence of a trasformation process necessary to bring a misoriented view of an object into register with the encoded, canonical view. The larger the degree of misorientation, the longer this transformation process (which is likened to mental rotation in some theories) takes, and the longer it will take subjects to recognize the object. To explain the decrease in misorientation effects over test blocks, these theories propose that multiple views of an object can be stored in memory. Once an object is seen lying on its side in the first block of test trials, a representation is encoded of the object in that orientation. When this stimulus is encountered in subsequent blocks of trials, the transformation process is no longer necessary because the test object can be directly compared to the newly encoded representation of the object on its side.

In structural description theories, orientation effects are explained as a function of shifting categorical relations between parts. The structural description of a car will include the proposition that the windshield is ABOVE the front wheel. When the car is rotated 90° in

the picture plane though, the wheel will be BESIDE the windshield, causing, as in view-based theories, an imperfect match between perceived and encoded representations, which leads to an increase in response times. The same type of mechanism also provides an interesting account for the dip in the response time function at 180°. Parts that had BESIDE relationships in upright objects (e.g., the front and rear wheels of the car, assuming the car is viewed from the side) shift to ABOVE–BELOW relations when the object is rotated 90°, but return to BESIDE relations when the object is fully upside down. Thus, in some cases the structural description of a 180° rotated object matches the upright object better than does the 90° rotated version.

Note that this account implies that structural descriptions do not include information as to whether one part is to the left or to the right of another—both LEFT and RIGHT relations are coded as BESIDE. If this is the case, then two images that are mirror reflections of each other should share the same structural description, and image reflections should have little, if any, effect on recognition accuracy or response time. As noted in Section I, this pattern of reflection invariance has, in fact, been empirically demonstrated.

Other experiments indicate that size transformations and object translations also generally have minimal effects on object perception responses. Effects of lighting direction are only starting to be studied systematically (before the ready availablility of 3D modeling software, it was difficult to generate stimuli for such experiments), with early results suggesting that lighting changes also cause only small, though systematic, disruptions to object perception processes. Object perception across rotations in the depth plane (i.e., changes in viewpoint) are also the focus of increasing scrutiny since the development of inexpensive computer modeling programs. Consistent with the research on picture plane rotations, most studies have found systematic and substantial effects of viewpoint shifts on object perception response time and error rates.

The relative invariance of object perception over mirror reflection, size, position, and lighting changes appears to favor structural description over view-based theories because, as noted in Section I, these transformations all lead to large changes in images (which are the presumed representations in the simplest view-based theories). However, structural description theories also predict at least limited viewpoint invariance, because structural descriptions should only be altered by a viewpoint shift when parts become occluded or uncovered or when categorical relations are altered. Careful investigation has shown that, even when part accretion and deletion are minimized, viewpoint costs to object perception performance are still incurred. Small picture plane rotations, which should also have no effect on categorical relations, can also have measurable effects on recognition time. Thus, view-based models appear to provide a better account than structural description theories for findings of orientation and viewpoint dependence.

The description of psychophysical research given here is, by necessity, oversimplified. There are numerous exceptions to these generalizations (e.g., object perception has been shown to be orientation-invariant in some circumstances and size-dependent on others), and many investigators have seized upon this ambiguity to argue that view-based representations are used in some object perception contexts and structural descriptions are used in others. Perhaps the most pervasive proposition is that recognition in contexts where all candidate objects are easily discriminable from each other (e.g., distinguishing between a car, a bicycle, and a jogger) relies on structural descriptions, whereas object perception in more demanding circumstances (identifying a sparrow in an area where warblers and finches also live) requires view-based representations. As intuitive as it appears to be, experiments designed to directly test this particular dual-system hypothesis have provided mixed evidence; some studies support it but others do not. Thus, the more exciting possibility remains that either a single view-based or structural description theory, or a model employing some type of hybrid representation, will eventually be able to explain all of the observed patterns of dependencies and invariances across image transformations.

B. Subordinate-Level Classification and Face Perception

In addition to the psychophysical experiments reviewed earlier, a second collection of behavioral experiments has examined the relative ease of object perception when stimuli must be identified at different classification levels. The *entry* level for any given object is operationally defined as the first name that comes to mind for that object (e.g., dog); *subordinatate*-level labels are more specific (beagle), and *superordinate* labels are more general (animal). Numerous studies have demonstrated that common objects are easiest to

classify at the entry level. These experiments typically use a label verification task, in which a word is followed by a picture of an object on each trial and the subject decides whether the word and picture match. Response times are faster and error rates lower for entry-level than for suborinate- and superordinate-level labels.

It is generally held that this entry-level advantage is at least partially perceptual in nature, that is, object perception processes are specialized to produce representations that are most efficient for identifying objects at the entry level. Neuroimaging studies have supported this assumption by showing that the extra time taken to identify objects at the subordinate level is due to additional processing by the visual system, presumably supplementing the object perception processes that allow for entry-level identification.

The most subordinate level of identification is the individual level (Snoopy), and, as mentioned already, a large literature is devoted to individual-level recognition of one particular class of objects: faces. Much of this literature is dedicated to demonstrating that face perception involves qualitatively different processes than the perception of other objects. The most well-known finding in this regard is the *inversion effect*. As already discussed, almost all objects are more difficult to recognize when inverted (turned upside down) than when upright, but the increase in difficulty for faces is especially pronounced. Faces are also more difficult to recognize than other objects when the top and bottom halves of images are misaligned (Fig. 7 demonstrates both the inversion and misalignment effects).

Although there are a number of hypotheses concerning exactly how faces are processed, most agree on the basic premise that a precise specification of the configuration of face parts is crucial for face perception. In other words, a face representation must include not just the information that the nose is ABOVE the mouth but must specify the exact distance by which these parts are separated. Such precision is not necessary to discriminate between members of most other classes of objects, such as the chairs in Fig. 7.

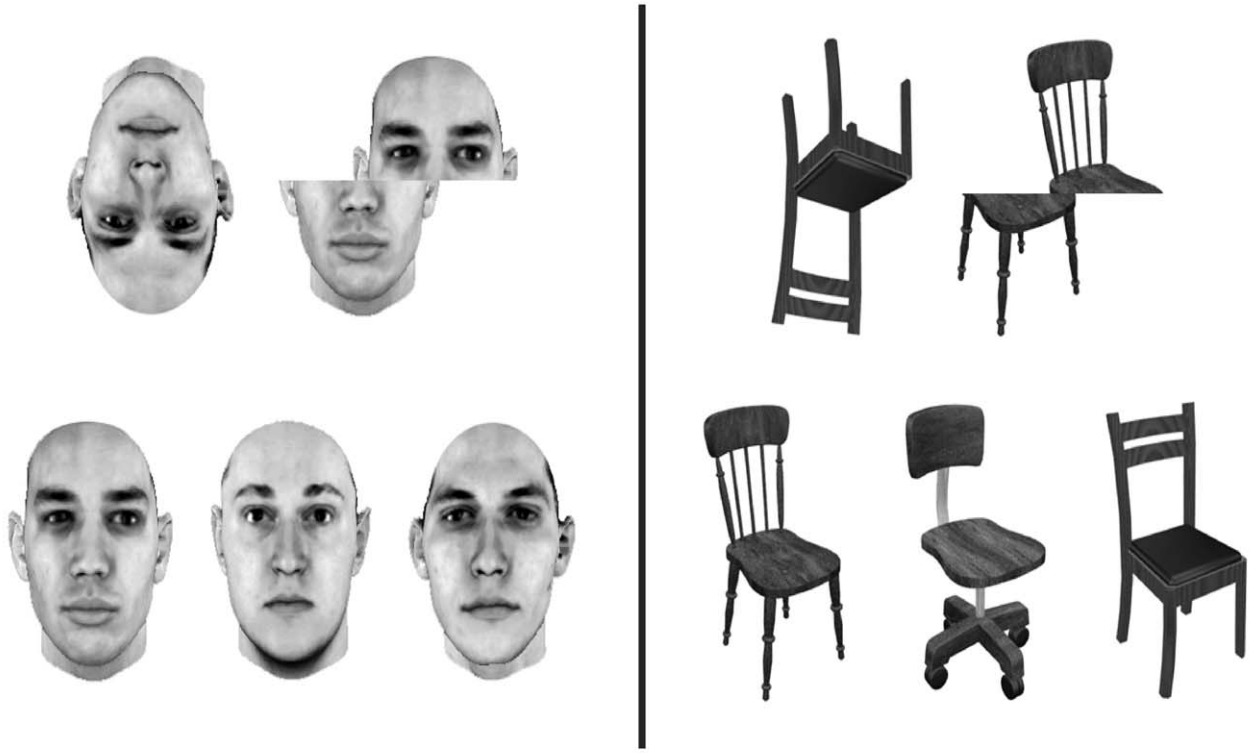

Figure 7 Face perception can be dissociated from the perception of other classes of objects by a number of behavioral effects, two of which are demonstrated here. It is quite difficult to pick out the upright faces in the bottom left triad of images that match the inverted and misaligned faces in the upper left of the figure. By contrast, matching upright with inverted and misaligned chairs is relatively easy, as shown at right.

Many researchers believe that configural processing is carried out in the anterior fusiform face area identified in the neuroimaging studies described earlier. A lively debate is currently underway in the literature concerning the nature of the processing going on in this area, most crucially whether it is a truly face-specific processing system or whether it instead can contribute to the recognition of other objects at subordinate levels. Prosopagnosic patients can recognize some types of objects at subordinate levels (one patient was even able to learn to recognize individuals from his flock of pet sheep), but careful testing shows that they are generally poorer at subordinate- than at entry-level identification.

Other research points to expertise as a crucial factor in face-specific behavioral effects. Dog show judges and bird watchers show inversion and other face-specific effects for their domains of expertise, and exciting research has shown the anterior fusiform responding preferentially to a class of novel objects only after subjects were trained to be experts at recognizing these objects at the individual level. All normally developing humans are face perception experts, so it is possible that the anterior fusiform is specialized for processing any class of objects that is both recognized at a highly subordinate level and highly overlearned. Whether this processing involves representations that are qualitatively or only quantitatively different from those involved in entry-level object perception remains a subject for future research.

GLOSSARY

cerebral achromatopsia The inability to perceive and discriminate colors due to pathology within the cerebral cortex. It is to be distinguished from the more common form of color blindness caused by anomalies in the photoreceptors of the eye.

cerebral akinetopsia A rare deficit in the ability to perceive and discriminate movement thought to arise from lesions of cortical visual areas involved in the processing of visual motion information.

functional magnetic resonance imaging (fMRI) Several neuroimaging techniques capable of showing areas of the brain that are activated during sensory, motor, or cognitive tasks. The most common technique highlights areas of the brain in which blood flow and oxygenation are altered by the experimental task. fMRI images are typically displayed as an overlay on conventional structural MRI images depicting the anatomical structure of the brain.

positron emission tomography (PET) Like functional MRI, PET imaging is capable of showing areas of the brain that are active during sensory, motor, or cognitive tasks. PET is based on the injection and measurement of radioactive tracers whose concentrations are altered at brain sites where activity is experimentally altered. Depending on the tracer, this technique can be sensitive to changes in oxygen or glucose utilization or other chemical factors.

prosopagnosia Deficit in the ability to recognize previously familiar faces. It is thought to be associated with lesions of ventral occipitotemporal cortex.

receptive field That region of the retina (one in each eye), or equivalently the visual field, within which a stimulus is able to alter the response of a visual system neuron.

retinotopy The representation of retinal topography within the connections, nuclei, and cerebral cortex of the visual system. A retinotopic map is a collection of neurons whose receptive fields, in the aggregate, preserve the two-dimensional topography of the photoreceptors that provide their input, albeit to a variable degree of precision and completeness depending on the brain site. A retinotopic map may be distorted, typically due to expansion of the area devoted to the visual field near the center of gaze.

stereopsis The phenomenon of simultaneous vision with two eyes in which there is a vivid perception of the distances of objects from the viewer; it is present because the two eyes view objects in space from two points, so that the retinal image patterns of the same object are slightly different in the two eyes.

V1, V2, V3, VP, V4, hMT+, V8, FFA, LO, and KO Abbreviated names of human cortical visual areas. V1 is the primary visual cortex, also known as striate cortex. Other visual areas are collectively referred to as extrastriate visual cortex. Some extrastriate visual areas are simply numbered (e.g., V2, V3, V4, and V8); others have more descriptive names. VP, ventral posterior visual area; hMT+, middle temporal[1] visual area, also known as V5; FFA, fusiform face area; LO, lateral occipital visual complex; KO, kinetic occipital region.

visual field That portion of the world visible to the observer at any given instant. The foveal visual field refers to the portion of the visual field near the center of gaze (strictly that portion imaged on the fovea of the retina).

The occipital lobe encompasses the most posterior portion of the human cerebral cortex and is primarily responsible for vision. Direct electrical stimulation of the occipital lobe produces overtly visual sensations. Damage to the occipital lobe typically results in either complete or partial blindness or visual agnosias, depending on the location and severity of the lesion. This article will summarize the structure and function

[1]Although hMT+ derives its name from the homologous monkey visual area, its location is near the junction of the occipital, parietal, and temporal lobes on the lateral aspect of the brain, not in the middle of the temporal lobe as its name would seem to imply.

of the human occipital lobe, stressing its role in vision. Although the discussion is primarily based on studies of normal human subjects, clinical reports of brain-damaged patients and animal studies are discussed when they directly illuminate particular issues.

I. INTRODUCTION

The surface area of the human occipital lobe encompasses approximately 12% of the total surface area of the neocortex of the human brain. Its primary role is to provide the sense of vision. Vision begins with the spatial, temporal, and chromatic pattern of light falling onto photoreceptors of the retina and culminates in the perception of the properties of the objects and surfaces within the world around us. Fundamentally, then, vision is the ability to infer the attributes of objects in the visual scene from an analysis of the light patterns imaged in the eyes. The occipital lobe contains the bulk of the neural "machinery" responsible for this. However, visual perception can be affected by the context of previous experience as well as by current goals and expectations. To permit these more cognitive functions, the occipital lobe is heavily interconnected with other lobes of the brain, especially the parietal and temporal lobes, as well as with an array of subcortical structures. Through these connections, the results of visual processing in the occipital lobe enter into and can be influenced by more general processes involved in goal-directed, motivated behavior and "thinking." With these considerations in mind, the following discussion begins by describing the structure and function of the occipital lobe as a separate entity but ends with a consideration of its potential role in more cognitive functions whose neural basis may include other brain regions.

II. ANATOMICAL ORGANIZATION

Anatomy provides a description of the physical structure of the occipital lobe but can also provide a basis for identifying functionally distinct subdivisions. Although anatomy is not infallible in this respect, the discovery of new anatomical distinctions can trigger the discovery of previously unsuspected functional differences. Accordingly, the following discussion begins with descriptive anatomy but then introduces anatomical features and principles that have been useful as indicators of functional differentiation.

A. Descriptive Anatomy

1. Gross Anatomy of the Occipital Lobe

Figure 1 illustrates the location and extent of the human occipital lobe. Viewed from the medial surface of the cerebral hemisphere, it is bounded anteriorly by the parieto-occipital sulcus (POS). Ventrally and laterally there are no major anatomical features that clearly and consistently demarcate the anterior extent of the occipital lobe. For practical purposes, an imaginary line running laterally from the dorsal tip of the POS to the preoccipital notch is considered the effective boundary separating the occipital lobe from the parietal and temporal lobes.

Medially, the most prominent feature of the occipital lobe is the calcarine sulcus, which is flanked above by the cuneus and below by the lingual gyrus (cf. Fig. 1, top). The lingual gyrus is separated from the more laterally placed fusiform gyrus by the collateral sulcus. The fusiform gyrus is then bounded laterally by the occipitotemporal sulcus (OTS), although this sulcus tends to be variable and interrupted as it extends posteriorly toward the occipital pole. The lateral surface of the occipital lobe is especially variable from individual to individual. Consequently, the lateral occipital gyrus can be irregular and can be split by the lateral occipital sulcus. This latter fissure has several important variants, sometimes appearing as one, two, or even three small sulci running approximately in the anterior–posterior direction. Most dorsally on the lateral surface is the transverse occipital sulcus, which often forms the most posterior end of the intraparietal sulcus. A thorough treatment of individual variants of the occipital anatomy can be found in the atlas of Ono, Kubik, and Abernathy.

2. Cytoarchitecture, Myelination, and Histochemistry

Traditionally, occipital cortex has been subdivided into anatomically distinct regions based on cytoarchitecture. As for all neocortex, the occipital gray matter is clearly laminated, though the criteria for identifying and naming different layers have varied considerably. Figure 2A illustrates one of the more popular laminar numbering schemes. Primary visual cortex is the most cytoarchitecturally distinct region of the occipital lobe. It is also known as striate cortex due to the stria of Gennari, which can be identified even in a cross section of freshly cut tissue. This band of myelinated axons running horizontally in layer 4B demarcates the extent

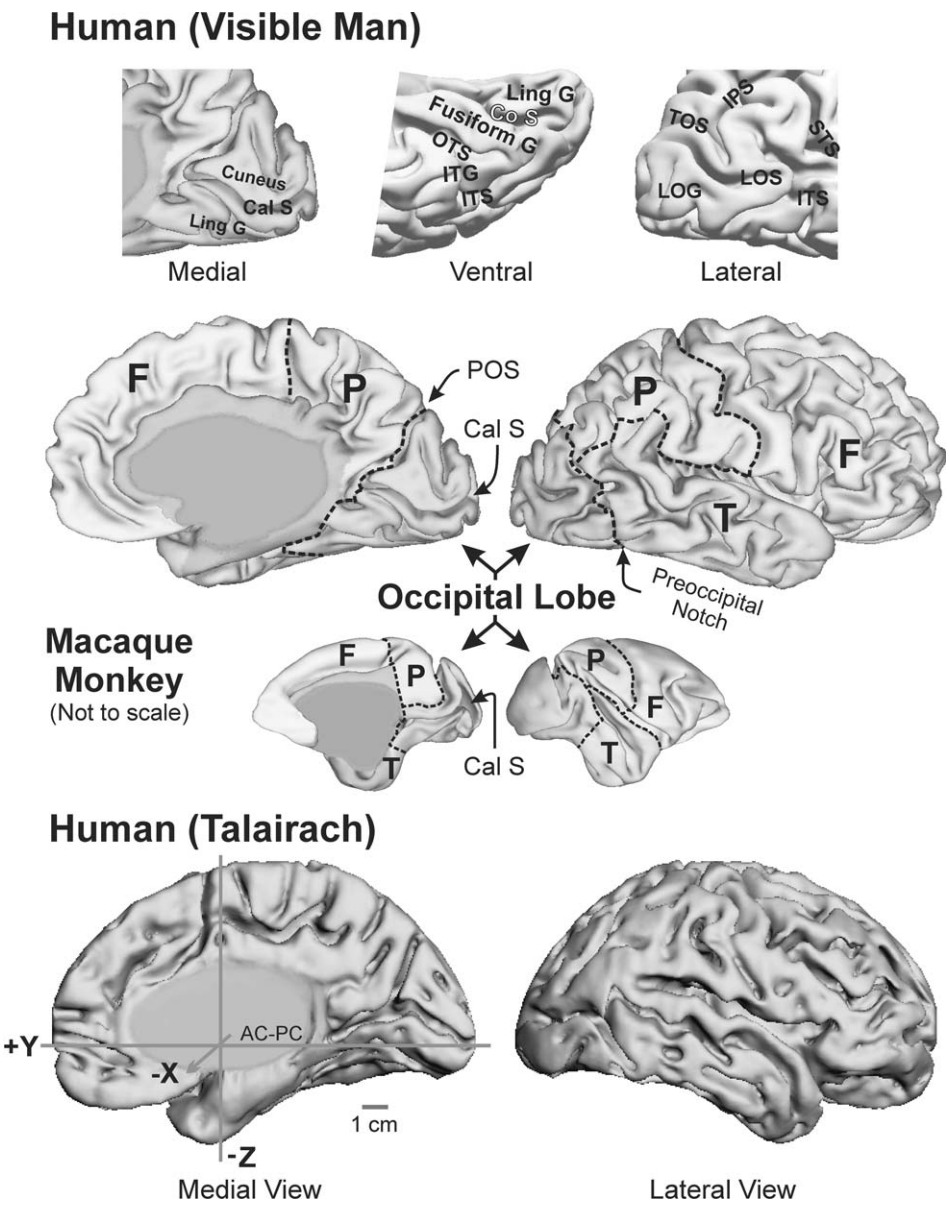

Figure 1 Gross anatomy of the occipital lobe in humans and macaque monkeys. Top: Medial, ventral, and lateral views of the occipital lobe with medial and lateral views of the whole cerebral cortex (below) from the Visible Man database. Middle: Identification of cortical lobes in the macaque monkey. Color code same as for top. Bottom: Computer brain model reconstructed from the Talairach and Tournoux *Co-Planar Stereotaxic Atlas of the Human Brain* showing the standard Talairach coordinate system, with the origin located at the anterior commissure (not shown) and the *y* axis passing through both the anterior and posterior commissures (not shown). Polarity of axes indicates conventions used in this article. Abbreviations: AC–PC, anterior commissure–posterior commissure reference line; Cal S, calcarine sulcus; POS, parieto-occipital sulcus; F, frontal lobe; P, parietal lobe; T, temporal lobe. (Figures of Visible Man and Macaque monkey brains courtesy of David Van Essen.)

of striate cortex within, and adjacent to, the calcarine sulcus (Fig. 2B). Cytoarchitectural differences among visual areas outside the striate cortex (known as extrastriate cortex) tend to be less obvious and more inconsistent, perhaps accounting for significant differences in the accounts of cytoarchitectonic parcellation of occipital cortex by early investigators.

One of the most widely used cytoarchitectonic schemes for subdividing cerebral cortex has been that of Brodmann (Fig. 2D). His scheme was primarily

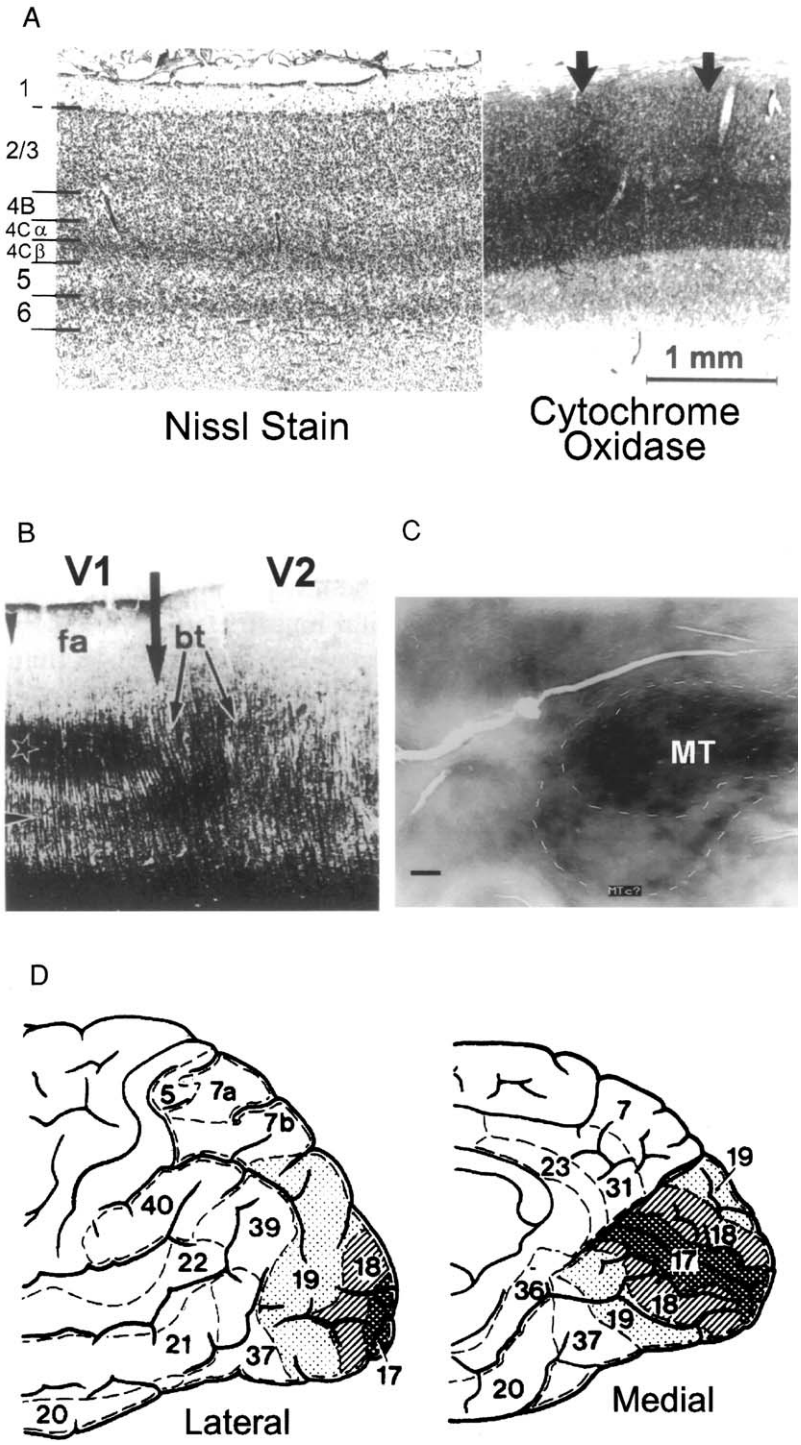

Figure 2 (A) Example of the laminar architecture of primary visual cortex visible with common Nissl stain (left) and with histochemical stain for cytochrome oxidase activity (right). Arrows indicate cytochrome oxidase dense puffs in layers 2–3. Note that different stains reveal different features. (Adapted from Horton, 1992.) (B) Example of myeloarchitecture near the border of areas V1 and V2 marked by a large vertical arrow. Abbreviations: bt, border tuft; fa, fringe area. A star marks the stria of Gennari. Small arrowhead on the left marks the inner band of Baillarger. (Adapted from Zilles and Clarke, 1997.) (C) Illustration of dense cytochrome oxidase histochemistry in human MT visual area. (From Tootell and Taylor, 1995.) (D) Brodmann's parcellation (numbers) of the human occipital lobe and adjacent cortex based on cytoarchitectonic features. (From Zilles and Clarke, 1997.)

based on differences in cell morphology (e.g., stellate–pyramidal), density, and distribution, as well as the overall thickness, proportion, and development of different layers within the cortical mantle. According to this plan, striate cortex is designated area 17 and is immediately surrounded by area 18, which in turn is bounded by area 19. Portions of Brodmann's area 37 may also be included in what we have defined here as occipital cortex (though Brodmann considered it part of the temporal cortex). Except for visual areas 17 and 18, Brodmann's areas often correspond poorly with functional distinctions identified by more modern techniques such as neuroimaging. This has resulted in diminished use of Brodmann's nomenclature as a basis for describing the functional organization of visual cortex.

Although some of Brodmann's original criteria for differentiating occipital cortex have not been functionally diagnostic, other cytoarchitectural features have been found to fare better in some cases. Indeed, researchers have argued in favor of a renewed interest in architectonic data as a useful correlate of function. Histological stains that reveal the distribution of myelinated fibers within the cortical gray matter have been successful in delineating some functionally defined visual areas. This is certainly the case for the stria of Gennari, which distinguishes the primary visual cortex. Dense myelin staining also characterizes the middle temporal visual area, hMT+, located in lateral occipital cortex near the confluence of the occipital, temporal, and parietal lobes (Fig. 2C). In macaque monkeys, the third visual area, V3, can also be identified by heavy myelin staining, though it is not clear whether this is also true in humans.

One alternative to the study of cytoarchitecture that can provide functionally relevant information is to examine the distribution of chemically distinct molecules within the cortex. This has been accomplished through a wide variety of histochemical and immunological techniques, though, historically, enzyme visualization has been especially useful in this respect. The discovery of circumscribed zones of high cytochrome oxidase activity in striate cortex (puffs, blobs) and extrastriate cortex (V2 "stripes", V4 "patches") triggered the identification and characterization of functionally distinct "modules" within occipital visual areas that had previously been thought to be functionally homogeneous. These discoveries led to the concept that individual cortical visual areas can contain multiple, distinct processing pathways or streams, thereby extending (though not necessarily reiterating) the organizational principle of multiple processing pathways found in the retina and LGN (outlined later). To a large extent, the features of cortical organization revealed by these studies are on a spatial scale that, until very recently, had been beyond the resolution of human neuroimaging and electrophysiological techniques, and so are outside the scope of this article.

B. Connectivity

Our knowledge of the anatomical connectivity of human occipital cortex largely arises from inferences based on animal experiments. In animals, differences in connectivity within the occipital lobe provide an important key to identifying different functional subdivisions and their interrelationships. To the extent that connectivity information derived from animals accurately reflects connectivity in the human brain, it provides a valuable basis for interpreting the results of neuroimaging studies and other types of human data.

1. Visual Input to the Occipital Lobe

Figures 3A and 3B summarize the major thalamic projections to occipital visual cortex. Visual input from the retina is relayed through the lateral geniculate nucleus (LGN) of the thalamus to terminate in the primary visual cortex (striate cortex, area 17, V1). A second major pathway arises from retinal projections that bypass the LGN and project to the superior colliculus. The superior colliculus then projects to the thalamic pulvinar nucleus, which in turn distributes widely to the cortex of the occipital lobe.

The geniculocortical pathways are subdivided into three main components associated with different neuronal subclasses in the retina and LGN. One pathway originates from small P-cells in the retina and is relayed through the parvocelluar layers of the LGN to terminate in layer 4Cβ of V1 and more sparsely in layers 4A and 6 (not illustrated in Fig. 3B). A second pathway to striate cortex begins with large M-type retinal ganglion cells and is relayed through the magnocellular layers of the LGN to terminate in layer 4Cα accompanied by a light projection to layer 6 (not shown in Fig. 3B). A third source of projections to V1 comes from a class of small cells within the koniocellular (K) or intercalated layers of the LGN. These neurons typically receive input from both the retina and the superior colliculus and terminate in the supragranular layers (above layer 4) of striate cortex. These afferents tend to cluster into "pufflike" regions of layers 2–3 that are also unique for their high levels of the metabolic enzyme cytochrome oxidase (co).

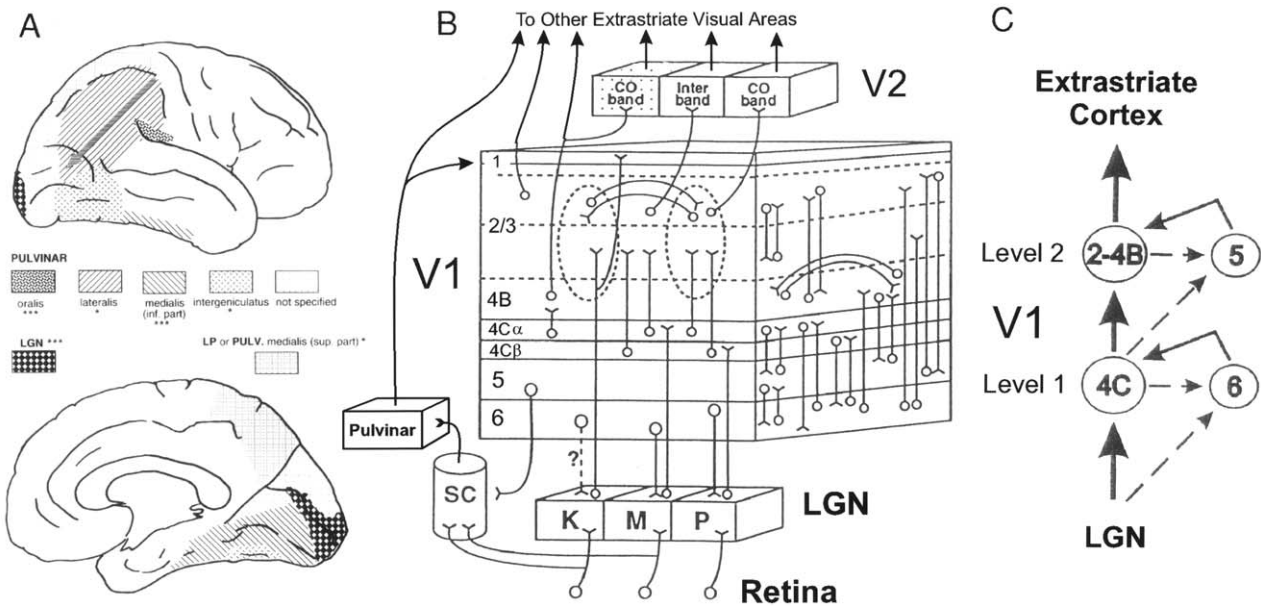

Figure 3 (A) Distribution of thalamic inputs to the occipital lobe and nearby portions of the parietal and temporal lobes. (From Zilles and Clarke, 1997.) (B) Concurrent input to V1 from K, M, and P retinogeniculate pathways with a schematic of intrinsic circuitry and cytochrome oxidase defined puffs (dashed ellipses). V2 receives segregated input from different sets of output neurons in V1 and distributes projections to different sets of extrastriate visual areas via distinct populations of output neurons in the different cytochrome oxidase defined compartments. Such circuitry forms the anatomical basis of multiple concurrent processing pathways within and among occipital visual areas. (Adapted from Casagrande and Kaas, 1994.) (C) Functional interpretation of V1 circuitry. (Adapted from Callaway, 1998.) Abbreviations: LGN, lateral geniculate nucleus; sc, superior colliculus; K, koniocellular; M, magnocellular; P, parvocellular.

Afferents to striate cortex via the alternate tectopulvinar pathway terminate most heavily in laminae 1 and upper 2–3.

Neurons of the P, M, and K, pathways differ in their visual response properties. Neurons of the parvocellular path tend to be relatively more numerous in the central retina, have smaller receptive fields with sustained responses, and are often color opponent. This makes them well-suited for conveying information about fine spatial detail and color. Magnocellular neurons tend to have larger receptive fields, prefer low spatial frequencies, and have more transient responses. They do not discriminate wavelength differences well but tend to have the greatest sensitivity to luminance contrast, especially at low spatial frequencies and low luminance levels. They are optimized for processing rapid temporal changes such as flicker and movement. The function of K-pathway neurons has not been studied as extensively as that of the M and P systems, but they appear to be a major determinant of co–puff cell properties and may play a key role in the modulation of responses evoked by the M and P pathways.

Although these three pathways are distinct, their functional capabilities can overlap significantly. It is primarily at the extremes of spatial and temporal frequencies that the M- and P-cell capabilities are most different. Both M and P pathways may contribute to processing intermediate spatial and temporal frequencies, but P-cells will tend to dominate for high spatial frequencies that are slowly varying. Conversely, magnocellular neurons will respond better than P-cells at low spatial frequencies that are rapidly varying. Chromatically, P-cell color opponency (activation by some wavelengths and suppression by others) appears to be critical for hue discrimination, but M-cells can respond more strongly to some wavelengths than others, though they are not opponent and their tuning is typically broader than that of P-cells. The significance of this functional overlap is that, under natural viewing conditions, all three inputs to the visual cortex are likely to be concurrently active. Under extreme visual conditions, the specialized capabilities of one or another of the pathways may take over and thereby extend the range of useful sight.

2. Intrinsic Circuitry

The retinal information relayed through the LGN is processed further by the intrinsic circuitry of V1 and

then distributed to other cortical areas via output neurons in layers 2–3 and 4B (see Fig. 3B). Subcortical projections to the superior colliculus and feedback projections to the LGN originate from layers 5 and 6, respectively. It is through this selective distribution of visual information combined with the characteristics of local processing that different visual areas achieve their functional uniqueness. Although a detailed review of the local circuitry of the occipital cortex is outside the focus of this article, Figs. 3B and 3C attempt to summarize the basic plan for V1. The intrinsic processing of V1 can be divided into two major levels. Input from the LGN terminates at the first level in the different subdivisions of layer 4C. Information is then distributed primarily to level 2 output neurons within layers 2–3 and 4B. The latter output signals are modified by neurons in layers 5 and 6 that combine information about the inputs and outputs of each processing level and feed it back onto neurons at the same level.

The laminar organization of V1 circuitry is complemented by horizontal connections that tend to connect functionally similar zones distributed within specific laminae. In layers 2–3, long horizontal projections preferentially interconnect pufflike zones containing cells that have similar visual response properties and that are rich in the metabolic enzyme cytochrome oxidase. Likewise, interpuff zones tend to be interconnected most strongly with other interpuff zones. In V2, a similar pattern of specific horizontal connections link co-defined compartments termed the thick-, thin-, and interstripe zones.

Together, the laminar specificity of vertical intrinsic connections and the functional specificity of horizontal connections provide an anatomical substrate for creating different subsets of output neurons whose visual response properties reflect different combinations of the P, M, and K afferent pathways, as well as modulatory effects of cortical feedback pathways and other subcortical inputs. Output neurons in layer 4B of V1 are dominated by M-pathway characteristics, as are the responses of the extrastriate visual areas, such as V2 thick stripes and area MT, to which the 4B cells project. In contrast, output neurons in the interpuff regions of V1 tend to be strongly biased by P-cell characteristics, which are subsequently imparted to downstream visual areas such as V2 (thin- and interstripe compartments), VP, and V4. Output neurons in co–puff subdivisions tend to exhibit characteristics that appear to reflect a mixture of influences. As a result, later processing stages, such as V4, also can be shown to exhibit a mixture of influences. Overall, then, the intrinsic circuitry of V1 acts to process, combine, and redistribute the visual information available in the different afferent pathways, thereby creating a new set of output signals that reflects the afferent inputs but that also encodes more complex visual properties or features. Intrinsic circuitry within subsequent cortical processing stages, though less well-studied, presumably functions in a similar manner.

3. Corticocortical Connectivity

The output neurons of layers 2–3 and 4B of V1 selectively distribute different types of visual information to subsequent processing stages in extrastriate visual cortex. Each extrastriate visual area itself has unique feedforward and feedback connections within and, often, outside the occipital lobe. These patterns of selective connectivity are a primary determinant of the functional specificity of each visual area. Finally, interhemispheric projections through the corpus callosum connect the left and right halves of each visual area into a functionally integrated whole.

In monkeys, connections among cortical visual areas tend to follow a consistent pattern of laminar distribution that differentiates forward, backward, and lateral types of connectivity (Fig. 4). Generally, forward connections arise from neurons in layers 2–3 of the lower area and distribute to layer 4, tapering off into the lower reaches of layer 3 in the higher visual area. In some visual areas, however, forward projections can also originate in subgranular layers (below layer 4), though the terminal distribution remains targeted at layer 4 of the recipient area. In contrast, backward-type projections tend to originate in layer 6 of the higher area and distribute outside layer 4 of the lower area, though some feedback projections can have a bilaminar origin. Finally, some visual areas have interconnections whose terminal fields engage nearly all laminae. This distribution pattern is thought to characterize lateral connections between visual areas at approximately the same processing level. On the basis of these patterns of connectivity, it is possible to arrange the various occipital visual areas into a processing hierarchy. This is illustrated in Fig. 5. The extent to which this plan applies to human visual cortex is not known, though the overall scheme is likely to be similar.[2]

[2]New techniques in neuroimaging, including the analysis of functional connectivity (correlation strengths among visual areas) and diffusion–tensor imaging, hold promise for directly charting connectivity in the human brain.

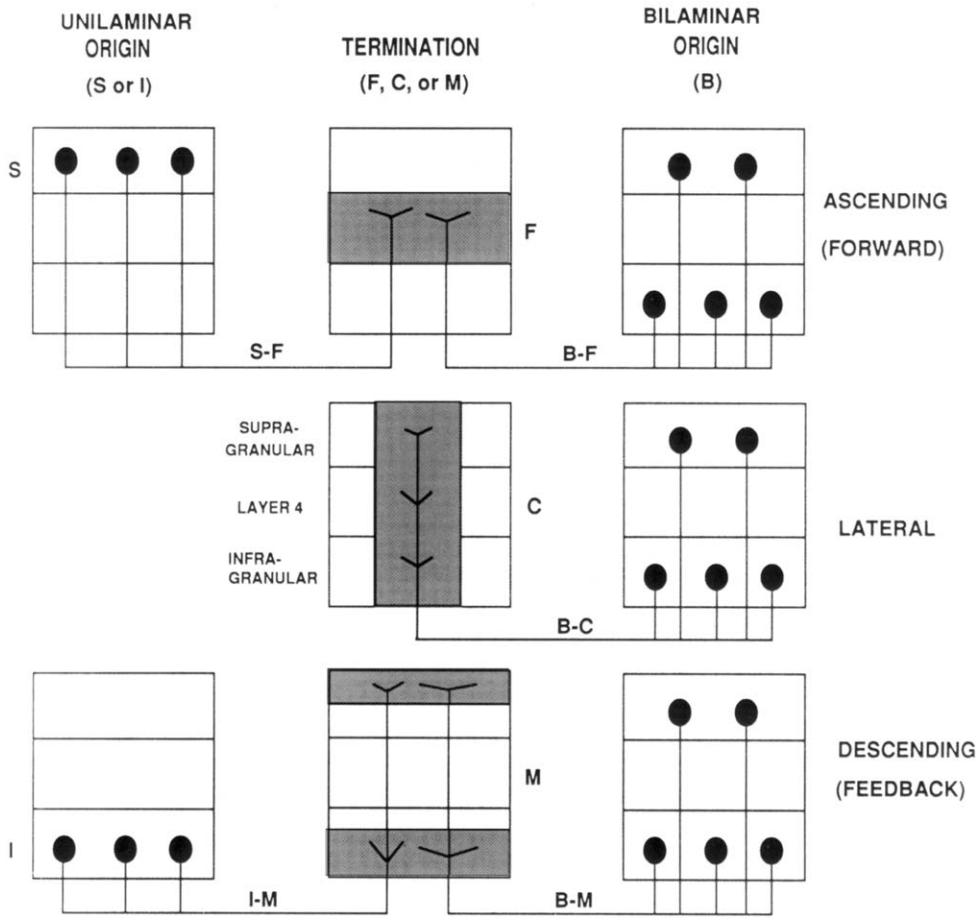

Figure 4 Schematic diagram of the laminar patterns of corticocortical connections among visual areas in macaque monkeys used to define ascending, descending, and lateral types of connectivity. The cell bodies of projection cells are found in one of two common patterns, unilaminar (left) or bilaminar (B) (right). Unilaminar projections can originate from supragranular layers (S) or infragranular layers (I). Ascending terminations tend to be focal in layer 4 (F). Lateral terminations tend to be columnar (C). Descending terminations tend to be multilayered (M). (From Felleman and Van Essen, 1991.)

This connectional hierarchy incorporates several important organizational features. First, it is generally consistent with the concept that successively more complex visual response properties are represented at successive processing stages, though detailed comparisons of the response properties of efferent neurons at one stage with the properties of recipient neurons at the next stage are generally lacking. Another key aspect of this corticocortical network is that nearly every forward connection is matched by a corresponding backward connection, thereby establishing reciprocity between visual areas. Alternate connectivity schemes based on the strength of response correlation among visual areas rather than anatomical connectivity have stressed this reciprocity and suggest that a less hierarchical, more dynamic, processing network may also provide a useful model of occipital connectivity. A third important principle illustrated in Fig. 5 is that multiple, parallel pathways exist within, and between, each processing level. There are no hierarchical levels that are interconnected by only a single pathway. [In Fig. 5, the multiple connections between entorhinal cortex (ER) and hippocampal cortex (HC) are represented only schematically.] The arrangement of multiple parallel pathways within the cortex thereby provides a basis for concurrent processing of different aspects of the incoming visual information. Thus, the M, P, and K pathways that provide concurrent

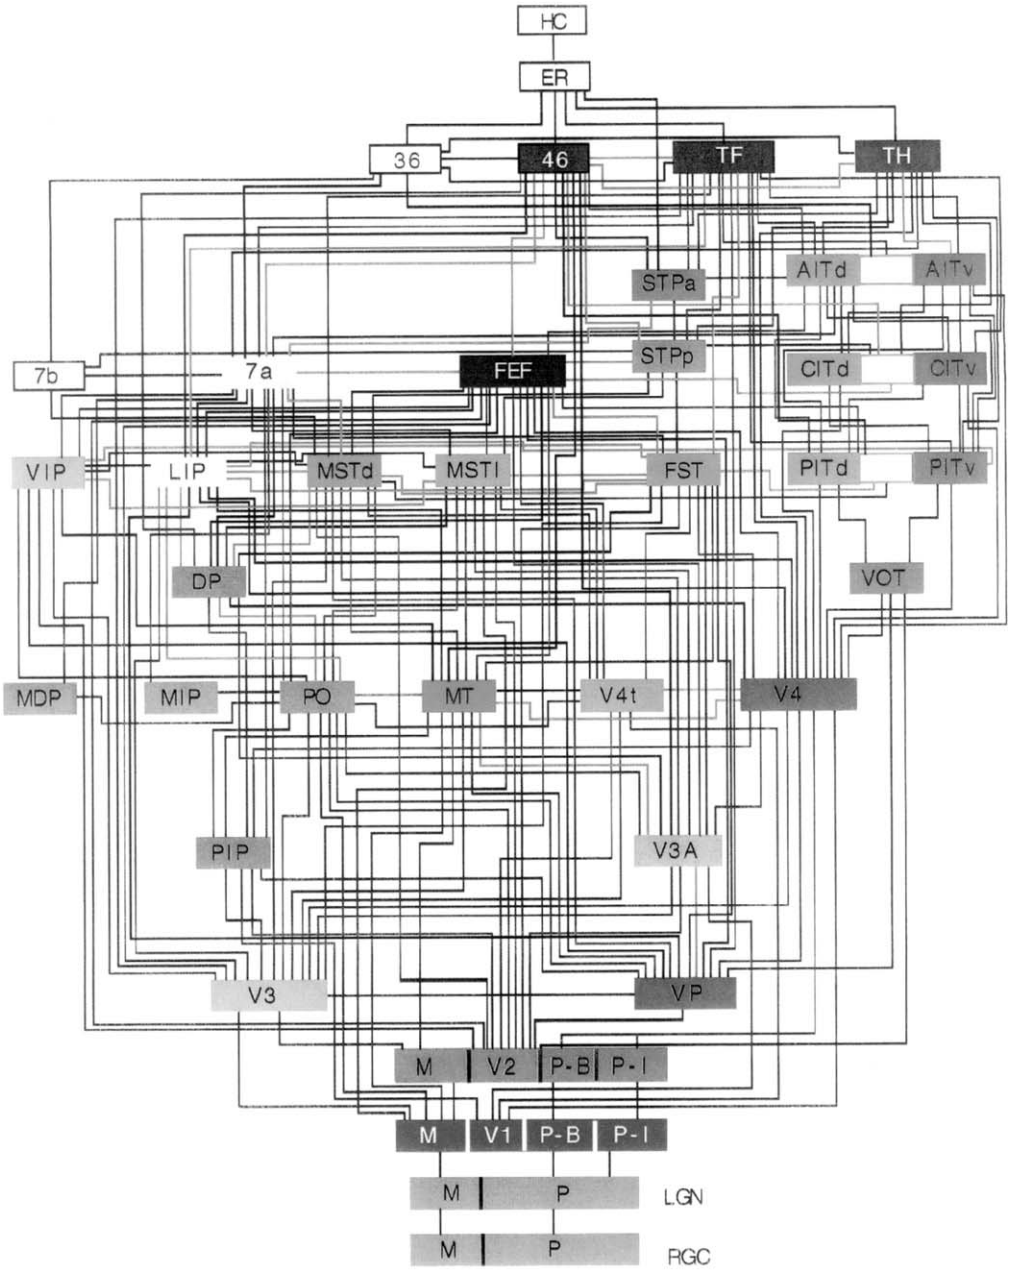

Figure 5 Connectivity and hierarchy of vision-related areas in the macaque cerebral cortex. Visual areas at a given hierarchical (vertical) position typically receive forward projections from areas below and backward projections from areas above. Most connections between areas are reciprocal (one forward, one backward). Areas at the same hierarchical level tend to have lateral connections. Forward, backward, and lateral types of connectivity are defined in Fig. 4. Visual areas V1, V2, V3, VP, V4, and V3A are completely or partially within the macaque occipital lobe. (From Felleman and Van Essen, 1991.)

processing within the retina and LGN are further modified in V1 to yield a new set of signals. These are then passed on to subsequent stages of processing via distinct sets of corticocortical output neurons. This same process is then reiterated at each successive processing stage.

Altogether, the pattern of afferent connections, the intrinsic circuitry, and the selective distribution of

multiple output signals at each stage are ultimately responsible for the unique functional properties of neurons in each cortical visual area. We turn now to a more detailed account of the topography of these areas and their functions.

III. FUNCTIONAL ORGANIZATION

Our understanding of the functional organization of the human brain has blossomed as never before thanks to the development of neuroimaging technologies that allow direct observation of the patterns of brain activity in human subjects actively engaged in sensory, motor, or cognitive tasks. In conjunction with more traditional electrophysiological, clinical, and psychophysical approaches, we now are developing a detailed picture of the topography of different visual areas and are beginning to outline their functional contributions. These new developments have taken place within the historical context of extensive earlier, and ongoing, studies of visual system organization in animals, especially nonhuman primates. Accordingly, the next section outlines this context before addressing more recent data.

A. Subdivisions of Visual Cortex

The organization of visual areas delineated in nonhuman primates provides a working hypothesis about the organization of visual cortex in humans. Figure 6 summarizes the topography of visual areas of several simian and prosimian species. The different visual areas identified in this figure have typically been defined by a convergence of several lines of evidence, including anatomical connectivity, neurophysiology, and lesion-related characteristics. Not all areas are equally well-defined, and some (possibly many) have significant internal heterogeneity. The degree to which these schemes apply to the human is not well-established. A few visual areas such as V1, V2, and MT are almost certainly homologous, whereas areas such as V3 (DM)–VP, V3A, and V4 are likely to have homologs but their identity is not yet established. For some areas, there may be no homolog. Accounts of visual area topography in humans have been heavily influenced by the macaque monkey scheme shown in Figs. 6F and 6G, though it is important to note that several alternative schemes for the macaque have been published. Due to such uncertainties, identifying homologies may not necessarily provide a definitive characterization of human visual areas. In the future, our understanding of the relationships among human and animal visual areas is likely to evolve as more data become available.

B. Visual Field Topography

Traditionally, visual field topography has been a primary source of information used to identify and map different visual areas in animals. Early work showed that a number of cortical visual areas contain a complete representation of the visual field, though each representation is split along the vertical meridian so that half of the field is represented in each hemisphere. Generally, then, the topographic arrangement of photoreceptors in the retina is maintained in the central connections. This results in an orderly arrangement of cells responsive to different locations in the field of view. In the cortex, neighboring positions in the visual field tend to be represented by groups of neurons that are adjacent but laterally displaced within the cortical gray matter. Neurons representing the vertical midline of the visual field are represented in both hemispheres and are functionally linked by interhemispheric, callosal connections. The end result is that the topography of the visual field is preserved in the visual cortex. [Because the visual field is directly imaged on the retina by the optics of the eye, visual field topography translates into retinal topography (retinotopy) but is upside down and backward due to the optical properties of the cornea and lens of the eye. Also, as will be described later, visual space is systematically distorted in the cortical representation.]

1. Charting Human Visual Areas by Retinotopy

Functional neuroimaging has been used to chart the retinotopic organization of visual areas in the human occipital lobe. Figures 7A–7C illustrate the results of such an experiment that used functional MRI. Subjects viewed a checkered hemifield that flickered at 8 Hz and slowly rotated about the center of gaze. During an fMRI scan series lasting approximately 4 min, the hemifield made five complete rotations, thereby sweeping through each angular position five times. Each location in the visual cortex went through five cycles of alternate activation and quiescence. However, cortical locations representing different angular positions in the visual field were stimulated at different times in the rotational cycle. Measurement of the temporal phase of the cyclic activation thereby

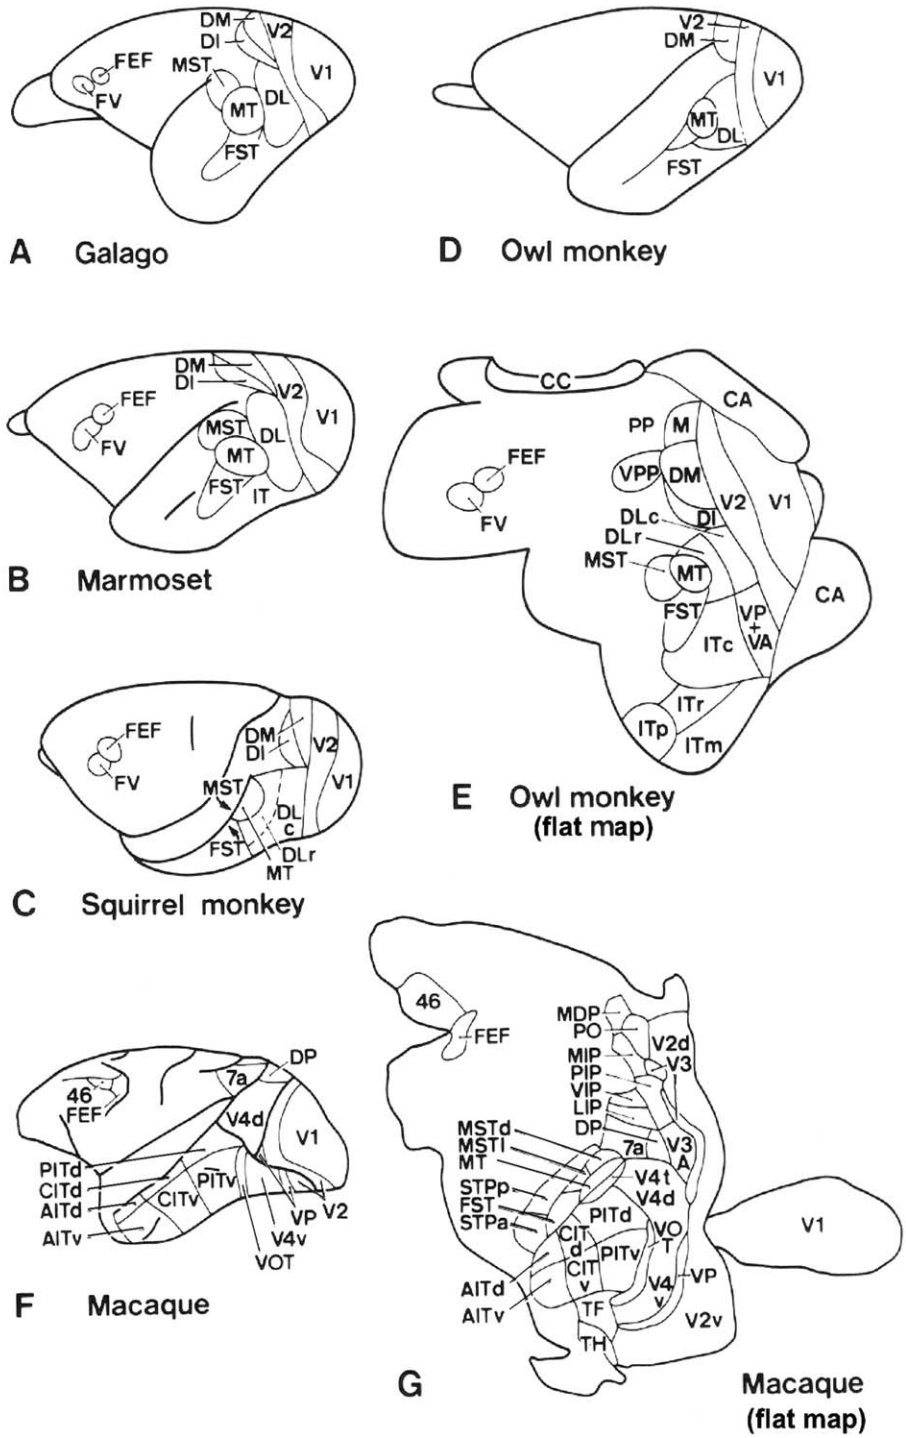

Figure 6 Summary of visual area topography for a variety of simian and prosimian species. Areas with the same name in different species are generally thought to be homologous. Other areas with apparent topographic similarity may or may not be functionally identical. Area DL is likely to be at least partially similar to macaque V4. DM may be homologous to macaque V3 and/or V3A. Note that this figure depicts left hemispheres unlike other figures in this article. (Adapted from Zilles and Clarke, 1997.)

identified the angular position represented at that cortical location. (See upper legend in Fig. 7.)

The polar angle representations depicted in Figs. 7A–7C are displayed on 3-dimensional models of each subject's occipital lobe and on corresponding maps of the unfolded and flattened cortical surface (Figs. 7A′–7C′). To facilitate the identification of cortical areas representing different visual field quadrants, the maps are pseudo-colored with a coarse scale to show brain regions that were maximally responsive when the midpoint of the checkered hemifield was within 45° of the horizontal meridian (white), the superior vertical meridian (dark gray), or the inferior vertical meridian (light gray). To produce these flat maps, the 3-dimensional cortical surface model was slit along the lateral occipital sulcus and was then unfolded using a computer algorithm. The resulting flat maps show bands of activation corresponding to alternating representations of quadrants at the horizontal and vertical meridia. On the medial wall of the hemisphere, these bands are oriented roughly parallel to the calcarine sulcus (cf. Figs. 7B and 7B′). Comparison across the three cases illustrated in Figs. 7A–7C provides an indication of the overall consistency across subjects as well as the degree of variation within each subject.

Visual field mapping can also be accomplished in a complementary manner using an expanding checkered annulus to provide information about the representation of visual field eccentricity (distance from the center of gaze). Figures 7D–7F illustrate the resulting patterns of activation.

The right side of Fig. 7 depicts the extraction of contours representing isoeccentricity and isopolar angle bands and their compilation into a final composite map showing the layout of visual space in the occipital lobe. Note that there are actually several reiterated representations of visual space, as indicated by the alternation of vertical and horizontal meridian representations (VM vs HM) labeled along the right margins of the meridia and composite maps.

From maps of the meridian representations, it is possible to estimate the locations of the borders between different visual areas. To do this, it is assumed that the borders are found at the representations of the horizontal and vertical meridia, as they are in subhuman primates. On the basis of this assumption, the layout of cortical visual areas in the human occipital cortex is illustrated on the large cortical flat map in the center of Fig. 8. To create this map, the 3-dimensional brain model (top) was slit (yellow dashed line) along the calcarine sulcus rather than along the lateral occipital surface. As a result, the vertical meridian representations (marked by black arrowheads) are oriented approximately vertically in Fig. 8 rather than horizontally as in Fig. 7.

Consistent with previous human studies, area V1 occupies the calcarine fissure but can extend onto the surface of the cuneus and lingual gyrus. The representation of the horizontal meridian contained within the calcarine fissure separates the upper and lower fields of V1 (split along the yellow dotted line in the large flat map of Fig. 8). It does not mark a border between different visual areas. As in the macaque, the borders between V1 and the two halves of V2 (V2d, V2v) are marked by vertical meridian representations for the inferior and superior halves of the visual field (VMi, VMs). The inferior vertical meridian representation is located along the upper lip of the calcarine sulcus, whereas the superior vertical meridian is located along the bottom lip. V2d and V2v together provide a second complete representation of the visual hemifield, but it is split in half with the inferior field represented dorsally and the superior field represented ventrally.

In the dorsal cortex of the cuneus, the border between V2d and V3 is marked by another representation of the horizontal meridian (HM). In complementary fashion, the border between V2v and VP is also delineated by a ventrally placed horizontal meridian representation (HM). Areas V3 and VP each contain a map of a quadrant of the visual field. Together these partial maps make up a third complete hemifield representation. In the macaque, these two quarter-field maps contain neurons with somewhat different visual response properties and anatomical connections. This suggests that they are functionally distinct, and, as a result, they have been given different names by some investigators. Others consider the formation of a complete hemifield representation as a more parsimonious way to summarize the data, even if some internal heterogeneity must be accepted. In this framework, the two quarter-field representations are termed V3d and V3v.

The anterior border of V3 is an inferior vertical meridian representation (VMi). In the macaque, this would form the border with area V3A, at least for visual field eccentricities within 10° of the fovea. Accordingly, this area has been termed V3A in humans. Some investigators have argued that parts or all of macaque V3 and V3A should be considered a single dorsomedial area (DM), such as that seen in owl monkeys (see Figs. 6D and 6E). V3A in macaque monkeys contains both an inferior and a superior quadrant representation. In one study, human V3A

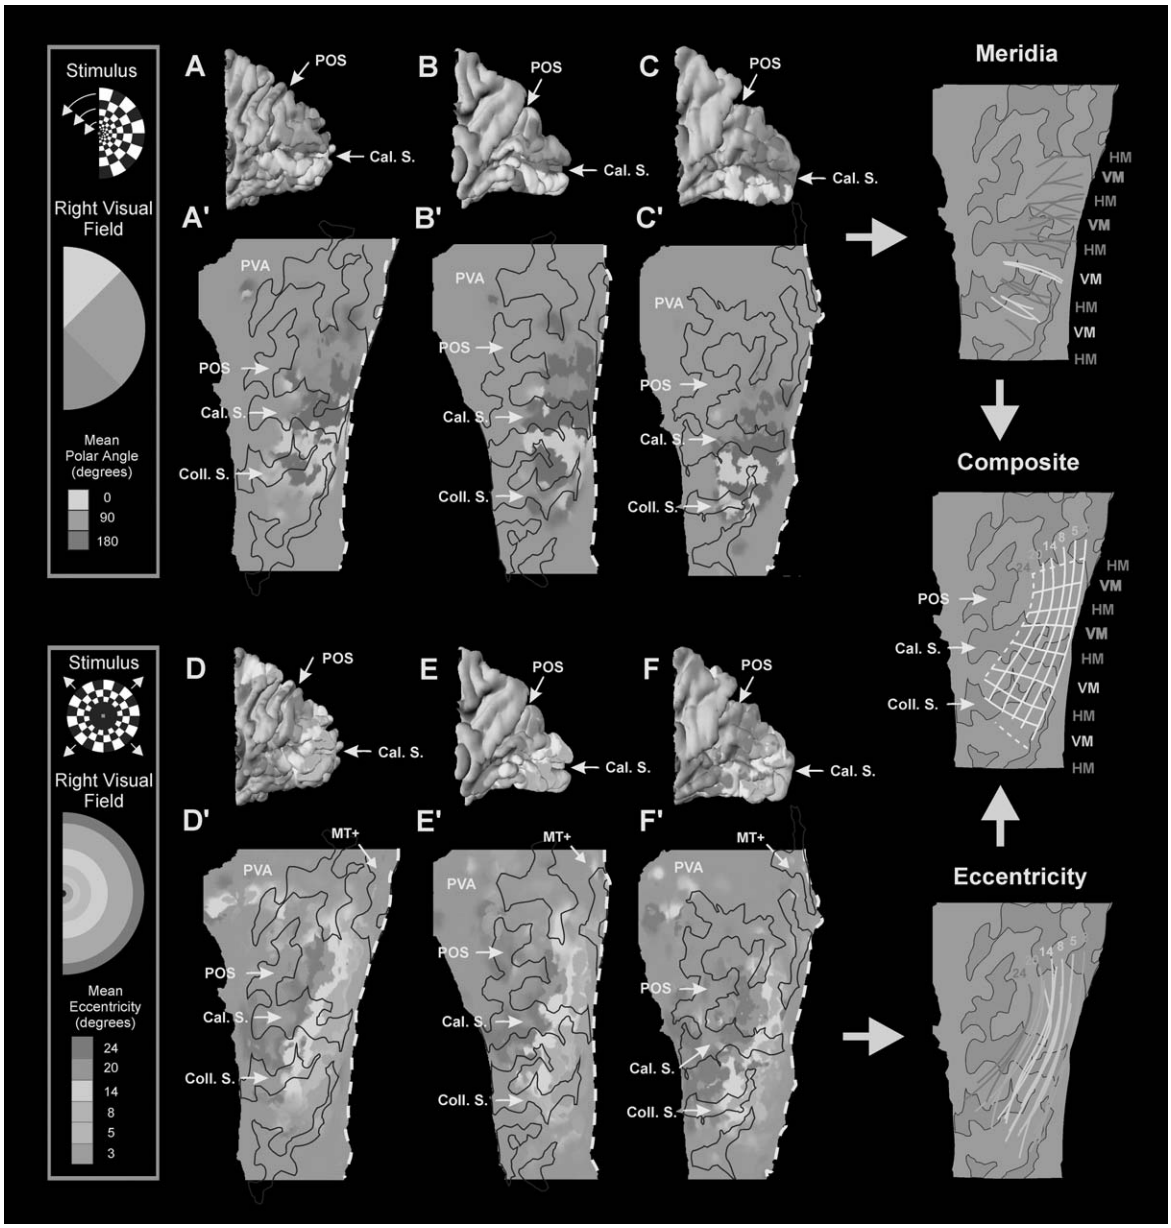

Figure 7 Visual field mapping in human occipital cortex. (A–C, A′–C′): The cortical representation of polar angle in the visual field in three subjects. The stimulus depicted at left was a counterphase flickering (8 Hz), checkered hemifield rotated slowly about the fixation point. For display purposes, the color code shows brain sites that were maximally activated when the center of the hemifield was within 45° of the horizontal meridian (white), the superior vertical meridian (dark gray), or the inferior vertical meridian (light gray). (A–C) 3-dimensional surface models of the occipital lobe plus adjacent parietal cortex, medial view, anterior to left. (A′–C′): Cortical flat maps showing the same data. White dashed lines at the edges of flat maps show margins of slit running from the occipital pole along the lateral occipital sulcus. Upper and lower halves of the dashed lines would be juxtaposed along the hidden lateral aspect of the 3-dimensional models shown in A–C. (D–F, D′–F′): Cortical representation of visual field eccentricity for the same three subjects. Stimulus: Flickering, checkered annulus that expanded slowly from 1.4° to 24°. Color code (gray to white) represents activation by six groups of three successive annuli. Inclusive eccentricities (degrees): 1.4–4.5, 2.3–7.6, 3.7–12.4, 6.3–20.8, 10.5–30, and 17.1–30. The coloring of the hemifield in the legend is only approximate; true mean eccentricities are shown at bottom. Right: Composite retinotopic grid (middle) combining data across subjects for vertical and horizontal meridian representations (right top) plus eccentricity (right bottom) displayed on a flat map of subject A. Lines in meridia and eccentricity maps pass through centers of corresponding meridian and isoeccentricity domains in A′–F′. Note multiple representations of meridia indicated at right of the composite and meridia maps. Abbreviations: HM, horizontal meridian representations; VM, vertical meridian representations (orange, lower field; yellow, upper field); Cal S, calcarine sulcus; Coll S, collateral sulcus; MT+, human middle temporal visual area and neighbors; POS, parieto-occipital sulcus; PVA, parietal visual areas. has also been shown to contain both upper and lower field representations, though in other respects this area may be functionally different from V3A in the macaque. Therefore, the designation V3A should be considered provisional for humans.

The anterolateral border of area VP (V3v) is formed by a second representation of the superior vertical meridian (VMs). In the macaque, this forms the border between area VP and the ventral half of V4. Correspondingly, the human area anterolateral to VP has also been designated as V4v. In both humans and macaques, V4v contains a representation of the superior field quadrant. In macaques, however, this is paired with an inferior quadrant representation located dorsally in the prelunate gyrus (cf Figs. 6F and 6G). This dorsal division, V4d, borders area V3A along an inferior vertical meridian representation. Human imaging studies have not identified a consistent focus dorsally that would correspond topographically and functionally to macaque V4d.

Anterior and lateral to V4v, near the occipitotemporal junction, lies an area, like V3A, that contains a complete representation of both the upper and lower visual fields. Topographically, this area is most equivalent to a region in the macaque known alternately as the posterior inferotemporal visual area (PIT, cf. Figs. 6F and 6G) or the temporal–occipital visual area (TEO). This area has been termed V8, but it also has been proposed as an alternative candidate for human V4 due to its selectivity for colored stimuli. The retinotopic organization of this area in both humans and monkeys is less distinct than in more posterior visual areas due to the presence of visually responsive neurons with large receptive fields (at least in the macaque).

Dorsal and lateral to V4v at the junction of the parietal, occipital, and temporal lobes is another visually responsive region that has a representation emphasizing the peripheral visual field ($>10^{\circ}$). It is strongly responsive to motion stimuli. This region is likely to be at least partly homologous to the MT–MST complex in macaque monkeys. In the macaque, visual area MT is adjacent to several small, motion-responsive areas (see Fig. 6G). The latter include V4t (a small transition area between V4 and MT), area MST (the medial superior temporal area), and area FST located in the fundus of the superior temporal sulcus. Due to the complexity of this region in the macaque, we prefer to call this region in humans the hMT+ complex pending further clarification.

The topography of human visual areas described previously is consistent with earlier anatomical studies of human post mortem material. The latter studies charted the pattern of interhemispheric callosal connections between visual areas in each hemisphere. In monkeys, axons interconnecting visual areas in the left and right hemispheres tend to terminate along the visual field representations of the vertical meridian. Accordingly, they provide an independent source of information about the boundaries of some visual areas, such as V1–V2, VP–V4, and V3–V3A. This is most convincing for the strongly retinotopic areas of visual cortex but becomes increasingly less precise for areas in which the retinotopy breaks down due to the

Figure 8 Topography and function of identified visual areas in human occipital lobe and neighboring cortex. Top: Anatomical features and topography of visual areas as displayed on a computer graphics model of the Talairach brain. Whole brain at right shows the plane used to create the separate occipital lobe model. Dashed yellow lines on the model and flat map show a cut along the depths of the calcarine sulcus to permit low-distortion unfolding of the cortical surface. A yellow asterisk marks the tip of the occipital pole. Dark gray outlines on all flat maps represent cortex buried within sulci of the 3-dimensional brain. Scale bar at the far left applies only to the 3-dimensional models. Center: Enlarged flat map of occipital cortex showing the topography of visual areas. Borders between visual areas drawn with solid black lines are relatively well-defined though the exact position of borders will vary from individual to individual. Black arrowheads indicate area borders that correspond with representations of visual field meridia: superior vertical meridian (VMs), inferior vertical meridian (VMi), and horizontal meridian (HM). Visual areas whose borders are shown as dashed lines or shading indicate greater uncertainty at the time of this writing. Center left: Flat maps showing sites (colored dots) reported in the neuroimaging literature to be selectively responsive to some aspect of visual motion (A) or color (C). Each dot is positioned at the point on the surface model that is closest to the Talairach coordinates reported in the original studies. Red-orange dots and swath in the motion map represent the approximate location of hMT+. Purple dots show other motion-responsive sites. Light-green dots and swath represent the location of the kinetic occipital area, KO. Light-blue swath in the color map represents the approximate location of area V8. Center right: Flat maps of form (B) and face or space (D) selective sites. Yellow swath in the form map represents the approximate location of the LO (lateral occipital) visual complex. Dark-green swath in the faces map represents the approximate location of the fusiform face area (FFA), Bottom: Flat maps showing Talairach coordinate isocontours (values in millimeters). Approximate Talairach coordinates of dots in the functional maps can be determined by tracing dots onto a transparent outline of the map and placing it successively over the X, Y, and Z isocontour maps. (See text for a note about accuracy.) Abbreviations: CoS, collateral sulcus; Fusg, fusiform gyrus; IPS, intraparietal sulcus; KO, kinetic occipital visual area; LO, lateral occipital visual complex; LOS, lateral occipital sulcus; MTg, middle temporal gyrus; OTS, occipitotemporal sulcus; POS, parietal–occipital sulcus; STS, superior temporal sulcus; TOS, transverse occipital sulcus. (See color insert in Volume 1).

increasing size of single-cell receptive fields. In these latter areas, the callosal connections become less focused along the vertical meridian and are less useful for marking borders between visual areas. Nevertheless, the results from the human anatomical studies are in reasonably good agreement with the neuroimaging evidence for strongly retinotopic visual areas along the medial and ventromedial wall of the occipital lobe. For visual areas extending onto the dorsolateral and ventrolateral surfaces, the agreement is less certain, in part due to variability in both the imaging and anatomical data within these regions.

Several other visually responsive regions in occipital or nearby parietal and temporal cortex have been proposed as distinct visual areas. Some of these, such as the kinetic occipital area (KO), the lateral occipital area (LO), and the fusiform face area (FFA), are indicated in Fig. 8. Identification of the borders of these areas is more difficult than for the strongly retinotopic areas, and so they are intentionally shown as indistinct in Fig. 8. Other proposed visual areas, such as the parieto-occipital visual area PO–V6 and area V7, are not shown in Fig. 8 because their existence and characteristics are not yet firmly established.

2. Quantitative Retinotopy

Besides the qualitative aspects of visual field topography used to define visual area boundaries, neuroimaging has produced new data concerning quantitative features of human retinotopy. Although the qualitative topography of the visual field is preserved in cortical retinotopic maps, the metric of visual space is warped. That is, the representation of the fovea is greatly expanded relative to the representation of the periphery. (In macaques the warping is also known to be different for different visual areas.) Figure 9A shows the representation of visual field eccentricity in striate cortex as described by the researchers Horton and Hoyt in 1991. Their figure was based on a consideration of the extent of blindness in the visual field produced by partial lesions of calcarine occipital cortex. The foveal representation is located posteriorly at the occipital pole, with more eccentric visual field positions (farther from the center of gaze) located successively more anteriorly along the calcarine fissure. The representation of eccentricities close to the center of gaze is expanded relative to more peripheral eccentricities. The representation of the central 10° covers nearly half of the calcarine cortex, with the remainder of the field to beyond 40° covering the other half of cortex. At the time this article was published, little was known of the retinotopic organization of extrastriate cortex in humans. Figures 9B–9D illustrate more recent data from several neuroimaging experiments. As can be seen in Fig. 9C (and Figs. 7D–7F), the representation of visual field eccentricity within V1 of the calcarine sulcus extends both dorsally and ventrally across the entire medial surface of the occipital lobe and onto the dorsolateral and ventral surfaces. As described earlier, this region of cortex contains several different extrastriate visual areas. The results shown in Fig. 9C suggest that the representation of visual field eccentricity in these areas is topographically concordant with the representation in V1. But different visual areas vary in total size, so that the extent of cortex representing 1° of visual angle—the cortical magnification factor—will vary from area to area. Cortical mapping functions are illustrated in Figs. 9B and 9D. One study compared

Figure 9 Quantitative retinotopic organization of human visual cortex. (A) Right: Medial view of the occipital lobe with lips of the calcarine sulcus opened to show retinotopy of V1 as estimated from visual field defects in patients with occipital lobe lesions. Numbers along the lip of the calcarine sulcus indicate degrees of visual angle from the center of gaze, as indicated in the adjacent visual field schematic (A, left). (Adapted from Horton and Hoyt, 1991.) (B) Human cortical mapping function according to Engel *et al.*, 1997, *Cereb. Cortex* **7,** 181–192. Open symbols are measurements from two observers. The solid curve shows the best fitting exponential (least-squares) to the four hemispheres measured in the study. The dotted line shows an estimate derived from scotomata in human stroke patients and electrophysiological data from nonhuman primates. The x's are fMRI measurements by another researcher (see D). (C) Retinotopy of striate and extrastriate visual cortex as determined by functional MRI displayed on 3-dimensional models of the surface that would correspond to cortical layer 4 (i.e., with supragranular layers removed). The surface model has been smoothed and slightly unfolded to provide a better view of the topography within the calcarine sulcus. White lines represent the loci of constant visual field eccentricity (3, 5, 8, 14, 20, and 24+ degrees of eccentricity). Dashed black lines show representations of horizontal and vertical meridia. Dashed line within the fundus of the calcarine sulcus is the horizontal meridian representation running through the middle of V1. (Based on data from DeYoe *et al.*, 1996, *PNAS* **93,** 2382–2386.) (D) Cortical mapping functions (scale on left axis) and magnification functions (scale on right axis) for upper field striate cortex and three extrastriate visual areas in the human. Also shown are the mapping functions for V1 in the macaque monkey and owl monkey (MM* and OM*, respectively, in the first panel). The cortical mapping functions (heavy lines) show the relationship between distance along the cortex and the representation of visual field eccentricity (Note the difference in graph axis labeling compared to B.) Cortical magnification is the extent of cortex representing 1° visual angle. (Adapted from Sereno *et al.*, 1995, *Science* **268,** 889–893.)

data across visual areas and, for V1, across species. They suggested that there may be an even greater foveal expansion in humans than in monkeys, but this has been challenged. There is some disagreement among studies concerning the degree of expansion of the most central 2–3° in humans. Researchers addressed this issue by comparing their own data, with those of others and with a best fitting exponential function (solid line in Fig. 9B). These studies confirm the contention that the human foveal representation in V1 is larger than had been suggested by earlier studies, and, together, they provide the best quantitative description of visual space mapping in the human visual cortex so far available.

3. Summary of Topography

Overall, the topography of occipital visual areas in the human brain is generally consistent with the topography in macaque monkeys, but with some potential departures related to the expansion of the foveal representation and uncertainties concerning areas such as V4 and posterior–lateral occipital cortex. Compared to the macaque monkey, the placement of visual areas relative to anatomical structures in the two species is also different. Human visual areas in lateral cortex appear to be displaced posteriorly toward the occipital pole or onto the medial occipital surface. For example, the hMT+ complex is located posterior to the superior temporal sulcus (STS) in humans but is buried deep within the STS in macaques. Most of the human retinotopic visual areas (V1, V2, V3–VP, V4, V3A) are located entirely or partially on the medial and ventral aspects of the occipital lobe. In macaques, they are located partly or completely on the lateral surface of the brain. This displacement of human visual areas places the foveal representation of the visual field at the occipital pole. In macaques it is situated laterally near the ends of the lunate and inferior occipital sulci. Although the positioning of visual areas relative to anatomical features in humans and macaques is distinctly different, the positioning of visual areas relative to each other may be more consistent across species. This suggests that topographic maps of the visual cortex that are abstracted from gross anatomy (e.g., as seen in cortical flat maps) may provide a more functionally consistent view of cortical organization.

Maps of visual field topography provide one line of evidence for defining and differentiating visual areas. Such maps also provide a good organizational framework for understanding the contributions of different areas to specific visual functions such as color or movement perception. The following section uses this approach to review data concerning the functional specialization of the human visual cortex.

C. Analysis of Visual Information

1. A Conceptual Framework

To discuss the functional specialization of the human occipital lobe, it is helpful to have a conceptual framework for organizing and interpreting the relevant experimental data. One fruitful approach in this respect is to outline the computational task of vision. In other words, "What must the visual cortex accomplish?" A complete and detailed answer to this question is still lacking. Nevertheless, a broad outline such as that illustrated in Fig. 10 can be of use.

Visual information available to the brain arises from the patterns of light on the retina of each eye. These patterns vary spatially, temporally, and in wavelength composition as objects in the visual scene change and as the observer moves and explores. In a sense, the brain knows nothing about the immediate state of the external world but, rather, must infer its attributes from the incoming retinal information (potentially with help from prior experience). Our resulting visual perception is amazingly rich and includes the appreciation of object form and rigidity as well as surface properties such as color, lightness, texture, and specular reflectance. We effortlessly discern the spatial arrangement of things and surfaces as well as their movements relative to each other and relative to ourselves. Finally, we can distinguish lighting properties such as shadows and the direction of ambient illumination. On the whole, the brain does a surprisingly good job of providing a veridical impression of the attributes of the world around us, despite occasional exceptions such as those that occur in visual illusions.

The true complexity of the visual computations becomes more evident when considering how retinal image information is used to infer specific object attributes. Initially, early stages of visual processing must extract and isolate different types of information that will be useful for inferring each of the various attributes. Work in computational vision and psychophysics has helped to identify such visual cues and to outline how they contribute to the computation of specific attributes such as distance and form. For instance, each eye has a slightly different direction of

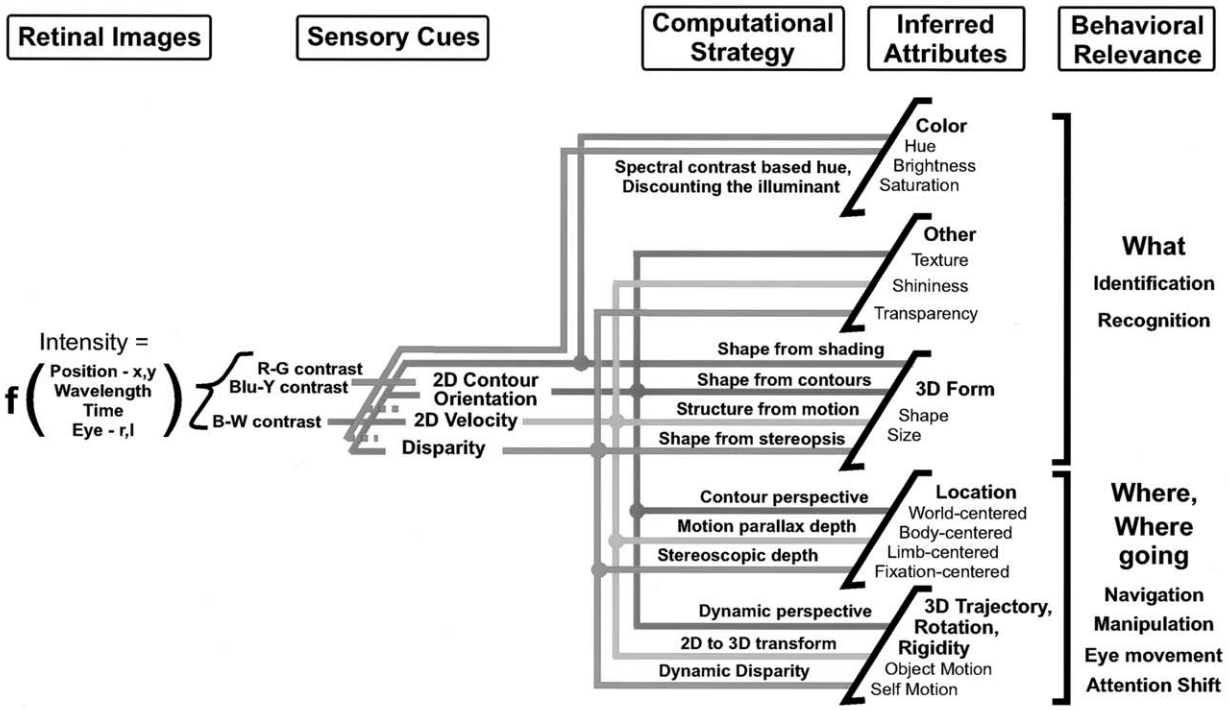

Figure 10 Conceptual framework of the information processing task of vision. Information about the characteristics of the visual scene is provided by the patterns of light imaged on the retinae of the two eyes over time. These patterns can be described physically as functions of retinal position, wavelength composition, time, and eye (left or right). From this information, the brain must infer the attributes of objects and surfaces within the visual scene. This may be accomplished through a variety of computational strategies, some of which are noted in the figure. Inferences based on any particular computational strategy depend strongly on specific "sensory cues," meaning a particular subset of the information available in the retinal images. For example, inferences about hue depend heavily on chromatic contrasts but little on motion-related information. Sensory cues noted in the diagram provide only a few rudimentary examples that are readily identified with the visual response properties of neurons at early and intermediate stages of visual processing. Red dotted lines for chromatic contrast cues indicate potential contributions of chromatic information to form and motion (see text section on color). The diagram expresses the idea that each low-level sensory cue may contribute to inferences about more than one world attribute. Moreover, each world attribute often may be inferred from more than one cue. This manifold relationship among sensory cues and inferred attributes provides a useful rationale for the multiplicity of visual areas and concurrent processing pathways within the visual cortex. In the brain, a particular path from a sensory cue to an inferred attribute may consist of many synaptic levels containing further divergent or convergent branching as well as the computation of intermediate cues. The diagram also expresses the idea that there is not usually a one-to-one relationship between a low-level sensory cue and a single inferred attribute. Missing from this outline are the effects of previous experience, expectation, and attention on the attributes inferred at any given moment. (Adapted from DeYoe and Van Essen, 1988, and Van Essen and DeYoe, 1994.)

gaze with respect to a viewed object. As a result, the images of that object in the two eyes are also slightly different. The resulting disparity in the retinal images provides a cue that can lead to a vivid impression of distance and 3-dimensional structure. Similarly, computer-generated displays of moving dots representing the vertices of an invisible, rotating cube can yield a strong impression of its 3-dimensional form. In many viewing situations, however, both types of cues—retinal disparity and motion parallax—act in concert to jointly specify an object's form. In general, different visual cues often redundantly specify a particular object attribute, thereby helping to eliminate any ambiguity in the interpretation of the retinal image data. It is also true that single visual cues can contribute to the computation of more than one attribute. Motion cues can specify both the 3-dimensional form of an object as well as the trajectory of the object through space.

As can be seen from the previous examples, the relationships among visual cues and inferred object attributes can be complex. Fig. 10 outlines some of the relationships among different visual cues and a variety of world attributes. Several important concepts are

illustrated by this figure. First, it is clear that the goal of the visual system is not to act like a camera and simply preserve the patterns of light falling on the retinae. Rather, the brain must actively convert the retinal information into neural representations of the attributes of objects and surfaces in the visual scene. This is further complicated by the need to eliminate the effects of irrelevant changes in the retinal images caused by factors such as shifts of viewing position or changes in ambient illumination. Second, the notion that the retinal images yield a number of low-level visual cues that, in turn, ultimately contribute to the inference of object attributes suggests an analysis that, overall, is inherently hierarchical in nature. At the same time, the fact that different cues can be derived from the images and can contribute simultaneously to different attributes suggests that concurrent processing will also occur. Third, the relationships between visual cues and inferred attributes are manifold. That is, multiple cues can specify a single attribute, and, conversely, a single cue can specify multiple attributes. Thus, a particular visual cue may be represented in different ways by several concurrent neural systems related to different attributes. Fourth, this leads to the more general notion that functionally specialized visual areas and networks will not be organized as isolated centers devoted exclusively to the processing of a single visual cue. This also means that we should not usually expect to find isolated processing "conduits" extending from the retina to high levels of the visual system that are dedicated along their entire length to processing a single visual cue–attribute combination. This does not preclude the possibility that some processing pathways may, at points, be confined to restricted anatomical loci, thereby allowing focal lesions to cause specific perceptual loss. Finally, it may be helpful to conceive of the visual computations as occurring in stages, even though it may be difficult to precisely identify or define such stages in a real neural network that has extensive forward and backward interconnections. At each successive stage, different types of information made explicit in the previous stage are mixed and combined in different ways in order to achieve the next level of representation. Particular attributes may become explicit at different stages. For example, the orientation of individual texture elements may be explicitly represented in V1, whereas the relatively invariant colors of a Mondrian painting may not be explicitly represented until a later stage.

With these concepts in mind, we turn now to a consideration of specific functional systems within the human occipital lobe.

2. Functional Subsystems

a. A Map of Functional Specialization[3] The middle section of Fig. 8 summarizes data from 56 neuroimaging studies concerning the functional specialization of human visual cortex. Each colored dot on the small cortical flat maps (A–C) represents a focus of activation identified in one or more of these studies. The location of each dot represents the closest point on the cortical surface model of the Talairach brain (Fig. 1) that matched the published Talairach coordinates of the site.[4]

[3]To provide a systematic frame of reference for describing the locations of functionally distinct regions of the occipital lobe, we will use the standardized coordinate system of Talairach and Tournoux as illustrated in Fig. 1. In this stereotaxic system, left–right coordinates (x axis) are measured in millimeters relative to the midline (here positive values = right). Anterior-posterior (y axis) coordinates are expressed relative to the anterior commissure (here positive numbers = anterior to AC). Superior–inferior (z) coordinates are measured relative to an axis passing through the anterior and posterior commissures (here positive values = superior). A brain normalized to this system is spatially transformed so as to match the overall size and orientation of the standard brain depicted in the Talairach and Tournoux atlas. Generally, this transformation tends to reduce the variability of coordinates for major anatomical and functional features. However, it may or may not improve the correspondence of local features, especially for structures located far from the coordinate reference points at the anterior and posterior commissures. This can be the case for occipital lobe structures and can limit the ability to make fine distinctions among functional or anatomical features in different subjects. Other, more reliable coordinate systems have been developed and are likely to become popular, but, at this juncture, the Talairach system is the most widely used.

[4]Although the creation of a composite map based on Talairach coordinates is advantageous for summarizing the results of a large number of studies, it should be stressed that there are several sources of potential inaccuracy in the resulting map. First, the process of normalizing a subjects' brain to the Talairach standardized coordinate system can be imprecise. Moreover, the published coordinates of cortical activation sites typically represent the mean centers of mass or peak responses across multiple subjects. They do not provide a measure of the extent of the activated area. Second, markers (dots) positioned on the brain model will be located at the coordinate on the surface that is closest to the actual 3-dimensional coordinate in the brain volume. If the original coordinates were not located within the cortical gray matter, the displayed location will only be an approximation. Finally, there are inevitable, though modest, distortions associated with flattening the folded cortical surface onto a plane. Due to these various inaccuracies, issues concerning differences in function of neighboring visual areas can rarely be settled on the basis of Talairach coordinates or summary maps derived from such coordinates. Nevertheless, a summary map does provide a useful starting point for discussing the functional differences that are obviously discernble in the data despite mapping inaccuracies.

It is important to recognize that this summary map represents a necessary simplification of complex neuroimaging data. To say that an area within the human brain is functionally specialized typically means that it responds differentially to two or more experimental test conditions that, ideally, are perfectly matched in all factors other than the factor of interest. We will use the term "selective" to refer to activation sites that respond in this differential manner. Selectivity at a site does not imply that it responds exclusively to changes in one particular visual cue or attribute. Rather, it means that the response is modulated most strongly by one cue, attribute, or task factor relative to the others tested. In contrast, an area that responds nonselectively will have roughly equivalent responses to different test conditions.

b. Early Stages of Cortical Visual Processing The earliest stages of visual processing involve the extraction of visual cues and rudimentary visual attributes from the incoming retinal information. Virtually all visual processing tasks activate primary visual cortex, V1, and neighboring visual areas on the medial wall of the occipital lobe. This is consistent with the known connectivity of the visual pathways in monkeys, whereby the incoming visual information is relayed from the retina through the lateral geniculate nucleus to V1 and then to V2 and other extrastriate visual areas (Fig. 5). (The role of alternate subcortical routes to the cortex has not been explored extensively in human neuroimaging studies.) At hierarchical levels beyond V1 and V2, part of the visual information goes to areas V3 and VP[5]. Although V3 and VP in the macaque are closely connected with V1 and V2, it is not clear whether they are as ubiquitously involved in visual processing as V1 and V2. Some single-unit studies of color and motion processing in monkeys suggest that, on the whole, these two areas contain cells with somewhat different visual response properties and presumably different functional roles. This may be in accord with occasional reports from neuroimaging studies of selective activation in the cuneus and lingual gyrus close to the presumed human counterparts of V3 and VP.

Early stages of cortical processing tend to be activated by virtually all visual tasks. If two tasks are similar in many respects, then subtraction of functional brain images from the two conditions (e.g., experimental vs control) can effectively "cancel out" activity at early processing stages (e.g., V1–V2), while highly specific and differential activation of later cortical visual areas remains. In the following discussion, the common activation of early cortical stages will not always be mentioned, though it should be assumed to be present unless otherwise indicated. Also, it is important to note that functional heterogeneities such as cytochrome oxidase puffs and stripes within V1 and V2 are sufficiently small that the different compartments tend to be blurred together by the relatively large size of the imaging samples (voxels) used in most human neuroimaging studies. As a result, differential patterns of activity in the microcircuitry of early visual areas may appear equivalent in fMRI or PET.

c. Motion Flat map A of Fig. 8 summarizes the results of nearly two dozen neuroimaging studies that have been concerned with the processing of visual motion information. Many of these studies involved comparison of a coherently moving field of dots or small squares with a similar but motionless field. The subject typically viewed the stimulus without performing a visual discrimination task (passive view), though in some experiments a judgment about the stimulus was required. Most of these studies found activation in visual areas V1 and V2 concordant with the presumed flow of visual information through these early processing stages to higher extrastriate areas. In addition, many of these studies reported activation within a separate area of lateral occipital cortex near the junction of the temporal and parietal lobes (red dots in Fig. 8A). The mean Talairach coordinates computed from 15 of these studies are as follows: right hemisphere, lateral 42, posterior 69, dorsal 2; left hemisphere, lateral 42, posterior 69, dorsal 3. Across the various studies, these coordinates varied by 1 cm or more in all directions. The area encompassing the average coordinates as well as a large cluster of individual sites has been shaded in red in Fig. 8. The relationship between this motion-responsive region and the local gyral–sulcal pattern in individual subjects can vary to some extent. This not only reflects true variation in the activation foci across studies but also

[5]The notion of a hierarchy is used here to facilitate discussion of a complex system that processes the visual input concurrently through multiple sequences of neuronal connections. In such a system, it may be difficult to delineate specific functional stages and pathways due to complex forward, backward, and lateral interconnections. Nevertheless, there is an overall sense in which the retinal representation is successively transformed through connections that are farther and farther removed from the input. In such a case, it is useful to talk about "higher" or "later" stages of processing, even though it may not be possible to assign a precise rank to every connection or cortical area.

reflects the irregularity of each individual's anatomy in this region.

Converging evidence suggests that at least part of the lateral occipital motion focus is homologous to the middle temporal visual area (MT) in monkeys (also referred to as V5 by some investigators). Figure 11A illustrates how human fMRI responses in this area are concordant with the known motion-selective properties of single neurons in monkey MT. These effects include selective activation by moving stimuli, high contrast sensitivity, and reduced responses to equiluminant colored gratings. Anatomical and histological features in this region are also consistent with characteristics of macaque area MT. These features include dense myelination, high cytochrome oxidase activity, and staining by the antibody CAT-301. It remains to be determined whether these anatomical features are exactly coextensive with the activation sites observed in the imaging studies. In fact, the lateral occipital area activated in these studies may also include motion-selective areas other than MT. In the macaque monkey, area MT projects to neighboring area MST (of which there are three subdivisions: MSTd, MSTl, MSTf) and to FST (fundus of the superior temporal sulcus). In monkeys, these areas juxtapose MT and contain cells that are also motion-responsive. It is quite possible, then, that the area identified previously as human MT may include these areas as well. Here, we will use the term hMT+ to indicate the complex of MT and its motion-responsive neighbors.

Human hMT+ responds selectively to moving vs stationary stimuli, but also responds to other aspects of motion stimuli in ways that appear to parallel reported single-unit response properties or perceptual effects. Comparisons between globally coherent (dots move together) vs incoherent (dots move independently) motion produce a significant change in activation within hMT+, yet can result in little or no change in activation in V1–V2. This is consistent with the understanding that, on the whole, neurons in monkey V1–V2 do not readily distinguish global coherent motion from incoherent motion but that later stages of processing, such as area MT, do. hMT+ responses are also directly related to the relative coherence of a moving random dot pattern, concordant with the corresponding motion percept. Neuroimaging tests of motion opponency as well as tests contrasting first- and second-order motion (contrast- or flicker-modulated sinusoids) also differentiate hMT+ from V1–V2, in agreement with single-unit studies. As shown in Fig. 11B, motion stimuli that evoke a strong perceptual aftereffect (waterfall illusion) produce fMRI signals in human hMT+ that persist after the inducing stimulus is turned off, thereby tracking the time course of the illusory percept. Altogether, these observations provide strong evidence that motion perception may arise in hMT+ or is likely to be derived from hMT+ signals. This inference is further supported by human clinical studies in which akinetopsia (the failure to perceive motion) or more subtle motion deficits tend to be associated with lesions of the occipital lobe in the vicinity of hMT+. Together, these findings further indicate that there is a good case for homology between human and monkey MT.

In addition to hMT+, a variety of other cortical sites are activated by motion stimuli or tasks. These sites are shown by the purple and light-green dots on flat map A of Fig. 8. The complex and widespread distribution of these foci reflects the fact that motion cues contribute to a variety of perceptual phenomena, such as self-motion, "biological motion," figure–ground segmentation, structure from motion, and the control of eye movements. This complexity is consistent with the concept outlined in Fig. 10 that there are multiple motion processing pathways related to the manifold relationships between low-level motion cues and various inferred attributes of the visual scene. Attempts to identify homologies and functions for these various sites are outlined next.

Figure 11 Comparison of visual response properties of human hMT+ and V1. (A) Left: Selective fMRI activation of hMT+ by moving vs static stimuli consisting of random dots, which in the moving condition (MOV) expanded or contracted radially but in the static condition (STAT) were motionless. In the intervening periods, no dots were presented. Graphs show the time course of the fMRI signal in V1 (top) and hMT+ (bottom). (A) Right: V1 discriminates different contrast levels of grating stimulus but hMT+ does not. Graphs show the time course of fMRI signal averaged over voxels in V1 or hMT+. Human MT+ signal tends to be nosier due to smaller number of voxels contributing to the average. (From Tootell *et al.*, 1995, *J. Neurosci.* **15,** 3215–3230.) (B) fMRI-based estimate of the time course of motion aftereffect (MAE) and its relation to the psychophysical estimate of the perceptual MAE. MAE was induced by having the subject view a grating consisting of concentric rings drifting continuously outward or inward for 40 sec. This was followed by a period in which the rings were stationary. The graph at right of the dotted line shows the time course of residual fMRI signal in the presence of the stationary grating. Squares indicate the strength of the perceived motion aftereffect measured with a nulling technique. Note the correspondence of the fMRI time course and psychophysical effects. (From Tootell *et al.*, 1995, *Nature* **375,** 139–141.)

Coherent motion stimuli have been shown to activate sites in occipital cortex other than V1–V2 and hMT+. One possible function of at least some of these sites is the processing of optical flow information. Flow fields are generated when the viewer moves through space and they provide a key source of visual information on self-motion. (The flow can be noticed by staring fixedly out a car window as it speeds by a building or fence.) Flow fields often contain large areas of coherent motion with salient expanding or contracting components, depending on the viewer's direction of gaze relative to the direction of movement. Cells in monkey MST, but less so MT, are selectively responsive to these components and to coherent rotational motion as well. Because of this, complex flow patterns might be expected to identify the human homolog of macaque MST. In humans, stimuli that evoke a strong perception of illusory rotational motion activate foci that are partially or completely distinct from sites activated by linear coherent motion. On the basis of such data, it has been proposed that MST (also known as V5A) might be located very close to area MT, as it is in the monkey (perhaps included in the zone designated here as hMT+). A different study, employing shifts of visual attention, identified a motion-related focus in the inferior parietal lobule that might be an alternate site for human MST. In other tests, this region was activated by visually guided, smooth-pursuit tasks, concordant with the properties of neurons in macaque MST but not MT. However, such a correlation is not conclusive because other sites in ventral cortex have also been found to be responsive during smooth-pursuit tasks. At this time, it is unclear which human site, if any, should be considered strictly homologous to monkey MST.

Several studies have identified motion-selective sites that were thought to be potentially homologous to macaque visual area V3. In monkeys, cells in V3 respond better to moving than to stationary stimuli and respond better to second-order motion stimuli than to first-order. This appears to be the case for the human sites as well. However, some of these studies concluded that the activated sites were part of V3 solely on the basis of Talairach coordinates, leaving open the possibility that they were really located in adjacent visual areas such as V3A. This is important because evidence from experiments combining retinotopy with motion tests suggests that, in humans, the area corresponding retinotopically to macaque V3A may be more motion-selective than retinotopically defined human V3. The human V3A candidate contains representations of both upper and lower visual fields and possibly a separate foveal representation, consistent with V3A in macaques. Contrary to this, single-cell recordings in monkeys suggest that V3, rather than V3A, responds more selectively to motion stimuli. Whether this represents a true functional difference between monkeys and humans is unclear. All in all, differences in technique between monkey and human experiments combined with the uncertainty of Talairach coordinates make a definitive statement about differences in motion processing between human V3 and V3A premature, though clearly one (or both) of these areas is involved in motion processing.

Another potentially important function of motion processing systems is in visual tracking. Human hMT+, plus some frontal and parietal sites, are activated by moving targets that are being tracked either overtly by eye movements or covertly by shifts of attention. The human hMT+ site appears to be equivalently activated by both passively viewed target motion and active attentional tracking, whereas later processing stages are markedly more responsive during active tracking. This is consistent with the notion that motion analyses in hMT+ provide target-related signals used at later stages to control eye movements and/or shifts of attention. Indeed, visual areas in monkey parietal cortex including VIP and LIP are involved in integrating information about visual motion and eye movements, and these areas receive projections from MT–MST.

Another intriguing use of motion cues is in the perception of "biological motion," that is, the movement of people and animals. Small lights attached to a subject's joints can allow a viewer in an otherwise dark room to identify the nature of the movement (walking, dancing, jumping) and even the gender of the subject. In such instances, motion information is being used to identify and recognize the subject and his or her actions in addition to conveying information about trajectory. A few neuroimaging studies have investigated this topic and have shown that a region anterior to hMT+ in the superior temporal sulcus (STS) responds selectively to biological motion sequences of the whole body. Although located well into the temporal lobe, such a site may represent an important branch of the occipital motion processing systems, perhaps feeding into object recognition systems of the temporal lobe rather than into dorsal motion pathways concerned with trajectory or optic flow. Biological motion involving grasping movements of the hand (signaled by lights attached to the hand) activates a region of the intraparietal sulcus as well as the STS site activated by whole-body movements. Single-unit studies have

shown that specific subregions of the intraparietal sulcus in macaque monkeys contain neurons that appear to represent reaching movements in body-centered coordinates. The existence of multiple sites responsive to biological motion suggests that this type of motion information may be analyzed in different ways depending on the coordinate frame or class of motion involved.

Though retinal image motion often indicates the movement of objects (or self), motion cues can also be used to identify the boundaries and 3-dimensional shape of objects rather than their trajectories. As will be discussed later, the ventral occipitotemporal cortex appears to be heavily involved in the analysis and identification of objects. Brain regions that utilize motion for such purposes might be expected to include ventral cortical areas rather than, or in conjunction with, dorsal motion sites such as hMT+. There are sites in the ventrolateral occipital cortex that are consistently activated by motion-defined shapes rather than by uniform motion itself (light-green dots in Fig. 8A). Discussion of such sites is covered later in the section on form processing.

d. Color A number of imaging studies have investigated color processing in human visual cortex. Recordings from both implanted and scalp electrodes have also been useful in this respect. Fig. 8C shows the distribution of color-selective responses reported for ventral occipitotemporal cortex. The most recent studies have identified several distinct foci within this region. Human visual areas VP and V4v are activated somewhat more strongly by chromatic than by achromatic stimuli, but greater selectivity and task specificity are found anterior to V4v. Such selectivity has been shown to be associated with visual area V8 and, in some tasks, with a more anterior site, as shown in Fig. 12. V8 is retinotopically distinct from V4v and contains a representation of both superior and inferior visual fields. Color-selective activation sites in dorsal occipital cortex have also been observed on occasion, but their location and identity remain poorly defined.

The presence of occipitotemporal color-related sites is consistent with human lesion studies in which damage to ventral cortex results in diminished or absent color discrimination (achromatopsia). Often, these lesion studies report color perception losses in both upper and lower visual fields, even though the lesions appear to be confined to ventral cortex. Because retinotopically defined visual areas V4v and VP contain only upper field representations, they are unlikely to be the sites responsible for this cerebral achromatopsia. In contrast, area V8, which is located within the lesion-sensitive zone, does have both upper and lower field representations, thereby making it a prime candidate for the achromatopsia site. Moreover, V8 is located adjacent to the fusiform face area described in the next section. This juxtaposition of V8 and the FFA is likely to account for the fact that prosopagnosia (inability to recognize faces) is commonly associated with cerebral achromatopsia.

Although there is fairly good agreement among experts concerning the cortical locations of color- and achromatopsia-related sites in humans, there is significant controversy concerning the relationship between those sites and their counterparts in other primates. It has been proposed that the more anterior color-selective sites in human occipitotemporal cortex (labeled here as V8) should be considered the true homolog of macaque V4. Supporting evidence is based on the observation that macaque V4 (see Fig. 6) contains a significant number of cells with color-selective properties, consistent with a role in color vision. Yet the uniqueness of macaque V4 in this respect has been challenged, and there are important reservations concerning the role of simian V4 in the perception of color. Lesion studies of monkey V4 have typically failed to demonstrate severe disruption of color discrimination. Sometimes more subtle effects are observed such as the loss of color constancy under different lighting conditions, whereas hue discrimination is only mildly affected. In contrast, lesions in the posterolateral aspect of the macaque temporal lobe anterior to V4 (i.e., in area PIT) produce deficits that closely resemble those of a human achromatopsia patient tested in an identical manner. These results are consistent with the idea that, in humans, cerebral achromatopsia does not arise from lesions of V4v but from more anterior lesions encompassing V8 and/or additional neighboring areas. Despite these findings, the total number and precise topography of visual areas within posterior inferotemporal cortex in humans are still poorly defined, as are the roles of each individual area in color perception. In sum, the known properties of V8 make it a likely candidate for the achromatopsia site. This does not necessarily imply that V8 or any single visual area is solely responsible for color vision or for all color-related deficits. An achromatopsia site may simply be an especially susceptible nexus in a more extensive system of color-related processing.

Finally, it is important to note that neurons in other visual areas can be chromatically selective, that is, respond better to some colors than others, yet fail to

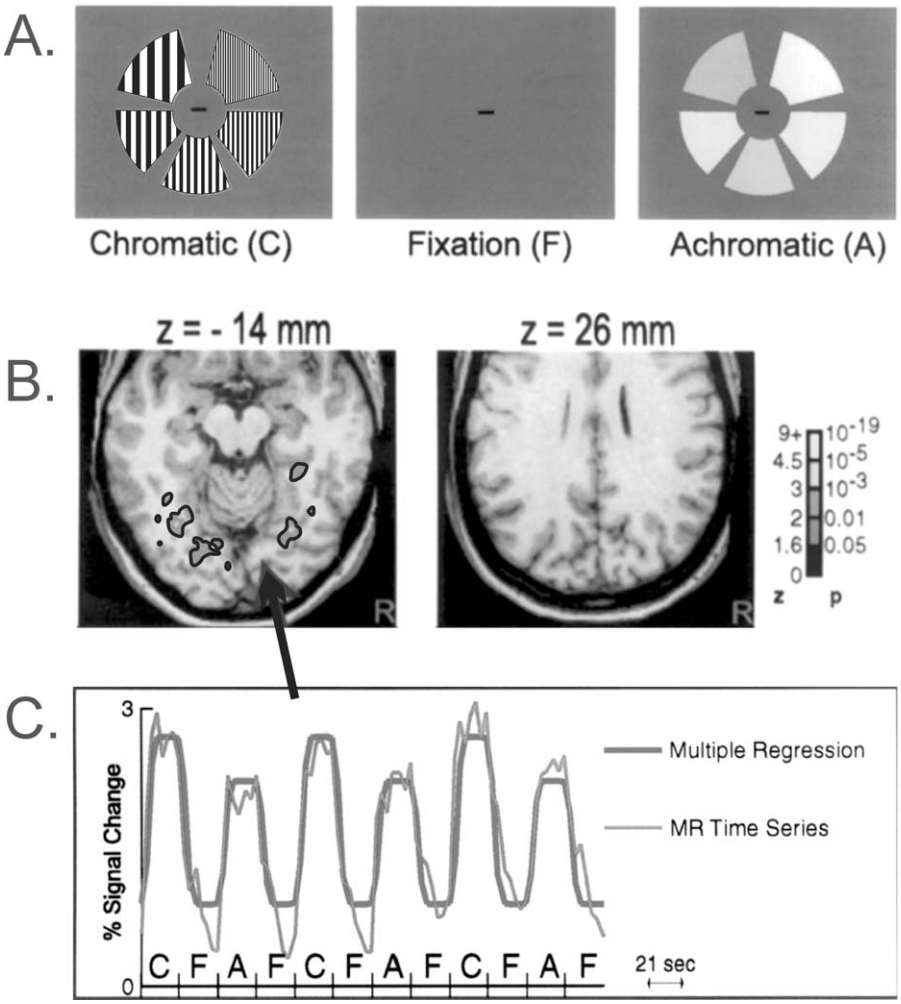

Figure 12 fMRI activation of color-selective sites in ventral occipitotemporal cortex. (A) Stimuli presented during alternating periods of the fMRI scan. (An ordered sequence of hues is represented here by different texture patterns.) During presentation of the chromatic stimuli, the subject indicated whether the hues in the color wheel were arranged in order or were random. For the achromatic stimulus, subjects made an identical judgment about the different gray levels in the wheel. (B) Brain slices through ventral occipitotemporal cortex (left) and dorsal occipitoparietal cortex (right) showing foci at which responses during the chromatic task were stronger than during the achromatic task. Note the lack of color-selective sites in dorsal cortex. (C) Time course of an average fMRI waveform for chromatically selective sites shown in B. (Adapted from Beauchamp *et al.*, 1999, *Cereb. Cortex* **9,** 257–263.)

contribute to the perception of hue. For instance, differences in chromatic contrast can help segregate an object from its background or can produce an unambiguous percept of motion in an otherwise ambiguous display. In fact, moving stimuli consisting of pure chromatic contrast can readily activate human hMT+. The amplitude of the resulting signal correlates with the perceived speed of the moving stimulus, even though the latter may not accurately reflect the true speed of the stimulus. If differences in sensitivity for chromatic vs luminance contrast are taken into account, human hMT+ (and presumably other components of the dorsal motion system) can be driven by color stimuli, though the resulting signals do not contribute to the perception of hue. These findings support the concept outlined in Fig. 10 that low-level visual cues, in this case chromatic cues, can support the perception of attributes such as movement in ways that may be unexpected.

e. Form Human imaging experiments have addressed a number of aspects of form processing ranging from the representation of simple contours to the identification of complex objects such as faces. There is general agreement that a major portion of the form processing system is located in the ventral

occipitotemporal cortex. This is illustrated in flat maps B and D of Fig. 8, which show cortical sites activated by a variety of tasks involving form perception, including recognition of faces.

i. Contours, Edges, and Contrast Passive viewing of luminance-based contours and edges readily activates retinotopic visual areas of the medial and ventral occipital cortex in humans. Generally, the higher the contrast of contours or grating patterns, the stronger the fMRI response. In one notable study, the researcher found that the size of a detectable increment in the contrast of a plaid grating was quite precisely tracked by a proportional increment in the fMRI response of visual areas V1, V2d, V3, and V3A. In area hMT+, however, the fMRI response tends to saturate above a few percent contrast, consistent with the high contrast sensitivity of MT neurons studied in animals. This suggests that accurate representation of the contrast of contours and edges is not a primary function of dorsal occipital visual areas such as hMT+, though a complete survey of contrast coding especially in the ventral occipitotemporal cortex (e.g., VP, V4, V8) has not been performed at the time of this writing. Consequently, it is not known whether the correlation between the fMRI signal and perceived contrast is best in a few key visual areas or is equivalently good throughout a wide variety of areas.

An alternate way to probe early stages of form analysis is through the use of "illusory contours," such as those illustrated in Fig. 13. Such contours—the apparently continuous outlines of the circle, square, and triangle in Fig. 13—do not exist in the physical stimulus but are nevertheless inferred by the brain mechanisms used to extract contour information from a variety of visual cues (luminance, color, and texture differences, occlusion boundaries, etc.). Single-cell recordings in animals have shown that neurons in V2, but less so in V1, are capable of responding selectively to these contours, thereby suggesting a hierarchical processing mechanism. Neuroimaging studies with human subjects have shown that illusory contours tend to activate the same neural systems that are activated by real luminance-based contours, though some types of illusory contours (Kaniza type) may preferentially activate later processing stages, including V3A, V4v, V7, V8, and LO.

ii. Motion-Defined Form In contrast to illusory contours, edges formed by motion differences along a boundary (Fig. 13) can activate early processing stages more strongly than later stages, though the effects for individual visual areas depend on the spatial density of the contours and stimulus size. It is important to note that selective responses to motion-defined edges (rather than to movement itself) are not known to be a hallmark of visual areas such as hMT+, which commonly are associated with motion processing. Rather, the most selective responses to motion-defined contours and shapes have been associated with a region termed the kinetic–occipital area (KO, indicated by light-green dots in Fig. 8A). It is located approximately 1.5 cm posterior to hMT+ in lateral occipital cortex. Whether KO is a distinct visual area or a portion of another visual area such as V4 or LO is not entirely clear, though the available evidence supports a separate designation. A more important issue is whether KO constitutes a separate, concurrent processing pathway for motion information. In one study combining evoked potential analysis with fMRI, no difference in latency of response was observed between hMT+ and ventrolateral areas (presumably

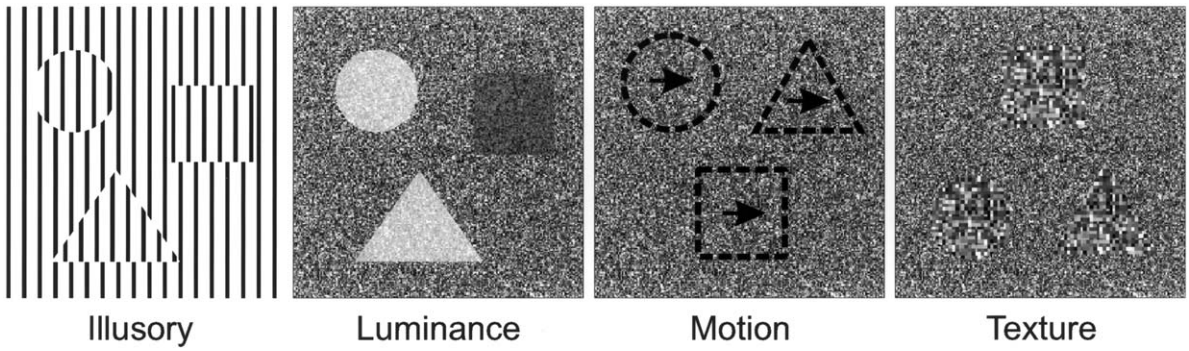

Figure 13 Examples of shapes delineated by illusory contours or by differences in luminance, motion, or texture. In the motion example, arrows indicate that dots within the dashed areas drift relative to dots in the surrounding area. Dashed lines are not present in actual stimuli. A visual area that supports a cue-invariant representation of shape would be expected to respond equivalently to a shape defined by any cue (given equivalent salience). Cue invariance is thought to be a characteristic of an abstract neural representation of shape.

KO) responding to motion-defined forms. This is consistent with the idea that low-level motion cues are processed concurrently in multiple pathways and contribute to the computation of other attributes besides trajectory.

iii. Cue Invariance From a theoretical standpoint, it would be satisfying if contour and edge properties, such as orientation, had a common neural representation regardless of the cues used to define the contour (see Fig. 13). Single-unit studies in animals indicate that at least some neurons in posterior inferotemporal cortex (PIT) are orientation-tuned for edges defined by more than one cue. Such response properties are said to be "cue-invariant" and may constitute an abstracted representation of the attribute of contour orientation. In humans, several neuroimaging studies have tested for cue-invariant responses to contours, edges, or outline figures defined by luminance, color, texture, binocular disparity, or motion. In the most comprehensive study, similar responses were observed for luminance-, texture-, and motion-defined figures in lateral occipital cortex posterior to hMT+ (labeled LO in Fig. 8) and in, or near, area V3A. In the context of human neuroimaging experiments, cue invariance simply means that the same amplitude of fMRI response to each cue condition was obtained from individual imaging voxels. This does not necessarily mean that within each voxel the individual neurons themselves are cue-invariant, but the results are consistent with that possibility. If true, the cue-invariant representation of contour information in LO and V3A may represent an important stage of abstraction in the inference of object attributes from the available retinal information.

iv. Figure–Ground Segmentation Closely related to the computation of contours and edges is the problem of segmenting the visual scene into regions associated with distinct objects or surfaces. It is thought that such figure–ground segmentation is a necessary prelude (or concomitant) to inferring more detailed attributes of objects, such as their shape and true surface color. In monkeys, it has been shown that the activity of single neurons at cortical stages as early as V1 can accurately distinguish the difference between the interior and exterior of a figure. Whether this is also true for V1 in humans is unclear, though likely. Lateral occipital cortex in humans has been shown to respond better to objects or object silhouettes than to random textures or "scrambled" objects that are not easy to segment into figure vs ground. It has been proposed that a swath of cortex located posterior to area hMT+ forms a complex specialized for the segmentation and processing of object information. This area, labeled LO in Fig. 8, is more strongly activated by discrete objects than by gratings, textures, or motion fields. Intriguingly, image manipulations that degrade the perception of a discrete object (e.g., addition of noise) also degrade the response. Conversely, manipulations that enhance the perception of an object (e.g., low-pass filtering of a coarse pixel image) also enhance the response in LO. Image manipulations that do not affect object perception, such as scaling and translation, have less of an effect on LO responses. This region does not appear to be strongly retinotopic, thereby suggesting that it contain neurons with receptive fields that encompass large portions of the visual field. This is thought to be a necessary characteristic of neurons that must represent the more global attributes of objects. Whether LO involves the representation of complete 3-dimensional objects or is primarily involved with initial stages of object representation such as figure–ground segmentation remains to be determined.

v. Complex Forms Discrimination of a change in the shape of simple rectangular targets activates a region of cortex in the collateral sulcus and adjacent lingual gyrus that is similar to retinotopically defined V4v and/or VP. These simple form tasks can also activate more lateral cortex in the fusiform gyrus or adjacent inferior temporal gyrus, sometimes extending into area LO. Complex forms or form discriminations often produce activation in ventral occipitotemporal cortex anterior to the strongly retinotopic visual areas. Together, these sites encompass a swath of cortex that extends from the occipital lobe into ventral temporal cortex. This swath is not functionally homogeneous and may be composed of subregions that are specialized for processing different types of form information. This is perhaps most consistently apparent for the analysis and recognition of faces.

Faces, Furniture, and Expert Knowledge: Identification of faces may be one of the more complex and subtle problems of form analysis. Accordingly, face stimuli and face discrimination have been studied extensively. They have been the focus of numerous animal single-unit and human neuroimaging studies. As illustrated in Fig. 14, the results from the human studies have been quite consistent and show that the fusiform gyrus from the occipital junction forward to midtemporal lobe is activated by tasks requiring face recognition. This area is selectively activated even when compared with a task requiring only classification of the face as male or female. The posterior extent

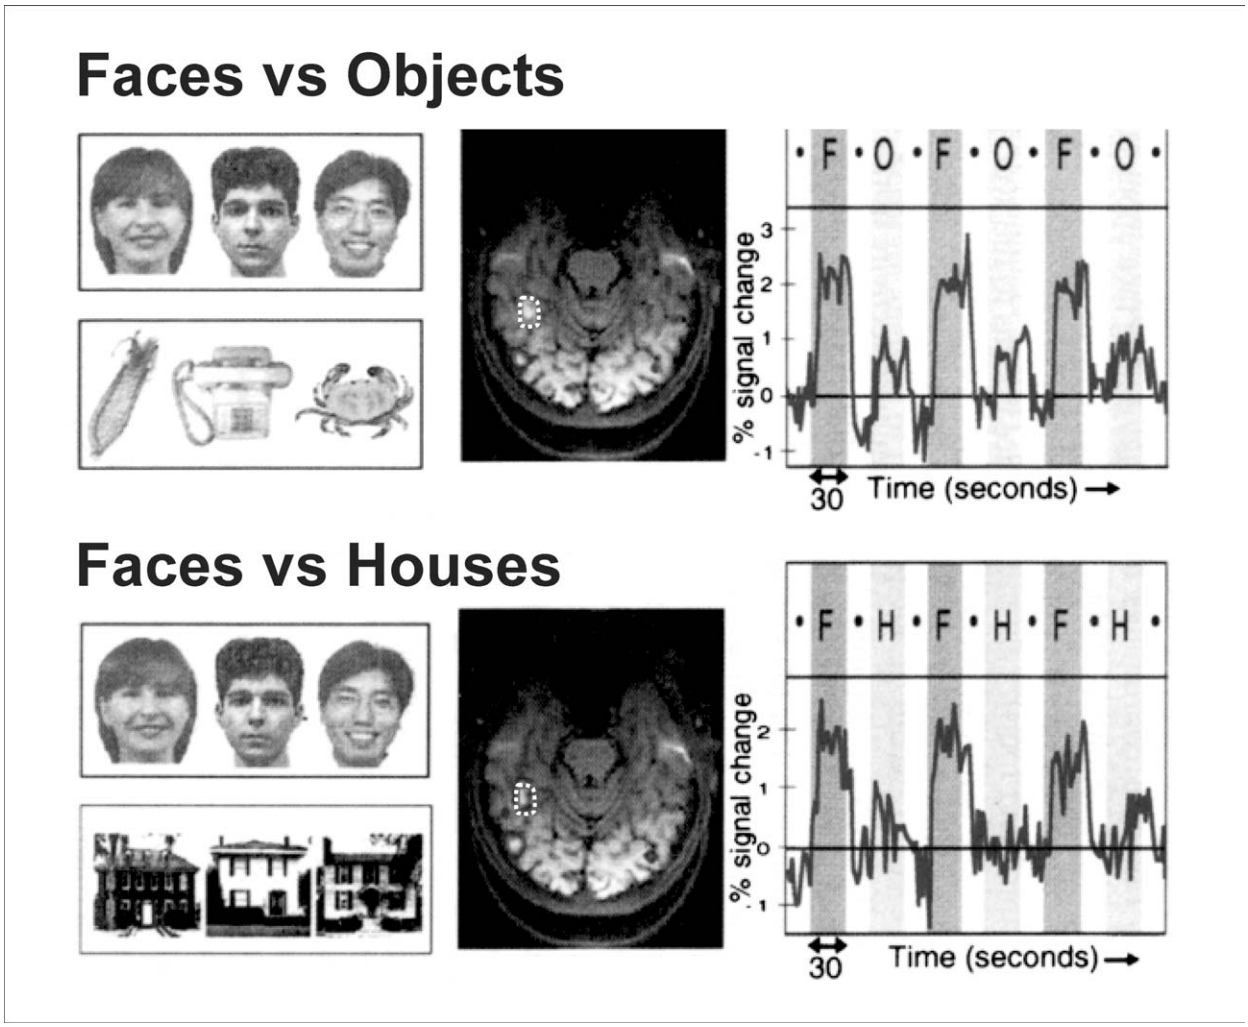

Figure 14 Selective activation of the fusiform face area by faces vs objects and houses. (Top) Left: Examples of stimuli viewed in alternating epochs during fMRI scan. Middle: Axial slice through the ventral occipital lobe and adjacent temporal cortex showing the site of the fusiform face area (dotted outline). Right: Time course of the fMRI signal during epochs in which the subject viewed fixation alone (epochs marked with dots), faces (marked with F), and objects (marked with O). (Bottom) Same as for the top but for alternation of faces and houses. (Adapted from Kanwisher *et al*., 1997, *J. Neurosci.* **17,** 4302–4311.)

of this region is lateral to the area activated during color processing (V8) or during the presentation of ''scrambled'' faces and has been termed the fusiform face area (FFA, Fig. 8).

The potential existence of a localized region of ventral occipitotemporal cortex that is critical for face recognition is consistent with the clinical syndrome of prosopagnosia, the inability to recognize previously familiar faces. Lesions that cause propopagnosia tend to have common involvement of the fusiform gyrus within the general vicinity of the FFA. Yet other evidence suggests that, if adequately tested, patients suffering from prosopagnosia can also exhibit deficits for objects other than faces. Such findings have prompted contrasting proposals that the form system either contains specialized ''modules'' for the analysis of different object categories or consists of a more universal network for analyzing all types of objects (or some combination of the two). In support of the latter concept, it has been shown that different types of objects—faces, buildings, furniture—all activate a large swath of ventral occipital cortex, but within that region there are spatially distinct ''hot spots'' whose configuration changes with object class.

Another alternative is that face recognition requires a uniquely high level of detailed, subtle analysis. Faces and their expressions convey unique social information, which is of critical importance for the individual

in terms of survival and well-being. In this sense, we are all accomplished ''experts'' at recognizing and interpreting faces. Some investigations have explored the possibility that the FFA actually constitutes an area specialized for acquiring such expert knowledge. For example, hobbyists who are particularly adept at discriminating different cars or birds will have activation in the vicinity of the FFA when performing those tasks as well as when performing face recognition tasks. This suggests the possibility that the form system may consist of both a generalized network that can deal with a vast variety of objects and specializations for fine discrimination within object categories that are especially important to the individual. These latter specializations may be malleable, thus allowing for the acquisition of new areas of expertise.

The existence of face-related modules or hot spots in human visual cortex was anticipated by studies in nonhuman primates that revealed neurons whose visual response properties were remarkably selective for face stimuli. It would seem simple to posit homology between face processing areas in the human and sites containing face-selective neurons in the macaque. In humans, face-selective responses are located ventrally, adjacent to color-selective regions in and near the collateral sulcus. In macaques, face-selective neurons have been found predominantly in anterior portions of the STS and lateral inferotemporal cortex, apparently separated from visual areas such as V4 that were traditionally thought to support color processing. This apparent discrepancy across species may be explained by more recent findings. As discussed earlier, cortex that, when lesioned, destroys hue discrimination in the macaque is located within posterior inferotemporal cortex rather than in V4. If true, color- and face-related sites in monkeys are located closer to each other than previously thought, and so are more consistent with the topographical organization in humans.

Semantic Aspects of Form Processing: Perception of the form of an object typically evokes associated semantic information, such as the class of items to which the object belongs, the utility of the object, or its ownership (*my* car). In reality, recognition of an object may be inseparably linked to at least some semantic associations. A theoretically satisfying notion in this respect is that early stages of visual processing located in the occipital lobe are most heavily involved in the direct perception of the form of an object but that later stages, especially in temporal cortex, are increasingly related to semantic associations. For instance, one researcher asked subjects to categorize pictures of objects as living or natural vs nonliving or man-made. In a control task, the subjects were asked to classify sinusoidal gratings as being oriented vertically or horizontally. Subtraction of images from the two tasks revealed activation sites in the fusiform and inferior temporal gyri that may be related to the classification of objects into semantic categories such as living vs nonliving. These results are consistent with clinical reports of patients with selective deficits in the identification of either animals (live objects) or tools (man-made objects). More recently, researchers have found that activation patterns within occipitotemporal visual areas even as early as V1–V2 can vary depending upon the semantic task involved (naming tools vs naming animals). These latter effects probably do not reflect the representation of semantic information itself in early visual cortex, but rather reflect the necessity of additional form processing when the task requires subtle distinctions between similar members of the same object class. Although such notions need to be confirmed by further study, they emphasize the fact that visual form analysis potentially involves dynamic interactions within, and across, multiple stages of cortical processing. The existence of localized brain sites that respond selectively to faces (or color or motion) does not preclude the capacity of these sites to function dynamically as part of a larger network whose operation can be modified to meet the informational needs of the observer.

Written Words and Dyslexia: Another potentially unique category of form analysis is the perception and interpretation of written words. Because this function is most highly developed in humans, it may distinguish us from other primates. Some neuroimaging studies have implicated ventral occipitotemporal cortex near, but distinct from, the FFA in the analysis of visual word form, though other studies have obtained different results. So far, then, it is unclear whether there are unique neural systems for the analysis of character and word shapes within the ventral form system.

Several studies have found an association between specific visual pathways and developmental dyslexia, an impairment of visual word processing and reading. Specifically, dyslexics appear to have impaired function of magnocellular-dominated pathways extending into the dorsal occipital cortex, especially through hMT+ to the parietal cortex. Neuroimaging studies of dyslexics have found reduced hMT+ responsiveness to both visual motion and drifting sinusoidal gratings presented at low average luminance. Such conditions stress the function of the magnocellular-dominated

dorsal stream. It has been proposed that such deficits may be related to the role of dorsal occipitoparietal systems in rapidly redirecting attention to specific targets in optically crowded environments such as printed text. If true, this suggests that dyslexia might reflect an abnormality of attentional control in addition to an inability to correctly interpret the visual form of the characters or words.

f. Depth and the Analysis of Space Compared to the concentrated work on motion and form processing, fewer human imaging studies have focused on the analysis and representation of space. The analysis of space involves inferences about a variety of spatial attributes. These include the assignment of distances of objects and surfaces relative to the self and to each other, the representation of spatial maps for navigation, the extraction of locations and orientations of objects relative to the limbs for purposes of manipulation, and, finally, the computation of object positions relative to the center of gaze or relative to the current focus of attention. (Studies concerning spatial attention, rather than the perception of space per se, are discussed in more detail in the section on attention.) Like the analysis of form and movement, the analysis of space can involve complex relationships between low-level visual cues derived from the retinal images and the various inferred attributes (see Fig. 10). In turn, this implies that there will be complex relationships in the neural pathways and cortical areas performing these analyses, including the likelihood of multiple concurrent pathways and computational hierarchies. The available evidence indicates that the cortical analysis of space heavily involves parietal and medial temporal lobe structures that receive direct or indirect projections from occipital lobe visual areas. A few such sites identified in neuroimaging studies are indicated in Fig. 8D. The following discussion mainly concerns the potential role of the occipital lobe in space-related computations.

It is clear from electrophysiological studies in animals that one important function of occipital visual areas is the extraction of relative depth–distance relationships from stereoscopic cues (retinal disparities). Although retinal disparity is not always sufficient to account for all perceived spatial attributes, nevertheless it is a major cue about distance relationships in the environment near the observer and, in combination with motion-parallax and perspective cues, typically provides for an unambiguous percept of spatial layout. Many monkey visual areas including V1, V2, V3, V3A VP, MT, and MST contain neurons that respond selectively to disparity differences. In humans, stimuli consisting of random dots alternating between zero and nonzero disparity elicit fMRI responses in the comparable human visual areas. Of these areas, V3A appears to be the most sensitive to changes in the disparity range, though all of the activated areas show a correlation between response magnitude and disparity size. One study also examined cortical responses to stimuli whose movements evoked the percept of either a 2-dimensional or 3-dimensional surface. Under passive viewing, the 3-dimensional stimuli evoked stronger fMRI activation in hMT+ and in several other foci, which (as nearly as can be determined from the report) included LO, V3A, and several parietal foci that are likely to receive projections from hMT+ or V3A. Although these studies identified visual areas that are responsive to depth cues and that may even represent the magnitude of perceived depth, it remains unclear which specific computational steps are associated with each area and which, if any, of these areas contains a comprehensive depth map of the visual scene.

Another approach to studying spatial relationships is exemplified by several imaging studies in which subjects matched the positions occupied by objects in a 2-dimensional array with a concurrently or previously presented positional cue. These tasks were typically compared to tasks in which subjects matched the identities of the objects regardless of position. In another study, subjects memorized the locations of objects in an array and then indicated whether their positions matched those of the same objects in a subsequently presented display. Most of these studies observed selective activation at one or more sites in dorsal occipital or parietal cortex (flat map D of Fig. 8). Some of these foci, especially in the superior parietal cortex, may be involved in the control of spatial attention, though it is quite possible that such sites may concurrently mediate the perception of spatial location itself. The visual areas associated with the activated sites in dorsal occipital cortex (two overlapping orange dots in the transverse occipital sulcus in Fig. 8D) were not determined, though their positions in Fig. 8D are consistent with V3A or a nearby visual area. Saccade-related activity has been found in similar locations in other studies, thereby supporting the possibility that this region may be eye-movement-related. This does not exclude a role in space perception because the constant shifting of the retinal images due to head and eye movements must be factored out to extract the invariant positions of objects relative to each other or to the self.

Accordingly, visual areas involved in the extraction of spatial information also may be involved in the analysis of eye movements. This is supported by the observation that parietal visual areas such as VIP and LIP in macaques contain cells that are active during different types of eye movements (smooth vs saccadic) and may be capable of compensating for such movements.

Other aspects of spatial processing such as the representation of mental maps of space appear to involve visual areas in the parietal, frontal, and medial temporal cortices outside the occipital lobe. Moreover, there are likely to be multiple representations of space using different coordinate frames, such as body- vs world-centered representations, rather than the retinotopic representations that are characteristic of many occipital visual areas. Given that there are a number of functionally distinct areas in macaque parietal cortex (e.g., VIP, LIP, MIP, PRR), it is likely that a similar multiplicity related, in part, to spatial processing will be described for human parietal cortex in the near future.

D. Summary: Principles of Functional Organization

From the preceding review of occipital lobe function, we can extract several general organizational principles. (1) Occipital visual cortex is composed of a number of distinct visual areas that, in many respects, resemble those of nonhuman primates such as the macaque monkey. At present, at least eight different human visual areas have been tentatively identified: V1, V2, V3–VP, V4v, V3A, hMT+ (MT plus neighboring areas such as V4t, MST, and FST), and V8. The topographic relationships among these areas are similar to those in macaques, though their positions relative to anatomical landmarks differ. Other functionally distinct zones that may or may not constitute additional visual areas include LO and KO. Also, there are additional zones of visually responsive cortex within the occipitotemporal and occipitoparietal cortices whose characteristics have not been fully explored (e.g., proposed V7). These zones may include additional homologs such as the ventral intraparietal area (VIP) or the parieto-occipital visual area (PO, also known as V6), but additional studies are needed for a comprehensive accounting. (2) Several stages of cortical visual processing (V1, V2, V3–VP, V4v, V3A, and V8) are organized retinotopically, though some areas may lack a complete representation of the visual field or may have somewhat disparate visual properties in upper vs lower field subdivisions (e.g., V4v, V3 vs VP). As in the macaque, retinotopic organization tends to become less distinct or absent in later stages of processing extending into the parietal and temporal lobes. (3) At each processing stage in the visual system there are multiple pathways that operate concurrently. By extension from animal data, these distinct pathways are undoubtedly interleaved on a fine scale within visual areas at early stages of processing (V1–V2) so that lesions there tend to produce virtually complete blindness, at least within the retinotopic confines of the damage. (4) There is a general tendency for spatial and motion-related tasks to activate dorsal sites extending into parietal cortex, whereas color and form tasks tend to activate ventral occipitotemporal sites. This is generally consistent with the principle of dorsal and ventral processing streams popularly known as "where" vs "what" pathways. However, there are examples that seem to defy this principle, such as the activation of ventral sites by motion stimuli. One key to understanding these seeming discrepancies is to clarify the distinction between the processing of low-level cues (e.g., local motion) and that of high-level attributes (e.g., motion-defined form). (5) All visual tasks produce activation throughout extended networks of visual areas, including medial occipital areas (V1–V2), plus a variable complement of extrastriate areas depending on the nature of the stimuli and the visual task. Neuroimaging data exist that are consistent with the concept that the different visual areas are arranged into a rough processing hierarchy with early stages tending to extract information about local visual cues and attributes, whereas later stages construct representations of increasingly global attributes. (6) Some specific cortical sites are preferentially activated by restricted classes of stimuli or tasks (V8–color, FFA–faces, hMT+–motion), but in all cases these areas can be activated to some extent by other classes of stimuli or tasks. The existence of functionally selective cortical sites that are critical for accurate perception is consistent with, and may explain, the fact that restricted lesions of extrastriate cortex can result in selective deficits in the discrimination of motion, color, faces, and possibly other attributes. Even so, such sites are components of extended processing networks, so that it is inaccurate to conceive of them as isolated centers or modules. Rather, such sites likely represent unique processing stages at which particular world attributes become explicitly represented in a localized population of neurons, thereby becoming vulnerable to the effects of localized cortical trauma.

IV. ADDITIONAL COGNITIVE ROLES

The preceding description of occipital lobe function was largely concerned with the neural systems involved in extracting the attributes of objects and surfaces from the incoming retinal information. However, analysis of the incoming retinal information in isolation cannot completely account for the more cognitive characteristics of vision. For example, studies of "biological motion" have demonstrated that the movement of a few lights attached to the joints of a person walking in an otherwise dark room can yield a vivid impression of the person and even allow identification of their gender. Such demonstrations suggest that the "bottom-up" analysis of the incoming visual information can be strongly affected by context and prior experience. At any given moment, we appear to be consciously aware of only a fraction of the visual information available in the retinal images. If we do not attend to a feature or event for at least a split second, we appear to be unaware of it (or at least unable to report or remember it). Together, these examples highlight the role of the observer as an active agent who is able to direct and interpret visual processing depending on the needs of the task at hand. We are still in the early stages of uncovering the neural mechanisms involved in these more complex aspects of vision, so the following discussion will only touch upon a few key cognitive functions in which the occipital lobe may participate.

A. Visual Imagery

One issue that has prompted a variety of experiments is the role of occipital visual cortex in mental imagery. In a review of experimental evidence concerning mental imagery, Farah concluded that there is "converging evidence that supports the modality-specific nature of mental images, and suggests that at least some of their neural substrates have a spatial representational format: Damage to visual areas representing such specialized stimulus properties as color, location, and form results in the loss of these properties in mental imagery." Particularly intriguing is the observation that the surgical removal of one occipital lobe appears to alter the size of the imagined visual field in a manner commensurate with the loss of a hemifield. If true, then this finding strongly suggests that occipital networks are essential for visual imagery.

A more specific question is whether mental images arise only from activity at high levels of cortical processing where, presumably, whole objects and scenes are represented. Alternatively, mental images might arise from the activation of all stages of visual processing in a way that more or less duplicates the cortical activity evoked by a real visual scene. As illustrated in Fig. 15, several studies have claimed to show activation of occipital visual areas during mental imagery, and a few have even implicated primary visual cortex. In one of these studies, subjects mentally compared the lengths of imagined stripes. This produced clear activation of V1. If transcranial magnetic stimulation (thought to directly stimulate cortical neurons) was applied to medial occipital cortex before the mental imagery task, then the subject's ability to perform the task was impaired relative to a sham control condition. However, other studies have failed to obtain clear activation of primary visual cortex during some types of imagery, thereby leading to the proposal that the neural mechanisms involved will vary depending on the specific imagery task. This suggests the possibility that a visual area may be activated if the mental image consists of a feature or attribute that is explicitly coded by the constituent neurons regardless of the area's hierarchical processing level. Whether this conjecture is true awaits further study. It is also unclear whether the activation evoked in visual cortex by mental imagery represents the imagined percept itself or rather the effects of a correlated process such as directed visual attention. Attention directed to a particular visual field location will modulate retinotopically corresponding sites in a number of occipital visual areas such as V1, V2, and V4–V8 (see later discussion). Presumably, this also occurs if attention is directed toward a mental image in order to note its features. In such a case, there is potential confusion between cortical activation representing a mental image and cortical activation associated with the processes used to explore and report on the imagined image.

B. Attention

Visual attention refers to the ability to prepare for, select, and maintain awareness of specific locations, objects, or attributes of the visual scene (or an imagined scene). The focus of visual attention can be redirected to a new target either reflexively or through the purposeful effort of the observer. The center of gaze typically follows the focus of attention, but the observer can intentionally dissociate the two, thereby demonstrating that the neural systems controlling

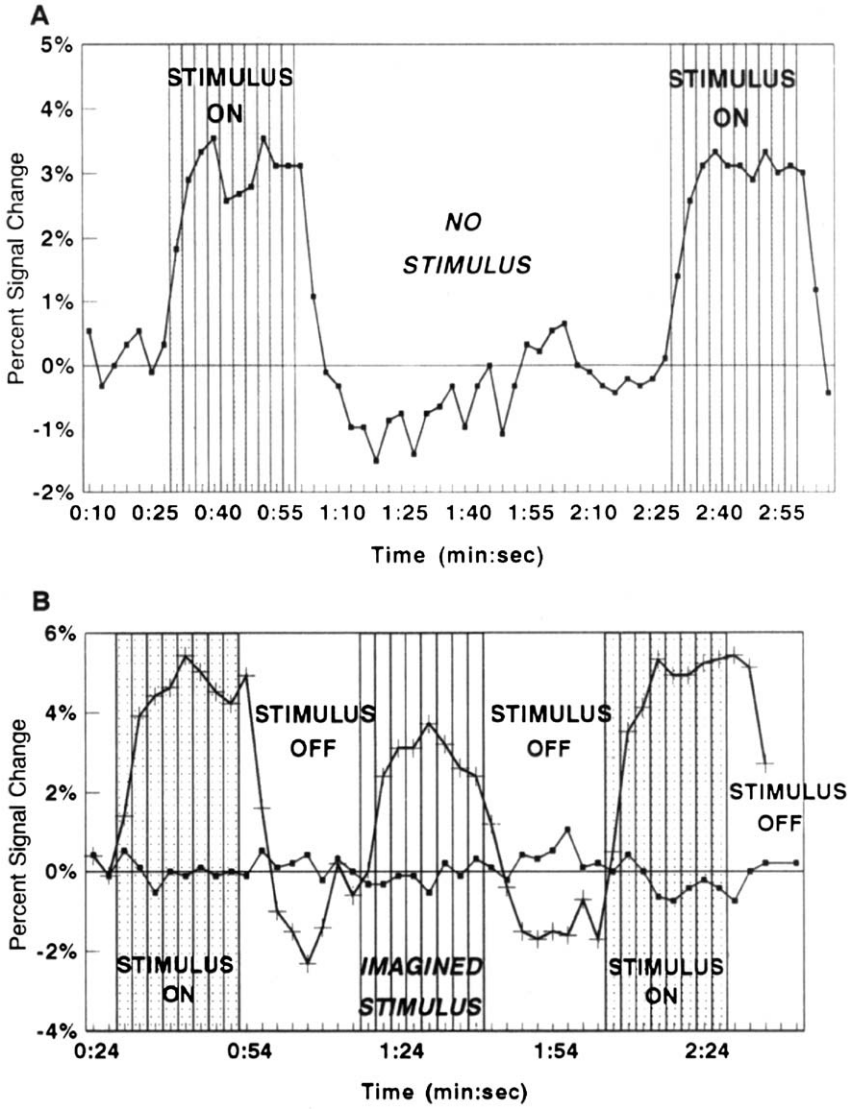

Figure 15 fMRI activation of striate cortex during mental imagery. Plots of relative fMRI signal intensity changes vs time. In A, the subject was resting between presentations of stimuli consisting of light emitting diodes arranged to form two squares. In B, the subject was asked to mentally recall an image of the stimulus in the period between the actual stimulus presentations. In this panel only, + = striate cortex and square symbols = nonstriate cortex. (From Le Bihan *et al.*, 1993.)

eye movements and attention are at least partially distinct.

The specific purpose and mode of action of attention are topics of significant debate. Direction of visual attention to a target can enhance the detection of subtle changes in brightness, color, or virtually any other attribute of interest. Changes in the visual scene not associated with the target are less readily detected unless they are sufficiently salient to reflexively redirect attention. Some visual attributes require focused attention to be perceived correctly. For example, detection of a conjunction of color and form (e.g., a red X in a field of red and blue X's and O's) requires the observer to attend to each letter in turn until the correct match is found. In a crowded visual environment, directed attention may be required if different attributes of the same object are to be correctly associated. There have been demonstrations that directed visual attention also can alter the perceived motion of certain stimuli, such as an ambiguously rotating "pinwheel" grating. In fact, quite substantial changes in the visual scene can go completely unnoticed if, for some reason,

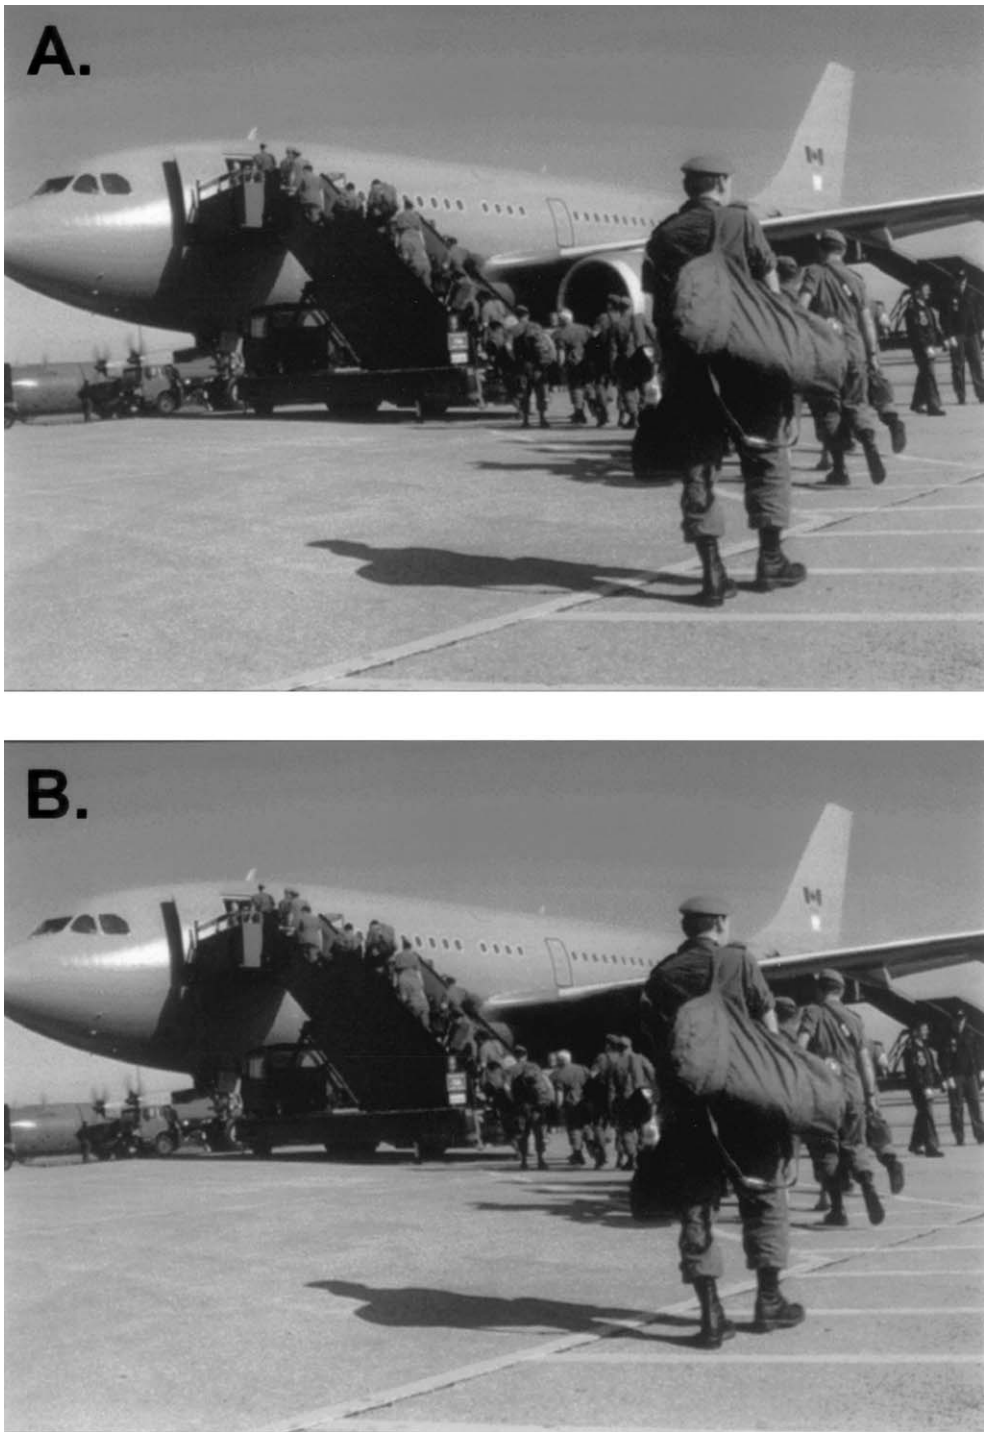

Figure 16 Stimuli used to demonstrate change blindness. The subject views A, and then the whole image flashes white at the moment that B replaces A. The two images are identical except for the missing jet engine. The subject will be unable to report the disappearance of the engine unless he or she is allowed to search the picture for an apparent discrepancy. A variety of other transient manipulations occurring at the moment of change can also block awareness of the change. It is theorized that the flash blocks the normal reflexive capture of attention by the change in the image. If the change does not capture attention, then there is no awareness. (Courtesy of R. Rensink.)

the reflexive systems that redirect attention are disabled at the moment the change occurs. This can be shown dramatically using a psychophysical procedure to induce "change blindness." By using the images shown in Fig. 16, it is easy to show that a flash occurring at the moment the images are switched can prevent a subject from detecting the disappearance of the jet engine from the wing of the airliner. It is thought that the flash reflexively redirects attention at the moment when the disappearance of the jet engine normally would have captured attention, thereby resulting in loss of awareness. (If the subject is allowed to peruse the scene after the switch, he or she can eventually infer the loss of the jet engine, though this can take considerable time.)

How and where attention exerts its effects over the processing of incoming visual information are becoming clearer. Ample evidence from animals and humans now shows that attention can modulate the responses of neurons in occipital visual cortex. Shifts of attention can alter the response amplitude or discriminability of cells in macaque visual areas such as V1, V2, MT, and V4. Attention also can selectively alter the responsiveness of neurons in V4 to one of two or more targets falling within its receptive field. In humans, electrophysiological studies have shown that evoked potentials associated with occipital visual cortex are enhanced if the subject actively attends to the location at which the stimulus is flashed. Moreover, the enhancement is localized to the occipital lobe contralateral to the attended site. Neuroimaging studies, such as the one illustrated in Fig. 17, have shown that a shift in attention from one visual target location to another results in focal enhancement of cortical activation at retinotopically corresponding sites throughout retinotopically organized occipital visual areas, including V1, V2, V3–VP, V4, and possibly V8 or neighboring cortex. Within these areas, the retinotopic locus of attentional enhancement precisely matches the retinotopic locus of activation evoked by the attended target when presented in isolation. This strongly suggests that attention exerts its spatially selective effects within occipital cortex, perhaps as early as V1 (though the latter may be due to a delayed effect relayed back from extrastriate cortex). Surprisingly, attention directed to the site of an expected stimulus will activate visual cortex before the target actually appears. This is consistent with the notion that attention is modifying responsiveness at the cortical site representing the cued location in preparation for the anticipated appearance of a target.

Although we tend to be quite familiar with directing our attention to a particular location, it is also possible to direct attention to a particular visual feature (e.g., noticing the shape vs the color of an object). By using PET imaging, researchers produced a seminal study demonstrating the featural specificity of cortical attentional modulation in humans. Attention directed to different attributes of an array of small, drifting rectangles of different shapes and colors resulted in different distributions of enhanced activation in occipital cortex, depending on the feature of interest (color, speed, shape). The patterns of activation tended to be functionally appropriate for the attended feature (e.g., attention to speed resulted in enhanced activation of hMT+). Subsequent studies have been able to show that specific visual areas such as hMT+, V4–V8, and FFA can be modulated by attention to visual attributes processed by the corresponding area (speed, hMT+; color, V4–V8; faces, FFA). Moreover, it has been demonstrated that attention to a given feature and attention to a given location can each have modulatory effects that are at least partially summative.

The preceding results suggest that the selection and enhancement of restricted aspects of the incoming visual information by visual attention occur, at least in

Figure 17 Retinotopic mapping of attention effects in the human occipital cortex. Shift in the focus of spatial attention without moving the eyes produces retinotopically corresponding foci of activation in the occipital cortex. (A) Left: Schematic representation of attended target locations. Subject fixated on the center of the target array (B) and shifted attention from the most central segment to successively more peripheral segments on the right (1–4) according to prearranged auditory cues presented briefly every 10 seconds. Middle: fMRI signals showing attention-related activation recorded at sites indicated by corresponding numbers on the right. Right: Parasagittal slice through the occipital lobe showing the foci of attentional activation (dotted outlines) that were displaced anteriorly (1–4) as the subject shifted attention to more peripheral target locations. (B) Target array. Orientation and colors of target segments changed randomly every 2 sec. No unique visual features marked the attended target segments. (C) Anatomical image. Abbreviations: CaS, calcarine sulcus; CoS, collateral sulcus; POS, parieto-occipital sulcus. (D) Quantitative comparison of visual field eccentricity (coded by temporal phase of fMRI response) for foci of attentional enhancement (y axis) vs foci activated by attended target segments presented alone (x axis). Each circle in the graph represents a single responsive voxel. Data are pooled across subjects. Left: Medial occipital cortex consisting primarily of V1 and V2. Right: Ventral occipitotemporal cortex within and surrounding the collateral sulcus. R = correlation coefficient. Dashed line indicates the locus of perfect correlation. An exceptionally high degree of correlation shows that the topography of the attentional enhancement within the visual cortex is precisely retinotopic. part, within occipital visual cortex. How these spatially and functionally restricted patterns of attentional enhancement are set up and impressed upon occipital cortex is not yet fully known, though the mechanism seems to involve interactions of occipital cortex with parietal and frontal cortices as well as with the pulvinar. This is an area of intense investigation, so that the underlying neuronal mechanisms are likely to be further clarified in the near future.

C. Visual Awareness

As is apparent from the foregoing discussion, visual attention is closely linked to the issue of visual awareness (though they are not synonymous). Given the extensive evidence for attentional effects in occipital cortex, one is easily led to ask whether occipital cortex directly participates in visual awareness. In other words, is our subjective perceptual experience a direct correlate of the activity of occipital neurons? Or, is occipital cortex merely extracting information from the retinal images and then passing it on to other brain regions that are responsible for awareness?

The answers to these questions are far from evident, but some relevant observations are beginning to accumulate. Several studies have used binocular rivalry in conjunction with single-unit recordings or neuroimaging to try to establish which neurons or visual areas show activity that correlates closely with perception. If an upward-drifting grating is presented to one eye but a downward-drifting grating is presented to the other eye, humans typically report the percept of one or the other and more rarely a combination of the two. In single-unit studies of monkeys performing this task, some direction-selective neurons in the superior temporal sulcus, including MT, responded in close correspondence with the alternating percept of the gratings, even though the visual stimuli themselves were unchanging. In humans, a similar rivalry experiment in which a picture of a face was presented to one eye while a house was present to the other eye resulted in alternate fMRI activation of the fusiform face area (FFA) vs the parahippocampal place area (a region in the medial temporal cortex shown to respond selectively to spatial structures) as the subject's percept alternated between face and house.

Despite these demonstrations of a close correspondence between awareness and activity in higher level visual areas, psychophysical studies indicate that at least some of the neural activity in occipital visual cortex is not accessible to consciousness. Orientation-specific adaptation to a visual grating patch can occur even when subjects cannot consciously report the orientation of the grating due to nearby distracters. Because the orientation-specific adaptation undeniably occurs (and is generally accepted to be a function of occipital neurons), it follows that the cortical activity representing the orientation-specific information itself is not accessible to conscious awareness. Furthermore, some neurons in macaque area MT apparently can discriminate the direction of motion of a noisy random dot display better than is indicated by the behavioral response. This, too, suggests that not all neural activity in the occipital cortex is capable of generating a conscious percept. Indeed, it has been proposed that consciousness may only arise when occipital activity is transferred to frontal cortex. In such a case, attention may act as a simple gating mechanism that controls the transference of sensory information to "awareness systems" in the frontal cortex. However, the available evidence does not yet support the conclusion that conscious awareness arises exclusively outside the occipital lobe or that occipital circuits never directly participate in awareness. An alternative possibility is that, at any given moment, assemblies of neurons in various locations are dynamically linked together to create a substrate for awareness. In such a scheme, attentional control mechanisms (in parietal cortex and the pulvinar?) dynamically link specific occipital circuits with frontal neurons to form an "active" configuration that generates awareness. In this fashion, neurons in a variety of cortical areas, including the occipital lobe, could transiently participate in awareness as mental events shift from one thought to another over time. At present, the validity of any of these concepts has yet to be firmly established.

V. CONCLUSION

Thanks in large part to the advent of sophisticated neuroimaging techniques, there has been a rapid increase in our understanding of the functional organization of the human occipital lobe. This progress has been built on decades of previous work in humans and animals and now permits observations from different primate species to be compared and interrelated as never before. So far, what has emerged is the realization that, in many respects, occipital lobe organization in humans is similar to that in monkeys, though we are now beginning to see indications of

potential differences. The extent of these differences and their ultimate functional importance are not yet clear, but they hold the key to a more specific understanding of the extent to which humans do or do not differ from other species in brain organization. Due to the unprecedented ability to probe brain function in humans as they perform complex perceptual and cognitive functions, it is now possible to identify and characterize the specific neural substrates of our more complex and fascinating visual abilities. Practically, this gives us new ways to understand how sensation and perception operate and to understand how they are disturbed by brain pathology. The advances in basic research have already prompted exploratory applications of brain mapping techniques in presurgical planning and in the diagnosis of visual dysfunction. Altogether, the progress of recent years has yielded a more comprehensive, predictive, and clinically relevant understanding of human occipital lobe function and, by extension, a better understanding of the relationship between brain and mind.

Olfaction

RICHARD L. DOTY
University of Pennsylvania

GLOSSARY

anosmia Inability to perceive odors.

dysosmia (parosmia) Distorted smell sensations.

hyposmia (microsmia) Decreased ability to perceive odors.

olfactory bulb Multilayered structure at the base of the brain where incoming olfactory information is first processed.

olfactory fila Collections of olfactory nerve cell axons formed by ensheathing glial cells that pass from the nasal to the brain cavity via the foramina of the cribriform plate.

olfactory nerve Collectively the ~6,000,000 odorant-sensitive receptor cells located within the olfactory neuroepithelium that send axons to the olfactory bulb.

olfactory neuroepithelium The epithelium in the upper recesses of the nose that contains, among other cells, the olfactory receptor cells where airborne environmental chemicals activate neural responses.

olfactory receptors Seven-transmembrane proteins specialized to bind odorants and transduce information that leads to neural firing and ultimately the perception of odors.

olfactory tract Fiber bundle at the base of the brain through which afferent and efferent connections pass between the olfactory bulb and higher brain structures.

Olfaction largely determines the flavor of foods and beverages and serves as an early warning system for the detection of environmental hazards, including spoiled foods, leaking natural gas, smoke, and various pollutants. This primary sensory system contributes to our quality of life, allowing us to more fully appreciate flowers, perfumes, culinary creations, the sea shore, the mountains, and the seasons of the year. From a medical perspective, smell dysfunction can be the first clinical sign of such neurodegenerative disorders as Alzheimer's disease and idiopathic Parkinson's disease, making smell testing of particular value in neurological diagnosis. This article provides basic information on the anatomy, physiology, and function of the olfactory system, emphasizing quantitative measurement and clinical applications.

I. ANATOMY

A. Intranasal Neural Systems

Three specialized neural systems are present within the left and right sides of the human nose: (i) the main olfactory system (Cranial Nerve I or CN I); (ii) the trigeminal somatosensory system (CN V); and (iii) the nervus terminalis or terminal nerve (CN 0). CN I mediates what we commonly term odor sensations (e.g., chocolate, strawberry, apple, etc.), whereas CN V mediates, via both chemical and nonchemical stimuli, somatosensory sensations, including irritation, tickling, cooling, and burning. The cool sensations of menthol are mediated by CN V, as are the sharp burning sensations of ammonia. CN 0, whose function is largely unknown, was discovered after the other

cranial nerves had been named and has remarkably constant anatomy across all vertebrates, including humans. Its peripheral component is a loose neural plexus distinguished by ganglia at nodal points. CN 0, notable for its high gonadotropin-releasing hormone (GnRH) content, ramifies throughout the nasal epithelium before coalescing into bundles that eventually traverse the cribriform plate to enter the forebrain.

Despite the fact that nearly all adult humans possess, in the lower recesses of each nasal chamber, a tube-like rudimentary vomeronasal organ (VNO) and a VNO duct approximately 15–20 mm from the posterior aspect of the external naris, they lack an accessory olfactory bulb and their vomeronasal system apparently is not functional. Attempts to trace neural connections from this organ to the brain have been uniformly unsuccessful in humans, despite the fact that local electrophysiological responses have been recorded within the VNO lumen. In contrast to the receptor-rich medial and receptor-free (but vascular-rich) lateral elements of the VNOs of species with a functioning vomeronasal organ system, the human VNO has comparatively homogeneous epithelium along both its medial and lateral aspects. Adult human VNOs contain cilia and short microvillae, unlike the elongated microvillae typical of functional VNOs.

B. The Olfactory Neuroepithelium

The olfactory epithelium, which contains the sensory receptors of the main olfactory system, lines the upper recesses of the nasal chambers, including the cribriform plate, superior turbinate, superior septum, and sectors of the middle turbinate. This neuroepithelium loses its general homogeneity postnatally as islands of respiratory-like epithelia appear a few weeks after birth, presumably as a result of insults from environmetal toxins, bacteria, and viruses. Such islands accumulate across the lifespan. Surprisingly, the size of the epithelium in humans is still not well-established, and there is some evidence that it may extend farther onto the middle turbinate than previously believed.

The mature olfactory epithelium comprises at least six biochemically and morphologically distinct cell types (Fig. 1). The first cell type—the *bipolar sensory receptor neuron*—contains the cilia that bind the odorants as they permeate the olfactory mucus. Collectively, these cells constitute CN I. In aggregate, the surface area of the cilia of these cells is quite large, exceeding 22 cm^2 in humans. The number of olfactory receptor cells ($\sim$6,000,000 in the adult) exceeds that of any other sensory system except vision. The second cell type is the *microvillar cell*, whose cell body is located near the epithelial surface. These cells, which occur in $\sim$1:10 ratio with the bipolar receptor cells, have microvillae at their apical surfaces and resemble the "brush" cells of the upper and lower airways of many species. Whether microvillar cells play any role in chemosensation is not clear, although preliminary *in vitro* patch clamp studies of dissociated microvillar cells suggest that they are not responsive to odorants. The third cell type is the *supporting* or *sustentacular cell*. Like the microvillar cells, these cells project microvillae into the mucus. Supporting cells appear to (i) insulate the receptor cells from one another, (ii) regulate the local ionic composition of the mucus, (iii) deactivate odorants, and (iv) help protect the epithelium from damage from foreign agents. These cells contain xenobiotic-metabolizing enzymes (e.g., cytochrome P-450), a feature shared with the acinar and duct cells of Bowman's glands, the primary source of mucus in the region of the olfactory epithelium. The fourth cell type is the *cell that lines the Bowman's glands and ducts*, whereas the fifth and six cell types are the *globose* (*light*) *basal cell* and *horizontal* (*dark*) *basal cell*—cells located near the basement membrane from which most of the other cell types arise. The same type of basal cell, most likely a globose cell, can give rise to neurons and nonneural cells when the olfactory epithelium is markedly damaged, expressing a multipotency rarely observed in stem cells.

The cilia of the bipolar receptor cells differ from the cilia of the cells making up the respiratory epithelium in that they are much longer and lack dynein arms (hence, intrinsic motility). It is these cilia that contain the seven-domain transmembrane receptors that interact with incoming odorants. Movement of odorants through the mucus to the cilia is aided by transporting molecules termed "odorant-binding proteins." Approximately 1000 putative odorant receptors are believed to exist, reflecting the expression of the largest known vertebrate gene family. In fact, this gene family accounts for $\sim$1% of all expressed genes. *In situ* hybridization studies suggest that the olfactory receptors of rodents are topographically organized into four strip-like zones that roughly parallel the dorsal–ventral axis of the cribriform plate. Receptors of a given type are largely confined to one of these zones. Whether the situation is analogous in humans is not yet known. Work employing a scanning electron microscope has shown a possible morphological correlate to these zones in rats—by embryonic day 16, the posterior

Figure 1 Low-power electron photomicrograph (× 670) of a longitudinal section through a biopsy specimen of human olfactory mucosa taken from the nasal septum. Four cell types are indicated: ciliated olfactory receptors (c), microvillar cells (m), supporting cells (s), and basal cells (b). The arrows point to ciliated olfactory knobs of the bipolar receptor cells. Abbreviations: d, degenerating cells; bs, base of the supporting cells; lp, lamina propria; n, nerve bundle; bg, Bowman's gland. Photo courtesy of Dr. David T. Moran.

regions (roughly corresponding to zones 1 and 2) have much higher receptor cell knob densities than the more anterior regions (corresponding to zones 3 and 4). The supporting cell microvilli appear to be longer in region 1 than in region 2, and the apical ends of the cells adjacent to the receptor cells are flatter in regions 1 and 2 than in regions 3 and 4. Regions 3 and 4 also have glandular openings and scattered microvillous cells similar in appearance to the hair cells of the inner ear.

C. The Olfactory Bulb

In humans, the axons of the bipolar receptor cells coalesce into 30–40 fascicles, termed the olfactory fila,

formed by ensheathing glia. The fila traverse the cribriform plate and pia mater. The incoming axons make up the first layer of the olfactory bulb and synapse with dendrites of the second-order neurons of the bulb in spherical structures termed glomeruli. The major discernible concentric layers of the olfactory bulb are the olfactory nerve layer, the glomerular layer, the external plexiform layer, the mitral cell layers, the internal plexiform layer, and the granule cell layer. In the rat and mouse, neurons expressing a given receptor type typically project their axons to one or, at most, two glomeruli. Thus, a given odorant activates a spatially defined or restricted set of glomeruli. Hence, the olfactory code is reflected, at this early stage, as different patterns not only across the mucosa but across the glomeruli as well. Glutamate appears to be the main, if not sole, neurotransmitter of the receptor cells.

The activity of the mitral and tufted cells is modulated by other cells within the bulb, including periglomerular cells and more deeply located granule cells. The latter cells are the most numerous cells of the olfactory bulb, and centrifugal fibers from higher brain centers serve to alter the activity of these cells. It is generally believed that both intrinsic and extrinsic feedback processes sharpen or alter the neural information transmitted from the bulb to more central olfaction-related structures. The primary second-order neurons of the bulb, most notably the mitral and tufted cells, project directly to the primary olfactory cortex via the olfactory tract without synapsing with the thalamus. Although the olfactory tract, which is relatively flat posteriorly and becomes the olfactory trigon just rostral to the anterior perforated substance, is commonly divided into ''lateral'' and ''medial'' aspects in textbooks of anatomy, there is, in fact, no medial tract in primates.

D. The Olfactory Cortex

The olfactory cortex comprises (i) the anterior olfactory nucleus (AON), (ii) the olfactory tubercle (poorly developed in humans), (iii) the prepiriform cortex, (iv) the lateral entorhinal cortex, (v) the periamygdaloid cortex (a region contiguous with the underlying amygdala), and (vi) the cortical nucleus of the amygdala. Major connections between the primary olfactory cortex and the secondary olfactory cortex in the orbitofrontal region occur via the mediodorsal nucleus of the thalamus, as well as via direct cortico-cortical projections from prorhinal cortex to the posterolateral orbitofrontal region.

The AON is located in a rostral segment of the olfactory bulb, as well as in a segment of the olfactory peduncle near the anterior perforated substance. The dendrites of the pyramidal cells of the AON receive synapses not only from the olfactory bulb but also from both ipsilateral and contralateral brain structures, including the contralateral AON and elements of the olfactory cortex via the anterior segment of the anterior commissure. The anterior commissure represents the first CNS structure through which olfactory information crosses contralaterally.

Extensive interactions occur among cells comprising the superficial and deeper laminae of each component of the olfactory cortex, as well as among the components themselves. In addition to receiving direct projections from the olfactory bulb, the entorhinal cortex also receives input from both the prepiriform and the periamygdaloid cortices. The entorhinal cortex sends projections to a number of cortical structures, including the hippocampus. However, no direct pathways exist between the hippocampus and either the olfactory bulb or the AON, and anatomic, physiologic, and ontogenic evidence suggests that the hippocampus is not a main component of the olfactory system, even though it does play a role in odor memory.

II. TRANSDUCTION MECHANISMS

A. Olfactory Receptors

During the past 10 years considerable progress regarding the initial events of olfactory transduction has occurred, beginning with the aforementioned identification of the gene family that encodes olfactory receptors. Despite the fact that a given receptor cell seems to express only one type of receptor derived from a single allele, each cell is electrophysiologically responsive to a wide, but circumscribed, set of stimuli. This suggests that a single receptor accepts a range of molecular entities and that a complex cross-fiber patterning of responses provides the neural code. Odorant binding leads to an inwardly depolarizing current within the cilia of the bipolar receptor cells, which leads to the triggering of the action potentials that collectively provide the information that is forwarded to higher brain centers.

Two approaches for functionally characterizing odorant receptors have been employed. In one, an adenovirus-mediated gene transfer procedure was used to increase the expression of a specific receptor

gene in rat olfactory receptors, demonstrating ligand-specific increases in the amplitude of summated electrical activity at the surface of the epithelium (termed the electro-olfactogram or EOG). In the other, an olfactory receptor library was generated using a polymerase chain reaction from which cloned receptors were screened for odorant-induced responsiveness to a panel of odorants (as measured by an assay of intracellular Ca^{2+} changes). Several receptor types with ligand specificity were found, including one differentially sensitive to the stereoisomers of citronellal.

B. Transduction Pathways

In general, olfactory receptor proteins are linked to the stimulatory guanine nucleotide-binding protein G_{olf}. When stimulated, they activate the enzyme adenyl cyclase to produce the second messenger adenosine monophosphate (cAMP). G_{olf}-induced cAMP activates cellular depolarization via the opening of cyclic-nucleotide-gated ionic channels and Ca^{2+}-dependent Cl^- or K^+ channels. The amount of adenylate cyclase activity produced by various odorants in a frog ciliary preparation is positively correlated with the magnitude of the frog's EOG, as well as with the perceived intensity of these same odorants to humans. Cyclic guanosine monophosphate (cGMP) is also activated by some odorants. cGMP is believed to play a role in the modulation of the sensitivity of olfactory receptor neurons, such as during adaptation. Although olfactory receptor cells express G proteins other than G_{olf} (e.g., G_{i2} and G_o), they probably are not involved in early transduction events. More likely they assist such processes as axonal signal propagation, axon sorting, and target innervation.

Before the discovery of G_{olf}, another G protein, $G_{s\alpha}$, was believed to play a major role in the initial phases of olfactory transduction in humans. Evidence for such a role came from findings of variably decreased olfactory ability in type Ia pseudohypoparathyroidism (PHP), a disease associated with generalized hormone resistance and a deficiency of $G_{s\alpha}$, as measured in erthrocytes. However, this disorder has other features that could cause or contribute to olfactory dysfunction, including Albright hereditary osteodystrophy (AHO), an unusual constellation of skeletal and developmental deficits. Whereas a more recent study has confirmed that PHP type Ia patients perform poorly on tests of odor detection, identification, and memory, patients with type Ib PHP, who have no AHO, no generalized hormone resistance, and normal $G_{s\alpha}$ activity, also exhibited olfactory dysfunction relative to matched controls. Furthermore, patients with pseudopseudohypoparathyroidism (PPHP), who have AHO, no generalized hormone resistance, and deficient $G_{s\alpha}$ protein activity, were found to have relatively normal olfactory function. These observations suggest that the olfactory dysfunction associated with PHP is not the result of generalized $G_{s\alpha}$ protein deficiency and imply that other mechanisms are responsible for the olfactory deficits of this disorder. Whether PHP patients are deficient in epithelial G_{olf} has not been determined.

Whereas a second transduction pathway—i.e., that which activates the enzyme phospholipase C to produce the second messenger inositol triphosphate (IP_3)—has been implicated in odor-mediated responses in some vertebrates, its involvement in mammalian olfaction is controversial. Recent studies have employed knockout mice in which genes responsible for both the cyclic-nucleotide-gated ion channel and G_{olf} have been deleted. In this mouse, EOG responses to all odors tested were eliminated, including those previously believed to be mediated by the IP_3 system. To date, IP_3-gated channels have not been demonstrated in mammalian olfactory nerve cells using patch clamp techniques.

III. OLFACTORY RECEPTOR CELL REGENERATION

The sensory cells of the olfactory epithelium have a propensity to replace themselves after damage, unlike the sensory neurons of most other major sensory systems. It was previously thought, on the basis of [^{3}H]thymidine studies, that the entire olfactory neuroepithelium undergoes complete cell turnover approximately every 30 days. However, it is now known that the situation is much more complex. Thus, long-lived receptor cells have been identified despite continuous neurogenesis within the basal sectors of the neuroepithelium, and endogenous and exogenous factors have been found that promote receptor cell death or replenishment from stem cells. There is evidence that some receptor cells of older animals may live longer than those of younger animals.

Subgroups of stem cells can be made to differentiate into mature olfactory receptor cells by stressing them mechanically or biochemically. Furthermore, differentiated neurons, in effect, send back regulatory signals to inform progenitor cells as to the number of

new neurons that need to be produced to maintain cell population equilibrium. Apoptotic cell death has been observed in cells representing all stages of regeneration (e.g., in proliferating neuronal precursors, immature olfactory receptor neurons, and mature olfactory receptor neurons), implying apoptotic regulation of neuron numbers at all levels of the neuronal lineage. The mitral cells of the bulb appear to contain a trophic substance that helps to maintain the survival of olfactory receptor neurons. Currently, there is considerable interest in chemical factors that inhibit (e.g., fibroblast growth factor-2, bone morphogenetic proteins, dopamine) or promote (e.g., transforming growth factor-α, olfactory marker protein) neurogenesis or differentiation or actively produce apoptotic cascades (e.g., tumor necrosis factor-α, Fas ligand).

It is of interest that the olfactory ensheathing cells, which form the bundles of axons that make up the olfactory fila, have unique properties useful in the repair or regeneration of both central and peripheral nerves. Thus, they enhance remyelination and axonal conduction in demyelinated spinal tract nerves, as well as in severed rat sciatic nerves, exhibiting both Schwann-cell-like and astrocyte-like properties.

IV. FUNCTIONAL IMAGING STUDIES OF THE HUMAN OLFACTORY SYSTEM

The development of functional imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI), has made it possible to determine, *in vivo*, brain regions influenced by odors, as well as by behaviors associated with smelling (e.g., sniffing). Although the spatial resolution of these techniques limits the degree to which activity in some structures can be visualized (e.g., the olfactory bulbs), odor-induced activation of most of the major olfactory-related cortical structures has been observed, albeit in some cases sporadically. Such activation includes the piriform cortex, the orbitofrontal cortex, and the inferior frontal lobe. Work suggests that the inconsistent fMRI activation of primary olfactory cortex (POC) may reflect sampling factors and temporal components of activation of these regions.

In accord with basic psychophysical observations are fMRI studies demonstrating decreased activation with age, as well as greater activation in women than in men. Also in accord with psychophysical findings are observations that the right hemisphere may be more specialized than the left for central olfactory processing, particularly regions within the orbitofrontal cortex. Odor familiarity judgments have been associated with increased rCBF in the right orbitofrontal area, the subcallosal gyrus, the left inferior and superior frontal gyri, and the anterior cingulate cortices. Edibility judgments made based on odors appear to be associated with selective activation in the primary visual areas, implying that visual imagery is evoked by this task.

An intriguing discovery from several functional imaging studies is that odors reliably and significantly activate regions of the human cerebellum, a structure classically considered to be involved primarily in motor learning. The cerebellar activity was unexpected and serendipitous in light of current knowledge of the olfactory projection pathways and views of the cerebellum, even though functional imaging studies have implicated this structure in a broad range of sensory and cognitive processing tasks. Odors appear to activate, in a concentration-dependent manner, largely posterior lateral areas of the cerebellum, whereas sniffing by itself tends to activate mainly anterior cerebellar regions.

V. PSYCHOPHYSICAL MEASUREMENT OF HUMAN OLFACTORY FUNCTION

During the past few years, psychophysical tests of olfactory function have become commonplace in medical, industrial, and academic centers, largely because of their widespread commercial availability. Traditionally, a determination of the lowest odorant concentration that can evoke a sensation or discernible odor quality was the primary means for assessing the ability to smell. Today, straightforward tests of odor identification and memory are widely used for this purpose.

A. Tests of Odor Identification

The proliferation of easy-to-use commercially available tests of odor identification has significantly increased our understanding of smell function in humans, including the influences of such factors as age, gender, exposure to toxic agents, and various disease states on its function. Such tests, most of which are self-administered, include a 3-odor Pocket Smell Test™, a 12-odor Brief-Smell Identification Test™, and the University of Pennsylvania Smell Identification Test (UPSIT, commercially known as the Smell

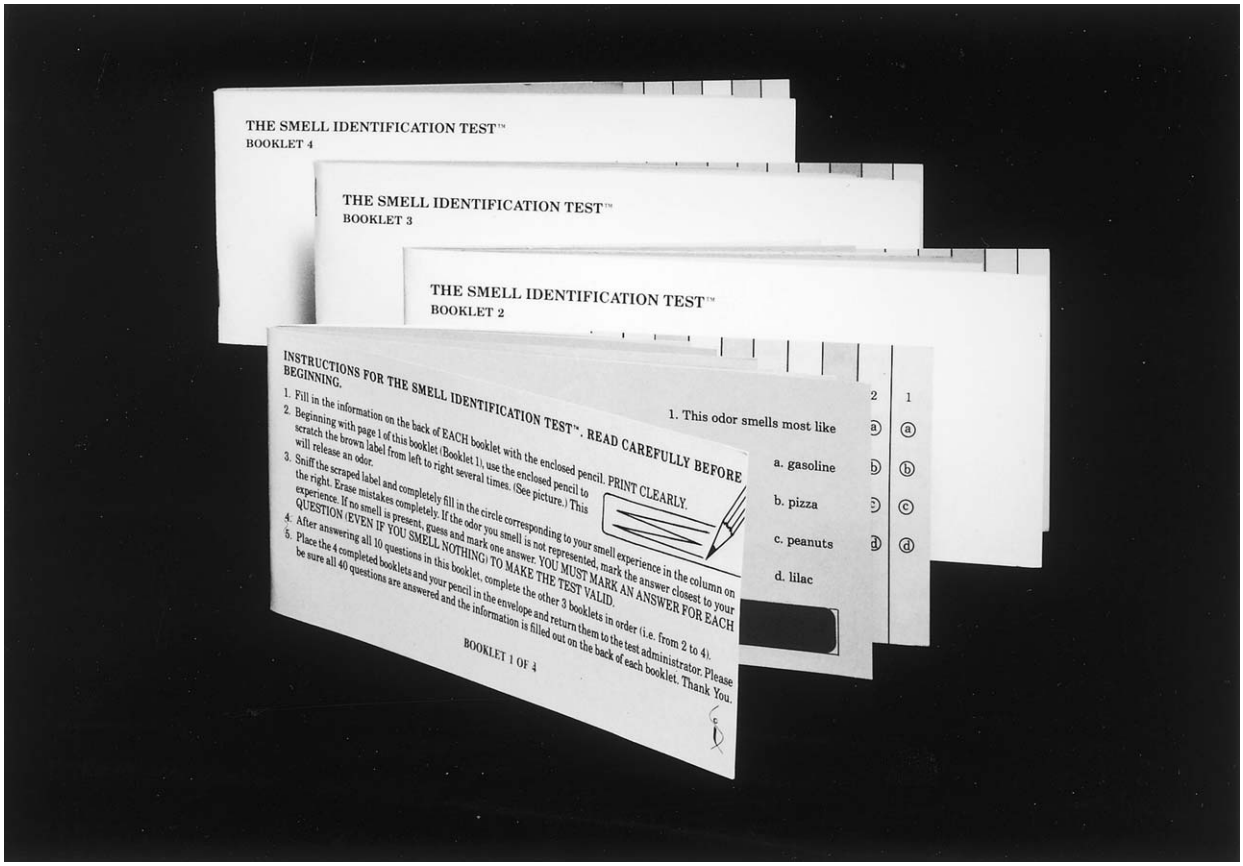

Figure 2 Picture of the University of Pennsylvania Smell Identification Test, the most widely used quantitive test for evaluating smell function. This test has been administered to nearly 200,000 persons over the past 15 years. Photo courtesy of Sensonics, Inc., Haddon Heights, NJ.

Identification Test™). Of these tests, the UPSIT has been employed the most widely, having been administered to ~180,000 people in Europe and North America in the past decade. This microencapsulated odorant test, shown in Fig. 2, employs norms based upon nearly 4,000 persons and is available in English, French, German, and Spanish language versions. In this test, the subject is asked to release, using a pencil tip, a microencapsulated odorant located on a page of a test booklet and to indicate its smell by responding to four alternatives. The subject's smell ability is divided into four categories of dysfunction (anosmia and mild, moderate, or severe microsmia) and one category of function (normosmia). Probable malingering is also defined on the basis of improbable responses (i.e., low test scores suggestive of avoidance of the correct responses). This highly reliable test (test–retest $r = 0.94$) was the impetus for a massive smell function survey sent to nearly 11 million subscribers of *National Geographic Magazine* in 1986.

B. Olfactory Threshold Measures

Before the advent of odor identification tests, olfactory threshold measures were the most common means employed for assessing human olfactory function. Today, such procedures are still used, although not as frequently as odor identification tests.

The lowest concentration of an odorant that can be reliably detected (usually defined as that concentration where detection is midway between chance and perfect detection) is termed the *detection* or *absolute threshold*. At very low concentrations, no odor quality can be discerned, only that something is present that differs from air or the comparison diluent blank or blanks. In modern olfactory detection threshold testing, the subject is asked to report which of two or more stimuli (i.e., an odorant and one or more blanks) smells strongest, rather than to simply report whether an odor is perceived. Such forced-choice procedures are less susceptible to contamination by response biases

(e.g., the conservatism or liberalism in reporting the presence of an odor under uncertain conditions) than non-forced-choice procedures. In addition, they are more reliable and produce lower threshold values. The instructions provided to a subject are critical in measuring a detection threshold, because if the subject is instructed to report which stimulus produces an odor rather than which stimulus is stronger, a spuriously high threshold value may result (odor quality is present only at higher perithreshold concentrations).

The *recognition threshold* is defined as the lowest concentration at which odor quality is reliably discerned. Unfortunately, it is nearly impossible to control criterion biases in recognition threshold measurements. Thus, in a forced-choice situation, guesses are not randomly distributed among alternatives, potentially leading to a spuriously low recognition threshold for the preferred alternative. A classic example of this problem comes from taste psychophysics, where some subjects report ''sour'' much more frequently than the other primary qualities in the absence of a clearly discernible stimulus, resulting in an erroneously low sour taste recognition threshold measure.

A third type of threshold is the *difference threshold*, the smallest amount by which a stimulus must be changed to make it perceptibly stronger or weaker. This is also termed a differential threshold or a just noticeable difference (JND). The size of the increment in odorant concentration (ΔI) required to produce a JND increases as the comparison concentration (I) increases, with the ratio approximating a constant, i.e., $\Delta I/I = C$.

Two types of procedures for determining detection thresholds have received the most use in the past two decades: the ascending method of limits procedure (AMS) and the single staircase procedure (SS). In the AML procedure, odorants are presented sequentially from low to high concentrations and the point of transition between detection and no detection is estimated. In the SS method, the concentration of the stimulus is increased following trials on which a subject fails to detect the stimulus and decreased following trials where correct detection occurs. An average of the up–down transitions (''reversals'') is used to estimate the threshold value. In both the AML and SS procedures, the direction of initial stimulus presentation is made from weak to strong in an effort to reduce potential adaptation effects of prior stimulation.

It has generally been believed that threshold measures exhibit considerable variability. Unfortunately, this conclusion is based mainly upon studies employing unreliable AML techniques for measuring detection thresholds. Procedures employing more trials, such as the SS procedure, produce less variable and more reliable measures than simple AML procedures and negate the notion that thresholds vary markedly from day to day within an individual.

A modern, commercially available threshold test kit that employs a SS procedure is shown in Fig. 3. This kit utilizes squeeze bottles containing various concentrations of an odorant known to stimulate primarily CN I. Norms based upon hundreds of subjects spanning the entire age range allow for the practical application of this test for medical and industrial uses.

Among the major findings derived from modern olfactory tests, primarily the UPSIT, are the following: first, there is a substantial genetic influence on the ability to identify odors; second, women, on average, have a better sense of smell than men, and this superiority is noticable as early as 4 years of age and is culture-independent; third, loss of significant olfactory function occurs after the age of 65 years, with over half of those between 65 and 80 years of age and over three-quarters of those 80 years of age and older having such loss (Fig. 4); fourth, women, on average, retain the ability to smell longer than men; fifth, the decreased smell ability associated with smoking is present in past smokers and recovery to presmoking levels, while possible, can take years depending upon the amount and duration of past smoking; and sixth, olfactory function is compromised in urban residents and in workers in some industries, including the paper and chemical manufacturing industries.

Clinical studies employing odor identification tests during this period have found decreased smell function, relative to matched controls, in dozens of diseases and disorders, including alcoholism, amyotrophic lateral sclerosis (ALS) and related forms of motor neuron disease, the ALS–parkinsonism–dementia complex of Guam (Guam disease or GD), attention deficit hyperactivity disorders, Alzheimer's disease (AD), estrogen-receptor-positive breast cancer, severe stage anorexia nervosa, chronic obstructive pulmonary disease, cystic fibrosis, Down's syndrome, epilepsy and surgical procedures designed to control intractible seizure activity, head trauma, human immunodeficiency virus, Huntington's disease, Kallmann's syndrome, Korsakoff's psychosis, multiple sclerosis, multiple system atrophy, nasopharyngeal carcinoma, nasosinus disease, Parkinson's disease, psychopathy, restless leg syndrome, schizophrenia, schizophrenia-like affective disorders, schizotypy, seasonal affective disorder, and Sjögren's syndrome. Additionally, a

Figure 3 A modern test kit for determining an odor detection threshold. This test kit comprises of bottles containing half-log concentrations of an odorant or blank. The pairs of stimuli (blank vs odorant) at a given concentration are presented in a randomized order, and a single staircase presentation procedure is employed across trials. Figure 4 Scores on the University of Pennsylvania Smell Identification Test (UPSIT) as a function of age and gender in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. From Doty *et al.* (1984). Smell identification ability: Changes with Age. *Science* **226,** 1441–1443. Copyright © American Association for the Advancement of Science.

number of studies have employed these tests in evaluating the effects of surgical or radiological interventions on the ability to smell. Psychophysical testing has found no meaningful smell losses in patients with corticobasal degeneration, depression, panic disorder, progressive supranuclear palsy, MPTP(1-methyl-4-phenyl-1,2,3,6-tetrohydropyridine)-induced parkinsonism, essential tremor, or multiple chemical hypersensitivity (MCS).

The ability to quantify olfactory function using such tests, along with the aforementioned advances in *in vivo* medical imaging, has made it possible to better understand the physiological basis of olfactory loss in some patients. For example, it is now apparent that congenital anosmia is associated with markedly deformed or absent olfactory bulbs and stalks. Furthermore, head-trauma-related smell loss is typically accompanied by contusions of the frontal and temporal poles of the brain, as well as diminuition in the size of the olfactory bulbs and tracts. The latter phenomenon may reflect mitigation of trophic factors from the olfactory receptor neurons, which are often sheared off or otherwise altered in head trauma. The smell loss associated with chronic alcoholism has been found to be correlated with MRI-determined (i) increased cortical and ventricular cerebral spinal fluid volumes and (ii) reduced volumes of the thalamus and of the cortical and subcortical gray matter.

VI. *IN UTERO* LEARNING OF ODORS

It has become increasingly evident, in a wide range of species including *Homo sapiens*, that the olfactory system is functional *in utero* and that intrauterine odor experiences can influence postnatal preferences and behaviors toward odors. Thus, in rats, intrauterine injections of odorants paired with lithium chloride (an agent that induces sickness) result in postnatal avoidance of the injected odorant. The olfactory system is functional by at least 20 gestational days, as rat fetuses transferred from the abdominal cavity of their mothers into saline without interrupting the maternal blood supply exhibit responses to odors. *In utero* learning of chemicals is also believed to occur in humans. Thus, human neonates find the odorous components of human amnionic fluid attractive postnatally. More importantly, the human newborn can distinguish between the odor of the amnionic fluid of his or her mother and that of a strange mother, preferring the former. Because these preferences are equivalent in formula- and breast-fed infants, they cannot be attributed to a generalization of learning of preferences of breast odors. Thus, human neonates selectively respond to the biological fluid they encountered within the prenatal environment.

VII. CONCLUSIONS

Remarkable progress has been made in the past decade in understanding the function of the olfactory system. At the transduction level, the discovery of the gene family that controls the expression of olfactory receptors has been a monumental event. At the ontological level, it is clear that the organism can sense odors long before birth and that experiences with odors in the uterus can alter postnatal odor preferences. At the psychophysical measurement level, the development and proliferation of practical and reliable olfactory tests have spawned hundreds of studies that otherwise would not have been made, demonstrating olfactory dysfunction in a wide range of clinical disorders and leading to the discovery that olfactory loss is a very early clinical sign of several major neurodegenerative diseases. The application of such new technologies as functional imaging is beginning to unravel the mysteries of central olfactory coding and should lead, within the next decade, to a much more complete understanding of the way the brain processes olfactory information.

Opiates

CLIFFORD M. KNAPP
Boston University School of Medicine and Boston Veterans Affairs Health Care System

GLOSSARY

analgesic A medication used to reduce pain.

brainstem Region consisting of the medulla, pons, and midbrain that connects the rest of the brain to the spinal cord.

medulla oblongata Lowest portion of the brain stem, which extends from the spinal cord to the pons.

nociceptors Peripheral elements of the nervous system (commonly nerve endings) that activate pain pathways when exposed to noxious stimuli.

periaqueductal gray matter Gray matter located in the midbrain that contains nuclei that are involved in modulating the perception of pain.

The term opiates connotes drugs containing opium, derivatives from opium such as morphine, and synthetic compounds that have pharmacological actions that are similar to those of morphine. The term opioids has been taken to mean non-opium derived compounds whose actions are similar to those of morphine, and also to designate endogenous substances such as β-endorphin that act upon the same receptors as do the opiates. These receptors referred to as opioid receptors have been cloned relatively recently, and their structure has become well-characterized. At present, by definition, any compound that interacts with these receptors is classified as being an opioid. Opioid agonists activate opioid receptors, producing effects such as analgesia and sedation that are produced by drug like morphine. Opioid antagonists block agonists from interacting with these receptor sites.

I. HISTORY

The Sumerians and Egyptians may have been familiar with the effects of opium. Theophrastus made one of the first clear references to opium in the third century BC. Opium is derived from the Greek word, opion, for poppy juice. Opium is a complex mixture of substances obtained from the juice of the poppy plant, *Papaver somniferum*. Opium is prepared by drying the milky juice of the poppy. The dried brown material is then powdered.

In 1806, the German chemist Fredrich Saturner isolated the pure alkaloid substance morphine from opium. Morphine was one of the first pure drugs to be isolated from a natural source. Codeine, whose chemical structure is very similar to that of morphine, was found in opium by Robiquet in 1832. The composition of opium consists of approximately 20 alkaloids. The concentration of morphine in opium is about 10%. Opium contains less than 0.5% codeine.

In 1874, the pharmacist C. R. Alder Wright produced heroin (diacetylmorphine) by boiling morphine with acetic anhydride. Heinrich Dreser at Bayer Laboratories in Germany developed a method for the synthesis of large quantities of heroin. This drug was

marketed in 1898 as a cough suppressant and for the treatment of respiratory disorders. At first it was believed that heroin did not have the addictive properties that were associated with morphine.

In the nineteenth century opium was used as an analgesic agent and a sedative and used to treat diarrhea produced by diseases such as cholera and dysentery. Opium was consumed in a variety of preparations. Laudanum is an example of such a preparation. It was prepared by dissolving opium in an alcoholic vehicle such as wine or port. Other ingredients were added to this mixture including cinnamon, cloves, or saffron. Paregoric is another opium-containing preparation that is still used for the treatment of diarrhea. It is a camphorated tincture of opium. Dover's powder consisted of powdered ipecac, a powerful emetic, and powdered opium. It was used as a diaphoretic (sweat-inducing) medication.

Opium was also a common ingredient in a large number of patent medications whose use became increasingly more widespread as society became industrialized. These products included "soothing syrups" that were used to sedate infants, a practice that may have led to the impaired development of many children. With no regulations controlling their sale, opium-containing preparations were consumed on a large scale by adults during the nineteenth century in both the United States and England.

With the introduction of the syringe, morphine could be administered by injection. Individuals with the means to purchase a syringe, i.e., members of the middle and upper classes, began to develop the habit of injecting themselves with morphine. This led to the appearance of an addictive disorder that was called morphinism. During the American Civil War, morphine was used as an analgesic agent and morphine dependence became a problem for many veterans of that conflict.

In 1878, Edward Levinstein wrote a study describing the character of morphine dependence. Toward the end of the nineteenth century and the beginning of the twentieth, the concept of opiate addiction as a specific disorder that needed to be studied and treated by the medical community began to be further developed and elaborated by T. D. Crothers, J. B. Mattison, and others. As the problems associated with addiction to opiates became more apparent, both public and governmental concern about the use of opiates grew. Governments became increasingly involved in attempts to control the problems associated with opiate use for nonmedical purposes. In the United States, the Harrison Narcotics Act was passed in 1914 as one of the first attempts at the federal level to regulate trade in opiates.

II. CHEMICAL CLASSIFICATION OF OPIATES

Morphine is a phenanthrene derivative (see Fig. 1). Many synthetic opiates are structural analogs of morphine. These include heroin, hydromorphone, hydrocodone and oxycodone (see Table I). Codeine, i.e., methylmorphine, although found in nature, is produced commercially by adding a methyl (CH_3) group to morphine. Some analogs of morphine are opioid receptor antagonists (see Table II). That is, they can block and reverse the effects of opiates. Naloxone is an example of an opioid antagonist that is synthesized by replacing the methyl group (CH_3) on the nitrogen (N) found in the structure of morphine with an allyl group ($CH_2CH=CH_2$).

Synthetic opiates also have been developed through the modification of the basic phenanthrene structure of morphine. Pentazocine is an example of such a compound, having a benzomorphan structure. Methadone and meperidine are examples of opiates whose structures are dissimilar from that of morphine (Fig. 2). Meperidine is a phenylpiperidine compound. Many synthetic opiates are piperidines or phenylpiperidines. Methadone is a phenylheptylamine agent, as is propoxyphene. Although methadone and propoxyphene have similar structures, methadone has much more efficacy as an analgesic agent than does propoxyphene, demonstrating that even modest alterations in the structure of an opiate can produce marked differences in the activity of opiate compounds.

III. OPIOID RECEPTORS

Opioid receptors are proteins that extend onto the surface of cell membranes and that act as communication links between the external environment and the cell by interacting with either drugs or neurotransmitters. These receptors are heptahelical structures, i.e., they loop between the inner and outer surfaces of the cell membrane seven times. Opioid receptors are located throughout the brain and spinal cord. They also are found on white blood cells and in the gastrointestinal tract.

The analgesic action of systemically administered opiates results from interaction of these agents with receptors located both in the spinal cord and in the brain. Pain arising from peripheral areas of the body is

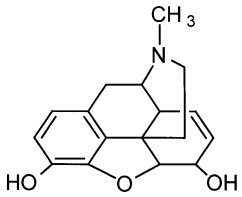

Figure 1 The chemical structure of morphine.

Table II
Opioid Receptor Antagonists

Generic name	Trade name
Nalmefene	Revex
Naloxone	Narcan
Naltrexone	ReVia

produced by the stimulation of nociceptors that arise from dorsal root neurons located in the spinal cord. Pain signals are transmitted via either myelinated axons of the A group or unmyelinated C fibers. Activation of C fibers results in release of the sensory neurotransmitter substance P in the spinal cord. Infusion of morphine and other opiates into the dorsal horn can block the transmission of pain stimuli. This may, in part, be due to morphine-induced inhibition of substance P release. In the brain, morphine and other opiate analgesics block pain by interacting with receptor sites located in the periaqueductal gray and other areas. Opiates, when administered into the brain, may activate inhibitory descending pain pathways that project down into the spinal cord.

Table I
Chemical Classification of Opiates

Chemical class	Generic name (Trade name)
Phenanthrenes	Buprenorphine (Buprenex)
	Codeine
	Hydrocodone (Hycodan, in Vicodin)
	Hydromorphone (Dilaudid)
	Morphine
	Nalbuphine (Nubain)
	Oxycodone (Oxycontin)
Benzmorphans	Dezocine (Dalgan)
	Pentazocine (Talwin)
Morphinans	Butorphanol (Stadol)
	Levorphanol (Levo-Dromoran)
Phenylpiperidines and piperidines	Alfentanil (Alfenta)
	Diphenoxylate (in lomotil)
	Fentanyl (Sublimaze)
	Loperamide (Imodium)
	Meperidine (Demerol)
	Remifentanil (Ultiva)
	Sufentanil (Sufenta)
Phenylheptylamines	Levomethadyl (Orlaam)
	Methadone (Dolophine)
	Propoxyphene (Darvon, in Darvocet)

Opiates have been show to interact with three types of receptors: the μ (mu), δ (delta), and κ (kappa) receptors. Endorphins, enkephalins, and dynorphins, peptide substances that are naturally produced in the body, can also activate these receptors. A fourth type of opioid receptor has been identified, the orphan receptor. The orphan receptor does not appear to play a role in the analgesic actions of opiates. An endogenous substance called nociceptin–orphanin FQ activates this receptor.

The effects of a particular opioid are determined by the nature of its interaction with the opioid receptors, that is, what types of receptors it acts on and to what extent it activates the specific receptor types with which it interacts. Many opiates, including morphine, meperidine, codeine, and oxycodone, exert their analgesic effects primarily by stimulating μ receptors. Opiates differ with respect to the maximal analgesic action (efficacy) that can be produced by the administration

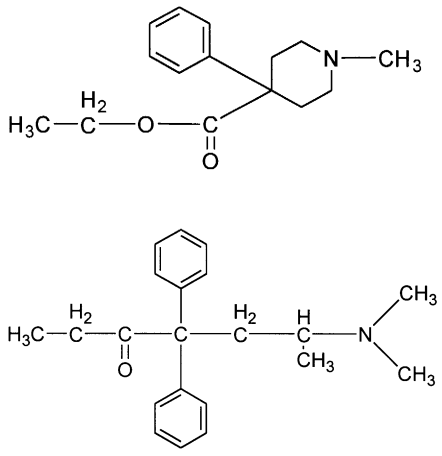

Figure 2 The chemical structures of meperidine (top) and methadone (bottom).

Table III
Maximal Efficacy of Opiate Analgesics

High efficacy (Severe pain)	Moderate efficacy (Moderate pain)	Low efficacy (Mild pain)
Morphine	Hydrocodone	Codeine
Fentanyl	Oxycodone	Propoxyphene

Levorphanol	Tramadol	
Meperidine		
Methadone		
Butorphanol		
Nalbuphine		
Buprenorphine		

of high doses of them (Table III). Morphine can almost fully activate these receptors and, consequently, in sufficient doses can be used to relieve severe pain. The maximal efficacy of codeine is much lower than is that of morphine. Thus, the administration of even high doses of codeine can not reduce severe pain to tolerable levels.

Opiates that cannot produce maximal activation of opiate receptors are referred to as partial receptor agonists. Buprenorphine is a well-characterized partial, μ-receptor agonist for which there seems to be a limit (ceiling) to the degree to which it can produce adverse effects, such as respiratory depression. This can be contrasted with morphine, which at high enough doses depresses respiration severely enough to cause death.

Antagonists such as naloxone do not activate opioid receptors, but instead block opioid agonists from stimulating receptors. Nalbuphine, butorphanol, dezocine, and pentazocine are examples of mixed agonist–antagonists. These agents are either μ-receptor antagonists or partial agonists but also act as agonists at the κ receptor. Because mixed agonist–antagonist opiates have a pattern of interaction with opioid receptors different from that of μ-selective agonists such as morphine, they produce a distinct range of effects.

IV. THERAPEUTIC USES

Opiates are administered to relieve pain that ranges in intensity from mild to severe. These agents can often reduce pain at doses that do not markedly diminish the perceptions of other kinds of sensations. Pain that results from the activation of pain pathways by noxious stimuli is usually alleviated by the administration of opiates. Neuropathic pain, i.e., pain resulting from nerve damage or irritation, frequently is not readily decreased by opiates unless they are administered in high doses.

Experimental evidence suggests that morphine and other opiates can elevate the threshold level for the amount of noxious stimulation needed for pain to be experienced. There is usually a large emotional component that contributes to the distress and discomfort produced by pain. The experience of pain may involve reactions of panic, anxiety, fear, and depression. The administration of opiates can produce calming and sedative effects that make pain more tolerable. Thus, whereas opiates may not eliminate all sensation of pain patients may find that it is no longer bothersome. After the administration of high doses of opiates, patients may exhibit what appears to be indifference to pain.

Codeine and hydrocodone are used to decrease coughing. These drugs and most of the other opiates will act in the medulla to diminish the effects of stimuli that activate the cough reflex. Reduction of coughing can provide patients with respite from the physical demands of coughing and from its disruptive effects on rest and sleep. Coughing, however, can play a role in the elimination of secretions, so that problems such as airway obstruction may occur if coughing is suppressed in certain situations.

Opium has been used to treat diarrhea for many centuries. Drugs that are currently used for this purpose are listed in Table IV. The administration of opiates decreases propulsive peristaltic waves in the colon and can increase colon tone. These actions reduce the rate of transit of material through the colon, which leads to enhanced resorption of water from fecal matter. The drier fecal matter is retained longer in the colon.

Opiates are used for the induction and maintenance of surgical anesthesia and to reduce the discomfort produced by medical procedures such as endoscopy. The use of these agents for these purposes has increased with the introduction of opiates such as fentanyl and related compounds that enter the brain rapidly and are cleared from the blood rapidly. During induction of anesthesia, opiates are often administered in combination with sedative agents such as midazolam (Versed) and propofol (Diprivan). Coadministration of opiates reduces the amount of anesthetic gas that needs to be administered to maintain anesthesia. When administered during surgery, opiates can reduce

Table IV

Major Adverse Effects Associated with Opiate Administration

Respiratory depression
Nausea and vomiting
Constipation
Pupil constriction
Hallucinations and bizarre thoughts (mixed antagonist–agonists)
Sedation and impaired concentration
Mood alteration
Itching

increases in blood pressure and heart rate that may occur in response to surgical procedures.

As will be discussed in greater detail later, some opiates are used in the treatment of opioid dependence. Methadone and L-α-acetylmethadol (levomethadyl, LAAM) are currently utilized as substitutes for drugs like heroin. Methadone is also used to facilitate detoxification from opiates. Buprenorphine is being investigated as an agent that can substitute for street opiates and that can be used to decrease the severity of symptoms associated with heroin withdrawal that occur during detoxification.

V. ADVERSE EFFECTS

The administration of opiates may produce a variety of toxic effects (Table V). The occurrence of these effects places a limit on the usefulness of opiate agents in the treatment of pain. Intensive efforts have been put into the development of synthetic opiate analgesics that can provide relief from pain while minimizing adverse effects. Morphine, however, still remains one of the best medications available for the treatment of severe pain.

Morphine and other opiates act on respiratory control centers in the brain stem to inhibit respiration. Deaths that result from opiate overdose are often the result of respiratory depression. The administration of higher doses of morphine depresses both respiratory rate and the volume of air exchanged during respiration. Opiates appear to decrease the sensitivity of respiratory centers to carbon dioxide, a compound that, under normal conditions acts as a respiratory stimulant.

Opiate-induced depression of respiration can be markedly enhanced by the concurrent administration of central nervous system depressants, including sedatives, anesthetic agents, or alcohol. Patients with respiratory disorders such as emphysema are particularly sensitive to the respiratory depressant effects of opiates, so that caution needs to be exercised when administering these agents to such patients. Similar caution needs to be exercised when opiates are administered to head injury patients.

Many patients experience nausea and vomiting following the administration of opiates. These effects are more likely to occur in patients when they are ambulatory, with up to 40% of these patients experiencing nausea and 15% vomiting. Morphine and other opiates may produce nausea and vomiting by acting on the chemoreceptor trigger zone located in the medulla. They also may act on elements of the vestibular system, the system that regulates balance.

Opiates act directly on receptors located in the gastrointestinal tract. These actions produce a reduction in the rate of transit of fecal material through the colon. These effects may play a role in the production of opiate-induced constipation. Opiates may blunt the awareness of stimuli that promote defecation. This may be another factor that leads to opiate-related constipation. Only a limited amount of tolerance develops to the constipating effects of opiates. Patients who must receive opiates for prolonged periods of time often experience severe constipation. This problem can frequently be corrected by increasing the amount of bulk fiber that patients consume in their diet and by administering stool softeners and laxatives. Mixed agonist–antagonist agents such as pentazocine and nalbuphine are less likely to produce constipation than are other opiates.

The administration of opiates can produce constriction of the smooth muscle of the gallbladder. Administration of morphine may cause the sphincter of Oddi in the bile duct to constrict and can greatly increase pressure within this duct. Pressure within the gallbladder also may be increased by morphine treatment. These effects of opiates on the gallbladder may cause some patients to experience epigastric discomfort or, in some cases, even the severe pain associated with biliary colic.

Opiate administration can increase the tone of the urinary bladder and the ureters. Treatment with morphine can promote the retention of urine by inhibiting the urinary voiding reflex and by increasing the tone of the bladder's external sphincter. Opiates can have an antidiuretic effect that can lead to reduced urine flow.

Pupil constriction, miosis, is frequently observed after the administration of opiates. This effect results from the activation of parasympathetic nerves. Tolerance to the pupil-constricting effect of opioids does not readily develop. Because of the persistence of opiate-induced pupil constriction, the presence of miosis can be used to establish a diagnosis of opiate-induced toxicity even in individuals who have been using opiates on a chronic basis.

Sedation is often produced by the administration of opiates. Whereas this effect is sometimes of value in helping patients to rest, it can become bothersome particularly in patients who need to receive opiates over prolonged periods of time. Opiate treatment also often results in difficulty in concentrating and other forms of cognitive impairment. Tolerance to the sedative effects of opiates often may develop rapidly.

Opiates can alter mood in a number of ways. Individuals who have abused opiates may experience euphoria and a sense of calm after the administration of heroin, morphine, or related drugs. In contrast, individuals without a history of drug abuse may feel dysphoric when being treated with opiates. For some individuals, opiates may relieve symptoms of depression and decrease feelings of anger and anxiety. It has been suggested that such individuals may seek out opiates to provide relief from symptoms of psychological distress.

Several unpleasant psychological effects, including hallucinations, bizarre thoughts, dysphoria, and anxiety, may occur in patients being treated with the mixed agonist–antagonist pentazocine. Similar effects may be produced by the administration of other mixed agonist–antagonists such as nalbuphine or butarphanol. However, hallucinations and bizarre thoughts occur with greater frequency with pentazocine administration than during treatment with either nalbuphine or butorphanol.

The acute administration of opiates can disrupt hormonal regulation of physiological activity. Endocrine effects of opiates include the inhibition of the release of gonadotropin-releasing hormone (GRH). This hormone facilitates the release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH), both of which play important roles in reproductive processes. Opiate administration can disrupt the menstrual cycle of women and cause a reduction in testosterone levels in men. Opiates can also inhibit the release of corticotrophin-releasing factor (CRF). This factor promotes the release of adrenocortropic hormone (ACTH), which enhances the release of cortisol, a hormone that helps the body in reacting to stress. Concentrations of the hormone prolactin are increased in the blood by the administration of morphine and heroin. Tolerance develops to the disruptive effects of opiates on hormone release.

Opiates can produce peripheral vasodilation and will decrease peripheral resistance. These effects may cause patients who are being treated with opiates to sometimes experience a sudden drop in blood pressure when they sit or stand up rapidly. Opiate-induced reductions in blood pressure can be a source of risk for patients who have reduced blood volumes produced by internal hemorrhage or other factors.

Administration of the mixed agonist–antagonist agent pentazocine, in contrast to that of μ-receptor agonists like morphine, can result in an elevation in blood pressure and an increase in heart rate. These effects are not produced by the administration of therapeutic doses of the mixed agonist–antagonist nalbuphine.

Morphine administration may lead to the release of histamine which can produce itching and contributes to the morphine-induced vasodilation, allergic reactions such as skin rashes may be produced by the administration of opiates. Such allergic responses to opiates, however, occur only rarely.

The toxic effects of an acute overdose of opiates can include impaired consciousness, which can grade into coma, pupil constriction, and respiratory depression, sometimes occurring in conjunction with fluid accumulation in the lungs. Seizure may occur after high doses of opiates have been administered. Pupils will become dilated if respiratory depression produces marked decreases in blood oxygen levels. Patients who are experiencing symptoms of opiate overdose need to have adequate ventilation reestablished. Administration of the opioid antagonist naloxone will reverse the toxic effects of most opiates. Reversal may be difficult to achieve in the case of certain agents, such as buprenorphine.

VI. OPIATE DISPOSITION AND CLEARANCE

A. Absorption

Many of the opiates are well-absorbed when administered orally. Morphine, when absorbed from the

gastrointestinal tract, is extensively metabolized in the liver. This "first pass" metabolism involves a chemical reaction in which glucuronide is added to morphine to form morphine glucuronide. Oral doses of morphine therefore must be larger than the doses used when morphine is injected to produce analgesia. Chemical modification of the morphine molecule can provide protection from the first pass effect. Morphine analogs such as codeine and oxycodone, for example, are not extensively biotransformed in the liver as they pass from the gastrointestinal tract into the general circulation.

Fentanyl will readily pass through the skin, thus allowing it to be administered transdermally. Fentanyl has been added to patches that can be attached to the skin. These transdermal fentanyl patches can be used to produce analgesia over prolonged periods of time (up to 72 hr).

B. Distribution

In most cases, opiates need to reach sites in the brain, such as the periaqueductal gray, to produce analgesia. The brain is protected by the blood–brain barrier, which acts to hinder many compounds from crossing into the cerebral spinal fluid (CSF) that bathes the brain. Opiates such as codeine, hydromorphone, and heroin readily cross the blood–brain barrier to enter into the CSF. The entry of morphine into the brain is, in contrast, somewhat delayed, and the onset of the central effects of this agent is slower than the onset of action of compounds such as heroin. Another opiate, loperamide, is effectively blocked by the blood–brain barrier. This drug, when administered in the treatment of diarrhoea, does not produce the sedation and euphoria that may result from the administration of morphine and many of the other opiates.

C. Metabolism

The biotransformation of exogenous chemicals often results in a decrease in the activity of the parent compound and frequently leads to the production of compounds that are readily excreted into the urine. Morphine combines with glucuronic acid in the liver to form glucuronides that pass into the urine more readily than does morphine itself. Morphine is primarily converted to morphine 3-glucuronide, but morphine 6-glucuronide is also formed. Interestingly, morphine 6-glucuronide acts similarly to morphine. In patients who are receiving morphine on a chronic basis, the 6-glucuronide metabolite may play a significant role in the production of analgesia. This metabolite is eliminated into the urine, and decreased kidney function can lead to a reduction in the rate at which morphine 6-glucuronide is eliminated from the body.

Normeperidine is produced by the biotransformation of meperidine. This product can accumulate in the body if meperidine is repeatedly administered to patients who have severely compromised kidney function. These patients may experience neurotoxic effects as normeperidine accumulates in the body. These effects can include the development of seizures, tremors, twitching, and mental confusion.

Renal function is often decreased in elderly individuals. Caution must be exercised when agents like morphine or meperidine, drugs that form toxic metabolites that are eliminated via the kidney, are administered to older individuals.

Heroin is rapidly hydrolyzed into 6-monoacetylmorphine, which then undergoes conversion to morphine. Heroin itself may have little activity at opioid receptors. In contrast, 6-monoacetylmorphine readily stimulates these receptors. The euphoria and analgesia produced by heroin administration are due in large part to the actions of its metabolites, morphine and 6-monoacetylmorphine. Similarly, codeine does not readily stimulate opioid receptors, and much of its analgesic actions may be produced by morphine that is formed by the metabolism of codeine.

Codeine, oxycodone, and hydromorphone are metabolized in the liver by the enzyme cytochrome P450. This enzyme exists in many forms, and it is the CYP2D6 form that has been implicated in the biotransformation of these compounds. Some individuals may have mutant forms of CYP2D6 that do not act as efficiently as enzymes as they do in most of the population. Individuals with these forms of CYP2D6 are poor metabolizers of codeine and related drugs. Poor metabolizers of codeine may include between 4 and 10% of populations with European ancestry.

L-α-Acetylmethadol (LAAM) is structurally related to methadone. This drug is used like methadone to reduce the use of heroin and other abused opiates by reducing opiate-related withdrawal symptoms and craving for opiates. The metabolites of LAAM, noracetylmethadol and dinoracetylmethadol, have activity that is similar to that of methadone. These metabolites remain in the plasma for a relatively long period of time. Consequently, LAAM administration

may be effective in preventing opiate withdrawal from developing in heroin addicts for 3–4 days after the administration of a single dose.

VII. TOLERANCE AND PHYSICAL DEPENDENCE

Many of the effects of morphine and the other opiates diminish in magnitude if they are repeatedly administered. This reduction in opiate efficacy is a form of drug tolerance. Opiate tolerance entails both reduced duration and reduced intensity of opiate-induced effects. Profound tolerance can develop to the analgesic and sedative effects of opiates. Marked tolerance can also develop to opiate-induced respiratory depression, nausea, and vomiting. In contrast, tolerance to opiate-induced miosis and constipation tends to be limited in extent.

The development of tolerance to the analgesic effects of opiates can be a problem for patients with conditions, such as cancer, that must be treated with these agents over long spans of time. Very large doses of opiates may have to be administered to produce analgesia in these patients. Patients with malignant disorders, however, may require increased doses of opiates to control pain because of factors other than tolerance. These factors include tumor growth, impingement of tumor onto nerves, and the development of inflammation at the tumor site.

Patients who are treated chronically with opiates and addicts who continually self-administer opiates experience symptoms of withdrawal either when opiate administration is discontinued or when an opioid antagonist such as naloxone is administered. Symptoms of withdrawal may also appear when mixed agonist–antagonist agents such as pentazocine are administered to individuals who have become physically dependent on opiates. Withdrawal symptoms in individuals who have been receiving μ-receptor agonists such as morphine and heroin include a runny nose, tearing, abdominal cramps, muscle pain, gooseflesh, nausea, anxiety, difficulty sleeping, yawning, sweating, restlessness, and dysphoric feelings. This complex of symptoms bears a resemblance to an influenza-like illness.

Addicts often experience intense cravings for opiates during withdrawal that can last for extended periods. In contrast, most patients who have been receiving opiates for therapeutic purposes, particularly those without a prior history of substance abuse, do not experience a compulsive need for these drugs. Some patients display what might be interpreted as addict-like behavior if they experience pain because inadequate doses of opiates are being administered. These patients may become angry and will make frequent requests for pain medications. Such requests are expressions of genuine need for pain relief and should not be confused with the compulsive drug-seeking behavior that is associated with addictive disorders.

The administration of an opioid antagonist such as naloxone can precipitate an intense episode of withdrawal in dependent individuals within a matter of minutes. The time at which withdrawal symptoms occur after the discontinuation of opiate administration is directly related to the rate of clearance of opiate from the body. Withdrawal may occur in 8–12 hr after the termination of rapidly cleared drugs, such as heroin, hydromorphone, or morphine. Symptoms of withdrawal from methadone, which is slowly eliminated from the body, may not appear until 36–48 hr after its discontinuation.

VIII. OPIATE ADDICTION

A. Opiate Dependence and Abuse

Addiction to opiates involves the compulsive use of opiates for nonmedical purposes that may stem from the motivation to experience the pleasant sensations produced by opiates and to prevent the onset of withdrawal symptoms. In an effort to more precisely characterize opiate addiction, the diagnostic categories of opioid abuse and dependence have been developed. Abuse entails recurrent drug use, but the use is not frequent enough to result in marked physical dependence. The opioid-dependent individual compulsively uses opiates and does so frequently enough to become physically dependent on them. Dependent individuals will persist in self-administering opiates even when such behavior results in significant physical, social, psychological, and/or financial harm.

Opiate addiction frequently involves the use of heroin. When administered intravenously, this drug may produce a short-lived, pleasurable sensation known as a "rush" that may occur even in individuals who have developed marked tolerance to the effects of opiates. As an alternative to intravenous administration, the practice of smoking heroin has become more common. In addition to heroin, commercially marketed opiates such as hydromorphone (Dilaudid) and oxycodone-containing products including Percocet,

Percodan, and Oxycontin may be self-administered by individuals with opiate use problems.

The reasons for the development of opioid dependence are, despite extensive investigation, in many respects still poorly understood. The social environment can play a critical role in who will become and remain dependent. This is illustrated by the finding that, whereas heroin was used extensively by American soldiers who fought in the Vietnam Conflict, the incidence of heroin use by these individuals was markedly reduced when they returned to their lives at home in the United States. Patterns of opiate use appear to vary over the course of history. As mentioned earlier, opium and morphine addiction became prevalent during the nineteenth century. Following a wane in opiate addiction, heroin dependence increased in the 1960s and 1970s and began to increase again in the 1990s. Fluctuations in opiate use over time serve as additional support for the view that social factors are involved in regulating the incidence of opiate addiction in a society.

The pleasurable effects that opiate users experience during the self-administration of heroin, morphine, and related agents may play an important role in the development and maintenance of opiate addiction. These pleasurable effects may result from the interaction of opiates with areas of the brain that are responsible for the seeking of rewarding stimuli in the environment. These areas include the ventral tegmental area and the nucleus accumbens of the brain. These structures are part of the mesolimbic system. Dopamine is a primary neurotransmitter within this system that has been linked to the rewarding actions of drugs. Morphine and other μ-receptor agonists act within the ventral tegmental area to enhance the release of dopamine, particularly in the nucleus accumbens. In contrast, compounds that activate κ receptors do not promote dopamine release, which may explain why the administration of κ agonists such as pentazocine produces dysphoria more often than euphoria.

During prolonged abstinence, former users of heroin and other opiates may become depressed and feel heightened distress in stressful situations. They also may feel anxious and experience other forms of psychological discomfort. It has been hypothesized that these feelings of discomfort, which may last for months after opiate withdrawal, may contribute to relapse to drug use. Whereas biological factors may play a role in the persistence of this discomfort, at present the identity of these factors remains to be discovered.

B. Treatment of Opiate Withdrawal and Opiate Dependence

Patients who are not psychologically dependent on opiates can usually be withdrawn from these agents by gradually tapering the daily dose of the drug. Withdrawal can be assisted, if necessary, by the administration of α_2-noradrenergic agents such as clonidine and lofexidine. These drugs can attenuate many symptoms of withdrawal, including nausea, vomiting, sweating, cramps, and diarrhea. Clonidine and lofexidine will not, however, reduce drug craving.

The opiate buprenorphine has been used to facilitate opioid withdrawal. The administration of buprenorphine to opiate-dependent individuals may reduce withdrawal symptoms, including drug craving. Unlike α_2-noradrenergic receptor agents such as clonidine, buprenorphine administration does not produce a marked decrease in blood pressure. Patients will experience mild symptoms of withdrawal after buprenorphine administration has been discontinued.

Many individuals with a history of opioid dependence are unable to remain abstinent following initial periods of withdrawal. Opioid substitution therapy has been devised as an approach to integrate these individuals back into the mainstream of society. Methadone is the drug that has been used most frequently for this purpose. LAAM has also been used in substitution therapy. Because they are slowly cleared from the body, methadone and LAAM allow opiate-dependent individuals to remain free of withdrawal symptoms throughout the day. This allows these individuals to work and engage in other forms of normal daily activities and frees them from the compulsive pursuit of drugs and the disruptive effects of the rapid changes in mood that are associated with heroin use.

IX. MOLECULAR BIOLOGY OF OPIOID SYSTEMS

Genes for the μ-, δ-, and κ-opioid receptors have all been cloned. *MOR-1* is a gene that encodes for the μ receptor. Morphine will not produce analgesia in mice that are missing the *MOR-1* gene. *DOR-1* is a δ-receptor gene and *KOR-1* is a κ-receptor gene. There is evidence that variants (subtypes) of the μ-, δ-, and κ-opioid receptors may exist, but the existence of distinct genes that encode for each of these receptor subtypes has yet to be demonstrated. The possibility also exists, however, that different opioid receptor subtypes could result from processes such as alternative pathways of

RNA splicing that might occur after the messenger RNA is formed by transcription of opioid receptor genes.

Opioid genes contain information for the synthesis of opioid receptors in the cell. These receptors are composed of amino acids that are linked together to form the receptor protein. The μ-, δ-, and κ-opioid receptors share between 50 and 70% of the same amino acid structure.

The activation of opioid receptors by endogenous peptides may serve a variety of important functions, including helping animals to survive the occurrence of traumatic stress and injury. Specific examples of endogenous opioid peptides are β-endorphin, methionine- and leucine-enkephalin, and dynorphins A and B. These peptides are derived from the breakdown of larger precursor molecules. Prepro-opiomelanocortin (POMC) is the precursor of β-endorphin and also several other bioactive substances, including ACTH, melanocyte-stimulating hormone, met-enkephalin, and β-lipotropin. Met- and leu-enkephalin are derived from preproenkephalin, whereas dynorphins A and B are produced from preprodynorphin.

Opioid receptors belong to the G-protein superfamily, meaning that they are coupled to G proteins. These proteins act to link drug-induced changes in receptors to the internal function of the cell. Opioid receptors are coupled to G_1 and G_0 proteins. Opioid receptors interact with these G proteins to inhibit adenylate cyclase, an enzyme that promotes the formation of the intracellular messenger cyclic adenosine 3′,5′- monophosphate (cyclic AMP). G proteins also may mediate the inhibitory effects of opioids on voltage-gated calcium channels and their activating effects on inwardly rectifying potassium channels. Inhibition of calcium channels may lead to a decrease in the release of neurotransmitters such as substance P, which mediates pain signals. Opioids may have a host of other effects on cells, including the activation of phospholipase A_2 (PLA_2) and protein kinase C, enzymes that regulate a number of cellular activities. Opioid-induced activation of PLA_2 in the periaqueductal gray region increases voltage-sensitive potassium conduction. This effect produces inhibition of the activity of cells in this region that can release the inhibitory neurotransmitter γ-aminobutyric acid (GABA). This action, in turn, may produce disinhibition (i.e., activation) of inhibitory descending pathways that block pain signals that ascend through the spinal cord.

Chronic exposure to opiates leads to the development of both tolerance to and dependence on these agents. The exact nature of the changes within neurons that are responsible for the occurrence of opiate tolerance and dependence remains to be fully characterized. Tolerance to the analgesic effects of opiates can be reduced by the administration of agents that block the effects of the excitatory neurotransmitter glutamate at the *N*-methyl-D-aspartate (NMDA) receptor. This suggests that these receptors play some important role in the development of opioid tolerance. NMDA receptors also may be involved in the development of sensitization to the effects of opiates. Opiate-induced sensitization may occur after the repeated administration of drugs like morphine and is characterized by enhanced sensitivity to the motor-activity-enhancing effects of opiates.

The effects of opioid exposure on neurons of the brain structure called the locus ceruleus have been examined in an effort to discover the mechanisms that are involved in the appearance of opiate withdrawal. Compounds that are μ agonists will act to inhibit the activity of neurons in the locus ceruleus. This structure contains many of the brain's norepinephrine neurons, which, when activated, may play a role in the production of anxiety. Opiates may decrease anxiety by inhibiting the firing of cells located in the locus ceruleus. This may occur because opiates decrease the excitability of these cells by opening potassium channels in the cell membrane and by blocking sodium channels. After acute administration, opiates will decrease levels of cyclic AMP. Chronic exposure of locus ceruleus cells to opiates results in an increase in the excitability of cells. This increase in excitability becomes evident following the withdrawal of opioids after periods of prolonged treatment with these agents. Opioid-induced increases in cellular excitability may be produced by increases in cyclic AMP levels, which leads to enhanced activity of sodium channels. Chronic opioid administration may up-regulate cyclic AMP systems by increasing certain forms of adenylate cyclase, the enzyme responsible for cyclic AMP formation. CREB (cyclic AMP response-element-binding protein) is a cyclic-AMP-regulated transcription factor that may play a key role in the opioid-induced increases in adenylate cyclase activity. Opiate withdrawal appears to be less severe in mice that are CREB-deficient.

Following agonist activation of opioid receptors, G-protein-coupled receptor kinases (GRKs) may add a phosphate group to these receptors and facilitate their interaction with β-arrestin 2. When bound to opioid receptors, β-arrestin may inactivate the receptor. It has been hypothesized that β-arrestins may play a role in

the desensitization of opioid receptors that occurs when they are exposed to agonists for prolonged periods of time. It has been shown that the analgesic effects of morphine will persist for much longer than usual in animals that do not have the gene for β-arrestin 2. This finding supports the idea that β-arrestins may play a role in the development of reduced sensitivity to opiates. There is evidence that this form of desensitization is involved in the development of tolerance to the effects of opiates that is associated with the chronic administration of these agents.

X. SUMMARY

Opiates remain the most efficacious agents available for the treatment of severe pain. Unfortunately, they produce a range of adverse effects, including sedation, nausea, and respiratory depression, that make these medications difficult for some patients to tolerate. The development of opiate tolerance and dependence is another concern associated with the use of opiates for therapeutic purposes, particularly when they are needed for the treatment of chronic pain. Problems associated with the abuse of heroin and related drugs have become an increasing concern as infection with the human immunodeficiency virus (HIV) has become widespread in individuals who self-administer drugs by injection or who engage in other high risk behaviors associated with drug cultures.

The use of molecular biological techniques has begun to greatly expand our understanding of how opioid systems function in the brain and other areas of the body. The opioid receptors have been cloned and their molecular structures are now known. Work has begun on how opiates can act through these receptors to influence activity in the cell via intermediary messengers such as cyclic AMP. As knowledge concerning the molecular basis of the interaction between opiates and cell function increases, solutions to the problems currently associated with opiate use and abuse may begin to emerge.

Oxytocin

HANS H. ZINGG
McGill University

GLOSSARY

action potential Short-lasting depolarization of the neuronal cell membrane that is propagated along the neuronal processes.

exocytosis The process by which a secretory granule fuses with the cell membrane and releases its content into the extracellular space.

hypothalamo–neurohypophysial system A neuronal system that consists of neurons that are present in two specific nuclei of the hypothalamus (supraoptic and paraventricular nuclei) and that extend their axons to the neurohypophysis.

magnocellular neuron Specific neuron type present in the supraoptic and paraventricular nuclei of the hypothalamus. These neurons are capable of producing and secreting large amounts of secretory peptides (mostly vasopressin and oxytocin) and releasing them into the general circulation. They represent a classical example of neuroendocrine cells. To be distinguished from the smaller parvicellular neurons, present in the paraventricular nucleus which do not project to the neurohypophysis.

neurohypophysis (synonyms: neural lobe of the pituitary, posterior pituitary) Site of release of oxytocin and vasopressin into the general circulation. It consists of the posterior part of the pituitary gland and contains the nerve endings of magnocellular hypothalamic OT- and AVP-producing neurons.

neurosecretion Release of a soluble messenger from a neuron mostly, but not exclusively, from axon terminals.

secretory granule Intracellular particle that contains secretory peptides and is surrounded by a bilayer membrane. Secretory granules are produced at the level of the cell body, involving the so-called Golgi apparatus. To be distinguished from the smaller *secretory vesicles*, which contain small neurotransmitter molecules that are enzymatically synthesized at the level of the nerve terminal.

Oxytocin (OT) is a nonapeptide hormone that is produced in specific hypothalamic neurons and is secreted into the general circulation from the neural lobe of the hypophysis. In addition, OT also acts as a neurotransmitter. As a circulating hormone, OT induces milk ejection from the lactating mammary gland and uterine contractions during parturition. Indeed, OT represents the most potent uterotonic agent known and is commonly used in obstetrical practice to augment labor and prevent postpartum hemorrhage. Moreover, OT antagonists represent promising pharmacotherapeutic tools for the treatment of premature labor. As a neurotransmitter, OT mediates specific behaviors, including sexual, maternal, social, and affiliative behaviors. In addition, an anxiolytic action has also been observed. These effects have led to the speculation that, in humans, defects in the OT system may underlie mood disorders, such as depression and obsessive–compulsive behaviors, as well as disorders in interpersonal relationships, such as autism. Additional proposed functions of OT include a role in natriuresis, pituitary prolactin release, cardiac atrial natriuretic factor release, penile erection, sperm transport, and vasodilation as well as T-cell and bone maturation. This article will review the mechanisms of neural biosynthesis, release, and action of OT and discuss its established and proposed roles in mammalian and human physiology.

I. THE HYPOTHALAMO–NEUROHYPOPHYSIAL SYSTEM

A. Anatomy

Among all of the known neuropeptides, oxytocin (OT) and the related peptide arginine vasopressin (AVP)

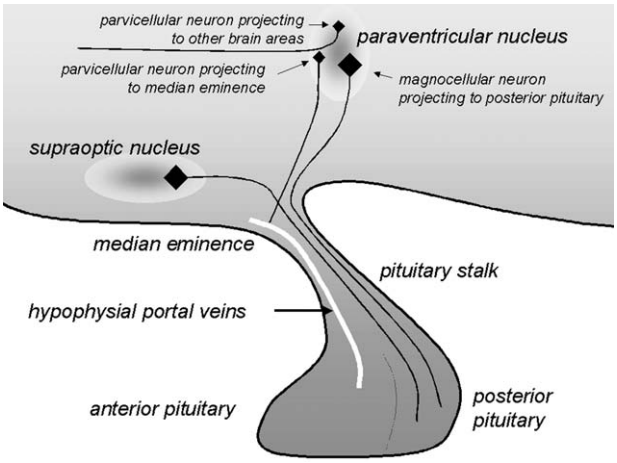

Figure 1 Schematic diagram of the hypothalamo–neurohypophysial system.

share a unique characteristic: on the one hand, both peptides are produced in cells that exhibit all the hallmarks of classical neurons, whereas on the other hand, both neuropeptides are released into, and act via, the general circulation, much like a classical hormone. This feature was recognized long before the precise structures of the two hormones were known and led to the development of the concept of *neurosecretion* during the first half of the last century.

OT is produced in specific hypothalamic neurons present within the supraoptic and paraventricular nuclei of the hypothalamus. The axons of these neurons extend through the internal zone of the median eminence and end in the neural lobe of the pituitary gland, also called the posterior pituitary or neurohypophysis (Fig. 1). The neural lobe represents not only the site of OT release into the general circulation but also the site where microgram quantities of OT are stored in preparation for acute release. The related peptide AVP is produced in a set of different but similar hypothalamic neurons that also extend their axons to the neurohypophysis. Together, these neurons and their axonic extensions constitute the *hypothalamo–neurohypophysial system*. Due to their relatively large size, these specialized neurons have been termed magnocellular neurons. These cells share all of the characteristics of a classical neuron. In addition, they also fulfill the definition of an endocrine cell. Thus, they represent a classical example of a so-called neuroendocrine cell type.

The hypothalamo–neurohypophysial system was initially thought to be unique for its ability to produce and release hormonal substances. We now know that neurons in general are capable of peptide biosynthesis and release and that neuropeptides play a major role as neurotransmitters. The hypothalamo–neurohypophysial system is, however, still unique in the sense that its peptide products act as circulating hormones. As a consequence, the hypothalamo–neurohypophysial system has long served as a classical model system for the study of the mechanisms of neurosecretion and excitation–secretion coupling.

OT, as well as AVP, is also produced in additional, smaller neurons, so-called parvicellular neurons, present within the paraventricular nucleus of the hypothalamus. In contrast to the magnocellular neurons, the axonal processes of these neurons project not to the neural lobe but to different brain areas as well as to the spinal cord, where OT and AVP exert different neurotransmitter functions (see later discussion). Other parvicellular OT and AVP neurons project to the external zone of the median eminence. There, the secretory products are released into the pituitary portal system, a specialized vascular system that allows further transport of the hormones to the anterior pituitary gland, where they exert roles as releasing factors for pituitary hormones (Fig. 1).

B. Electrophysiology

1. Neurosecretion

Excitation of a neuron occurs by the production of action potentials. An action potential is a short-lasting reversal of the electrical potential across the cell membrane. This reversal of the membrane potential originates at the level of the cell body, but then spreads like a shock wave along the different neuronal extensions, including axons and dendrites. At the level of the nerve endings, the arrival of action potentials leads to membrane depolarization, which, in turn, triggers the opening of voltage-sensitive calcium channels. The resulting increase in intracellular calcium concentration stimulates a process termed exocytosis, by which peptide-containing secretory granules fuse with the cell membrane and thereby release their contents into the extracellular space. Through this mechanism that couples excitation to secretion, an increase in the frequency of action potentials arriving at the nerve terminus results in a proportional increase in neuropeptide secretion.

In summary, the axon of a neurosecretory cell fulfills a dual function: Through axonal transport, the secretory granules are delivered to the nerve ending, where they are initially stored. Second, the axonal membrane serves as the medium for the propagation of

the action potentials and thus relays the signal for acute neuropeptide release from the cell body to the nerve ending.

2. Patterns of Electrophysiological Activity

In the lactating rat, continuous suckling of the pups triggers the episodic release of milk from the mammary gland every 5–10 min, a phenomenon known as the milk-ejection reflex. The underlying neuronal mechanism involves a dramatic activation of the entire hypothalamic magnocellular OT neuron population that is induced by the suckling stimulus and that lasts several seconds only. These rhythmic bursts of neuronal activity lead to a rhythmic release of OT from the neurohypophysis into the circulation. The burst of circulating OT induces milk ejection via contraction of the network of myoepithelial cells that surrounds mammary gland milk ducts. In lactating women, milk-ejection activity has also been shown to be rhythmic, and breast feeding is associated with a rise in circulating OT levels.

In all placental mammals studied thus far, parturition represents another condition that is associated with a strong increase in the electrical activity of OT neurons and, as a consequence, an increase in circulating OT levels. Whether this increased activity of OT neurons initiates, or is stimulated by, parturition has remained unclear. On the one hand, electrical stimulation of the neurohypophysis can bring about parturition; on the other hand, parturition-induced distention of the cervix and vagina represents a stimulus for OT release. Detailed measurements of OT secretion in humans revealed that, in parturient women, OT secretion occurs in short pulses. Pulse frequency as well as pulse duration increases during spontaneous labor. These findings suggest that, in humans, pulsatile activation of the OT neuronal system may be involved in triggering and/or augmenting labor. OT secretion also follows a diurnal pattern: in late gestation, OT levels are higher at night than during daytime.

Additional stimuli that affect, seemingly indiscriminately, the activity of both OT and vasopressin neurons include increased serum osmolality and decreased blood pressure, mating, and certain kinds of stress, including fever. In contrast to suckling, which induces short bursts of activation that are punctuated by relative silence, the preceding stimuli lead to a continuous activation of OT neurons.

The patterns of electrophysiological activity displayed by AVP neurons differ very markedly from those of OT neurons. Upon activation by either an increase in blood osmolality or a decrease in blood pressure, AVP neurons display a phasic firing pattern of activity. This pattern is characterized by individual bursts of activity that alternate with periods of silence, each lasting 20–40 sec. In contrast to the highly coordinated activity of OT neurons during lactation, the phasic bursts of AVP neurons are not temporally coordinated between individual neurons, and each neuron follows its own pattern controlled by an intrinsic rhythm generator. These characteristics make it possible to distinguish OT and AVP neurons during electrophysiological investigations on the basis of their distinctive firing patterns.

The mechanisms underlying these differential patterns of activity have been the subject of intense electrophysiological and biochemical investigations. Cell-intrinsic factors include the differential distribution of specific calcium-binding proteins, voltage- and ligand-gated ion channels, internal calcium release mechanisms, and gap junction conductances. In addition, these neurons are synaptically connected via an intrahypothalamic network as well as by afferences from a large number of limbic and sensory structures. Among the neurotransmitter receptors localized to magnocellular neurons, the most numerous appear to be the ones for amino acid transmitters, with glutamate providing excitatory input and GABA providing inhibitory input. The glutamate receptors that mediate excitatory postsynaptic potentials are mainly of the AMPA type. $GABA_A$ as well as $GABA_B$ (but not $GABA_C$) receptors are present on the postsynaptic membrane of supraoptic magnocellular nucleus, where they carry chloride currents inducing inhibitory postsynaptic potentials. In addition, metabotropic GABA receptors have also been shown to be expressed postsynaptically. Finally, OT and AVP release from dendrites and recurring axon collaterals provides the means by which OT- and AVP-containing magnocellular neurons are capable of influencing their own activity. This short-loop feedback control is being referred to as an autocontrol mechanism.

II. BIOSYNTHESIS

A. Peptide Structure

The structure of OT is shown in Table I. The structure is the same in all mammalian species studied. The cysteines in positions 1 and 6 are linked by a disulfide bond. Therefore, the molecule consists of a cyclic part with a C-terminal linear extension. Both cyclization

Table I
Sequences of Oxytocin, Vasopressin, and Vasotocin

	┌──────S-S──────┐
Oxytocin	Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH_2
Vasopressin	Cys-Tyr-Phe-Gln-Asn-Cys-Pro-Arg-Gly-NH_2
Vasotocin	Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Arg-Gly-NH_2

and amidation are important for biological activity. OT differs in positions 3 and 8 from its related molecule AVP. Both peptides have likely evolved from a common precursor molecule. A neurohormone present in several nonmammalian species, termed vasotocin, represents an intermediate between OT and AVP (Table I).

Both OT and AVP are produced as parts of two similar precursor molecules. The OT precursor molecule contains OT at its N-terminus, linked via a pair of basic amino acids to a 10-kDa peptide called neurophysin-I of unclear biological function. Following synthesis on ribosomes of the rough endoplasmic reticulum, the peptide precursors are packaged into secretory granules and transported via fast axonal transport mechanisms to their destination at the nerve terminals, where they are released in response to membrane depolarization. While residing in the secretory granule, the precursor molecules are processed by specific endoproteases (called processing enzymes) that are copackaged into the granules to generate the biologically active nonapeptides.

B. Gene Structure and Regulation

The genes encoding OT and AVP are in close proximity on the same chromosome in all mammalian species studied and have evolved by gene duplication of an ancestral gene. In humans, the OT and AVP genes are in close linkage on chromosome 20p13, separated by only 12 kb of intergenic sequences. The two genes are positioned tail to tail and are thus transcribed from opposite strands. In all species studied, the OT and vasopressin genes consist of three exons that are separated by two relatively small introns. In each gene, the biologically active nonapeptide is encoded by exon 1.

Studies on the human, rat, and bovine OT genes revealed that the OT gene is under positive and negative control by a composite hormone regulatory region that is able to interact with several members of the nuclear receptor superfamily. This element is located about 160 nucleotides upstream of the site of transcriptional initiation and mediates positive transcriptional regulation by interacting with the estrogen, retinoic acid, and thyroid hormone receptors as well as with the nuclear orphan receptor SF1. Negative control is exerted by the nuclear orphan receptors COUP-TF I and II, involving competition with stimulatory factors as well as active silencing. *In vivo*, hypothalamic OT gene expression is stimulated during pregnancy and lactation in response to dehydration and following a combination of estrogen stimulation and progesterone withdrawal.

Outside the central nervous system, the OT gene is expressed in ovarian granulosa cells, fetal membranes and uterine decidua, placenta, testicular Leydig cells, and thymic epithelium. OT released from these sites is likely to have a role as a local paracrine mediator.

III. PHYSIOLOGY

A. Peripheral Effects

OT plays an essential role in mediating milk ejection from the lactating mammary gland. This has been clearly demonstrated in the mouse, where ablation of the OT gene by gene targeting leads to a complete inability to lactate, despite normal mammary gland milk production. In humans, suckling-induced and spontaneous increases in mammary gland milk pressure occur concomitantly with increased circulating OT levels, and morphine administration during lactation attenuates both OT pulses and milk-ejecting activities.

In contrast to the clear-cut, essential role of OT in lactation, there are arguments both for and against the importance of OT in the processes of labor and parturition. Mice in which the gene for OT has been inactivated are able to deliver normally. This indicates that, at least in the mouse, OT is not essential for normal parturition. Considering the multiplicity of interconnected mechanisms that are mediating the important function of parturition, it is not surprising that there is redundancy in this system and that knocking out one of its components does not necessarily lead to the breakdown of the entire process. More importantly, this finding does not rule out that premature overactivation of the OT system may be a determining factor in cases of idiopathic premature labor. Support for this idea stems primarily from a large number of studies that attest to the effectiveness of OT antagonists in inducing uterine quiescence in

normal labor as well as in cases of naturally occurring or experimentally induced premature labor. The effectiveness of OT antagonists, specifically atosiban, to delay premature labor has been demonstrated in many different species, including humans.

B. Central Effects

OT-containing nerve endings as well as functional OT receptors are present at various sites in the mammalian brain, including the ventromedial nucleus of the hypothalamus, the bed nucleus of the stria terminalis, ventral subiculum, lateral septum, caudate nucleus, limbic system, hippocampus, and olfactory nuclei. A potential role of OT in human brain function has mainly been inferred from studies in nonprimate mammals, including rats, sheep, and voles. The combined evidence demonstrates that OT induces specific sexual, affiliative, social, and maternal behaviors. In addition, it reduces anxiety and impairs short-term memory. Several of these behavioral effects depend on previous priming by gonadal steroids, most likely via steroid-induced up-regulation of OT receptors.

1. Female Behavior

Among the sexual behaviors, the lordosis reflex has been intensively studied in the rat. This reflex represents a sign of female sexual responsiveness that can be quantitated. In female rats primed with gonadal steroids, the reflex is strongly enhanced by central OT administration and attenuated by OT antagonists. Concomitantly, central OT administration decreases rejection behavior against male sexual advances. Detailed microinjection studies with OT antagonists injected into discrete brain areas implicate the medial preoptic area and the ventromedial nucleus of the hypothalamus in OT-mediated lordosis, whereas the ventral tegmental area appears to regulate OT-mediated social behaviors.

For studies of OT effects on social attachment and affiliation, two types of voles, the prairie and the montane vole, have provided a valuable model system. Despite their close relation, these two species differ markedly with respect to their social behaviors. The prairie vole manifests the classic features of monogamy. A breeding pair shares the same nest and stays together until "death do them part," and even then a new mate is accepted by the surviving mate only one-fifth of the time. In contrast, montane voles live in isolated burrows, have little social contact, and clearly are not monogamous. Despite an overall similar distribution of neuropeptide receptors, these two species differ very radically in the neural distribution of OT as well as AVP receptors, and both are expressed within very different pathways. Whereas prairie vole OT receptors are found in brain regions associated with reward, such as the nucleus accumbens and the prelimbic cortex, montane vole OT receptors are found in the lateral septum, where they may be responsible for the effect of OT in this species on self-grooming. Proof that OT is involved in mediating these very specialized behavioral patterns came from experiments that demonstrated that OT centrally injected to female prairie voles facilitated the development of partner bonding in the absence of mating and that the mating-induced partner bond formation was blocked by central administration of an OT antagonist before mating. These results indicate that OT released during mating is both necessary and sufficient for the formation of a pair bond in the female prairie vole.

Maternal behavior is another complex behavior that can be induced in virgin, steroid-primed female rats, and the natural occurrence of the behavior following parturition can be blocked by central OT antagonist application. Typical OT-induced maternal behavior includes nest building and recognition and acceptance of the pups, as well as retrieval of the pups into the nest. This function also involves olfactory clues, and a role of OT in olfactory memory has indeed been suggested, consistent with the occurrence of OT receptors in brain areas involved in processing olfactory information.

Because in women OT is released during intercourse and during lactation, it is tempting to speculate that the associated central release of OT may contribute to the strengthening of the emotional bond between sexual partners as well as of the affiliative bond between mother and infant. No direct studies are available in humans, but studies in squirrel monkeys have demonstrated that central OT administration is capable of influencing social interaction also in primates. Preliminary findings in nonlactating women indicate that positive emotions (relaxation, massage) induce a rise in circulating OT levels. This increase appears to be more pronounced in women that display a lesser degree of anxiety in close relationships. In addition, there is also one anecdotal report of increased sexual receptivity in a woman in response to OT administration by nasal spray.

2. Male Behavior

The role of central OT in controlling sexual and social behavior in the male is less well-defined and complex.

In the male rat, sexual activity increases the activity of parvicellular OT neurons in the paraventricular nucleus of the hypothalamus. Some of these OT neurons project to sensorimotor nuclei regulating penile erection, and microinjections of OT into the paraventricular nucleus indeed induce penile erection. Moreover, erections that are physiologically induced due to the presence of a female are inhibited by injection of a specific OT antagonist into the lateral ventricles. Whereas central administration of low acute doses of OT facilitates copulative performance, high acute doses attenuate sexual responses, and chronic intracerebroventricular OT infusion results in markedly enhanced social, but not sexual, contact with the female partner. These observations taken together indicate that OT's effects on social behavior can be separated from its effects on sexual behavior and that these effects are likely mediated by OT receptors located in different brain areas.

Interestingly, in the male vole, it is not OT but rather AVP that influences parental behavior. AVP given centrally increases affiliative behavior in male prairie voles in the absence of mating and induces aggression against other sexually mature males. Administration of a specific AVP antagonist blocks the mating-induced partnership bonding. This effect was only present in the prairie vole but not the montane vole. A most elegant demonstration of the importance of region-specific receptor expression in behavioral patterns has been provided by the group of Insel with the creation of a transgenic mouse in which the prairie vole vasopressin V_{1a} receptor was expressed under the control of its own species-specific promoter. In these transgenic mice, the V_{1a} receptor was expressed at sites within the brain that are typical for the prairie vole. As a result, central injection of AVP increased affiliative behavior in the transgenic, but not the wild-type, mice. These data indicate that the specific pattern of V_{1a} receptor gene expression in the brain is functionally associated with species-typical social behaviors.

3. Disorders of Mood and Behavior

On the basis of the demonstrated effects of OT on affiliative and social behaviors in rodents, it has been speculated that a defect in central OT release or OT responsiveness may underlie the manifestations of autism and/or obsessive–compulsive disorders in humans. The evidence from clinical studies to support this idea, however, is limited. Some clinical data suggest that a subgroup of obsessive–compulsive disorder patients have increased OT concentrations in the cerebrospinal fluid. On the other hand, a strong decrease in OT plasma levels has been observed in autistic children, and these children failed to show the normal developmental increase of plasma OT with age.

An additional central OT effect involves the reduction of anxiety. Central OT administration to estrogen-primed rats or mice induces them to spend significantly longer times in the open arm of a maze. These effects have led to the speculation that, in humans, OT may act as an endogenous antidepressant and anxiolytic hormone and that defects in the OT system may underlie mood disorders that are accompanied by increased anxiety levels, such as depression and obsessive–compulsive behaviors. The presence of OT receptors in the limbic forebrain area in humans represents supportive evidence that OT may be involved in the control of emotional and affective behavior in humans. Because, in laboratory animals, serotonin receptor agonists as well as serotonin re-uptake inhibitors produce a marked increase in plasma OT levels, it has also been proposed that OT may mediate, at least in part, the antidepressant effects of serotonin re-uptake inhibitors in humans.

The marked differences in the OT pathways between different species preclude a simple extrapolation from mice to men. However, the available animal data strongly suggest that OT is an important modulator of several specific behaviors related to reproduction and interindividual relationships. Therefore, their role in human behavioral pathologies, such as autism, depression, and obsessive–compulsive behaviors, deserves to be explored. Because animal studies have shown that discrete changes in the regional expression of OT receptors can have an impact on social behaviors, measurement of levels in CSF or plasma OT concentrations will not be sufficient, and functional or structural variations in OT or OT receptor genes and their specific expression in brain tissues will also have to be investigated.

C. Additional Functions

On the basis of animal studies, roles for OT have been proposed in pituitary, renal, cardiovascular, immune, and male reproductive functions. Although a corresponding role in humans is likely, no evidence is available from clinical studies to support this idea.

OT released from nerve terminals at the median eminence reaches the anterior pituitary via the pituitary portal system where it acts as a releasing factor,

potentiating the release of pituitary corticotropin, prolactin, and gonadotropins. At the level of the kidney, OT induces natriuresis, and this effect involves nitric oxide and cyclic GMP. Additional proposed roles of OT in male reproductive functions include the stimulation of sperm transport and testicular androgen production. The detection of OT receptors in endothelial cells as well as in the atria and ventricles of the heart led to the concept that OT has a role in negatively regulating blood pressure. The presence of functional OT receptors on T-cells implies a role in T-cell function, and OT effects on human and mouse mammary cancer cells suggested an antiproliferative effect of OT.

IV. MECHANISMS OF ACTION

A. Oxytocin Receptors

The various central and peripheral actions of OT that were discussed earlier all appear to be mediated by a single type of OT receptor. The structures of the human, rat, pig, sheep, cow, and mouse OT receptors have been elucidated by molecular cloning. The deduced amino acid sequences indicate that the OT receptor forms part of the family of G-protein-coupled receptors consisting of seven hydrophobic transmembrane α-helices. This receptor is closely related to the three receptors that mediate the actions of AVP, namely, the V_{1a}, V_{1b}, and V_2 receptors. Whereas AVP is a weak activator of the OT receptor, OT does not interact with the V_{1a} or V_2 receptor and interacts only weakly with the V_{1b} receptor. The gene encoding the human OT receptor is located on chromosome 3p25, in close apposition to the caveolin 3 gene.

The distribution of OT receptors in the brain has been carefully mapped in several rodent species. In contrast to the high degree of conservation with respect to the structure of the OT receptor in all mammalian species, important differences in the pattern of OT receptor expression in the CNS have been observed between different species. Therefore, any extrapolation of insights gained from animal studies to humans has to be done with caution. In humans, OT receptors have been described in (but are probably not limited to) the basal forebrain cholinergic nuclei, the nucleus basalis of Meynert, the diagonal band of Broca, and the preoptic area of the hypothalamus. The localization in the diagonal band of Broca is consistent with a role of OT in memory. The preoptic area of the hypothalamus is an area considered important for the mediation of reproductive behaviors; therefore, the presence of OT receptors in this area is consistent with the role of OT in human reproductive behavior.

In the periphery, specific OT-binding sites are present within the uterus at the level of the myometrium as well as the uterine epithelium or decidua. Whereas myometrial receptors mediate uterine contractions directly, activation of the decidual receptor elicits prostaglandin $F_{2\alpha}$ release, which, in turn, not only enhances uterine contractions but also promotes cervical ripening and luteolysis. Additional OT-binding sites have been detected in mammary gland myoepithelial cells, pituitary lactotrophs, cultured astrocytes, certain spinal cord neurons, renal macula densa cells, thymic T-cells, ovarian follicular cells, testicular Leydig cells, cardiac myocytes, vascular endothelial cells, and cultured osteoblasts.

Compared to other members of the OT–vasopressin receptor family, relatively little is known of the specific regions of the OT receptor involved in ligand binding and signaling. It is assumed that the cyclic part of the OT molecule is lodged in the upper one-third of the receptor binding pocket and interacts with transmembrane domains 3, 4, and 6, whereas the linear C-terminal part of the OT molecule remains closer to the surface and interacts with transmembrane domains 2 and 3 as well as with the connecting first extracellular loop. This hypothesis is supported by studies employing site-directed mutagenesis, photoaffinity labeling as well as by experiments involving domain swapping between the V2 vasopressin receptor and the OT receptor.

Activation of the OT receptor leads to phospholipase C-mediated phosphoinositide hydrolysis, followed by activation of protein kinase C and intracellular calcium mobilization. The rise in intracellular calcium is greatly attenuated in the absence of extracellular calcium, indicating that OT receptor activation also stimulates calcium influx, probably via calcium-induced (capacitative) calcium entry. Experiments with antibodies against different G-proteins demonstrated that coupling to phospholipase C occurs mainly via a G-protein of the $G_{q/11}$ family. However, evidence for coupling to other G-proteins, including G_i and G_{ha}, has also been presented. The regions of the OT receptor implicated in G-protein interactions have been delineated by examining the inhibitory effect of coexpression of different intracellular domains of the receptor. The studies indicate that all four intracellular domains are involved in coupling to $G_{q/\alpha 11}$.

Additional effector mechanisms involve coupling to phospholipase A_2 and phosphorylation and activation of MAP kinase. These two pathways are relevant for the stimulation of prostaglandin $F_{2\alpha}$ and prostaglandin E_2 synthesis. The precise mechanisms by which OT receptor activation induces smooth muscle contractions and prostaglandin synthesis remain to be defined. In myometrial cells, calcium-induced activation of the calcium–calmodulin complex leading to activation of myosin light chain kinase is involved in initiating the contraction process. In decidual cells, stimulation of prostaglandin synthesis is the consequence of an OT-induced activation of cyclo-oxygenase II expression. In vascular endothelial cells and renal macula densa cells, OT receptor activation leads to a calcium-dependent activation of nitric oxide synthase, inducing vasodilation and natriuresis, respectively.

B. Oxytocin Receptor Regulation

An outstanding feature of the OT receptor gene is the dramatic change in the expression of this gene in different tissues. This highly regulated expression sets the OT receptor apart from the majority of other G-protein-coupled receptors in general and from the closely related vasopressin receptors in particular. During gestation, uterine OT (but not vasopressin) receptors are up-regulated by one to two orders of magnitude in all mammalian species studied, including humans. This phenomenon induces a strong increase in uterine sensitivity toward OT and is due to a dramatic increase in uterine OT receptor gene expression just prior to parturition. Indeed, the increase in uterine OT receptors is much more striking than, and precedes, the increase in circulating OT. Therefore, it has been proposed that OT receptor up-regulation represents the trigger for parturition. Whereas the number of *uterine* OT-binding sites decreases quickly following parturition, *mammary gland* OT-binding sites reach a maximum shortly after parturition and remain elevated throughout lactation. This differential, tissue-specific regulation of OT receptor expression enables a switch in target organs and allows circulating OT to assume a dual role: uterine contractions during labor and milk ejection during lactation. The same OT receptor gene is expressed in both tissues, and the molecular basis underlying this tissue-specific differential regulation of OT receptor gene expression remains to be elucidated.

Several studies have shown that uterine OT receptors are up-regulated by estrogens and down-regulated by progesterone. Indeed, in most mammals, the situation before term is characterized by high estrogen levels (involving placental conversion of fetally produced dehydroepiandrogen and androstenedione to estradiol) and a sharp decline in progesterone (induced by luteolysis; exceptions include humans and primates, in whom no fall in progesterone occurs). The sudden drop in the progesterone: estrogen ratio is thought to be causally involved in triggering parturition. This idea is further supported by findings in the prostaglandin F receptor "knock-out" mouse. In this mouse model, preterm luteolysis and the ensuing fall in progesterone are prevented. This leads to complete suppression of parturition and suppression of OT receptor gene expression. However, both OT receptor expression and parturition are restored if a fall in progesterone is induced by ovariectomy.

We and others have determined that the estrogen-induced up-regulation is due to a genomic estrogen-mediated increase in OT receptor gene expression. On the other hand, progesterone may act to decrease OT binding via both a genomic effect and a nongenomic effect, leading to the inhibition of OT receptor binding and signaling functions. Moreover, the effect of estrogens on OT receptor expression is region-specific: some, but not all, central OT receptors are up-regulated at the end of pregnancy and in response to estrogen administration. Specifically, OT receptors in regions rich in estrogen receptors, including the ventromedial nucleus of the hypothalamus and the bed nucleus of the stria terminalis, are highly up-regulated in response to estrogens and prior to parturition. Up-regulation of OT receptors in these two key limbic brain regions prior to parturition is coincident with the onset of maternal behavior. On the other hand, OT receptors expressed at other central OT target sites, such as the subiculum or the olfactory nuclei, remain (in the rat) unaffected by gonadal steroids.

In the periphery, estrogens stimulate OT receptor gene expression in the uterus, pituitary, and kidney, but OT receptor expression in the mammary gland remains unaffected by steroid treatment. Although the rat and human OT receptor genes contain potential estrogen-responsive sites in their promoter regions, none of these sites turns out to be estrogen-responsive when analyzed at the original distance from the transcriptional initiation site. Cell-specific estrogen responsiveness may be mediated indirectly or via other functional OT receptor promoter elements, including AP1 sites and a cAMP response element. Interleukins, specifically IL-1β and IL-6, represent additional

potential regulators of OT receptor expression. They are present in high concentrations in amniotic fluid at term labor and are mediators of infection-induced preterm labor. Indeed, the rat and human OT receptor genes contain potential interleukin response elements in their promoter regions; however, proofs of their functionality have not been provided yet. Certainly, the mechanisms regulating OT receptor gene expression in neural and nonneural tissues as well as the precise molecular mechanisms that underlie OT signaling represent exciting areas for future research.

Pain and Psychopathology

DAVID FISHBAIN
University of Miami School of Medicine

GLOSSARY

Axis I, II, and III DSM-IV classifications of pain disorders; Axis I is for any acute or chronic mental disorder, Axis II is for personality problems, and Axis III is for non-psychiatric medical disorders, e.g., pneumonia.

soft tissues Tendons, ligaments, and muscles, as opposed to the hard tissues (bones, cartilage).

trigger points A tender point on the soft tissues, pressure on which results in acute pain radiating in a predictable direction.

worker's compensation patients Patients who have been injured while performing their job and as a result of their injury are now receiving worker compensation benefits.

Pain plays a major role in the development of psychopathology in chronic pain. Research also indicates that psychiatric comorbidities often impact negatively on chronic pain and functional status.

I. THE PROBLEM OF NONSPECIFIC LOW BACK AND NECK PAIN AND THEIR IMPACT ON PSYCHOPATHOLOGY IN CHRONIC PAIN

There are three possible relationships between pain and psychopathology. Psychopathology could *cause* the development of pain, it could follow or be caused by the development of pain, or prepain psychopathology could predispose one to the development of pain. There is now good evidence that the development of psychopathology follows–is caused by the development of pain or that preexistent behavior vulnerability predisposes one to the development of psychopathology after the onset of pain. In addition, there is also good evidence that the severity of psychopathology parallels the severity of perceived pain. The fact that pain may be an important etiological factor in the development of psychopathology leads to a major problem in utilizing the current psychiatric diagnostic nomenclature system, the DSM-IV. Here, in a diagnosis termed pain disorder, the psychiatric diagnostician is required to determine whether psychological factors have a major role in the onset, severity, exacerbation, or maintenance of the pain. Yet, as pointed out earlier, pain plays a major role in the development of psychopathology in chronic pain. At the time the psychiatrist sees the patient, he or she is assessing both prepain- and pain-associated psychopathology. As such, at that time it is almost impossible to make a distinction between what was present before the onset of pain and what developed after. There is also a tendency to attribute all of the assessed psychopathology as preexistent to the pain or causing the pain if a cause for the pain cannot be found. Thus,

the issue of "nonspecific" low back pain (LBP) or neck pain is of great importance to pain medicine.

Nonspecific is the opposite of "specific pain," which is defined as pain for which an underlying cause can be defined, such as infection, vertebral fracture, systemic disease, etc. Currently, it is believed that the vast majority of pain problems do not fit into the classical biomedical model that links symptomatology and disease process. As such, a definite somatic cause for pain can only be identified in no more than 10–20% of cases. Thus, the nonspecific pain diagnosis is determined or defined by the process of excluding specific pain. Because so few pain patients can be given a specific diagnosis, many patients are suspected of having psychopathology that causes their pain or makes it worse. If these nonspecific patients do have psychopathology such as depression, the presence of this psychopathology serves as proof that there is not an organic reason for their pain. The nonspecific label can thus color the psychiatric diagnostic process and lead to erroneous psychopathology data.

II. THE PROBLEM OF FIBROMYALGIA–MYOFASCIAL PAIN SYNDROME AND ITS IMPACT ON ALLEGED PSYCHOPATHOLOGY IN CHRONIC PAIN

Fibromyalgia (FMS) and myofascial pain syndrome (MFPS) are a group of soft tissue syndromes characterized by widespread pain and tender points in FMS and regional pain and trigger points in MFPS. The important issue in reference to these syndromes is that they are commonly found in patients with intractable pain. At pain facilities, the numbers range from 30 to 100%. Thus, it is unlikely that a significant number of pain patients presenting to a pain facility will have true nonspecific pain, if an adequate soft tissue examination is performed.

The issue of whether the pain patient has nonspecific pain or actually suffers from a soft tissue syndrome such as FMS or MFPS is important behaviorally in two ways. First, the pain patient needs and awaits an explanation for the pain and feels that the pain needs to be legitimized. Pain patients consider "delegitimization," referring to the repudiation of the patient's pain and suffering, as one of the major perceived difficulties of the pain experience. A pain patient's satisfaction with his or her medical care is dependent on receiving an adequate explanation for his or her care. Pain patients that want more diagnostic tests are less satisfied with their care and are less likely to want the same doctor again. Clearly, the nonspecific label does not provide an explanation nor does it satisfy the patient's expectation of knowing the exact cause of the pain. The patient to whom the nonspecific label applies generally suffers from chronic pain (to be discussed later). The process of learning how to manage this pain can only begin after the patient understands that his or her condition is chronic. FMS and MFPS provide the framework for this understanding, as these syndromes are understood as chronic. Thus, pain patients labeled with FMS or MFPS should, in theory, decrease their health care utilization. This is indeed the case: once the diagnosis is made, hospitalizations and health care utilization drop dramatically for FMS patients. There is, therefore, reason to believe that the labeling of pain patients with an FMS or MFPS diagnosis, if appropriate, can have positive behavioral consequences that can affect pain treatment outcome. The issue of no diagnosis or the nonspecific pain label as the reason for pain is such a common patient complaint that it is considered to be a behavioral comorbidity usually associated with having chronic pain. The various comorbidities usually associated with chronic pain will be discussed in detail later.

The second reason why the presence–absence of a soft tissue diagnosis is important behaviorally is because the absence of MFPS and FMS makes the patient a candidate for a DSM-IV diagnosis of pain disorders on Axis I, which makes it a mental disorder. However, if a patient is diagnosed with MFPS or FMS and has chronic pain, in the DSM-IV this is diagnosed as a pain disorder associated with a general medical condition and is placed on Axis III. This is not a mental disorder. Thus, in the context of chronic pain, the presence of MFPS or FMS can determine whether a patient receives a mental disorder diagnosis and is thus "Labeled."

III. WHAT IS CHRONIC PAIN?

It is to be noted that nonspecific pain is grouped in the ICD-9 (World Health Organization, 1997) classification scheme under the heading "other and unspecified disorders of the back." However, nonspecific pain is not the same and does not necessarily equal chronic pain (CP). The American Medical Association in the *Guides to the Evaluation of Permanent Impairment* (4th ed.) has, however, defined chronic pain and developed operational criteria for its diagnosis. Here chronic pain is defined as "persistent pain… recalcitrant… with

Table I
Diagnostic Characteristics for the Diagnosis of Chronic Pain Syndrome: At Least Four of the Following Are Required for a Presumptive Diagnosis of Chronic Pain Syndrome

1. Persistent pain of greater than 2–4 weeks duration
2. Pain behaviors (verbal and nonverbal)
3 Vague, inconsistent, and inaccurate, indicating nonspecific pain
4. Substance abuse and/or dependence
5. Depression
6. Muscular dysfunction and deconditioning resulting in secondary pain of musculoskeletal origin
7. Withdrawal from work, recreational, and family endeavors
8. Dependence on physicians, spouses, and families

major psychosocial consequences… not a symptom of underlying acute somatic illness but a disease of the whole person… characterized by enhanced pain perception with maladaptive pain-related behaviors… .'' In addition, the AMA *Guides* point out that, if chronic pain is not recognized and properly treated, deterioration of coping mechanisms and limitations of functional capacity will ensue. Other consequences will be despair, alienation from family and society, loss of job, isolation, invalidism, and suicidal thoughts. However, the AMA *Guides* state that chronic pain *is not* a psychiatric disorder. The AMA *Guides*' diagnostic criteria for a presumptive diagnosis of chronic pain syndrome are presented in Table I. Four criteria are required for this diagnosis. It is to be noted that most of these criteria are either psychiatric or other comorbidities (to be discussed later). Thus, *the chronic pain syndrome cannot be defined and characterized without an evaluation for psychiatric or other comorbidities*. In addition, it is to be noted that criterion 3 (Table I) relates to nonspecific pain. Thus, nonspecific pain is encompassed within the chronic pain definition.

IV. PSYCHIATRIC COMORBIDITIES USUALLY ASSOCIATED WITH CHRONIC PAIN

Comorbidity is defined as any distinct clinical entity that has existed or that may occur during the clinical course of the patient who has the index disease under study. It has become clear that the presence of comorbid disease can dramatically affect the treatment of the index disease. Specifically, the presence of comorbid disease can often complicate, interfere with, or make the treatment of the index disease more difficult, making the prognosis worse. In addition, the presence of comorbid disease, because of its impact on the treatment of the index disease, can lead to spurious medical outcome data, especially if the comorbid disease is not classified or analyzed and its effect controlled for. For these reasons, the identification and treatment of psychiatric comorbidities associated with chronic pain have become extremely important to pain medicine.

As discussed earlier, the presence of chronic pain can predispose one to the development of psychiatric psychopathology. As such, one would expect to find significant psychiatric comorbidity within the chronic pain patient (CPP) population. In addition, other reasons why there should be significant psychopathology within CPPs are the following: (1) CPPs consider themselves to suffer from a physical illness for which physicians cannot seem to develop a cure; (2) this physical illness is associated with significant impairment and disability, which has tremendous impact on the CPP's life; (3) in order to control pain, CPPs are often placed on psychoactive substances that have dependence–addiction potential; and (4) because often no apparent tissue damage can be found to explain the etiology of chronic, benign, nonmalignant pain, CPPs are often given the nonspecific pain diagnosis by physicians who then attribute the CPP's pain to underlying psychiatric illness. Because of these and perhaps other less well-defined issues, it is

Table II
Types of Psychiatric Comorbidities Found within CPPs

I	Between the chronic pain state and any psychiatric disorders on Axis I of the DSM-IV
II	Between the chronic pain state and any psychiatric disorders on Axis II of the DSM-IV
III	Within CPPs and between psychiatric disorders on Axis I of the DSM-IV
IV	Within CPPs and between psychiatric disorders on Axes I and II of the DSM-IV
V	Within CPPs and between Axis I psychoactive drug use disorders and other Axis I disorders of the DSM IV
VI	Within CPPs and between various Axis I psychoactive drug use disorders of the DSM-IV

well-established that there is significant psychiatric comorbidity associated with chronic pain. There are six types of psychiatric comorbidities found within CPPs. These are presented in Table II and will be discussed individually next.

A. Comorbidity between the Chronic Pain State and Any Psychiatric Disorder on Axis I of the DSM-IV

This type of comorbidity has been studied extensively in CPPs and is the most exhaustively documented major category of psychiatric comorbidity in CPPs. This type of comorbidity data is presented in Table III. Here data from various research studies for prevalence percentages in CPPs for Axis I disorders are summarized.

Table III indicates that the affective disorders (depression) group is the most commonly found group of comorbid disorders. For example, some authors have reported a prevalence rate for depression approaching 100%. One reviewer concluded that depression is found more commonly in CPPs than in the general population and that the depression seen in CPPs is a consequence of chronic pain and is not

Table III
Percentages of Comorbidly Associated DSM Axis I Disorders with Chronic Pain

Psychiatric disorder	Prevalence within chronic pain patients (%)
Affective disorders (depression):	
Major depression	1.5–54.5
Dysthymia	0–43.3
Adjustment disorder with depressed mood	28.3
All forms of affective disorders	10–100
Psychoactive substance-related disorders:	
Current alcohol abuse–dependence	2–10.6
Current drug dependence (opioids, barbiturates, sedatives, cannabinoids)	5.2–34.0
Current illicit drug abuse (cocaine, cannabinoids, speed)	6.41–12.5
Total current alcohol and other drug dependence	14.9–23.4
Somatoform disorders:	
Somatization disorder	1–16.2
Conversion disorder	2–37.8
Psychogenic pain–pain disorder	0.3–97.0
Hypochondriasis	0.6–1.0
Anxiety disorders:	
Panic disorder	3–11
Panic disorder with agoraphobia	2.0–2.1
Posttraumatic stress disorder	1–9.7
Adjustment disorder with anxious mood	10–62.5
Obsessive–compulsive disorder	1.1–2.0
Phobic disorder	9
Total anxiety disorders	7–62.5
Other diagnoses:	
Psychotic disorders including schizophrenia	0–15.1
Marital problems	7–8.2
Psychological factors affecting medical condition	0–34
Adjustment disorder with work inhibition	5–14
Intermittent explosive disorder	9.9
No diagnosis on Axis I	3–5.2

involved in the cause of chronic pain. There are, however, discrepancies between authors on reported prevalence rates of the various types of affective disorder. This is demonstrated in Table III and is the reason why ranges are reported. These discrepancies relate to three problems: (1) differences in pain center CPP selection criteria; (2) a lack of operationally specified instructions for determining organic factors for the depression as required by the DSM-III-R and DSM-IV; and (3) the effect of pain on mood. The effect of pain on mood may be an extremely important issue and may be the reason for the high prevalence of comorbid affective disorders in CPPs.

The second most common group of Axis I psychiatric comorbidities to be found in CPPs is that of psychoactive substance use related disorders (see Table III). A review of this research area concluded that the prevalence percentages for the diagnoses of drug abuse, dependence, or addiction in CPPs were in the range of 3.2–18.9%. A significant percentage of CPPs, 6.41–12.5%, was reported to abuse illicit drugs (marijuana and cocaine). There was, however, little evidence that addictive behaviors were common.

The third most common group of Axis I psychiatric comorbidities to be found in CPPs is that of somatoform disorders (see Table III). Here, both conversion disorder and psychogenic–pain disorder are reported to have high prevalence rates (see Table III). There are major discrepancies, however, between authors on the prevalence of these two disorders. These discrepancies relate to reliability problems with DSM-III criteria for both of these diagnoses. Both of these diagnoses contain or have contained criteria that require the examiner to make a value judgment about a symptom. As a result of these problems, the DSM criteria for psychogenic pain were changed in the DSM-III-R and further changed in the DSM-IV. In addition, as discussed earlier, the identification of a patient as suffering from conversion disorder or pain disorder is heavily determined by whether the patient has received the nonspecific label as a cause of his or her pain. It is, therefore, likely that the data for the prevalence of these disorders are unreliable.

The fourth most common group of Axis I psychiatric comorbidities to be found in CPPs is that of anxiety disorders (see Table III). The reported high prevalence of anxiety disorders is not surprising because anxiety is the only psychiatric disorder that is commonly associated with any chronic medical condition. It is also reported that this association develops more quickly than any other association between a psychiatric disorder and a chronic medical condition. Although, as demonstrated in Table III, anxiety is common in CPPs, evidence indicates that these reported prevalences are underestimates. The evidence for this statement comes from studies performed with non-CPPs. One study reported that 81% of panic disorder patients had pain as a presenting complaint. In a second study it was reported that, in general practices, low back pain patients are more likely to have a diagnosis of anxiety than non-low back pain patients. Finally, CPPs, when compared with non-CPPs, are more likely to demonstrate avoidance of particular situations [e.g., injections and minor surgery, hospitals, sight of blood, thoughts of injury and illness (blood or injury phobia), being watched or stared at, and speaking or acting to an audience (social phobia)]. It is, therefore, likely that anxiety syndromes are comorbidly associated with chronic pain at a greater frequency than reported.

The fifth most common group of Axis I psychiatric comorbidities to be found in CPPs is that of the other diagnoses group (see Table III). Here, two diagnoses are important: psychotic disorders, including schizophrenia, and psychological factors affecting medical condition. Psychotic disorders, schizophrenia, delusional disorder, and bipolar affective disorder are not overrepresented within CPPs compared with the general population and are probably underrepresented. However, in patients with atypical facial pain, 10.3% have been reported to suffer from either schizophrenic or delusional disorder, and one study reported a 15% prevalence of psychotic disorders in reflex sympathetic dystrophy patients. It is likely that these discrepancies are related to CPP treatment selection criteria and self-selection. It is also possible that some select pain problems, such as reflex sympathetic dystrophy, may not share the same distribution of DSM disorders as other pain problems, such as low back pain. For the diagnosis of psychological factors affecting physical condition, there are major discrepancies between authors. These differences are likely related to reliability problems with the criteria for this diagnosis. These problems are the same as those pointed out for the somatoform disorders.

B. Comorbidity between the Chronic Pain State and Any Psychiatric Disorder on Axis II (Personality Disorders) of the DSM-IV

Comorbidities between chronic pain and Axis II psychiatric disorders are the second best studied group. The results of these studies are summarized in

Table IV
Percentages of Comorbidly Associated DSM Axis II Disorders with Chronic Pain

Psychiatric disorder	Prevalence within chronic pain patients (%)
Paranoid	2.8–33
Histrionic	4–30
Dependent	3–25
Mixed	22.0
Borderline	1–15
Passive–aggressive	12–14.9
Avoidant	14.0
Narcissistic	2.4–10.0
Self-defeating	10.0
Compulsive	6–6.7
Antisocial	5
Schizoid	1–4
Schizotypal	4
Total of samples	31–59.0

Table IV. Here, studies indicated that the prevalence of personality disorders in CPPs may range from 31 to 59%. These rates may be high because of a number of problems related to difficulties in identifying personality disorders when chronic pain is present. This area thus requires further study. In reference to the types of personality disorders comorbidly associated with chronic pain, no consistent trends are evident, and there are discrepancies between authors as to prevalence rates (note the ranges in Table IV). Thus, authors are in conflict as to which personality disorders are most commonly found in CPPs.

C. Comorbidity between the Chronic Pain State and Multiple Psychiatric Disorders on Axis I of the DSM-IV

Psychiatric research has determined that large numbers of psychiatric patients demonstrate more than one Axis I diagnosis, i.e., there is comorbidity between Axis I diagnoses. At issue then is whether chronic pain patients as a group demonstrate this type of comorbidity. Unfortunately, this type of comorbidity has been ignored by chronic pain researchers. There has only been one report on this issue, which reported on the number of Axis I diagnoses by sex within a group of CPPs. For males the distribution was as follows: no diagnoses, 5.7%; one diagnosis, 35.9%; two diagnoses, 33.3%; three diagnoses, 16.0%; and three plus diagnoses, 9.0%. For females, the distribution was as follows: no diagnoses, 4.7%; one diagnosis, 33.9%; two diagnoses, 34.6%, and three or more diagnoses, 7.9%. Therefore, 58.4% of the males and 61.4% of the females *had more than one diagnosis* on Axis I. Therefore, a significant number of CPPs should have Axis I diagnoses comorbidly associated with *other* Axis I diagnoses. The specifics of this comorbidity category have not yet been investigated within CPPs. This category of comorbidity will significantly affect CPP treatment outcome, as has been demonstrated with psychiatric patient groups.

D. Comorbidity between the Chronic Pain State and Psychiatric Disorders on Axis I and Axis II

Comorbidity between Axis I and Axis II (personality disorders) is also frequently found in psychiatric patients. This type of comorbidity is important because it has been demonstrated that it can significantly affect psychiatric treatment outcome. At issue then is whether CPPs as a group demonstrate this type of comorbidity. Unfortunately, this type of comorbidity has also been ignored by pain researchers. There has been only one report that addressed this issue indirectly. In 283 CPPs, 62.3% of the males and 55.1% of the females were assigned an Axis II diagnosis. In the same sample, 94.3% of the males and 95.3% of the females had one or more diagnoses on Axis I. Therefore, it is highly likely that this type of comorbidity is commonly present within CPPs. The exact details of this type of comorbidity have yet to be determined.

E. Comorbidity between the Chronic Pain State and between More Than One Psychoactive Drug Use Disorder on Axis I

Comorbidity between psychoactive drug use disorders on Axis I is also frequently encountered in psychiatric patients. An example of this type of comorbidity is a patient who abuses both alcohol and cocaine. This type of comorbidity is important because it has been shown that it can significantly affect psychiatric pathology in reference to presentation and outcome. At issue then is whether this type of comorbidity is present within CPPs. This type of comorbidity has also

been ignored by pain researchers. However, one study has demonstrated some indirect evidence that points to the presence of this category of comorbidity in CPPs. In this study, two groups of CPPs were compared for the prevalence of Axis I psychoactive drug use disorders: a group positive on urine toxicology giving correct information on current illicit drug use according to urine toxicology and a group positive on urine toxicology giving incorrect information on current illicit drug use according to urine toxicology. The results indicated that the false information group was more likely to have a past history of illicit drug use disorders. This indirect evidence indicates that subgroups of CPPs may suffer from multiple comorbid psychoactive drug use disorders.

F. Comorbidity between the Chronic Pain State and between Psychoactive Drug Use Disorders and Other Axis I Disorders

Comorbidity between psychoactive drug use disorders and other Axis I disorders is frequently found within psychiatric patient groups. This type of comorbidity, e.g., depression and alcohol use, can often complicate treatment and affect treatment outcome. One pain study has addressed this issue. In it, three groups of CPPs were compared for the prevalence of Axis I diagnoses other than psychoactive drug use disorders. The three groups were (1) CPPs with a current alcohol use disorder diagnosis, (2) CPPs with a current drug use disorder diagnosis, and (3) groups 1 and 2 combined. These groups were compared to CPPs without any of the aforementioned alcohol or drug use diagnoses. Some DSM affective and personality disorder diagnoses were found to be more frequently associated with all of the psychoactive drug use disorder groups than with the remaining CPPs. These results indicate that, as for psychiatric populations, this category of comorbidity is to be found in CPPs.

V. BEHAVIORAL COMORBIDITIES COMMONLY ASSOCIATED WITH CHRONIC PAIN

Because of chronic pain and resultant disability, CPPs usually encounter innumerable environmental problems. Some of these are significant enough to cause major stress. These then manifest as a behavioral concern or complaint with resultant anxiety or depression surrounding that issue. Some of these behavioral problems occur frequently enough to be labeled as behavioral comorbidities. These are presented in Table V. The behavioral comorbidities that can be thought of as usually being related to environmental circumstance are labeled nos. 1–7, 12, 13, and 14. Behavioral comorbidities 8–11 can be thought of as being a function of an interaction between the stress that the CPP is experiencing and the CPP's personality structure. Some of these behavioral comorbidities will be discussed next.

The importance of the no diagnosis problem (problem 1, Table V) has already been discussed under nonspecific pain. The vast majority of CPPs, if they are Worker's Compensation (WC) patients, complain of and are adversely stressed by the following stressors. Because of the adversarial nature of the WC system, the vast majority WC CPPs complain of major problems with their disability carriers (Table V). These have been noted by the author to be the following: (1) compensation checks always arriving late; (2) compensation benefits terminated for no reason, according to the CPP; (3) denial of medical care (doctors, medical procedures, or medical supplies) (Table V, 14) that the CPP has requested, wants, or has been recommended by his or her physician; (4) forcing the CPP to go to physicians he or she does not wish to go to; (5) forcing the patient to do a job search when the patient feels he or she is incapable of going back to work; (6) patient unable to reach adjustor; and (7) patient unable to reach an equitable settlement with the carrier. It is to be noted that these problems are the CPP's perceptions, which may be colored by the litigation process. From the nature of these complaints, however, it is clear that for a segment of the WC CPP population, the relationship with his or her carrier is a very stressful one. The author believes that when there is associated litigation (Table V, 3) between the WC patient and the carrier, the stress is even greater. As an indication of the stressful relationship between the carrier and the WC patient, it is not unusual to hear that the patient retained a lawyer because of the perception that he or she was being treated badly by the carrier. Occasionally, these perceptions can interact with paranoid tendencies of the CPP, or this situation can occur to a CPP who has been habitually violent. Under these circumstances, the CPP might begin to harbor fantasies (Table V, 17) about getting even in a violent fashion with the insurance carrier or the "insurance physicians." If there are such fantasies or wishes, the CPP should immediately be referred to a psychiatrist. It is interesting to note here that a multicenter CPP

Table V
Behavioral Comorbidities

(1)	Does not know or understand reason for chronic pain? Has no diagnosis? Conflicting diagnostic opinions?
(2)	Disability carrier problems and stress
(3)	Litigation stress
(4)	Preinjury job stress
(5)	Postinjury involuntary job loss
(6)	Perception of lack of support from spouse
(7)	Financial difficulties
(8)	Guilt over not being able to perform spouse and/or parental functions
(9)	Unrealistic expectations of recovery or function, e.g., ability to weight-lift
(10)	Coping strategies
(11)	Anger–irritability
(12)	Spouse solicitousness
(13)	Perception of employer negligence or other type of negligence for the injury
(14)	Dissatisfaction with medical care
(15)	Fear of pain
(16)	Self-efficacy
(17)	Violence ideation and risk
(18)	Suicidal ideation and risk

study has found that the presence of violent ideation is greater within CPPs than in general medical controls.

Perception of employer negligence or other types of negligence such as reckless driving as a cause of the CPP's pain is a common behavioral comorbidity (Table V, 13). This situation is typified by the patient who has warned his or her superior of a potentially dangerous situation at work or that a job that he or she is being asked to do is too hard or too dangerous, or both. As an example, a WC patient tells his boss that the object that he is being asked to lift is too heavy. He is told to lift this object or he will lose his job. The worker lifts the object and develops LBP, which later becomes chronic. The CPP then develops much anger at his employer and considers some form of litigation. He would then rationalize the litigation with the wish to "get even" with the employer for his or her apparent misconduct in causing the accident.

Often CPPs complain bitterly that, after years of service at a company, he or she was fired soon after the injury (Table V, 5). Thus, many CPPs are subject to involuntary job loss. Because work serves many adaptive functions, involuntary job loss can result in various degrees of loss of self-esteem and resultant depression. In addition, people who are not psychologically healthy may not react to the trauma of job loss in an adaptive fashion. Another issue in involuntary job loss is the loss of retirement benefits. It is not unusual for companies to terminate the CPP after an injury but a short time before the CPP is vested in the plan. Such a situation creates great anger and anxiety in the CPP, raising the issue of monetary gain on the part of the company. In some situations, the CPP's anger is channeled into the litigation process, and the CPP may even admit that he or she is seeking revenge in these actions. CPPs may also complain of anxiety about performing adequately in a new job because of their chronic pain. Finally, many CPPs are often fearful that they will never be able to get another good job because they will forever be labeled a back patient, or someone who has been on WC, or both. This is a correct perception. Often CPPs are denied employment because of their previous injuries.

The perception of preinjury job stress is also often noted to be a common behavioral complaint in CPPs (Table V, 4). This behavioral comorbidity was investigated in a series of four studies for its impact on CPP return-to-work behavior. In the first report it was demonstrated that CPPs not intending to return to work after pain facility treatment were more likely to

complain of job dissatisfaction at their preinjury job. In the second report, an association between nonintent to return to work after pain facility treatment and preinjury job dissatisfaction was similarly found across worker's compensation and non-worker's compensation chronic pain patients. In the third report, it was found that actual return to work was predicted at 1 month after pain facility treatment by intent, perceived job stress, and job like (job dissatisfaction) plus other variables. At 36 months, return to work was predicted by intent and by perceived job stress plus other variables. The final study attempted to predict actual return to work after pain facility treatment in relation to intent to return to work. Intent was predicted by perceived preinjury job stress plus other variables. In addition, those CPPs who intended to return and did not were predicted by whether there was a job to go back to. Also, CPPs not intending to go back to work at the preinjury job but doing so were predicted by having a job to go back to. Overall, this series of studies indicates that there is a strong relationship between preinjury work variables such as job dissatisfaction and intent to return to that job posttreatment. It appears that, in treating the CPP, it is important to understand work-related perceptions such as those of perceived job dissatisfaction and job stress.

Irritability–anger is another common behavioral complaint encountered in CPPs (Table V, 11) but has not been well-studied. Commonly, CPPs verbalize anger against the causal agent of the injury–illness, medical health care providers, attorneys and the legal system, insurance companies, the social security system, and employers but rarely against a significant other, God, self, and the whole world. Anger may represent one of the affective components of pain and may predict perceived pain interference and activity level. Anger expression among males was found to correlate negatively with lifting capacity improvement. Anger may be a function of anxiety and therefore may respond to relaxation coping skills intervention and, if necessary, medication.

The perception of unrealistic expectations for treatment for chronic pain is also often encountered as a behavior comorbidity in CPPs (Table V, 9). This unrealistic expectation applies to surgical treatment and/or pain facility treatment. Often, the CPP wishes to be the "same" as before the injury, i.e., to be able to do all activities including those that may be contraindicated for patients with chronic LBP, e.g., competitive weight-lifting. In the quest to be the same, the CPP will seek more aggressive–risky treatments as the less risky treatments fail. In this quest there is often physician collusion. Rather than provide realistic expectations about a treatment for chronic pain, the physician may provide inflated claims for the possible success of his or her treatment. Thus, some authors have noted that clinicians should be cautions in the prognostic information they give their patients as generally optimistic prognoses may create disappointment and anger. It is important to provide the CPP with information about the limits of the treatment and what can be reasonably expected.

Many CPPs complain or show a significant fear of increased pain (Table V, 15) and thereby fear of any stimuli, such as exercise, that could increase their pain. These fears may be related to measures of catastrophizing and depression and may characterize dysfunctional CPPs. This construct is important because these fears can affect pain facility treatment outcome and should be the focus of treatment efforts if they appear to interfere with treatment.

There has been some dissatisfaction with traditional psychological assessment tools for the behavioral assessment of the CPP, e.g., Minnesota Multiple Personality Inventory. Because of this issue and the development of the Cognitive Behavioral Model of Pain, there has been an attempt to develop new inventories that may be more applicable to the CPP. These new inventories attempt to tap three major concepts: patient pain beliefs (discussed earlier), self-efficacy expectations, and coping strategies. Self-efficacy expectations are beliefs regarding one's capacity to execute the behavior required to produce a certain outcome. Coping strategies are the process of executing a cognitive response to threat. These three concepts are important because there is some evidence that CPPs have some incorrect perceptions regarding their pain and that CPPs' coping behavior is dependent upon judgments regarding their ability to perform that behavior. Finally, training in the use of CPP coping strategies decreased reported pain and increased pain tolerance and threshold. Thus, these three concepts address problem areas where treatment interventions could be initiated.

The behavioral comorbidities of perception of spousal lack of support, guilt over not being able to perform marital and/or parental functions, and alleged spouse over-solicitousness to the CPP's pain behavior are all interrelated. Early in the development of the pain behavioral literature, it was postulated that a solicitous spouse would serve as a reinforcer to continued painful complaints, thus satisfying a secondary gain wish on the part of the CPP. There is some evidence for this assertion. These two approaches,

however, took attention away from the fact that spouses are often much affected by the illness of the CPP. There appears to be significant correlation between the psychiatric distress scores of the CPPs and their spouses, especially when CP is high. Evidence indicates that 28% of CPP spouses report significant depressed mood. This depression is predicted by the CPP's average pain, his or her level of anger and hostility, and the spouse's level of marital satisfaction. The CPP family is prone to two psychological tensions as result of the CPP's pain: uncertainty about the CPP's diagnosis and the authenticity of the pain. This situation arises because for most CPPs the diagnosis is elusive, i.e., nonspecific. Spouse or family perception of nonauthenticity can lead to CPP perception of marital nonsupport and thereby lead to marital–family conflict. This in turn can affect the CPP's pain.

Suicidal ideation and/or attempts are not infrequently encountered with CPPs. Because chronic physical illness is associated with depression, one would expect chronic physical illnesses such as chronic pain to be associated with suicide and/or suicide ideation. Indeed, patients with chronic migraines are at increased risk for suicide attempts. Similarly, the suicide rate for chronic LBP and neck pain populations is twice that of the general population. Therefore, CPPs are at risk for suicidal ideation and suicide attempts–completions. Any evidence of suicide ideation should immediately trigger a request for a psychiatric consultation.

VI. OTHER COMORBIDITIES COMMONLY ASSOCIATED WITH CHRONIC PAIN

There are a number of other comborbidities that are commonly associated with chronic pain. These are listed in Table VI. They are classified as other comorbidities because they do not translate into the DSM psychiatric diagnostic nomenclature and, although some of them appear to be behavior complaints, nevertheless they are more somatic in nature. These other comorbidities dramatically affect the difficulties involved in the care and treatment of the CPP. Usually, treatment plans cannot be developed without taking these problems into account. Each of these other comorbidities will be elaborated on here.

Sleep problems are a universal CPP problem. The vast majority complain of severe sleep disturbance. The sleep problems are usually a result of pain and may be directly associated with pain intensity. Although the CPP can usually fall asleep, he or she is frequently aroused from sleep by pain. Thus, the sleep is fragmented and of poor quality. These sleep disturbances are not a function of depressed mood.

Table VI
Other Comorbidities Commonly Associated with Chronic Pain

(1) Sleep problems
(2) Sexual problems
(3) Fatigue
(4) Somatization
(5) Nonorganic physical findings
(6) Perception of disability
(7) Pain behavior
(8) Memory and concention
(9) Neuropathic pain component
(10) Impaired functional status out of proportion to physical findings
(11) Perception of secondary gain issues
(12) Possibility of malingering

Sexual dysfunction is also a frequent complaint of the CPP. It has been claimed that up to 63% of men complaining of low back pain were found to be impotent. However, according to the author's experience, very few male CPPs are actually truly impotent. The usual complaint is that sexual intercourse is painful, and because of this the CPP is unable to maintain an erection. This serves as a disincentive to further sexual intercourse, which in turn results in decreased interest in sex. The decreased interest in sex can in turn lead to marital difficulties. Complaints of sexual dysfunction should be investigated, and those CPPs whose complaints actually indicate a possibility of impotence should be referred to a urologist.

Fatigue (Table VI, 3) is not an infrequent complaint in CPPs. However, fatigue has not been well-studied. To the author's knowledge there have been only two studies in this area. Both studies indicate that fatigue is commonly found in CPPs and that pain predicts fatigue. Because chronic fatigue syndrome overlaps with fibromyalgia, i.e., most chronic fatigue patients will have chronic pain, it is to be expected that fatigue should be a frequent problem in CPPs.

Somatization may be another other comorbidity that may be a significant problem within CPPs, and CPPs with this problem may be at risk for poor treatment outcome. Somatization has been defined as "a tendency to experience and communicate somatic distress and symptoms which are unaccounted for by

pathological findings, and to attribute them to physical illness, and to seek medical help for them. It is usually assumed that this tendency becomes manifested in response to psychosocial stress brought about by life events and situations personally stressful to the individual'' (Fishbain *et al.*, 1998). Somatization does not represent a specific DSM psychiatric or medical diagnosis and does not necessarily imply that a psychiatric disorder must be present. Because somatization is not a specific diagnosis, it does not have operational criteria by which it can be established. Thus, in CPPs somatization has been studied by questionnaires. These studies indicate that a high percentage of CPPs demonstrate elevated hypochondriasis scores and somatization scores. In addition, when patients with various types of chronic pain are compared to appropriate controls on somatization measures, CPPs frequently have greater somatization scores. This has been demonstrated for CPPs with orofacial pain, migraines, noncardiac chest pain, chronic low back pain, and fibromyalgia. Finally, somatization scores appear to be predictive for treatment outcome in CPPs with temporomandibular disorders and low back pain.

Another common other comorbidity found in CPPs has been termed pain behaviors. CPPs can be characterized as displaying pain behaviors. Pain behaviors are ''any and all outputs of the patient that a reasonable observer would characterize as suggesting pain, such as (but not limited to) posture, facial expression, verbalizing, pain expressions, taking medications, seeking medical assistance and receiving compensation'' (Fishbain *et al.*, 1998). Pain behaviors can often be elicited during physical examination and correlate with physical examination findings, number of operations, and longer pain histories. In addition, pain behaviors correlate with perceived severity of pain and extent of functional impairments. As pain improves, pain behavior diminishes.

Another other comorbidity often demonstrated by CPPs is that of nonorganic physical findings. These are eight physical examination signs found in CPPs with lower back or neck pain. Earlier in this century, these signs were identified as predominantly nonorganic. A large percentage of patients with chronic lower back pain demonstrate these eight nonorganic physical signs. These signs appear to be predictive of treatment outcome, and it has been suggested that their presence or absence should be used as a basis for surgical decisions. Most importantly, these signs correlate with a greater degree of pain behavior and, therefore, a more difficult treatment problem. In addition, the presence of one or more of these signs makes that patient a candidate for the psychiatric diagnosis of conversion disorder, a somatoform disorder. It has been stated that these signs are not a test of credibility or faking but represent a ''psychological yellow flag,'' indicating that psychological factors need to be considered.

CPPs often perceive themselves as disabled. The perception of disability was postulated to be the reason for failure of rehabilitation with some CPPs. However, it has been found that the perceived disability is a result of the pain. The perception of disability as a factor in chronic pain maintenance has not been well-studied.

Concentration and memory problems are another class of other comorbidities often encountered in CPPs. Generally, these patients complain of significant pain and demonstrate severe pain behavior. One study demonstrated that these problems were related to depression, nervousness, family conflicts, dissatisfaction with sexual activities, pain interfering with recreation, irritability, and worse pain when sitting.

At the present time, increasing amounts of evidence indicate that neuropathic pains may be very commonly found in CPPs. Neuropathic pain encompasses a diverse group of syndromes characterized by an injury to the nervous system. The resultant neuropathic pain has several distinctive clinical characteristics: localization in an area of sensory deficit; a burning and/or shooting quality with unusual tingling, crawling, or electrical sensations (dysesthesias); and gentle mechanical stimuli such as bending of hairs may evoke severe pains (allodynia). In some of these CPPs there may be involvement of the sympathetic nervous system called sympathetically maintained pain. Here it has been found that sympathetic activity can sensitize nonceptors following nerve damage. In addition, it has become clear that there may be different subtypes of neuropathic pain, which may have different underlying etiologies. Because myofascial syndrome CPPs often describe their pain as burning, this large group of CPPs could also have an element of neuropathic pain. At the present time this issue has not been researched. There is also some evidence in the literature that CPPs with a neuropathic pain syndrome have significant psychiatric comorbidity, including personality disorders, although not at a greater frequency than other groups of CPPs.

CPPs often demonstrate discrepancies between reported pain level and functional status versus the physician's perception of what the CPP should be able to do functionally according to the physical findings

(Table VI, 10). This perception discrepancy is attributable to a number of complex problems: CPPs perceive their pain as a disability that limits their functional status; the pathology model does not predict back pain, making the reliability and validity of this model questionable; and for a proportion of CPPs nonverbal expression may be discordant with self-reports. The resultant discord in perceptions between CPPs and their physician often leads to the labeling of the CPP as having psychiatric problems, having secondary gain (discussed next), or being a malingerer (discussed later). The key here is for the examining physician to understand that this problem is one of the other comorbidities in CP and that this problem is the *norm* for CPPs. Under these circumstances, it would be expected that fewer of these CPPs would be characterized as having psychiatric problems, having secondary gain, or being a malingerer.

Secondary gain has been defined as "acceptable or legitimate" interpersonal advantages that result when one avoids an activity noxious to him or her or gets support from the environment not otherwise forthcoming. As can be surmised from this definition, secondary gain can encompass many situations in which the patient can receive some gain. Examples of these situations are the following: fulfillment of dependency needs; prevention of desertion by the spouse; desire to get away from a bad job situation; desire to be retired before the injury; increased attention; avoidance of coercive activities (e.g., sexual intercourse); increased self-esteem; increased attachment needs; aggressive gratification (revenge); dissatisfaction with impairment rating before settlement (believes should have a 100% impairment rating); dissatisfaction with settlement terms; desire for retraining or to go back to school (had wanted to increase educational status before the injury); decrease in home–family responsibility; and so on. Secondary gains occur by unconscious mechanisms. It is, therefore, not clear whether desire for financial compensation should be classified along with the other secondary gains. Yet most CPPs who are involved in litigation, may or may not have excessive pain behavior, have significant functional impairment out of proportion to the physical findings, and have nonorganic findings are usually perceived as having secondary gains. This may or may not be the case, which is what the pain physician should keep in mind. Being involved in litigation does not necessarily mean that one has with a secondary gain agenda.

The final other CPP comorbidity is the likelihood of being suspected of malingering. This occurs because of the following other comorbidities described earlier; (1) the organic diagnosis is often elusive or nonexistent, i.e., nonspecific; (2) there is excessive disability versus the medical impairment; (3) nonorganic physical findings are present; (4) CPPs are usually financially dependent on compensation or disability benefits; (5) CPPs are usually involved in litigation; and (6) CPPs may have other secondary gain issues besides number 4 and 5. As such, CPPs are at risk for the accusation that they are malingering their complaints. Malingering is not classified as a mental disorder. The DSM-III-R states that malingering is an "act" and classifies malingering under the V codes that are included for a supplementary classification of factors influencing health status and contact with health services. The DSM-III-R suggests that the possibility of malingering should not be entertained unless there is evidence that physical symptoms are intentionally produced. Rarely is there strong evidence or any evidence for this conclusion. The Institute of Medicine report on pain and disability has also concluded that malingering is rare. The presence of secondary gain, or even monetary gain, is not evidence of malingering. Although malingering is often discussed in reference to CPPs, there are none or few studies of this problem within the chronic pain literature. Pain physicians should not consider this label unless they have definite proof, such as that obtained via covert observation.

VII. IMPORTANCE OF PSYCHIATRIC, BEHAVIORAL, AND OTHER COMORBIDITES TO CHRONIC PAIN TREATMENT

What is the importance of different types of psychiatric comorbidities to chronic pain? Research indicates that psychiatric comorbidities often impact negatively on chronic pain and functional status. As an example, anxiety can change pain threshold and tolerance and increase pain ratings. Comorbidly depressed CPPs demonstrate more automatic hyperactivity (muscle tension) and may be more sensitive to acute pain stimuli. In addition, evidence indicates that depression may magnify medical symptoms. Depression and phobias have also been reported to be associated with role impairment and loss of function. For example, individuals with subsyndrome depressive symptoms of major depression report significantly more impairment in 8–10 functional domains than individuals without subsyndrome depressive symptoms. Comorbidities between Axis I psychiatric

disorders in association with chronic pain can also significantly affect chronic pain treatment and outcome. This is because each of the comorbid Axis I disorders causes more severe symptoms of the *other* Axis I disorders. Because a high percentage of CPPs have more than one comorbid Axis I disorder, they are at risk for this problem. Comorbidities within CPPs between Axis I and Axis II psychiatric disorders can also affect the treatment of CPPs. For example, atypical depression (the type seen in pain facilities) is more frequently associated with personality disorders, making this type of depression more difficult to treat. This type of comorbidity could, therefore, also affect chronic pain treatment. Finally, conceptualization of pain-associated psychiatric comorbidity in terms of the preceding types of psychiatric comorbidities can help pain patient treatment decisions.

Behavioral comorbidities are also important because they can complicate treatment, as most of them are a source of additional stress. As such, these comorbidities can become the focus of psychological intervention. It is most important to understand and remember that these comorbidities should be present in most CPPs.

The other comorbidities characterize the CPP. This is their importance. The understanding that most CPPs will have these other comorbidities can potentially make diagnosis and treatment easier. Their impact on treatment outcome by their presence cannot be overstated.

Pain

A. D. CRAIG
Barrow Neurological Institute, Phoenix

GLOSSARY

ATP Adenosine triphosphate.

bradykinin An agent released from mast cells that activates and sensitizes pain receptors.

homeostasis The general process that maintains optimal conditions for survival.

hyperalgesia State in which increased pain is perceived in response to noxious stimuli.

sensitization Enhanced sensitivity due to peripheral or central changes in sensory processing.

Pain is a distinct, multidimensional sensory experience that is a common clinical complaint but is essential for survival. This article describes the characteristics of acute and chronic pain, the specialized neural elements in the periphery, spinal cord, and brain that subserve pain or that modulate pain, the roles of various neurochemicals, and the changes induced by damage or disease.

I. AN OVERVIEW

Pain is essential for the maintenance and survival of an individual. Pain is a somatic distress signal. It warns of the danger of bodily harm, it alerts to trauma and injury, and it signals unhealthy conditions or inflammation in tissues of the body. The accepted definition of pain is as follows: "an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage" (International Association for the Study of Pain). The alleviation or absence of pain is analgesia. Individuals with congenital insensitivity to noxious stimuli or bodily damage (who lack the requisite small-diameter peripheral nerve fibers) disregard injuries and infections and normally do not survive everyday life.

Pain is integrated within the context of current physiological and environmental conditions, together with past experience and future plans. Aristotle taught that pain is an emotion, but in the late 1800s physiologists began to recognize pain as a specific, discriminative sensation. It can be dissociated from other modalities of somatic sensation (for example, by anterolateral cordotomy), and, though subjective, it can be cognitively evaluated and reproducibly localized, scaled, and timed. Different types of pain can be distinguished qualitatively, for example, burning, stinging, aching, throbbing, or cramping, which reflect subpopulations of receptors and the tissue of origin.

Pain is often thought of as an exteroceptive, discriminative sense, like touch, yet it can originate from most tissues of the body, of which skin is but one vital organ. In addition, like all feelings from the body and in contrast to exteroceptive (touch) and teloreceptive (vision, hearing) modalities, the sensation of pain is innately endowed with a distinct unpleasantness, i.e., a characteristic affect that motivates behavior, which can be distinguished from its discriminative sensory aspect and also from the

long-term psychological experience called "suffering." Pain reflexly generates autonomic responses that signal its primal role in homeostasis (the processes underlying the maintenance of the body). Thus, pain can be regarded as a specific, emergent aspect of interoception, the sense of the physiological condition of the body itself, or, as Sir Charles Sherrington put it in 1900, a feeling from "the material me." The level of unpleasantness that is regarded as painful varies in different individuals (and in different contexts and cultures) and extends across a range of intensities in all individuals; think of the gnawing discomfort of a cold room, the burn of fatigued muscles, the stress of colonic tension, or the sting of a blister and compare these feelings to the excruciating agony of a smashed finger, a severe burn, a deep wound, a colonic spasm, a toothache, a kidney stone, or a migraine headache. The peripheral receptors that cause pain sensation are sensitive to changes in a variety of different tissue conditions (mechanical, thermal, and chemical), and, under normal circumstances, the fibers that report the physiological status of the tissues of the body to the central nervous system engage systemic survival mechanisms at several functional levels, i.e., autonomic, homeostatic, motoric, neuroendocrinologic, motivational, behavioral, and mnemonic. These responses must be integrated with ongoing homeostasis and behavior to maintain the health of the individual's body.

Injury or disease affecting either the peripheral or central nervous system can alter the balance of these integrative systems, and, in some cases, persistent, pathological pain results. There is a great need for the development of better methods for the alleviation and control of both acute, traumatic pain and chronic, long-term pain. Analgesic substances, for instance aspirin or morphine, that interact with the endogenous transmitters and modulators of the pain processing system are helpful for many people with pain, but not all and not always. Acute pain is signaled by specialized pathways that command immediate attention, but chronic pain can involve chemical, physiological, and even anatomical changes in the underlying substrates and these changes can produce a neuropathological state. In some patients with intractable pain, pharmaceutical agents administered orally, intravenously, or intrathecally (in the spinal canal) can produce analgesia. In others, deep brain stimulation or neurosurgical intervention is more effective, and in all cases behavioral management is an important therapeutic adjunct.

The following paragraphs describe the specialized neurons in the peripheral nervous system (primary receptors) and the central nervous system that subserve pain, the interactions with other somatic sensory pathways and with homeostatic processing systems, the neurochemicals associated with these elements, and, finally, the significant changes in these systems that can be induced by injury or disease.

II. PERIPHERAL RECEPTORS

Peripheral receptors localized in nearly all tissues of the body transmit their activity to the spinal cord (and its trigeminal equivalent in the caudal medulla) by way of axons that course in the sensory nerves. These primary afferent fibers have cell bodies in the dorsal root ganglia, and their central terminals enter the spinal cord by way of the dorsal roots. Low-threshold mechanoreceptors and proprioceptors (responsible for touch and movement sensations) generally have large-diameter fibers and large cell bodies, whereas high-threshold receptors (involved in pain sensations) and thermoreceptors (responsible for temperature sensation) generally have small-diameter fibers and smaller cell bodies. These include small myelinated (Aδ or Group III) and unmyelinated fibers (C or Group IV) that conduct slowly (approximately 3–30 and 0.5–3 m/sec, respectively). There is considerable overlap between these categories, however. There are also many C-fibers that innervate distinct low-threshold mechanoreceptors or histamine-sensitive chemoreceptors (that may subserve tickle or itch, respectively). The small dorsal root ganglion cells develop in a later phase than the larger ones and are histologically differentiable as dark neurons.

Receptors that respond selectively to noxious or potentially damaging stimuli are called nociceptors (a term introduced by Sherrington). The receptive elements of nociceptors are free nerve endings without accessory structural specializations, albeit ultrastructural studies suggest that Aδ and C nociceptive endings may be differentiable in fine details. In skin, the Aδ-nociceptors innervate one or a few neighboring spots, whereas most C-fiber nociceptors are sensitive over a 1–4 mm^2 receptive field. Subtypes have been differentiated physiologically in skin and in various somatic tissues (e.g., muscle, joint, gallbladder, colon, genitalia, esophagus, tooth pulp). In general, most Aδ-nociceptors respond only to noxious mechanical stimulation (e.g., pinch) or to both noxious mechanical and noxious heat stimuli, whereas a few respond only to noxious heat. Many C-nociceptors are similarly submodality-selective, but most are polymodal,

responsive to several forms of noxious mechanical, thermal, and chemical stimulation (apparently by separate biophysical transducers). Polymodal C-nociceptors are also responsive to chemical (or metabolic) stimuli, such as acidic interstitial pH, bradykinin, serotonin, ATP, and hypoxia or hypoglycemia. The Aδ-nociceptors in muscle can be activated by pinch though some are activated by contraction, and the C-nociceptors in muscle can be activated by static exercise, pinch, heat, algogenic chemicals, or ischemia.

Nociceptors have been characterized by peripheral nerve recordings not only in animals but also in humans using a technique called percutaneous microneurography, in which a microelectrode is inserted into a peripheral nerve in awake volunteers. Electrical microstimulation during microneurographic recordings supports the specific sensory roles of nociceptive fibers; human volunteers report sharp pain upon stimulation at Aδ nociceptive fiber recording sites, burning pain from stimulation at C-fiber recording sites, and aching or cramping pain upon the stimulation of C-nociceptors innervating muscle, but no pain upon stimulation near low-threshold mechanoreceptive fibers. Blockade of peripheral C-fiber conduction with lidocaine eliminates burning pain sensation. A pressure block of peripheral nerve conduction that blocks Aδ-fiber conduction eliminates sharp pain sensation (and touch and temperature sensations), yet pinch or cold still causes a painful burning sensation. The rapid stinging or pricking sensation associated with Aδ-nociceptors is called first pain, and the slower, burning sensation (or from deep tissues, the dull, aching sensation) associated with activity in C-nociceptors is called second pain.

The mean threshold for mechanical cutaneous pain is approximately 10 gm of force per mm of circumference of a flat probe. The mean heat and cold cutaneous pain thresholds are approximately 45 and 15°C, respectively. The mean activation thresholds and the incremental detection thresholds of nociceptors correspond to human psychophysical sensory measurements; nonetheless, the thresholds for activation of nociceptors in all tissues extend over a broad range encompassing these stimulus intensities. Many are responsive only to overtly damaging stimuli, and some are insensitive (silent) and respond only subsequent to inflammation or actual tissue damage. The discharge activity of C-nociceptors is slow (few fire faster than 20 Hz), and microneurographic stimulation results show that temporal summation of C-fiber activity is required to produce a perception of pain. (Also, C-nociceptors from muscle or joint can have ongoing discharge, consistent with a role in ongoing homeostasis below perceptual threshold.) Above threshold, the intensity of perceived pain is directly related to the number of action potentials that nociceptors fire or the frequency of microneurographic stimulation. Maintained noxious mechanical or heat stimuli, however, generate increasing pain sensations that must result from central summation, because the responses of the peripheral nociceptors to maintained tonic stimuli adapt to low firing levels.

III. PAIN PROCESSING IN THE SPINAL CORD AND BRAIN

The central axons of small-diameter primary afferent fibers enter the spinal cord through the lateral portion of the dorsal roots. Their collateral branches reach 1–3 segments longitudinally in Lissauer's tract. Within the superficial dorsal horn of the spinal cord or the equivalent trigeminal nucleus caudalis in the caudal medulla, cutaneous C nociceptive fibers arborize and terminate in lamina I and outer lamina II, and cutaneous Aδ nociceptive fibers terminate in lamina I as well as deeper in lamina V (the neck of the dorsal horn). Nociceptive afferents from muscle, joint, and viscera terminate primarily in lamina I, but a few also extend into laminae II, V, and X (near the central canal).

Nociceptive cells in laminae I and V are the main second-order pain projection neurons that send ascending axons to the brain. Nociceptive neurons in lamina I have little or no ongoing activity, and they respond specifically to noxious stimuli within a small receptive field (in skin, muscle or viscera). Two distinct functional types of nociceptive cells are present in lamina I, one dominated by Aδ input (fusiform nociceptive-specific cells), whose discharges closely parallel first pain sensation, and the other dominated by C-fiber input (multipolar polymodal nociceptive cells), whose discharges closely parallel second pain sensation. Other lamina I cells respond specifically to innocuous thermal stimuli (cooling or warming) or to histamine application (which causes the sensation of itch). The different physiological types of lamina I cells are also morphologically and pharmacologically distinguishable. The nociceptive neurons in lamina V have large receptive fields and considerable ongoing discharge, and they are multireceptive because they respond to both nonnoxious and noxious mechanical stimuli (often called wide dynamic range or WDR cells). Subclasses of lamina V cells can be distinguished

that are sensitive primarily to low-, medium-, or high-threshold stimulation, but as a population their activity is directly related to the overall intensity or the cumulative integration of afferent activity from all somatic tissues. A few WDR cells can also be found in lamina I. Different neurons in each anatomical location respond to A-fibers only or to both A- and C-fibers (monosynaptically in lamina I, polysynaptically in lamina V). Both lamina I cells and lamina V cells encode the intensity of noxious stimulation with the frequency of their discharge, albeit in a modality-selective and modality-nonselective manner, respectively. Laminae I and V neurons that are activated by noxious stimuli can be observed immunohistochemically by labeling for the immediate early gene *c-fos*; such labeling in lamina I seems to reflect numerically the intensity of graded noxious heat stimulation. The discharge activity of a subset of trigeminal WDR cells in laminae I and V has been closely correlated with the operant detection of intensity changes in noxious heat stimuli by behaviorally trained monkeys. Nociceptive information is conveyed to spinal motoric systems mainly by lamina V cells and to spinal autonomic systems mainly by lamina I cells. Nociceptive cells that respond to visceral stimulation also usually have a cutaneous receptive field. This convergence may be the basis for referred pain, in which activity originating from nociceptors in deep tissues is perceived as arising from (and induces hyperalgesia in) a cutaneous zone represented in the same spinal segments. For instance, in angina pectoris pain is referred to the left shoulder, and pain and hyperalgesia are referred to different portions of the face and head with a toothache in different teeth.

The small neurons in lamina II (the substantia gelatinosa or SG) that receive C-fiber inputs are generally interneurons whose processes extend rostrocaudally at most 2–3 spinal segments. Most of these are inhibitory neurons with varicose dendrites and short or even no axons (Golgi type II neurons) that contain GABA, about half of which also contain glycine. Subclasses of SG cells can be distinguished immunohistochemically by labeling for somatostatin, enkephalin, substance P (SP), nitric oxide synthase, acetylcholine, and many other modulators, as well as particular intracellular messengers such as protein kinase Cγ (PKCγ). At the ultrastructural level, C-fiber terminals in SG are characterized by distinct glomerular structures containing pre- and postsynaptic elements that can be differentially labeled for various peptides, amino acids, or receptor subunits (such as NK1r, mGluR1, or gephyrin). However, the functional, anatomical, and neurochemical organization of the superficial dorsal horn, and particularly the SG, is still a profound mystery that needs to be elucidated in order to understand pain processing at the spinal level.

The ascending projections of laminae I and V spinal nociceptive neurons terminate in several hierarchically organized regions that reflect the various reactions to a painful stimulus. Within the spinal cord, lamina I (and some lamina V) cells project to the sympathetic preganglionic regions in the thoracolumbar cord and to parasympathetic regions in the sacral spinal cord and at the spinomedullary junction. In the lower brain stem, lamina I axons terminate bilaterally in several preautonomic sites, especially the major catecholamine cell groups in the ventrolateral medulla and the dorsolateral pons. These projections provide a basis for modality-selective somatoautonomic reflexes in cardiorespiratory function caused by noxious or thermal stimuli or by adverse tissue metabolic changes. Lamina V axons terminate diffusely in the reticular core of the brain stem and may affect somatomotor integration and behavioral state. There are dense projections from lamina I cells (and a few lamina V cells) to the parabrachial nucleus at the pontomesencephalic junction, which also receives vagal afferent input by way of the solitary nucleus; the parabrachial nucleus is a major viscerosensory (homeostatic) integration site that is interconnected with the periaqueductal gray, hypothalamus, amygdala, and homeostatic cortical regions. The lamina I spinoparabrachial projection provides an indirect spinal pathway to the central amygdala that appears to be involved with fear-associated conditioning by nociceptive activity and probably also with cardiovascular responses and the initiation of opiate-related descending antinociceptive activity. There is a similar spinal projection to the periaqueductal gray, which is the major mesencephalic site for homeostasis, defense reactions, and vocalization. The hypothalamus receives ascending nociceptive activity by way of the parabrachial nucleus, by way of the noradrenergic cells in the caudal ventrolateral medulla, and perhaps also by a direct input from spinohypothalamic neurons. These projections may affect goal-directed aversive and feeding behaviors and neuroendocrine and immune responses to homeostatic or nociceptive activity, as well as thermoregulatory and osmoregulatory control.

The main ascending pathway for pain sensation is the crossed lateral spinothalamic tract (STT), which courses in the middle of the lateral funiculus and consists primarily of lamina I axons from the

contralateral side. This pathway is clinically and behaviorally critical for pain and temperature sensibility, as well as for itch and sexual sensations, based on cordotomy lesions. The main termination of this pathway in primates is a dedicated nociceptive- and thermoreceptive-specific relay nucleus in the posterior thalamus (VMpo), which projects topographically to a cytoarchitectonically distinct field in the dorsal margin of insular cortex and has a collateral projection to area 3a in the fundus of the central sulcus. The homologous pathway in cats and rats exists only in a rudimentary, primordial form; this pathway is proportionately greatly enlarged in humans. Microstimulation of this thalamic region in awake humans produces sensations of graded pain or cold. Lamina I spinothalamic neurons also terminate in a ventral portion of the main somatosensory thalamic relay nucleus (VPI), which in turn projects to the second somatosensory region (SII) in the parietal operculum of the lateral sulcus, and in a posterior portion of the medial dorsal thalamic nucleus (MD), which projects to the anterior cingulate cortex. The axons of spinothalamic lamina V cells ascend in the anterior spinothalamic tract and constitute another major pathway conveying tactile and pain-related activity; these axons terminate in VPI and also in conspicuous patches in the main somatosensory relay nuclei (VPM and VPL) around immunohistochemically distinct (calbindin-positive) cells, where WDR nociceptive neurons can be identified. In contrast to most sensory thalamocortical pathways, these neurons seem to project to the superficial layers of the primary somatosensory cortical region (SI) in the postcentral gyrus. Nociceptive WDR cells have been recorded in SI, and clusters of nociceptive-specific cells have been recorded in area 3a.

There are also other multisynaptic pathways that may provide ancillary pain information to the forebrain. Nociceptive spinothalamic cells in the spinal intermediate zone, especially at upper cervical segments, project bilaterally to the medial thalamus and to motor-related thalamic nuclei. Spinomedullary lamina X neurons that project to the dorsal column nuclei or the nucleus solitarius may be important for visceral pain. A spinoreticulothalamic pathway by way of the dorsal medulla may provide a substrate for widespread activation of supragranular frontal cortex.

The main regions of the human cerebral cortex that are activated by painful stimuli in functional imaging (PET, fMRI) and laser-evoked potential studies are the insula (limbic sensory cortex) and the anterior cingulate (limbic motor cortex). In addition, in many studies activation is also observed in the primary and secondary somatosensory areas. Other regions activated by painful stimuli include dorsolateral prefrontal cortex, striatum, cerebellum, hypothalamus, amygdala, and periaqueductal gray. These areas together form a complex forebrain network involved in pain sensation. Some of these areas may subserve distinguishable roles in pain perception, which are currently being vigorously investigated. Possible associations are as follows: the insula with qualitative sensory differentiation, homeostasis, and memory; the anterior cingulate with affect, motivation, response selection, and attention; and the somatosensory areas with intensity discrimination and somatomotoric integration. The insular cortex seems to be a primary sensory field for pain, temperature, and visceral (interoceptive) sensation, and abnormal activation of this region has been observed in neuropathic pain patients. Activation of the anterior cingulate appears to be particularly important for distressful cutaneous stimulation, because it is selectively associated with the perception of pain and unpleasantness with noxious thermal stimulation and also with itch. Noxious heat inhibits primary somatosensory cortical area 3b as it activates the adjacent area 3a. The distribution of activation of the somatomotor cortex of the central sulcus is related to the occurrence of phantom limb pain in amputees. However, many of these areas of the forebrain are interconnected, and thus the effects of stimulation or lesions in any one of these regions on pain sensation are equivocal and may produce imbalanced integration rather than a discrete change in function. Lesions involving posterolateral thalamus or the parietoinsular cortex can reduce pain and temperature sensation, but they can also result in the central pain syndrome (described later). Large lesions of the postcentral gyrus have no effect on pain, but small lesions (that probably include area 3a in the fundus of the central sulcus) can affect pain. Lesions of the anterior cingulate have had varied effects, including blunting the emotional aspect of pain (also produced by frontal lobotomy) or thermal hyperalgesia. Anatomical variability between human brains has been documented and presents a serious confound to these issues.

IV. MODULATION OF PAIN PROCESSING

Fast endogenous antinociceptive circuits are thought to have evolved to facilitate defense or escape behaviors and thereby enhance survival. The classic example supporting the existence of endogenous central pain control systems is the observation of soldiers with

massive wounds who did not complain of pain. In addition, there are well-documented occurrences of placebo-induced analgesia in patients with organic causes of pain. Central neural controls of the circuits involved in pain transmission make sense because nociceptive processing has significant interactions with integrative homeostatic and immune system function, and because healing following traumatic injury or inflammation requires a prolonged time period.

Descending supraspinal projections modulate nociceptive processing in the dorsal horn. These projections terminate in laminae I–V and originate primarily from homeostatic control regions in the brain stem, that is, the rostroventromedial medulla (including the raphe nuclei) and the enkephalinergic cells and catecholamine cell groups (A5, A6, A7) in the dorsolateral pontine tegmentum. The antinociceptive actions of these systems depend on serotonergic, adrenergic ($\alpha 2$), and enkephalinergic transmission at the spinal level. These descending systems act in part by way of inhibitory interneurons (causing indirect presynaptic actions on primary afferents) and in part by direct postsynaptic inhibition of transmission neurons. However, these projections include pronociceptive (facilitatory) actions on dorsal horn nociceptive processing as well. The descending inhibitory actions can be activated by noxious stimulation over the whole body, which may underlie the phenomenon of counterirritation, and the descending facilitatory actions can be activated by low-threshold mechanoreceptors, which might be involved in touch-evoked pain (mechanical allodynia) in neuropathic conditions. In addition, direct projections to lamina I from the hypothalamus probably underlie the spinal antinociceptive actions of oxytocin, vasopressin, and hypocretin (orexin), although these agents also have actions on thermoregulation and homeostatic integration.

Inhibition of second or tonic pain by low-threshold mechanoreceptive activity (e.g., rubbing, vibration) can be demonstrated with peripheral electrical nerve stimulation. The inhibition of spinal nociceptive processing by low-threshold afferent activity and by descending activity was an important aspect of the gate control theory of pain; this historically important contribution focused attention on spinal integration and endogenous modulation, albeit without regard for the role of nociceptive-specific neurons. Inhibition of pain processing by low-threshold stimulation occurs partially at the spinal segmental level and partially at the cortical level, although the mechanisms are still unclear. Dysfunction of such inhibition is another possible cause of touch-evoked allodynia in neuropathic pain. These inhibitory mechanisms may be engaged by transcutaneous electrical nerve stimulation (TENS) and by dorsal column stimulation, procedures used by some clinicians for pain control.

Innocuous thermosensory (cool or warm) stimulation can inhibit C-fiber-evoked pain. Application of cold or warmth is a well-established therapy that has peripheral effects on inflammation, sensitized nociceptors, and tissue perfusion. In addition, there is a central inhibitory effect of cooling on pain that is demonstrated by the thermal grill illusion, in which a painful, icelike burning sensation is elicited by spatially interlaced innocuous warm and cool stimuli. (This illusion is on display at many science museums.) In this illusion, the reduction of innocuous thermosensory activity (by simultaneously cooling and warming the skin) unmasks the cold activation of the pathway responsible for the burning sensation associated with noxious cold, which is normally inhibited by ongoing innocuous thermosensory activity. Functional imaging results indicate that noxious cold is distinguished by its activation of the anterior cingulate cortex (by way of lamina I spinothalamic input to the medial thalamus), and the thermal grill illusion causes the same pattern of activation in the forebrain (and in lamina I spinothalamic neurons). A conduction block of peripheral nerve fibers that eliminates ongoing activity in Aδ thermoreceptive fibers responsible for cooling sensation produces a similar disinhibition and enables a normally innocuous cool stimulus to produce a burning sensation (via polymodal C-nociceptors and lamina I polymodal nociceptive neurons). The intense burning experienced when lukewarm water is applied to a foot numbed by cold is directly comparable to the thermal grill sensation, and this highlights the thermoregulatory significance of the cold inhibition of burning pain. Descending modulation by the thermosensory region in the insular cortex of lamina I and of integration sites in the brain stem and thalamus may underlie this inhibitory mechanism.

Stimulation-induced analgesia can be produced by the electrical or chemical activation of sites in the brain that are the source of both descending and ascending pathways. Clinical deep brain stimulation of the periaqueductal gray (PAG), the hypothalamus, and other forebrain sites can be behaviorally antinociceptive, can reduce the responses of nociceptive dorsal horn neurons, and can alleviate certain kinds of chronic pain in patients. Stimulation of the periaqueductal gray activates descending pathways that involve serotonergic and peptidergic (substance P) neurons in the rostroventral medial medulla (including the

midline nucleus raphe magnus) and the noradrenergic and enkephalinergic neurons in the dorsolateral pons. These descending systems are also activated by systemic opiates or cannabinoids. Just as pain has direct effects on cardiorespiratory activity, these descending bulbospinal antinociceptive pathways also have direct actions on sympathetic preganglionic neurons and on brain stem autonomic sites. In addition, stimulation in the periaqueductal gray can cause intense negative or positive emotional experiences in awake patients. Nonetheless, stimulation-produced analgesia in human patients is often reported to be selectively effective with long-term use, without any autonomic changes or sensory experiences.

The endogenous pain control systems can, of course, be activated naturally, for example, by environmental stressors (so-called "stress-induced analgesia"), by behavioral danger signals that can be classically conditioned, and perhaps by meditation or biofeedback training. Significantly, there are also endogenous anti-analgesia (pronociceptive) circuits, which can be behaviorally activated by conditioned safety signals that indicate when danger will not occur. These circuits may be distinct from the antinociceptive and pro-nociceptive medullary circuits described earlier. Behavioral pronociceptive actions seem to be powerful enough to reverse the effects of the endogenous antinociceptive systems at the spinal level. Learned safety signals cause the spinal release of peptides (particularly cholecystokinin) that can block analgesia produced by stress, danger, or even morphine. Such antianalgesia mechanisms could have an important role in chronic pain and in the development of morphine tolerance.

V. NEUROCHEMISTRY OF PAIN

The neurochemical attributes of peripheral nociceptors and central pain processing are being studied vigorously. All small-diameter fibers appear to contain the neurotransmitter glutamate, and many contain various peptides and cotransmitters. Several markers have been identified, although none are entirely specific for a particular class of receptor or a particular submodality of pain. Neurochemicals that are not associated with low-threshold receptors are of particular interest. Many, but not all, C-nociceptors contain peptides such as substance P (SP), calcitonin-gene-related peptide (CGRP), neuropepetide Y, galanin, or somatostatin. Some C-nociceptors have the vanilloid receptor (VR1), which responds to protons and heat and is the channel responsible for chemogenic pain caused by the pungent red pepper ingredient capsaicin. Many nociceptive C-fibers also have tetrodotoxin (TTX) resistant sodium channels that are found only in small dorsal root ganglion cells (SNS or PN3 and SNS2 or NaN). In addition, C-fibers that contain SP or CGRP have particular neurotrophin receptors (TrkA and p75) that are sensitive to nerve growth factor (NGF), whereas a subset of C-fibers that can be labeled for the surface lectin IB4 are sensitive to glial-derived growth factor (GDNF). Selective augmentation, blockade, and gene knockout experiments have confirmed that each of these factors affects pain processing.

The peripheral nociceptors respond to a variety of chemicals. Agents that can directly activate nociceptors include glutamate, ATP, potassium, bradykinin, and protons, all of which are released from damaged tissue or mast cells. In addition, these and other agents can sensitize nociceptors, causing spontaneous discharge, increasing their responsiveness to noxious stimulation, and lowering their thresholds to natural stimuli. Sensitization can be produced by repeated noxious stimulation or by chemical agents [such as bradykinin or the pro-inflammatory cytokines, like interleukin 1 (IL-1β) and tumor necrosis factor (TNFα)].

The eicosanoids, derivatives of the cell membrane lipid arachidonic acid, which include the prostaglandins and the leukotrienes, are particularly important sensitizing agents (especially PGE2 and PGI2). The formation of prostaglandins depends on cyclo-oxygenase (COX), which is inhibited by aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen and naproxen. Most NSAIDs inhibit both COX-1 (constitutive) and COX-2 (inducible), and aspirin does so irreversibly. Whereas COX-1 is essential for the health of the stomach and kidney, the induction of COX-2 has a primary role in inflammation, sensitization, and fever. Thus, newly developed selective COX-2 inhibitors might reduce the deleterious effects of aspirin on stomach and kidney function. Corticosteroids produce a similar anti-inflammatory effect by blocking the induction of COX and the release of arachidonic acid stores, although they also have many other effects on immune function and metabolism.

Antinociceptive chemical agents that might act peripherally have been sought, but few have been found useful so far. Serotonin 5HT1 receptor agonists (such as sumatriptan, which is effective against migraine headaches) block the discharge activity of trigeminal cerebrovascular afferents. They also block

the peripheral release of SP and CGRP from the terminal branches of active nociceptors, which is a significant effect because the release of SP promotes plasma extravasation (edema), and CGRP is a potent vasodilator that contributes to neurogenic inflammatory flare (see Section 6), actions that are thought to contribute to headaches. Adenosine and somatostatin also appear to have direct inhibitory effects on nociceptive terminals. Following inflammation, the opiates have indirect peripheral antinociceptive actions by way of receptors on immunocytes.

The agents that act at the peripheral terminals can also act at the central terminals (presynaptic modulation) of primary afferent nociceptors. The central terminals of nociceptive primary afferent fibers release neurotransmitters, neuromodulators, and trophic agents in the dorsal horn. They all seem to release glutamate and/or aspartate, major excitatory amino acid (EAA) neurotransmitters that are also used by low-threshold primary afferents and many other neurons. Nociceptive (and other) primary afferent fibers may corelease ATP, and some nociceptive C-fibers also corelease peptides, such as SP, CGRP, neuropeptide Y, and galanin. The release of cocontained neurotransmitters may be under differential, independent control. Release at central nociceptive terminals is presynaptically inhibited by GABA, opiates, noradrenalin, adenosine, cannabinoids, and other agents, but enhanced by prostaglandin (PGE2) and cytokines.

The EAAs released by nociceptive fibers act on several types of receptors in the dorsal horn, which include both ionotropic (AMPA, kainate, and NMDA) and metabotropic (mGluR) receptors. Activation of ionotropic glutamate receptors leads to a rapid depolarization in the postsynaptic cell due to the influx of Na^+ through the AMPA receptor or Na^+ and Ca^{2+} through the NMDA receptor. Selective blockade of AMPA receptors (with antagonists such as CNQX) reduces nociceptive activation of dorsal horn neurons and acute pain behaviors in rats. Depolarization can remove the Mg^{2+} blockade of NMDA channels, and NMDA receptor activation produces a more prolonged depolarization and second messenger activation that can lead to long-term changes within dorsal horn neurons. Selective blockade of postsynaptic NMDA receptors (such as with MK-801 or dextromethorphan) can prevent the development of hyperexcitability in dorsal horn neurons (central sensitization) and reduce inflammatory or nerve-injury-induced pain behaviors in animal studies; however, in clinical trials the side effects of these agents are prohibitive. Nonetheless, coadministered NMDA antagonists might permit the use of lower doses of spinal morphine for analgesia and delay the development of opiate tolerance. Antagonists to metabotropic EAA receptors (in particular, mGluR1), which are G-protein-coupled receptors that activate the second messenger protein kinase C (PKC), also seem to reduce or inhibit nocifensive responses; these may also have presynaptic effects.

The SP-containing nociceptive fibers can activate several neurokinin receptors, but especially the neurokinin 1 receptor (NK1r). This G-protein-coupled transmembrane receptor is located almost entirely on lamina I neurons (and a few laminae III–V neurons). Activation of NK1r causes a delayed, long-lasting (tens of seconds) depolarization that can summate, and it results in phosphorylation of the NMDA receptor complex (by way of PKC), rendering it more active. The activation of NK1r in lamina I cells by different noxious stimuli (or its inhibition) can be observed anatomically, because after activation it is translocated from the cell membrane (internalized) into the cytosol of the cells. Abolition of SP fibers, NK1r neurons, or PKCγ in the dorsal horn reduces central sensitization of nociceptive neurons and sensitivity to tonic noxious stimuli in behavioral models.

Inhibitory neurotransmitters are present in intrinsic spinal cord neurons, especially in the substantia gelatinosa (SG). These interneurons are activated by afferent fibers and by descending modulatory fibers. Nociceptive dorsal horn neurons can be inhibited by GABA, glycine, opioids (enkephalin, dynorphin), acetylcholine (epibatadine), adenosine, noradrenaline, dopamine, and serotonin. Both direct synaptic and extrasynaptic actions have been shown. These actions can be modulated locally by steroids, such as cortisol or estrogen. The organization of the intrinsic inhibitory circuits is not well-understood.

Opioid actions have been closely scrutinized, because the classic opiate morphine and its congeners and the opioid peptides with similar actions are still the most potent analgesics known. In the spinal cord, opioids produce presynaptic inhibition of transmitter release from nociceptive primary afferents by the inhibition of calcium entry; this action is antagonized indirectly by cholecystokinin (CCK). Opioids produce postsynaptic inhibition of nociceptive dorsal horn cells via a G-protein-coupled potassium conductance increase. All three types of opiate receptors (μ, δ, and κ) are involved, and the subunit composition of these receptors may be dynamic. Epidural or intrathecal injections of fast-acting μ-selective opiates (such as fentanyl) clinically (in humans) and behaviorally (in

rats) are most effective. Spinal injections usually include bupivicaine, a long-lasting local anesthetic that blocks activity in small-diameter primary afferent fibers, thereby reducing the amount of opiate needed and the danger of respiratory depression due to rostral spread. κ opioids seem to be effective for labor pain in women. δ opioid actions appear to be important for the development of spinal tolerance.

Systemically administered opiates engage endogenous pain control mechanisms in the forebrain, particularly in the brain stem periaqueductal gray, the amygdala, and the anterior cingulate cortex. In the periaqueductal gray, μ-selective agonists disinhibit the endogenous descending antinociceptive pathways involving serotonergic and noradrenergic fibers that are activated by stimulation-induced analgesia. A different opioid antinociceptive pathway normally activated by endogenous β-endorphin (from the hypothalamus) in the periaqueductal gray is not engaged by morphine. Aspirin potentially could synergize with the effects of morphine in the periaqueductal gray, where morphine's mechanism of action involves an eicosanoid pathway. The development of associative (context-dependent) tolerance to morphine can be blocked by microinjection of CCK antagonists in the amygdala. Opiates traditionally have been underprescribed for acute or postoperative pain relief because of the well-publicized fear of dependency; however, usage of opioids for analgesia is now strongly recommended, because controlled studies have shown that fewer than 1% of patients are at risk and because pain itself can affect outcome. Coadministration of synergistic adjuvants that help prevent the development of pharmacological tolerance has further encouraged increased clinical use of opiates, for example, in bedside minipumps for patient-controlled analgesia.

The neurochemistry of supraspinal pain processing regions is not well-known, in large part because many clinically relevant sites in primates have been identified only relatively recently. The terminals of lamina I spinothalamic neurons in primates contain glutamate, and some can be immunohistochemically labeled for calbindin, SP, or enkephalin. Presumably, many of the same neuromodulators found at spinal levels are also involved supraspinally.

VI. PAIN IN INJURY AND DISEASE

Tissue damage or infection elicits a local injury response, which includes the production of eicosanoids (from arachidonic acid), bradykinin (from plasma kalikrein), lactic acid and superoxide free radicals (from leukocytes and mast cells), serotonin, histamine, and various pro-inflammatory cytokines (e.g., IL1-β and TNF-α). All of these inflammatory (and antibacterial) agents have direct effects on nociceptors, resulting in activation or sensitization. Activated nociceptors also contribute a neurogenic component to inflammation by the peripheral release of agents such as glutamate, SP, CGRP, and ATP, which affect sympathetic efferents, mast cells, and small blood vessels, causing vasodilatation and plasma extravasation (increased permeability between capillary endothelial cells). This in turn increases tissue infiltration with blood cells, plasma, cytokines, immune complement agents, and more bradykinin, serotonin, and glutamate. Peripheral inflammation is modulated by ascending nociceptive activation of the hypothalamo–pituitary–adrenal (HPA) axis. Inflammation-induced trophic agents, such as nerve growth factor (NGF) or glial-derived growth factor (GDNF), that are involved in regeneration and healing can have long-term effects on the expression of chemicals and receptors in primary afferent fibers, and they are potentially significant for neuropathic changes.

Sensitization of nociceptors (lowered threshold for activation and increased activity to a noxious stimulus) produces the condition of primary hyperalgesia. An example of primary hyperalgesia is the increased sensitivity caused by a sunburn, where light touch or warmth on the sunburned area hurts (lowered threshold) and a hot shower is more painful than normal. Inflammatory hyperalgesia is an important aspect of pain in many diseases. The pain of arthritis, for example, is due to the activity of sensitized joint nociceptors that otherwise would not be activated by normal movement. The effectiveness of aspirin and other NSAIDs in relieving such pain is based on the role of prostaglandins in producing the sensitization of nociceptors that underlies primary hyperalgesia.

Hyperalgesia results not only from the peripheral sensitization of nociceptors but also from increased excitability of central nociceptive neurons. Sustained activity in nociceptive C-fiber afferents causes chemical changes in dorsal horn neurons so that they become hyperexcitable. Sensitized dorsal horn neurons with increased spontaneous activity, enlarged receptive fields, lowered thresholds, and increased responsiveness to peripheral stimulation are responsible for a zone of secondary hyperalgesia surrounding an injury. Nociceptive-specific cells can become responsive to input from mechanoreceptive A-fibers. Such sensitization may be one basis for the tactile allodynia (pain

from low-threshold stimulation) often observed in neuropathic pain. Central sensitization is dependent on the activation of NK1 and NMDA receptors and the subsequent mobilization of PKC. Activation of immune-competent microglia in the spinal cord may play an important role in central sensitization; spinal pro-inflammatory and anti-inflammatory cytokines can have significant effects. Prevention of the central sensitization initiated by afferent C-fiber nociceptive activity is the justification for preemptive analgesia, in which local and systemic analgesics are administered prophylactically before major surgery.

The NSAIDs also can affect hyperalgesia by a central action. Afferent nociceptive activity causes the release of prostaglandins in the spinal cord, which have presynaptic effects (increasing neurotransmitter release from primary afferent terminals) and probably postsynaptic effects as well. Spinal administration of NSAIDs reduces central sensitization. In addition, they reduce peripheral neurogenic inflammation caused by pathological, centrifugal activity (so-called dorsal root reflexes) carried by nociceptive fibers into peripheral tissues on both sides of the body.

Generalized illness and immune system challenges (infection) can induce hyperalgesia. Circulating pro-inflammatory cytokines have direct effects on primary afferent nociceptors and central neurons. Illness-induced hyperalgesia can be reduced by agents that antagonize pro-inflammatory cytokines (IL-1ra, IL-10). Hyperalgesia may be an important component of immune-activated, neurally organized illness behavior (which includes fever, decreased activity, decreased food and water intake, and increased sleep), consistent with a role for C-fiber afferents in metaboreception and homeostasis. Pain sensation can be strongly influenced by the general health of the body, as well as by hormone levels, nutrition, time of day, and behavioral state. Conversely, pain itself can have strong negative effects on health. Pain, just as stress or surgery, can inhibit immune function, enhance tumor growth, and increase morbidity. Unrelieved pain usually leads to disturbance of sleep, loss of appetite, depression, severe impairment of general health, and even suicide.

Pain due to organic causes (injury or disease) can usually be relieved by treating the source of nociceptive activation, but pain due to injury to the nervous system in some cases becomes chronic and intractable. The nervous system itself is insensate—only the epineurium surrounding peripheral nerves and the meninges surrounding the brain are innervated by C-fiber afferents—and, thus, pain due to neural injury is called neuropathic pain. Peripheral nerve damage due to trauma (e.g., carpal tunnel syndrome, neuroma), vascular malformations (e.g., trigeminal neuralgia), or due to pathogenic processes (e.g., diabetic neuropathy, postherpetic neuralgia, rheumatoid inflammation) can initiate cellular changes in primary afferent fibers that result in ectopic neural activity (originating at the site of nerve injury or in the dorsal root ganglion cells), molecular phenotype changes, or anatomical sprouting in the periphery and in the spinal dorsal horn. For example, nerve lesions can cause mechanoreceptive A-fiber afferents to produce SP or to sprout terminals into laminae I and II, small-diameter afferents to up-regulate peptides (galanin) and trophic (NGF) receptors, and nociceptive fibers to become sensitive to circulating adrenalin and sympathetic efferent activity. The latter effect may be particularly important for a condition known as reflex sympathetic dystrophy (RSD), complex regional pain syndrome or causalgia, which can often be relieved by sympatholysis. Permanent pathological changes may be abnormal sequelae of healing and regeneration, and they can cause a vicious cycle of pain-related activity. In such conditions, cytokines (TNFα), elements of the immune complement cascade (C3a), or antibodies to gangliosides (GD2) that are present on primary afferent fibers can activate C-nociceptors. Central inflammatory (microglial) reactions may be very significant, and the use of intrathecal anti-inflammatory agents (NSAIDS, IL-10) is being studied. Systemic lidocaine and intrathecal gabapentin may relieve neuropathic pain by interfering with such mechanisms peripherally and centrally.

Central spinal hyperexcitability can also result from brachial plexus root evulsion; this form of deafferentation pain can be effectively treated by a dorsal root entry zone (DREZ) lesion, which eliminates hyperactive neurons from the dorsal horn of the cervical spinal cord. Phantom limb pain, which can occur following amputation, particularly if there was significant preoperative pain, may similarly involve changes in both peripheral nerve fibers and central function.

Damage to the central nervous system can also result in intractable pain. In Wallenberg's syndrome (anesthesia dolorosa), an infarct in the caudal medulla produces the loss of evoked pain and temperature sensation in the ipsilateral face (due to damage to the trigeminal dorsal horn) and contralateral body (due to interruption of the spinothalamic tract), and ongoing burning pain can occur in these regions. Similarly, so-called central pain can appear following a spinal lesion

(from trauma, multiple sclerosis, or even an anterolateral cordotomy performed to eliminate cancer pain) or following stroke-induced damage in the forebrain, particularly in the posterolateral thalamus or the parietoinsular cortex. In such cases, ongoing burning pain is reported in deep and cutaneous tissues in a region in which the lesion has eliminated normal pain and (especially) temperature sensation in the contralateral body. Pain from innocuous cooling or touch (allodynia) is typical. Central pain results from the release (disinhibition) of activity in the brain; this could be due to the loss of endogenous analgesia mechanisms like the normal inhibition of pain by cold. Central pain is unresponsive to opiates, but tricyclic antidepressants (amitryptyline) or antiepileptics (carbamazepine) can be effective.

Parkinson's Disease

MELVIN D. YAHR and MATTHEW A. BRODSKY
Mount Sinai Medical Center—New York University

GLOSSARY

akinesia An inability to move; the absence of movement.

alpha synuclein A protein found to be misfolded in its expression in the brain in an autosomal-dominant form of familial parkinsonism. It is the product of the gene *PARK1*, which is located on chromosome 4q21-22.

basal ganglia The deep nuclei of the cerebrum, including the caudate nucleus, putamen, globus pallidus subthalamic nucleus, and pedunculopontine nucleus.

bradykinesia Slowness of movement.

carbidopa An inhibitor of the enzyme dopa decarboxylase, which converts levodopa to dopamine and increases its efficacy in the brain. Its action is limited to tissues outside the brain because it does not cross the blood–brain barrier and thus prevents side effects such as nausea.

caudate nucleus One of the two nuclei comprising the corpus striatum; lesions of the caudate rarely cause motor disorders but are more likely to cause behavioral problems.

cortical basal ganglionic degeneration A form of atypical parkinsonism that is highly asymmetric, with primarily features of rigidity, akinesia, and apraxia.

dopamine A neurotransmitter; its depletion in Parkinson's disease is responsible for symptoms of the disorder.

dopamine agonist A compound that binds to dopamine receptors, stimulates them, and mimics the action of dopamine.

dysphagia Difficulty in swallowing.

dystonia Abnormal involuntary muscle contraction and posture, usually action induced.

festination An abnormal rapid forward gait, which leads to falling.

globus pallidus One of the deep nuclei of the brain; it is anatomically divided into a "pars externa" and "pars interna." The pars interna is the final common output from the basal ganglia circuit to the cerebral cortex via the thalamus.

glutathione An important compound in antioxidant defense and in the repair of oxidized proteins. Glutathione levels are decreased in the substantia nigra in Parkinson's disease.

hyperhidrosis Excessive sweating.

hypomimia Decreased facial expression.

hypophonia Decreased volume of speech.

levodopa The molecular precursor to dopamine; it remains the most effective agent for pharmacotherapy of Parkinson's disease.

Lewy body The pathologic cellular marker of Parkinson's disease; it is composed of protein aggregates.

micrographia Small handwriting.

mitochondria The organelle in the cell that provides the majority of energy for cellular function via oxidative phosphorylation; it may be a source of oxidative damage in neurodegenerative diseases such as Parkinson's disease.

monoamine oxidase An enzyme that metabolizes monoamines; it has two subtypes, A and B. Type B metabolizes dopamine in the brain.

multiple system atrophy A progressive neurodegenerative syndrome characterized clinically by autonomic dysfunction, parkinsonism, and cerebellar ataxia.

orthostatic hypotension The abnormal decrease in blood pressure when one goes from a supine to standing position.

oxidative phosphorylation The process by which oxygen is utilized by mitochondria in the cell to form ATP, the basic currency of energy by which cellular processes occur.

parkin The protein found in an autosomal-recessive young-onset form of parkinsonism. It is the product of the gene *PARK2*, which is found on chromosome 6q25.2-27.

progressive supranuclear palsy A neurodegenerative condition with parkinsonian features; progressive gait and balance impairment, downward gaze paralysis, and rigidity are its major features.

putamen One of the two nuclei composing the corpus striatum; its innervation from substantia nigra pars compacta becomes deficient in Parkinson's disease.

retropulsion The tendency to fall backwards.

striatum Composed of the caudate nucleus and putamen; the striatum forms the input zone from the cerebral cortex to the basal ganglia.

substantia nigra Collection of melanin-containing neurons of the midbrain that is divided into two distinct anatomic compartments, the pars compacta and the pars reticulata. The pars compacta contains the dopamine-producing cells that project to the striatum which degenerate and die in Parkinson's disease.

subthalamic nucleus One of the deep nuclei of the cerebrum; it is the only nucleus of the basal ganglia that uses glutamate as its neurotransmitter. It is overactive in the pathological state of Parkinson's disease, and this overactivity has been purported to cause downstream damaging effects in Parkinson's disease excitotoxicity promulgated by glutamate.

thalamus Composed of a series of nuclei in the diencephalon, this anatomic structure forms the major relay for afferent pathways to the cerebral cortex.

ubiquitin A protein that accumulates within pathologic intracellular or extracellular deposits in neurodegenerative diseases, such as the Lewy body in Parkinson's disease. It has multiple functions but it is primarily known for its involvement in a pathway that regulates the bulk of intracellular protein turnover.

Parkinson's disease (paralysis agitans, shaking palsy) is a slowly progressive neurodegenerative disorder of the central nervous system. It is characterized by the presence of bradykinesia (slowness of movements), rigidity, and tremor.

I. INTRODUCTION

First described in 1817 by James Parkinson, a practicing physician in London, in a monograph titled "Shaking Palsy," Parkinson's disease (PD) attracted little attention until approximately 50 years later when the famous French neurologist Jean Charcot more fully defined its phenomenology. Charcot pointed out that there was little if any palsy, that the difficulty in movement related to its initiation and maintenance as well as to stiffness of the musculature, and that the tremor was distinctive in that it occurred at rest rather than with action. He suggested the term "shaking palsy" be discarded and that the disease be given the pseudonym Parkinson's disease honoring its discoverer.

Although many other disorders of the nervous system may show signs and symptoms akin to PD (so-called secondary parkinsonism), PD is a distinctive clinical and pathological entity, accounting for approximately 75% of all cases of parkinsonism.

II. EPIDEMIOLOGY

PD is one of the most common causes of neurological disability, affecting 1% of the population over age 55. The prevalence is 1 in 350, giving an overall lifetime risk of approximately 1 in 40. It is typically a disease of the middle to late years, beginning at a mean age of 50–60 years and progressing slowly over a 10- to 20-year period. The age of onset assumes a broad bell-shaped distribution, with approximately 5% of cases beginning before age 40.

The reported incidence rates of PD range from 4.5 to 21/100,000 population/year in community-based studies. Prevalence rates of PD vary from 18/100,000 persons in a Shanghai, China, population survey to 328/100,000 in the Parsi community in Bombay, India. There are currently at least 500,000 PD cases in the United States. The incidence and prevalence of PD increase with increasing age of the population surveyed. In most studies PD is slightly more common in men than in women.

Identified environmental risk factors include heavy metals such as iron and manganese, drinking well water, farming, living in a rural residence, working in wood pulp mills and steel alloy industries, and exposure to herbicides or pesticides.

III. CLINICAL MANIFESTATIONS OF PD

Parkinsonism, as a clinical syndrome, is readily recognizable by the fixed, expressionless facies and stooped body posture. It is characterized by specific motor deficits: tremor, akinesia (or bradykinesia), muscular rigidity, and postural instability. At least two of these cardinal features should be present to make a firm diagnosis. A wide variety of unrelated disease states can result in parkinsonism; however, the most common form is Parkinson's disease.

PD begins insidiously and is slowly progressive. It is postulated that the underlying pathology (i.e., the loss of pigmented brain stem nuclei) precedes the onset of symptoms by many years. Indeed, at least 80% of dopaminergic neurons must be lost before overt signs and symptoms first appear.

As measured by clinical signs and degree of functional impairment, PD proceeds through five stages.

The first stage shows predominantly one-sided involvement, with little or no functional impairment. Stage II is characterized by bilateral body involvement and minimal functional difficulties. Stage III marks a critical development in that in addition to the symptoms on both sides of the body, postural instability with impaired balance occurs. Some elements of daily living activities may need assistance in this stage. In stage IV, all the previous symptoms are intensified and more reliance on others to perform activities of daily living is needed. Stage V is practically an end stage to the disease, with wheelchair or bed existence and need for nursing care. The rate of progression through these various stages is quite variable and markedly modified by individual tolerance and responsiveness to anti-Parkinson drug therapy.

The signs and symptoms of PD are motor and nonmotor in nature.

A. Motor Features

1. Akinesia or Bradykinesia

The absence, paucity, or slowness of movement is often a disabling sign. Sequential and complex motor acts are particularly difficult. Quick repetitive movements typically show a decrease in both amplitude and frequency. Other manifestations of bradykinesia include drooling due to poor swallowing of saliva and loss of facial expression (hypomimia). Gait disturbance is prominent, with a shuffling quality, decrease in stride length, and reduced arm swing. Attempting to turn becomes difficult, requiring an extra step or two. Freezing, a form of akinesia, is the transient inability to perform active movements. It most often affects the legs and occurs when walking.

2. Muscular Rigidity

On examination, rigidity is noted as increased resistance to passive movement of a limb segment. The amount of resistance remains fairly constant through the entire range of motion, in both flexion and extension, and is not greatly influenced by the speed or force with which the movement is performed. This distinguishes it from spasticity. The rigidity of PD is most often cogwheeling, but such may not be present. Voluntary movement in one limb may induce rigidity in the contralateral limb. The patient may develop truncal rigidity with a flexed or stooped posture.

3. Resting Tremor

In 75% of patients, tremor is the first motor manifestation, usually beginning unilaterally in the distal segment of a limb, in most cases the fingers. The tremor often involves rhythmic, alternating opposition of the forefinger and thumb in the classic stereotypic pill-rolling variety. The characteristic frequency is 3–5 Hz. Over the course of several years, tremor usually spreads proximally in the affected arm before involving the ipsilateral leg and, finally, the contralateral limbs. Although tremor is bilateral in advanced disease, it often maintains some asymmetry throughout the course. In later stages, an accompanying tremor of the face, lips, or chin is not uncommon. The tremor occurs at rest and usually abates when the affected limb performs a motor task.

4. Postural Instability

In general, loss of postural reflexes is the last cardinal sign to appear and often proves to be the most disabling. Patients with postural instability develop festination, manifested by increased rapidity of gait, which leads to falling. Retropulsion, the tendency to fall backwards, is prominent and readily demonstrated in the erect position with a mild pull or push.

5. Other Features

Other motor features of PD include development of smaller handwriting (micrographia), softer voice (hypophonia), start-hesitation and freezing episodes, decreased frequency of eye blinking, and dysphagia. Dystonic phenomena may occur in association with PD, particularly involving the limbs and occurring in early morning hours.

B. Nonmotor Features

1. Autonomic Dysfunction

Autonomic features of PD include orthostatic hypotension, intestinal motility disorders resulting in constipation, bladder and erectile dysfunction, excessive sweating (hyperhidrosis), and pupillary abnormalities.

2. Cognitive Dysfunction

Tests of cognitive function demonstrate mild-to-moderate deficits, including visuospatial impairment,

attentional set-shifting difficulties, and poor executive function. Although not an early finding in PD, dementia eventually occurs in 20–30% of PD patients.

Depression is not an uncommon psychiatric symptom in PD. Prevalences ranging from 45% with minor symptoms to 8% with major symptoms have been reported. It may precede the motor disturbances and be responsive to drugs used for the treatment of PD.

Disturbances in sleep, with altered REM patterns, occur frequently. These vary from frank insomnia to interrupted sleep intervals.

3. Sensory Abnormalities

Paresthetic phenomena as well as impaired olfactory function occur in PD. Indeed, loss of olfaction may be an early sign in Parkinson's patients.

IV. ANATOMY AND PATHOLOGY

A. Anatomy

The motor signs and symptoms of PD result primarily from dysfunction of the basal ganglia. The central mechanism for the physiological dysfunction of the basal ganglia in PD is a progressive decline in the concentration of dopamine. Neuronal loss and depigmentation have been demonstrated in the substantia nigra pars compacta of parkinsonian patients. Profound reductions in the concentration of dopamine in the caudate nucleus and putamen have also been discovered. Pigmented neurons of the substantia nigra project to the striatum and provide it with dopaminergic input. The regional "fallout" of dopaminergic neurons in the substantia nigra pars compacta of patients with PD appears to be specific and selective. Although other neurotransmitters are affected in PD, the nigrostriatal dopaminergic tract is most significantly affected by the neurodegenerative process.

The basal ganglia form a network of parallel loops that integrate cortical regions (motor, limbic, and associative) with the basal ganglia nuclei and thalamus. Cortical motor projections make excitatory glutamatergic synaptic connections with medium spiny neurons of the posterolateral putamen containing GABA. These neurons give rise to two pathways that connect the striatum to the output nuclei of the basal ganglia—the globus pallidus pars interna (GPi) and the substantia nigra pars reticulata (SNr). Neurons in the "direct pathway" project from the putamen to the GPi/SNr, have Dl dopamine receptors, coexpress the peptides substance P and dynorphin, and provide a direct inhibitory effect on GPi/SNr neurons. Striatal neurons in the "indirect pathway" connect the putamen with the GPi/SNr via synaptic connections in the globus pallidus pars externa (GPe) and subthalamic nucleus (STN). They contain D2 receptors and the peptide enkephalin. Projections from putamen to GPe and from GPe to STN are GABAergic and inhibitory. Neurons originating in the STN use glutamate as a neurotransmitter and activate neurons in the GPi/SNr. Stimulation of neurons in the indirect pathway leads to inhibition of the GPe, disinhibition of the STN, and excitation of the GPi/SNr. Thus, the output activity of the basal ganglia is influenced by the opposing effects of inhibitory inputs from the direct pathway and excitatory inputs from the indirect pathway. This, in turn, provides an inhibitory effect on brain stem and thalamocortical neurons involved in motor activities.

In the parkinsonian state, there is increased neuronal activity in the GPi/SNr output nuclei of the basal ganglia, which leads to excessive inhibition of thalamocortical and brain stem motor systems. Reduced activation of dopamine receptors caused by dopamine deficiency results in reduced inhibition of neurons of the indirect pathway and decreased excitation of neurons of the direct pathway. Reduced inhibition from the indirect pathway leads to overinhibition of the GPe, disinhibition of the STN, and increased excitation of GPi/SNr neurons, whereas decreased activation from the direct pathway causes a reduction in its inhibitory influence on the GPi/SNr. The net result is an excessive activation of basal ganglia output neurons accompanied by excessive inhibition of motor systems, leading to parkinsonian motor behavior (Fig. 1).

B. Imaging

1. Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) in patients with typical PD is usually normal, but a high field strength heavily T2-weighted MRI may show a wider area of lucency in the substantia nigra probably indicative of increased accumulation of iron. Prominent hypointensity in the putamen strongly indicates the presence of atypical parkinsonism, such as multiple-system atrophy.

2. Positron Emission Tomography Studies

Using [^{18}F] fluorodopa positron emission tomography (PET) scans to assess the integrity of the striatal

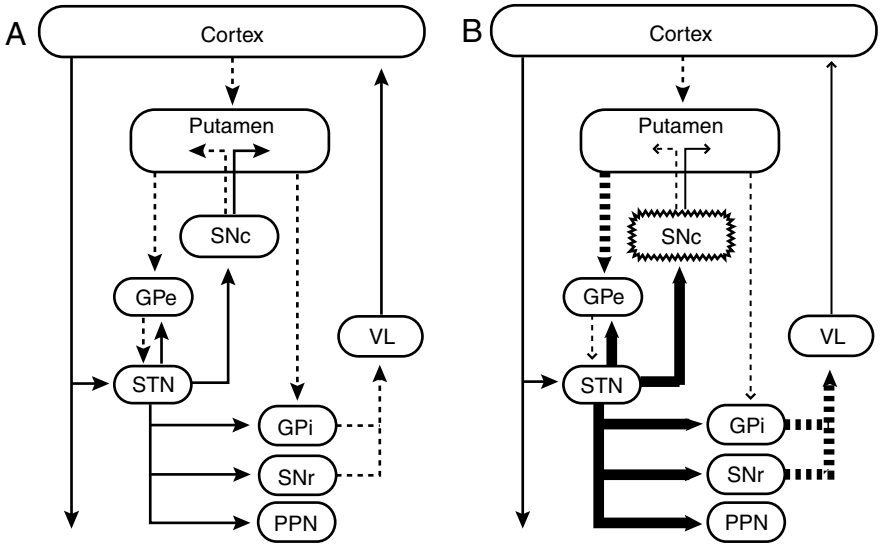

Figure 1 The basal ganglia circuit in normal (A) and Parkinson's disease (B). Solid arrows represent excitatory projection and broken arrows represent inhibitory projections. The thickness of the arrows indicates the degree of activity of each projection.

dopaminergic terminals, characteristic reduction of the [^{18}F]fluorodopa uptake, particularly in the putamen, can be demonstrated in virtually all patients with PD, even in early stages. As estimated on the basis of PET with [^{18}F]fluorodopa, the rate of nigral neuronal loss is faster initially and then tends to approach the normal age-related decline (Fig. 2).

3. Single Photon Emission Computerized Tomography

Single photon emission computerized tomography imaging of the striatal dopamine reuptake sites with ^{123}I-labeled β-CIT [2β-carboxymethoxy-3β-(4{^{123}I}iodophenyl)tropane] and of presynaptic vesicles with [^{11}C] dihydrotetrabenazine may also be helpful in differentiating PD from atypical parkinsonism.

C. Neuropathology

The pathological hallmarks of PD include massive loss of pigmented neurons in the substantia nigra as well as the presence of Lewy bodies. The Lewy body (LB) is a hyaline intraneuronal inclusion, and its presence is essential for pathological confirmation of PD. The LB is not specific to PD because it is found in a number of other conditions including Hallervorden–Spatz disease, ataxia–telangiectasia, and subacute sclerosing panencephalitis. The LB contains protein, free fatty acids, sphingomyelin, and polysaccharides, and it stains for neurofilament (Figs. 3 and 4).

V. ETIOLOGY AND PATHOGENESIS

Despite extensive investigative studies, the cause of PD has not yet been defined. Considerable interest initially centered on an infectious agent (i.e., virus) since a number of instances of parkinsonism followed the pandemic of influenza and encephalitis lethargica in 1917. However, postencephalitic parkinsonism differes from PD in many features and is more in keeping with a secondary type of a disorder. To date, viral DNA probes of tissue from PD brains and serum antibody titers have failed to reveal the presence of any known virus or bacteria.

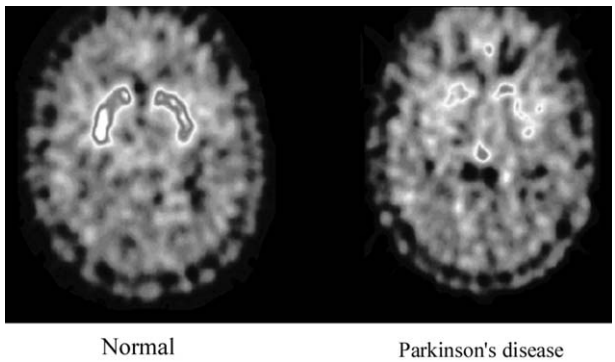

Figure 2 PET study using [^{18}F] fluorodopa.

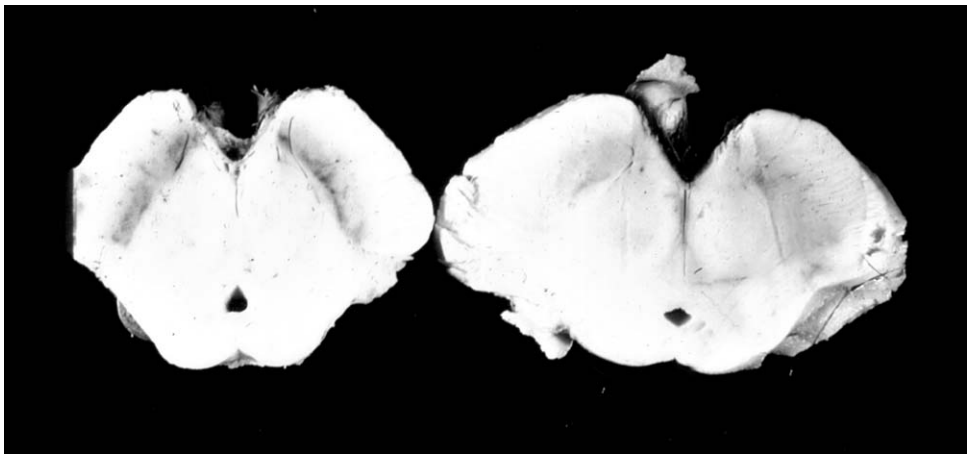

Figure 3 Gross midbrain specimen from a normal (left) and Parkinson's disease (right) brain. Note the decreased pigmentation indicating cellular loss in the substantia nigra pars compacta.

Considerable attention has been directed toward environmental toxins as being causative. The finding that manganese miners develop a form of parkinsonism has led to a search for heavy metal intoxication. This search has been fruitless. The serendipitous finding that the injection of an inadvertently produced meperidine analog, MPTP, led to the development of a relatively acute form of parkinsonism with many characteristics of PD prompted an extensive search for similar agents producing PD, particularly pesticides existing in the environment. None have been found. However, MPTP has become a valuable tool for studying the mechanism of dopaminergic cell death. Systemic injection of MPTP into nonhuman primates also produces parkinsonism with bradykinesia, rigidity, and freezing. Like humans, MPTP-treated monkeys develop severe dopamine depletion in the striatum with marked nigrostriatal neuronal loss.

Evidence supports the view that MPTP causes cell death through inhibition of oxidative phosphorylation and the generation of free radicals. MPTP is a protoxin, being converted to its active form l-methyl-4 phenylpyridinium (MPP^+). MPP^+ is a substrate for the dopamine reuptake system. Thus, MPP^+ is

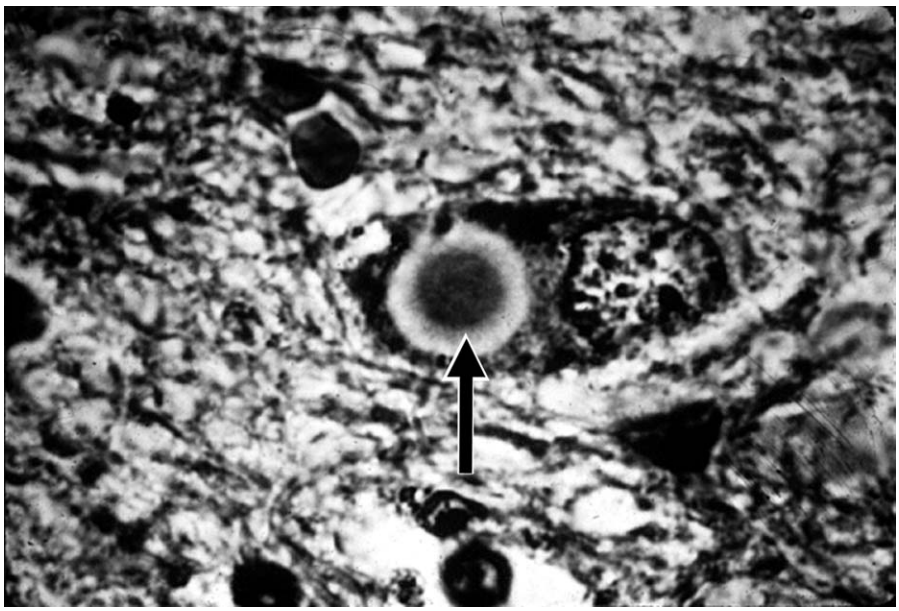

Figure 4 Histological view of a Lewy body (arrow) in the substantia nigra pars compacta stained with H & E.

actively concentrated into dopaminergic neurons. Although taken up via the nerve terminals in the striatum, MPP^+ may be concentrated in the cell body through its affinity with neuromelanin. Once inside the cell MPP^+ is concentrated to millimolar proportions by an energy-dependent mitochondrial ion concentrating system. Once within mitochondria, MPP^+ inhibits NADH CoQl reductase (complex I), the first enzyme of the mitochondrial respiratory chain. There is also evidence that MPP^+ generates free radicals and that the nitric oxide synthase inhibitor, 7-nitroindozole, can prevent MPP^+ toxicity in monkeys. The current assumption is that MPP^+ induces cell death through a combination of inhibition of ATP synthesis and free radical generation.

Since the discovery of MPP^+ toxicity on mitochondria, interest has been focused on mitochondrial functions in PD. Current concepts of nigral cell death emphasize mitochondrial dysfunction and impaired oxidative metabolism. The discovery of complex I deficiency in PD substantia nigra raised the possibility that the mutation of genes (nuclear or mitochondrial) encoding complex I subunits might be involved in determining the enzyme's defective activity. There is a reduction of about 35% in complex I activity of the mitochondrial metabolic chain in the substantia nigra pars compacta. Complex I deficiency is not found elsewhere in the brain in PD.

The substania nigra pars compacta is particularly vulnerable to oxidative stress. Dopamine metabolism by monoamine oxidase forms superoxide and hydrogen peroxide. Excess iron in the substantia nigra may promote the formation of the hydroxyl radical from hydrogen peroxide. Dopamine autooxidation in the presence of iron forms superoxide, reactive quinones, and semiquinones. Neuromelanin in dopminergic cells binds ferric iron and reduces it to the reactive ferrous form.

Glutathione (GSH) in its reduced form is an important compound in antioxidant defense and in the repair of oxidized proteins. It is oxidized to its disulfide, GSSG. High GSH/GSSG ratios are maintained by glutathione reductase, which converts GSSG to GSH. There is evidence for decreased activity of glutathione peroxidase in PD nigra, putamen, and globus pallidus, and evidence that GSH levels are decreased in PD substantia nigra.

Superoxide dismutase (SOD) exists in cytosolic SOD and mitochondrial manganese SOD forms and is important in dismutating superoxide ions. Thus, levels of this enzyme are indicative of superoxide generation. Both forms appear to be increased in PD substantia nigra. High levels of copper/zinc SOD are expressed at the mRNA level in control and PD nigral pigmented neurons. Taken together, these observations suggest that PD nigral neurons in particular are exposed to increased superoxide generation.

Levels of polyunsaturated fatty acids, malondialdehyde, and hydroperoxides are increased in PD substantia nigra. These are the products of free radical damage to lipid membranes and imply oxidative damage in PD. Free radical damage to DNA produces intracellular 8-hydroxydeoxyguanosine. Elevated concentrations of this product are seen in PD in the nuclear DNA and particularly in the mtDNA fractions from patients with PD. Levels of these products are also particularly high in control brains in the substantia nigra and striatum, confirming that, even in controls, this area of the brain is a site of high oxidative stress.

Evidence exists for disturbances in oxidative phosphorylation in PD, particularly a reduction in the activity of complex I of the mitochondrial electron transport chain and increased levels of free iron, which may enhance the formation of toxic free radicals.

A. Genetic Subtypes

The greater than expected incidence of PD within family groups has prompted consideration of a genetic factor as playing a prominent role. Studies of large family kindreds have revealed at least seven mutant genes as being present. These genetic abnormalities may only be applicable to the familial form of PD and not to the largest segment of the Parkinson population. However, they may lead to a better understanding of the pathogenesis that underlies the disease. Currently, it is generally held that a genetic predisposition to PD exists due to multiple gene abnormalities, but an additional factor—either an endogenous or exogenous neurotoxin—is necessary to trigger the disease process.

During the past few years, several genes for inherited forms of PD have been mapped and/or cloned. In a large family with autosomal-dominant inheritance and typical LB pathology, a gene locus has been mapped to the long arm of chromosome 4, and mutations in this and a few other families linked to this locus have been identified in the gene for α-synuclein. α-synuclein is expressed abundantly in brain, including the substantia nigra and LBs. First isolated from plaques in Alzheimer's disease, it is found abundantly in LBs

from both hereditary and sporadic cases, in which its expression overlaps with that of ubiquitin. α-Synuclein normally is a soluble unfolded protein, but it can aggregate to form insoluble amyloid fibrils. This common theme of protein misfolding joins PD with a number of other neurodegenerative conditions in which insoluble protein aggregates eventually lead to neuronal death. The recent elucidation of the proteasomal system in protein degradation, and its dysfunction in substantia nigra in PD, lends further credence to this mechanism of protein misfolding as a crucial cog in the etiology of PD.

A gene causing autosomal-recessive parkinsonism of juvenile onset has been mapped to chromosome 6, and the causative gene has been identified and named parkin. This form of parkinsonism, first identified in a Japanese kindred, clinically resembles PD and is associated with nigral degeneration but without LBs.

A third locus, again in families with dominant inheritance, typical LB pathology and late onset, has been mapped to chromosome 2p13, and two additional genes on chromosome 4p have been linked to other dominantly inherited forms of the disease. A genetic locus on chromosome 2p is associated with more typical PD in a larger number of families. Rare pedigrees show an exclusively maternal inheritance pattern consistent with a defect in mitochondrial DNA. Currently, there is no direct evidence that any of the genes for familial parkinsonian syndromes have a direct role in the etiology of the common sporadic form of PD.

VI. SECONDARY FORMS OF PARKINSONISM

The following conditions have in common many features of PD but differ in a variety of ways:

A. Multiple system atrophy: Several subtypes of this neurodegenerative condition exist—pure autonomic failure (Shy–Drager syndrome), striatonigral degeneration, and olivopontocerebellar atrophy.

B. Progressive supranuclear palsy: Gait disturbance is the presenting feature in more than 60% of cases. Personality change is the next most common presenting feature. Gaze palsy, dysarthria, and dysphagia are also prominent. Contracted facial muscles, retrocollis, predominantly proximal rigidity, predominantly vertical supranuclear gaze abnormality, spastic dysarthria, dysphagia, and behavioral abnormalities complete the list of signs of this progressive neurodegenerative disease.

C. Cortical basal ganglionic degeneration (CBGD): CBGD encompasses features pointing to dysfunction in both the cerebral cortex and basal ganglia. It was first described in the 1960s. Symptoms include those of typical PD and limb dystonia. Tremor may be postural or kinetic, and reflex myoclonus is common. Cortical signs include apraxia, cortical sensory loss, and alien limb phenomenon. Other signs include athetosis, orolingual dyskinesias, frontal lobe reflexes, impaired ocular movements, dysarthria, speech apraxia, dementia, hyperreflexia, and Babinski's signs. Findings are highly asymmetrical. Asymmetric cerebral atrophy is seen on the medial frontal and parietal lobes.

D. Parkinsonism–dementia complex of Guam: A high incidence of parkinsonism has been reported among the Chamorro population of Guam. Signs are similar to those for PD, except that tremor is not prominent. It is invariably accompanied by progressive dementia. The majority of patients also have clinical signs of motor neuron disease, and some have features similar to those of progressive supranuclear palsy.

E. Diffuse Lewy body disease.

F. Drug-induced parkinsonism: Dopamine-blocking agents have been implicated in causing a condition that resembles PD. Such drugs include phenothiazines, butyrophenones, and metoclopramide. This condition represents one of the most common causes of secondary parkinsonism.

G. Toxin-induced parkinsonism (MPTP, manganese, carbon monoxide, and cyanide)

H. Hemiatrophy hemiparkinsonism

I. Postencephalitic parkinsonism: Between 1916 and 1927, a worldwide epidemic of encephalitis lethargica (sleeping sickness) took place, affecting as many as 750,000 people. Approximately one-third of them died acutely, one-third recovered completely, and the remainder were left with chronic neurological deficits. Parkinsonism following encephalitis lethargica can be indistinguishable from the manifestations of PD.

J. Vascular: Multiple lacunar infarctions involving the corpus striatum are seen on MRI. Deficits usually occur in a stepwise progression.

K. Trauma: Parkinsonism is a rare sequela of head trauma. Repetitive trauma seen in boxers may result in progressive parkinsonism as well as dementia (dementia pugilistica). Diffuse neuronal loss and neurofibrillary tangle formation are seen on pathology.

L. Tumor: All the clinical features of parkinsonism may occur as a consequence of brain tumors. They are most commonly supratentorial meningiomas. The

mechanism may be mass compression or invasion of the corpus striatum.

VII. TREATMENT: CURRENT APPROACH, PHARMACOLOGICAL AGENTS, AND SURGERY

Treatment of PD is currently directed to control of symptoms. There are no curative measures, nor any agents that retard the progressive nature of the disorder. As is the case for instances of symptomatic treatment, the decision to utilize therapeutic agents depends on the severity of symptoms and the degree of disability.

A. Medical Treatment

The most effective pharmacological agents for the control of Parkinson's symptoms are those capable of restoring dopaminergic activity in the striatal region of the brain. Of the many drugs having this capability, levodopa administered orally with a peripheral DOPA-decarboxylase inhibitor (e.g., carbidopa) is the most effective. This combination blocks the conversion of levodopa to dopamine outside the nervous system, making it completely available for use in the brain. Given the appropriate dosage more than 80% of patients will experience beneficial effects in the form of symptom control. Such results are usually optimal during the first 3–5 years of treatment and then tend to wane off. Not only does the therapeutic effect become less optimal but also erratic responses occur in addition to the development of adventitious movements of the body and not infrequently behavioral abnormalities. Therefore, it is generally believed that treatment should be withheld until it is a necessity and the dosages used should be kept at a minimum.

The L-DOPA effects may be enhanced by the addition of a number of drugs that inhibit the metabolic pathways of dopamine; for example, *l*-deprenyl, an agent capable of inhibiting monoamine oxidase B, may prolong the effects of a given dose of levodopa, and entacapone or tolcapone, which inhibit the methylation pathway of dopamine degradation, not only prolong its effect but also give a modulated pharmacological response.

Despite complications in the use of levodopa, it has had a profound effect in maintaining the functional capacity of patients with PD for many years beyond that previously experienced. Furthermore, life expectancy has been markedly prolonged for such patients since its introduction.

Other agents utilized to enhance striatal dopaminergic function are agonists of the postsynaptic dopamine receptors. These consist of pergolide, ropinirole, pramipexole, and bromocriptine. They may be used as substitutes for levodopa or in combination with it. These agents may have the advantage of inducing less adventitious movements but are also less potent at restoring dopaminergic function.

A number of ancillary drugs are utilized in a limited fashion and primarily to delay the use of dopaminergic agents. Amantadine is an antagonist at the NMDA-type receptor of the excitatory amino acid system. Amantadine has been shown to have some beneficial effects on tremor in addition to decreasing the severity of L-DOPA-induced dyskinesias. A number of anticholinergic agents, such as trihexyphenidyl and benztropine, have been used for years because they are mildly effective and may be used to delay the use of dopaminergic drugs.

B. Surgery

A number of surgical approaches to the treatment of parkinsonian symptoms have been developed. In general, they have been reserved for patients who have failed pharmacologic agents or whose response to medications has led to a variety of untoward reactions.

The first surgery performed for PD involved excision of parts of the cerebral cortex for parkinsonian tremor and dystonia by Bucy and Case (1939) and Klemme (1940). This surgery produced spastic hemiparesis, however. Corticospinal tract lesioning was performed for relief of dyskinesia (Putnam, 1938), which also produced ipsilateral hemiplegia. Surgical lesioning in deeper structures within the cerebral hemispheres for movement disorders was introduced by Meyers (1940). Lesions in both caudate nucleus and globus pallidus were performed. Initial results found improvement in both tremor and rigidity in 40% of patients with parkinsonism. Dyskinesia improved as well, without accompaniment of weakness or spasticity. In 1953, Cooper accidentally cut the anterior choroidal artery, followed by its ligation, which significantly relieved tremor and rigidity. He subsequently performed anterior choroidal artery ligations in a series of more than 50 patients, with benefit in tremor and rigidity in two-thirds of patients, with a mortality rate of 10%.

Stereotactic neurosurgery, developed in the 1950s, allowed for more accurate targeting of deep brain nuclei. Microelectrode recording techniques, developed

in the 1960s, further improved localization of targets for lesioning. Neurosurgical therapy for PD reached its peak in the 1960s but declined after the introduction of levodopa. The past decade has brought about a resurgence of neurosurgery for PD with improved localization techniques and lower morbidity/mortality rates. Hyperactivity of the subthalamic nucleus in PD leads to increased excitation of the GPi and SNr, which in turn inhibit the motor projections to the thalamus and brain stem. The STN and Gpi have thus become the preferred targets for surgery to treat PD.

There are several procedures currently in use.

1. Pallidotomy

A lesion is made in the ventroposterolateral part of the internal segment of the pallidum (GPi), which is overactive in PD. This lesion also destroys the pallidothalamic pathway (the ansa lenticularis). The major benefit of this procedure is a reduction of contralateral levodopa-induced dyskinesias. Reduction of tremor, rigidity, and bradykinesia is also seen but to a lesser degree.

2. Thalamotomy

Thalamotomy is most efficacious for tremor, with a success rate of approximately 95%. It is much less effective for bradykinesia, which is usually more disabling. The target for treating tremor is the ventral intermediate nucleus of the thalamus. Selective ablation of thalamic nuclei and pallidal regions has had inconsistent beneficial results.

3. Deep Brain Stimulation

Chronic deep brain stimulation (DBS) has been used for treatment of parkinsonian, essential and cerebellar outflow tremors. In addition to parkinsonian tremor, deep brain stimulators have recently been implanted in the GPi and STN to treat other motor signs of PD. They have been reported to improve all the cardinal motor symptoms, including tremor, rigidity, bradykinesia, and gait, as well as drug-induced dyskinesias and motor fluctuations. DBS simulates the effects of a lesion without the need to make a destructive brain lesion. In this procedure, an electrode is implanted in the brain target and connected to a subcutaneous pacemaker. The STN is overly active in patients with PD. Because surgical lesions of the STN run the risk of the patient developing hemiballism, electrical stimulation of the STN has been carried out. The long-term effect of these procedures has not been defined.

4. Transplant

Transplantation of embryonic mesencephalic dopamine cells into the striatum of patients with PD is being investigated as potential therapy. It is not possible to make a definitive conclusion concerning the results. Techniques utilizing stem cell transplantation are also currently under investigation.

Pattern Recognition

WILLIAM R. UTTAL
Arizona State University

GLOSSARY

association A hypothetical second stage of the pattern recognition process in which the represented image is connected to a name or category.

elementalism A theoretical position stressing the precedence of the parts or local features of an object.

holism A theoretical position stressing the precedence of the entire object or the arrangement of its parts.

representation A hypothetical first stage of the pattern recognition process in which the incoming image is transformed or coded for the subsequent association.

stimulus equivalence The ability of the human to recognize objects in the face of severe transformations in shape, orientation, position, or size.

Pattern or form recognition, in the context of this article, is the process by which visually presented objects are identified, categorized, and named. In other words, the challenge of pattern recognition is to answer the question ''What is it that I am seeing?'' This is a different visual question than that asked in detection, ''Is there anything there,'' or in discrimination, ''Are the two things I see the same or different?'' This definition of recognition specifically excludes the even higher cognitive processes by which the categories, inclusive concepts, or names of the objects are themselves created. Rather, the topic is treated purely as a problem in visual perception in this article. Two hypothetical stages of processing can be distinguished: Stage 1, the transformation and representation of the image into a form suitable for stage 2, the comparison or analysis that permits a concept, name, or category to be attached to or associated with the image.

This article is adapted and updated from one of the same title previously published in *The Encyclopedia of Human Behavior* (1994) by Academic Press.

I. INTRODUCTION

The problem of form or pattern recognition is a classic one in visual psychology. From the time of the classic Greek philosophers until today, it has been appreciated that the brain is capable of carrying out amazing feats of object recognition and identification. Despite its antiquity, the psychological problem is still generally considered to be unsolved and a topic of active research in psychology, computer science, and, to an arguable degree, neurophysiology. As we shall, see many controversies and uncertainties currently exist in this field.

It is clear now that one of the easiest ways to conceptualize the problem is to propose that at least two hypothetical functional components—*image representation and memorial comparisons or associations*—must be involved in the recognition process. The object, image, or scene must be represented in some way so that it can be either compared with an existing set of alternative stored categories or processed by some other kind of logic that allows naming or classification to occur. It is important to appreciate that both possible means of association are plausible

explanations—a structural comparison process on the one hand and a logical analysis on the other. If there is any "law" of visual perception, it is that the visual system is capable of using many different strategies to meet the recognition challenges it confronts in daily life.

The true nature and complexity of the visual aspects of the human pattern recognition problem were not clarified until contemporary computer scientists such as D. Marr began to cope with the challenge of producing comparable image processing programs. The requirement that the computer program contain a precise statement of the necessary processing steps forced workers in this field to consider in detail the equivalent processes that are likely to be carried out by the human. In this context, we must appreciate that the study of pattern recognition is a thoroughly modern interdisciplinary issue that transcends psychology, neuroscience, and computer science. Pattern recognition is not, however, a monolithic problem. A number of subsidiary issues have emerged that have attracted significant research attention. In the remainder of this section, some of the most important subtopics will be introduced.

A. The Whole versus Part Controversy

One of the major issues, if not the major issue, in developing a biologically valid theory of pattern recognition concerns the initial image processing strategy used by the viewer to represent the image. The specific question is as follows: Is the image analyzed into its parts, or is it examined as an organized whole prior to and during the recognition process? All computer models and psychological theories must be based on at least an implicit *a priori* judgment that pattern recognition is governed by either the nature of the parts or the arrangement of the parts. In contemporary fact, however, most modern theories are elementalist and assert that the features from which the image is constructed are precedent in recognition. A minority position—holism or Gestaltism—holds that the arrangement of the parts is more important than their nature.

The probable main reason for the predominance of feature theories is that pattern recognition research exists in a context of developments in other highly elementalist sciences. Contemporary theory and experimentation in neurophysiology, on the one hand, and computer technology, on the other, have both had an immense effect on the field. Modern neurophysiology is primarily a science of components and parts—the neurons of which the brain is made and which carry out the mysterious information processing that accounts for pattern recognition. Existing computer programming techniques also tend to force us to examine and manipulate the parts of an image detailed down to the individual feature or even the individual pixel. Conceptually, it "demagnifies" the problem down to one emphasizing elemental parts rather than global patterns. It also must be acknowledged, in the light of this criticism, that another major impetus toward the predominantly part- or feature-based theory orientation in this field is that we do not yet have a satisfactory holistic theory of arrangement, a sufficiently powerful holistic empirical methodology, or even a suitable mathematical tool to provide the bases for a compelling theory of recognition based on global rather than local attributes.

Most perceptual experiments reported in the current scientific literature manipulate features or parts of the stimulus image. Data from such studies, therefore, also conceptually support theories of pattern recognition that are based on the nature of the features or components of which the stimulus image is composed. The intellectual system so created is, therefore, essentially circular. Experimental designs are based on feature-based theoretical premises; the experiments inevitably then produce results that support the initial hypothesis. The initial theory then becomes reified as a valid statement of reality rather than what it was originally intended to be—a working hypothesis or a convenient metaphor.

Nevertheless, there is an increasing, though still relatively small, body of evidence that argues, to the contrary, that global or holistic strategies dominate human pattern recognition instead of feature-based ones. One such body of evidence deals with the manifestation of the final phenomenal outcome itself—the exemplar demonstration or visual phenomenon displaying the outcome of the entire perceptual process. Demonstrations (as opposed to parametric experiments) are all too often ignored by researchers in this field when it comes to generating theory. Nevertheless, this kind of "first-order" phenomenology should not be underestimated. Demonstrations reflect the overall nature of perception in a direct and immediate fashion and should set the stage for research and theory rather than being discarded as irrelevant. The work of V. S. Ramachandran, S. Antsis, and N. Wade, among others, utilizing illusions as probes of recognition mechanisms, is especially notable in running counter to this trend.

One argument against a pure part- or feature-based theory of pattern or object recognition is based on the fact that the specific features of which objects are composed often do not seem to be very important in the recognition process. For example, the letters of the alphabet or chairs of various kinds can be recognized as exemplars of their general class (an A or a chair) regardless of the font or specific shapes of the pieces of which they are made. Caricatures consisting of only a few well-chosen lines can easily be identified as representing a particular person. The essential emerging fact is that no specific feature is necessary for the recognition of an object. The relationship of the features (i.e., the object organization) seems to be the key to pattern recognition, and virtually any feature can serve as the salient cue for recogntion.

Another classic body of evidence that supports holistic or global precedence in pattern recognition can be found in the literature of Gestalt psychology. Many of their rules of the organization of visual perception, in particular the idea that forms have a certain fundamental unity or *Pragnanz*, speak strongly for the priority that the global, whole attributes of an image must have in many aspects of visual perception. Other experiments that deal with stimuli that are virtually free of any continuous features (for example, arrangements of dots or subjective contours) also support a holist point of view.

The ability to recognize an object from a vast number of viewing angles and under a vast number of distortions is referred to as *stimulus equivalence*. Stimulus equivalency reflects the extraordinary capacity of an observer to recognize an object (for example, a plate or a face) as an example of a particular class of objects even though the parts may be substantially distorted by the variations in the viewer's point of view or even partially occluded. It is also considered by many theoreticians to be strong evidence for a holistic interpretive process rather than one driven by local features.

Despite the vigor of the debate between the holist and elementalist theorists, a prudent review of the contemporary scene reveals that the issue is not yet resolved. Repeated demonstrations, experiments, and caveats have supported the precedence of *both* the arrangement of the parts into a meaningful global pattern and the specific nature of the parts. This may signal that we cannot yet definitively specify which of these theoretical points of view best describes this powerful human perceptual skill. As in many human perceptual problems, it may be that there is no single all-inclusive answer to this conundrum. Rather, the method used by the human observer in each case depends upon a number of situational and environmental variables. Another possibility is that the problem is actually irresolvable. Several researchers such as C. Latimer and S. Rakover have considered this possibility.

B. Do Pattern Recognition Theories Explain Human Recognition Activity?

Without delving too deeply into the philosophical foundations of this problem, it should also be noted that cognitive and behavioral psychologies have radically different points of view concerning the accessibility of the underlying human thought processes. Behaviorists look at all psychological theories as being, at best, descriptions of the phenomena. Cognitivists see theories as truly explaining the underlying working mechanisms that are responsible for the observed behavior. Empirical evidence is strongly on the side of the behaviorist position; in general, people cannot give reliable or valid reports of their underlying thought processes any more than they can describe the neural mechanisms that account for those mental events. Many other arguments also assert the neutrality of theories and emphasize their descriptive rather than explanatory nature. Many of the computer-based or mathematical theories discussed in this article must, therefore, be considered to be process descriptions, regardless of how well they fit the empirical data or how useful they are as engineering tools.

There is, it should be noted, a major controversy currently raging concerning the ultimate resolvability of the problem of internal representation that may make all of these models interesting process descriptions rather than true reductive explanations. A number of psychologists have argued that the representation of the image within the visual system is indeterminate through either behavioral or neurophysiological techniques. Behavior is not a satisfactory probe because it is neutral with regard to the internal mechanisms in a fundamental way; neurophysiology is not satisfactory because of the enormous complexity of the coding schemes used by the nervous system to represent spatio temporal patterns beyond the peripheral portions of the sensory pathways. These arguments raise doubts about the utility of, for example, single-cell neurophysiological research for contributing to a satisfactorily complete solution of the human visual pattern recognition problem. Early studies that showed lateral inhibitory interconnections in simple

peripheral structures such as the horseshoe crab eye may have been misleading harbingers for the future. Whereas interneuronal inhibition may have been a good model of the Mach Band, most pattern recognition processes certainly take place at high and complex neural levels and are poorly served by explicitly neural models of this genre. A trend toward computational models led by the thoughtful contributions of computer scientists such as D. Marr, T. Poggio, and W. E. L. Grimson based on transforms, operations, and processes (rather than neural structures) seems more promising. Even the development of neural network or connectionist theories of pattern recognition is now appreciated to be that of process models describing interactions between symbolic nodes rather than between anything close to biologically realistic neurons.

In summary, the problem of going from behavioral observations is what mathematicians denote as an *ill-posed* problem. That is, there is not enough information in the available data to backtrack to the underlying mechanisms. It is only by assuming certain constraints that the problem becomes tractable. That assumption, however, is the equivalent of adding additional degrees of freedom and, thus, detaching any theory from a unique explanation of the underlying psychobiological reality.

II. THEORIES OF PATTERN RECOGNITION

As noted earlier, contemporary theories of pattern recognition are mainly dedicated to answering two kinds of questions. The first concerns the initial transforms that are carried out on the input image. The foundation issue in this case is the nature of the representation of the image information. The second question concerns the process by which the transformed images are linked with a particular prototype name. The foundation issue in this case is the nature of the association between the incoming image, transformed and altered as it may be, and a name or category learned at some previous time.

A. The Representation Problem

Many modern pattern recognition theories that concentrate on the visual process take for granted that, if the image is appropriately represented, the problem is essentially solved, the association of the appropriately represented image with a particular name being a trivial final step. (Of course, for those interested in the higher cognitive and linguistic processes, this second stage of the pattern recognition problem is central.) Much of the emphasis by many contemporary pattern recognition theorists is, therefore, on image transformations and representations prior to the comparison process.

The image transformation process is by no means simple or immediate. It is, itself, a major challenge to explanatory theory. Human vision is wonderfully adaptive. At some stage, it seems that the human pattern recognizer normalizes the stimulus so that, even when an object is rotated, translated, or magnified over wide ranges, it can still be recognized. (This invariance is another way of defining stimulus equivalence.)

Most computer models cum theories, as well as psychological models of perception, usually include some preliminary normalization to a canonical configuration or to an invariant representation. (This is especially true for connectionist or neural net models.) If the normalization is done properly, recognition is not dependent upon the particular situational properties of the stimulus, and the model mimics human recognition invariance in a reasonably complete way. For example, simply transforming a stimulus to a polar, as opposed to a Cartesian, coordinate system is one useful means of establishing invariance to rotation and magnification. It is also possible to transform a stimulus to a completely different representational system such as a spectrum of spatial frequencies, for example, a Fourier or a Walsh transform, to provide another means of precluding any sensitivity to irrelevant spatial translations.

In spite of the ubiquitous nature of this theoretical approach, whether such a standardization or canonical transformation of the stimulus actually occurs in human pattern recognition remains an unresolved question. At a behavioral level, human recognition skills exhibit a profound insensitivity to an object's location or its size. It is conceivable, however, that the organic analysis system is so powerful that this minor miracle can be accomplished without any image normalization of the kind to which computational theorists usually retreat. Such a preliminary modification of the image may merely be a convenience, if not a necessity, for the computer modeler or psychological theoretician because of our incomplete understanding of the later stages of processing. The difficulty of solving problems without some kind of a fixed frame of reference may be much less for the human visual system than for the computer program.

The mathematical problem of defining a canonical coordinate system to achieve good invariance to the various distortions and displacements is not trivial. However effortlessly nervous systems seem to adjust to changes in stimulus position and shape, the general problem posed to the modeler or theoretician whose goal is to describe human pattern recognition is profound, refractory, and clearly not yet solved.

B. The Association Problem

The next stage in the pattern recognition process, following the initial image transformation and representation stage, requires that the modified image be associated with a prestored name or category. This second stage is even more mysterious in terms of the specific underlying mechanisms than the representation stage, even though it has been the object of considerable psychological research. There are, again, two major schools of thought concerning the nature of this second stage. In the first, the process is considered to be a simple correlational comparison with a library of templates, prototypes, or reference images. This type of comparison process depends upon at least a topological kind of isomorphic representation in which the geometrical relationships among the parts of the image are maintained. Depending upon the theoretician's proclivities toward a holist or elementalist approach to the first stage, the second stage may invoke (a) the triggering of a network in which decisions are made concerning the presence or absence of a feature or component until a final "recognition" occurs or (b) the comparison of the whole picture with the library of prototypes until a best fit is achieved. Preservation of the topological relations of the parts of the stimulus image, at least, is assumed in either case, if not the specific Cartesian geometry of the original image. That is, the image objects are assumed to be represented by a nervous system that preserves the spatial characteristics of the original stimulus. The match is made by a maplike superimposition, although on maps that may be very elastic. Size, orientation, and even shape may be distorted, depending upon the association procedure, as long as some semblance of topological order is maintained.

The other approach to name association (the second stage of the pattern recognition process) does not involve preservation of the topological and geometrical relations of the original image and its comparison with the prototypes in an isomorphic manner. Rather, the process may be symbolic and the analysis carried out as a series of logical decisions, analyses, or constructions. That is, an object may be represented in a nonisomorphic code that describes the object as a series of logical steps or in a descriptive language that specifies the rules that would allow the object to be reconstructed. From this point of view, the comparisons are not between maps that are at least topologically constant, but rather between symbol systems. This latter approach, in fact, does not require any kind of isomorphic comparison. It permits an alternative strategy in which the descriptive language or logical construction process acts as a decision tree, directing the recognition process to a category or name for the object. Such a process is intrinsically faster than one that requires an exhaustive search (such as template matching) and can be implemented in a more economical manner than one requiring many multiple processes to be carried out in parallel.

A substantial body of work associated with pattern recognition utilizes the dichotomy of attentive and preattentive processes as an assay of recognition processes. The work of B. Julesz and A. Triesman is especially notable. In each case, they have distinguished between dimensions of a stimulus object that preattentively "pop out" and those that must be attentively scrutinized to become effective in the recognition process.

C. Some Contemporary Pattern Recognition Theories

Theories of pattern recognition come in many forms and stem from many different traditions. The best way to concisely include a broad range of pattern recognition theories in this article is to provide capsule descriptions of the ways in which theories are categorized. The brief typologies presented here are based upon comprehensive taxonomies of pattern recognition methods suggested by J. T. Townsend, D. E. Landon, F. G. Ashby, S. Watanabe, S. Pinker, and the work of other contemporary metatheoreticians.

Townsend and his collaborators, Landon and Ashby, are mathematical psychologists and approach their taxonomies from the point of view of human perceptual theories. All members of the four classes of recognition methods that these authors describe are *descriptive*, in that no allusion to the possible physiological or cognitive mechanisms underlying the pattern perception process is made. They are also mainly based on statistical rather than deterministic kinds of mathematics.

Townsend and his colleagues divide pattern recognition theories into two major subdivisions. The first subdivision includes those pattern recognition theories that are "based on an internal observation." Members of this class of pattern recognition theories contend that each stimulus event is dealt with separately by the perceptual processing system. The probability of a correct recognition (i.e., a response with the correct name of the stimulus or the name of the appropriate category) depends, therefore, upon the evaluation of that stimulus item by a set of internal rules and criteria couched only in the terms of a particular stimulus presentation event. This class of theory attempts to describe the specific processes (e.g., feature detection) that are presumed to exist within the cognitive structure of the observer as an incoming image is processed.

The second major subdivision includes those theories that are designated as "descriptive," with a narrower interpretation of the word than that just used. In this case the role of the individual event is minimized. Instead, the process of recognition is modeled as a kind of guessing or choosing an item from a set of possible responses on the basis of probabilistic rules involving context properties that go far beyond the immediate event. Rather than processing the attributes of a single stimulus, as the internal observation theories did, this second class of models merely uses the stimulus as one of many influences leading to an appropriate guess or choice of the proper response by the observer.

The first major division made by Townsend and his colleagues—the "internal observation" category—is further broken down into two subdivisions, the *general discriminant* models and the *feature confusion* models. General discriminant models are characterized by decision rules and procedures that evaluate the attributes of a particular stimulus and calculate a numerical value or "discriminant" for all possible responses that could conceivably be associated with that stimulus. The largest numerical value associated with any possible response becomes the selection criterion leading to the emission of that correct naming response. Feature confusion models assume that a matrix is actually constructed that tabulates the probabilities of confusing specific responses.

The second major kind of pattern recognition model described by Townsend and his colleagues—feature confusion models—is also divided into two subcategories. The first gathers under a single rubric called sophisticated guessing type models, consisting of a number of different theories including the sophisticated guessing models themselves, *all-or-none models*, *overlap models*, and *confusion-choice* models. The second subcategory, which they designate the choice category, includes but a single exemplar: the *similarity choice model*. As noted, all of these theories are completely descriptive: they make no effort to consider the neural or cognitive processes underlying the statistical formalities. Rather, they involve the statistics of active decision making, choice behavior, or stimulus similarity as their conceptual basis.

Engineers, of course, approach the problem of designing models of pattern recognition from a different point of view. They often invoke a number of different kinds of techniques that do not depend on and are not limited to the observed peculiarities of human perception. Watanabe points out that techniques such as *entropy minimization*, *covariance diagonalization*, and *structural analysis* are often used in that field. Interestingly, though the two traditions have grown up separately, inspection of the respective models indicates that there may be more similarities than their different names and origins suggest. For example, the category of covariance diagonalization is hardly distinguishable from *factor analysis*, terminology with which psychologists are more familiar. In a similar way, some of these methods are comparable to *multidimensional scaling*, which also seeks to reduce large amounts of information to a smaller set of nonredundant measures. It is clear that there has been a vigorous cross-fertilization of pattern recognition models between engineering and psychology; data from psychology often lead to insights for the engineer, and ingenious engineering inventions provide the framework for psychological thinking about the pattern recognition process.

In this context of interdisciplinary interaction, it is interesting to note that the engineering methods are virtually always feature-based. In some cases, such as the structural analysis method, the features are the same as the those defining the geometry of the image—the corners, sides, etc. But in others, such as discrimination and decision-making procedures, a list of geometrical features is not necessary: any collection of attributes, spatially absolute (e.g., square) or relational (e.g., larger), can be used to define a pattern. Patterns may even be dealt with in the abstract. That is, measurements of virtually any kind can be used to set up "vectors" or collections of measurements that can compare with each other or with stored nongeometrical (i.e., symbolic) prototypes to recognize patterns of other kinds.

Other theories of pattern recognition are intuitively more straightforward. For example, the classic

template matching theory assumes that an incoming visual image is compared with a library of prestored dimensionally isomorphic images, each of which has a name already associated with it. Template theories are correlative: the best match of the incoming image with one of the stored library of templates determines which one will be associated with the incoming image. In their most basic form, template models are essentially global or holistic. However, the fact that they require enormous libraries of prestored images has always mitigated against them. Because the phenomenon of stimulus equivalence suggests that it is not even necessary to have previous experience with a particular view of a form (and thus to have an exact prestored image) for recognition to occur, it is not likely that template matching in its simplest version is a likely candidate to be the best model of human pattern recognition.

A theory that models some kind of logical decision-making system is a more plausible candidate to explain human pattern recognition. That is, one that does not require exhaustive searching for the best match in an extensive library would be preferred over one in which the attributes of the incoming image direct the process through a decision-making tree to a final recognition point.

Many neural-network-type theories operate in this mode. One of the classic neural network theories was developed in 1959 by O. Selfridge. His *pandemonium* model assumed that an array of specialized form detectors, sensitive to local geometrical features of the stimulus, become active to the degree that the feature was present. The pattern of activity constitutes a "vector" of activity that directly determines which name will be associated with the stimulus. No correlation with prestored images was necessary—only the response names themselves, which were located, in a conceptual sense, at the end of the decision tree through which the classification logic proceded.

In more recent years (after a hiatus stimulated by an important critique by M. Minsky and S. Papert in 1969), pattern recognition theories based on the operation of neural networks have become increasingly popular. This renaissance in network or connectionist-type theories can be directly attributed to the extraordinary impact of the twin books on parallel distributed processing by D. E. Rumelhart, J. L. McClelland, and their colleagues. Some of these multilayer neural networks or *perceptrons* (a term invented by F. Rosenblatt) type theories include training processes so that a particular output can be associated with a particular input by repetitive reinforcement as the network experiences incoming stimuli. The effect of reinforcement in this type of model is to modify the strength of connections between nodes in the network. (The nodes have been conceptualized as either neurons or higher order symbol processing units at various times in the history of neural networks.) The final outcome of this progressive change in the organization of the network is reminiscent of the pandemonium model: logical routing from multiple, alternate stimulus pattern inputs to appropriate singular response outputs. The distinctive property of modern neural network models, however, is the nature of the adaptive processes by means of which the weights between nodes can be modified.

Most of the theories that have been considered so far use the features or attributes of the stimulus in the same space as originally presented. For example, an angle defined in a Cartesian (x, y) coordinate system is dealt with in terms of that geometry. Currently, there are other very important theories of pattern recognition and vision that base their action on a significantly different foundation: spatial domain transformations. That is, these alternate models transform the stimulus from its original spatial representation to another one that has some other more general, useful, or computationally convenient property. For example, a stimulus originally presented in the familiar (x, y) coordinate space of the visual display may be transformed into a spatial frequency (u, v) space by means of a two-dimensional Fourier transform.

There are two disadvantages to the use of images defined only in the x, y space. First, the original picture may be represented as a collection of component features that can only be laboriously transcribed or exhaustively tabulated. Second, the original picture is a multidimensional pictorial representation that is not quantified in a way that would permit calculations to be made on it. The Fourier-transformed image, however, varies along only three dimensions: spatial frequency, phase, and amplitude. Therefore, this kind of transformation (which usually produces a picture that appears to be more complicated than the original one) also produces a numerically manipulable and computable spectrum or vector (of the frequency components) from the original unquantified pictorial representation. This is the main advantage and *raison d'etre* of the Fourier technique: it takes geometrical forms that are not represented quantitatively and represents them in a form on which computations can be made.

Fourier transforms, or any of the many other similar transforms that are now available, are merely a means

of representing the image. Representation of an image in the (u, v) domain is a process that does not speak at all to the association problem, a matter that must be dealt with separately in a subsequent processing stage. This is not unusual. Theories purporting to be "explanations" of pattern recognition often turn out to be nothing more than methods for representing objects in a computationally useful form. For example, there is a closely related field of computer vision called visualization. In this field, cognate to the pattern recognition field we have been discussing, the task is to draw good images on a display. Theories of image representation aimed at solving this problem describe how complex geometrical forms can be reduced to simple standard shapes. D. Marr and H. K. Nishihara, as well as A. Pentland, have made major contributions to this field by suggesting ways in which images may be represented as sets of basic solid shapes or linear axes.

Other approaches to modeling human pattern recognition and/or developing new engineering techniques have been tried: progress in more advanced forms of neural networks has continued; pruning algorithms and other tree methods have also been advanced; progress has been made in distinguishing between semantic and syntactic methods; and novel new approaches using such mathematical esoterica as fuzzy logic, Bayesian logic, Markov logic, and Dempster–Shafer theory have been explored. Obviously, there is continued development in methodology even if the mechanisms by which the brain recognizes patterns remain obscure.

III. EXPERIMENTAL RESEARCH

The whole–part question continues to be one that attracts a considerable amount of research attention. D. Navon, for example, has worked with stimulus patterns that are composed of two levels of features. The whole stimulus pattern defines one form, whereas the parts of which it is composed consist of another. The question is, "Which level of processing dictates what is recognized?" Navon's experiments, along with those of S. J. Lupker and H. Bourna, all support the idea that the global form is precedent.

Results with stimuli that varied in their degree of symmetry carried out by H. Pashler and B. Jenkins also speak for the holistic theoretical point of view. This type of experiment typically showed that a symmetrical global arrangement of the parts of the stimulus made for much more efficient recognizability. Because the same features were present in each case, once again arrangement is implicated as the key variable in recognition.

The argument for holistic precedence is made even more profoundly made when stimuli are chosen in which the features are not even present. This can be done, for example, if one uses dot patterns, a stimulus form in which there are no continuous geometrical features present, only arrangements of the featureless punctate component. In an extensive series of experiments, my colleagues and I have shown that the arrangement of the dots is critical in pattern recognition. Even more important was the fact that certain specific arrangements were shown to have particular perceptual potency. Specifically, a general rule—*the law of linear periodicity*—which asserts that the best recognized arrangement is a straight line of evenly spaced dots, explained a very large number of different experiments, in both spatial and dynamic environments.

Another class of experiment in which support for the holistic point of view is obtained is generically classified as the *object* or *word superiority* paradigm. In this procedure, a comparison is made between the recognizability of a letter or an oriented line either isolated or in a context—a word or a stick figure. G. M. Reicher, working with letters and words, and N. Weisstein, M. C. Williams, and C. S. Harris, working with lines and outline objects, all found that the lines and letters were better recognized when embedded in a relevant context than when isolated. It seems, therefore, that the arrangement of the stimulus and its context play primary, if not definitive, roles in the recognition process.

During the last decade of the twentieth century, there has been a subtle shift in the research program. Nowadays the words *object perception* (a sidelight only a few years ago) have taken over from the phrase *pattern recognition*, suggesting an increasing emphasis in research on the recognition of three-dimensional objects. One area that has been especially active has been the study of how we recognize faces. Stimuli of this kind are hard to quantify, and much of the salient research has manipulated the integrity of the face, moving, deleting, or rearranging parts and components.

A considerable amount of work is also being done on how attributes such as color, movement, and texture affect recognition. A considerable amount of evidence indicates that coherent motion may make recognizable what is otherwise totally hidden in visual clutter. Color has been shown to have an important influence on objects for which the color is particularly

diagnostic, such as a banana. Other specific parameters and attributes of an object have also been shown to be influential in their recognition. However, much of this research raises new possibilities about the semantic or high-level processing of cues that goes far beyond the prevailing low-level processing theories that were stimulated by important, but possibly irrelevant, discoveries in the neurophysiological laboratory.

For example, one set of experimental findings that the author does not believe helps very much in explaining pattern recognition depends on the recording of single neuron action potentials. Although this is an immensely popular field these days, it seems to some students of the field that such research is aimed at the wrong level of analysis. Pattern recognition, like all other forms of mentation, must arise from the coordinated information processing of many, many neurons. Individual neurons may signal some relevant activity, but are unlikely to be the neural equivalents of pattern recognition or anything else mental.

IV. CONCLUSIONS

This brief article has surveyed some of the theories and empirical data in the field of pattern or object recognition. Obviously, this is a vital and exciting field of contemporary science that has much to gain from the interdisciplinary interaction of biological, psychological, and engineering sciences. Clearly, the generic problem of human pattern recognition (how do we classify an incoming visual image?) has not been solved to the satisfaction of anyone despite continuing progress in the development of engineered systems capable of ever closer approximations to human recognition. We do have a number of interesting theoretical approaches and an abundance of human psychophysical research. We realize what some of the fundamental issues are, but have not yet been able to answer the most fundamental of them.

The field of pattern recognition, as presented in this article, is not, by any means, complete. There are many other important research areas that could have been included if space permitted. We have made no mention of the one-dimensional patterns of speech and music that humans also recognize so effortlessly. Many of the general problems and issues that are identified for vision, however, generalize to the other senses. Even in the context of visual perception, this article could not be all-inclusive.

In conclusion, it does seem as if there is a contemporary contradiction between the majority of the theoretical models that emphasize features and a considerable portion of the findings from psychophysical experiments that attack the pattern recognition problem. Most parametric psychophysical studies of human pattern recognition, and even more strongly most first-order demonstrations, seem to suggest that the human observer recognizes patterns in a manner that is more sensitive to the global and holistic attributes of the incoming image than to the local features, components, or parts. The resolution of this contradiction is one of the major challenges facing this field in the future.

Peptides, Hormones, and the Brain and Spinal Cord

LEE J. MARTIN
Johns Hopkins University School of Medicine

GLOSSARY

astrocyte A class of nonneuronal glial cell in the central nervous system that has long, radial processes that ensheathe neurons and synaptic complexes, regulate the extracellular chemical and ionic environment, and secrete brain peptides, growth factors, cytokines, and chemokines.

central nervous system The brain and spinal cord.

chemokine A chemoattractant small peptide or protein cytokine.

cytokine Extracellular signaling peptide or protein that acts as a local mediator in cell–cell communication.

glial cell Nonneuronal cell in the nervous system (e.g., astrocyte, oligodendrocyte, microglial cell, and Schwann cell).

growth factor An extracellular peptide or protein that functions as a cell survival factor that can maintain cell survival or stimulate a cell to grow or proliferate.

hormone A chemical produced by a cell to regulate the functioning of another cell.

microglia the resident small phagocytic cells of the central nervous system that are related to the mononuclear phagocyte lineage and function as immune accessory cells that secrete cytokines and chemokines.

neuromodulator A chemical signal that modulates the response of a neuron to a neurotransmitter.

neuropeptide Peptide secreted by neurons or nonneuronal cells as either a synaptic or nonsynaptic cell–cell signaling molecule.

neurotransmitter Signaling molecule secreted by the presynaptic terminal of a neuron at chemical synapses to relay a signal to a postsynaptic neuron.

oligodendrocyte Glial cells that provide myelin sheaths for axons within the CNS and secrete peptide growth factors.

programmed cell death A form of cell death that is mediated by the activation of intrinsic mechanisms.

Schwann cell Glial cells that provide myelin sheaths for axons within the peripheral nervous system and that secrete peptide growth factors.

tyrosine kinase Enzyme that transfers the terminal phosphate of ATP to a specific tyrosine residue in a target protein.

Brain peptides are amino-acid-comprised molecules that are synthesized and released by neuronal and nonneuronal cells that function as intercellular signaling molecules, serving as neurotransmitters, neuromodulators, neurohormones, cytokines, chemokines, or growth factors.

I. INTRODUCTION

The field of brain peptide research has been revolutionary in neuroscience. Many fundamentally new concepts about brain organization and function, as well as abnormal function and disease, have been revealed by studying brain peptides. Through brain peptides, new interactions have been disclosed between the nervous system and endocrine system, the nervous system and gastrointestinal system, and the nervous system and immune system. New principles about cell–cell signaling and intracellular signal transduction pathways have come to light from studies of brain peptides and related molecules. These studies are particularly important because a variety of these naturally occurring chemicals have been implicated in modulating basic nervous system functions such as sensibility, emotions, and behavior, and they most likely participate in the pathobiology of neurologic and psychiatric diseases in humans. The accumulating information on brain peptides may have ramifications as far-reaching as the further understanding of the pathophysiology of Alzheimer's disease, amyotrophic lateral sclerosis, multiple sclerosis, stroke, acquired immune deficiency syndrome (AIDS), obesity, anorexia, sleeping disorders, and brain–spinal cord trauma.

At the same time, however, advances in the field of brain peptides tend to cloud the conventional classification of intercellular signaling molecules within the body. For example, the tachykinins are a family of peptides including substance P and neurokinins that are present widely throughout the body, including the brain and spinal cord. These peptides have several clearly identified functions outside the central nervous system (CNS) and within the CNS, participating in cardiovascular function and inflammation. In the spinal cord, tachykinins function in the synaptic transmission of nociceptive (pain) information and, thus, are important neurotransmitters. Yet tachykinins (as well as several other well-known brain peptides) also function in neuromodulation, participating in the regulation of neuronal excitability by modulating glutamatergic excitatory synaptic transmission via glutamate receptors, and they also function in neuronal survival akin to neurotrophic factors. Another example that emphasizes the breakdown of the walls of conventional classification of brain peptides is illustrated by the functions of vasoactive intestinal peptide. An early identified function of vasoactive intestinal peptide was the regulation of blood flow in the autonomic nervous system and CNS. Now, it has been shown that vasoactive intestinal peptide has diverse neurotransmitter, neuromodulator, cytokine, and neurotrophic factor actions that regulate neuronal survival and growth as well as glial activation and release of glial-cell-derived soluble factors. Work has revealed exciting new evidence that vasoactive intestinal peptide can prevent neuronal death induced by the AIDS virus envelope protein gp102, and another more recently identified vasoactive intestinal peptide family member (i.e., pituitary adenylate cyclase activating polypeptide) can block apoptosis of cultured granule neurons and necrosis of hippocampal pyramidal neurons after cerebral ischemia. These few examples highlight the fact that the highly diverse actions of brain peptides can make it difficult to discretely classify these naturally occurring brain chemicals. Furthermore, these examples emphasize their pathophysiological and potential therapeutic importance in disorders of the human CNS.

The discovery of each brain peptide involves its isolation, chemical characterization, anatomical localization, gene cloning, receptor identification and cloning, and functional assessment at the micro (electrophysiological and intracellular signaling) and macro-levels (behavior). Substance P was the first neuroactive peptide found in nervous tissue. Originally, there was considerable debate about the suitability of referring to brain peptides as neurotransmitters. Many of these peptides had been identified previously as peripheral tissue hormones with physiological actions at target organs outside the brain. Cholecystokinin, somatostatin, and insulin-like growth factors are only a few examples in this regard (Table I).

The possibility that small peptides acted as neurotransmitters was a new concept in the early emerging field of neuroscience (Fig. 1). Generally, four criteria should be fulfilled for a chemical to be considered a neurotransmitter: (1) a neurotransmitter is synthesized in neurons (Fig. 2); (2) a neurotransmitter is present in the presynaptic terminal and is released after depolarization in quantities sufficient to effect a response postsynaptically (Fig. 1); (3) exogenous application of a candidate neurotransmitter at physiological concentrations mimics the actions of endogenously released chemical; and (4) the action of the candidate neurotransmiter at the synapse is terminated by a specific mechanism. Many different types of brain peptides (old and recently identified) have now been shown to be neurotransmitters (Table I).

More than one neurotransmitter may coexist in neurons. Neuroactive peptides and small-molecule

Table I
Classical Neuroactive Peptides[a]

Peptide	Size[b]	Family	Major functions
Vasopressin	9	Neurohypophyseal hormone	Renal H_2O resorption, vasoconstriction
Oxytocin	9	Neurohypophyseal hormone	Uterine contraction, milk ejection, natriuretic effects
Gonadotropin-releasing hormone	10	Hypothalamic peptide	Stimulates secretion of FSH and LH
Thyrotrophin-releasing hormone	3	Hypothalamic peptide	Stimulates TSH secretion
Corticotropin-releasing hormone	41	Hypothalamic peptide	Stimulates ACTH secretion
β-Endorphin	30	Endogenous opioid	Analgesia, stress response, inhibition of dopamine release
Dynorphin	17	Endogenous opioid	Analgesia, inhibition of dopamine release
Enkephalin	5	Endogenous opioid	Analgesia, primary afferent modulation
Cholecystokinin	8	Gastrointestinal peptide gastrin	Inhibition of feeding
Neuropeptide Y	36	Gastrointestinal peptide	Feeding behavior, modulation of neuronal excitability
Neurotensin	13	Gastrointestinal peptide	Modulation of dopaminergic neurons
Somatostatin	14	Gastrointestinal–hypothalamic peptide	Inhibits growth hormone release, inhibits synaptic transmission, neurotrophin
Substance P	11	Gastrointestinal–tachykinin peptide	Pain transmission, neurotrophin
Vasoactive intestinal peptide	28	Gastrointestinal–secretin peptide	Cerebral blood flow regulation
Insulin-like growth factor	67–70	Insulin	Neuronal survival

[a]Represents only a selection of the more than 50 classical neuroactive peptides that have been identified.
[b]Number of amino acid residues.

neurotransmitters are often found within the same neuron (Fig. 1). This observation was iconoclastic because, until this discovery, it was believed that each neuron used only one neurotransmitter. Now it is known that, at synapses, peptides are stored in dense-core vesicles that contain ATP. These dense-core vesicles (called dense-core because they appear to have a dark core when viewed in the electron microscope) are usually much less numerous than small, clear synaptic vesicles that contain neurotransmitters such as acetylcholine, GABA, and glutamate (Fig. 1). Peptide-containing dense-core vesicles are large (100–150 nm) compared to small, clear synaptic vesicles (40–60 nm). Dense-core vesicles are released at higher frequencies of stimulation of the axon and are not released solely at the presynaptic active zone like small-molecule neurotransmitters, because they do not require the presynaptic membrane specialization for their exocytotic release. The inactivation of the neuroactive peptide at the synapse occurs extracellularly and is slower than the inactivation of the small-molecular-weight neurotransmitter; thus, peptides act over a longer period of time than classical neurotransmitters.

II. BRAIN PEPTIDES OCCUR AS MANY DIFFERENT KINDS WITH MANY DIFFERENT FUNCTIONS

The diversity of brain peptides is extensive (Tables I–IV). These peptides can be grouped into families. One way to classify neuroactive peptides is based on structural similarities, notably, commonalities in amino acid sequences (i.e., primary structure). Similarities in the physiological responses (i.e., biological activities) that are evoked by different brain peptides are another way to group these chemical messengers, although each brain peptide can have multiple physiological actions. More recently, similarities in the nucleotide base sequences in the genes that encode precursors of neuroactive peptides are used identify membership in peptide families.

A. Classical and More Recently Discovered Neuropeptides

The classical brain peptides can be grouped into broad families such as the hypothalamic-releasing hormones,

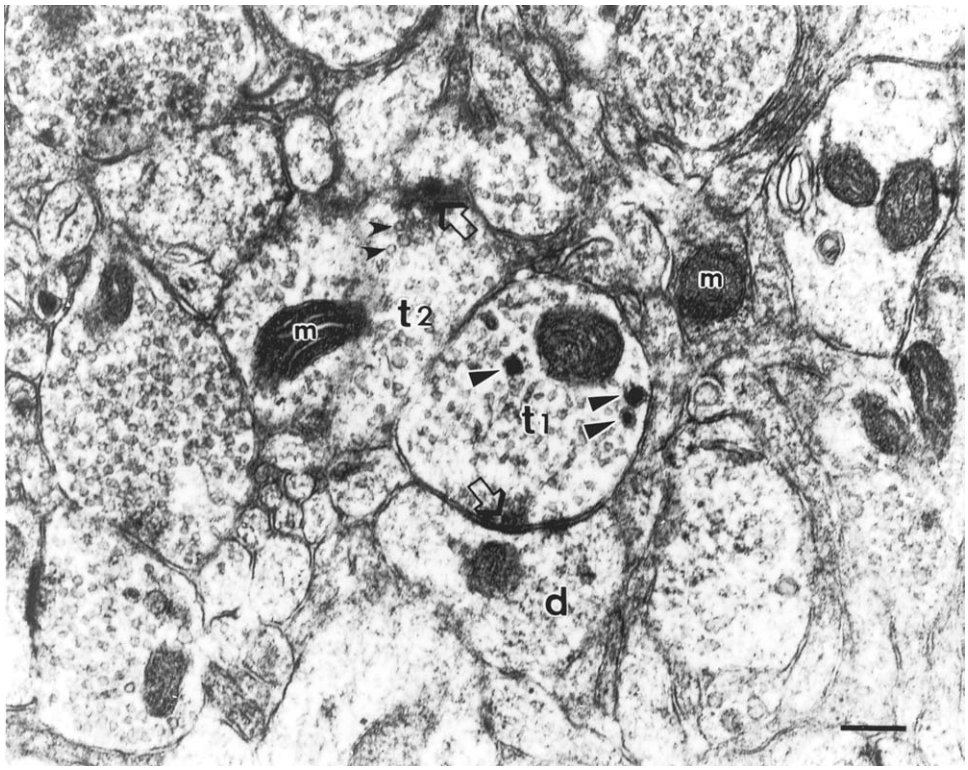

Figure 1 Synaptic structure as revealed by electron microscopic examination of rhesus monkey cerebral cortex. Nerve terminals (t1 and t2) contain numerous small, clear, round synaptic vesicles (t2, small, black arrowheads) but only a few dense-core synaptic vesicles that can contain neuropeptides (t1, black-on-white arrowheads). Mitochondria (m) are present in nerve terminals for the energy-dependent release of synaptic vesicles. Nerve terminals form synaptic contacts with dendrites (d). The active zone of the synapse (t1 and t2, open arrow) is the site of synaptic vesicle exocytosis. Scale bar = 0.4 μm.

the neurohypophyseal hormones, the pituitary peptides, the gastrointestinal peptides, the opioids, and the tachykinins (Table I). The classical brain peptides are located differentially throughout the CNS (Fig. 3). For example, forebrain structures (cerebral cortex, striatum, and amygdala) tend to have greater diversity in neuropeptides than hindbrain structures (cerebellum and spinal cord). Remarkably, regions that have the same embryonic derivation within the diencephalon (thalamus versus hypothalamus) can have vastly different neuropeptide profiles (Fig. 3).

Major advances have been made in understanding brain peptide regulation of feeding and body weight. In the 1950s a recessive obesity mutation was identified that results in profound obesity and adult-onset (type II) diabetes. It was thus postulated that an obese gene product may be a component in a signaling pathway regulating body fat deposition. Mice with mutations in the obese gene are obese and diabetic and are found to have reduced activity, metabolism, and body temperature. It was discovered that leptin, a 16-kDa secreted protein hormone, is the product of the obese gene and is believed to be synthesized only in adipose tissue. Leptin is an integral component in a homeostatic loop that regulates body weight. Leptin acts to control food intake and energy expenditure by both classical and newly discovered neuropeptides in the hypothalamus. One classical neuropeptide that functions in weight control is neuropeptide Y (Table I).

The brain neuropeptides that function in this loop are the orexins (or hypocretins because they are hypothalamic neuropeptides similar to the gut hormone secretin). Orexin-A and orexin-B are peptides of 33 and 28 amino acid residues, respectively, that are derived from the proteolytic processing of a single prepro-orexin precursor protein. These peptides are produced exclusively by a specific group of neurons in the lateral hypothalamus (Fig. 3) called the perifornical nucleus. These orexin-utilizing neurons have widespread projections to the olfactory bulb, cerebral cortex, thalamus, hypothalamus, and brain stem. These brain peptides are endogenous ligands for two

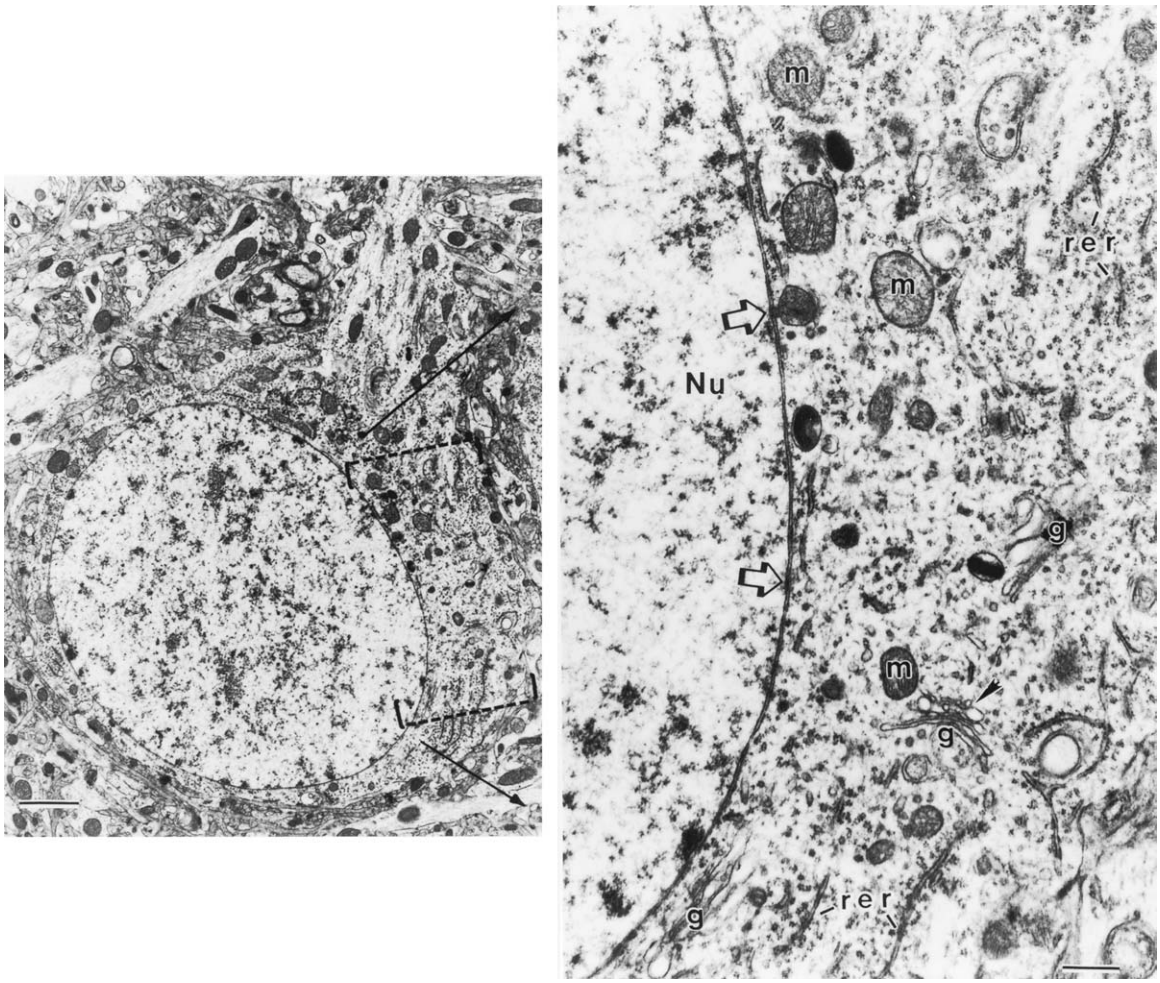

Figure 2 Electron microscopic identification of subcellular organelles in neurons of piglet striatum. Low-magnification view (left panel) of a primary neuron found in the striatum. At higher magnification (right panel), these neurons have abundant polyribosomes distributed throughout the cytoplasmic matrix (small granules), arrays of rough endoplasmic reticulum (rer), stacks of Golgi complex (g) with budding secretory vesicles (black-on-white arrowhead), and mitochondria (m). The nucleus (Nu) has a predominantly pale matrix and is surrounded by a continuous, bilaminar nuclear membrane that contains nuclear pores (arrows). Scale bars = 0.85 μm (left panel) and 0.25 μm (right panel).

G-protein-coupled receptors found in the brain that function at synapses to increase the presynaptic release of GABA and glutamate.

In addition to these peptides functioning in energy homeostasis, it has been discovered that the orexin neuropeptide–receptor system functions in sleep regulation. Two animal models dramatically highlight this point. Mice deficient in the orexin gene display abnormal sleep–wakeful states, and autosomal recessive mutations of the hypocretin (orexin) receptor-2 gene cause a sleep disorder in Doberman Pinschers. Both of these abnormalities are believed to cause sleep disorders similar to narcolepsy in humans. Support for this conclusion is derived from studies showing that orexin is undetectable in many people with narcolepsy.

B. Growth Factors

A growth factor is a secreted peptide or protein that functions as a cell survival factor and can stimulate cell growth, differentiation, or proliferation (Table II). In the nervous system, growth factors are called neurotrophins. They can act locally as autocrine or paracrine regulators of cell function. The first neurotrophin to be isolated, chemically characterized, and physiologically

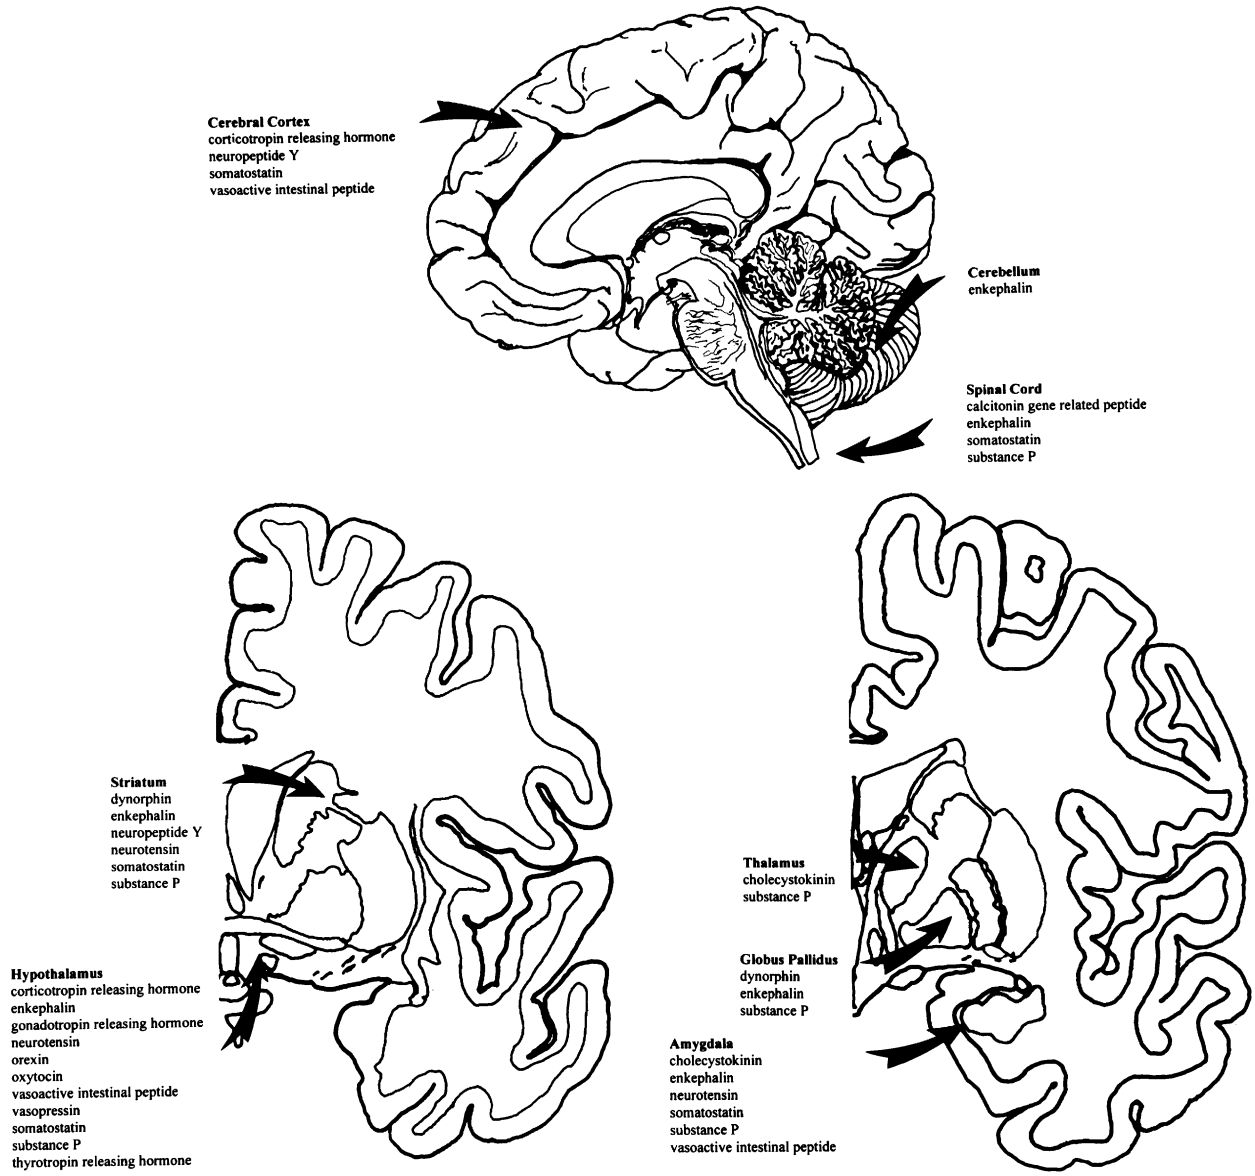

Figure 3 General locations of some classical neuropeptides in the human CNS. The top image is a view of the brain and upper spinal cord from a midsagittal perspective, and the two lower panels are transverse views through the forebrain and anterior or mid-diencephalon. Some of the major neuropeptides found in these regions are indicated.

evaluated was nerve growth factor. Neurotrophins act as target- or afferent-derived growth factors for specific populations of neurons and can have survival-promoting effects on immature and adult neurons. In general, the effects of neurotrophins are mediated by binding to a specific high-affinity tyrosine kinase receptor on the presynaptic terminal (Fig. 1), followed by internalization and then retrograde transport of the neurotrophin–receptor complex to the neuronal cell body (Fig. 2), where it can regulate neuronal differentiation and survival according to the traditional neurotrophin concept. Some neurotrophins (e.g., brain-derived neurotrophic factor) regulate the expression of neuropeptides (e.g., somatostatin and neuropeptide Y) in neurons. More recent discoveries, however, have now altered this concept. Neurotrophins can be transported away from the neuronal cell body down the axon, stored in nerve terminals, and then released

Table II
Survival Peptides and Growth Factors for Neurons

Growth factor	Cellular sources	Responsive cell populations
Nerve growth factor (NGF)	Schwann cells, neurons in hippocampus, neocortex, olfactory bulb	Neurons in peripheral ganglia, basal forebrain magnocellular complex (BFMC), striatum
Ciliary neurotrophic factor (CNTF)	Schwann cells, astroglia	Peripheral ganglion neurons, motor neurons, hippocampal neurons, astroglia, oligodendroglia
Brain-derived neurotrophic factor (BDNF)	Neurons in neocortex, hippocampus, BFMC, striatum, hypothalamus, cerebellum	Neurons in peripheral ganglia, retina, BFMC, substantia nigra, cerebellum
Neurotrophin-3 (NT-3)	Neurons in hippocampus, cerebellum	Neurons in peripheral and enteric ganglia, hippocampus, cerebellum, motor neurons
Neurotrophin-4/5 (NT-4/5)	Neurons in neocortex, hippocampus, BFMC	Peripheral ganglion neurons, BFMC, motor neurons
Glial-cell-derived neurotrophic factor (GDNF)	Neurons in neocortex, hippocampus, striatum, peripheral ganglia, motor neurons, chromaffin cells, muscle	Peripheral ganglion neurons, motor neurons, substantia nigra neurons, cerebellar neurons
Insulin-like growth factor (IGF)	Schwann cells, muscle	Motor neurons, astroglia, oligodendroglia
Leukemia inhibitory factor (LIF)	Astroglia, microglia, Schwann cells	Peripheral ganglion neurons, spinal motor neurons, astroglia, oligodendroglia, microglia
Fibroblast growth factor (FGF)	Peripheral ganglion neurons, motor neurons, muscle	Peripheral ganglion neurons, motor neurons

presynaptically, thus functioning as afferent-derived (instead of target-derived) growth factors or neurotransmitters.

C. Cytokines

Cytokines are a highly diverse group of extracellular signaling molecules that act as local mediators in cell–cell communication (Table III). These molecules are peptide hormones that regulate a wide variety of inflammatory and immune processes. Furthermore, they can function by modulating cellular responses to growth factors by either potentiating or antagonizing signals. Their activity is mediated by binding to specific, high-affinity cell surface receptors on target cells. The production of cytokines is triggered by an activation event, broadly including brain injury or infection. In the nervous system, cytokines are produced by glial cells (astrocytes, microglia, oligodendrocytes, and Schwann cells), and their cellular targets can be other glial cells and neurons. They can initiate, propagate, and suppress inflammatory and immune responses. Some cytokines that are synthesized by astrocytes (e.g., interleukin-1, interleukin-6, and granulocyte macrophage colony stimulating factor) participate in the recruitment of microglia into damaged areas, whereas other cytokines (e.g., interleukin-1α, interleukin-1β, and tumor necrosis factor-α) are produced predominantly by activated microglia.

D. Chemokines

Chemokines are small peptides or proteins that are members of a superfamily of inducible, secreted, proinflammatory cytokines that function as cellular chemoattractant signals (Table IV). These highly diverse inflammatory molecules are classified, according to the topology of cysteine residues, into four groups: C, C-C, C-X-C, and C-X_3-C. The C subfamily lacks the first and third cysteine residues of the conserved motif, whereas the C-C subfamily members have the first two cysteines adjacent. In the C-X-C group, the first two of four cysteine residues are separated by a single amino acid, and in the C-X_3-C group the first two cysteines are separated by three amino acid residues. By activating G-protein-coupled membrane receptors on their target cells, chemokines can signal cells to migrate to or remain at the site of chemokine production. An important example for chemokine activity is the governing of inflammatory cell accumulation during immune-mediated demyelination of axons.

Table III
Cytokines[a]

Cytokine	Cellular sources	Functions
Tumor necrosis factor α (TNF-α)	Astroglia, microglia	Inflammation, cell death through necrosis or apoptosis
Fas ligand (FasL)	T-cells	Promote apoptosis
Interleukins	Astroglia, microglia, endothelial cells	Promote or suppress inflammation, modulate chemokine production, molecule specific (at least 15 interleukins have been identified)
Interferon-γ	T-cells	Antiviral activity, antiproliferation, immunomodulation, microglial activation
Transforming growth factor β (TGF-β)	Neurons, astroglia, microglia, Schwann cells	Regulate extracellular matrix and proliferation of astroglia and Schwann cells, suppress inflammation, modulate chemokine production
Leukemia inhibitory factor (LIF)	Astroglia, microglia, Schwann cells	Promote neuronal repair

[a]Represents a tabulation of only selected cytokines found in brain.

III. NEUROACTIVE BRAIN PEPTIDES ARE MADE FROM PROTEIN PRECURSORS THAT UNDERGO PROTEOLYTIC PROCESSING

Neuroactive peptide hormones are generated from precursor proteins. Several different neuroactive peptides are usually encoded by a single continuous mRNA that is translated into a large, inactive protein precursor. Prior to translation, these mRNA transcripts can undergo alternative RNA splicing within the nucleus to generate different mature mRNAs that encode protein precursors with different amino acid sequences. These secretory proteins are formed in the cell bodies of neurons and nonneuronal cells on polyribosomes attached to the cytosolic surface of the endoplasmic reticulum (Fig. 2). Neuroactive peptides or their precursors, like other secretory proteins, are processed in the endoplasmic reticulum and then shuttled to the Golgi apparatus for further processing (Fig. 2). The processing of larger precursor proteins occurs through specific, regulated proteolytic cleavage by serine proteases, thiol endopeptidases, amino peptidases, and carboxypeptidases. These cleavages are thought to begin in the *trans*-Golgi network, and they continue in the secretory vesicles. Proteins destined for secretory dense-core vesicles (Fig. 1) are packaged into appropriate vesicles in the Golgi apparatus by a sorting signal mechanism involving the selective aggregation of secretory proteins. The peptide-containing secretory vesicles leave the

Table IV
Chemokines in the Brain[a]

Chemokine	Cellular expression	Functions
Macrophage inflammatory protein-1 (MIP1)	T-cells, monocytes, macrophages, platelets, astroglia, microglia	Attraction of T-cells, monocytes, basophils, eosinophils, natural killer cells
Monocyte chemoattractant protein-1 (MCP1)	Monocytes, macrophages, endothelial cells, astroglia	Attraction and activation of monocytes, lymphocytes, basophils
Interferon inducible protein-10 (IP10)	Astroglia	Attraction of T-cells
RANTES[b]	Astroglia, microglia, Schwann cells, endothelial cells	Monocyte chemoattraction, neuronal migration
Fractalkine	T-cells, endothelial cells, neurons, microglia	Suppression of inflammation and microglial activation

[a]Only selected cytokines are shown.
[b]RANTES: regulated upon activation, normal T-cell expressed and secreted.

trans-Golgi apparatus by a process involving clathrin-coated budding (Fig. 2). After the immature secretory vesicles bud from the Golgi apparatus, their contents undergo rapid and extreme condensation resulting from acidification of the vesicle lumen by the activity of a vesicle membrane ATP-driven H^+ pump. In neurons, the mature vesicles are then moved to the presynaptic terminal (Fig. 1) by fast axonal transport. This traveling along the axon occurs by kinesin motor proteins attached to the surface of the secretory vesicle that propel them along microtubules. The release of the peptide-containing vesicle at the axon terminal occurs by exocytosis in response to a depolarization-induced local increase in intracellular Ca^{2+}.

IV. BRAIN PEPTIDES AND HORMONES ACT AT CELL MEMBRANE RECEPTORS

The signal transduction mechanisms through which most neuroactive brain peptides operate involve G-protein-linked receptors or enzyme-linked receptors. Most classical neuroactive peptides (Table I, e.g., substance P–neurokinins, somatostatin, neurotensin, opioid pentapeptides, vasopressin, and angiotensin) and some cytokine peptides (interleukin-8) are ligands for G-protein-linked receptors. These receptors activate a chain of events that alters the concentration of one or more small, intracellular, second messenger signaling molecules that, in turn, amplify the signal and pass it on by altering the functioning of specific proteins. Two of the most widely used second messengers for classical neuroactive peptides are Ca^{2+} and cyclic adenosine monophosphate (AMP). The effects of somatostatin, vasopressin, and adrenocorticotropic hormone are mediated by cyclic AMP.

In contrast, enzyme-linked receptors function directly as enzymes or as receptor-associated enzymes when activated. Neuropeptides, growth factors, cytokines, and chemokines can operate through one of five known classes of enzyme-linked receptors, including the following: (1) receptor guanylyl cyclases that catalyze the production of cyclic guanosine monophosphate (GMP) in the cytosol; (2) receptor tyrosine kinases that phosphorylate specific tyrosine residues on a small set of signaling proteins; (3) tyrosine-kinase-associated receptors that interact with proteins that have tyrosine kinase activity; (4) receptor tyrosine phosphatases that remove phosphate groups (dephosphorylate) from tyrosine residues of signaling proteins; and (5) receptor serine–threonine kinases that phosphorylate serine or threonine residues in specific proteins.

V. BRAIN PEPTIDES PROVIDE A BIOCHEMICAL FINGERPRINT FOR MANY BRAIN REGIONS AND REVEAL NEW FEATURES ABOUT THE PARCELING OF THE BRAIN

Very important and novel information about the nervous system has been obtained by charting the location of brain peptides (Figs. 4–7). Generally, these data are gleaned immunocytochemically by using highly specific antibodies that recognize unique amino acid sequences in brain peptides and proteins. Such experiments can provide critical information on the brain regions that contain peptides–proteins and their detailed cellular and subcellular localizations in experimental animal and post mortem human brain and spinal cord tissues. Over the past two decades, exciting results on brain peptides have been obtained that feature how the brains of humans and animals are organized, how they function, and how they are changed in abnormal conditions. Many prominent examples can be provided about how the charting of brain peptides reveals novel information on brain organization and the abnormalities in brain peptides that occur in experimental animals with profound neurobehavioral disorders. Two forebrain regions, the amygdala–bed nucleus complex and the striatum, provide informative examples.

A. The Amygdala–Bed Nucleus of the Stria Terminalis (BST) Complex

By studying the chemical neuroanatomy of the basal forebrain of humans and monkeys, it was discovered that the bed nucleus of the stria terminalis (BST) and the amygdala form a large, multidivisional complex (Figs. 4 and 5). This complex has been also called the extended amygdala by other investigators. The BST is continuous with the central and medial divisions of the amygdala through the ventral forebrain substantia innominata, and it intermingles with the nucleus basalis of Meynert of the basal forebrain magnocellular complex. The amygdala–BST continuum is a hotbed of neuropeptides, including somatostatin, enkephalins, substance P, neurotensin, cholecystokinin, vasoactive intestinal peptide, and galanin (Figs. 4 and 5). Specific chemically delineated zones and cellular compartments contain these brain peptides. The locations of these brain peptides reveal that the amygdala–BST complex is a very prominent and discretely compartmental structure in the basal

forebrain of humans and monkeys (Figs. 4 and 5). On the basis of neuropeptide distribution and cytology, this complex can be divided into at least 10 subdivisions. Furthermore, both subtle and dramatic differences in brain peptides are found in the amygdala–BST complex in different species, with humans having unique patterns that differ from those of animals.

Prominent gender differences (sexual dimorphisms) occur in the BST of humans and experimental animals. In humans, some divisions of BST are ~ 2.5 larger in the male brain than in the female brain. Major differences in the neuropeptide composition of the BST occur as well. These differences are thought to be caused by gonadal steroid hormones and also by glial-cell-derived peptide growth factors and cytokines such as transforming growth factor-β. Neurons of the BST and centromedial amygdala are among the chief testosterone- and estradiol-concentrating cells in animal brains. The sexual differentiation of the human brain takes place much later than originally believed, suggesting that, in addition to genetic factors, environmental and psychosocial factors may have ample opportunity to exert a profound influence on the sexual differentiation of the brain. This information is important because it could have implications for the determination of sexual orientation, and the BST is known to participate in sexually dimorphic functions, including aggressive behavior, sexual behavior, and feeding behavior. Furthermore, a relatively well-identified role of the amygdala–BST complex is the mediation of stress, fear, and anxiety responses, which

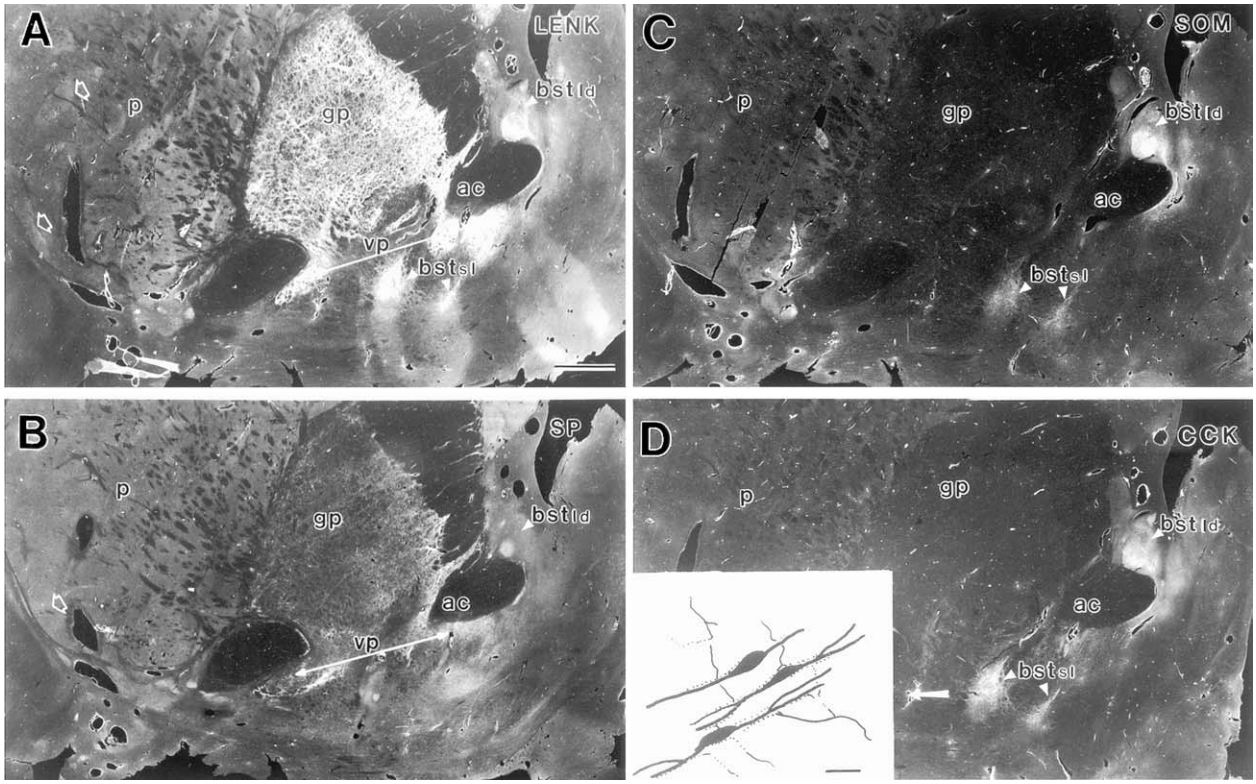

Figure 4 Neuropeptides delineate the compartments within in the basal forebrain and basal ganglia of humans. Antibodies were used to identify leucine-enkephalin (LENK, A), substance P (SP, B), somatostatin (SOM, C), and cholecystokinin (CCK, D) in postmortem human brain sections. Abbreviations: ac, anterior commissure; bstld, bed nucleus of the stria terminalis, lateral dorsal division; bstsl, bed nucleus of the stria terminalis, sublenticular division; gp, globus pallidus; p, putamen; vp, ventral pallidum. White areas represent neuropeptide immunoreactivity. The globus pallidus, its ventral extension (the ventral pallidum), and the bed nucleus are enriched in enkephalin. The striatal mosaic in the putamen (A, white, open, arrowheads) can be identified by enkephalin. The bed nucleus and its sublenticular extension are clearly divisible from the globus pallidus and the ventral pallidum by the presents of somatostatin and cholecystokinin. Somatostatin and cholecystokinin specifically mark the sublenticular division of the BST, so that it can be distinguished from the ventral pallidum. The inset (D) shows the typical distributions of LENK, SOM, and CCK in the BST sublenticular division. These neuropeptides are highly concentrated in many nerve terminals (small dots) that innervate neuronal cell bodies and dendrites that form the cellular columns that bridge the BST and amygdala in the human basal forebrain. Scale bars = 2.5 mm (A, same for B–D) and 40 μm (inset).

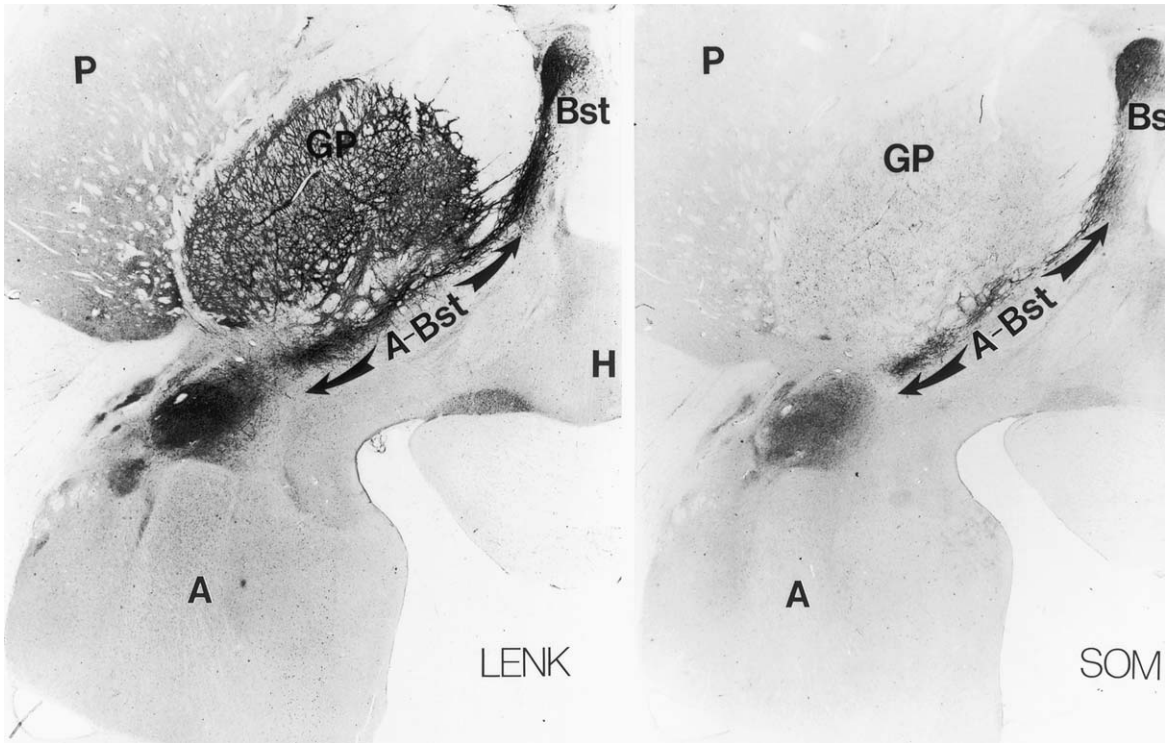

Figure 5 Neuropeptides delineate the amygdala–bed nucleus complex within in the basal forebrain of nonhuman primates. Antibodies were used to identify leucine-enkephalin (LENK, left panel) and somatostatin (SOM, right panel) in brain sections of rhesus monkeys. Abbreviations: A, amygdala; A–Bst, amygdala–bed nucleus continuum; Bst, bed nucleus of the stria terminalis; GP, globus pallidus; H, hypothalamus; P, putamen. Black areas represent neuropeptide immunoreactivity. The amygdala–bed nucleus continuum and the globus pallidus are both enriched in enkephalin. The amygdala–bed nucleus complex is specifically identified by the high concentration of somatostatin. Scale bar = 1.3 mm.

are likely to be regulated by brain peptides such as corticotrophin-releasing hormone.

B. The Striatal Mosaic

The basal ganglia are subcortical brain regions that function in sensory–motor integration, planning and initiation of somatic movements, cognition, and some types of social–emotional and species-typical behaviors. The striatum (caudate nucleus, putamen, and nucleus accumbens), globus pallidus (external and internal divisions and ventral pallidum), substantia nigra (pars compacta and reticulata), and subthalamic nucleus are the major components of the basal ganglia (Figs. 6 and 7). The striatum is divisible into at least two primary compartments designated as striosomes (patches) and matrix (Figs. 6 and 7). This forebrain region, thus, is like a jigsaw puzzle because it has different pieces that fit together, comprising a structure called the striatal mosaic. Neurons within striosomes and matrix differ with respect to their time of embryogenesis, connections with other brain regions, and expression of brain peptides. Striosomes are much more enriched in substance P and enkephalins than the striatal matrix, whereas the matrix is more enriched in somatostatin and neuropeptide Y than the striosomes. These general neuropeptide patterns change when comparing the dorsal striatum (caudate and putamen) with the ventral striatum (nucleus accumbens) (Figs. 6 and 7).

An important relationship exists between the regulation of gene expression for brain peptides within neurons of the striatal mosaic and the expression of excitatory glutamate receptors. Inputs into the striatum participate in the steady-state regulation of peptide expression in medium-spiny, striatal neurons, which are the principal neurons of the striatum. For example, ablation of corticostriatal projections reduces preprotachykinin and preproenkephalin mRNA in neurons of rodent striatum. Synaptic activity and membrane depolarization regulate neural gene

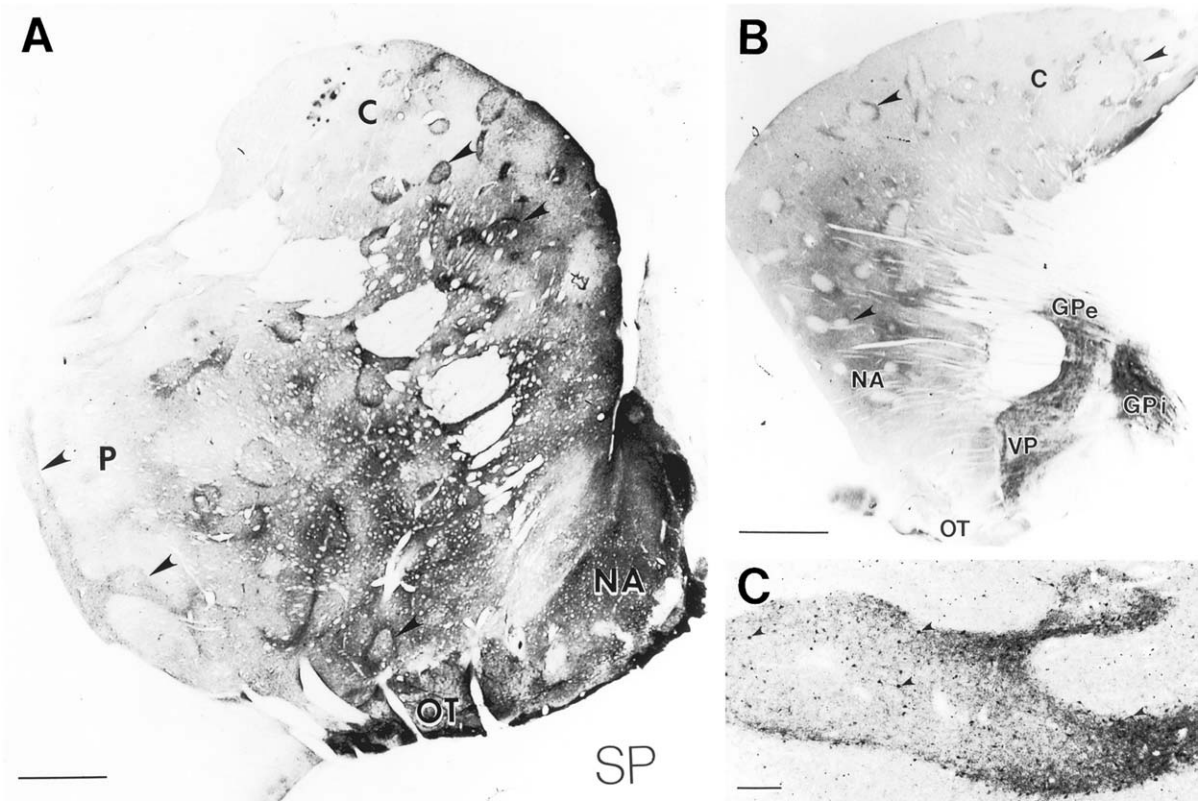

Figure 6 The localization of substance P reveals that the striatum is a mosaic and extends to the ventral surface of the brain. Antibodies were used to identify substance P in brain sections of rhesus monkeys. Shown are photographs of striatum in the transverse (A) and parasagittal (B) planes and a higher magnification view of a striosome (C). Abbreviations: C, caudate nucleus; GPe, globus pallidus external part; GPi, globus pallidus internal part; NA, nucleus accumbens; OT, olfactory tubercle; VP, ventral pallidum. Black–gray areas represent neuropeptide immunoreactivity. These photographs illustrate the discrete topography and heterogeneity of the striosome (A and B, black arrowheads) and matrix compartments throughout the dorsal striatum (caudate nucleus and putamen) and the ventral striatum (nucleus accumbens and olfactory tubercle). The chemical organization of striosomes is different in the dorsal striatum from the ventral striatum. In the caudate and putamen, striosomes are enriched in substance P or they have a ring (dark) and hollow (pale) pattern compared to the surrounding matrix. The more uniform striosomes contain numerous neurons with substance P (C, small black arrowheads) that are embedded in a dense plexus of nerve terminals containing substance P. In the nucleus accumbens, striosomes are poor in substance P compared to the surrounding matrix (B). Scale bars = 1.7 mm (A), 2.2 mm (B) and 130 μm (C).

expression, possibly through a Ca^{2+}-dependent mechanism that may involve calmodulin. Striatal neurons are enriched in calmodulin. Thus, excitatory glutamatergic neurotransmission may directly regulate, in an activity-dependent manner, neuropeptide expression within subsets of striatal neurons. Support for this idea is derived from our studies showing that glutamate receptors are expressed by substance P- and enkephalin-containing neurons within striosomes. This enrichment of glutamate receptors at postsynaptic sites within striosomes of the dorsal striatum may reflect a more dominant glutamatergic regulatory control of neuropeptide expression within striosomal neurons than within matrix neurons. An informative example in this regard is provided by striatal dopamine receptors. Dopamine receptors regulate the relative levels of expression of opiate and tachykinin peptides in subsets of striatal neurons through cyclic AMP, protein kinase A, and cyclic AMP response-element-binding protein. Several genes for striatal neuropeptides contain cyclic AMP response elements, including dynorphin, enkephalin, and somatostatin. Although the activation of different molecular subtypes of glutamate receptors may engage signal transduction pathways for neuropeptide gene expression in striatal neurons, the intracellular signaling pathways have not been identified completely.

For many years, the neuropeptide organization of the forebrain in normal monkeys and humans has been studied, thereby laying a foundation for concepts

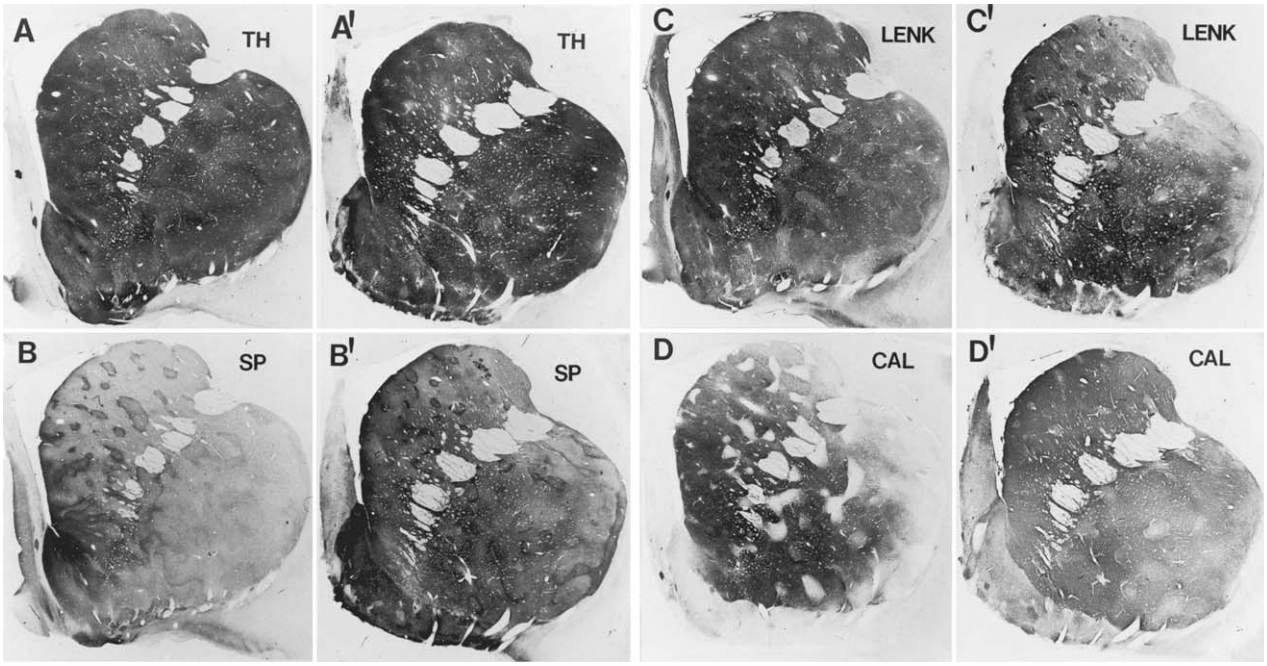

Figure 7 The primate striatum undergoes prominent remodeling of its chemical structure after birth. Antibodies were used to identify tyrosine hydroxylase (TH, a marker of dopamine innervation of the striatum), substance P (SP), leucine-enkephalin (LENK), and the calcium-binding protein calbindin (CAL, a striatal matrix marker) in brain sections of rhesus monkeys. The left image of each pair (A–D) shows the relative amounts and distributions of these striatal peptides–proteins in a monkey 4 months of age. The right images (A′–D′) show the same chemicals in the striatum of an adult monkey. In each pair, the caudate nucleus is on the left and the putamen is on the right. (A, A′) The dopaminergic innervation of the striatum is not fully established at 4 months of age, nor is the adultlike striosome–matrix organization. In the infant, the striosomes are slightly more enriched in dopaminergic innervation than the surrounding matrix. The reverse pattern is present in adults. (B, B′) The substance P pattern at 4 months is immature compared to the adult, but the differences appear to be of degree (intensity) and not in basic pattern (like TH). The caudate nucleus in the infant and adult has numerous striosomes enriched in substance P; however, striosomes in the infant putamen are less developed than the striosomes in the adult putamen. Furthermore, the matrix in the infant caudate and putamen is deficient in substance P compared to adult. Furthermore, the ventral striatum (the nucleus accumbens and olfactory tubercle) has not yet attained adultlike levels of substance P. (C, C′) The distribution and relative amount of enkephalin in the infant striatum are very different from those found in adults. In the 4-month-old monkey, the caudate nucleus has striosomes that are poor in enkephalin and a matrix that is enriched in enkephalin. The reverse pattern is present in the caudate nucleus in adults. (D, D′) The distributions of calbindin in the infant striatum and adult striatum also differ. At both ages the striosomes have less calbindin relative to the matrix; however, in the infant, the striosomes are essentially devoid of calbindin compared to those in the adult, and the infant striosomes are much larger. In the infant putamen (lateral region), the level of calbindin is deficient compared to that in the adult.

about areas of the brain that could be selectively vulnerable to environmental conditions and experiences in early life. We have put forth a hypothesis that neuropeptide transmitter systems in the striatum of infant rhesus monkeys undergo prolonged postnatal maturation, which may render this brain region highly vulnerable to environmental and experiential influences. So far, our studies of developing rhesus monkeys have revealed that peptide neurotransmitters undergo remarkable remodeling during the first year of postnatal life (Fig. 7). Many brain peptides in the striatal mosaic are present in early stages of life, but they need time to develop their proper distributions, amounts, and roles (Fig. 7).

It was hypothesized that an insufficient social environment for infant monkeys might interfere with the development of neurotransmitters in the basal ganglia, because animals raised under such conditions have abnormal movements and social behaviors. The brains of two groups of monkeys with different environmental rearing conditions have been studied: one group of monkeys that experienced social deprivation when they were infants and had many abnormal behaviors, and another group of monkeys that was raised in a highly social environment and behaved like normal monkeys.

It was discovered that the development of the structural organization of peptide neurotransmitter

systems of the basal ganglia is highly vulnerable to early postnatal experience. The normal compartmental arrangements of brain peptides of the major output striatal neurons and the localization of neuropeptides within synaptic targets of the striatum (globus pallidus and substantia nigra) are altered selectively in adult rhesus monkeys that experienced severe sensory–social deprivation during the first year of infancy (Fig. 8). Immature rhesus monkeys that have insufficient infant–mother and infant–peer interactions during early development manifest psychosocial abnormalities and motor impairments, including withdrawal and fearfulness, lack of play, apathy, learning deficits, stereotypic movements, and self-injurious behavior. Furthermore, as adults, these monkeys do not show appropriate parental behavior and are indifferent and abusive to their offspring. Certain brain areas are more vulnerable to the effects of social deprivation than other brain regions. Surprisingly, the neuropeptides in the amygdala–BST complex (Fig. 5) did not appear vulnerable, but the same neuropeptides were profoundly vulnerable in the striatal mosaic (Fig. 8). Because monkeys that experienced social–sensory deprivation have neurochemical alterations in their basal ganglia, and because the behavioral dysfunction induced by social–sensory deprivation of infant primates persists into adulthood and suggests functional abnormalities of the basal ganglia, it has been suggested that the normal postnatal development of peptide neurotransmitter systems in the basal ganglia, particularly the neostriatum, is partly dictated by the environment and experience.

These results were very novel and interesting because they showed, for the first time in a well-controlled experiment, that social deprivation can produce changes in brain chemistry in selectively vulnerable regions in animals that have brains very similar in many respects to the human brain. These changes may underlie the abnormal social, repetitive, and self-harmful behaviors of these monkeys, and they may be related to similar abnormal behaviors of children with developmental problems. Certain peptide neurotransmitters in the striatal mosaic and other basal ganglia areas of monkeys raised with insufficient social contacts do not develop and mature like they do in socially raised monkeys. Some of these altered neurotransmitters have important functions in signaling aversive messages. These findings are important because these animals, as well as children with some developmental disorders, can harm themselves. These experiments are also exciting because similar numbers of neurons are present in both groups of monkeys (i.e., they do not degenerate or die), although some neurons are unable to make the appropriate neurotransmitter. Lithium can increase the expression of enkephalin and substance P in neurons of the striatum of rats. Because the neurons appear to be still alive in these monkeys, they could be stimulated by drugs so that they can make their normal neurotransmitter, thereby possibly modifying the abnormal behaviors of these monkeys.

This seminal study by Martin and colleagues explored important relationships between the early experience of infants, the postnatal maturation of the brain, and the susceptibility of some neurotransmitters in certain brain areas to environmental factors. There are growing concerns about the long-term effects of parental–peer neglect or abuse and exposure to drugs or environmental toxins in early childhood on the development of brain structure and function. As a result of this study, it is now known that the basal ganglia is very vulnerable in infants. The implications may be profound. For example, environmental factors (social–sensory deprivation of varying severity) can interfere with the normal postnatal progression of brain peptides and other neurotransmitters in the maturing basal ganglia. However, the specific events producing these changes are not clear, and considerably more work is needed on how external or environmental experiences can turn on and off vulnerable genes in immature neurons of the brain. The normal maturational events that occur with neuropeptides in the basal ganglia of primates during postnatal development must be understood more completely before this theory of experience-dependent neurodevelopment of the basal ganglia can be clarified and before the possible cellular and molecular mechanisms responsible for the mutability of basal ganglia organization by early postnatal experience can be understood.

Several disorders that affect young people are characterized by abnormal conduct such as repetitive or stereotyped movements, poor skills in communication, self-preoccupation or withdrawal from family and society, and self-inflicted harm. Children with mental retardation and autism, Rett syndrome, and Lesch–Nyhan syndrome show some or all of these abnormal behaviors. In the United States, it was estimated that 160,000 young individuals with developmental disabilities exhibited harmful behaviors involving aggression toward themselves, other people, and property. The self-harmful behaviors of people with these disorders are primary reasons for institutionalization, failure in school environments,

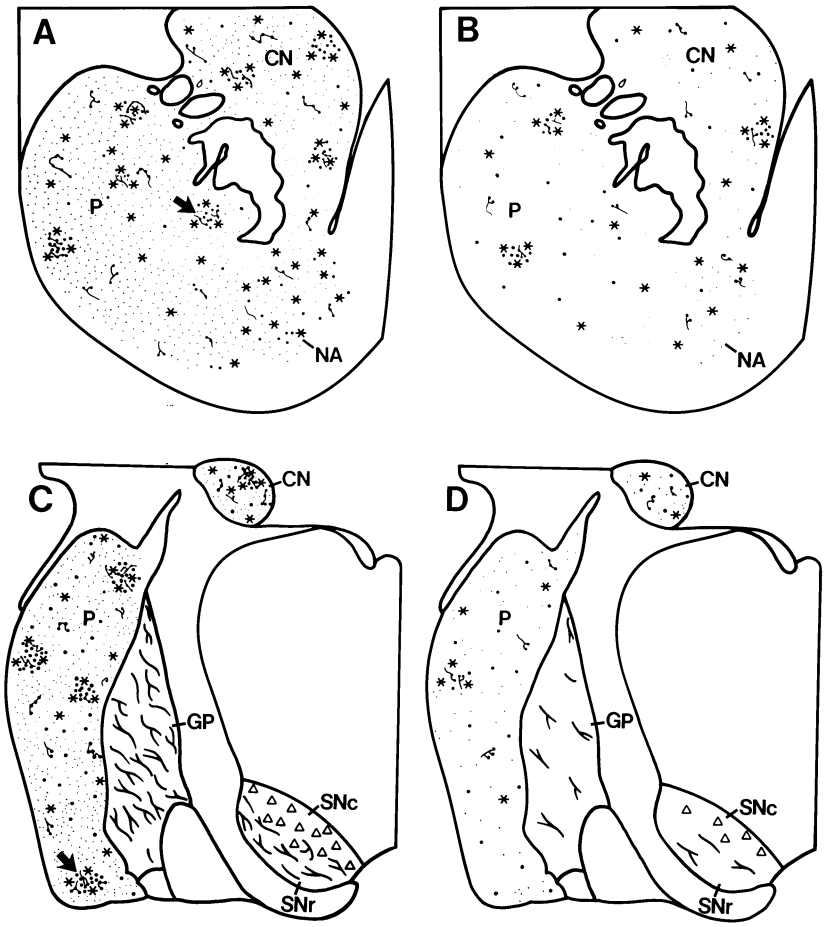

Figure 8 The chemical composition and structural organization of the primate basal ganglia are highly vulnerable to early postnatal experiences and environmental conditions. This diagram depicts some of the organizational features of the primate basal ganglia in monkeys raised in a socially healthy environment and their changes in monkeys raised in an inappropriate social environment. Abbreviations: CN, caudate nucleus; GP, globus pallidus; P, putamen; SNc, substantia nigra compact part; SNr, substantia nigra reticular part. In normal rhesus monkeys (A and C), substance-P-containing neurons (asterisks), processes (short, beaded lines), and axonal terminals (solid circles) are concentrated in some foci forming discrete patches (striosomes, black arrow) in the caudate and putamen. Striosomes are also enriched in enkephalin. The neuronal elements that comprise striosomes are found in lower amounts and diffuse throughout the surrounding matrix (the compartment that makes up the majority of the striatum). The nucleus accumbens has a matrix very enriched in substance P and enkephalin. The striatum receives an extensive synaptic terminal innervation (fine, small dots) from dopamine-utilizing neurons in the substantia nigra compact part (triangles). The neurons in the striatum that contain substance P and enkephalin innervate the globus pallidus and substantia nigra reticular part (smooth, branching lines). In monkeys that were raised in a socially inadequate environment (B and D), this organization of the basal ganglia is abnormal. These monkeys have fewer striosomes, they have less substance P and enkephalin in the matrix, and the dopamine innervation from the substantia nigra is deficient in the striatum. Also, striatal target regions (e.g., the globus pallidus and substantia nigra reticular part) are deficient in substance P and enkephalin due to the loss of innervation from substance-P- and enkephalin-expressing striatal neurons. The ability of neurons in the substantia nigra to make dopamine is impaired, although the neurons remain. [Reproduced with permission from *J. Neurosci.* **11**(11), 3344–3358, 1991, copyright the Society for Neuroscience].

and improper adjustment in communities. In some communities, 6–21 individuals out of 100 people have behavioral and emotional disorders, with a tendency for higher numbers in groups subject to social deprivation. The causes of these behavioral problems are unknown, although animal model experiments suggest a likely connection with brain peptides.

VI. ABNORMALITIES IN BRAIN PEPTIDES OCCUR IN BEHAVIORAL, PSYCHIATRIC, AND NEURODEGENERATIVE DISORDERS OF HUMANS

The participation of brain peptide neurotransmitters, cytokines, and growth factors in many forms of

behavioral and neurological disorders is now very evident (Tables V and VI). The most widely studied disorders in which brain peptides have been implicated are schizophrenia, mood disorders, Huntington's disease, Alzheimer's disease, and multiple sclerosis.

In schizophrenia, cholecystokinin neuronal systems seem to be the most vulnerable by some reports and are prominently depleted in the temporal cortex and hippocampus. Somatostatin, vasoactive intestinal peptide, substance P, neurotensin, and thyrotropin-releasing hormone have been reported to be abnormal in cerebral cortex, amygdala, and basal ganglia. Some of these findings have not been replicated. It is also very possible that ongoing drug treatment of patients diagnosed with schizophrenia will confound observations on brain peptide levels.

In depression, the hypothalamic–pituitary–adrenal axis and the hypothalamic–pituitary–thyroid axis have been examined thoroughly. It is believed that corticotropin-releasing hormone and thyrotropin-releasing hormone are hypersecreted in individuals with major depression. Furthermore, prodynorphin mRNA expression is elevated in the striosomal compartment of the striatal mosaic in individuals that commit suicide. Thus, dysfunction of the endogenous opioid dynorphin system might contribute to depression and the risk of suicide.

In neurodegenerative diseases, the major brain areas affected by the disease process tend to exhibit changes in neuropeptide systems. In Huntington's disease, substance-P- and enkephalin-containing neurons are lost in the striatum. Neurons in neocortex that contain neuropeptides are depleted in Alzheimer's disease, with somatostatin and corticotropin-releasing hormone showing high vulnerability. In neurodegenerative diseases of the human CNS that have prominent inflammatory components, such as multiple sclerosis, Alzheimer's disease, and AIDS, the proinflammatory cytokine tumor necrosis factor-α is up-regulated. Thus, brain and spinal cord inflammation and autoimmune reactions participate in the nervous system degeneration in these diseases. This idea is greatly emphasized by the finding that nonsteroidal anti-inflammatory drugs (such as aspirin, ibuprofen, and indomethacin) strongly protect against Alzheimer's disease.

The observation that anti-inflammatory drugs are helpful in Alzheimer's disease could be related to the discovery that astroglia and microglia are primary generators of amyloid deposits in the aging brain. Amyloid (Aβ) is a protein fragment fibril made up of a 4-kDa peptide consisting of 40–42 amino acid residues that is derived proteolytically from the amyloid precursor protein. Aβ is a major component of senile plaques, which are brain lesions that occur in individuals with Alzheimer's disease, Down's syndrome, and, less frequently, people aging normally. In addition to Aβ, these lesions have a complex composition, consisting of dystrophic neurites (damaged and swollen dendrites or axon terminals) and activated astrocytes and microglia. Our studies of aging monkeys revealed that senile plaques are dynamic brain lesions that evolve from early synaptic defects within the neuropil to mature plaques and extracellular deposits of Aβ. The staging of these lesions is thought to be the degeneration of neuritic structures, followed by the attraction of reactive glia, and the subsequent deposition of extracellular Aβ derived from microglia or

Table V
Behavioral, Psychiatric, and Neurological Disorders Involving Brain Peptides

Abnormality	Possible brain peptides involved
Stress–anxiety	Corticotropin-releasing hormone
Obesity	Neuropeptide Y
Anorexia–cachexia	Orexins, tumor necrosis factor-α, interleukins, leukemia inhibitory factor, ciliary neurotrophic factor
Sleep disorders	Orexins
Epilepsy	Substance P, somatostatin, galanin, neuropeptide Y
Migraine headache	Calcitonin gene-related peptide
Schizophrenia	Cholecystokinin
Mood disorders	Corticotropin-releasing hormone, thyrotropin-releasing hormone, dynorphin

Table VI
Neurodegenerative Disorders Involving Brain Peptides

Disorder	Brain peptide groups involved
AIDS dementia	Classical neuropeptides, cytokines, chemokines
Alzheimer's disease	Classical neuropeptides, growth factors, cytokines, chemokines
Amyotrophic lateral sclerosis	Growth factors, cytokines
Cerebral ischemia (cardiac arrest and stroke)	Growth factors, cytokines
CNS trauma	Growth factors, cytokines, chemokines
Multiple sclerosis	Cytokines, chemokines
Parkinson's disease	Growth factors

astrocytes. These experiments demonstrated that structural and biochemical perturbations within neuronal and nonneuronal cells occur before the deposition of extracellular Aβ fibrils. Furthermore, our results suggest that focal abnormalities in synaptic contacts within the neuropil (synaptic disjunction) may initiate a complex series of inflammatory events resulting in the formation of diffuse senile plaques and deposits of Aβ. In response to synaptic disjunction in the aged brain, astroglia and microglia produce Aβ. This event may be signaled by cytokines.

VII. BRAIN PEPTIDES MODULATE NEURONAL DEGENERATION AND REGENERATION IN EXPERIMENTAL MODELS

Classical neuropeptides as well as brain peptide growth factors and cytokines play important roles in neuronal degeneration and brain repair. It is now very evident that numerous small, diffusible peptide–protein factors modulate the growth, differentiation, survival, proliferation, and migration of neurons and/or glial cells. In the developing nervous system, neuronal death occurs normally and is thought to be necessary for regulating the size of neuronal groups in relation to target size and synaptic inputs. This developmental neuronal death is thought to be partially controlled by growth factors, including the conventional neurotrophic factors (Table II), as well as by some of the classical neuropeptides (Table I, e.g., somatostatin and vasoactive intestinal peptide). After brain and spinal cord injury, many cellular and molecular responses occur simultaneously or in phases, some of which are degenerative and others regenerative events. The vague concept for the release of tissue-soluble factors that may play a role in the degeneration, regeneration, and survival of nerve cells was introduced in the early 1900s by Santiago Ramón y Cajal. Subsequently, Levi-Montalcini, Hamburger, Prestige, and others established this concept. Many of the current ideas about the critical dependence of neurons on survival molecules or trophic factors (Table II) have been developed from experiments of cultured neurons and injured motor neurons *in vivo*.

A. Cell Culture Models

When neurons are removed from the developing nervous system, they require survival factors to grow in a dish. Some of these neuronal survival factors are neuroactive peptides and proteins (Tables I and II). Immature sympathetic ganglion neurons, cerebellar granule neurons, and cortical and hippocampal neurons are used commonly for culture experiments. The classical example for this concept is the survival of sympathetic ganglion neurons being dependent on serum factors such as nerve growth factor. When these cells are deprived of serum or nerve growth factor, they undergo apoptosis by a programmed cell death (PCD) mechanism that is dependent on specific cell death molecules. Bax and caspase-3 are critical for neuronal death by apoptosis, involving Bax translocation to mitochondria and mitochondrial release of cytochrome *c* to participate in the activation of caspase-3, which subsequently activates proteins including DNA fragmentation factor-45 that cleave genomic DNA. Nerve growth factor also controls sympathetic neuron survival by Ras suppression of a p53-mediated cell death pathway. Serum or potassium deprivation of cerebellar granule neurons and cortical neurons also results in apoptosis. Roles for neuropeptides in neuronal survival pathways have come to light. Apoptosis of granule neurons *in vitro* can be delayed by angiotensins II and IV, and angiotensinogen knockout mice have fewer granule neurons in the cerebellum and hippocampus than wildtype-mice, suggesting that the renin–angiotensin system has a role in neuronal survival by preventing apoptosis during the period of developmental cell death. In addition, pituitary adenylate cyclase activating polypeptide can block apoptosis of sympathetic ganglion and granule neurons by activation of the extracellular signal-regulated (ERK) type of MAP kinase via a cyclic-AMP-dependent pathway and proteosome-mediated degradation of caspase-3.

B. Animal Models

In animal models of spinal cord and nerve injury, brain peptide hormones, growth factors, and cytokines can be studied for their roles in degeneration and for their applicability for therapeutics. The extent of neuronal death or of regeneration and survival after spinal cord injury is influenced by the age of the animal at the time of injury and the location of axonal trauma in relation to motor neurons. Motor neurons with axonal damage in the immature CNS die rapidly. In contrast, in some settings, axotomized motor neurons in the adult CNS are more likely to persist in some altered form. This observation

could have major importance with regard to the recovery of neurological function in infants, children, and adults.

Cytokines (Table III) have stimulated much excitement in the pathobiology of spinal cord and peripheral nerve injury. A cytokine called leukemia inhibitory factor might be important for the successful regeneration of injured sensory and motor axons in immature and adult animals by altering neuronal gene expression. Other molecules that may be relevant to neuronal degeneration and regeneration after spinal cord and peripheral nerve injury are inflammatory factors. Tissue inflammation is believed to be a critical component of the degenerative process after nervous system injury. Following CNS damage, a variety of changes occur, including the extravasation of serum proteins through the compromised blood–brain barrier, activation of neuroglial cells, and rapid synthesis and liberation of proinflammatory cytokines. A major proinflammatory cytokine in the CNS is tumor necrosis factor-α, which promotes inflammation and cell death through its p55 receptor. Tumor necrosis factor-α also promotes cell death by inhibiting receptor signals initiated by key survival peptides such as insulin-like growth factor. Thus, brain peptide cytokines can interact antagonistically or synergistically with brain peptide growth factors. Interestingly, the remarkable anti-inflammatory and antipyretic actions of α-melanocyte-stimulating hormone occur by inhibition of glial-derived tumor necrosis factor-α. Other cytokines function as potent anti-inflammatory factors. Interleukin-10 reduces the production of tumor necrosis factor-α by astroglia. Interleukin-10 reduces inflammation and improves functional outcome in humans and in animal models of spinal cord injury. In contrast, interleukin-3 appears to cause spinal cord damage. Overexpression of interleukin-3 in mice leads to motor neuron degeneration and progressive muscular atrophy, suggesting that an autoimmune reaction may participate in the degenerative process in humans with amyotrophic lateral sclerosis.

VIII. THE FUTURE OF CNS PEPTIDE RESEARCH HAS GREAT PROMISE

The use of animal models will be necessary to advance our understanding of brain peptide function and their roles in nervous system development, maturation, degeneration, and repair. An interesting feature of the different classical neuropeptide systems is that many of these brain peptides undergo prominent changes during development (Fig. 7). However, it is not yet clear whether these changes direct maturational events involved in the pattern formation of brain structure or whether changes in the expression are consequences of brain maturation. For example, brain peptides and hormones may be critical for pattern formation during development of the cerebral cortex and striatum, and abnormalities may cause neurodevelopmental defects. With regard to CNS degeneration, paradigms should include animal models of brain and spinal cord injury and aging. Animal models of CNS degeneration are crucial for improving our understanding of the mechanisms and stages of degenerative and repair processes. These models can provide an *in vivo* system to identify how neurons and neuroglia change in paradigms that mirror certain neuropathological and clinical features of neurological conditions that occur in humans (Table VI). With animal models, the process of nervous system degeneration and repair can be studied directly at the structural and molecular levels, the roles for brain peptides and hormones can be identified, and the model subsequently can be used to test new therapies to prevent the neuropathology and improve neurologic recovery in a biologically relevant system. In addition, the application of molecular genetics and transgenic mouse technology will be essential. The development of transgenic mouse systems for peptide growth factors and cytokines should be expanded.

Pharmaceutical drug development centering around neuroactive brain peptides holds immense promise for the future treatment of a wide range of neurobehavioral, neurological, and neurodegenerative disorders (Tables V and VI). For example, the design of drugs that mimic the actions of satiety neuropeptides could be useful for weight management in obesity or blocking the functions of brain satiety peptides for the treatment of anorexia or cachexia in chronically or terminally ill patients. The neuropeptides that function in sleep–wakefulness could be targets for sleep disorders. The anti-inflammatory actions of certain cytokines and the blockade of proinflammatory cytokines could be exploited for the treatment of Alzheimer's disease, multiple sclerosis, head and spinal cord injury, and cerebral ischemia after stroke and cardiac arrest. Furthermore, the well-known neuronal survival actions of neurotrophins should continue to be targets for drug discovery as well as the neuronal survival effects of classical and more recently identified brain peptides. The application of research on survival peptides has enormous potential for the treatment of

Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis, and cerebral ischemia, and CNS trauma (Table VI).

The current inability to effectively and rationally help people with nervous system abnormalities is in large part due to the of lack of understanding of how neurons communicate with other neurons and how neurons communicate with neuroglia or other non-neuronal cells. It is very likely that future discoveries in brain peptides and hormones will add to the formulation of new therapies for humans with neurobehavioral disorders and neurodegenerative conditions.

Peripheral Nervous System

ANDREI V. KRASSIOUKOV
University of Toronto

GLOSSARY

axon Neuronal process that carries impulses away from the neuronal cell body, usually covered by myelin.

afferent–afferent fiber An axon that carries sensory information to the central nervous system.

dermatome A striplike projection on the skin supplied by sensory neurons of a single spinal segment.

efferent–efferent fiber An axon that carries impulses away from the central nervous system.

effector The target organs, which respond to the stimuli carried by the efferent part of the peripheral nervous system.

ganglion A collection of neuronal cell bodies outside the central nervous system.

Node of Ranvier A gap in the myelin sheath of an axon where the action potential occurs during saltatory conduction.

Schwann cell A myelin-containing cell in the peripheral nervous system.

synapse A specialized structure at the point of contact between a neuron and the next in the circuit, where unidirectional transmission of information occurs.

Wallerian degeneration The changes that occur in peripheral nerves distally from the site of the injury.

The nervous system is made of cells specialized for the transmission of information, called nerve cells or neurons. Neurons are the building blocks of both the central and the peripheral nervous systems. Each neuron has a cell body (soma) and processes (axon and dendrites), which carry information to and away from the cell body. The peripheral nervous system connects the central nervous system to the different tissues and organs of the body. The cranial, spinal, and autonomic nerves and their ganglia form the peripheral nervous system. From this article, the reader will learn about anatomical and physiological subdivisions of the peripheral nervous system. Some practical applications of neuroanatomical facts regarding the peripheral nervous system will also be presented.

I. GENERAL ORGANIZATION OF THE PERIPHERAL NERVOUS SYSTEM

Traditionally, the nervous system is divided into central and peripheral components. The brain (cerebrum, cerebellum, and brain stem) and spinal cord form the central nervous system (CNS). The peripheral nervous system (PNS) connects the CNS to the different tissues and organs of the body. The modern view of the organization of the PNS is based on the work of the English physiologist John Newport Langley (1852–1925). The PNS has two components, a sensory (afferent) and a motor (efferent) component. The sensory component, also known as the afferent component (*ad* meaning to + *ferre* meaning carry), is responsible for conveying information to the CNS from the body itself and from the environment (Fig. 1). We receive sensory information through the sensory endings (receptors) that are scattered throughout the body. These receptors are biological transducers,

associated with the peripheral ends of afferent axons, which transform different stimuli into action potentials in these axons. Sensory nerve fibers are the axons of a group of neurons situated within the dorsal root ganglia (DRG) at the distal end of dorsal roots (Fig. 1). These ganglia are also known as sensory or spinal ganglia and convey information from the body. The sensory information from the face travels through the specialized cranial nerves. The motor or efferent (*ex* meaning from + *ferre*) component carries information from the CNS to the muscles. The target organs, which respond to the stimuli carried by the efferents, are called effectors (Fig. 1). The motorneurons that innervate skeletal muscles are localized within the ventral horns of the spinal cord.

The elements of the efferent component of the PNS can be further categorized into a somatic and an autonomic division. The somatic division controls skeletal muscles and acts mainly under the direction of conscious voluntary control from the brain. The autonomic division innervates smooth muscles, cardiac muscle, and glands. The term autonomic comes from *auto* (meaning self) and *nomos* (meaning law). The autonomic nervous system exerts control over the functions of many organs and brings the fine internal adjustments necessary for the maintenance of the optimal internal environment of the body. This system functions according to its own internal laws, largely unconsciously.

Neurons do not function in isolation; they are organized into specific neuronal circuits that process particular different kinds of information and control particular efferent organs. The simplest type of circuit is called a "reflex" or reflex arc and involves the interaction of sensory and motor neurons. The effector response mediated by such a circuit is called a reflex response or simply a reflex. Some reflexes are extremely important in the diagnosis and localization of neurologic problems. Several neuronal components of the PNS and CNS are involved in a reflex arc. The first component of the reflex arc is a receptor, such as a special cutaneous receptor or a neuromuscular spindle, the stimulation of which initiates an action potential in afferent fibers. The second component is an afferent neuron (sensory neuron with a soma within the DRG), which transmits impulses though the peripheral nerves to the CNS. The third component is an interneuron within the CNS, which relays the information to the efferent neuron. In some reflexes, known as monosynaptic reflexes (such as a stretch reflex, the circuits of which are shown in Fig. 1), this component is missing. The next component of the reflex arc is the efferent (motor) neuron, which delivers information from the CNS to the effector organ. At the point of contact between a neuron and the effector, where unidirectional transmission of information is occurs, there is a specialized structure called a synapse. Finally, the effector, such as a muscle or gland, will respond to the action potential delivered through the efferent fibers. Interruption of the reflex arc at any point will abolish the response.

II. GROSS ANATOMY OF THE PERIPHERAL NERVOUS SYSTEM

The peripheral nervous system consists of the cranial and spinal nerves and their associated ganglia. There are 12 pairs of cranial nerves, which exit the skull through various openings called foramina. There are

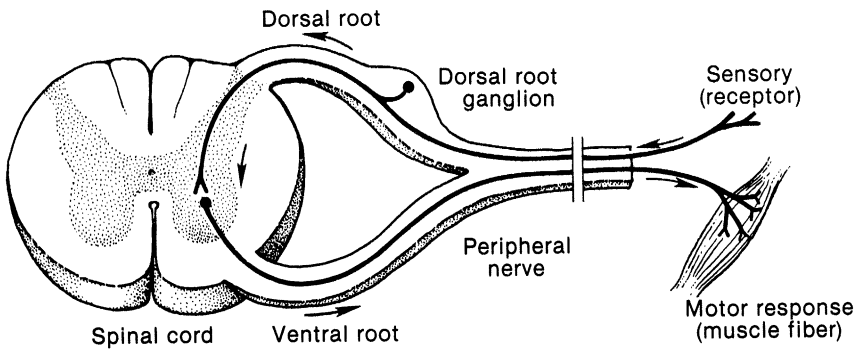

Figure 1 Monosynaptic reflex arc, consisting of a primary sensory neuron activating a motoneuron by a single synapse. Adapted from DeMeyer, W. *Neuroanatomy*, Ch. 2, Copyright © 1988. Reprinted by permission of John Wiley & Sons, Inc.

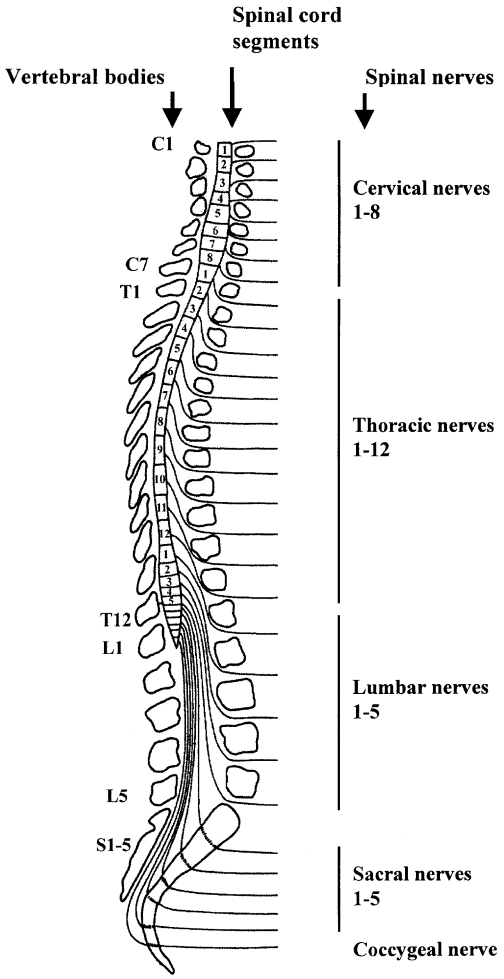

Figure 2 A schematic diagram of the relationship of spinal cord segments and spinal nerves to the vertebral column. The relation between the level of the spinal nerves–spinal segments and the vertebral body is clinically important. Note that the spinal cord extends only to vertebrae L1–L2, but the spinal roots continue down to the appropriate intervertebral foramina. Most spinal levels do not correspond to the same vertebral level. Abbreviations: C, cervical; T, thoracic; L, lumbar; S, sacral; Co, coccygeal.

31 pairs of spinal nerves, each identified by its association with the vertebra where the nerve leaves the vertebral canal (Fig. 2). The spinal cord segment from which a given spinal nerve arises is identified in the same way. The cervical region of the spinal cord gives rise to 8 cervical spinal nerves (C1–C8), the thoracic region to 12 thoracic spinal nerves (T1–T12), the lumbar region to 5 lumbar spinal nerves (L1–L5), the sacral region to 5 sacral spinal nerves (S1–S5), and finally the coccygeal region to 1 coccygeal spinal nerve (Co1). A spinal nerve is made from the confluence of the ventral (efferent, motor) and dorsal (afferent, sensory) roots distal to the DRG (Fig. 1). From the spinal nerve, axons leave through a dorsal and a ventral ramus, which then form peripheral nerves, providing motor and sensory innervation to the whole body.

To free the PNS from the CNS, we cut the spinal nerve roots just at their attachment to the spinal cord (Fig. 1). Each spinal nerve (except for C1 and Co1) is attached to the spinal cord by dorsal (posterior) and ventral (anterior) roots (Fig. 1). Each of these individual roots is broken up into a series of rootlets that are attached to the spinal cord. Spinal nerve C1 often lacks a dorsal root, and the coccygeal nerve may be absent. The dorsal and ventral roots take a lateral and descending course within the subarachnoid space and pierce the arachnoid and dura mater, at which point these meninges become continuous with the epineurium as they approach the intervertebral foramina. The dorsal and anterior roots unite immediately beyond the DRG and form the spinal nerves, which then exit through the intervertebral foramina. Spinal nerves may extend directly to their target tissue, as is seen in intercostal nerves, or they may form a complex structure such as a plexus in which the nerve trunk may interchange fibers with neighboring trunks. The spinal nerves form three major plexuses—the cervical, brachial, and lumbosacral. The cervical plexus (Fig. 3) is formed by the spinal nerves of the upper cervical segments (C1–C4). The phrenic nerve arises from the cervical plexus. This nerve innervates the diaphragm, the most important muscle for breathing. The last four cervical and the first thoracic spinal nerves (C5–T1) form the brachial plexus (Fig. 4). Numerous nerves arise from various parts of the brachial plexus and innervate the skin, muscles, and bone of the shoulder girdle, upper chest wall, arm, and hand. Like the brachial plexus, the lumbosacral plexus (L1–S4) gives off a number of nerves to paravertebral and pelvic girdle muscles and to the lower extremities (Fig. 5).

A. Clinical Note

The peripheral nerves that rise from a plexus convey sensory and motor information. An area of the skin innervated by a single spinal nerve, and, therefore, a single segment of the spinal cord, is called a dermatome (*derma* meaning skin). The distribution of dermatomes on the anterior and posterior surfaces of the body is shown in Fig. 6. The cutaneous areas supplied by adjacent spinal nerves overlap. Therefore, only little

sensory loss, if any, is observed following injury of a single dorsal root of the spinal cord. The dermatomes that must be known to solve neurological problems are summarized in Table I.

Skeletal muscles also receive segmental innervation. It is important to recognize that skeletal muscles are innervated by more than one spinal nerve and, therefore, by more than one spinal segment. The segmental innervation of some skeletal muscles is of clinical importance, because it is possible to test them by eliciting simple muscle reflexes (see the section on stretch reflexes) in the patient. Table II summarizes some muscle reflexes and muscle innervation by spinal segments and peripheral nerves. Testing of sensory and motor functions is an important part of the neurological examination and is particularly important in determining the level of injury. For example, the lesion of a segment of the spinal cord, or dorsal root, will result in a sensory loss and/or a motor deficit that is different from that occurring after the lesion of a peripheral nerve.

III. HISTOLOGY OF THE PERIPHERAL NERVOUS SYSTEM

A. Dorsal Root Ganglia

The dorsal root ganglia contain unipolar neuronal cells. A single process leaves rounded or oval-shaped cell bodies and bifurcates into peripheral and central branches or processes. The former terminate in a peripheral sensory ending (sensory receptors), and the latter usually enter the spinal cord through the dorsal root. Neurons within the DRG are closely surrounded by a layer of satellite cells. Each ganglion is covered by a layer of connective tissue that is continuous with the wrapping of the peripheral nerves.

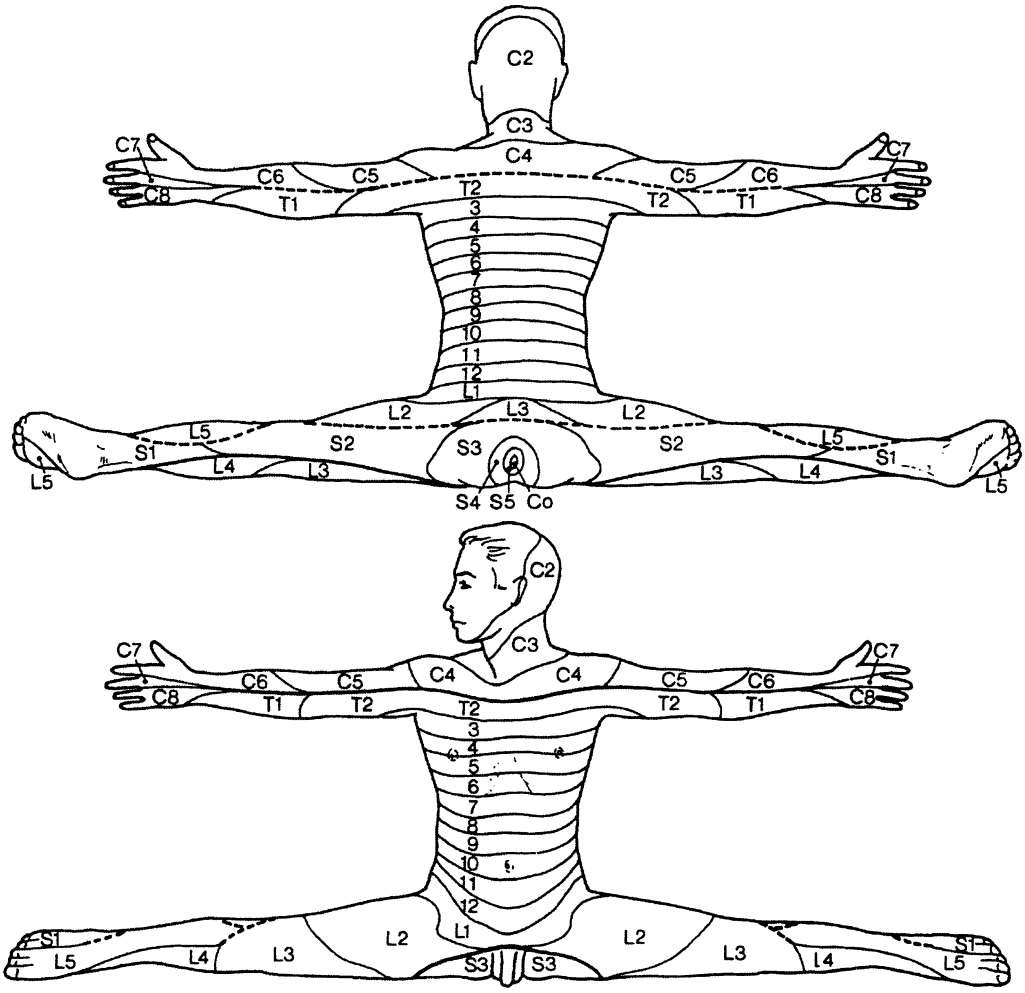

Figure 6 Pattern of dermatomal distribution and innervation by the spinal roots. Abbreviations same as for Fig. 2. From DeMyer, W. *Neuroanatomy*, Ch. 5, Copyright © 1988. Reprinted by permission of John Wiley & Sons, Inc.

B. Peripheral Nerves

Peripheral nerves are bundles of axons of motor and sensory neurons within the PNS enveloped by Schwann cells. Schwann cells form and maintain the myelin sheaths within the PNS. In contrast to an oligodendrocyte (a myelin-producing cell within the CNS), the Schwann cell myelinates only a small segment of an axon (the internode), whereas a single oligodendrocyte can myelinate several axons simultaneously. A majority of axons within the PNS receive circular wrapping by the surface membrane of Schwann cells, forming myelinated axons (Fig. 7). Other axons within the PNS merely indent the surface membrane of Schwann cells, forming unmyelinated axons. The segment of axon myelinated by one Schwann cell constitutes an internode. Between each internode (Schwann cell) is a short, myelin-free segment of axon called a node of Ranvier (Fig. 7). A similar segmentation of myelin sheaths occurs in the CNS. However, the gap between adjacent Schwann cells at the node is much smaller than that between adjacent oligodendrocytes of the CNS. External to Schwann-cell-enveloped axons, a layer of collagen fibers and scattered fibrocytes form a sheath called the endoneurium (Fig. 8). Bundles of endoneurium-ensheathed axons, called fascicles, are enveloped in layers of connective tissue called perineurium. The entire nerve is covered by the epineurium, which consists of fibrocytes and collagen fibers. This loose layer also contains blood and lymphatic vessels. These three sheaths with their interwoven collagen fibers provide

Table I
Essential Dermatomes

Spinal cord segment	Cutaneous innervation
C2	Back of the head
C3	Neck
C6	Thumb

S5	Perianal region

strength with flexibility and protection to the peripheral nerves.

IV. CLASSIFICATION OF NERVE FIBERS

Myelin has an important effect on the speed of the action potential conduction within the axon. By acting as an electrical insulator, myelin greatly speeds up action potential propagation. The action potential skips electrically from node to node; therefore, the transmission of a nerve impulse along a myelinated fiber is called saltatory conduction (*saltare* meaning to jump). Myelinated axons can conduct at velocities up to 120 m/sec, whereas unmyelinated axon conduction velocities range from about 0.5 to 3 m/sec. Human peripheral nerves contain fibers ranging in size from 1 to 20 μm in diameter (myelin sheath included). A commonly used classification of peripheral nerve fibers is based on fiber diameter, which correlates with the rate of conduction of nerve impulse. Each category and subcategory of nerve fibers arc associated with one particular type of nerve conduction (Table III). In general, the larger the axon, the thicker the myelin sheath and the faster the conduction velocity.

V. SENSORY RECEPTORS AND EFFECTOR ENDINGS

A. Sensory Receptor Endings: General Considerations

We receive information from the outside world or from within the body by special sensory nerve endings or sensory receptors. The sensory endings are scattered widely throughout the body. There are two categories of sensory endings and afferent neurons: somatic and visceral. The somatosensory afferents convey information from sensory receptors of the skin, muscles,

Table II
Summary of Some Muscle Reflexes

Reflex	Spinal segments	Plexus	Peripheral nerve	Expected action
Biceps brachii tendon reflex	C5–C6	Brachial	Musculocutaneous nerve	Flexion of the elbow joint by tapping the biceps tendon
Triceps tendon reflex	C6–C8	Brachial	Radial nerve	Extension of the elbow joint by tapping the triceps tendon
Brachioradialis tendon reflex	C7–C8	Brachial	Radial nerve	Supination of the radioulnar joints by tapping the insertion of the brachioradialis tendon
Abdominal reflexes	T7–T12	N/A	T7–T12	Contraction of underlying abdominal muscles by stroking the skin
Patellar tendon reflex (knee jerk)	L2–L4	Lumbar	Femoral nerve	Extension of knee joint on tapping the patella tendon
Achilles tendon reflex (ankle jerk)	L5–S2	Sacral	Tibial nerve	Plantar flexion of ankle joint on tapping the Achilles tendon
Plantar superficial reflex	S1, S2	Sacral	Tibial nerve	Flexion of toes on firmly stroking the sole of the foot

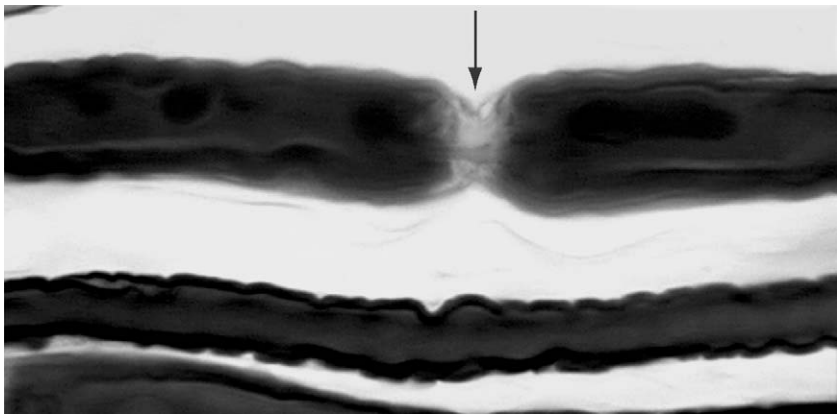

Figure 7 Myelinated nerve fibers (longitudinal section). Arrow points to the node of Ranvier. Stained with osmic acid.

and joints (general somatic afferents). The visceral afferents process information from the sensory receptors of the body cavities and internal organs (general visceral afferents). The general visceral afferents mostly travel within the cranial nerves. On the basis of localization within the body, sensory receptors can also be divided into three groups. Sensory endings that are superficially localized, such as those in the skin, are called *exteroceptors*. These receptors respond to stimuli for pain, temperature, touch, and pressure (Fig. 9 and Table IV). The second group is the *proprioceptors*, localized in muscles, tendons, and joints that monitor the position of our body in space. Finally, the third group of sensory endings is the *interoceptors*, localized in the viscera. On the basis of the sensory stimulus to which receptor endings respond, they can also be classified as mechanoreceptors, photoreceptors, chemoreceptors, thermoreceptors,

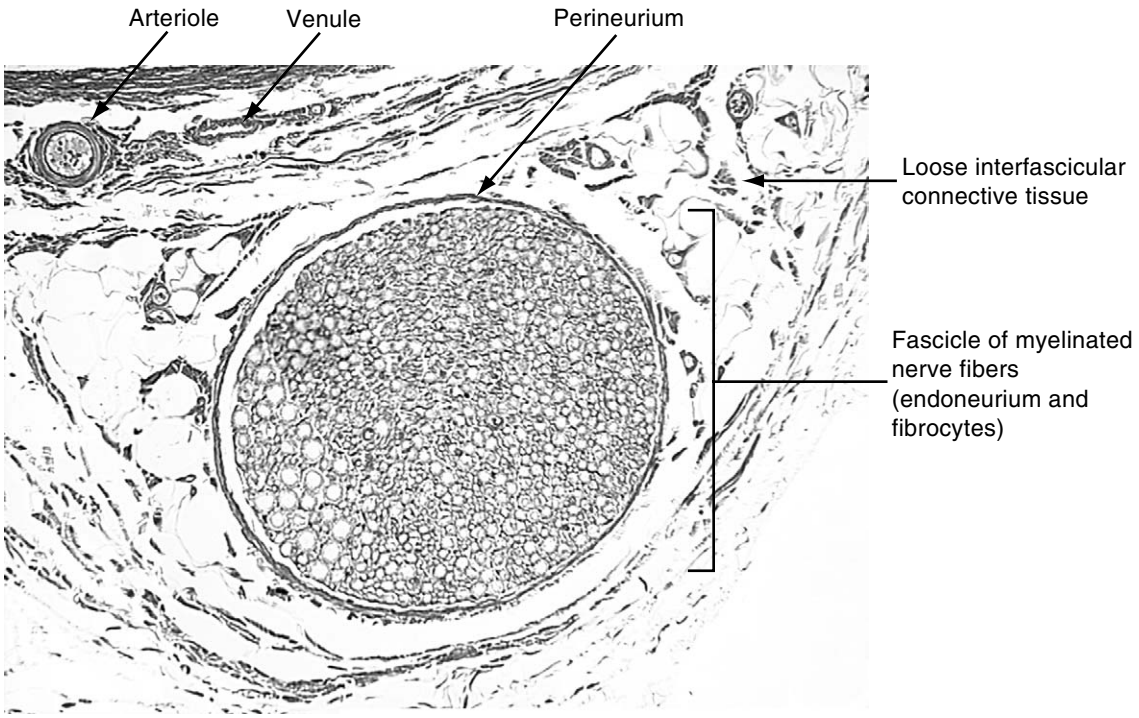

Figure 8 Peripheral nerve (transverse section). Stained with hematoxiline–eosin.

Table III
Classification of Nerve Fibers by Conduction Velocity, Diameter, and Function

Fiber type	Fiber diameter (μm)	Conduction velocity (m/sec)	Function
Somatic and visceral efferents			
A	12–20	70–120	To extrafusal fibers of skeletal muscles from α motor neurons
	2–8	10–50	To intrafusal fibers of skeletal muscles from γ motor neurons
B	<3	3–15	Preganglionic fibers to autonomic ganglia
C	0.2–1.2	0.7–2.3	Postganglionic autonomic fibers to smooth muscles and glands
Cutaneous afferents			
A (α)	12–20	70–120	From joint receptors
A (β)	5–12	30–70	From pacinian corpuscles (vibration) and touch receptors
A (ϵ)	2–5	6–30	From touch, temperature, and pain (sharp, localized) endings
C	<2	0.5–2	From pain and temperature endings
Muscle afferents			
Iα	12–20	70–120	From muscle spindles (anulospiral endings)
Iβ	12–20	70–120	From Golgi tendon organs
II	5–12	30–70	From muscle spindles (flower spray endings)
III	2–6	4–30	From pressure–pain endings
IV	<2	0.5–2	From pain endings

and nociceptors. Finally, on a structural basis, nerve endings can be divided into two classes: nonencapsulated, which may lie freely in the connective tissue, and encapsulated, which are enclosed by a distinctive arrangement of nonneuronal cells.

B. General Sensory Receptors of the Skin

Different types of skin receptors are presented in Fig. 9. For convenience, a detailed comparison of receptors, axon type, and sensory modality is summarized in Table IV.

C. Musculoskeletal Innervation

1. Sensory Endings

Proprioceptors in the joints, muscles, and tendons provide the CNS with the information required for awareness of the position of the body and for coordinated movements (Table IV). These complex actions are possible through the involvement of numerous reflex mechanisms.

a. Neuromuscular Spindles Proprioceptors contained in skeletal muscles are the neuromuscular spindles (muscular spindles). A single spindle is a bundle of specialized muscle (intrafusal) fibers that is a fraction of a millimeter wide, up to 6 mm long, and surrounded by a fusiform capsule of connective tissue (Fig. 10). The spindles lie in the long axis of the muscle and are especially numerous near the tendinous insertion of a muscle. Each spindle has two types of muscle fibers, two types of afferents, and one type of efferent. Within the capsule are numerous (up to 14) intrafusal muscle fibers. The latter are considerably smaller than the extrafusal fibers situated outside the spindle, which comprise the main mass of a muscle. Two types of intrafusal fibers can be identified within

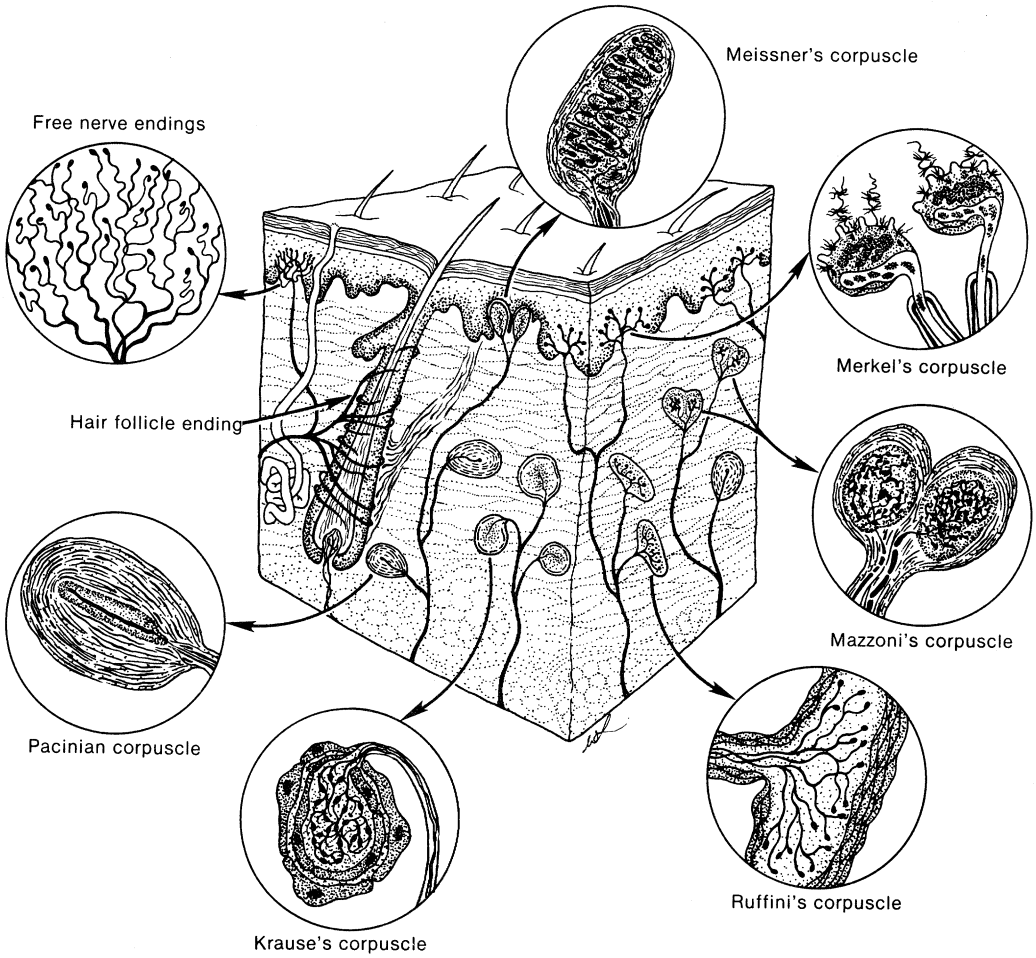

Figure 9 Skin receptors. From DeMyer, W. *Neuroanatomy*, Ch. 7, Copyright © 1988. Reprinted by permission of John Wiley & Sons, Inc.

the spindle: nuclear bag and nuclear chain fibers. The nuclear bag fibers have an expanded equatorial region because of the presence of numerous nuclei. They also extend beyond the capsule at each end before inserting into extrafusal connective tissue or a tendon. The nuclear chain fibers are smaller in diameter than the nuclear bag fibers. In these fibers, the nuclei form a single longitudinal row or chain in the center of each fiber. Finally, the neuromuscular spindles are innervated by smaller γ motor neurons.

b. Neurotendinous Spindles (Golgi Tendon Organs) Tendons are the noncontractile part of the muscles and consist of cords and sheets of collagen fibers attached to bones. Neurotendinous spindles are encapsulated nerve endings woven among the collagen fibers in tendons. The majority of Golgi tendon organs are localized near the junction of tendons and muscles. Information from these receptors is transmitted to the spinal cord by afferents classified as the Ib type.

c. Muscle Spindle–Golgi Tendon Organ Interaction The neuromuscular spindles provide sensory information about the length and the rate of change in the length of the muscle, which is very important in the control of muscle activity. At rest, the muscle spindles constantly send afferent information, and most of the time this information is not consciously perceived. During passive or active stretch of the muscle, spindles are elongated and there is an increase in the firing rate of the afferents. As soon as a muscle relaxes, it results in a decrease in the firing of the afferents to the spinal cord or brain. In order to maintain the sensitivity of the spindle, the γ motor neurons can regulate the stretch or tautness in the central part of the muscle spindle. Increased muscle tension also stimulates the Golgi

Table IV
Receptors, Associated Axons, and Adequate Stimuli

Receptor type	Axon type	Location	Sensory stimulus	Sensory modality
Nonencapsulated receptors				
Free nerve endings	Aδ and C	Skin, cornea, ligaments, joint capsule, bone, etc.	Mechanoreceptor, thermoreceptor, nociceptor	Pain, temperature
Hair follicle endings	Aβ	Hairy skin	Mechanoreceptor	Touch
Merckel's corpuscles	Aβ	Hairless skin	Mechanoreceptor	Touch
Encapsulated receptors				
Meissner's corpuscles	Aβ	Dermal papillae of skin of palm, sole of foot, nipple, and external genitalia	Mechanoreceptor	Touch
Pacinian corpuscles	Aβ	Dermis, ligaments, joint capsule, peritoneum, external genitalia, etc.	Mechanoreceptor	Vibration
Ruffini's corpuscles	Aβ	Dermis of hairy skin	Mechanoreceptor	Stretch
Muscle spindles		Skeletal muscles	Mechanoreceptor	Muscle stretch
Annulospiral sensory endings	Ia			
Flower spray sensory endings	II			
Golgi tendon organs	Ib	Tendons	Mechanoreceptor	Tendon tension

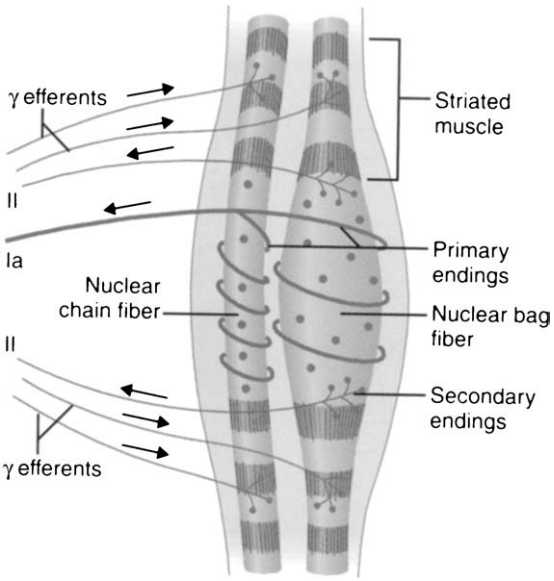

Figure 10 Simplified illustration of a muscle spindle. The intrafusal muscle fibers are nuclear chain and nuclear bag fibers. A stretch of the central region of intrafusal fibers is sensed by primary and secondary endings. The sensory information is conveyed to the central nervous system by groups Ia and II afferents. Efferent control of intrafusal fibers is via γ motor neurons. From Lundy-Ekman, L. *Neuroscience Fundamentals for Rehabilitation*, Ch. 6, p. 90, Copyright © 1998. Reprinted by permission of W.B. Saunders Co.

tendon organs and causes an increase in the firing rate of afferents. These afferent impulses have an inhibitory effect on α motor neurons, causing relaxation of the muscle. The opposing effects of the neuromuscular spindles and the Golgi tendon organs are very important in the integration of spinal reflexes. The myotatic or stretch reflex is one of clinical importance. This reflex is monosynaptic and involves only two neurons (Fig. 1). To initiate the reflex, the muscle is stretched by a sharp tap of the physician's reflex hammer on the tendon of the muscle. This stimulates the stretch receptors of the muscle, and the resultant excitation reaches the spinal cord by way of Ia afferent fibers. These fibers are axons of the sensory neurons of the dorsal root ganglia. The central branches of these neurons have excitatory synapses on spinal α motor neurons. The axons of the motor neurons synapse in the stretched muscle, thereby causing it to contract.

2. Effector Endings

a. Neuromuscular Junctions in Skeletal Muscles A single α motor neuron (located within the ventral horn of the spinal cord; see Fig. 1), with the muscle fibers

that it innervates, is defined as the motor unit. As soon as the large myelinated axon of an α motor neuron enters a skeletal muscle, it branches many times. Each small branch terminates on muscle fibers at the motor end plate or neuromuscular junction (Fig. 11). The plasma membrane of the axon terminal (axolemma) is separated by the synaptic cleft (gap of 20–50 nm) from the plasma membrane of the muscle fiber (sarcolemma). The surface area of sarcolemma (postsynaptic membrane) at a motor end plate is thrown into numerous folds. These serve to increase the contact area of muscle to the naked axon (presynaptic membrane). The neurotransmitter, acetylcholine, is released from synaptic vesicles into the synaptic cleft when a nerve impulse reaches the motor end plate. Once the acetylcholine is released, it will stimulate receptor sites on the postsynaptic muscular membrane, causing the contraction of skeletal muscle fibers. The acetylcholine remains in contact with the postsynaptic membrane for a very short period of time (about 1 msec), and it is rapidly inactivated by the enzyme acetylcholinesterase (AChE). Acetylcholinesterase hydrolyzes acetylcholine into acetic acid and choline. The choline is taken up by the presynaptic terminals for the synthesis of new molecules of acetylcholine.

VI. RESPONSE OF THE PERIPHERAL NERVOUS SYSTEM TO INJURY

Injury to peripheral nerves may cause transection of axons, with resulting degenerative changes in the nerve. Once severed from the cell body, the distal segment of the axon undergoes a process known as Wallerian degeneration. A classic work by Santiago Ramon y Cajal gave a detailed description of degenerative and regenerative changes within the peripheral nervous system after injury. "When one interrupts the continuity of a nerve by the scalpel or destructive agents, the peripheral stump degenerates rapidly, but all its constituent factors do not disappear" (Fig. 12). "Thus those parts, such as the axons and myelin, which trophically depend on the nerve cell, are destroyed and later restored." Clinically, injury to the peripheral nerve manifests in sensory loss and skeletal muscle weakness. Injury to axons of the spinal motor neurons (lower motor neurons) results in flaccid paralysis (paralysis with decreased muscle tone), decreased or absent superficial or deep reflexes, and spontaneous twitches or fasciculation within the muscles. Finally, atrophy in the denervated muscles could occur within a period of time after injury (Fig. 13). These changes occur because the lower motor neurons maintain the

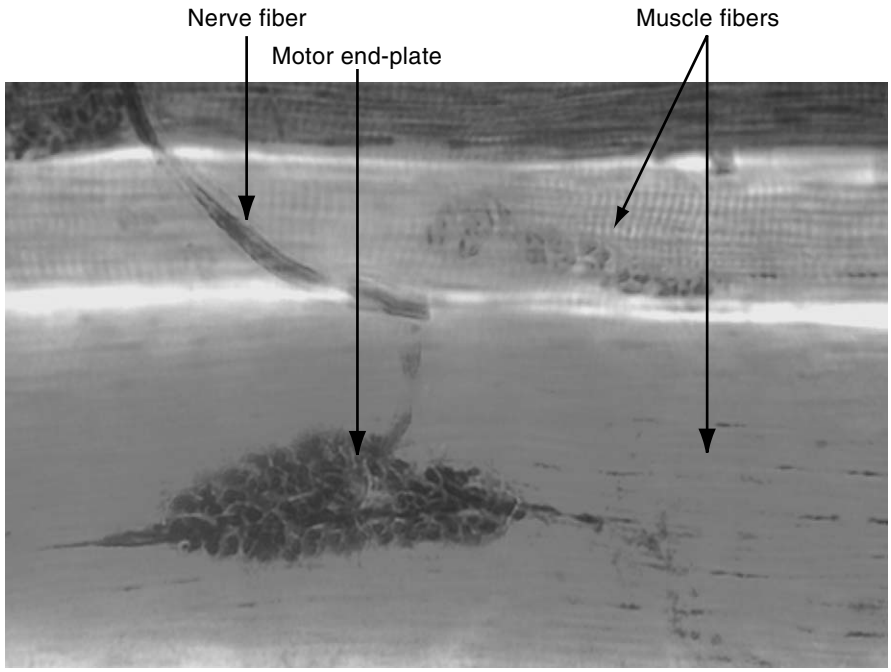

Figure 11 Motor end plate on skeletal muscle. Gold chloride method.

normal tone of the skeletal muscles and also provide trophic support to the muscle fibers.

Degeneration of the peripheral nerves is more likely to be followed by regeneration and recovery of function of the target organ. Many new axonal sprouts of motor or sensory neurons will make a passage through the longitudinal cords of Schwann cells within the distal part of the injured peripheral nerve. When an axon in the PNS is severed, the chain of Schwann cells remains, providing a pathway that guides axon regrowth. A regenerating axon within the peripheral nerve can grow approximately 1 mm per day. In contrast, in the CNS this pathway does not remain after axons are damaged. The tissue often becomes disorganized, and a physical barrier to axonal growth can develop as a result of the proliferation of astrocytes. This process, known as glial scarring, is among the other complex factors inhibiting regeneration within the CNS. Finally, oligodendrocytes and central myelin contain cell surface molecules that inhibit axon outgrowth in culture and *in vitro*. To overcome the nonpermissive environment of the CNS for regeneration, peripheral nerve implants and genetically modified Schwann cells were used in experiments to bridge the gap in the injured spinal cord.

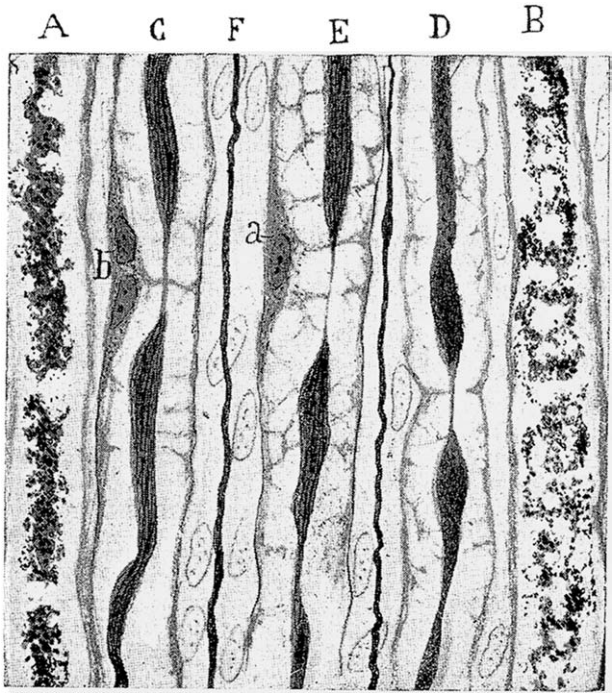

Figure 12 Piece of the peripheral stump of the sciatic nerve of a cat, killed 48 hr after the operation (nerve injury). Region far from the wound. Staining by reduced silver nitrate. (A, B) Axons that were destroyed at an early stage; (C–E) axons in the varicose phase, relatively resistant; (F) barely altered nonmedullated fiber. Figure 13 Posterior view of the legs of a 68-year-old male. Severe atrophy is noticeable within the right gastrocnemius muscle. Neurological examination showed the absence of an Achilles reflex on the right side, and the patient also described a decrease in sensation in response to touch and pinprick on the lateral aspect of the right leg. These clinical findings result from the compression and degeneration of the spinal nerves at the L5–S1 level by herniation of the intervertebral disk.

Phantom Limb Pain

HERTA FLOR
University of Heidelberg

GLOSSARY

cortical reorganization Changes in the functional architecture of the sensory and motor cortex related to injury or stimulation and learning.

nonpainful phantom sensation and nonpainful sensation in the residual limb Sensations in the phantom or the residual portion of the limb that are clearly not painful, such as tingling or itching or a sense of the position and size of the phantom.

preemptive analgesia Analgesia that is applied before the onset of acute pain (e.g., before and during surgery).

referred sensation Sensation in the phantom elicited by stimulation of adjacent but also distal body parts.

residual limb pain Pain in the part of the body adjacent to the amputation site; also referred to as stump pain.

telescoping Retraction of the phantom limb toward the residual limb; sometimes accompanied by shrinking of the limb.

Phantom limb pain is pain in a body part that is no longer present. It is a frequent aftereffect of amputation, occurring in 50–80% of all amputees. Phantom limb pain is commonly classified as neuropathic pain and is assumed to be related to damage of central or peripheral neurons. The French physician Ambroise Paré, who postulated that peripheral factors as well as a central pain memory might be causing the phenomenon, first described it in 1552.

I. EPIDEMIOLOGY, DESCRIPTION, AND COURSE

Although some studies have cited lower rates of prevalence, it is likely that they did not assess the true occurrence of the phenomenon since patients are often reluctant to admit pain in a part of the body that is no longer present. Although phantom limb pain is more common after the amputation of an arm or leg, it may also occur after the surgical removal of other body parts, such as a breast, the rectum, the penis, the testicles, an eye, the tongue, or the teeth. It has also been described subsequent to lesions of peripheral nerves or the central nervous system, such as in brachial plexus avulsion or paraplegia.

Phantom limb pain seems to be more common if the amputee suffered from chronic pain prior to the amputation, may be less frequent if the amputation occurred at a very young age, and is virtually absent in congenital amputees (i.e., those born without a limb). It is usually episodic with brief attacks of pain but may also be continuous and seems to be more intense in the distal portions of the phantom. The pain may have a number of different qualities, such as stabbing, throbbing, burning, cramping, and it may also consist of a painful position or painful movements of the phantom. The long-term course of phantom limb pain is unclear. Whereas some authors reported a slight decline in prevalence over the course of several years, others have not described such changes. Frequently, the pain in the phantom is similar to the pain that existed in the limb prior to amputation. There have been some reports that phantom limb pain is more frequent in male than in female amputees; however, other studies did not confirm these findings. It is also not clear to what extent age of the amputee and

medical status show a relationship to the severity and/or incidence of phantom limb pain.

Phantom limb pain needs to be differentiated from pain in the residual limb, also referred to as stump pain (i.e., pain in the portion of the body adjacent to the amputated or deafferented body part). Patients and physicians alike often have difficulty separating the two types of pain that are only moderately positively correlated. In addition to phantom limb pain, nonpainful sensations may be present in the phantom and/or the residual limb. They may consist of spontaneous movements of the phantom or the residual limb, tingling, cramping, or the sensation of the shape and volume of the limb. Phantom sensations seem to be an invariable consequence of traumatic amputation of a limb, whereas they are very rare in congenital amputees.

Many patients report the phenomenon of telescoping, i.e., the retraction of the phantom toward the residual limb and often the disappearance of the phantom into the limb. It was long assumed that telescoping might be an adaptive phenomenon and be negatively correlated with phantom limb pain and as such an expression of changes in the central nervous system that were beneficial. However, recent evidence suggests that central changes, phantom limb pain, and telescoping are positively correlated, i.e., that telescoping is associated with more phantom limb pain. Patients with phantom limb pain also often report sensations that are referred to the phantom when skin areas adjacent, but also far removed, from the amputated limb are stimulated. They may have a point-to-point correspondence between stimulation sites in other body parts and the phantom, and the modality and quality of the sensations are usually the same. However, in most cases (80–95% of amputees) referred sensations lack this topographic correspondence, which seems to be present in only a small percentage of amputees. Ramachandran suggested that these referred sensations might be a perceptual correlate of cortical changes occurring in the primary somatosensory cortex in amputees. Earlier studies also reported enhanced perceptual acuity of the residual limb as assessed by two-point discrimination and lower perception and pain thresholds compared to those in the contralateral limb in amputees. These changes in sensory perception were also thought to be positively related to the phenomenon of telescoping. Recent studies, however, could not confirm this relationship and have questioned the assumption that stump perceptual acuity might be a correlate of central changes related to the experience of a phantom.

II. PATHOPHYSIOLOGY

Both peripheral and central factors have been discussed as determinants of phantom limb pain. Psychological factors do not seem to contribute to the etiology of the problem but, rather, may affect the course and the severity of the pain. The general view today is that of multiple changes along the neuraxis contributing to the experience of phantom limb pain.

A. Peripheral Factors

Peripheral changes such as nociceptive input from the residual limb have been viewed as an important determinant of phantom limb pain. This is supported by the moderately high correlation (0.40–0.70) between residual limb and phantom limb pain. Ectopic discharge from a stump neuroma has been postulated as one important peripheral mechanism. When peripheral nerves are cut or injured, regenerative sprouting of the injured axon occurs. In this process a neuroma in the residual limb may be formed (i.e., enlarged and disorganized endings of C fibers and demyelinated A fibers that show an increased rate of spontaneous activity). Mechanical and chemical stimulation further increases the rate of discharge, which seems to be mainly related to ectopia (i.e., neuronal discharge that is generated along the axon or in the soma). These ectopic discharges have been related to stimulation of the stump (e.g., by pressure or cold) but can also occur spontaneously as a consequence of nerve injury. In addition, nonfunctional connections between axons (ephapses) may contribute to this spontaneous activity. However, phantom limb pain is often present immediately after amputation, before a neuroma could have formed. Moreover, local anesthesia of the stump does not eliminate phantom limb pain in all amputees.

A further site of ectopic discharge may be the dorsal root ganglion (DRG). This ectopia in the DRG can amplify discharge coming from the residual limb or can lead to cross-excitation and instigate the depolarization of neighboring neurons (Fig. 1). In humans it was found that an anesthetic block of a neuroma eliminates nerve activity related to the stimulation of the stump but not spontaneous activity, which may originate in the DRG. Sympathetic discharge that may also be caused by emotional distress may lead to increased levels of circulating epinephrine that can trigger and exacerbate neuronal activity from neuroma. If a phantom pain eliciting neuroma develops,

Figure 1 This figure shows how hypertonic saline excites ectopic impulses in dorsal root ganglia associated with an injured nerve. (A) Spontaneous activity in a dorsal root ganglion in a rat whose sciatic nerve was subjected to constriction injury. (B) Topical application of 6% saline accelerated the firing and recruited previously silent afferents. All active units were C fibers [reproduced with permission from Devor, M. (1997). Phantom pain as an expression of referred and neuropathic pain. In *Phantom Pain* (R. A. Sherman, Ed.), p. 43. Plenum, New York].

depends on the type of the amputation, exacerbating stimulation, and genetic predisposition to develop neuropathic pain problems.

The role of the sympathetic nervous system in animal models of neuropathic pain such as constriction injury or autotomy has been well documented. However, research on its role in phantom limb pain is scarce. The mechanisms that have been discussed are sympathetically triggered ephaptic transmission, sympathetic activation of nociceptors, or activation of low-threshold mechanoreceptors that trigger sensitized spinal cord neurons. In addition to sympathetic sensory coupling at the level of the periphery (neuroma), sympathetic sensory coupling also occurs at the level of the DRG.

The sympathetic maintenance of some types of phantom limb pain has been supported by evidence that for beta-adrenergic blocking agents, temporary or surgical blockade of the sympathetic activation can reduce phantom limb pain. Injections of epinephrine resulted in an increase of phantom limb pain and paresthesias in some amputees. Katz suggested that paresthesias might be related to postganglionic sympathetic activity acting on primary afferents and that painful sensations might develop when nociceptors are involved and/or central sensitization has occurred. He assumed that the release of acetylcholine and noradrenaline from sudomotor and vasomotor efferents might contribute to the psychophysiological changes observed in amputation stumps and might lead to enhanced discharge from the primary afferent neurons in this region. Stump neuroma may further intensify this process. Katz also pointed out that cognitive and affective processes can trigger phantom limb phenomena and phantom limb pain (Fig. 2) via a hypothalamic–sympathetic route.

Although sympathetically maintained pain does not necessarily covary with regional sympathetic abnormalities, in some patients sympathetic dysregulation in the residual limb is apparent. Reduced near surface blood flow to a limb has been implicated as a predictive physiological correlate of phantom limb pain. A number of studies have demonstrated that (i) the ends of the nerves that used to serve the amputated limb are still sensitive to stimuli; (ii) cooling the nerve ends, especially those of C fiber nociceptors, causes increased firing rates; and (iii) reducing blood flow to the extremity results in the cooling of it. Measurements of skin temperature in amputees by Sherman and collaborators revealed that the residual limbs of amputees with phantom limb pain were cooler at the distal end than paired points on the opposite extremity and that the cooler areas did not warm when attempts were made to increase cutaneous blood flow. Amputees were found to be generally more sensitive to cooling of the affected limb. Most amputees with phantom limb pain showed different patterns of temperature than those without phantom limb pain. Consistent, inverse relationships between intensity of phantom limb pain and temperature in the residual limb relative to that of the intact limb have been demonstrated for burning, throbbing, and tingling descriptions of phantom pain but not for other descriptions. It has also been established that (a) for these descriptors of phantom pain there is a day to day relationship between the relative amount of blood flow in the stump and pain intensity and that (b) there is an immediate change in pain when blood flow changes. This tight relationship has been replicated numerous times and indicates that there is more than a casual relationship between the two. The existence of a vascular-related mechanism for burning phantom pain is also supported by the short-term effectiveness of invasive procedures such as sympathetic blocks and sympathectomies, which increase blood flow to the limb and reduce the intensity of burning phantom and stump pain but not other descriptors. It is indirectly supported by the virtual ineffectiveness of surgical procedures involving severing nerves either in the spinal cord or running between the amputation site and the spinal cord. Beta blockers such as propranolol cause dilation of peripheral blood vessels and have been reported to successfully ameliorate phantom pain at least in the short term. Relationships between muscle tension and burning phantom

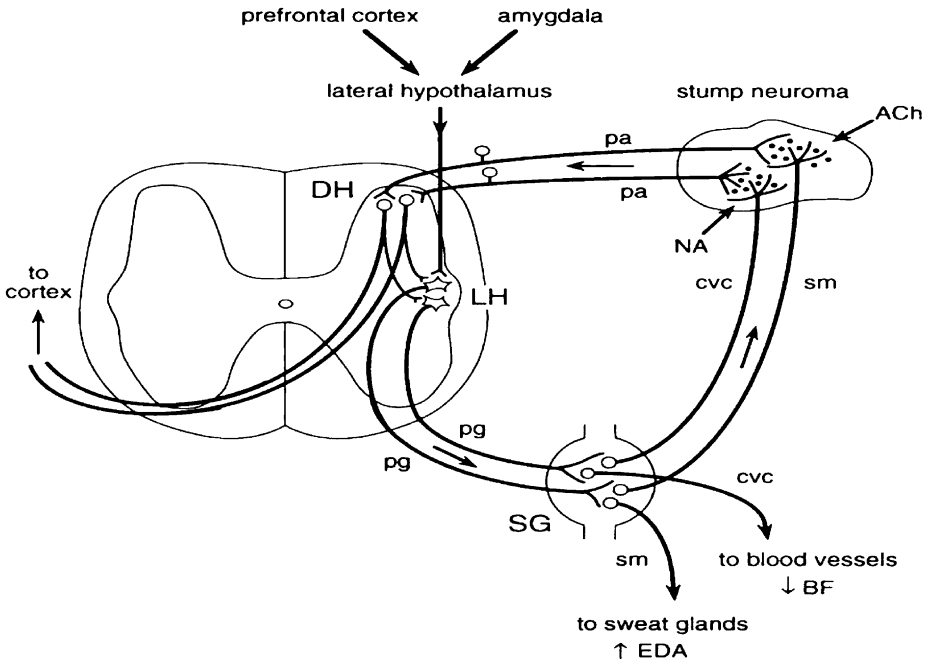

Figure 2 Schematic diagram illustrating a mechanism of sympathetically maintained phantom limb parasthesias. pa; pg, preganglionic sympathetic neurons; DH, dorsal horn; LH, lateral horn; SG, sympathetic ganglion; sm, sudomotor; cvc, cutaneous vasoconstrictor; NA, noradrenaline; Ach, acetylcholine [reproduced with permission from Katz, J. (1997). The role of the sympathetic nervous system in phantom pain. In *Phantom Pain* (R. A. Sherman, Ed.), p. 86. Plenum, New York].

limb pain have been shown to be largely due to the change in near surface blood flow that accompanies increased muscle tension.

Onset and intensity of cramping and squeezing descriptions of phantom pain have been related to muscle tension in the residual limb. A variety of studies have demonstrated that the amount of muscle tension in the residual limb changes before alterations in intensity of cramping phantom pain both from day to day and from moment to moment. Changes in surface electromyographic representations of muscle tension in the residual limb precede changes in cramping and squeezing phantom pain by up to several seconds. This relationship does not seem to hold for any other descriptions of phantom pain. The relationship between cramping phantom pain and muscle tension in the residual limb is supported by the success of treatments resulting in reduction of residual limb muscle tension for cramping phantom pain. Numerous amputees report that cramping phantom pain decreases with any activity that tends to decrease muscle contraction levels in the residual limb and increases with activities that increase overall levels of contraction. Thus, activities such as phantom exercises, which result in changes in muscle tension in the residual limb, can result in temporary changes in intensity of phantom pain.

As noted previously, peripheral factors alone cannot be the primary factor in the occurrence of phantom limb pain. Pain is present even if there is no pathology in the residual limb; it often has an onset immediately after the amputation, and anesthetic blocks do not uniformly eliminate phantom limb pain or they eliminate it for a period of time that clearly exceeds the time the block can be active. This suggests that peripheral factors may be of varying importance in the etiology and modulation of phantom limb pain and that central factors must also play a role.

B. Central Factors

Additional contributions to phantom limbs may come from sensitization of the dorsal horn of the spinal cord. Increased activity of peripheral nociceptors leads to an enduring change in the synaptic structure of the dorsal horn in the spinal cord, a process called *central sensitization*. Central sensitization is characterized by increased excitability of the dorsal horn neurons, the reduction of inhibitory processes, and structural

changes at the central nerve endings of the primary sensory neurons, the interneurons, and the projection neurons. This central sensitization is mediated by the NMDA receptor and its transmitter glutamate. Low threshold afferents may become functionally connected to ascending spinal projection neurons that carry nociceptive information and/or inhibitory interneurons may be destroyed by rapid discharge from injured tissue leading to a hyperexcitable spinal cord. In addition, afferents of the residual limb may invade the regions where the deafferented limb was previously represented. This process may be due to an unmasking of previously silent connections as well as a sprouting of new connections. It has also been proposed that the loss of input related to deafferentation may lead to a general disinhibition of the spinal cord.

Supraspinal changes related to phantom limb pain involve the brain stem, the thalamus, and the cortex. Melzack suggests that there is a neuromatrix (i.e., a network of neurons in several brain areas including the thalamus and somatosensory cortex, the reticular formation and the limbic system, and the posterior parietal cortex) that is the anatomical substrate of the self. The output from this system forms a neurosignature, which is specific for an individual and provides information about the body and its sensations. This neuromatrix is thought to be genetically determined but also modified by experience. Melzack suggests that amputation creates abnormal input into the neuromatrix that stems from either a lack of normal sensory activity or overactivity related to the abnormal firing pattern of damaged nerves. This then leads to an altered neurosignature and the experience of a phantom. He assumes that the reports of phantom phenomena in persons with congenital absence of a limb provide evidence of the genetic determination of the neuromatrix. However, the literature on the presence of phantoms in congenital amputees is controversial, potentially due to problems in the assessment of phantom limb pain. Moreover, the neuromatrix theory is difficult to test because it involves a wide range of brain areas and is not very specific. It also fails to explain why some amputees develop phantom limb pain and why others remain pain free. On the other hand, the brain areas cited as part of the neuromatrix are definitely importantly involved in the experience of phantom limbs and phantom limb pain.

New insights into phantom limb pain have come from studies that showed changes in the functional and structural architecture of primary somatosensory cortex subsequent to amputation and deafferentation in adult animals. It was previously thought that changes in the sensory and motor maps occur only during a limited time window in the development of the organism. In these studies the amputation of digits in an adult owl monkey led to an invasion of adjacent areas into the representation zone of the deafferented fingers. Whereas this type of reorganizational change spanned a distance of several millimeters, recordings from the somatosensory cortex of monkeys that had undergone dorsal rhizotomies 12 years earlier revealed reorganizational changes (invasion of the mouth and chin area into the deafferented arm and hand area) on a scale of several centimeters. Subsequently, Ramachandran *et al.* suggested that the cortical changes observed in these animal studies might be related to phantom phenomena since they noted a point-to-point correspondence between stimulation sites on the face and phantom sensations in upper extremity amputees. Several imaging studies have reported that amputees actually show such reorganizational changes, although they are less related to the perceptual changes observed by Ramachandran *et al.* but rather have a close association with phantom limb pain. It was shown in several studies of human amputees that reorganization in area 3b of primary somatosensory cortex is highly correlated with phantom limb pain (Fig. 3). This result seems to be a very stable finding.

The functional significance of these cortical changes was established by showing that the elimination of peripheral input from the amputation stump by brachial plexus anesthesia completely eliminated cortical reorganization and phantom limb pain in about 50% of the amputees that were studied. In the remaining 50%, both cortical reorganization and phantom limb pain remained unchanged. This result suggests that in some amputees, cortical reorganization and phantom limb pain may be maintained by peripheral input, whereas in others central, potentially intracortical, changes might be more important. It was recently shown that axonal sprouting in the cortex underlies the reorganizational changes observed in amputated monkeys, whereas thalamic reorganization occurs after lesions close to the dorsal horn that is then relayed to the cortex. Similar changes have also been observed in the motor cortex in both animals and human amputees. Computational models of deafferentation and related phenomena have suggested that reorganization of neuronal networks is enhanced when abnormal noise-like input as it might originate from a neuroma is created and fed into the system.

Thalamic stimulation and recordings in human amputees have revealed that reorganizational changes may also occur at the thalamic level and are closely

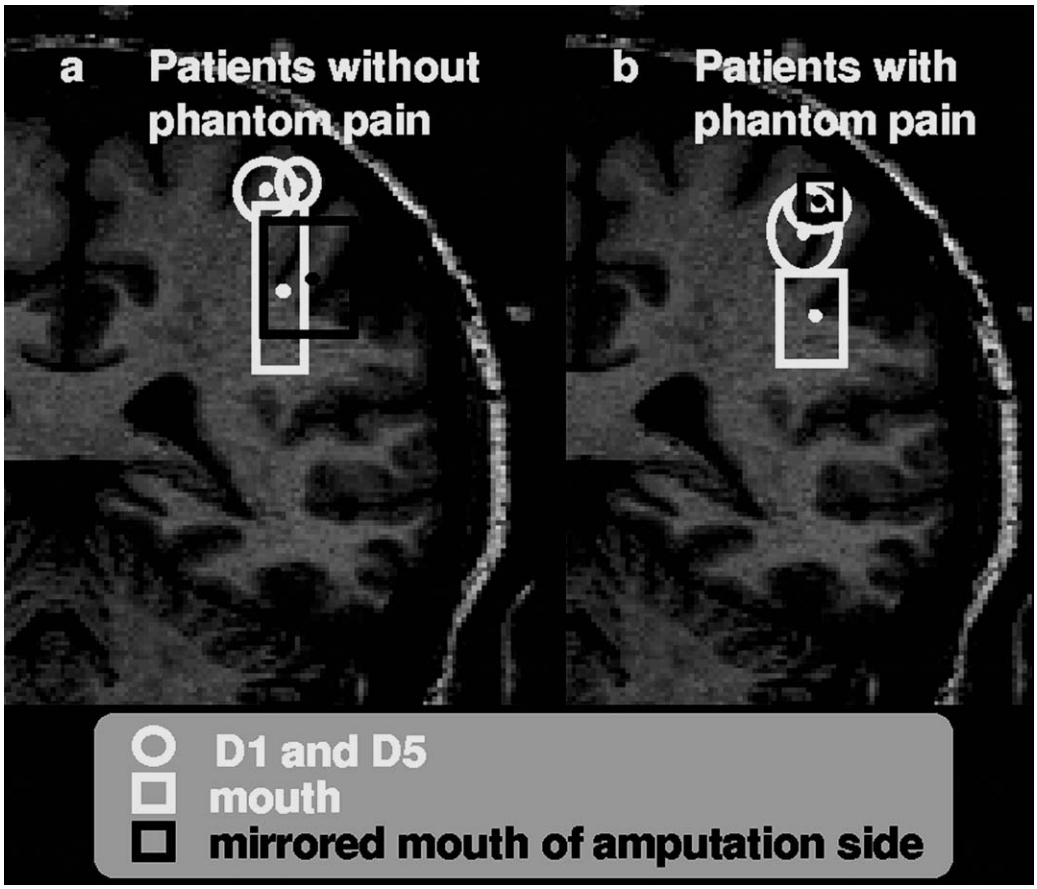

Figure 3 Reorganization in primary somatosensory cortex in unilateral upper limb amputees without phantom limb pain (a) and with phantom limb pain (b). The dots denote the means and the rectangles and circles the standard deviations of the respective localizations. Note that only in amputees with phantom limb pain has a shift of the mouth representation into the hand representation occurred, whereas the amputees without pain do not display a similar shift. Also note the very small standard deviation of the shifted mouth representation in the patients with phantom limb pain suggesting that all persons with pain show reorganization.

related to the perception of phantom limbs and phantom limb pain. Studies in animals have shown that these changes may be relayed from the spinal and brain stem level; however, changes on the subcortical levels may also originate in the cortex, which has strong efferent fiber connections.

A comprehensive model of the development of phantom limbs includes both peripheral and central factors and assumes that pain memories established prior to the amputation may be powerful elicitors of phantom limb pain. This assumption is based on findings that amputees often experience phantom limb pain that is similar in both quality and location to pain experienced before the amputation. Melzack and Katz called these memory traces somatosensory pain memories. In patients with chronic back pain it was shown that increasing chronicity is correlated with an increase of the representation zone of the back in primary somatosensory cortex. These data suggest that long-lasting noxious input may lead to long-term changes at all levels of the neuraxis, including the cortical level. It has long been known that the primary somatosensory cortex is involved in the processing of pain and that it may be important for the sensory-discriminative aspects of the pain experience. There have also been reports that phantom limb pain was abolished after the surgical removal of portions of the primary somatosensory cortex and that stimulation of somatosensory cortex evoked phantom limb pain. If a somatosensory pain memory has been established with an important neural correlate in primary somatosensory cortex, subsequent deafferentation and an invasion of the amputation zone by neighboring input may activate preferentially cortical neurons coding for pain. Since

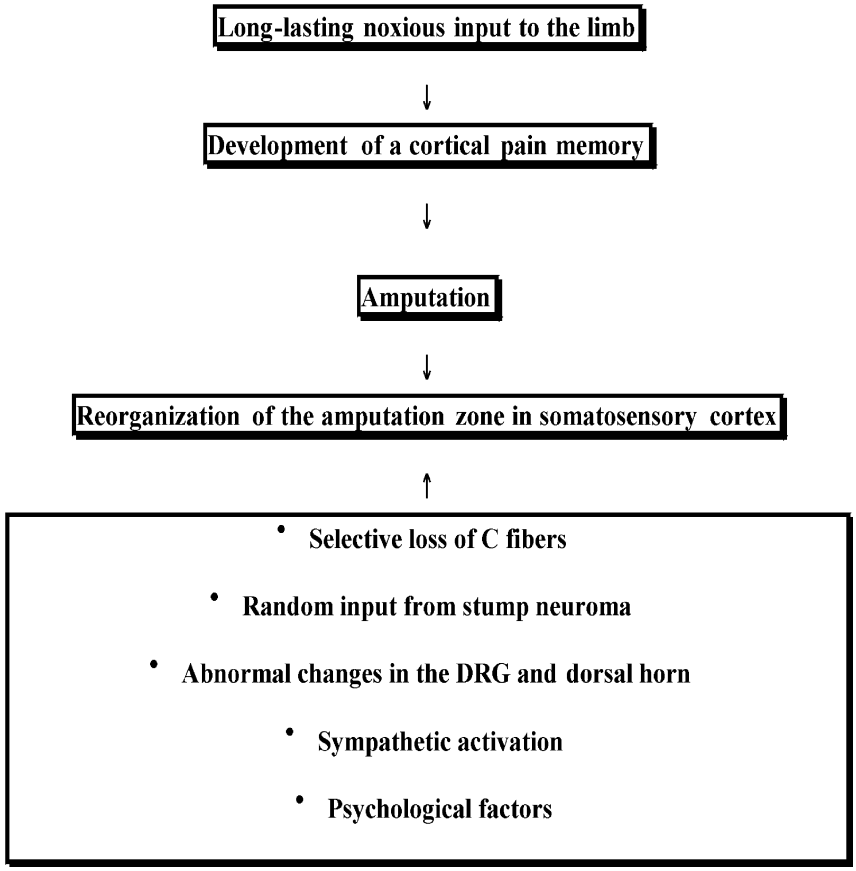

Figure 4 Schematic diagram incorporating the main factors thought to be relevant for the development of phantom limb pain.

the cortical area coding input from the periphery seems to remain assigned to the original zone of input, the activation in the cortical zone representing the amputated limb is referred to this limb and the activation is interpreted as phantom sensation and phantom limb pain. Figure 4 summarizes these change assumed to take place in patients with phantom limb pain.

It is likely that these factors are of varying importance in different patients with phantom limb pain and that subgroups of patients with distinct and differentiable pathologies exist, as suggested by Sherman.

C. Psychopathology

For a long time, it was assumed that phantom limbs and phantom limb pain might be related to unresolved grief over the loss of the limb and these were viewed as a psychosomatic manifestation of a premorbid personality. The idea that phantom limb pain is "just in the head" of the patient is still prevalent and may contribute to the large divergence in reported incidence and prevalence rates. Patients do not readily volunteer information on their phantom phenomena out of fear of being placed in a psychiatric diagnostic category. Empirical studies on psychological characteristics of patients who suffer from phantom limb pain and controls show very clearly that there are no pathological psychological processes in these patients. Phantom limb pain, however, is triggered and exacerbated by psychological factors. Longitudinal diary studies of amputees showed that there is a significant relationship between stress and the onset and exacerbation of episodes of phantom limb pain, probably mediated by sympathetic nervous system activity and increases in muscle tension as outlined previously. Cognitive factors also play a role in the modulation of phantom limb pain: Patients who lack coping strategies when confronted with episodes of pain are more affected by the pain and report more interference than patients who cope well with their problem. Likewise, higher levels of catastrophizing with respect to pain are

associated with higher levels of pain and distress. However, compared to other groups of chronic pain patients, such as patients who suffer from fibromyalgia syndrome or chronic low back pain, phantom limb pain patients do have normal psychological profiles and very little psychopathology. Psychological variables before the amputation have also been found to be predictive of phantom limb pain. Patients who were depressed and experienced little control over their lives tended to complain significantly more often of phantom limb pain 1 year after the amputation.

III. ASSESSMENT

As noted previously, the reliable and valid assessment of phantom phenomena and phantom limb pain is of great importance but has not been evaluated in most empirical studies and even less in clinical practice. Patients do have considerable difficulty in differentiating painful and nonpainful phenomena as well as differentiating to what extent sensations are confined to the residual limb, extend to the phantom, or are related to both. Recent studies have shown that the most reliable and valid way to assess phantom phenomena is by interview, where the interviewer very carefully explains the differences between the various phantom phenomena using visual material. In addition to an interview that should include the quantitative and qualitative assessment of painful and nonpainful phantom and residual limb phenomena, phantom limb pain should be assessed by standardized questionnaires. These instruments also show high stability in retests done weeks or months apart, suggesting that phantom limb pain is less variable than generally believed, at least in chronic amputees. Adjective checklists as included in the McGill Pain Questionnaire are useful since Sherman has shown that different types of phantom limb pain may be related to different underlying mechanisms and require different therapeutic interventions.

Sensory testing should also focus on two-point discrimination in the affected limb and a homologous site, the assessment of perception and pain thresholds, and the occurrence of referred sensation using both painful and nonpainful touch as described, for example, by Ramachandran. Since the use of a prosthesis seems to influence the occurrence of both phantom limb pain and cortical reorganization, details about the use of a prosthesis as well as the amount of use of the intact arm should be assessed. Both questionnaires and interview formats are available for this purpose.

IV. TREATMENT

Several studies, including large surveys of amputees, have shown that most treatments for phantom limb pain are ineffective unless they are related to the mechanisms underlying the production of the pain. Most studies are short-term assessments of small samples of phantom limb pain patients. The maximum benefit reported from a host of treatments, such as local anesthesia, sympathectomy, dorsal root entry zone lesions, cordotomy and rhizotomy, neurostimulation methods, and pharmacological interventions such as anticonvulsants, barbiturates, antidepressiants, neuroleptics, muscle relaxants, and opioids (Table I), seems to be approximately 30%. This does not exceed the placebo effect reported in other studies.

Mechanism-based treatments are very rare but have been shown to be relatively effective in a few small studies. For example, pharmacological and behavioral treatments resulting in vasodilatation of the residual limb are helpful for burning/tingling descriptions of phantom limb pain but not others, even when an individual patient reports several descriptive types. Treatments resulting in decreased muscle tension in the residual limb are helpful for cramping but not other descriptions of phantom pain. There has been no behaviorally oriented treatment identified for stabbing and shooting pains. Behavioral interventions for several descriptive types of phantom limb pain have been in use at least since the late 1970s. Small trials have shown that patients can successfully control burning phantom limb pain to the extent that they learn to control blood flow in the residual limb. Similarly, small trials have shown that amputees with cramping phantom pain can control it to the extent that they learn to control muscle tension in their residual limbs.

Based on findings from neuroelectric and neuromagnetic source imaging, changes in cortical reorganization might influence phantom limb pain. Animal work on stimulation-induced plasticity suggests that extensive behaviorally relevant (but not passive) stimulation of a body part leads to an expansion of its representation zone. Thus, the use of a myoelectric prosthesis might be one method to influence phantom limb pain. It was recently shown that intensive use of a myoelectric prosthesis was positively correlated with both reduced phantom limb pain and reduced cortical reorganization. When cortical reorganization was partialled out, the relationship between prosthesis use and reduced phantom limb pain was no longer significant, suggesting that cortical reorganization

Table I
Commonly Employed Treatments for Phantom Limb Pain

Pharmacological	Surgical	Anesthesiological	Psychological	Other
Conventional analgesics	Stump revision	Nerve blocks	EMG biofeedback	TENS
Opioids	Neurectomy	Epidural blockade	Temperature biofeedback	Acupuncture
Calcitonin	Sympathectomy	Sympathetic block	Cognitive–behavioral pain management	Physical therapy
Beta-blockers	Rhizotomy	Local anesthesia	Sensory discrimination training	Ultrasound
Neuroleptics	Cordotomy		Hypnosis	Manipulation
Anticonvulsives	Tractotomy			Prosthesis training
NMDA antagonists	Dorsal column stimulation			
Antidepressants	Deep brain stimulation			
Barbiturates				
Muscle relaxants				

mediates this relationship. An alternative approach in patients in whom prosthesis use is not viable is the application of behaviorally relevant stimulation. A 2-week training that consisted of discrimination training of electric stimuli to the stump for 2 hr per day led to significant improvements in phantom limb pain and a significant reversal of cortical reorganization. A control group of patients who received standard medical treatment and general psychological counseling in this time period did not show similar changes in cortical reorganization and phantom limb pain. A similar approach used asynchronous stimulation of the mouth and stump region and also achieved alterations in cortical reorganization and phantom limb pain specific for the type of pain. In both cases, the basic idea of the treatment was to provide input into the amputation zone and thus undo the reorganizational changes that occurred subsequent to the amputation. Ramachandran, who used a virtual reality box to train patients to move the phantom and reduce phantom limb pain, described another behaviorally oriented approach. A mirror was placed in a box and the patient inserted both his or her intact arm and the phantom. The patient was then asked to look at the mirror image of the intact arm, which is perceived as an intact hand where the phantom used to be. The patient was then asked to make symmetric movements with both hands, thus suggesting real movement from the lost arm to the brain. This procedure seems to reestablish control over the phantom and to reduce phantom limb pain in some patients.

Although these stimulation-based approaches might be beneficial in many patients who suffer from phantom limb pain, they might be insufficient for patients in whom peripheral factors contribute significantly to the problem. Here, biofeedback might be used as an alternative or adjunct treatment. Sherman reported substantial changes in phantom limb pain related to peripheral biofeedback in those patients in whom peripheral factors were found to be of relevance for the experience of phantom limbs.

Pharmacological interventions might also be useful in the amelioration of phantom limb pain related to central changes. As discussed previously, spinal sensitization as well as cortical and thalamic reorganization might be involved in the experience of phantom limb pain. Animal studies have shown that both spinal sensitization and cortical reorganization can be prevented or reversed by use of NMDA receptor antagonists. Reorganization was also found to be related to reduced GABAergic activity and increased cholinergic activity. Thus, these substances should be beneficial in the treatment of phantom limb pain. However, studies in patients are scarce and the data are controversial. For example, although some studies have reported a positive effect of the NMDA receptor antagonist ketamine on phantom limb pain, others have found no effects of the NMDA receptor antagonist memantine on chronic phantom pain phenomena.

V. PREVENTION

As noted previously, Katz and Melzack emphasized that there are somatosensory pain memories that may

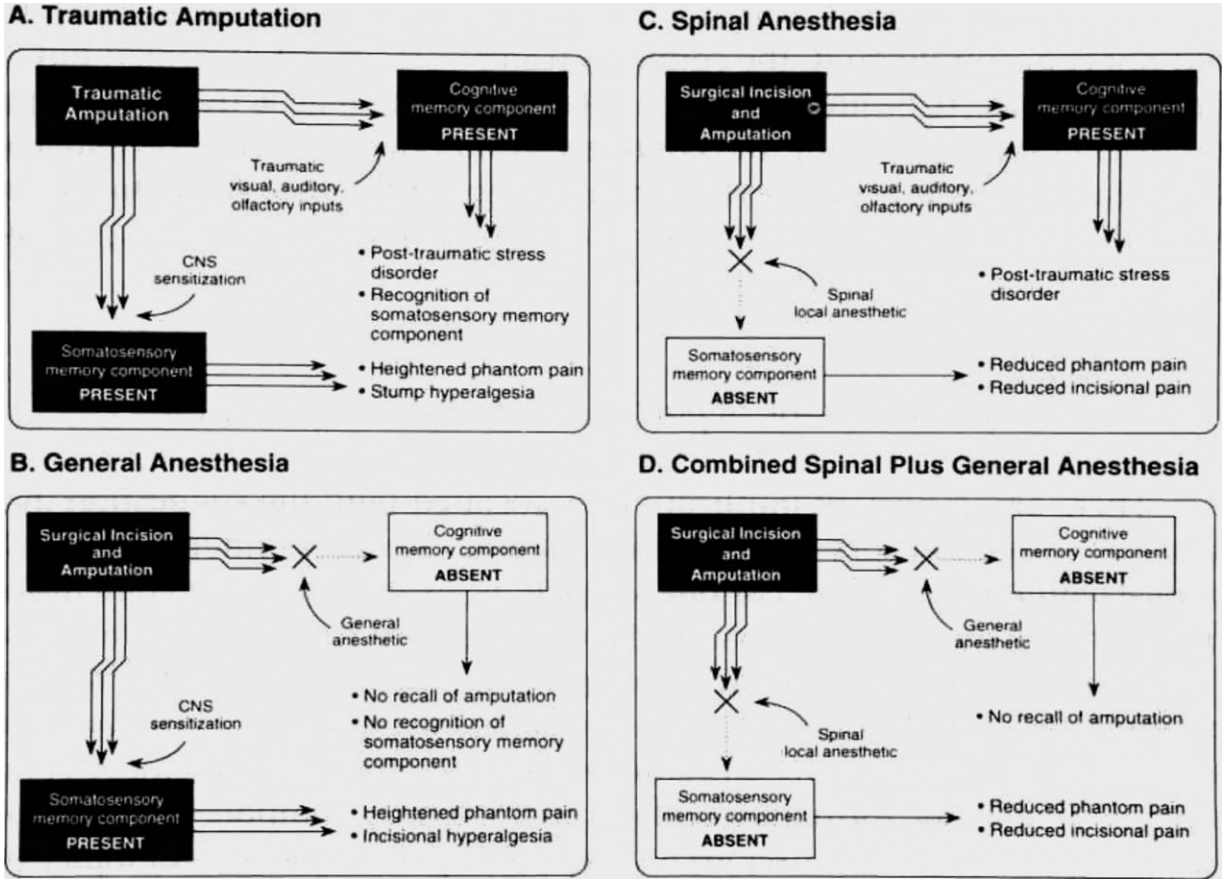

Figure 5 Predicted pain and psychological postoperative status following traumatic amputation as described by Katz [reproduced with permission from Katz, J. (1997). Central nervous system correlates and mechanisms of phantom pain. In *Phantom Pain* (R. A. Sherman, Ed.), p. 98. Plenum, New York].

be revived after an amputation and lead to phantom limb pain. They also noted that implicit and explicit memory components can be differentiated, both of which contribute to the experience of phantom limbs and phantom limb pain. Katz therefore suggested that both memory components (i.e., both general and spinal anesthesia) need to be targeted in preemptive analgesic trials destined to prevent the onset of phantom limb pain (Fig. 5).

Preemptive analgesia refers to the attempt to prevent chronic pain by early intervention before acute pain occurs (e.g., before and during surgery). Based on the data on sensitization of spinal neurons by afferent barrage, it has been suggested that general anesthesia should be complemented by peripheral anesthesia, thus preventing peripheral nociceptive input from reaching the spinal cord and higher centers. However, preemptive analgesia that included both general and spinal anesthesia has not consistently been efficacious in preventing the onset of phantom limb pain. Whereas several studies reported a reduction of the incidence of phantom limb pain when additional epidural anesthesia was used in the pre- and perioperative stage, recent studies failed to find a beneficial effect. A preexisting pain memory that has already led to cortical changes would not necessarily be affected by elimination of afferent barrage. Here, NMDA antagonists as well as GABA agonists—drugs that have been shown to reverse or prevent cortical reorganization—might be beneficial for prevention of phantom limb pain. A recent study used the NMDA receptor antagonist memantine versus placebo in addition to brachial plexus anesthesia in patients undergoing traumatic amputations of individual fingers or a hand. It was found that memantine significantly reduced the incidence of phantom limb pain 1 year after the surgery, whereas placebo failed to show a similar effect.

VI. FUTURE DEVELOPMENTS

Both peripheral and central factors and their interaction need to be examined more closely in animal models of amputation-related pain and in human amputees. To develop more powerful interventions for phantom limb pain, controlled treatment outcome, prospective, and double-blind placebo-controlled outcome research is necessary. Only then will effective evidence-based interventions become available.

Phineas Gage

MALCOLM MACMILLAN
Deakin University, Australia

GLOSSARY

antiphlogistic regimen Nineteenth century, pre-germ theory treatment based on the reduction of the inflammatory or phlogistic (Gr. *phlogos*, flame) state, that is, infection. Achieved mainly by bloodletting, purgatives, emetics, reduced diet, and rest.

cerebral fungi Nineteenth century term for extruded and disorganized brain tissue. Produced by infection.

frontal lobes Roughly the upper, forward half of the cerebral hemispheres.

prefrontal cortex Cortex of the anterior portion of the frontal lobes.

sensory–motor physiology The physiology founded in the first third of the nineteenth century that made the link between sensation and movement its basic unit of analysis.

In 1848, as the result of a bizarre accident, Phineas Gage had most of the left frontal lobe of his brain destroyed. Although his surviving the injury by some 11.5 years made him a considerable medical curiosity, it was the changes to his behavior that made him important in the neurosciences. Gage's is actually one of the most important cases in the history of the neurosciences: it revealed for the first time that complex functions might be localized in the brain. Its status is indexed by its still being cited in about two-thirds of all psychology and related neuroscience textbooks and by the fact that studies were still being undertaken some 150 years after the accident to establish which parts of Gage's brain were damaged.

I. GAGE'S BACKGROUND, WORK, AND ACCIDENT

Despite his importance in the neurosciences, very little was written about Phineas Gage at the time of or after his accident. John Martyn Harlow, the physician who treated Gage and followed up his case, wrote two papers about him, one in 1848 and the other in 1868. In between, Henry Jacob Bigelow, Professor of Surgery at Harvard, wrote another in 1850, and John Barnard Swets Jackson recorded additional information among his *Medical Cases*, some obtained from Gage's family. Jackson also recorded a little more, possibly obtained from Harlow, in his catalog of the Warren Anatomical Museum of the Medical School of Harvard University. In 1851, the editor of the *American Phrenological Journal* published a short comment. The written accounts of these four authors are the only contemporaneous ones and constitute the primary record of the case. A mute secondary record is provided by Phineas Gage's skull and the instrument with which it was damaged. It adds particular interest to his case by allowing us to see how his skull was damaged. Once forming part of the Warren Museum collection, both are now held in Harvard University's Francis J. Countway Library of Medicine.

Very little is known about Gage's behavior before his accident, which parts of his brain were destroyed or damaged, or what happened to him afterward. Partly

because so little is definite, a mythology has grown up about him and a large number of the references to his case in the literature are in grievous error. This article draws on the facts about him that were established or clarified only recently, mainly by the author. Except for Phineas' words of greeting to Williams, all of the direct and otherwise unacknowledged quotations are from Harlow's papers of 1848 or 1868.

Because so little is known about what Gage was like before his accident, there is no satisfactory baseline against which to evaluate the changes it produced. Something of his cognitive and organizational abilities may be inferred from the kind of work he was doing, the psychological and physical demands it made on him, and the context in which it was undertaken.

A. Gage's Background

Phineas Gage was born in Lebanon, New Hampshire. Although sometimes described as an Irishman, he was an eighth-generation American of Puritan origin, his remote ancestor being the John Gage of Massachusetts who arrived in the Americas in 1630, probably from Stoneham in Suffolk, England. The fourth generation of the family moved to New Hampshire some time before 1770 and farmed in the towns of Concord, Grafton, Enfield, and Lebanon. Phineas Gage was named after his grandfather and was the first of five children, three of whom were boys, born to Jesse Eaton Gage and Hannah Trussell Swetland. The precise date of his birth cannot be documented but may have been July 9, 1823.

We know nothing about Gage's early years, including his schooling, but during that time literacy rates were high in New Hampshire, and we know he was able to write. We are similarly ignorant about the work he did before his accident. We can be almost certain that he was skilled in such basics of farm work as growing crops and caring for cattle and horses, and probably sheep as well. More, the rocky soils of his family's farms probably meant that he had some knowledge of the use of explosives for obtaining building materials and in excavating cellar holes.

B. Gage's Work

By the time Gage was in his early twenties, a massive development of railroad construction had begun in New England. Phineas may have obtained or extended his knowledge of rock blasting in that industry while employed either on a nearby line, like that of the Northern Railroad Company, or in the equally close isinglass (mica) mines in Grafton. The first definite thing we know about him is that a firm of contractors had employed him as the foreman of a gang working on the route of the Rutland and Burlington Railroad (R&B RR). The gang was blasting a cutting, or cut, through a large rocky outcrop some 0.75 mile south of Cavendish, Vermont.

Although not a skilled occupation requiring formal training, blasting requires high-level cognitive abilities. The rifts or joints along which the rock will fracture have to be assessed, the sites, angles, and depths of the holes to be drilled must be decided, and the right amount of blasting powder has to be packed into place and fired safely. Incorrect judgments in planning or conducting any of these operations not only might result in ineffective or dangerous explosions but also could result in removal of too little rock, its fragmentation into pieces too large for easy removal, or its scattering over too large an area. Work that required considerable labor might then have to be repeated, and excessive damage at one site could increase the amount of work required at another.

In blasting of the kind Gage was undertaking, a hole was laboriously drilled by hand into the rock, a safety fuse (without the yet-to-be invented detonator) was put into it, and the blasting powder was poured over the fuse. Then, with a small crowbar-like tool known as a tamping iron, the powder was packed or tamped into the hole with a series of gentle but firm pats. Even though the charge so tamped contained a fuse, it was usually sufficiently stable not to explode. Sand, clay, or other material would then be placed over the charge and the whole tamped similarly, although more vigorously. The explosive force of a charge so prepared would then be directed into the rock at the end of the drill hole.

Gage's physical and psychological attributes suited him for this work admirably. Physically he was, Harlow tells us, "a perfectly healthy, strong and active young man," with an "iron frame," "vigorous physical organization," and an unusually well-developed muscular system, having had scarcely a day's illness from his childhood. He was of "middle stature" (actually 5 ft, 6 in.), weighed on average 150 lb, and had a "nervo-bilious temperament." He had an iron will, was of temperate habit, "possessed of considerable energy of character," and was "very energetic and persistent in executing all his plans of operation." He had a well-balanced mind, and his contractors said he was the most capable and efficient foreman in their

employ. Harlow described him as being known as "a shrewd, smart, business man." In the New England vernacular of the day, *shrewd* was synonymous with clever, keen-witted in practical affairs, and astute or sagacious in action or speech; *smart* was synonymous with being quick, keen, active, industrious, energetic, clever, and intelligent.

From today's perspective, Harlow's use of the two-word term *business man* may seem to conflict with Gage's position as foreman. But, like many other New England foremen in the nineteenth century, Phineas may well have been an independent subcontractor who tendered competitively for work to be performed by a gang he had recruited. On the other hand, *business man* was just beginning to acquire its modern meanings and then still meant mainly one who organized the work of others. Subcontractor or not, foreman Gage had to be able to plan and maintain an efficient work schedule.

Here the fact that Gage was "a great favorite" with his men is especially worth noting. In whatever position Phineas stood in relation to his men, he would have had to allot tasks to them fairly, record their working times accurately, treat them equally, and pay them properly. Foremen who did not so treat their men were unpopular and sometimes subject to violent and occasionally fatal attacks, and murderous assaults of this type were not unknown in the Cavendish area.

C. The Accident

At 4:30 PM on September 13, 1848, a charge Phineas was tamping accidentally exploded. Precisely how this happened is not known. The details in the primary sources differ, but what is fairly certain is that Gage's attention was distracted between the first and second stages of the tamping and he began the more vigorous tamping before the sand had been added. The tamping iron struck the hole and it caused a spark that set the blasting powder alight. The iron was 3 ft and 7 in. long, 1.25 in. in diameter at the larger end, tapering over a distance of about 12 in. to a diameter of 0.25 in. at the other, and weighed 13.25 lb. This now formidable missile was blown completely through Gage's skull. It entered, pointed end first, under the zygomatic arch or cheekbone, penetrated the base of the skull behind the eye, and emerged near the junction of the sagittal and coronal sutures to land some 20–25 m away.

Gage was knocked over but may not have lost consciousness. He walked, either by himself or with a little assistance, to a nearby ox cart in which, while sitting and supporting himself against the foreboard, he was driven about 0.75 mile to the inn or tavern in Cavendish where he lived. On arriving, Phineas got up, walked to the back of the cart, allowed himself to be helped down, and then walked to the veranda where he sat on a chair. From there he talked to the small crowd that had gathered about what had happened to him until Edward Higginson Williams, the first medical practitioner to reach him, arrived at about 5:00 PM. Phineas then greeted Williams with one of medicine's great understatements, "Doctor, here is business enough for you."

II. THE SEQUELAE OF THE ACCIDENT, 1848–1868

Gage's treatment lasted some 11 weeks, and during it there were minimal signs that his behavior had changed. He seems to have taken at least a further 6 months to recover, and there are no reports of any untoward consequences from that time or from when Henry Jacob Bigelow saw him in Boston 5 months later again. In 1868, Harlow gave a very condensed account of Gage's postaccident years that included about 200 words summarizing the main psychological changes.

A. The Treatment, 1848

Indeed there was business aplenty for Dr. Williams. That was so despite the myths that have Gage recovering with little or no treatment, sometimes with his having the tamping iron in his skull for the rest of his life, or walking several miles to a doctor's office to have it removed. Although Williams did not see the entry wound under the cheekbone until Phineas pointed it out, he could see the inverted funnel shape of the wound on the top of his head even before alighting from his carriage. Gage's major symptoms were profuse hemorrhaging with frequent vomiting of the blood and brain tissue that had drained into his stomach. The "deep burns" on his face, hands, and arms were of less significance.

Harlow arrived at about 6:00 PM and helped Gage walk up the stairs to his room, where he and Williams had the scalp shaved and cleaned the wounds. Harlow removed three small pieces of bone and examined the wound with his fingers, eventually joining the right index finger, which he had entered from the top of the skull, to the left entered through the cheek. So assuring himself that there were no bone fragments still inside

the skull, he and Williams proceeded to dress the wounds. They replaced the two large pieces of bone that had been detached or everted, brought the soft tissue edges together and held them there with adhesive straps, and covered the whole with a wet compress, a night cap, and roller, but they left the wound in the cheek open. They dressed the burns and left Phineas in the care of attendants who had been instructed to keep him in a semirecumbent position with his head elevated.

Harlow visited three times a day to change the dressings and soon had to treat an inflammation (i.e., infection). He based his treatment on the conventional antiphlogistic regimen, rest, and laxatives, prescribing the latter very moderately, but combined them with remedies from the stimulant regimen, probably brandy and milk. Apart from two short episodes of delirium associated with the infection, Gage was quite rational. Soon after the second episode, 11 days after the accident and just as Phineas seemed to be recovering, the fungi that had been sprouting from the wound for 5 days grew much worse. An abscess probably communicating with the left ventricle had formed, and, 14 days after the accident, Harlow was forced to treat Gage more energetically by cutting the protruding fungi away, applying caustic to the rest, and draining the abscess. After remaining semicomatose for about 10 days, Gage then began such steady progress that he was able to walk about the inn and town 56 days after the accident.

Two weeks later, during a short period when Harlow was away from Cavendish, Phineas disobeyed Harlow's (and his attendants') instructions and planned his return to Lebanon. His expedition to the local store, part of this plan, was in cold, wet weather and gave him a chill and such a fever that Harlow again had to resort to energetic treatment. This time purgatives and emetics were administered freely, and he was bled of some 475 ml of blood. Within 3 days Gage had recovered, and was well enough a week later, on November 25 only 73 days after the accident, to be taken home, although in a close carriage.

Harlow completed the first of his two papers on the case 2 days later, on November 27, and he sent it off as a Letter to the Editor of the *Boston Medical and Surgical Journal*, in which it was published on December 13. Much of the paper was based on his daily case notes, from which it is clear that apart from the episodes of delirium associated with the infection, Gage had been substantially rational throughout. Three of Harlow's entries are especially worth noting, however: Phineas had been unable to estimate size or money accurately and would not take $1,000 for a few pebbles; he was very childish; and his recovery was dependent on his being controlled. Harlow concluded by opining that the case would be of interest to "the enlightened physiologist and intellectual philosopher" and foreshadowed a future communication on "the mental manifestations."

B. The Real Gage, 1849–1851

After examining Phineas in Lebanon on January 3, 1849, and again when he came to Cavendish in April that year, Harlow said he was "inclined to say that he has recovered" physically. Phineas told Harlow that he had applied "for his situation as foreman," an intention he also foreshadowed to someone else a few weeks earlier in March. However, in August, J. B. S. Jackson learned from the family that Phineas had not been capable of more than half a day's farm work until May or June. Jackson did not see Gage then as he was away trying to regain his railroad job. And although Phineas seems to have sent his tamping iron to Henry Jacob Bigelow in May 1849, he does not seem to have been well enough to visit Boston and be examined by Bigelow until November. There is also some evidence that he was still physically weak as late as April 1850.

Almost all we know about the marked psychological changes caused by the accident comes from Harlow's 1868 summary. Gage never regained his job as foreman. Twenty years after the accident Harlow explained that his contractors "considered the change in his mind so marked that they could not give him his place again." In about 160 words, Harlow set out the basis for their decision:

> *The equilibrium or balance, so to speak, between his intellectual faculties and his animal propensities, seems to have been destroyed. He is fitful, irreverent, indulging at times in the grossest profanity (which was not previously his custom), manifesting but little deference for his fellows, impatient of restraint or advice when it conflicts with his desires, at times pertinaciously obstinate, yet capricious and vacillating, devising many plans of future operation, which are no sooner arranged than they are abandoned in turn for others appearing more feasible. A child in his intellectual capacity and manifestations, he has the animal passions of a strong man. Previous to his injury, although untrained in the schools, he possessed a well-balanced mind, and was looked upon by those*

who knew him as a shrewd, smart business man, very energetic and persistent in executing all his plans of operation. In this regard his mind was radically changed, so decidedly that his friends and acquaintances said he was "no longer Gage."

Some of the minor ominous changes that Harlow had mentioned in passing in 1848 seemed to have become permanent.

From Harlow we learn that Gage traveled around the larger New England cities, where he exhibited himself and his tamping iron, and spent some time as an exhibit with P. T. Barnum's American Museum in New York. Harlow also tells us that Phineas worked for Jonathan Currier for nearly 1.5 years until August 1852, after which Gage left for Chile. Gage could not, therefore, have begun work for Currier before the beginning of 1850, and that in turn means that his travels and self-exhibition could not have lasted more than 1.5 years, even if they began in mid-1849. We do not know exactly what he did during his period of travel because there seems to be no record of anyone seeing him. On the other hand, we do know that when Phineas worked for Currier it was in the livery stable associated with his Dartmouth Inn in Hanover, New Hampshire. Currier also ran a coach service, and it may be that Gage learned to drive coaches there. Certainly when he left Currier to go to South America it was with a man who intended to found a coach line at Valparaiso. Phineas was engaged to look after the horses, and he did drive coaches there.

C. The Real Gage, 1852–1860

After a period of 6 years in South America, Phineas' health began to fail and he had a long but unspecified illness. He therefore returned to the United States, now to San Francisco, where he lived with his mother, sister, and brother-in-law. By then he had acquired some nieces and nephews whom he used to entertain, his mother told Harlow, with

the most fabulous recitals of his feats and hair-breadth escapes, without any foundation except in his fancy. He conceived a great fondness for pets and souvenirs, especially for children, horses and dogs—only exceeded by his attachment for his tamping iron, which was his constant companion during the remainder of his life

When he regained his health, he began laboring work on a farm in Santa Clara County, south of San Francisco, and worked there until he had his first epileptic convulsion in February 1860.

Phineas then became unsettled and moved around from farm to farm, each time becoming dissatisfied with his employer. On May 18 he returned to his mother's, where, on May 20, he had a severe convulsion. It heralded the end. After a series of increasingly severe seizures, Phineas died at 11 PM on May 21, 1860. No death certificate has been found, but the funeral director's record gives the cause of death as "epilepsy." Harlow calculated that Phineas had survived "twelve years, six months, and eight days" after his accident, a degree of accuracy marred only by the fact that Harlow had been told that the year of death was 1861. We have known only since 1986, when the author published the correction, that 1860 is the correct date. Gage had, therefore, survived 11.5 years.

Harlow does not seem not to have learned of Phineas' death until some time in 1866. He then corresponded with Gage's mother and brother-in-law, eventually persuading them to allow an exhumation so that the skull could be removed for study. No date has been found for the exhumation, but it seems to have taken place in early December 1867, and Phineas' brother-in-law seems to have taken the skull immediately to Harlow, then practicing in Woburn, Massachusetts, where it arrived in 1868. Harlow had photographs made of the skull and tamping iron (Fig. 1a–c), and the woodcuts prepared from them, which he used to illustrate his second paper on Gage presented to the Annual Meeting of the Massachusetts Medical Society on June 3, 1868. It included, for the first time, the full, even dramatic, account of the changes in Phineas' behavior. At the conclusion of his paper, he presented the skull and tamping iron to the Warren Museum.

D. The Mythical Gage, 1849–1860

The myths about Gage tell a very different story. Either because he cannot hold a job down or because he does not want to work, Phineas becomes a vagrant who drifts around the United States, and sometimes South America, eking out a living as a fairground or circus attraction. The fanciful accompaniments to this story include Gage losing his ability to make and carry out plans, his becoming impossible to work with, his turning into an arrogant bully who flies into rages and loses his temper easily, his becoming a psychopath who cannot be trusted to honor his promises, his becoming sexually promiscuous, and his degenerating into a boastful alcoholic who dies of drink.

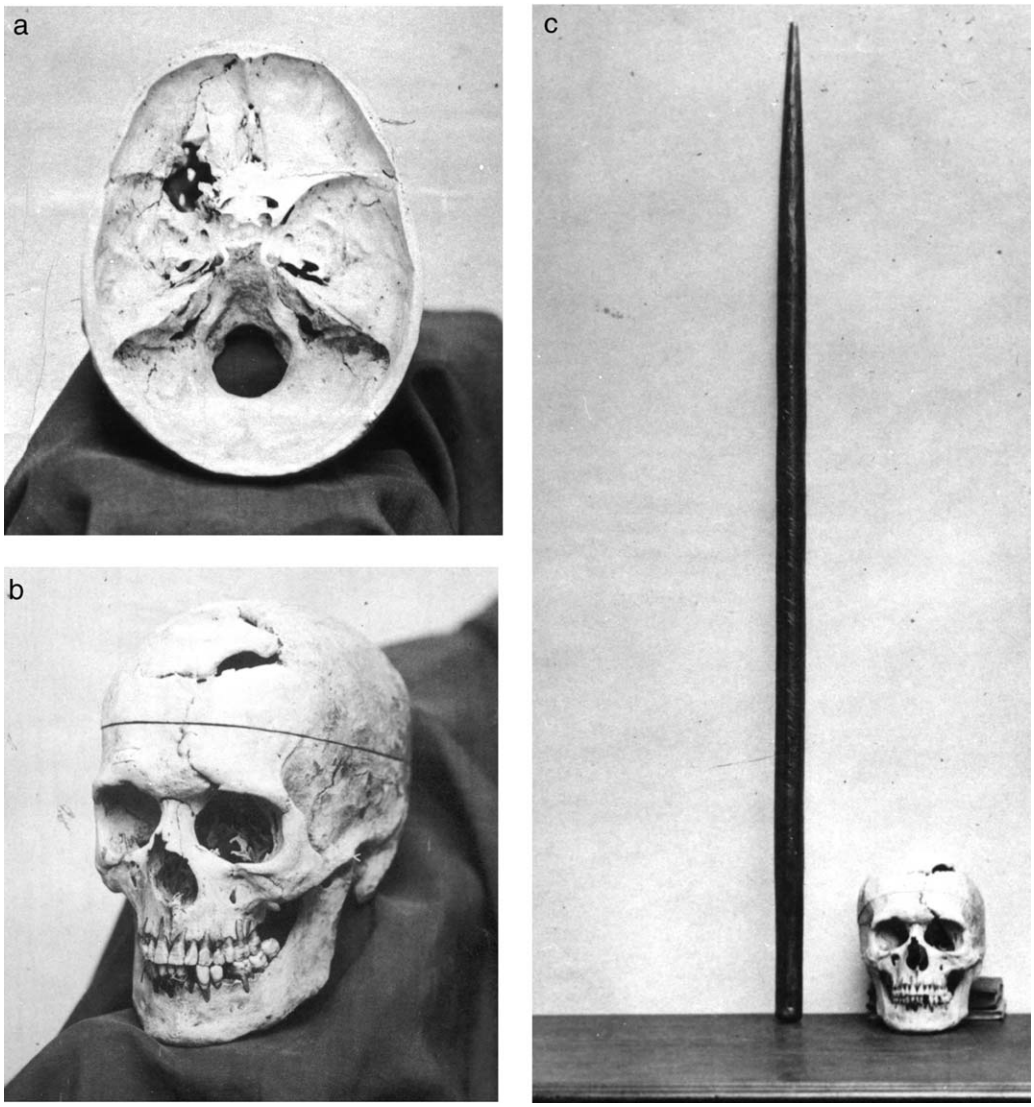

Figure 1 S. Webster Wyman's 1868 photographs of Gage's skull taken for Harlow: (a) base, (b) front left, and (c) in relation to the tamping iron. From the Glennon Archives, Woburn Public Library, Woburn, MA, reproduced by permission of the Trustees of the Library.

Many of the myths are based on a simple lack of knowledge of the primary reports, and many writers appear to have been content to parrot what they had read in versions far removed from the originals. Without the sources, it is not possible to calculate that the maximum time during which Phineas wandered could not have been more than 18 months, but the myth makers have him traveling over whole time of his survival. Similarly, unable to appreciate that Gage probably worked at the one occupation for just two employers during 7 of his 11.5 postaccident survival years, they have him drifting from job to job. And, without the sources, it is the popular memory of P. T. Barnum as the proprietor of a circus that surfaces to interpret Gage's time with him as traveling with Barnum's Circus rather than being in his stationary Museum in the city of New York.

Some parts of the myths do have a basis in fact, but others do not. One wonders, for example, where a Gage who sells his skeleton to two different medical schools, cash in advance, could come from. Where there are facts, they are sometimes not facts about Phineas. Thus, we know nothing about Phineas' sexual behavior, but we do know something about the effects of frontal lobotomy and frontal damage on that behavior in others, and it is that which matches the

Gage of myth. Similarly, none of the primary sources mention Gage's drinking. His reputation as a drunkard seems to have come from a coupling of a parallel some neurosurgeons drew between the euphorias produced by alcohol and frontal lobectomies with some gossip in the Boston medical community that commenced years after Gage's death. Those parts having some connection with Phineas are gross exaggerations of the real Gage. For example, his supposed psychopathic lying seems to be based on the "fabulous recitals" with which he entertained his nephews and nieces.

It must be remembered that, at the time of this writing (February 2002), only four records about Phineas Gage by contemporaneous authors survive. Anything about him not documented in sources as trustworthy as these must be fabrication.

III. THE DAMAGE TO GAGE'S SKULL AND BRAIN

There has always been some debate about the trajectory of the tamping iron through Phineas Gage's skull. In 1848 and the 15 years that followed that debate was fairly academic, but in the 1860s and 1870s it acquired greater significance because definite psychological functions were then assigned to or localized in the brain. From the passage of the iron through the skull, it was hoped to deduce which parts of Gage's brain had been damaged. It was also not until then that it became known in medical circles, although not widely, that his behavior had changed.

A. The Trajectory of the Tamping Iron

The tamping iron caused damage in three places: the area under the zygomatic arch, the base of the skull where it had entered behind the eye, and at the top of the head where it had emerged. Two things came to be important. First, how far forward or behind the junction of the coronal and sagittal sutures had it emerged? The answer would determine the extent to which the damage to Gage's brain was confined to the frontal areas. Second, how far to the left of the midline of the base of the skull had it entered and did it stay left of the midline at the top of the skull when it emerged? This would determine the extent to which the left and/or the right frontal lobes were damaged.

On the top of the skull the bony damage was extensive. There is an area of total bone destruction, roughly triangular in shape about 2.0 in. wide and 4.0 in. in circumference (D in Fig. 2). It is flanked by two semidetached flaps, the one from the frontal bone (B) being a rough quadrilateral about 2.0 in. wide at the widest point and 2.5 in. long and the one behind it about 2.0 in. wide and 1–1.5 in long (C). Williams had noticed their eversion even before alighting from his carriage. Together with the two areas of total destruction (A and D) these two flaps constitute an area of total damage about 2.0 in. by 5.0–6.0 in. Thus, there is not a *point* of emergence; rather, there is a large and irregular *area* of damage within which that point lies (Figs. 3 and 4).

Although the damaged area under the zygomatic arch was circumscribed, it was not at all clear where the iron had penetrated the base of the skull behind the eye. In 1848 Harlow could, naturally, only speculate about the locus and extent of that damage, and Bigelow had the same problem. When he drilled holes in a skull to show that the tamping iron could pass completely through it, he seems to have worked backward from where he estimated it had come out. His judgment of one-third of the exit to lie to the right of the midline on the top of the skull then placed the entry in the base well to the left of the midline. When Harlow examined Gage's skull in 1868, it was clear that the area of basal damage was very irregular and

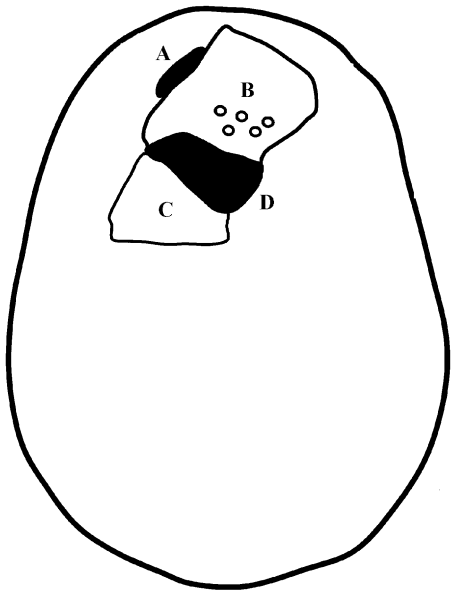

Figure 2 Gage's skull showing approximate dimensions of areas of loss and damage and the Damasio exit points (A) Left frontal (total loss) 2.6-in. circumference; (B) frontal flap (partly reunited) 2.0 × 2.5 in.; (C) rear flap (reunited) 2 × 1.5 × 1.0 in.; (D) top of skull (total loss) about 2.0 in wide and 4.0 in. in circumference. Circles indicate Damasio viable exit points.

not much bigger than the diameter of the tamping iron at its largest point. But it was bigger, and even after healing its major axes were about 1 in. wide and 2 in. long (Fig. 1a). Harlow concluded that the iron had entered closer than had Bigelow, about 1.25 in. to the left of the midline, but Jackson had placed it even closer, only 1 in. away.

A "true" entry point could be at a number of different places along the axes of the damaged area. This indeterminacy has two consequences: where the entry is placed along the now 2 in. axis affects the location of the exit point on the top of the skull relative to the coronal suture. If the trajectory were vertical, the further forward the entry, the further forward the exit point, and vice versa. Similarly, side to side variation along the now 1 in. axis affects the left–right placement of the exit point. The more the entry is to the left of the midline of the base, the more the exit will be to the right of the midline on the top of the skull, and vice versa.

In 1848, Harlow thought the iron had emerged in the midline and at the junction. Edward Elisha Phelps, Professor of the Theory and Practice of Physik and Pathological Anatomy at Dartmouth College and apart from Harlow and Bigelow the only person known to have examined the live Gage, thought it came out 0.5 in to the front and 1.0 in to the left of the midline. Bigelow, as we have seen, had it emerging in front of the junction but somewhat to the right. In 1868, after examining Gage's skull, Harlow still maintained that it had emerged in the midline but now only "near" to the junction. Jackson, who also used the skull, placed it in front and noted that the area of bone loss crossed the midline, but he was vague about the emergence of the iron in relation to the midline.

B. The Damage to Gage's Brain

None of the preceding investigators explicitly discussed the trajectory in relation to the debate over localization, which, apart from earlier inconclusive arguments over Franz Josef Gall's organology (phrenology), began in earnest in 1861. In that year, Paul Broca, a French surgeon, very tentatively localized a language function in the frontal areas, and by 1864 he had placed it firmly in the third left frontal convolution. That location was to be strengthened with David Ferrier's work, which followed Fritsch's and Hitzig's in demonstrating that limb movements could be elicited by electrical stimulation of precisely delimited areas in the brain on the side opposite the limb. By 1876 Ferrier had shown that areas controlling lip and mouth movements in the monkey's brain were adjacent to the homolog of the human language area and both were near those that controlled the limbs. Where Gage's tamping iron had emerged became important with Eugene Dupuy's claims in 1873 and 1877 that the pattern of damage contradicted both Broca's clinical and Ferrier's experimental data. Dupuy believed that the left-sided trajectory was posterior enough to destroy the language and motor areas, but Gage, of course, had no motor or language impairments.

At that time, Ferrier had no detailed knowledge of Gage's case and wrote to Henry Pickering Bowditch of Harvard in 1877 asking him to examine the skull and help resolve the trajectory of the tamping iron. Bowditch sent Harlow's photographs and his 1868 paper, and Ferrier's analysis of them convinced him that the iron had emerged more frontally without damaging those areas. Ferrier concurred with Harlow that only the left frontal lobe had been damaged, and his opinion prevailed over Dupuy's. The matter essentially well rested there until the 1982 CT scans of

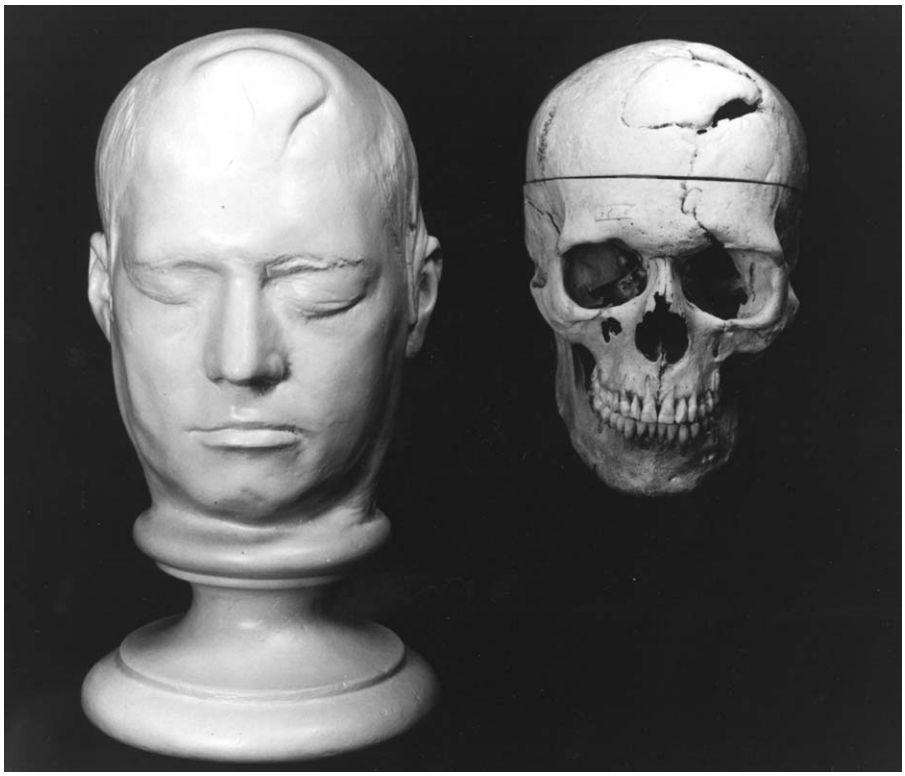

Figure 4 Frontal view Phineas Gage's life mask (probably made for Henry Jacob Bigelow in late 1849) and skull (body probably exhumed in late 1867). Reproduced by courtesy of the Warren Anatomical Museum, Harvard University.

H. Richard Tyler and Kenneth L. Tyler and the 1994 computer modeling of Hanna Damasio and her colleagues.

The Tylers' successive lateral and coronal (frontal) scans were made to determine the bony damage in the entry and exit areas. Imaginary lines joining the sides of the maximum openings at the top and base of the skull as viewed in coronal section defined a funnel shape, narrower at the bottom than at the top. If the funnel does set the limits of bony damage, most of it lies to the left of the midline. The Tylers could not determine precise entry and exit points, but they believed that Harlow was more likely to have been right about the entry and Bigelow about the exit encroaching over the midline. Most of the direct damage the tamping iron did to the brain was to the left anterior frontal lobe, part of the tip of the left temporal lobe, part of the anterior horn of the left lateral ventricle, the head of the caudate nucleus and the putamen, and the superior sagittal sinus. Some direct damage was also done to the right hemisphere, including parts of the right superior frontal and cingulate gyri. With the exception of right hemisphere involvement, their conclusion again is similar to Harlow's, and including the right-sided damage it is very similar to Bigelow's. However, the Tylers stressed that theirs was a minimal estimate of the damage to Gage's brain. Bony fragments being driven through the brain caused more damage, some tissue was lost during the vomiting caused by hemorrhaging, and more damage resulted from later infection.

Hanna Damasio and her group used measurements from Gage's real skull to create a computer model of it and estimate the trajectory of the tamping iron. They began on the top of the skull and confined themselves to what they called the area of bone loss—the area of total loss plus the reunited frontal flap—but they did not include the reunited posterior fragment. Half the diameter of the iron was used to set more precise boundaries to the area within which they tried to estimate its passage: no point could be closer to their margins than it. Within that area they located 15 possible exit points in addition to an undefined *a priori* most likely exit point. From each of these points they projected lines through the center of the area in the base of the skull to the area under and adjacent to the

zygomatic arch where the iron had first entered. There they again used half the diameter of the iron to limit their estimate of its point of entry. From the trajectories so produced, seven seemed anatomically possible, but they rejected two of these because they would have hit the front of the left lateral ventricle, damage they believed Gage would not have survived in the preantibiotic era.

Damasio's group then simulated the passage of the iron along these five trajectories through seven models of real brains closely matching a model of Gage's brain derived from the internal measurements of his skull and given an average position within it. Each simulation produced a similar pattern of damage in both frontal lobes, but it was more pronounced in the left: the anterior half of the orbital and the polar and anterior mesial frontal cortices and the anterior-most part of the anterior cingulate cortex.

Whether these modern methods have settled the pattern of bone and brain damage is doubtful. The Tylers claimed only to have established the maximum and minimum damage to the brain caused by the passage of the iron and pointed to three other factors (bone fragments, hemorrhage, infection) that must have added to that. The Damasio group did not search for trajectories in the rearward areas and rejected those that would have taken the iron through the area of total bone loss, and they settled on trajectories with "points" of emergence under the reunited but otherwise undamaged frontal flap itself (circles, Fig. 2). They also assumed that Gage could not have survived ventricular damage, but the likelihood of damage of that kind had surprised neither Harlow nor Bigelow.

C. The Relation between Gage's Brain and His Behavior

All of the methods used so far to estimate the damage to Gage's brain have been based on two fundamental assumptions. First, all assume that Gage's brain, or its model, lies in an average position relative to the bony landmarks of the skull. Yet it is known that the positions of real brains may vary by as much as 0.5 in from those markers. Second, all assume that there is little variation in the localization of functions in the brain. Yet it is also known that the same functions may be localized in somewhat different places in seemingly similar brains.

Suppose, however, that the brain damage could be estimated accurately. Would that estimate help us understand what functions localized there had been disturbed? Or which of Gage's functions? When the very limited information we have about Gage's postaccident behavior is contrasted with the even smaller amount we know about his preaccident characteristics, it is clear that both answers must be "No". There is another set of problems, however. Harlow noted some deficiency in the ability to judge size and the value of money, and Jackson recorded that the family believed Phineas had a memory defect; however, judging from his apparently long-term employment as a coach driver in a region notorious for its bad roads, high-level cognitive–motor skills may have survived. What can be inferred about the detail of Gage's postaccident cognitive functions is as uncertain as what can be inferred about the damage to his brain.

IV. GAGE AND LOCALIZATION

Four main factors make for complexity in the relation of the case of Phineas Gage to the debate over the psychological functions served by the brain. First, there were profound philosophical and possibly political differences between those supporting and those opposing any doctrine of localization. In the first half of the nineteenth century, admission that the mind was localized in the brain seemed to encourage a godless materialism. Second, there were differences, some legitimate, between medical innovators and the orthodox in evaluating Franz Josef Gall's organology. Were the faculties of the mind fractionated, as Gall argued, or did the brain operate as a whole, as Flourens' experiments seemed to indicate? Third, there was the effect of the 20-year interval between Harlow's first rather sanguine report and his 1868 account of the deleterious psychological effects of the damage. In the beginning the Gage case seemed to weigh against any doctrine of localization, but later there was little doubt of its general importance. Paradoxically, the fourth factor derived from that very significance: other than the limited sensory–motor physiology and psychology of the day, no explanatory framework existed within which the changes in Phineas' behavior could be placed.

A. Gage and Phrenology

Gall had postulated that the various nonmaterial faculties he required for explaining behavior were expressed through material organs localized in the brain under various bony prominences he believed he could detect on the skull. Near the junction of the

coronal and sagittal sutures he located the faculties of Benevolence and Veneration. Benevolence provided the individual's conscience and regulated such feelings as compassion and the moral sense, whereas Veneration, located posterior to it, regulated religious feelings and, at least in the eyes of some of Gall's followers, provided the basis for respecting others, especially those in authority. These feelings were well-developed or even exaggerated in those with large faculties, that is, with large prominences. In those in whom Benevolence and Veneration were underdeveloped, the character was malicious, vindictive, and ungrateful. Together with other anteriorly placed faculties, the two were also components of a system of Moral Sentiments that regulated the posteriorly located Animal Passions that humans shared with animals. These latter included the instincts of Love of Offspring, Propagation, Social Attachment, Self-defense, and Destructiveness.

There is evidence that Harlow accepted much of Gall's doctrine, probably in the form that Caspar Spurzheim had introduced to the United States. In 1848 he used the phrenological concept of nervobilious temperament to encompass the combination of great mental capacity and physical strength basic to Gage's character, and he used terms more common among the phrenologically inclined when he foreshadowed a future communication about those of Gage's "mental manifestations" that would be of interest to "the enlightened physiologist and intellectual philosopher." His drawing attention to the defect in Phineas' ability to value money is also consistent with damage to the Faculty of the Relation of Numbers that Gall located frontally. His 1868 description of Gage's mental operations being deficient in degree rather than in kind and his insistence that only the left lobe was damaged may reflect Gall's basic proposition that all of the faculties were localized equally in both hemispheres. Functions impaired through damage to one lobe were conducted by the other, although less efficiently.

Harlow himself did not explain the changes in Gage by invoking damage to Benevolence and Veneration. In early November 1848, an anonymous letter writer did mention that Veneration had been damaged but said nothing about the effects. In 1851, the editor of the *American Phrenological Journal* published the first description of the changes in Gage and explained them by damage to the two organs. In saying his information came from the best authority in Cavendish, he was very probably attributing them to Harlow himself. The description and phrenological explanation were part of a comment on Bigelow's report on Gage. Bigelow had seen Gage in Boston over a period of some weeks from late 1849 to early 1850, and not only did he say absolutely nothing about Gage's behavior having changed, he implied that there had only been an "inconsiderable disturbance of function." If we consider that Bigelow had also proposed that both frontal lobes had been damaged, his stance in this paper was as decidedly antiphrenological as his beliefs generally are known to have been.

B. Gage and Ferrier

In 1876, Ferrier had been unable to elicit responses by electrically stimulating the frontal areas of the exposed monkey brain, and ablation of the same areas did not seem to produce sensory or motor symptoms. Yet the behavior of the monkeys had changed. Even though they seemed as intelligent as monkeys with intact lobes, they were no longer curiously prying into everything around them but were either apathetic, dull, and dozing or restless, lacking purpose, and responding only to immediate sensations and impressions. The change was best summed up as a loss of the faculty of attentive and intelligent observation. Ferrier placed a hypothetical inhibitory–motor function in the frontal lobes that inhibited immediate motor responses to external stimulation until the most appropriate response could be selected from the pool of potential responses. He was otherwise unable to say what functions the lobes performed. He did not know then that Gage had changed and mentioned him, not because his behavior was like that of the monkeys, but simply because he had also survived similar frontal damage.

Estimation of the trajectory of the tamping iron was central to Ferrier's response to Dupuy's 1877 attack, and that task led him to Harlow's 1868 account of the change. In his *Gulstonian Lectures* of 1878, he now drew a parallel between the changes in the behavior of Gage and that of his monkeys: both had lost the ability to delay responses other than the one most appropriate to a given situation. This inhibitory–motor thesis had a very short life in Ferrier's own theorizing, being withdrawn between 1879 and 1886, but it lived on until some time after 1900 in discussions of the 'mental symptoms' that warranted surgery on the frontal lobes.

V. GAGE AND SURGERY FOR THE BRAIN AND PSYCHE

Brain surgery began almost as soon as the usefulness of localizing signs was recognized and safe, aseptic

operating techniques had been developed. In 1871 and 1876, respectively, Broca himself and William Macewen, the Scottish pioneer of brain surgery, apparently used aphasic symptoms to guide their intracranial operations. Bennett and Godlee, who performed the first operation for the removal of a tumor in the brain in 1885, specifically used localizing signs derived from Ferrier's experimental work and Hughlings Jackson's clinical deductions to plan theirs. Knowledge of Phineas Gage's case was important to the extension of brain surgery to the frontal lobes but not to psychosurgery itself.

A. Gage and Brain Surgery

In 1884, M. Allan Starr, an American neurologist, published the first major series of cases in which an attempt was made to relate symptoms to the site at which the brain was damaged or diseased. Gage figured prominently in Starr's considerations, as did Ferrier's inhibitory thesis (although not connected with his name), and he recommended that frontal lesions be considered when symptoms were present that indicated a lack of self-control: an inability to fix the attention, follow a train of thought, or conduct intellectual processes. In 1893, solely on the basis of such mental symptoms (inability to fix attention, dullness and slowness in thinking, difficulty in expressing ideas, and a general weakness and aversion to work), he and McBurney diagnosed and removed a frontal tumor. It is possible that Macewen had used, even earlier in 1879, what he took to be Gage-like symptoms of frontal impairment in planning a frontal operation. He seems to imply that it was mainly the mental symptoms shown by his patient (her obscured intelligence, slowness in comprehending, and lack of "mental vigour") that led him to explore the frontal lobes. There he found and successfully removed a tumor of the dura mater that had spread over two-thirds of the left frontal lobe.

Although some surgeons did follow Starr's recommendations, it soon became apparent there were major difficulties with them. Definite symptoms were, as Starr had himself noted, present in only about one-third of the cases, physicians were not trained to assess psychological changes, and there was wide variation about which mental symptoms indicated loss of self-control and inability to fix one's attention. There were also practical difficulties. Because they exerted their effects at places remote from their location, tumors localized using the signs were not always at the places indicated, and when they were, they were not always encapsulated enough for easy removal. Soon after the beginning of the twentieth century, Ferrier's thesis as understood by Starr and others ceased to be used diagnostically. In any case, various seemingly more reliable imaging techniques that became available at about that time displaced them.

B. Gage and Psychosurgery

In both popular and professional minds, Gage is firmly associated with the introduction of prefrontal lobotomy. However, apart from his being the main example of survival after frontal damage, there is no evidence that considerations of Gage's case played any part in the development of that form of psychosurgery or its precursors. That is, no one seems to have reasoned that the kind of disinhibited behavior produced accidentally in Gage would bring about benefit if deliberately induced in psychiatric patients.

Psychosurgery began in a small way toward the end of the nineteenth century with operations by Bennett (in collaboration with Gould) and Macewen to relieve psychiatric symptoms in otherwise essentially normal people. They surgically removed tissue and bone fragments that caused symptoms like visual and auditory symptoms. Gottlieb Burckhardt, who operated on psychiatric patients in 1888–1889, was more ambitious. He aimed to disconnect the sensory from the motor areas in the hope that violent behavior seemingly caused by sensory hallucinations then would not occur. In only one of his six cases did he venture into the frontal areas, and it seems to have been because he thought that the patient's ideas located there were the cause of his abnormal behavior. Neither he nor Emory Lanphear (who operated between 1891 and 1895) made any mention of Gage. What Ludwig Puusepp, the other psychosurgical pioneer, actually did and when are not clear, but the changes in Gage do not seem to have formed part of his rationale.

One of the main developments that made psychosurgery possible was the results of the radical resections conducted in the early 1920s, notably by Walter Dandy. He had concluded that, because most brain tumors were not encapsulated, the removal of that part of the brain in which they were located was indicated. The procedures he developed were successful and soon adopted by others, especially for the control of otherwise intractable epilepsy. By the early 1930s, when Egaz Moniz began planning his form of

psychosurgery, it was evident that life was not threatened by the removal of such large parts of the brain, nor did there seem to be any untoward psychological consequences.

The particular sources that Moniz drew on were his own confused ideas about brain function, the changes reported by Brickner in Joe A., the New York stockbroker who had had major bilateral frontal resections for a massive life-threatening tumor, and Moniz's selective and partial consideration of the experiments by Jacobsen and Fulton on the effects of frontal ablation on learning in chimpanzees. Moniz believed that morbid ideas, as he called them, were due to a fixed pattern of neuronal activity and that surgery altered the pattern by disconnecting the neurons. For no apparent reason, he associated psychological activity with the frontal lobes and decided to operate there. Gage did not come into his rationale.

It is true that Walter Freeman included Gage among the topics he mentioned when he spoke to a group of newspaper reporters at a press conference immediately prior to presenting the results of his and Watts' first lobotomies. But his unpublished account of the conference shows that this was part of an impromptu smokescreen to put one of the reporters off the track of a story he had already given another reporter. He said merely that Gage had survived with mental symptoms, which he did not specify, and later made nothing more of it. Freeman did publish a full account of Gage's case in his first book with Watts but made no connection between it and the new operation other than Gage surviving his injury. Rather like the newspaper reporters, none of whom mentioned Gage in their stories, Freeman did not mention the case at all in the second edition of his work.

If Gage is mentioned at all in various symposia devoted to the effects of frontal surgery, particularly those of the (American) Association for Research in Nervous and Mental Disease, it is only in a minor way, usually to reject him as providing a relevant behavioral standard for comparison.

VI. STORIES ABOUT PHINEAS GAGE, 1848–2002

Almost from the beginning, many of the stories about Phineas have included considerable inaccuracies and distortions. As noted earlier, some errors are due to ignorance. Few U.S. libraries hold either the *Publications of the Massachusetts Medical Society* or the pamphlet version of Harlow's 1868 paper, the key follow-up report, and many of the condensed versions in medical journals did not report the changes. Other distortions and inaccuracies are the result of theoretical bias sometimes combined with ignorance.

A. The Essentially Unchanged Phineas

One theoretical position, perhaps the main one, responsible for the stories that Phineas had not been changed by the accident was that of the antilocalizationists, especially the antiphrenologists. The most extreme instance is Bigelow's story. Having read Harlow's first paper, he would at least have known that Phineas had been of temperate habits, and having seen Phineas himself over some weeks, must have at least noticed his profanity. Yet he implied that the change was inconsiderable.

The same theoretical position is behind Dalton's denial of change. Dalton published what appears to be the first discussion in the physiological literature of Gage in relation to localization in his 1859 textbook, placing it between his discussion on the insensibility of the brain to stimulation, which he coupled with an account of Flourens' experiments, and an attack on Gall's organology. In that no account of the changes had been published in the medical literature at that point, this may not have been unreasonable, but what he did in his edition of 1875 was inexcusable. There he drew on Jackson's entry in the Warren Museum *Catalogue* but omitted Jackson's summary of the changes, so that this later version again presented an essentially unchanged Gage.

An even more deliberate antilocalization bias seems to be responsible for a similarly inexcusable treatment of the unchanged Gage in editions of Kirkes's famous textbook. Before 1896 it contained nothing at all about Gage, usually finishing its section on the functions of the frontal lobes with a statement to the effect that they had none. In 1896, Gage was mentioned in the context of frontal ablations having no appreciable effect, and, despite the editors having had their attention drawn to this error, they refused to make any changes. In 1909, when they did give in, they said merely that a recent examination of the case records showed that Phineas had become useless as a supervisor, and they essentially retained that account as late as 1937.

The dominant sensory–motor physiology and psychology that had displaced phrenology by the middle of the nineteenth century provided another theoretical basis for the stories of an unchanged Phineas. Basically, what that theoretical orientation encompassed were losses of sensation and movement and their

psychological consequences. Complex behaviors like those shown by a changed Phineas, or even a normal one, were not. The problem is seen most clearly in Ferrier's short-lived attribution of an inhibitory function to the frontal lobes. He really had no evidence: the facts were "negative" and it was "not actually motor." The very term inhibitory-motor mirrors sensory–motor (which in turn derives from Marshall Hall's earlier excito-motory), and its function of delaying responses could be and was applied to anything that, not being sensory–motor, had to be "mental." Thus, Starr could lump together as "mental symptoms" showing a lack of self-control, Gage, whom he described as having become emotional, easily excitable, and irritable, and another patient, whom he described as stupid and listless. Similarly, Walter Dandy, the pioneer American neurosurgeon, in commenting on what he saw as the psychological changes following radical lobe resection, could only call them "little peculiarities of mental origin."

B. The Changed Gage as a Theoretical Prop

Some of the distortions in the stories about Phineas have come about because their tellers use Phineas to exemplify one or other aspect of their theories of brain function. Luria and Treisman provide the least distorted of these kinds of stories. Luria, who gave the frontal lobes an important role in controlling cognitive processes, describes Gage in almost completely cognitive terms. Gage's deficiency is that he lacks initiative and the ability to critically appraise internally programmed action. Treisman invokes a deficiency of long-term planning in the context of social relations and interactions and turns Phineas into a drunkard.

Bloom, Lazerson, and Hofstadter provide a more distorted story when they use Gage to exemplify their theory that the frontal lobes control the emotions generated in the limbic system. As portrayed in the film made to accompany their book, their Phineas suffers from a lack of balance between his emotions and his intellectual propensities. He is almost the kind of mumbling madman once seen on the stage who sobs with self-pity and hallucinates almost as readily as he flies into fits of aggressive rage. Weisfeld has it that Gage's problems were primarily because he was unable to appreciate the effects of his behavior on others. He links Gage to observations that monkeys with orbitofrontal damage exhibit less appropriate reactions to the ranks of their cagemates and lose their positions in their hierarchies as a consequence, and he presumes that Gage suffered the same kind of damage. However, whereas the operated monkeys become less aggressive, most other storytellers have Phineas becoming more aggressive.

VII. CONCLUSIONS

What can be learned from the case of Phineas Gage? Four things stand out, the first two about Gage himself and the last two about historical figures like him in general (and not only in the neurosciences). We can say about Gage that the uncertainties about which parts of his brain were damaged or destroyed seem destined to remain, and that the chance that we will learn much more about his behavior and history is so slight that the limited comparison we can make between his pre- and postaccident behavior also does not seem likely to change. Of historical figures like him, we can say that his case emphasizes the importance of accurate description and the need to disentangle fact from theoretical preconception almost as much as it points to the need to return to the original sources. On these last two points, it is David Ferrier who provides us with the guide we need. In explaining to Bowditch why he wanted information about Gage he said, "In investigating the reports on diseases and injuries of the brain I am constantly being amazed at the inexactitude and distortion to which they are subjected by men who have some pet theory to support."

What we know about Phineas Gage provides too meager a foundation on which to base hypotheses of the relationship between the frontal lobes and their psychological functions. Is he now fit to be remembered only by such things as the plaque on Cavendish Town Green unveiled on September 13, 1998, to commemorate the 150th anniversary of his accident? I do not believe so. Phineas Gage's lasting importance is because his was the first case to point to a relation between brain and personality functions. All of the reports we have about Gage are reproduced as facsimiles in *An Odd Kind of Fame: Stories of Phineas Gage*.
