autoregulation The physiological process by which blood vessels change caliber to maintain constant cerebral blood flow over a wide range of cerebral perfusion pressures.

infarction Permanent tissue damage and death of all cellular elements (neurons, glia, and vessels) due to prolonged or severe ischemia.

ischemia Impairment of tissue function due to a reduction in blood supply relative to metabolic demand.

neuroprotection Strategies that ameliorate the biochemical and metabolic derangements induced by cerebral ischemia, thus limiting delayed neuronal injury.

penumbra The area surrounding the dense core of irreversibly damaged cells that has preserved ionic homeostasis and reduced neuronal electrical activity but that is capable of recovery.

transient ischemic attack Abrupt focal loss of neurologic function caused by reduction in blood flow that persists less than 24 hr and clears without residual disability.

vasospasm Blood vessel constriction in response to irritative stimuli.

Stroke is the third leading cause of death in the United States and is responsible for more hospitalizations than any other neurological disorder in adults. The term "stroke" encompasses three vascular disorders: (i) cerebral ischemia, which is due to interference with normal brain circulation; (ii) intracerebral hemorrhage, which results from blood vessel rupture within the brain substance; and (iii) subarachnoid hemorrhage, which results from bleeding of surface arteries located in the space between the pia and arachnoid membranes. This article focuses on the pathophysiology, clinical features, and management of each of the stroke categories. Since an understanding of these concepts requires knowledge of normal cerebral circulation and metabolism, cerebrovascular anatomy and physiology is reviewed first.

I. CEREBROVASCULAR ANATOMY

The brain receives its blood supply from two pairs of arteries: the right and left internal carotid arteries, which supply the anterior two-thirds of the corresponding cerebral hemisphere, and the right and left vertebral arteries, which converge to form the basilar artery and supply the brain stem and posterior portion of the hemispheres. The two internal carotid arteries and the basilar artery unite via anastomotic channels at the base of the brain to form the circle of Willis.

The internal carotid artery originates in the neck from the bifurcation of the common carotid arteries into internal and external branches. Each internal carotid artery enters the skull through the ipsilateral foramen lacerum, traverses the petrous bone and cavernous sinus, and gives off a major branch to the eye, the ophthalmic artery, before dividing lateral to the optic chiasm into its two terminal branches, the anterior cerebral artery and the middle cerebral artery (Fig. 1). The anterior cerebral artery passes rostromedially and approaches the corresponding artery of the opposite side with which it connects via the anterior communicating artery. It then gives off branches that supply the inferior surface of the frontal lobe, the

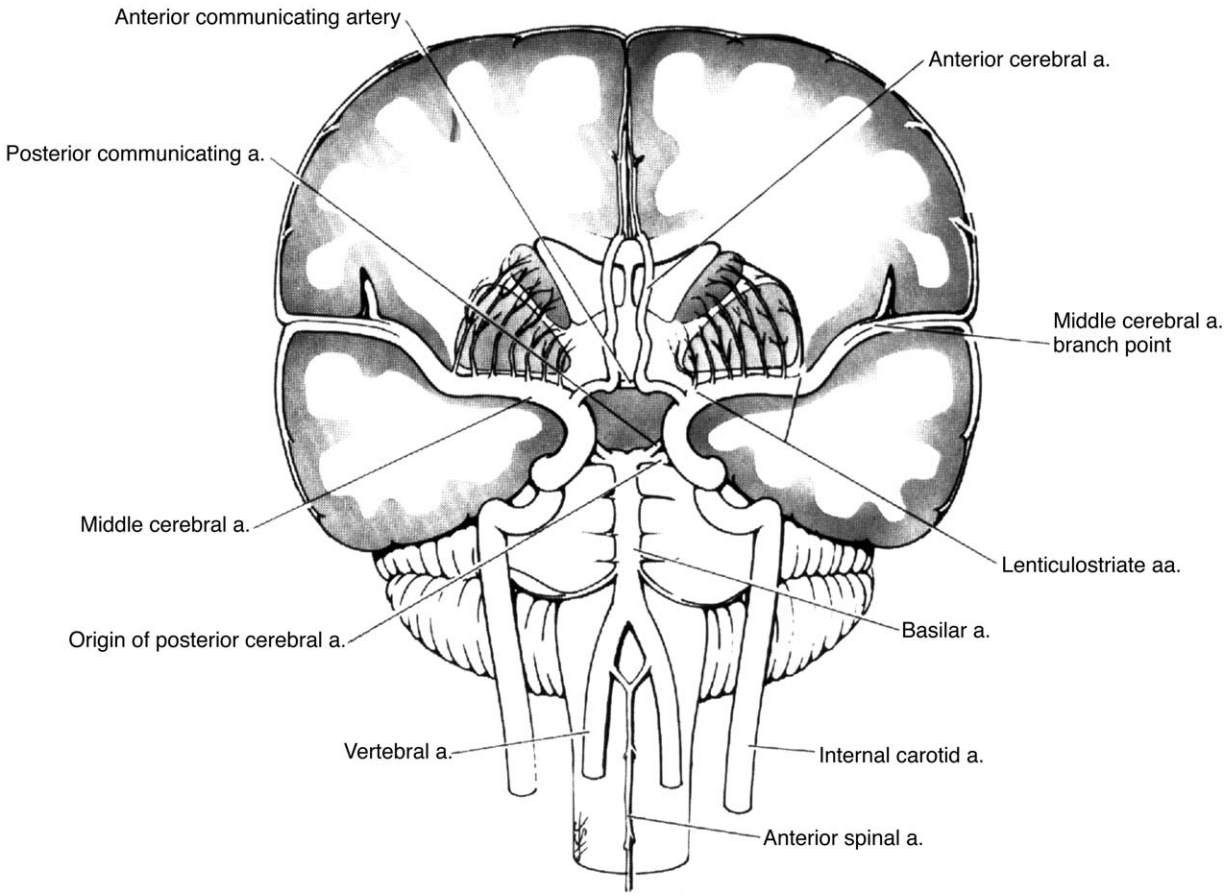

Figure 1 Coronal section through the front of the brain with the anterior portions of the frontal and temporal lobes removed. The major arteries of the anterior (internal carotid, middle, and anterior cerebral arteries) and posterior circulation as well as their interconnecting vessels (anterior and posterior communicating arteries) at the circle of Willis can be seen [from Powers, W. J. (1989). Stroke. In *Neurobiology of Disease* (A. L. Pearlman and R. C. Collins, Eds.), Copyright © 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.].

interhemispheric fissure, and the medial surface of the parietal lobe, thus supplying primary motor and sensory cortex for the contralateral lower extremity (Fig. 2). The middle cerebral artery travels laterally, immediately giving off a series of small lenticulostriate arteries, which supply the deep hemispheric gray and white matter that include the basal ganglia and internal capsule. It then continues laterally into the Sylvian fissure, where it divides in a fan-like fashion to carry blood to the lateral surface of the frontal, parietal, and temporal lobes (Fig. 3), thus supplying primary motor and sensory cortex (except for the lower extremity), the speech areas in the dominant hemisphere, and motor, sensory, and visual fiber tracts.

The vertebral arteries arise from the subclavian arteries in the neck, traverse the foramina of the cervical vertebrae, and enter the skull via the foramen magnum. They then course along the anteroleteral surface of the medulla, giving off branches that supply the medulla and inferior cerebellum before joining together at the pontomedullary junction to form the basilar artery (Fig. 1). The basilar artery, which lies on the ventral surface of the brain stem, supplies the pons, cerebellum, and midbrain and then bifurcates into the posterior cerebral arteries, which supply the posterolateral midbrain, thalami, and medial temporal and occipital lobes (Fig. 2).

Three collateral pathways can supply blood to ischemic brain in the event of compromise of one of the major vessels. The most important of these, the circle of Willis, allows for communication between all major vascular trees, thus serving as a potential bypass in the event of vascular compromise in the neck. Significant anatomic variation exists in the circle of

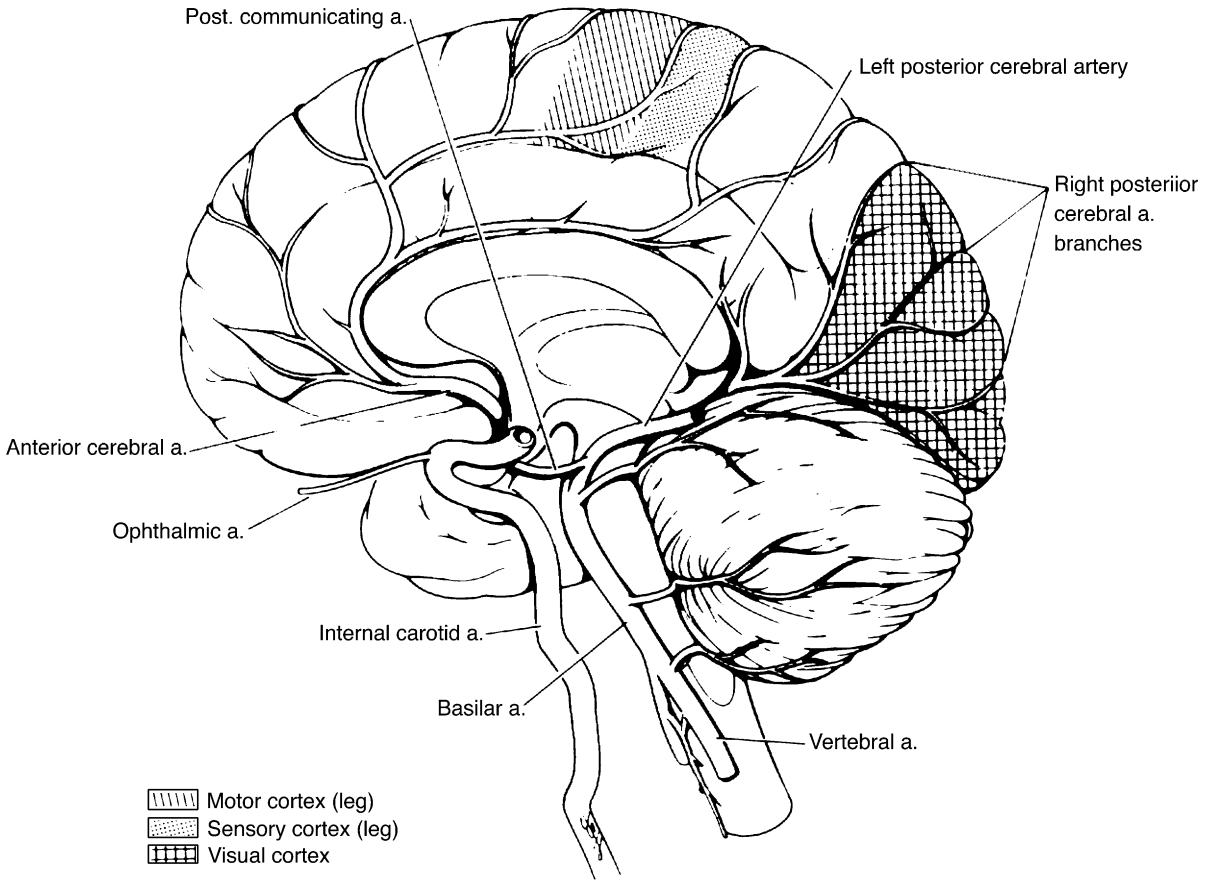

Figure 2 Saggital section through the corpus collosum revealing the medial aspect of the hemisphere. The anterior cerebral artery can be seen coming off the internal carotid artery and running in the interhemispheric fissure along frontal and parietal cortex. The posterior cerebral artery can be seen coming off the top of the basilar artery and traveling posteriorally to the occipital cortex. Also note the circumferential branches of the basilar artery supplying the lateral aspect of the brain stem and cerebellum [from Powers, W. J. (1989). Stroke. In *Neurobiology of Disease* (A. L. Pearlman and R. C. Collins, Eds.), Copyright © 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.].

Willis, however, and a communicating artery may be absent or inadequate in up to one-third of people. Another collateral pathway involves communication between the extracranial and intracranial circulations. Anastomoses between branches of the external carotid artery supplying the orbit and branches of the ophthalmic artery link the external carotid artery with the internal carotid artery. Anastomoses between branches of the external carotid artery supplying the posterior scalp muscles and branches of the vertebral artery link the carotid and vertebral systems. Finally, end-to-end arterial anastomoses of the superficial cortical branches of the anterior, middle, and posterior cerebral arteries form the border zone or "watershed" areas between vascular territories (Fig. 3).

The venous drainage of the brain consists of superficial veins draining the surface of the hemispheres into the superior sagittal sinus and deep veins draining the deep structures into the straight sinus. These sinuses then converge at the torcular, where blood flows into the right and left lateral sinuses and finally through the jugular foramina to form the internal jugular veins in the neck (Fig. 4). Collateral pathways exist both within and between the superficial and deep systems.

II. CEREBROVASCULAR PHYSIOLOGY

A. Cerebral Blood Flow and Metabolism

Under normal resting conditions, the adult human brain receives about 20% of the cardiac output, resulting in an average cerebral blood flow (CBF) of $50\,\mathrm{ml}\,100\,\mathrm{g}^{-1}\,\mathrm{min}^{-1}$. Flow to gray matter is

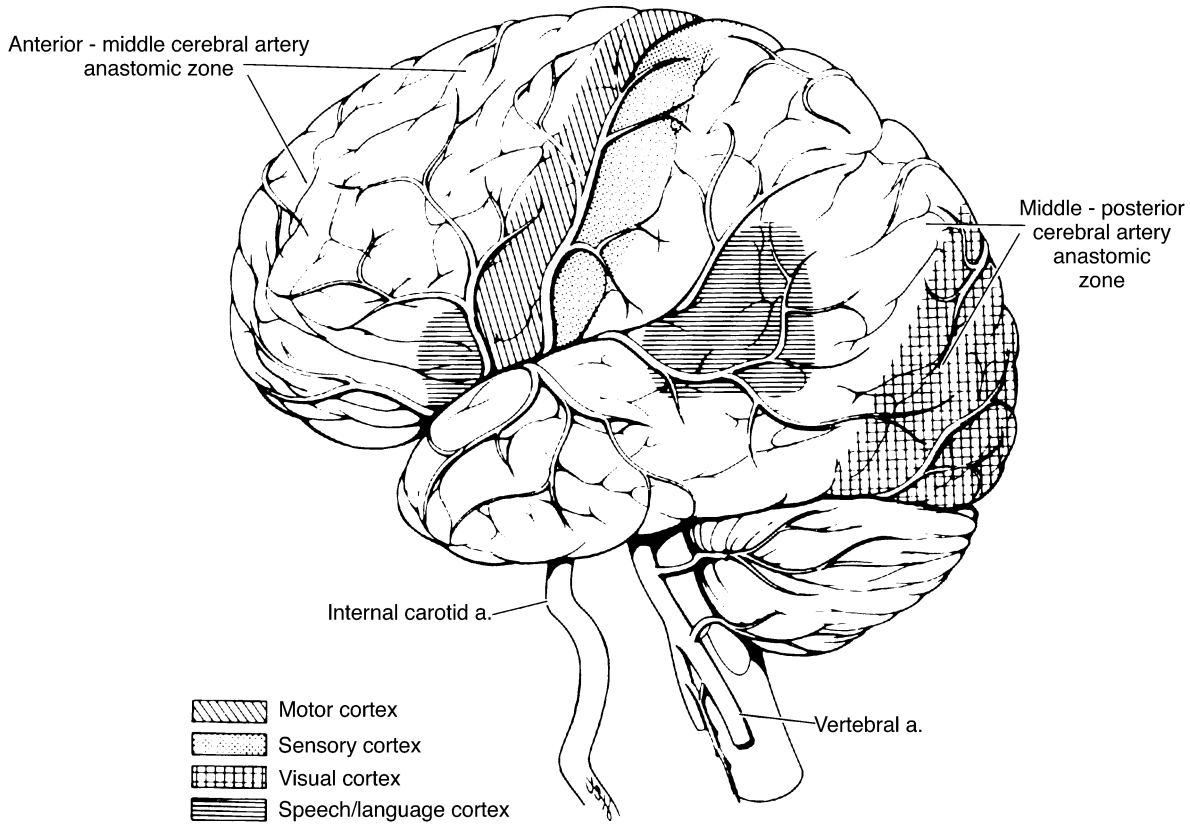

Figure 3 Lateral view of the brain showing the middle cerebral artery emerging from the Sylvian fissure and supplying branches to the lateral aspects of the frontal, parietal, and temporal lobes. Also shown are the watershed or border zone areas between the anterior and middle cerebral arteries and between the middle and posterior cerebral arteries [from Powers, W. J. (1989). Stroke. In *Neurobiology of Disease* (A. L. Pearlman and R. C. Collins, Eds.), Copyright © 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.].

approximately four times that of white matter, reflecting the higher metabolic rate and oxygen requirement of neurons. The brain relies almost entirely on oxidative metabolism of glucose for its energy needs in the resting state. Since it stores very little glucose, the brain is critically dependent on a continuous supply of blood-borne glucose and oxygen to maintain its functional integrity. The resting brain consumes approximately $3.5\,\text{ml}\,100\,\text{g}^{-1}\,\text{min}^{-1}$ of oxygen, which represents about one-forth of total body consumption, and approximately $5\,\mu\text{g}\,100\,\text{g}^{-1}\,\text{min}^{-1}$ of glucose, 90% of which is metabolized to carbon dioxide and water.

CBF is regulated by the relationship between cerebral perfusion pressure (CPP) and cerebrovascular resistance (CVR) by the equation

$$\text{CBF} = \frac{\text{CPP}}{\text{CVR}}$$

CPP represents the difference between arterial pressure forcing blood into the cerebral circulation and venous backpressure, which is mainly dependent on intracranial pressure (ICP). In normal circumstances, venous pressure is negligible, and CPP is equal to arterial pressure. CVR is determined primarily by vessel caliber and is defined by the equation

$$\text{CVR} = \frac{L\eta}{\pi r^4}$$

where L is vessel length, η is blood viscosity, and r is vessel radius. It bears emphasis that CVR is related to the fourth power of vessel radius, such that even small changes in luminal caliber can have significant effects on CVR; thus, in normal circumstances, vessel caliber is the most important determinant of blood flow. Factors that regulate vessel caliber include arterial carbon dioxide tension (P_aCO_2), arterial oxygen content (C_aO_2), perivascular ionic concentrations,

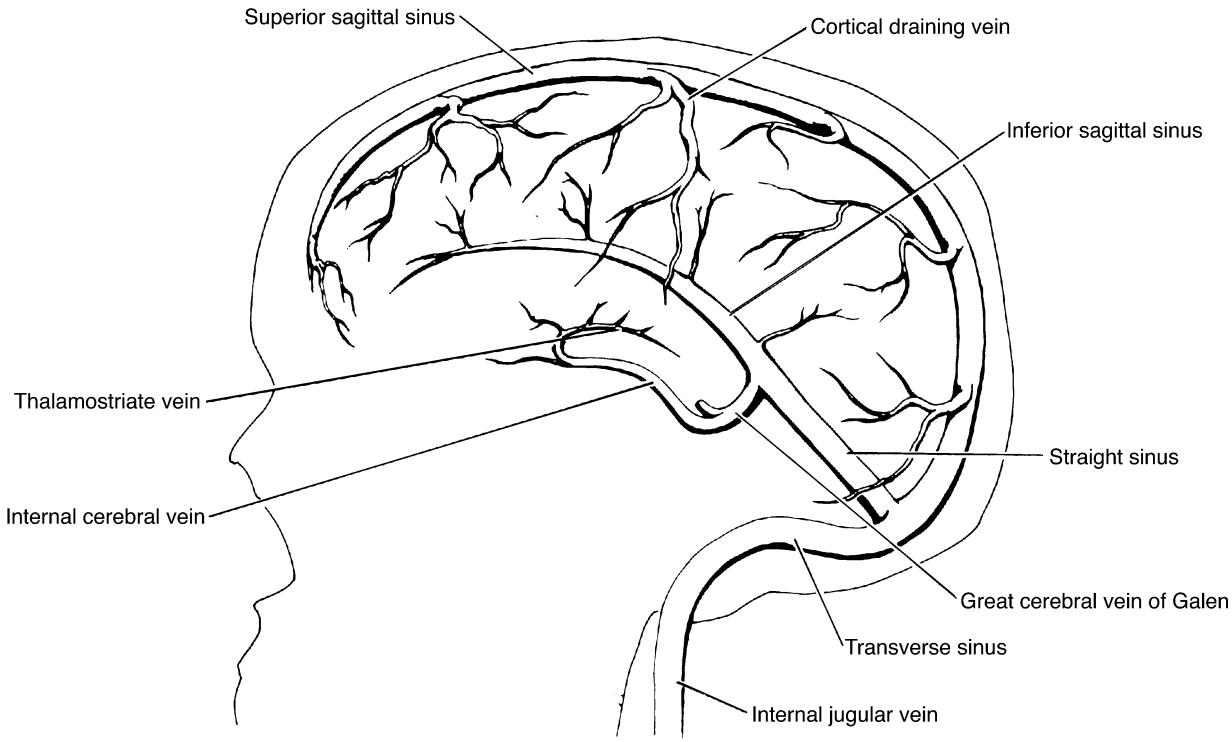

Figure 4 Sagittal section through the brain demonstrating the superficial and deep venous systems. The hemispheres drain superiorly into the superior sagittal sinus. The deep structures drain into the straight sinus. The superior sagittal and straight sinuses converge to form the two lateral sinuses, which ultimately drain into the internal jugular veins [From Powers, W. J. (1989). Stroke. In *Neurobiology of Disease* (A. L. Pearlman and R. C. Collins, Eds.), Copyright © 1989 by Oxford University Press, Inc. Used by permission of Oxford University Press, Inc.].

and innervation by sympathetic, parasympathetic, and trigeminal nerves. In addition, a host of diverse mediators that alter vessel tone and function, including vasoactive peptides, amines, lipids, phospholipids, and vasoactive gases, have been identified. Some of these (e.g., nitric oxide) are suspected to play a role in ischemia.

Carbon dioxide exerts a profound influence on cerebral vasculature, with hypercapnia (increased P_aCO_2) producing pronounced vasodilation through preferential effects on small cerebral arterioles, and hypocapnia (reduced P_aCO_2) producing vasoconstriction of all cerebral vessels. Inhalation of 5% CO_2 increases CBF by approximately 50%, and reducing P_aCO_2 from 45 to 25 mmHg lowers CBF by approximately 35%. Prolonged hypo- or hypercapnia alters CBF responsiveness to acute changes in P_aCO_2, such that CBF eventually returns toward normal despite continuous exposure. The effect of CO_2 on CBF appears to be primarily mediated by the hydrogen ion concentration of extracellular fluid, but prostaglandins, nitric oxide, and neural pathways may also play a role.

C_aO_2, which is dependent on oxygen tension (P_aO_2) and hematocrit, is another important determinant of CVR, with hypoxia (reduced P_aO_2) and anemia (reduced hematocrit) inducing vasodilation and increased blood flow. Cerebral vasculature is not as sensitive to changes in P_aO_2 as it is to changes in P_aCO_2 because of the shape of the oxygen–hemoglobin dissociation curve. Nevertheless, when P_aO_2 decreases below a threshold of approximately 50 mmHg, CBF begins to increase exponentially. The mechanisms by which hypoxia alters CVR include a direct effect on vessel relaxation, stimulation of oxygen-sensitive neurons in the ventral medulla, and possibly through accumulation of local metabolites. Prolonged hypoxia induces compensatory mechanisms, such that CBF eventually returns to normal.

Cerebral blood vessels receive innervation from sympathetic, parasympathetic, and trigeminal (serotonergic) nerve fibers, but the physiological role

of these systems is unclear. They appear to have minimal effect on CBF in normal circumstances but may serve a protective role at extremes of blood pressure (sympathetic system) or in response to ischemia or subarachnoid hemorrhage-induced vasospasm (parasympathetic and serotonergic systems).

B. Autoregulation

Autoregulation of blood flow is the well-developed mechanism whereby cerebral resistance arteries dilate during reductions in CPP and constrict during increases in CPP. As a result, blood flow to the brain remains constant over a wide range of pressures. The normal range for autoregulation is approximately 60–150 mmHg, but is higher in chronically hypertensive subjects.

Global reductions in CPP may be caused by decreased systemic arterial pressure or increased ICP. Regional reductions may occur in arterial occlusive disease or venous thrombosis. As CPP decreases, vasodilation maintains CBF until the capacity for autoregulation has been exceeded. At that point, the brain begins to extract increasing amounts of oxygen and glucose to maintain normal metabolism and brain function. It is not until oxygen extraction fraction (OEF) has been maximized that further decreases in CBF result in reduced metabolism and clinical symptoms of ischemia (Fig. 5). This occurs at a CBF of approximately 15–20 ml $100\,g^{-1}\,min^{-1}$.

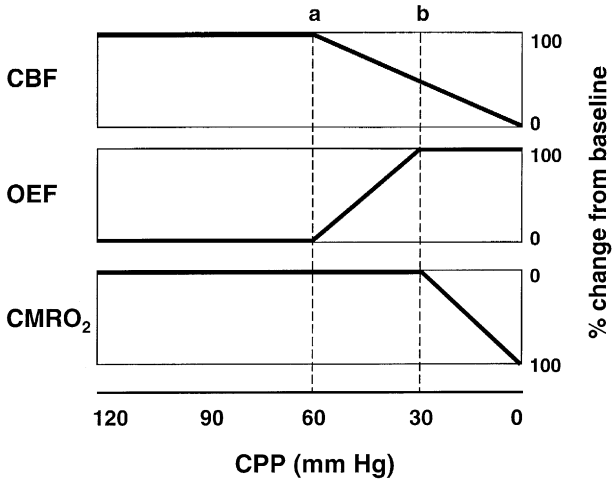

Figure 5 Compensatory responses to reduced cerebral perfusion pressure (CPP). As CPP decreases, cerebral blood flow (CBF) is initially maintained by dilation of resistance arteries (not shown). When vasodilation can no longer compensate, autoregulation fails and CBF begins to decrease (a). A progressive increase in the oxygen extraction fraction (OEF) now maintains cerebral oxygen metabolism ($CMRO_2$). Once OEF is maximal (b), further declines in CBF disrupt cellular metabolism and function (reproduced with permission from Powers, W. J., Cerebral hemodynamics in ischemic cerebrovascular disease. *Ann. Neurol.* **29,** 231–240, 1991).

III. CEREBRAL ISCHEMIA/INFARCTION

A. Pathophysiology

Based on the previous discussion, ischemia can be defined as an impairment of tissue function due to a reduction in blood supply relative to metabolic demand. Experimental models have provided a detailed description of the changes in CBF and metabolism that occur during focal ischemia. Occlusion of a vessel produces a severe reduction in blood flow to a central core of tissue and a less severe reduction in blood flow to a zone surrounding this core, where perfusion is maintained by collateral circulation. As long as CBF remains above approximately 20 ml $100\,g^{-1}\,min^{-1}$, no changes in brain metabolism or function occur. Below this level, brain electrical activity fails, and neurological symptoms appear. As the supply of oxygen becomes insufficient to maintain normal cellular biochemistry, stores of high-energy phosphates are quickly depleted. Anaerobic metabolism of the small amount of residual glucose in intracellular stores results in lactic acidosis. With more severe reductions in CBF to approximately 10–12 ml $100\,g^{-1}\,min^{-1}$, cell membrane integrity is lost and depolarization causes leakage of intracellular K^+ into the extracellular space and influx of extracellular Ca^{2+} into neurons. Spreading depression, a depolarization wave running over the brain cortex at a rate of 3 or 4 mm/min, is elicited by increases in extracellular K^+ and leads to increased energy consumption, as the Na^+–K^+ pump is activated in an attempt to restore intracellular K^+. Since the resultant increased substrate demand cannot be compensated for by increases in CBF, further ischemia occurs.

Surrounding the core of dense ischemia is the ischemic penumbra, in which blood flow is reduced to the point of interrupting neuronal electrical activity but ionic homeostasis is preserved. If blood flow is restored, neurons in the penumbra can be salvaged. If

reperfusion does not occur, the neurons usually die. Therefore, it is the fate of the neurons in the ischemic penumbra that often determines the final size of an infarct.

The ability of neurons to survive a period of transient cerebral ischemia depends on both severity and duration and varies in different brain regions, with cerebellar Purkinje cells, hippocampal CA1 cells, and cells in cortical layers 3, 5, and 6 being particularly vulnerable. Once a region's "ischemic threshold" is reached, cells become irreversibly damaged. The finding that in some cells death is immediate whereas in others it is delayed until after restoration of perfusion suggests that energy failure and loss of ionic homeostasis do not inevitably lead to cell death. Delayed cell death occurs as a result of a complex series of secondary events that are triggered by the ionic derangements, including release of excitotoxic neurotransmitters, calcium influx, activation of proteases, free radical production, programmed cell death (apoptosis), acidosis, and inflammatory mechanisms.

B. Causes/Risk Factors

The specific causes of cerebral ischemia can be divided into two general categories: those that cause global ischemia (a decrease in blood flow to the entire brain) and those that cause focal ischemia (a decrease in blood flow to a specific area within the brain).

Global ischemia occurs when decreased cardiac output (e.g., secondary to cardiac arrest or hypovolemic shock) or decreased peripheral vascular resistance (e.g., associated with vasovagal syncope or septic shock) lead to a reduction in systemic blood pressure. The most common sign is loss of consciousness. Only rarely does hypotension produce a focal deficit, even in the presence of a stenotic artery. If ischemia is moderate, damage is often restricted to the watershed or border zone areas between the major vascular territories. If severe or prolonged, it can result in infarction of the entire brain.

Focal ischemia occurs as a result of a local vascular disturbance. Causes of focal ischemia can be divided into three general categories: primary disease of the cerebral blood vessels, embolism from extracerebral sites, and hematological disorders (Table I). Regardless of the underlying etiology, the final common pathway is vascular compromise resulting in inadequate blood supply to a region of the brain. The primary vascular diseases and the hematological disorders produce stroke through thrombosis of cerebral blood vessels. Thrombosis is initiated by alterations in endothelial integrity and disruptions in the normal laminar flow of blood, with activation of the coagulation cascade and subsequent production of

Table I
Causes of Focal Cerebral Ischemia

Vascular disease
Atherosclerosis
Cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy
Connective tissue disease
Drugs (cocaine, sympathomimetics)
Fibromuscular dysplasia
Infective arteritis
Lipohyalinosis/fibrinoid necrosis
Metabolic diseases
Migraine
Moya-moya disease
Radiation vasculopathy
Sickle cell anemia vasculopathy
Vascular dissection
Vascular trauma
Vasculitis
Vasospasm
Venous thrombosis
Systemic embolism
Air embolism
Aortic arch atheroma
Cardiac thrombus (atrial fibrillation, atrial myxoma, dilated cardiomyopathy, myocardial infarction, ventricular aneurysm)
Fat embolism
Infective endocarditis
Paradoxical embolism
Tumor embolism
Valvular heart disease
Hematological disorders
Hypercoagulable states (antiphospholipid antibody syndrome, antithrombin III deficiency, disseminated intravascular coagulation, factor V Leiden mutation, heparin cofactor II deficiency, paraneoplastic, paroxysmal nocturnal hemoglobinuria, protein C deficiency, protein S deficiency, thrombotic thrombocytopenic purpura)
Hyperviscosity syndromes (dysproteinemia, myeloproliferative syndromes, polycythemia vera, thrombocytosis)
Other
Nephrotic syndrome
Oral contraceptives
Pregnancy/puerperium

thrombin. Thrombin, the key regulator of thrombosis, activates platelet aggregation and cleaves fibrinogen to fibrin, which then cross-links to form the basis for the clot matrix. Thrombi can either occlude the vessel at the site of endothelial injury or embolize distally through a combination of shear stress and the action of intrinsic antithrombotic mechanisms. With time, thromboemboli to the cerebral vessels spontaneously lyse, but this often occurs too late to prevent permanent infarction.

The most common cause of focal ischemia is atherosclerosis. Atherosclerosis is a multifactorial process by which plaque (''atheroma'') containing cholesterol, lipid-laden macrophages, inflammatory cells, abnormally proliferated smooth muscle cells, and dense connective tissue forms within arterial walls. Endothelial injury is one of the key events in the pathogenesis of atherosclerosis since it leads to fatty streak formation and contributes to smooth muscle cell proliferation. Stroke can occur if the atheroma produces sufficient arterial stenosis and/or promotes sufficient thrombus formation to reduce blood flow distally. More commonly, thrombus formed at the site of atheromatous plaque serves as a source for emboli that are carried distally where they occlude smaller intracranial vessels (artery-to-artery embolism). The factors that determine when atherosclerotic plaque will produce symptomatic ischemia are poorly understood but may include rupture of fragile plaque vessels resulting in hemorrhage, calcification of the fibrous surface leading to plaque rupture, and plaque ulceration. These plaque complications, which are related to local hemodynamic forces and increasing degree of luminal narrowing, expose the highly thrombogenic contents of the necrotic core and are therefore likely the basis for atherosclerosis-induced ischemia. Atherosclerosis has a predilection for bifurcation points and curves in vessels. Within the cerebrovascular system, it occurs most commonly at the origin of the internal carotid arteries in the neck, at the carotid siphon, in the distal vertebral arteries, and in the basilar artery. Its prevalence increases with age, and it affects men at a younger age than women. In addition, there are racial differences, with extracranial and large artery disease being more common in whites than in blacks and Asians. Hypertensive patients often have more advanced atherosclerotic disease for age as well as disease extension into more distal vessels. Primary disease of the small penetrating arteries and arterioles is most commonly related to the hypertension-associated conditions termed arteriolosclerosis, in which microatheroma form in the same manner as the atheroma affecting larger arteries, and lipohyalinosis, in which a fibrohyaline substance accumulates in the vessel wall. These conditions are the most frequent causes of the small infarcts (''lacunes'') that predominantly occur in the basal ganglia and white matter of the internal capsule and pons.

Among the systemic causes of cerebral embolism, the most clinically important are those arising in the heart since cardiac embolism is implicated in 15–25% of ischemic strokes. Embolic material is usually composed of fibrin and/or platelet thrombi, but it may also include debris from calcified or degenerated heart valves, fragments of heart valve vegetations, tumor cells, fat, air, or other foreign substances.

Primary hematological disorders can predispose to ischemia by increasing thrombotic potential (hypercoagulable states) or decreasing blood flow (hyperviscosity syndromes), but they underlie only a small minority of ischemic strokes. Hypercoagulable states are more convincingly related to venous thrombosis than arterial, and patients harboring these defects will often have a history of peripheral venous thrombosis, pulmonary embolism, or recurrent fetal loss.

Prospective epidemiological studies have identified a number of risk factors for stroke. Nonmodifiable risk factors include increasing age, black race, male gender, and family history of stroke. More important from the standpoint of stroke control, several modifiable risk factors have been established. Hypertension is the most powerful of these since it occurs in 25–40% of the U.S. population and increases stroke risk approximately three-fold. Even borderline hypertension (systolic 140–159 mmHg and diastolic 90–94 mmHg) is associated with a 50% increase in stroke risk. Pooled data from 14 treatment trials of hypertension indicate that a blood pressure reduction of 5.8 mmHg corresponds to a 42% reduction in stroke incidence. Diabetes confers a 1.8–3 times increased stroke risk, and increasing degrees of glucose intolerance correspond to increasing risk of stroke. Cardiac disease is a frequent comorbid factor in stroke by virtue of shared risk factors, but it also predisposes to stroke by serving as a source for embolism. Atrial fibrillation is associated with as much as a five-fold increase in stroke incidence depending on associated factors. In both primary and secondary prevention trials, anticoagulation treatment of nonvalvular atrial fibrillation reduces stroke risk by approximately 70%. In contrast to the known impact of blood lipids on coronary heart disease, the relationship between lipids and stroke is unclear, with inconsistent results among

epidemiological studies. Serum lipid levels have been directly related to atherosclerosis of extracranial and intracranial vessels, however, with low-density lipoprotein and total cholesterol increasing vessel wall thickness and high-density lipoprotein cholesterol protecting against the development of atheroma. In addition, clinical studies of the cholesterol-lowering HMG-CoA reductase inhibitors (statins) in patients with coronary artery disease have demonstrated a significant reduction in ischemic stroke. The mechanism by which statins exert this neuroprotective effect is unclear. Cigarette smoking is a significant independent risk factor for stroke. Risk increases with the number of cigarettes smoked per day, and inferences from observational studies suggest that cessation of smoking results in a decrease in stroke risk within 5 years to nearly that of persons who have never smoked. Since cigarette smoking is correlated with degree of carotid stenosis, the likely mechanism by which smoking increases stroke risk is through acceleration of atherosclerosis. The relationship between alcohol use and stroke appears to be U shaped: Total abstinence and excessive consumption are associated with the greatest risk, and moderate use is associated with the lowest risk. Elevated plasma homocysteine levels, which are inversely related to intake of folic acid and vitamins B_{12} and B_6, have been demonstrated to increase stroke risk in some studies but not in others. Other factors cited as contributors to stroke risk include elevated serum fibrinogen, low level of physical activity, and oral contraceptive use (especially in older women who smoke or suffer from migraine).

C. Clinical Features

The clinical hallmark of cerebral ischemia is the sudden onset of a focal neurological deficit. The onset is usually abrupt and the deficit maximal within minutes. When progression does occur, it too tends to be abrupt and stepwise, rather than a slow, steady decline. Other causes of sudden focal neurological deficit, including seizure, migraine, and trauma, should always be considered. The deficits caused by a stroke reflect the region of the brain (or retina) involved, thus allowing for localization of the lesion by neurological examination.

Lesions in the carotid circulation produce motor and/or sensory deficits on the opposite side of the body. Language dysfunction may occur with ischemia of the dominant (almost always left) hemisphere and impaired spatial perception with ischemia of the nondominant hemisphere. If deep white matter is involved, dysfunction generally affects face, arm, and leg and may be accompanied by visual field defects. Superficial lesions in the territory of the middle cerebral artery generally spare the leg, whereas those in the territory of the anterior cerebral artery primarily affect the leg. Retinal ischemia due to a lesion of the ophthalmic artery causes transient monocular blindness (amaurosis fugax).

Ischemia within the vertebrobasilar system characteristically produces cranial nerve or cerebellar dysfunction in addition to motor and/or sensory deficits affecting either the opposite or both sides of the body. Isolated unilateral motor deficits can occur with small lesions of the brain stem, creating diagnostic confusion with lesions of the carotid system, but more often neighboring signs suggest the correct localization. Involvement of the posterior cerebral artery causes visual symptoms due to ischemia of the occipital lobe. Although the posterior cerebral artery also supplies the inferior temporal lobe regions involved in memory, whether or not ischemia of this artery causes memory disturbance (e.g., transient global amnesia) is controversial. Ischemia in the territory of the vertebral and basilar branches to the cerebellum often produces ataxia. Thrombosis of the basilar artery may produce bilateral infarction of the brain stem or thalamus, resulting in coma or a "locked-in" state characterized by complete loss of speech and quadriplegia with retained consciousness.

The temporal course of ischemia is variable. Ischemic deficits may resolve completely, remain stable, or worsen. If complete resolution occurs within 24 hr, the event is called a transient ischemic attack (TIA). In actuality, most TIAs last less than 20 min. Persistence of deficits beyond 24 hr is labeled a completed stroke or infarction. The terms "progressing stroke" and "stroke in evolution" have been applied when clinical deficits are observed to worsen (increased severity of deficit or development of new deficits), whether this is a gradual decline or a stuttering progression over minutes to hours. The lack of uniformity to the definition of progressing stroke precludes meaningful comparisons between reports and makes interpretation of incidence and prognosis unsatisfactory. In addition, numerous mechanisms may underlie or mimic progressing stroke. Thrombus enlargement or distal progression along a vessel may extend the area of damage either by converting a partial occlusion to a complete occlusion or by obliterating connections to collateral circulation. Recurrent embolization may occur. With

clot lysis or upon establishment of reperfusion by collateral vessels, hemorrhage into the infarct may occur. Cerebral edema, which is maximal 3–5 days after stroke onset, may cause clinical deterioration and death due to herniation. Systemic factors such as fever, infection, electrolyte abnormalities, acid–base disturbances, and altered cardiopulmonary function may interfere with cerebral metabolism, leading to worsening of neurological deficits. Finally, stroke progression may occur as the ongoing cascade of biochemical events induced by ischemia leads to delayed cell death.

1. Diagnostic Studies

Diagnostic studies, including neuroimaging, analysis of blood and cerebrospinal fluid (CSF), and cardiac testing, are used to distinguish stroke from nonstroke entities, to exclude the presence of cerebral hemorrhage, to assist in localization of lesions when exam findings are ambiguous, and to help establish etiology and appropriate treatment. The neuroimaging manifestations of cerebral ischemia vary significantly with time. Within the first 24 hr after symptom onset, computed tomography (CT) can detect only subtle signs of infarction, such as blurring of the usually distinct border between gray and white matter or loss of sulci due to early edema. After 24–48 hr, most infarcts are visible as wedge-shaped areas of decreased attenuation that involve both gray and white matter in a typical vascular distribution. Increasing mass effect and edema become evident over the next few days. By the end of the first week, contrast enhancement can often be seen in a gyral pattern and may persist for months. Months to years later, there is encephalomalacic change and volume loss in the area of the infarct. Magnetic resonance imaging (MRI) of the brain is more sensitive to ischemic changes. Most infarcts can be recognized within 24 hr as bright signals within a vascular territory on conventional MRI sequences sensitive to water content (T2 and FLAIR). During the next week, intense parenchymal contrast enhancement develops. Edema and mass effect become prominent, then decrease during the second week. Encephalomalacia is seen in the chronic stage. Increasing MRI technology has allowed for even earlier detection of ischemia. Diffusion-weighted MRI can detect restricted water movement in brain tissue within hours of ischemia, but this finding is not specific. Initially thought to indicate permanent neuronal damage, reduced diffusion has been reported to occur in TIA, migraine, and seizure without the expected evolution of abnormalities typical of infarction on conventional MRI sequences. Attempts to predict final infarct volume using diffusion imaging in conjunction with perfusion imaging, an MRI technique that provides qualitative information on CBF, remain experimental. Although rarely performed in acute ischemia, cerebral angiography demonstrates vessel occlusion appropriate to neurological symptoms in more than 50% of patients studied within a few hours of stroke. Approximately half of the occluded vessels spontaneously recanalize within 1 week. Noninvasive techniques are available to assess for disease of the extracranial and intracranial vessels (carotid and vertebral Doppler sonography, transcranial Doppler, magnetic resonance angiography, and CT angiography), but conventional angiography remains the gold standard.

2. Prognosis

The possible outcomes in patients with recurrent TIA include spontaneous cessation of attacks, continued attacks, or cerebral infarction. The risk of stroke within the first year after TIA is about 10%, declining to 5% per year thereafter. Twenty to 50% of patients with an untreated TIA who have a subsequent stroke will do so during the first month. The presence of ipsilateral carotid stenosis $>70\%$ increases the risk of subsequent stroke to 15% per year. Retinal TIA (transient monocular blindness) carries a lower stroke risk than hemispheric TIA.

Mortality from stroke has declined dramatically during the past 30 years, variably attributed to reduced stroke incidence, declining stroke severity, improved sensitivity of diagnosing smaller infarcts with milder deficits, and improved stroke survival. Approximately 5–15% of patients die within the first 30 days of ischemic stroke, most commonly as a result of cardiopulmonary complications or brain death. Neurological deficits due to stroke tend to improve over time, with most recovery of function occurring in the first few months. The mechanisms underlying this recovery are poorly understood. No large-scale regeneration of infarcted tissue occurs, but undamaged brain may assume lost function or facilitate function of any remaining neurons. However, about one-third of stroke survivors will not return to independent function.

The longer term prognosis after completed stroke depends on the epidemiological factors that originally predisposed to the stroke. The 5-year mortality rate is approximately 50%, with one-third of deaths due to initial or recurrent stroke, one-third due to cardiac

disease, and one-third due to other causes. The risk of recurrent stroke is about 5–10% per year, but there is no universal agreement on the factors that predict this recurrence.

D. Treatment

Treatment of ischemic stroke aims to limit the extent of infarction and reduce disability by (i) augmenting fibrinolysis (thrombolytic therapy), (ii) salvaging neurons in the ischemic penumbra (neuroprotective agents), and (iii) preventing/treating stroke-related complications. The role of antiplatelet and anticoagulant agents in preventing thrombus progression in acute stroke is limited. Another major goal in the treatment of patients with ischemic stroke as well as those with TIA is to reduce the risk of subsequent stroke. This is accomplished via (i) antiplatelet or anticoagulant agents to decrease thrombotic potential, (ii) surgical treatment of extracranial carotid stenosis, and (iii) risk factor modification.

1. Acute Stroke Therapy

a. Thrombolytic Agents Since the extent of stroke-induced brain injury is related to the duration and severity of ischemia, agents that produce clot lysis and restore cerebral perfusion may limit the degree of injury and thus improve outcome. Intravenous thrombolytic therapy has been reported to achieve some degree of angiographic clot lysis in 30–60% of patients. In the mid-1990s, three trials of intravenous streptokinase in acute ischemic stroke were stopped because of excessive intracranial hemorrhage. A concurrent trial of tissue plasminogen activator (tPA) yielded positive results, leading to the 1996 approval by the U.S. Food and Drug Administration of tPA in acute ischemic stroke. When administered within 3 hr of symptom onset, tPA was associated with a 30% greater likelihood of excellent recovery at 3 months despite an increase in early symptomatic intracranial hemorrhage. Three randomized trials in which the treatment window was extended failed to demonstrate benefit of tPA when given after 3 hr.

Thrombolytic agents can be infused directly into occlusive thrombi via microcatheters, with the potential advantages of higher recanalization rates and improved safety (because of lower drug dose required) but the disadvantages of limited availability of interventional neuroradiology teams and delays in drug administration. One recent randomized open-label trial using pro-urokinase within 6 hr of symptom onset in middle cerebral artery occlusion showed marginally significant benefit, but because of methodological problems and small sample size, a larger trial is warranted before the drug can be recommended for clinical use.

b. Neuroprotective Agents The goal of neuroprotective therapy is to prevent cellular death in the ischemic penumbra, thus limiting infarct size and improving outcome. The most important factor in successful neuroprotection appears to be time because ischemia becomes irreversible within minutes to hours of onset. Thus, many agents that have shown marked efficacy when administered before or immediately after stroke induction in experimental models have failed to demonstrate any benefit in subsequent clinical trials. Potential neuroprotective strategies have targeted various steps in the ischemic cascade, but no neuroprotective drug has successfully completed phase III clinical efficacy trials.

c. Antiplatelet and Anticoagulant Therapy Although aspirin has a clear role in the treatment of acute myocardial infarction, it is of limited benefit in acute stroke. A recent randomized controlled trial of aspirin given within 48 hr of stroke onset revealed a modest reduction in early mortality (9 per 1000) among the aspirin-treated patients. Similarly, heparin (a parenterally administered polysaccharide that inhibits thrombin activation) prevents progression of thrombosis in experimental models and in patients with acute myocardial infarction, but six randomized trials of immediate anticoagulation with heparin or its related low-molecular-weight compounds after stroke revealed no consistent benefit in any stroke subgroup. Although heparin may reduce the risk of recurrent stroke, this benefit is offset by an increase in hemorrhagic stroke and extracranial hemorrhage.

d. Prevention/Treatment of Stroke-Related Complications Stroke-related complications and comorbid disease are a major cause of morbidity and mortality among stroke patients. Hypertension commonly occurs after stroke. Even in patients without a previous history of hypertension, blood pressure is often elevated acutely and typically returns to baseline spontaneously over the first week. The acute treatment of hypertension is controversial because of concerns that impaired autoregulation in the periinfarct area will result in further reduction of CBF if blood pressure is lowered. Most patients have coexisting cardiac disease, and concomitant cardiac ischemia or

arrhythmia occur frequently. Deep venous thrombosis occurs in up to 75% of hemiplegic patients in the first week after stroke and may lead to pulmonary embolism and death. The risk of venous thrombosis is greatly reduced by the use of low-dose subcutaneous heparin, elastic stockings and pneumatic compression devices on the lower extremities, and early mobility. Pulmonary function may be compromised by aspiration due to impaired cough reflex or hospital-acquired pneumonia. Dysphagia may impair adequate nutrition and hydration, so intravenous fluids, nasogastric tube feeding, or diet modifications may be necessary. Urinary retention and incontinence may require bladder catheterization. If the patient is unable to roll over in bed, pressure sores are a risk. Poststroke depression is common and usually responds to antidepressant medications.

2. Secondary Stroke Prevention

a. Antiplatelet Agents Platelets contribute to thrombosis as catalysts for thrombin generation and as constituents of thrombi. Antiplatelet agents inhibit platelet function by preventing platelet aggregation and adhesion to activated endothelium. Aspirin, an irreversible inhibitor of the platelet enzyme cyclooxygenase, is the best studied of the antiplatelet agents and remains the most commonly prescribed medication for stroke prophylaxis. Aspirin has been shown to reduce stroke risk among patients with recent TIA or stroke by 15–58%. Dipyridamole, a cAMP phosphodiesterase inhibitor, has been shown to reduce stroke risk by approximately the same degree as low doses of aspirin. The combination of dipyridamole and low-dose aspirin provides an additive effect, reducing stroke risk by 37%. Ticlopidine, an irreversible inhibitor of adenosine diphosphate-induced platelet aggregation, has been demonstrated to be slightly superior to aspirin in secondary stroke prevention, reducing the yearly stroke rate from 4.3% with aspirin to 3.3% with ticlopidine. This benefit is offset by a higher incidence of side effects. Clopidogrel, an agent chemically related to ticlopidine but with a lower incidence of side effects, is not superior to aspirin, but it remains a treatment option for aspirin-intolerant individuals.

b. Anticoagulants The clinical efficacy of anticoagulants has been well established for a number of systemic disorders, including prevention of venous thromboembolism and prevention of myocardial infarction. Despite having long been advocated for stroke prevention, the effectiveness of anticoagulants in this regard has been demonstrated only in select cardiac diseases. Long-term treatment with warfarin, an oral anticoagulant that antagonizes vitamin K, has been proven to reduce stroke risk in patients with nonvalvular atrial fibrillation (70% risk reduction) and in those with mechanical prosthetic cardiac valves. Because of a high risk of embolism, several other cardiogenic sources for stroke are often treated with warfarin, including mitral stenosis, recent myocardial infarction, left ventricular thrombus, and dilated cardiomyopathy. The value of oral anticoagulation in atherosclerotic stroke is currently being evaluated in several randomized trials, but one recent multi-center randomized trial in patients with non-cardioembolic stroke failed to show any benefit of warfarin over aspirin in any subgroup of patients.

c. Carotid Endarterectomy Clinical trials have established that carotid endarterectomy is the treatment of choice for patients with retinal or hemispheric TIA or stroke accompanied by severe stenosis of the appropriate carotid artery, as long as the perioperative complication rate is low. Such patients with symptomatic carotid stenosis of 70–99% have a 17% absolute risk reduction of ipsilateral stroke when treated with carotid endarterectomy and medical treatment compared to medical treatment only. This benefit is reduced or lost if surgical morbidity and mortality increase above 6%. In patients with symptomatic moderate carotid stenosis (50–69%), the benefit of endarterectomy is less clear-cut, with an absolute risk reduction of ipsilateral stroke of only 6.5%. Therefore, decisions about surgical treatment in this category must consider the patient's risk factor profile and the surgeon's complication rate. Patients with stenosis of less than 50% do not obtain any benefit from surgery.

The value of endarterectomy in asymptomatic carotid stenosis has also been evaluated. Among patients with $>60\%$ carotid stenosis who have not had an ipsilateral stroke or TIA, endarterectomy reduces the risk of subsequent stroke from about 2% per year to 1% per year. The risk reduction appears to be much less for women, however. In order for surgery to be beneficial, patients must have a reasonable life expectancy, and operative morbidity and mortality must be $<3\%$.

d. Angioplasty and Stenting Endovascular procedures, including percutaneous transluminal angioplasty and arterial stenting, are sometimes considered for surgically inaccessible stenotic lesions, restenosis after carotid endarterectomy, inflammatory vascular

disease, and for patients who are hemodynamically unstable or poor surgical candidates. Although case series have reported good results, the efficacy of these treatments for stroke prevention remains to be determined by randomized, controlled trials.

E. Cerebral Venous Thrombosis

Obstruction of cerebral venous drainage represents a special category of cerebral infarction. In cerebral venous thrombosis (CVT), occlusion of a cerebral vein or sinus produces an increase in venous pressure as well as an increase in tissue pressure within its drainage territory. Unless alternative venous pathways are available, tissue perfusion is reduced and ischemia occurs. Causes of CVT may be divided into local and systemic processes, with local causes consisting primarily of trauma and intracranial spread of infection or tumor, and systemic causes including the wide gamut of factors known to predispose to deep venous thrombosis. The most common of these are puerperal state, infection, and dehydration (in developing countries) and hereditary coagulation disorders such as factor V Leiden mutation and prothrombin gene mutation. The clinical presentation of CVT is varied but classically consists of evidence for increased ICP (e.g., headache, papilledema, and altered consciousness), focal neurological deficits, and seizures. Neuroimaging hallmarks of CVT include the empty delta sign on contrast-enhanced CT (in which a triangular pattern of enhancing dilated venous channels surrounds a nonenhancing clot in the superior sagittal sinus), multifocal hemorrhagic and nonhemorrhagic infarcts that do not conform to arterial vascular distributions on CT or MRI, and lack of venous filling on angiography. Treatment is directed at the underlying disorder (e.g., antibiotics for septic thrombosis), symptomatic control (e.g., anticonvulsants for seizures), and antithrombotic therapy (e.g., anticoagulants and thrombolytics). Because the disease is uncommon and has wide-ranging causes and variable outcome, the benefit of these treatments remains uncertain. The prognosis of CVT is highly variable but is influenced by such factors as age, rate of evolution and location of thrombosis, and nature of the underlying disease.

IV. INTRACEREBRAL HEMORRHAGE

Spontaneous intracerebral hemorrhage (ICH) accounts for approximately 10% of cerebrovascular disease and is associated with greater mortality and more severe neurological deficits than any other stroke subtype.

A. Pathophysiology

The pathophysiological mechanisms of brain injury due to ICH are complex. The primary injury is one of direct tissue destruction through mechanical compression. Rupture of a cerebral blood vessel introduces a sudden force of blood into the brain parenchyma where it acts as a mass to destroy tissue locally. In more than one-third of patients, continued bleeding or rebleeding result in hematoma enlargement and further mechanical injury within the first few hours after onset. The mass of blood produces tissue shifts within the intracranial cavity since the rigid skull prevents distension. If the volume of blood is large enough, brain herniation and death ensue.

In addition to the mechanical disruption produced by the hematoma, further damage is believed to occur after the bleeding stops. The mechanisms underlying this secondary injury are unknown, but ischemia and edema have been implicated. The importance of ischemia in the pathophysiology of ICH remains unsettled. Some experimental models of ICH have demonstrated a perihematomal zone of reduced CBF that may be below that necessary for neuronal viability. On the other hand, since ischemia requires insufficient blood flow to sustain metabolism, another possible explanation is that the reduced CBF simply reflects reduced metabolic demand of the damaged tissue surrounding the hematoma. Recent positron emission tomography (PET) studies in humans performed 10–22 hr after symptom onset have shown that CBF and metabolism are both reduced around the clot, with no evidence of ongoing ischemia. Cerebral edema has been demonstrated to occur within hours of induced ICH in some animal models, variably thought to result from the toxic effects of blood-derived enzymes, from increased osmotic pressure exerted by clot-derived serum proteins, or from ischemia. In humans, signal changes on radiographic studies after ICH indicate increased water content in the area surrounding the clot, but the clinical and pathophysiological significance of this is not known.

Hemostasis after hemorrhage is rapidly achieved at the site of vascular injury by the formation of a platelet-fibrin plug. Concurrent with the activation of local hemostatic processes, however, a localized fibrinolytic response is also activated to limit the extent of

coagulation, repair vascular injury, and reestablish normal blood flow. After several days, red blood cells within the clot begin to lyse, cellular infiltrates appear, and the process of reabsorption begins. Months later, a residual collapsed cavity is all that remains.

B. Causes/Risk Factors

The most common form of intracerebral hemorrhage, accounting for more than half of all cases, is hypertensive hemorrhage. Hypertensive ICH occurs predominantly in the deep portions of the cerebral hemispheres (putamen, thalamus, and deep white matter) and in the pons and cerebellum. What these sites have in common is that they are all supplied by small penetrating arteries—end vessels that have no collaterals and that are therefore vulnerable to the effects of increased blood pressure. Chronic hypertension contributes to the development of lipohyalinosis, fibrinoid necrosis, and microaneurysms (Charcot–Bouchard aneurysms). Although Charcot–Bouchard aneurysms have been demonstrated in the weakened vessel walls of patients with ICH, their pathogenetic role in vascular rupture is uncertain.

The occurrence of ICH in an atypical location, in multiple locations, or in association with subarachnoid hemorrhage raises suspicion of a nonhypertensive etiology, such as a cerebral vascular anomaly, blood dyscrasia, or trauma (Table II). Other risk factors for ICH include increasing age, black race, alcohol abuse, and low serum cholesterol. The relationship between smoking and ICH has not been convincingly established. Similarly, the impact of diabetes on risk of ICH is disputed.

Table II
Causes of Intracerebral Hemorrhage

Chronic hypertension
Coagulopathy
Drugs (anticoagulant therapy, cocaine, sympathomimetics, thrombolytic therapy)
Hemorrhagic transformation of cerebral infarcts
Thrombocytopenia
Trauma
Tumor
Vascular anomalies (aneurysms, arteriovenous malformations)
Vasculitis
Vasculopathy (amyloid angiopathy, moya-moya disease)

C. Clinical Features

The clinical presentation of ICH is often indistinguishable from that of ischemic stroke. As with ischemic stroke, the clinical manifestations of ICH depend on the location and size of the lesion, but they also reflect the presence of increased ICP. Thus, ICH more commonly produces alterations in level of consciousness as well as headache and vomiting. Symptoms are maximal at onset or develop over minutes to hours. Regression of deficits in the acute phase generally does not occur. Seizures may occur at onset, especially with lobar hemorrhages and underlying vascular or neoplastic lesions, but delayed seizures are rare.

Arterial blood pressure is elevated on admission in the majority of ICH patients, even in those with no history of hypertension, and generally declines to premorbid levels after 7–10 days without pharmacological intervention. Although this acute increase in blood pressure is often implicated as the cause of the hemorrhage, it may simply be a reflection of the brain's attempt to maintain CPP in response to the sudden increase in ICP.

Neurological deterioration after hospital admission has been reported to occur in 33–61% of patients with ICH. The cause for clinical worsening is not always evident, but increased hematoma size is found in more than one-fourth of cases. The role of edema in clinical deterioration is much more elusive.

1. Diagnostic Studies

Noncontrast CT scanning is the most widely used imaging modality in the diagnosis of ICH. Since acute blood has a high density, CT is sensitive in detecting even the smallest of hematomas. The typical CT appearance of an acute hematoma consists of a well-defined area of increased density surrounded by a rim of decreased density. The etiology of the hypodense rim is controversial, but it is at least partially explained by the process of clot retraction, in which the clot separates into a central mass of red blood cells and a surrounding area of serum. Also often apparent on the initial scan is mass effect of the hematoma on neighboring structures. Over time, the borders of both the high and low attenuation regions become increasingly indistinct, such that the hematoma is isodense with adjacent brain parenchyma by 2–6 weeks. A decrease in mass effect lags behind the signal changes, indicating that the apparent resolution of the hematoma is merely a manifestation of morphological changes within the extravasated blood. Peripheral contrast

enhancement can often be seen at this time and is thought to be due to angiogenesis and breakdown of the blood–brain barrier. By 2–6 months, true resolution of the hematoma and mass effect occurs, leaving an area of hypodensity, a slit-like scar, or no evidence of the previous hemorrhage. MRI of ICH is complex, reflecting the temporal evolution of hemoglobin degradation products. Because each hemoglobin oxidation state produces a predictable pattern of signal intensity, MRI is better able to determine approximate age of a hematoma than is CT. Its sensitivity to detect acute hematomas is controversial, however. Although MRI can be useful to visualize vascular abnormalities underlying a hematoma, angiography is indicated if a vascular lesion such as an aneurysm or arteriovenous malformation (AVM) is suspected.

2. Prognosis

Mortality following ICH is high (25–50%), with more than half of the deaths occurring in the first 48 hr. Transtentorial herniation accounts for a greater proportion of deaths in ICH than it does in ischemic stroke. Although patients who have small hemorrhages and mild deficits may recover completely, the majority of ICH survivors have significant residual disability. Many clinical and radiographic prognostic indicators have been identified, but all are not consistently recognized across studies. Clinical factors reported to predict poor prognosis include increasing age, reduced level of consciousness on admission, elevated blood pressure on admission, and in-hospital neurological deterioration. Radiographic features include large initial hematoma size, intraventricular spread of the hemorrhage, midline shift, hydrocephalus, and hematoma growth.

D. Treatment

Since the primary injury has already occurred by the time the patient obtains medical attention, treatment strategies have attempted to prevent or limit secondary injury. Unfortunately, no medical or surgical therapy has been shown to improve outcome after ICH. Trials of clot evacuation, aimed at achieving hemostasis and alleviating the potential for ischemia, have been disappointing. Ventriculostomy placement in patients with concomitant hydrocephalus or intraventricular blood has not been evaluated in a randomized trial, but retrospective data suggest that it does not improve outcome. Similarly, a benefit of osmotic therapy to reduce increased ICP has not been shown. Trials of corticosteroids to reduce edema have demonstrated no benefit but an increased complication rate. Therefore, the treatment of ICH is currently limited to supportive care. Trials of ultraearly clot evacuation and attempts to reduce the incidence of hemorrhage growth are ongoing. As with ischemic stroke, however, prevention through risk factor management remains the most effective means of reducing mortality and morbidity due to ICH.

The management of blood pressure in acute ICH is highly controversial, reflecting the competing theories that elevated blood pressure predisposes to hematoma growth and that lowering blood pressure exacerbates ischemic damage by impairing CBF. Data regarding the relationship between increased blood pressure and hematoma growth and mortality have been inconsistent. In addition, support for the theory that acutely lowering blood pressure reduces the likelihood of hematoma growth has not been demonstrated. Recent PET studies in patients with acute ICH and very elevated blood pressure (mean arterial pressure 120–150 mmHg) showed that a 15% reduction in blood pressure did not alter CBF in the periclot area.

V. SUBARACHNOID HEMORRHAGE

A. Pathophysiology

In subarachnoid hemorrhage (SAH), the primary site of bleeding is within the subarachnoid space; however, depending on etiology, it may also involve hemorrhage into the brain parenchyma, ventricular system, or subdural space. Rupture of an intracranial saccular aneurysm is by far the most common cause of spontaneous SAH. Saccular or berry aneurysms are small, rounded protrusions of the arterial wall occurring predominantly at arterial bifurcations at the base of the brain. Aneurysmal pathogenesis remains controversial, with the importance of developmental versus acquired factors in dispute. Proponents of the congenital theory suggest that aneurysms arise at sites of faulty fusion between muscular segments within the arterial wall. Supporters of the acquired-degenerative theory, on the other hand, focus on the role of vascular damage caused by hemodynamic stress. Citing the age-dependent occurrence of arterial defects and the predilection for aneurysms at arterial bifurcations (sites of maximal hemodynamic stress), those favoring the importance of acquired features postulate that degenerative changes within the internal elastic lamina

and media result in a local weakness that allows for aneurysm formation. A third possibility is that aneurysms develop at sites harboring congenital defects with superimposed degenerative changes.

What leads to aneurysmal growth and rupture is also debated. Hemodynamic stress and other factors intrinsic to the involved vessels may play a role. The time course over which aneurysms grow and subsequently rupture is unknown. One hypothesis is that most aneurysms that grow do so over a relatively short period of time (hours to weeks). If the limits of elasticity of the vessel wall are exceeded, the aneurysm ruptures; if not, the wall is stabilized by connective tissue deposition.

B. Causes/Risk Factors

Rupture of a saccular cerebral aneurysm is the cause of hemorrhage in approximately 80% of patients with nontraumatic SAH. Thus, genetic conditions that predispose to aneurysm formation, such as polycystic kidney disease, connective tissue disorders, and coarctation of the aorta, predispose to SAH. Other types of aneurysms that less commonly underlie SAH include atherosclerotic, mycotic, and traumatic aneurysms. Among the etiologies of nonaneurysmal SAH, trauma is the most common. AVMs, cocaine and stimulant abuse, neoplasia, and vasculitis account for the bulk of the remainder.

The risk of SAH increases with age, peaking at 55–60 years. There is a slight male predominance in younger age groups and a slight female predominance among older patients. Potentially reversible risk factors for SAH include cigarette smoking, oral contraceptive use, alcohol abuse, and hypertension. Prospective cohort studies have reported a relative risk of SAH as high as 5.7 for female and 4.7 for male smokers. No increased risk has been shown in former smokers, however. Oral contraceptive use, in addition to being an independent risk factor for SAH, dramatically increases the risk among smokers. A dose–response relationship exists between alcohol consumption and incidence of SAH. Finally, hypertension appears to increase the risk of SAH and may be the mechanism by which conditions such as polycystic kidney disease and stimulant drug use increase the risk for SAH.

C. Clinical Features

The most common initial symptom of SAH, occurring in more than 90% of patients, is sudden severe headache. Less severe warning (“sentinel”) headaches may precede the presenting event in as many as half and are thought to represent minor hemorrhages. In 45% of patients, transient or persistent loss of consciousness accompanies the headache. The mechanism responsible for this acute loss of consciousness is the sudden surge in ICP at the moment of hemorrhage that approaches systemic arterial pressure, resulting in inadequate cerebral perfusion. Vomiting can be prominent in awake patients. Seizure activity may be reported, but it is unclear whether this represents true epileptic seizures or reflex posturing related to the sudden increase in ICP. Focal deficits at onset are infrequent, but when present they may indicate the location of the lesion. After a few days, fever and stiff neck can develop, reflecting the sterile meningeal inflammation induced by the presence of blood in the subarachnoid space.

A worsening of neurological status following stabilization or improvement of symptoms often indicates one of the three major complications of SAH: rebleeding, hydrocephalus, or vasospasm. Rebleeding occurs in up to one-third of patients and is often fatal. The risk of rebleeding is greatest during the first 24 hr, declining rapidly after 1 or 2 weeks. It is heralded by a sudden worsening of headache, vomiting, development of a new neurological deficit, or arrhythmia. Hydrocephalus occurs if subarachnoid blood impairs CSF reabsorption at the arachnoid granulations or if ventricular blood obstructs its flow. It may develop acutely or gradually at any time after hemorrhage and most commonly produces a change in level of consciousness. Vasospasm, defined as segmental or diffuse narrowing of the arteries at the base of the brain, is a leading cause of morbidity and mortality following SAH. It can be detected angiographically in up to 70% of patients, of whom 20–30% become symptomatic. The pathogenesis of vasospasm is complex and not fully understood, but sustained exposure of vessels to

Table III
Fisher Grade of SAH on CT

Grade	Description
1	No blood detected
2	Diffuse or vertical layers < 1 mm thick
3	Localized subarachnoid clot and/or vertical layers $\geqslant 1$ mm thick
4	Intraparenchymal or intraventricular clot with diffuse or no SAH

extraluminal blood constituents and catecholamines is thought to play a role. It involves structural changes in the vessel walls and in adrenergic nerve fibers. The onset of vasospasm is delayed, commonly developing in the first week after initial hemorrhage, and it may persist for up to 3 weeks. The strongest predictor of subsequent vasospasm is the amount and distribution of subarachnoid blood on CT (Table III), with the greatest risk occurring in those having subarachnoid clots larger than 5×3 mm in the basal cisterns or layers of blood $\geqslant 1$ mm thick in the cerebral fissures (Fisher grade 3). Deficits reflect the territory of the involved arteries and may appear abruptly or gradually. Infarction may occur.

In addition to the neurological complications of SAH, several medical complications are common. Hypertension after SAH is associated with an increased risk of vasospasm and higher mortality. Multiple factors may underlie the increase in blood pressure, including increased catecholamine production induced by hypothalamic dysfunction, physiological response to increased ICP in an effort to maintain CPP, agitation, and pain. Blood pressure often returns to normal after hospital admission and/or after analgesics are administered. Disturbances in sodium and water balance occur in approximately one-third of patients, and hyponatremia and volume depletion after SAH are correlated with an increased risk of symptomatic vasospasm and poor outcome. Although hyponatremia was previously thought to be due to inappropriate secretion of antidiuretic hormone and was therefore treated with fluid restriction, later evidence suggested that both sodium and water are lost. The mechanisms underlying the volume contraction and inability to conserve sodium (cerebral salt wasting) are unknown. Finally, cardiac complications, thought to be due to catecholamine excess, are common in the first 48 hr after SAH. Arrhythmias are typically benign but can be severe or fatal.

Electrocardiographic abnormalities and elevated cardiac enzymes, resembling the changes in myocardial ischemia can be seen in more than half of patients. Rare patients may develop stunned myocardium, with transient cardiac pump failure and pulmonary edema.

1. Diagnostic Studies

CT is the imaging modality of choice in screening for SAH, having a sensitivity of $>90\%$. Blood appears as high attenuation within the subarachnoid cisterns. When blood is spread diffusely throughout the CSF spaces, its site of origin may be difficult to detect. Certain bleeding patterns are associated with specific aneurysm locations, however, such as that of blood in the anterior interhemispheric fissure commonly occurring with anterior communicating artery aneurysms. If CT scanning fails to demonstrate SAH and clinical suspicion is high, lumbar puncture is indicated to examine the CSF for blood. Following SAH, CSF contains red blood cells indicative of the hemorrhage, as well as a few white blood cells reflecting the secondary inflammatory response. A yellow pigment (xanthochromia), resulting from red cell breakdown, can be detected in the centrifuged fluid 2–6 hr after hemorrhage, allowing for differentiation from a traumatic spinal puncture. Xanthochromia persists for 1–4 weeks after SAH. Once SAH has been diagnosed, cerebral angiography is performed to identify the responsible vascular lesion, search for other lesions (multiple aneurysms are found in 20–30% of patients with aneurysmal SAH), and assist in operative management. Angiography is negative in 10–15% of patients with nontraumatic SAH. If the blood on CT is localized to the perimesencephalic cisterns and angiography is negative, prognosis is excellent and repeat angiography is almost always negative. Angiography is also used after the acute period in the detection of vasospasm. Another means of evaluating for vasospasm is transcranial Doppler.

2. Prognosis

Untreated aneurysmal SAH carries a poor prognosis, with an estimated mortality rate of approximately 50%. Ten percent of patients die before obtaining medical attention, and 25% die within the first 24 hr. Among survivors of the initial hemorrhage, 30–50% rebleed, an event that increases mortality even further. The risk diminishes after the first month, but even long-term survivors suffer a 3% annual risk of rehemorrhage. Overall, less than one-third of patients achieve good neurological recovery. Predictors of poor prognosis include loss of consciousness or poor neurological condition (i.e., high Hunt and Hess grade; Table IV) on admission, older age, hypertension, preexisting medical illness, $\geqslant 1$ mm thickness of subarachnoid blood on CT (Fisher grade 3), aneurysm location in the basilar artery, and symptomatic vasospasm.

D. Treatment

Management of SAH involves symptomatic treatment and prevention of secondary complications.

Table IV
Hunt and Hess Clinical Classification of SAH

Grade	Description
I	Asymptomatic or mild headache and neck stiffness
II	Moderate to severe headache and neck stiffness ± cranial nerve palsy
III	Mild focal deficit, lethargy, or confusion
IV	Stupor, moderate to severe hemiparesis, early decerebration
V	Deep coma, decerebrate rigidity

Analgesics, antiemetics, and sedatives relieve pain, nausea, and agitation, factors that can contribute to hypertension and rebleeding. Although elevated blood pressure increases the risk of rebleeding, lowering it may reduce cerebral perfusion in patients who have elevated ICP and may worsen neurological symptoms in patients who have vasospasm. Because seizures can increase the risk of rebleeding, anticonvulsants are indicated if seizures occur. The value of prophylactic anticonvulsants in patients who have not had a seizure is unknown. Multiple clinical trials have demonstrated that antifibrinolytic agents reduce the risk of rebleeding, but this benefit is offset by an increased incidence of vasospasm and hydrocephalus. Whether a shorter course of antifibrinolytic therapy (before the risk period for vasospasm begins) might eliminate the negative effect is unknown. In aneurysmal SAH, the most effective way to prevent rebleeding is to obliterate the aneurysm by surgical clipping of its neck. The optimal timing of surgery is controversial, but in patients with good clinical grade (Hunt–Hess grades I–III), favorable neurological outcome is seen more commonly when surgery is performed early (within 72 hr). The role of endovascular repair, using either detachable balloons that trap the aneurysm (but also occlude the parent artery) or electrolytically detachable coils that thrombose the aneurysm, awaits data on long-term efficacy.

Management of vasospasm is largely preventative, involving avoidance of volume contraction and hyponatremia (through hydration with isotonic saline) and administration of the calcium channel blocker nimodipine. Although its mechanism of action is unclear, nimodipine has been demonstrated in multiple controlled trials to significantly reduce the risk of symptomatic vasospasm and poor outcome after SAH. If symptomatic vasospasm develops, treatment strategies include hemodynamic augmentation and directly opening constricted vessels. In hemodynamic augmentation, blood volume and cardiac output are increased via aggressive hydration and blood pressure is increased via administration of vasoactive agents in order to enhance CBF and prevent cerebral infarction. Potential complications of the therapy include heart failure and myocardial ischemia. The second strategy involves endovascular treatment of constricted vessels with either balloon angioplasty or intraarterial infusion of vasodilating agents such as papaverine. Potential complications of endovascular treatments include arterial perforation, cerebral infarction, and aneurysm rebleeding. Each of these strategies has shown efficacy in case series (although the response to papaverine is often transient, with vasospasm returning after 24–48 hr), but controlled trials are lacking.

Suicide

BETH S. BRODSKY and J. JOHN MANN

New York State Psychiatric Institute and Columbia University College of Physicians and Surgeons

GLOSSARY

borderline personality disorder A disorder of the personality that is characterized by dysregulation in emotional and interpersonal functioning and self-destructive and impulsive behavior.

cerebrospinal fluid 5-hydroxyindole acetic acid The major metabolite of serotonin.

dialectical behavior therapy A type of psychotherapy in which cognitive behavioral techniques are aimed at the reduction of suicidal behavior.

major depression A mental disorder characterized by prolonged sadness, lack of pleasure, appetite and sleep disturbance, impaired concentration, extreme feelings of low self-worth and/or guilt, and sometimes suicidal thoughts or behaviors.

psychosis An emotional state characterized by unusual perceptual experiences, such as visual or auditory hallucinations, by delusional thoughts or beliefs, and/or by disorganized thinking or behavior.

serotonin A brain chemical (neurotransmitter) that is believed to have a role in depression and impulsivity.

stress–diathesis model A conceptual framework in which suicidal behavior is seen as a result of the interaction between a trait predisposition with an environmental event.

suicide attempt A self-injurious act committed with an intent to die.

Theories addressing the phenomenon of suicide have been put forth from numerous academic disciplines. However, in the past few decades, empirical research efforts toward improved understanding, prediction, assessment, treatment, and prevention of suicide have come mainly from within the fields of psychiatry and neurobiology. This article summarizes the research findings that both identify risk factors and challenge common myths regarding causal factors for suicidal behavior. A comprehensive hypothetical explanatory and predictive model that incorporates many of these correlates of suicide risk is described. The application of these findings toward improved prevention, treatment, and further research is outlined.

I. INTRODUCTION

A. Suicide Rates

Suicide accounts for more than 30,000 deaths in the United States annually. Men are two or three times more likely to complete suicide than women. Rates of completed suicide in males are higher in the age range of 65–80 years, although during the past 30 years the rates of adolescent suicide have reached levels seen in adults. It is estimated that there are about 10 suicide attempts for every completed suicide. Suicide attempts are more common in women.

B. Definition of Suicidal Behavior

In order to increase specificity in prediction of suicidal behavior, it is necessary to consider the spectrum of suicidal behavior that ranges in severity from completed suicide to suicide attempts and, finally, suicidal ideation. This article encompasses completed suicide and suicide attempts defined as a self-damaging act carried out with at least some intent to end one's life. We do not address various other forms of

self-destructive behavior, such as self-mutilation, failure to cooperate with medical treatment in severely ill patients, cigarette smoking and substance abuse.

Nonlethal suicide attempts are more complex to assess than completed suicide since they include a medical damage dimension. This can range from individuals who survive by chance despite inflicting extensive injuries requiring intensive care treatment to individuals who sustain little or no injury. The assessment of suicidal intent is another dimension that might be ambiguous in light of the individual's survival. Although medical lethality and intent to die are often closely related, this is not necessarily the case in a nonlethal suicide attempt, in which it is possible to have very little medical damage, despite high suicidal intent, or vice versa.

Thus, in the case of nonlethal suicide attempts, broad and not completely distinct categories of suicidal behavior can be generated along the dimensions of medical lethality, level of suicidal intent, and planning. The first category is that of failed suicide, in which a highly lethal method is used that inflicts considerable medical damage and is accompanied by careful preparation and planning. At the other end of the attempt spectrum is a suicide attempt that involves a low lethality method, inflicts little medical damage, and the level of objective intent or planning is relatively low.

In researching nonlethal suicide attempts, the most common predictive factor for suicidal behavior is whether or not an individual has made a suicide attempt (attempter vs nonattempter). Other potential outcome measures include the number of lifetime suicide attempts, the age at first suicide attempt, medical lethality of the most lethal attempt, suicide intent associated with the most lethal attempt, and level of suicidal ideation at different time points.

II. STRESS–DIATHESIS MODEL OF SUICIDAL BEHAVIOR

From the perspective of a stress–diathesis model, suicidal behavior results from the interaction of a behavioral/biologic/genetic predisposition to act on self-destructive urges, together with a stressor or trigger such as an acute psychiatric illness and perhaps an environmental or psychosocial factor (Fig. 1).

A. Predisposing Trait

The criteria for a predisposing trait are stability over time and a consistent correlation with suicidal behavior. Thus, by identifying certain predisposing personality, biological, or genetic traits, the model also further specifies individuals at risk for suicidal behavior within the context of a mood state, environmental stressor, or other state trigger. It also provides a theoretical framework for further research that will increase prediction and recognition of suicidal risk. Viewing risk factors in interaction with each other also allows a vantage point from which to reconsider prevailing misconceptions regarding suicidal behavior. For example, although it makes intuitive sense that a severe life stressor might trigger a suicide attempt, this interpretation does not explain why most individuals with the same objective life circumstances do not make a suicide attempt. Viewing the stressor in interaction with a predisposing trait within the individual can further clarify the role of the stressor without mistakenly concluding that the stressor is the sole explanatory factor or not relevant.

In addition, the recognition of a trait disposition to act on suicidal urges may help identify individuals at risk for suicide across diagnostic categories. Most studies of potential risk factors have examined a single diagnostic group, preventing the generalization of findings to a wider range of clinical patients. Moreover, most studies have examined a narrow range of potential risk factors, preventing the determination of their relative importance and the development of a comprehensive explanatory or predictive model.

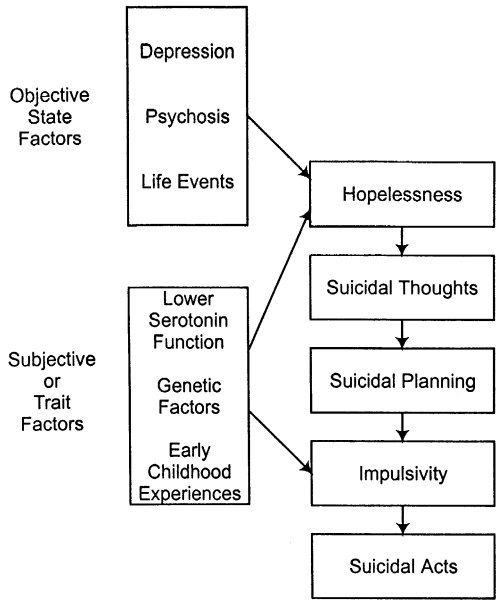

Figure 1 A model of suicidal behavior.

B. State Factors

A stress–diathesis model of suicidal behavior would define stressors as the recurrence of depressed mood or psychotic symptoms within the course of a psychiatric illness or a negative stressful life event, such as the death of a loved one or losing one's job. In the model, such a stressor might lead to the subjective experience of depressed mood, feelings of hopelessness, and suicidal thoughts. The suicidal thinking might lead to more active suicidal planning. At this point, these states would then interact with a trait disposition that might both increase the subjective experience of the depression, hopelessness, and suicidal ideation and interact with the lower threshold to act on the urges or thoughts (Fig. 1).

III. CLINICAL AND BIOLOGICAL CORRELATES OF SUICIDAL BEHAVIOR

A. Clinical Correlates

A previous suicide attempt is the best predictor of a future completed suicide or suicide attempt. However, only 20–30% of individuals who commit suicide have made a previous suicide attempt; therefore, to predict suicide attempts or suicide in the other 80% whose first suicide attempt is successful, it is necessary to identify other predictors of risk.

Much research has been devoted to identifying clinical correlates of suicidal behavior. In terms of demographic characteristics such as age and educational level, studies report conflicting findings. Generally, age tends to be higher among suicide completers but lower in those who attempt suicide than in comparable nonattempter patient populations. Different studies report both higher and lower educational levels in suicide attempters versus nonsuicidal patients. Income level has not consistently emerged as a correlate, although socioeconomic factors such as unemployment and lack of job security have been associated with higher suicide rates. The relationship between marital status and suicide is confounded by an interaction effect with gender. There are higher rates of suicide among whites than blacks. Women attempt suicide more often than men, but men employ more lethal methods and are more likely to complete suicide.

1. Psychiatric Disorders

Approximately 90% of suicide cases have a psychiatric diagnosis at the time of death. Mood disorders generally account for 60% of cases, with major depression being the most common. Lifetime mortality due to suicide is approximately 15% in individuals suffering from major depressive disorder, 20% in those with manic–depressive illness, 18% in alcoholics, and 10% in schizophrenia. In addition, certain personality disorders are known to be associated with high risk for suicidal behavior. In particular, 5–10% of individuals diagnosed with borderline personality, a disorder characterized by impulsive and self-destructive behaviors as well as emotional and interpersonal dysregulation, die by suicide.

Thus, suicide is not merely a complication of a personal crisis or a psychosocial setback; it almost always occurs within the context of a psychiatric illness. Suicide may be understood as an attempt to seek relief from the emotional pain and hopelessness regarding recovery that is often present in individuals with severe, recurrent major depression.

However, most patients with a psychiatric illness do not commit suicide. Moreover, objective severity of depression does not distinguish those individuals who suffer from recurrent major depression who make a suicide attempt from those who do not. This suggests that suicide is not just a logical response to extreme stress or depressed mood state, but that some patients have a vulnerability or predisposition to suicidal behavior. Finding ways of evaluating this predisposition or diathesis can be important for the detection of high-risk patients, and at the same time the diathesis is another potential target for a therapeutic intervention.

2. Personality Traits

Certain personality traits appear to contribute to a predisposition to suicidal behavior. Individuals with major depression, psychotic disorders, and personality disorders that have a history of suicidal behavior also have a greater lifetime history of aggression. Criminals who have a history of suicidal behavior have a history of more severe aggression than criminals who do not have a history of suicidal behavior. Thus, there may be a fundamental predisposition to aggressive behavior, whether it is self-directed, in the form of suicidal behavior or externally directed in the form of aggression against property of other persons.

Impulsivity, a personality trait or cognitive style characterized by a tendency to act more quickly on urges or to stimuli, has been found to be associated with suicidal and self-destructive behaviors within various adult psychiatric populations. Individuals who self-injure or make suicide attempts score higher on

clinical measures of impulsivity. In individuals with borderline personality disorder, the presence or absence of impulsive behaviors in at least two areas of life, such as binge spending, binge eating, reckless driving, gambling, and unsafe sexual practices, is the clinical feature most predictive of suicidal behavior.

Individuals with a past history of a suicide attempt exhibit greater lifetime aggression and impulsivity than nonattempters with the same psychiatric illness. Clinical studies that assess lifetime externally directed aggression and impulsivity have identified a trait aggression/impulsivity factor that distinguishes between suicide attempters and nonattempters regardless of psychiatric diagnosis, level of objective depression, and negative life events. Thus, the association of suicidal behavior and traits of aggression and impulsivity suggests there is a common underlying predisposition to suicidal and aggressive behavior that may relate to impulsivity.

3. Hopelessness versus Reasons for Living

Studies have shown that levels of hopelessness, subjective depression, and suicidal ideation are higher in individuals with previous suicide attempts, and that suicide attempters report fewer reasons for living. This is so despite a lack of significant difference in the objective amount of stressful or negative life events between suicide attempters and nonattempters. In addition, hopelessness is greater in suicide attempters compared to nonattempters during an acute depression, after successful treatment, and between episodes of depression. Hopelessness can predict the risk for suicide over a 10-year follow-up period. These observations suggest that the degree of hopelessness may be influenced by a trait as well as a state vulnerability.

4. Family History and the Familial Transmission of Suicide

Clinical studies show that a family history of suicide is associated with a greater risk of both suicide attempts and completed suicide. Genetic and familial factors have been investigated in association with psychiatric diagnoses in general and suicide risk in particular. Twin studies show that monozygotic twins have a greater concordance for suicidal behavior than dizygotic twins. Adoption studies report the transmission of a genetic risk factor for suicide, independently of psychiatric illness. This is illustrated by the Copenhagen Adoption study, which found a significantly higher percentage of suicide in the biological families of the suicided adoptees compared to matched adoptees who did not commit suicide. Recently, molecular genetic studies have reported that a polymorphism in the tryptophan hydroxylase gene is associated with suicidal behavior.

There is also evidence that suicidal behavior transmitted in families independently of psychiatric diagnoses is related to transmission of impulsive aggression. It is possible that genes might be responsible for lower serotonergic functioning, which is associated with trait aggression and impulsivity. Genetic transmission of a propensity for externally directed aggression and suicidal behavior, independent of transmission of major depression, is consistent with evidence that the diathesis for suicidal behavior is transmitted in families independent of psychiatric diagnosis.

Trait aggression and impulsivity may also be a result of early life family experiences, including a history of physical or sexual abuse. Indeed, adults who have made at least one suicide attempt are more likely to report a history of childhood abuse, independent of their psychiatric diagnosis.

5. Neuropsychological Correlates

Recent neuropsychological studies have begun to identify certain features of cognitive processing that distinguish individuals who have made a suicide attempt from those who have not. High lethality suicide attempters do worse than nonattempters on tasks that measure cognitive flexibility, which may affect decision making. On timed tasks that measure impulsive cognitive style, suicide attempters make more commission errors, suggesting that they may be more likely to act inappropriately under conditions of uncertainty. These neuropsychological measures of impulsivity and impaired decision making may ultimately prove to be more sensitive than a clinical history risk assessment.

B. Biological Correlates

Investigation of biological correlates of suicidal behavior has generated evidence for a trait predisposition that distinguishes between individuals at high risk versus low risk for suicidal behavior. Neurobiologic studies have also identified biological correlates of the clinical risk factors for suicide mentioned previously, such as depressed mood, trait impulsivity, and aggression. These findings have come from postmortem studies on the brain tissue from suicide victims as well as from studies of neurotransmitter function in live individuals with a history of serious suicide attempts.

1. Neurotransmitters

A large number of studies of postmortem brain tissue from suicide victims have been carried out examining indices of the serotonergic, noradrenergic, and dopaminergic neurotransmitter systems.

a. Serotonin Serotonin is a neurotransmitter that is implicated in depression and impulsivity. Studies of the serotonergic system have generally found evidence of reduced serotonergic activity in suicide victims, as indicated by decreases in presynaptic serotonin nerve terminal binding sites. Autoradiographic studies of postmortem brain tissue suggest that these abnormalities in suicide victims are more pronounced in the ventral prefrontal cortex than in the dorsolateral prefrontal cortex.

Similarly, postsynaptic serotonin receptors, such as the 5-HT1A and 5-HT2A receptors, appear to be increased in number in the prefrontal cortex of suicide victims. One possible explanation for the increases in these subtypes of postsynaptic serotonin receptors is compensatory upregulation in response to reduced serotonin neuron activity. Most of these altered serotonin receptor binding indices are detected in the ventral prefrontal cortex, which indicates that this brain region is of particular importance in relation to the risk for suicide. The reduction in the presynaptic serotonin nerve terminal transporter binding and the increase (possibly compensatory) in postsynaptic receptor binding are consistent with the notion of reduced serotonin input into this brain region.

The ventral prefrontal cortex is involved in the executive function of inhibition, and injuries to that area of the brain have been shown to result in cognitive and behavioral disinhibition. Reduced serotonergic input into this part of the brain may also result in impaired inhibition and a greater propensity to act on powerful feelings such as suicidal or aggressive feelings. In support of this hypothesis, most postmortem studies of brain stem levels of serotonin or its major metabolite, 5-hydroxyindole acetic acid (5-HIAA), have found modest reductions in suicide victims, suggesting that serotonergic activity may be reduced in these individuals.

Serotonin function has also been measured in survivors of nonlethal suicide attempts using several techniques. Samples of cerebrospinal fluid (CSF) are assayed to determine levels of serotonin metabolite 5-HIAA. Most studies report that about two-thirds of major depressives who have attempted suicide have lower CSF 5-HIAA levels compared to nonattempters with the same psychiatric diagnoses. In addition, low CSF 5-HIAA predicts future suicide attempts and suicide completion. Similarly, lower CSF 5-HIAA has been found in schizophrenics with a history of suicidal behavior compared to schizophrenics without such a history and also in individuals with personality disorders who make suicide attempts compared to patients with the same diagnosis who do not. Therefore, low CSF 5-HIAA, consistent with the notion of a biochemical trait, appears to be a relatively stable marker that is associated with suicide attempt behavior, independent of psychiatric diagnosis.

The medication fenfluramine, known to stimulate the release of serotonin, has been widely used in challenge studies in which prolactin levels in the blood (a proxy measure for serotonin response) are measured and compared in the same individual after administration of the active fenfluramine medication or a placebo. Individuals with major depression or personality disorders who have attempted suicide have a blunted prolactin response elicited in response to fenfluramine. The more lethal the suicide attempt, the more likely there is to be low CSF 5-HIAA or a blunted prolactin response to fenfluramine. Brain imaging techniques such as positron emission tomography (PET) scans provide an even more sensitive measure of serotonin functioning by evaluating regional changes in serotonin receptors or regional responses to fenfluramine. Such studies are currently in progress.

In addition, serotonin mediates a number of platelet functions, some of which are altered in suicide attempters. A relationship between lethality and higher platelet 5-HT2A receptor number has been reported. Thus, three different indices of serotonergic function appear to correlate with suicidal behavior. The serotonergic correlations with suicide appear to be equally strong regardless of the associated psychiatric disorder. Therefore, the serotonergic abnormality in the ventral prefrontal cortex of suicide victims may be related to the predisposition to suicidal behavior rather than to the psychiatric illness that may have triggered it.

b. The Noradrenergic System A number of alterations in noradrenergic indices are also reported in suicide victims, although the results are less consistent than those for the serotonergic system. The noradrenergic system is implicated in the neurobiological response to stress. In postmortem brain tissue of suicide victims, there is evidence of a reduced number of noradrenergic neurons in the locus coeruleus. In addition, levels of norepinephrine appear to be lower

in the brain stem of suicide victims and α_2- adrenergic autoreceptor numbers are increased. We have proposed that norepinephrine may be depleted from the smaller numbers of noradrenergic neurons present in the brain stems of suicide victims. Studies of chronic stress in rodents report depletion of norepinephrine. There is evidence of hyperactive stress response systems in depression. Thus, these biochemical findings could potentially be a result of the stress preceding a suicidal event in a serious psychiatric illness.

c. Dopamine Fewer studies have been carried out on the dopaminergic system. There is postmortem evidence of decreased dopaminergic binding in the prefrontal cortex of adolescent suicide victims. In live suicide attempters with major depression, there have been reports of reduced CSF homovanillic acid (the major metabolite of dopamine) as well as reports linking reduced dopaminergic function to major depression. Studies are under way to evaluate the dopaminergic system in suicide attempters.

C. Suicide, Aggression, Impulsivity and Neurobiology

Recent reports indicate that impulsivity and externally directed aggression are associated with low serotonin activity. Low CSF 5-HIAA has been shown to be present in impulsive murderers and arsonists compared to nonimpulsive murderers and other criminals as well as control subjects. A blunted prolactin response to fenfluramine (an indication of low serotonin activity) has been reported in association with aggressive behavior and impulsivity in individuals with personality disorders and major depression and medically healthy volunteers. Thus, reduced serotonergic function appears to be associated with impulsive aggression. This relationship is analogous to that between serotonergic function and suicidal behavior and leads to the more general hypothesis that serotonergic function supports a restraint mechanism, and a deficiency of serotonergic function results in greater impulsivity and aggression that also include self-directed aggression in the form of suicidal behavior.

D. Environmental Factors

Genetic and familial factors, as well as early childhood familial environmental factors such as childhood abuse, may be responsible for the transmission of suicidal behavior via trait aggression and impulsivity. Early childhood environmental factors might either contribute to the lower serotonergic functioning or personality traits of impulsivity/aggression or be correlated with them, with the lower serotonergic functioning as the underlying correlate of the trait factor. Demonstrating the interaction of genetics and environment, peer-reared monkeys when compared to maternally raised monkeys have their serotonergic activity reset to a lower level that persists into adulthood. The rank order of their serotonergic activity is not altered within the peer-raised monkeys. Thus, the effects of rearing are superimposed on the genetic effects. Given that a history of child abuse is associated with a greater risk for suicidal behavior in adulthood, it may be useful to extrapolate from the findings of these monkey studies that examine environmental deprivation. It is possible that child abuse resets serotonergic function at lower levels and this neurochemical effect persists into adulthood, contributing to the increased risk for suicidal behavior.

Other environmental suicide risk factors that might correlate with lower serotonergic function include alcoholism, substance abuse, smoking, and head injury. These risk factors might also interact with each other. Alcoholism and substance abuse are associated with head injury and higher scores on clinical measures of impulsivity. In fact, approximately 50% of head injuries are sustained while using alcohol, thereby resulting in disinhibition and a greater probability of suicidal behavior.

Potentially related to the increased rate of substance abuse and alcoholism in the suicide attempters is the observation that cigarette smoking is more common in individuals who have made a suicide attempt. Smoking is associated with higher rates of completed suicide as well, independent of any association of psychiatric illness with smoking.

In nonhuman primates, low levels of cholesterol or cholesterol-lowering treatments are associated with an increase in suicidal behavior and a decrease in serotonergic function. In addition, a low-cholesterol diet in nonhuman primates is associated with an increase in aggressive behaviors and a decrease in social contact. Thus, cholesterol levels appear to have a measurable, although small, effect on behavior involving aggression and suicidality. The link between the serotonergic system and cholesterol levels remains to be demonstrated in humans.

Given the evidence linking low serotonergic activity separately to suicidal behavior, aggression, and alcoholism, it is conceivable that low serotonergic activity may, to some degree, underlie all three problems and

that low serotonergic activity may mediate genetic effects on suicide, aggression, and alcoholism. Reports of increased aggression, impulsivity, cocaine and alcohol consumption in mutant mice lacking the 5-HT1b receptor indicate that a genetically-mediated serotonin abnormality can result in both increased impulsive aggression as well as possibly alcoholism and substance abuse. Although suicidal behavior is never observed in a rodent model, other elements of disinhibitory psychopathology are observed in this model.

In summary, much of clinical suicide research has focused on the identification of isolated demographic, diagnostic, and biological correlates of suicidal behavior. In addition, clinical assessment of suicide risk has focused on objective severity of symptoms as well as life stressors. However, recent findings identify an aggressivity/impulsivity trait that along with a biochemical trait of lowered serotonergic functioning are predictive of suicidal behavior independently of psychiatric diagnostic groups, depressed mood state, and level of external stressors.

IV. CLINICAL ASSESSMENT, INTERVENTION, AND PREVENTION

A. Risk Assessment

Recognition of risk is vital to suicide prevention. Conceptualizing risk as an interaction of trait predisposition and state mood and/or environmental trigger can lead to better detection of high-risk patients. Accordingly, a clinical history should focus on the parameters that reflect a diathesis or predisposition for suicidal behavior. These include the following: (i) impulsive behaviors such as binge spending, binge eating, substance abuse, reckless driving, and unsafe sexual practices; (ii) other outwardly directed aggression across the life span on a continuum from less severe incidents, such as temper outbursts, conflicts with authority figures such as teachers and supervisors, and arguments that involve verbal abuse, to more severe physical fights, legal problems, threatening behavior, assault, and use of weapons; (iii) family history of a suicide attempt and/or suicide and any report of physical and/or sexual abuse in childhood are associated with suicidal behavior in adulthood; and (iv) levels and patterns of hopelessness and suicidal ideation that are disproportionate to the objective severity of depression or life events in individuals with a history of suicidal acts. In terms of state, the sense of hopelessness, subjective depression, perception of fewer reasons for living, and especially severity of suicidal ideation correlate with suicide attempts.

In the near future, perhaps biological measures of serotonin and other neurotransmitter activity, as well as neuropsychological measures, will supplement clinical history to increase sensitivity of assessment and risk prediction. These measures currently involve the measurement of CSF 5-HIAA; however, newer techniques involving functional brain imaging of serotonergic activity and candidate gene markers hold promise. Given the rapid advances in PET imaging of serotonergic function *in vivo*, and the identification of polymorphisms in serotonin-related candidate genes, we now have the tools for developing neurobiological tests to detect patients at high risk for suicide.

B. Psychopharmacology

Unfortunately, despite the great progress made during the past 35 years in the development of effective medications for the treatment of major psychiatric illnesses, there has been little reduction in suicide rates. This is not due to a failure to contact health care professionals, because most studies report that the majority of patients (between 50 and 80%) have seen a health care professional within 30–90 days of suicide. However, among individuals who have committed suicide in the context of major depression, most studies find that only 10–14% of these individuals received adequate doses of antidepressant treatment prior to suicide. Thus, it appears that there is the potential for more effective recognition of psychiatric conditions such as major depression and the treatment of these conditions with adequate doses of antidepressants in terms of reducing suicide rates. A Swedish study in which primary care physicians were educated on the diagnosis and treatment of depression resulted in an increase in prescription rates of antidepressants and a decrease in suicide rates.

Choosing the best medication partially depends on the psychiatric disorder associated with suicidal ideation. Some studies suggest that selective serotonin reuptake inhibitors (SSRIs) produce a more rapid amelioration of suicidal symptoms in patients with major depression. This observation is consistent with a model of suicidal behavior that posits reduced serotonergic activity as underlying the vulnerability to suicidal behavior in the presence of major depression or any other psychiatric disorder that is accompanied by suicidal ideation. Lithium, which enhances

serotonergic activity, appears to reduce suicide risk in bipolar patients, providing further support for a role of serotonin in moderating suicide risk.

Treating patients with the newer SSRI antidepressant medications instead of older tricyclic antidepressants, which are more lethal on overdose, has the potential for reducing suicide rates. Non-antidepressant sedative medications, such as barbiturates or benzodiazepines, should be avoided in the treatment of patients with mood disorders. Failure to improve the mood disorder, combined with potential disinhibition by these sedatives and their lethality on overdose, makes for a risky treatment strategy.

C. Psychotherapy

Treatment should target impulsivity and aggression as well as depressed mood and psychotic symptoms. A promising psychotherapeutic approach to the treatment of self-injurious behavior in individuals with borderline personality disorder is dialectical behavior therapy (DBT), a form of cognitive behavioral therapy designed to specifically target self-injurious behaviors and the personality traits that contribute to self-injury, such as impulsivity. This therapy is based on the biosocial theory, in which borderline personality disorder is described as a disorder of emotional, cognitive, and behavioral dysregulation. According to this theory, dysregulation in these areas of function arises from a genetic predisposition to an emotionally vulnerable temperament in interaction with an emotionally invalidating environment. Such a conceptualization of interaction between biological and environmental factors is similar to a diathesis–stress model of suicidal behavior. DBT therapy involves the teaching of skills to regulate emotions and behavior as well as to reframe thinking that leads to hopelessness and suicidal ideation. Interpersonal skills target the types of life events that tend to trigger suicidal behavior in these individuals. Empirical studies testing the efficacy of DBT indicate that the therapy decreases self-injury without a concomitant decrease in depressive symptoms. These findings also support the idea of self-injury being related to behavioral traits that are independent of a diagnosis of depression.

Other interventions for suicide prevention include psychoeducation for primary care physicians to recognize the signs of depression and for the general public to be more familiar with the warning signs of suicide. An increase in the availability of parenting classes would help identify and address the stressors that often lead to early life experiences of physical and sexual abuse.

V. DIRECTIONS FOR FUTURE RESEARCH

The stress–diathesis model of suicidal behavior provides a comprehensive framework in which the interaction of various risk factors for suicidal behavior can be further explored in order to increase specificity in the prediction of suicidal risk. Prospective studies are under way to increase understanding of the interaction between biological and environmental factors. Newer technologies are being employed to measure biological and neuropsychological traits that interact with mood states and environmental triggers in the development of more sensitive tools for suicide risk assessment. Treatment outcome research with high-risk subjects is being conducted to compare the efficacy of serotonin reuptake inhibitor medications, DBT, and other psychotherapy approaches in decreasing suicidal behavior.

Superior Colliculus

BARRY E. STEIN, MARK T. WALLACE, and TERRENCE R. STANFORD
Wake Forest University School of Medicine

GLOSSARY

anuran A tailless amphibian such as a frog or toad.

contralateral Located on the opposite side of the body.

encephalization The evolutionary and developmental processes by which the cerebral cortex takes over the functions of lower brain structures.

geniculostriate Relating to the visual pathway connecting the lateral geniculate nucleus of the thalamus to the primary visual cortex.

habituation The diminution or loss of a response to a frequently repeated stimulus.

homolog A structure or organ similar in form and origin to that in another organism.

ipsilateral Located on the same side of the body.

lamina Layer.

motor error The distance of a target stimulus from the current position of gaze.

movement field The range of amplitude and direction (saccade vector) to which the motor-related discharge of a superior colliculus saccade-related neuron is associated (the motor counterpart of a neuron's sensory receptive field).

receptive field The area of the sensory field (or the receptor epithelium) that when stimulated influences the activity of a single neuron.

retinal error The difference between the location of a visual stimulus on the retina and the fovea.

saccade A very rapid, conjugate movement of the eyes (such as those used in reading).

somatotopy The topographic representation of the body in the brain.

spatiotopic A topographic representation of space (e.g., a map of auditory space).

stereopsis The ability to use binocular cues in order to determine depth.

tonotopy The topographic representation of frequency in the brain.

topography The delineation or description of a map of the features of a sensory representation in the brain (e.g., the arrangement of the visual receptive fields into a map of visual space).

vector The amplitude and direction of a movement.

ventricle One of a system of interconnected cavities in the brain that is filled with cerebrospinal fluid.

visuotopy The topographical representation of the retina, and hence visual space, in the brain.

The superior colliculus plays its primary role in generating and controlling orientation behaviors. It is best known for its role in initiating eye and head movements (collectively referred to as the control of gaze) made for the purpose of bringing an object of interested onto the fovea, the region of the retina that offers the greatest spatial acuity.

I. INTRODUCTION

The name superior colliculus (SC) is derived from the shape and location of this structure on the surface of the midbrain: ''colliculus'' because it reminded early

neuroanatomists of a small hill (the root "collis" is the Latin term for hill), and "superior" because it is found immediately above a second rounded structure, the inferior colliculus. Although most often associated with the visual modality, the SC receives information from multiple senses (visual, auditory, and somatosensory) and, like most structures in the central nervous system, it is paired: There is one SC on each side of the brain and each receives information primarily about contralateral space. Simply stated, sensory inputs originating from the left reach the right SC, which in turn generates leftward orienting movements. Similarly, the left SC receives input from right space and accordingly produces orientation shifts to the right.

Although a great deal has been learned about how the SC processes the sensory information and initiates the motor responses that comprise its behavioral role, overall views of its impact on overt behavior, its intrinsic organization, the functional properties of its constituent neurons, its interactions with other brain structures, and its evolutionary transition from an earlier premammalian form have changed significantly as a result of the intense scrutiny that has been directed toward this structure during the past few decades. It seems unlikely that current concepts of SC organization and function will change substantially in the future (and this will almost certainly be reflected in some of the categorical statements made in this article), but a note of caution is appropriate here because this also may have been the view of earlier researchers.

II. EVOLUTIONARY CONSIDERATIONS

In terms of the evolutionary history of the brain, the SC is a very old structure. Its nonmammalian homolog is the optic tectum, a structure that antedates the development of primitive mammals and the appearance of the neocortex. The optic tectum, like the SC, derived its name in part from its position in the brain (Fig. 1). The word "optic" pays heed to its massive retinal input, and the word "tectum," Latin for "roof," refers to the fact that it covers a large ventricle in the midbrain. Given the close homology between the optic tectum and the SC, it is not exactly clear why it is necessary to refer to them by different names. Presumably, part of the explanation lies in the fact that the SC does not overlie a large ventricle but rather a narrowed aqueduct between two ventricles and, thus, is not as rooflike in appearance as is the optic tectum. To add to the confusion, there are a number of general descriptive sources that continue to refer to the SC as the tectum. Sometimes there is no accounting for the oddities in anatomical nomenclature.

The optic tectum is considered the principal visuomotor structure in the central nervous system of nonmammalian vertebrates, and an excellent example of its sensory and motor roles is apparent in the prey-catching behavior of frogs and toads. This behavior can be readily evoked in alert animals by stimulating the structure through permanently implanted microelectrodes. The electrical stimulus mimics the effects of a natural sensory stimulus and elicits a complete prey-catching sequence. The behavior has a number of very specific components: The frog or toad turns toward the presumptive prey in contralateral space, flicks out its tongue to capture the prey, grasps this illusory prize with its jaws and brings it into its mouth, gulps, and then finally cleans its snout. Electrophysiological studies of the responses of individual frog or toad tectal neurons have shown that they respond best to the same kinds of stimuli that elicit natural prey-catching responses: dark objects that approximate the size of prey animals and move at appropriate speeds. These studies also indicate that the overall organization of tectal neurons, as well as their individual response properties, is well suited to the task of coding stimulus location and, via connections with motor structures, they are involved in initiating the motor programs through which the prey is captured. The stereotypical nature of tectal-mediated behaviors in the adult frog and toad, and their comparative insensitivity to alteration through learning, have made the anuran optic tectum a convenient and productive neural model for studies of visuomotor function. Behavioral and electrophysiological studies in other nonmammalian vertebrates, such as salamander, iguana, snake, pigeon, and barn owl, have collectively enhanced our knowledge of the stimuli that gain access to this circuitry and to the behaviors that it mediates.

Many of the characteristics of the optic tectum were altered during the evolutionary transition to mammalian forms nearly 200 million years ago. It was during this time that a host of radical changes were taking place in much of the brain that is believed to have characterized the premammalian reptile. The most prominent of these changes was the emergence of a neocortex (hereafter referred to simply as cortex). New capacities began to appear that were dependent on this new cortex and that were greatly elaborated with the appearance and increasing encephalization of new and more complex species. Brain circuits were redesigned, thereby transforming the sharing and/or localization

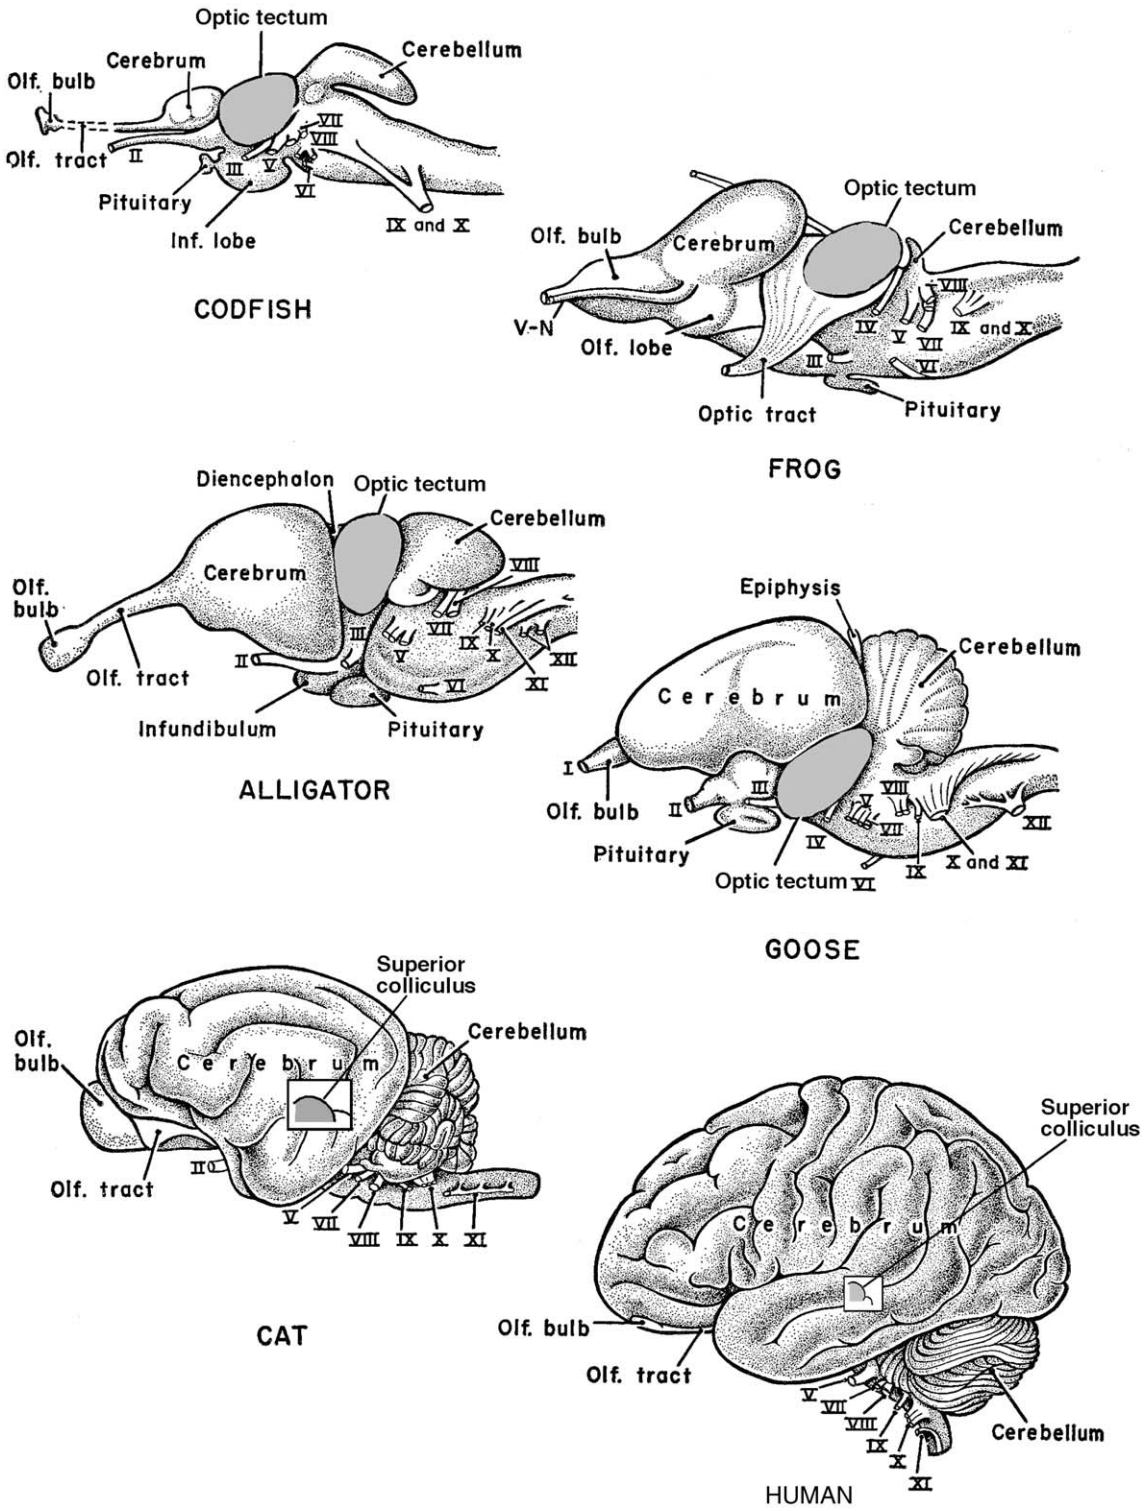

Figure 1 The optic tectum and superior colliculus in a variety of species. Note that in cat and man, an illustrative "window" is cut into the cortex in order to view the underlying superior colliculus (adapted with permission from Truex and Carpenter, 1964).

of older functions. The midbrain did not escape these evolutionary alterations. Not only did the anatomical appearance, relative size, lamination pattern, and internal organization of the optic tectum change but also its preeminent role in vision declined and some of its functional roles were altered and/or shifted to geniculostriate and extrastriate cortical systems. Although the stereotyped and complete behavioral sequences that were coded in the optic tectum (and released by an electrical stimulus) were lost during the evolution to the SC, its role in coordinating sensory inputs with motor commands was retained and adapted to changes that were taking place in peripheral sensory and motor organs. Indeed, at least some of the visual response properties of optic tectum neurons that served its functions so well are also recognizable in the properties of SC neurons that are described in this article.

III. CHANGING CONCEPTS OF THE ROLE OF THE SUPERIOR COLLICULUS

For some time it was believed that the role of the SC was restricted to reflex orientation of the eyes in response to visual stimuli, and some modern medical dictionaries still refer to it simply as the center of visual reflexes. The heavy direct retinal input to the SC and its homology with the optic tectum guaranteed that its visual role would be emphasized (and that its nonvisual inputs would receive considerably less early attention), and the recognition of its role in eye movements was a consequence of neurological studies in anesthetized animals that began more than 100 years ago. In these early studies investigators employed direct and localized electrical (and later chemical) stimulation to a host of brain structures. The idea was to determine the functional significance of these areas on the basis of the overt responses that could be evoked by directly activating them, a motivation shared by modern researchers interested in frog and toad tectum. Stimulation of the SC in this way produced rapid, contralateral movements of both eyes and began a long tradition of studies designed to determine how the activity of SC neurons is triggered by natural stimuli and how its neurons code the metrics of an eye movement or shift in gaze. The more sensory aspects of visual function, such as the ability to provide the subjective sensory experiences that are peculiar to this sensory modality or the ability to discriminate the form, pattern, or identity of a visual stimulus, were thought to be a consequence of activation of the geniculostriate system: The projection from the retina to the lateral geniculate nucleus in the thalamus and from there to primary visual cortex (also known as "striate" cortex).

Views of the role of the SC began to change in the mid-to-late 1960s when it was found that animals that had the SC removed exhibited a striking sensory neglect. An animal with the SC damaged on one side behaved as if it were unaware of, or totally disinterested in, sensory stimuli in its contralateral sensory field, even though its geniculostriate system was intact (Fig. 2). Although this deficit was not restricted to vision (auditory and somatosensory defects were noted as well), the visual impairment was the most prominent and received the greatest attention. In large part this was because the visual deficit did not fit the established dogma of how visual function was supposed to be segregated in the brain, and this provoked considerable surprise. Animals with SC lesions had no obvious motor impairments and could easily move about a room without banging into obstacles. However, they did not react to stimuli in the contralateral visual field, even those that were clearly rewarding or threatening. Although, given enough time after the lesion, these deficits were gradually ameliorated, presumably as a consequence of compensation through changes in other brain areas, contralateral visual stimuli never regained their prelesion effectiveness. Similar observations were made in rodents and primates. Experiments in which the same animals were tested on different visual tasks after experiencing damage limited to either

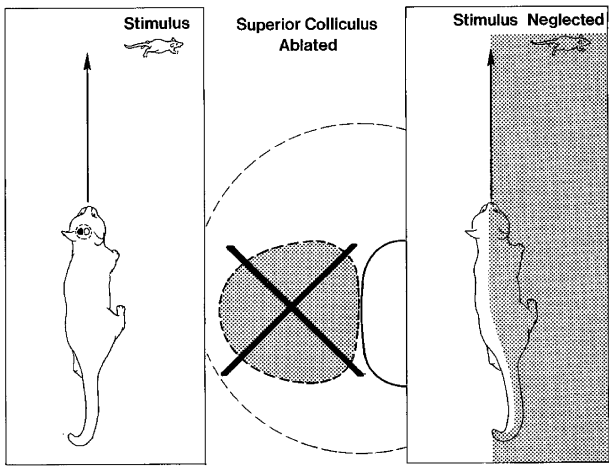

Figure 2 Ablation of a single SC results in contralateral sensory neglect. In this example, ablation of the left SC results in a neglect of stimuli in the right half of sensory space (reproduced with permission from Stein and Meredith, 1993).

the visual cortex on one side of the brain or to one SC yielded data consistent with the presence of two largely independent visual systems. The first of these, based in cortex, was involved primarily in evaluating the features of a stimulus. The second, based in the SC, was involved primarily in the initiation of an orientation to that stimulus. For simplicity, these were referred to as the "what" and "where" divisions of the visual system, highlighting the differential contributions of these regions to visual function (a dichotomy that has been revisited in terms of how visual information processing is now believed to be segregated in the primate neocortex).

The results of recent studies of the SC have tended to minimize this conceptual dichotomy and have stressed the anatomical and functional interdependence, rather than independence, of these structures. Without denying their differing roles, the SC and visual cortex are now believed to work cooperatively in order to ensure that a sensory stimulus is attended and scanned and its features are processed. The particular reliance of the SC on influences from the visual cortex has become evident from studies documenting the changes in SC-mediated behaviors in animals in which visual cortex has been damaged.

IV. INTERACTIONS BETWEEN VISUAL CORTEX AND THE SUPERIOR COLLICULUS: THE SPRAGUE EFFECT

One of the most striking examples of the delicate balance that normally is maintained among structures at different levels of the visual system was provided by James Sprague in 1966. Sprague used the cat's normal tendency to turn and examine a novel stimulus in order to map its visual field. He showed that when facing forward, the cat's visual field extended about 90–105° into peripheral space on either side of fixation. He then used this technique to evaluate the effects of large lesions of visual cortex on visually guided behavior. He found that large lesions that eliminated all visual cortex produced a profound contralateral visual neglect, similar to that produced by SC lesions. However, when he removed the SC on the opposite side, the defect was reversed (Fig. 3). Now the animal was able to react to stimuli in the previously "blind" hemifield but not to stimuli in the previously normal hemifield.

This finding became known as the Sprague effect and represents a dramatic demonstration of the

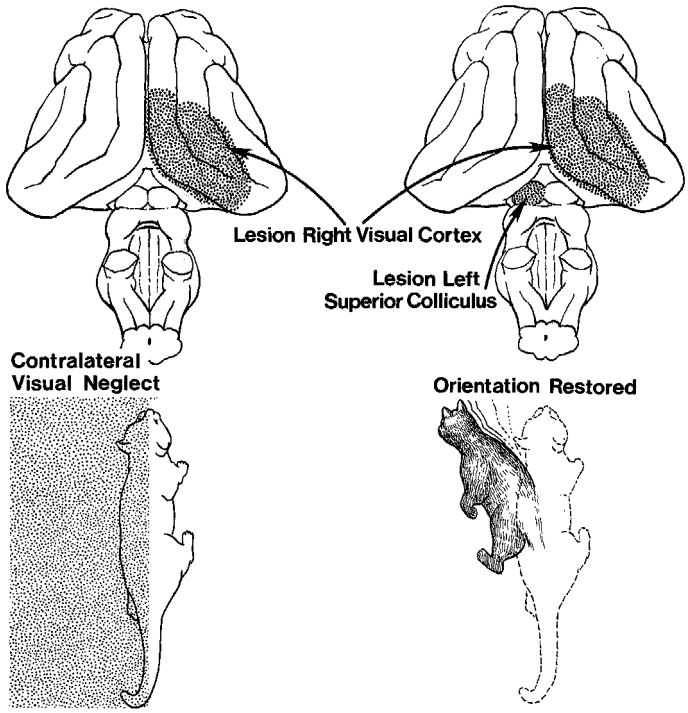

Figure 3 The Sprague effect. A large lesion of the right cerebral cortex, encompassing striate and extrastriate visual areas, results in a neglect of visual stimuli in the left hemifield. However, when this cortical lesion is paired with a lesion of the opposite (i.e., left) SC, orientation behavior is restored in the previously neglected hemifield (reproduced with permission from Stein and Meredith, 1993).

amelioration of a lesion-induced defect by another lesion (though a new defect is simultaneously induced). The explanation lies in the balance of excitatory influences the SC receives from the visual cortex on the same side of the brain and the inhibitory influences that are routed to it via the SC on the opposite side. Removing the cortical source of excitation allows SC neurons to become dominated by inhibition from the opposite side of the brain. These inhibitory inputs are derived from the basal ganglia, specifically from its output structure, the substantia nigra. The fibers carrying this inhibition pass through the SC on the opposite side, enter the intercollicular commissure, and finally synapse on their target neurons. Removing their inhibitory influences by removing the opposite SC or, as was shown later, by cutting the intercollicular commissure, restored a balance to the system, thereby freeing the SC to regain some of its function. Undoubtedly, its neurons did not recover all of the characteristics they had before visual cortex was removed, but enough of its neurons were functioning sufficiently well to support gross orientation behaviors.

At the heart of the Sprague effect is the importance of symmetry between the two halves of the brain. This interhemispheric balance appears to be crucial in some circumstances and may help explain the seemingly odd observation that removal of one SC produces a more pronounced visually guided defect than does removal of both. Apparently, it is easier for the brain to deal effectively with their combined loss than to compensate for the imbalances associated with one functional and one nonfunctional SC.

V. ANATOMICAL AND FUNCTIONAL ORGANIZATION OF THE SUPERIOR COLLICULUS

A. Laminar Organization

The SC is a layered structure consisting of seven alternating cellular and fibrous laminae. Its layering reflects the organization of its inputs, outputs, and interconnections, but it has generally been divided into two functional divisions: superficial (layers I–III) and deep (layers IV–VII). Sensory neurons in the superficial layers are responsive only to visual stimuli, whereas deeper layer neurons may be responsive to visual, auditory, or somatosensory stimuli (i.e., modality-specific neurons) or to inputs from two or three of these sensory modalities (i.e., ''multisensory'' neurons). Furthermore, the outputs of superficial layer neurons are directed primarily to sensory nuclei in the thalamus, whereas those of the deep layers project heavily to brain stem and spinal cord areas involved in motor responses. It is the deeper laminae that are most directly linked to the immediate overt behavioral responses mediated by the SC.

The possible behavioral differences served by the superficial and deep layer neurons were underscored in a study by Casagrande and colleagues in the 1970s in which selective lesions to the superficial layers in young tree shrews did not induce any obvious disruption of overt behaviors. Such overt behavioral defects were induced only by lesions that included the deeper layers. Extrapolations from the results of these experiments to adult animals were complicated by the well-known ability of the brain to compensate for early localized damage. Replications have not been forthcoming primarily because it is very difficult to produce lesions that are restricted to the superficial layers of the SC in any animal. There are unpublished observations suggesting that a superficial layer lesion in an adult cat that produced only minor damage in deeper layers did induce orientation defects. Although this must be replicated in other animals, the observation is consistent with findings suggesting that the superficial layer neurons can influence neurons in deeper layers via interlaminar connections. It is also possible that ascending projections from superficial layer neurons could exert their influence indirectly through a series of connections in thalamus and then to those cortical territories that target the deep SC. Though speculative, the heterogeneity of output pathways could allow superficial layer neurons to participate in the sensory discriminative functions carried out within thalamocortical systems as well as contribute to the orientation functions of the deep SC.

B. Visual Receptive Field Properties

Initial attempts to understand the properties of SC neurons were begun before superficial–deep layer distinctions had substantial impact on concepts of SC function. The objective of these early electrophysiological studies was to determine how the visual properties of SC neurons differed from those in other areas of the brain. Because visual neurons were most heavily represented in the superficial layers, these were the neurons most often examined. The general assumption guiding these studies was much the same as that guiding similar electrophysiological studies in other brain areas, specifically that those stimuli that

have the best access to the circuitry of the SC also have the best access to SC-mediated behaviors. In a quirk of science, initially the least amount of attention was devoted to the deeper layer neurons that were most relevant to the investigators' motivation, a situation that has since changed. Fortunately, however, superficial and deep layer neurons share many of the same visual receptive field properties, a surprising observation considering their different sources of visual information. Superficial layer neurons get heavy projections from the retina and from striate cortex, neither of which heavily target deeper layer neurons. In contrast, deep layer neurons receive their principal visual inputs from extrastriate cortical areas. Nevertheless, both superficial and deep layer neurons transform the signals they receive from their converging inputs into a set of response properties that distinguish them from their afferent sources, sometimes in subtle ways and sometimes in obvious ways.

By recording the activity of individual neurons, early investigators were able to identify these neuronal properties. The first step was to determine where a stimulus had to be placed in visual space in order to activate a given neuron (the neuron's visual receptive field). It was then possible to determine which visual stimuli, when presented within this region of visual space, would most reliably and most vigorously activate that neuron. The strategy was to use the same sorts of approaches that had proved so successful in the pioneering work of Hubel and Wiesel in the 1960s in which they studied the organization of visual cortex, a strategy that was also being used in studies of other geniculostriate structures. This entailed the presentation of a variety of simple visual stimuli whose characteristics were easily quantified and could be systematically varied to examine their effects on a neuron's responsiveness. Stationary flashed spots, edges, and bars of various sizes, intensities, orientations, and positions were presented within each neuron's receptive field, and similar stimuli were moved across the receptive field in different directions and at various speeds. The composite results describing the selective response properties for any given neuron were referred to as that neuron's receptive field properties. By studying many hundreds or thousands of neurons, it would be possible to determine the kinds of stimuli that were most effective in activating this population and then contrast them with the properties of neurons in other visual structures.

The receptive field properties of SC neurons proved to be unlike those of neurons in the retina, lateral geniculate nucleus, and the first stage of visual processing in striate cortex (i.e., the so-called simple cells). Retinal neurons and their target neurons in the lateral geniculate nucleus are readily activated by stationary flashed lights. Their receptive fields are characterized by a central core that is activated either by light onset or offset ("on" or "off") and a surrounding region with the opposite response ("off" or "on"). Larger stimuli within the "on" or "off" regions produce greater responses, but these different receptive field areas are mutually antagonistic so that when they are stimulated simultaneously they inhibit one another. A change in this receptive field structure takes place at the first stage of information processing in primary visual cortex, where the outputs of the lateral geniculate nucleus synapse on their simple cell targets. Although simple cells also have "on" and "off" regions that antagonize one another, these regions are now juxtaposed, forming an elongated receptive field for which angles and edges have now become the most effective stimuli. Although these properties are believed to be critical for the brain to ultimately construct a mechanism for detecting the angles, edges, and contours necessary to discriminate among shapes and patterns, these are not primary functions of the SC. SC neurons respond poorly to stationary flashed lights, and those that do respond to these stimuli do not show separate "on" or "off" receptive field subregions. Rather, they prefer stimuli that move across their receptive fields regardless of their shape or orientation. In addition, such neurons are tuned for the speed and direction of stimulus movement. Furthermore, unlike some of their geniculostriate counterparts, they always respond in transient fashion even to maintained stimuli. Thus, they seem adapted to signaling rapidly changing events.

Many of the receptive field properties of SC neurons are dependent on influences derived from cortex. Removal of cortex disrupts the ability of many of these neurons to respond selectively to specific directions of movement and decreases the proportion of binocular SC neurons. However, it does not change the transient nature of SC responses or their ability to signal the presence and location of a stimulus.

C. Auditory and Somatosensory Response Properties

The deep layers of the SC, unlike the superficial layers, receive considerable projections from auditory and somatosensory structures. The nonvisual signals

carried by these input systems are capable of reliably activating many SC neurons, and they can also initiate gaze shifts and other orientation movements via the circuitry of deeper SC. Many of these neurons respond to inputs from more than one modality, and they, like multisensory neurons elsewhere in the brain, have the remarkable ability to synthesize cross-modal inputs and thereby enhance (or degrade) their responses and the behaviors that depend on these responses. Multisensory neurons in the SC have served as a general model for understanding the principles governing this fundamental capability of the brain. However, because the mechanisms by which this multisensory integration takes place and the behavioral consequences of this integration are considered in detail elsewhere in this encyclopedia, this aspect of SC function is not discussed here.

Auditory-responsive neurons are well represented in the SC, and their organization is quite distinct from that found along the auditory thalamocortical or primary auditory projection pathway (the auditory equivalent of the geniculostriate system). Whereas the neurons in the thalamocortical system are specialized to represent the frequency content of stimuli, SC neurons do a poor job of discriminating stimulus frequency. Most auditory-responsive SC neurons respond best to complex sounds containing a broad range of frequencies, such as the sounds made by the voice, an object moving, the rustling of paper, a click, or a hiss. They are not particularly good at coding the intensity of the stimulus; they will respond with only a brief train of discharges even if the stimulus is maintained, and they respond well to a moving stimulus. Somatosensory-responsive neurons are also best activated by moving stimuli—in this case, stimuli moving across the hairs and/or skin. They, too, respond with a transient response even if the stimulus is maintained, and they can code the velocity of the stimulus.

Compared to visual receptive field properties, the nonvisual receptive field properties of SC neurons are less dependent on cortex. For example, removal of the somatosensory cortical areas that project to the SC has comparatively minor influences on these neurons, and these primarily involve changes in receptive field size. Similarly, removal of the most relevant areas of auditory cortex raises the threshold of auditory-responsive neurons in the SC but does not appear to alter their fundamental stimulus preferences.

The particular sensitivity of SC neurons to moving stimuli and their ability to code the parameters of movement, such as speed and direction (most evident in visual neurons), intuitively seem well suited for their role in detecting and orienting to sudden changes in the environment—changes that may signal important events for the animal and, therefore, should result in their examination. The presumptive importance and/or novelty of the stimulus are particularly significant in this context. Innocuous environmental stimuli that have little apparent significance to the organism but are presented repeatedly quickly lose their ability to activate SC neurons, a process known as habituation. Visual, auditory, somatosensory, and multisensory neurons exhibit response habituation. However, in experiments in which a neutral stimulus such as a flashing light was coupled repeatedly with a reward so that the animal associated one with the other, the stimulus not only became more effective than it was before but also failed to induce habituation even after many repetitions. Apparently, learning and experience can play substantial roles in crafting the vigor of SC neuronal responses and their resistance to response habituation. There is reason to suspect that this flexibility depends, in part, on influences from the cortex. Cortical neurons are particularly well suited to altering their properties as a consequence of experience and have been shown to be capable of imposing acquired characteristics on neurons in their target structures.

D. Sensory Topographies

1. Visual

For the SC to play its role in guiding orientating behavior, its neurons must be capable not only of detecting important events but also of specifying their locations so that appropriately directed movements can be generated. The need to localize stimuli is not unique to the SC, nor is its solution to the problem: the construction of a map, or topography, in which space is represented in a systematic manner within a structure. The visual map reflects the fact that the outputs from neighboring retinal neurons (ganglion cells), whose receptive fields are in neighboring regions of visual space, project to neighboring neurons in their target structures. The visual map in the SC (and in other central structures) has been recreated from experiments in which the receptive fields of neurons are plotted along vertical electrode penetrations that are made systematically at different locations. Generally, a grid-like pattern of electrode penetrations is made in order to sample the rostral-to-caudal (front-to-back) and medial-to-lateral (in the right SC this

would be midline-to-right) axes of the structure. Then the clusters of receptive fields that are recorded in each electrode penetration, and that define the regions of visual space represented there, are compared. This reveals that the two axes of visual space are nearly perpendicular to one another: The central-to-peripheral axis of visual space is represented across the rostral-to-caudal axis of the SC, and the superior–inferior axis of visual space is laid out along the medial-to-lateral axis of the SC (Fig. 4). Consequently, the receptive fields of a neuron at the rostral pole of the SC and in the middle of the medial–lateral axis will have a receptive field representing the foveal or parafoveal region. Neurons medial and lateral to this neuron will have receptive fields higher or lower in visual space, respectively. This visual topography, or visuotopy, is seen in the SC despite the variety of visual input sources, a result of the fact that all its inputs are distributed according to the same topographic scheme.

Although this visuotopy represents a fundamental vertebrate plan, there are considerable variations in the plan that reflect species differences in visual behavior. For example, the maps do not represent a simple linear transformation of the retina but, rather, geometric distortions of the retinal sheet: Some regions of the retina capture greater areas and, hence, more neurons in the target structure than do others. Cats, monkeys, and humans make heavy use of the central retina in fixating and evaluating a visual stimulus, and they require the greatest resolution in this region. In each of these animals there is an expansion of that region of the map devoted to central vision so that the neurons representing the foveal and parafoveal regions have smaller receptive fields and proportionally more of them are involved in representing a stimulus in comparison to regions of the map devoted to more peripheral regions of space (Fig. 4). Another obvious species variation is whether one or both eyes have direct input to the structure and, thus, whether individual neurons have direct access to binocular cues. In nonmammalian vertebrates, each optic tectum receives inputs from nearly the entire retina of the eye on the opposite side and therefore represents almost exclusively contralateral visual space; little binocularity is achieved. In rodents, the eyes are set further forward on the head and the retinal inputs from the opposite eye are nearly, but not completely, crossed. A region of the rostral SC is now devoted to representing the area of visual space common to both eyes (the binocular region) and has neurons activated by signals originating in both eyes (i.e., binocular neurons). In cat and monkey the eyes are set in the front of head and there is a large region of binocular overlap. This is represented centrally by having the outputs from the half of the retina near the nose (nasal) crossing the brain to terminate in the opposite hemisphere. The temporal half of the retina keeps its outputs uncrossed and directed to structures on the same side of the brain. This provides the right SC with a ''view'' of the left visual field, and it also endows many of its neurons with direct binocular input and the possibility of stereopsis. The reverse situation is present in the left SC. The binocularity of SC neurons is enhanced by projections from binocular neurons in cortex.

2. Auditory

As noted previously, the thalamocortical auditory projection pathway does an excellent job of coding for frequency. Neurons with similar frequency selectivities are organized into ''isofrequency'' bands in auditory cortex, thereby producing a ''tonotopic'' map. However, no clear map of auditory space is present there. This is not surprising given the fact that the cochlea codes sounds in terms of their frequency, not their spatial location. Consequently, when the outputs of the cochlea project topographically to their target structures, the result is a tonotopy. In the SC, however, it is the coding of space rather than frequency that is critical, and SC neurons are organized to represent the locations of auditory stimuli topographically. This spatiotopic map is unique because it, unlike the visual (or somatosensory) map, requires a computation for its creation. The construction of an auditory map relies, at least in part, on a comparison of the sound as it arrives at the two ears. Differences in both relative timing and intensity are cues to the location of a sound. For example, sounds coming from the right arrive sooner and are louder in the right ear. These inter-aural comparisons are made by binaural neurons that reflect in their discharge rate the relative timing and/or intensity of sound at the two ears. Although not the primary site of binaural interaction, spatially restricted receptive fields in the SC are presumed to reflect the results of this neural computation. With the eyes directed forward in the head, one finds auditory receptive fields that are organized in a manner that parallels the visuotopy in the SC: Auditory neurons with receptive fields in central space are rostral in the SC and those with progressively more peripheral receptive fields are found at progressively more caudal sites; neurons with receptive fields in upper space are medial, and those with receptive fields in lower space

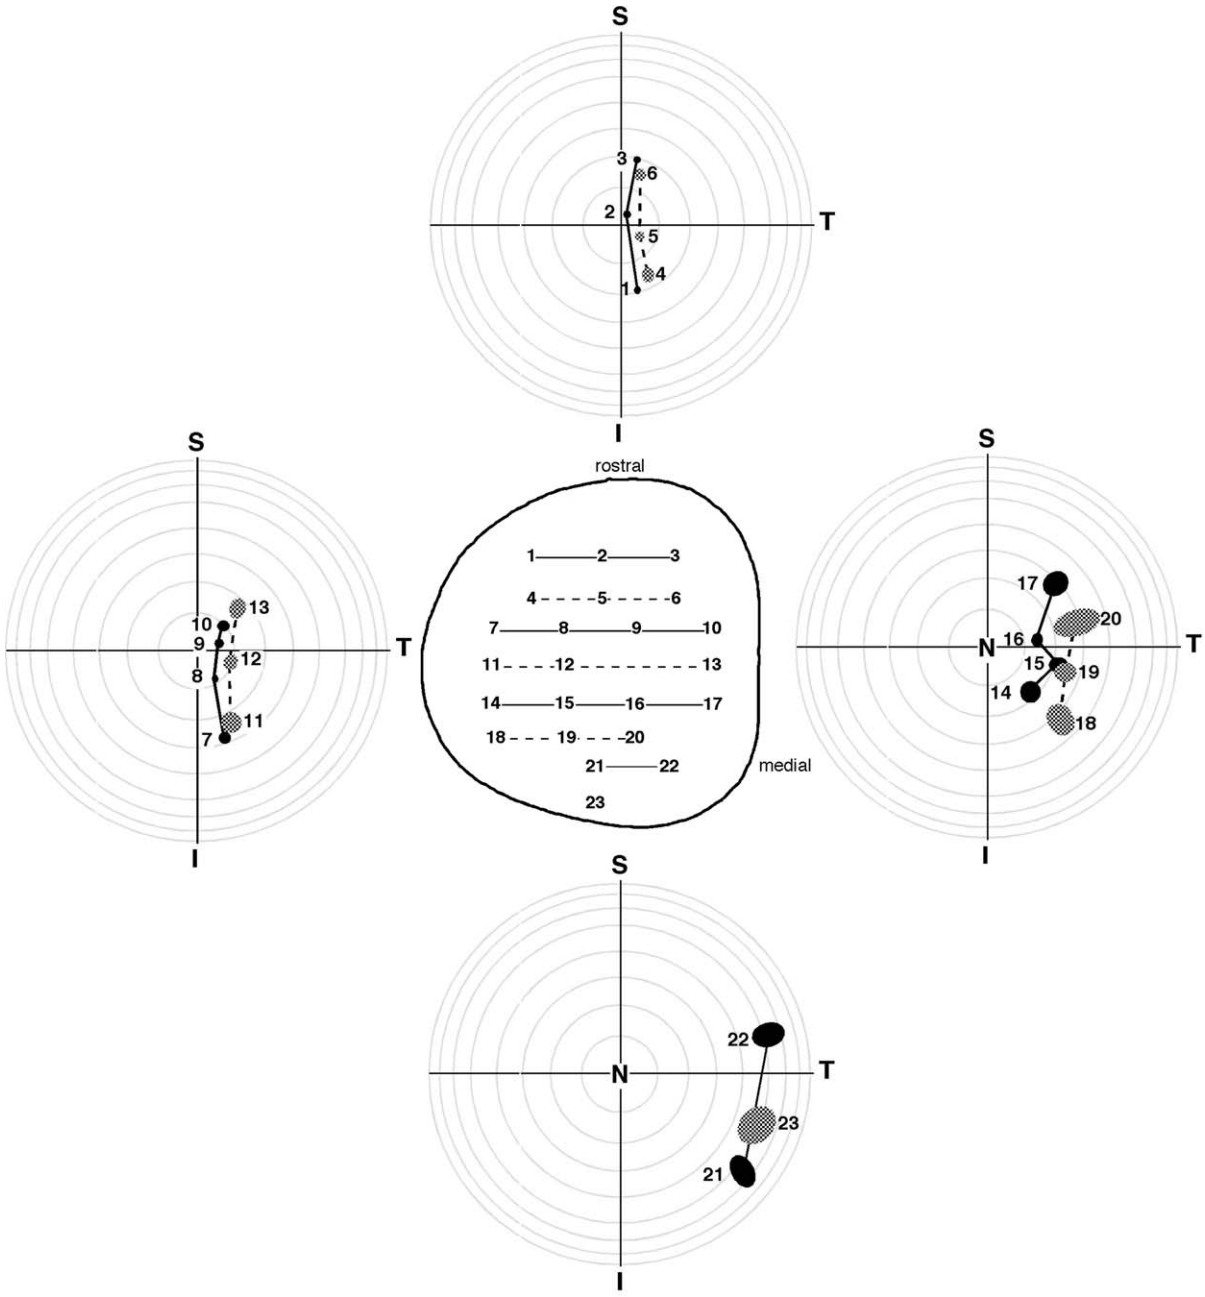

Figure 4 The SC is characterized by a topographic visual organization. In the center is shown a representation of a dorsal view of the left SC. The locations of a series of systematic electrode penetrations are plotted here. The corresponding receptive fields mapped in each of these electrode penetrations are shown on the four surrounding representations of visual space. In this standardized representation, the horizontal and vertical meridians are shown by the thick lines, and each of the concentric circles represents 10°. The size and location of receptive fields are shown by shading. Note the systematic shift of receptive fields from nasal (e.g., receptive fields 1–3) to temporal (e.g., receptive fields 21–23) as progressively more caudal regions of the SC are sampled. Similarly, note the superior-to-inferior shift as the sampling sites move laterally. N, nasal; T, temporal; S, superior; I, inferior (data from Wallace *et al.*, 1997).

are lateral (Fig. 5). As discussed in more detail later, the relationships among auditory, somatosensory, visual, and motor maps have important implications for the SC's role in the generation of orienting behaviors.

3. Somatosensory

The somatosensory representation follows the same general format, and its receptive fields are arranged in

a "somatotopic" map (Fig. 5). Again, given alignment of the eyes, ears, head, and body, one finds that this somatotopy registers with the visual and auditory topographies. Thus, neurons with receptive fields on the front of the body are located rostral in the SC and neurons with receptive fields progressively further back on the body (toward the tail) are located progressively more caudal in the SC. Similarly, upper portions of the body are represented medially and lower portions of the body are represented laterally in the structure.

Innocuous cutaneous stimuli have been found to be effective in activating many SC neurons in every species examined. However, based on early clinical observations, anatomical connections, and stimulation studies, early investigators speculated that the SC was also involved in processing information relevant to pain. One would therefore expect that some of its neurons would respond preferentially or solely to noxious stimuli. Confirmation of this speculation came in the late 1970s from experiments with hamsters. As one might expect, the neurons responsive to noxious stimuli had receptive fields, and later experiments showed that these receptive fields were organized into a map that paralleled the maps in each of the other sensory representations. Although these observations were confirmed in other rodents, they have not been reported in carnivores or primates.

It should be apparent from the previous descriptions that by aligning the individual sensory representations, a multisensory map is created. In principle, this simplifies considerably the process of localizing an event and activating the motor circuitry of the SC in order to initiate a response to that event. In fact, as discussed later, the SC sensory topographies are not only in register with one another but are also in register with the SC motor topography.

E. Motor-Related Function of the SC

Although electrophysiological studies of the sensory properties of SC neurons have a long history, the advent of similar studies to examine the motor-related activities of SC neurons has been much more recent. This delay was not due to a lack of interest in the motor properties of SC neurons but to the lack of a satisfactory means to study them. The technological advances that finally made it possible to examine the activity of SC neurons in association with a motor response in an awake behaving animal were a boon to motor physiology and led to a host of studies in awake behaving cats and monkeys. Although the term "motor" will be used here to describe the effector properties of SC neurons, some researchers prefer to describe these properties as "premotor" because SC neurons do not provide direct innervation to the muscles. Rather, they influence the final motor acts in which they are involved via direct or indirect connections to the motor structures of the brain stem and spinal cord. With this caveat in mind, it is fair to say that these studies have revealed that many SC neurons are both responsive to sensory stimuli and activated in a time-locked fashion before a motor response,

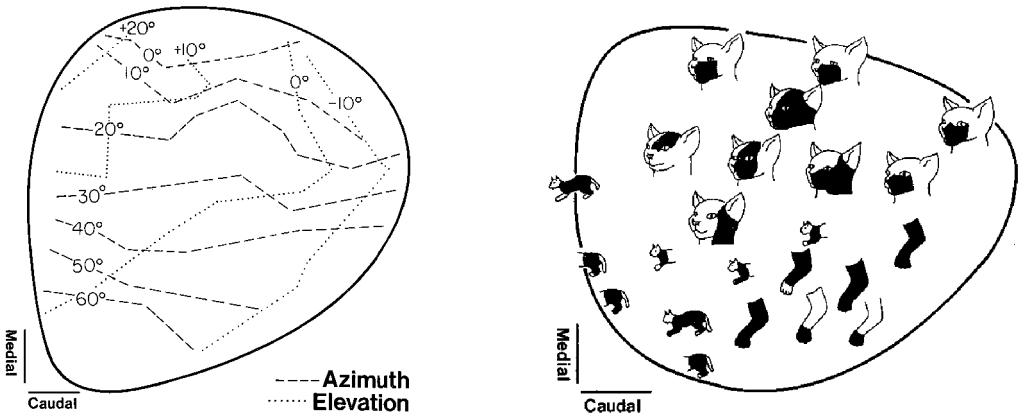

Figure 5 Auditory (left) and somatosensory (right) maps in the SC. In both maps, sensory space is depicted on a dorsal view of the SC. In the case of the auditory map, for each neuron studied the best area of its receptive field is related to its location in the SC. The map is derived from the raw receptive field data so that the dashed and dotted lines represent the progression in azimuth and elevation of receptive field best areas. Thus, auditory neurons with best areas centered on 60° of azimuth are found in the caudal SC, and those with best areas in inferior space or below (e.g., −10°) are found in the lateral SC. In the case of the somatosensory map, representative receptive fields, illustrated by shading on the figurines, are plotted directly onto the SC (adapted with permission from Stein and Meredith, 1993).

providing the impetus for the term "sensorimotor" to describe them.

Coupling sensory and motor properties in many SC neurons seems particularly appropriate in the case of visuomotor control, for which the SC is best known and in which it is most often involved, since visual cues are used continually to shift gaze in order to bring the most sensitive area of the retina (e.g., the fovea) to bear on an object of interest. However, historically, researchers have chosen to focus on either the sensory information processing capabilities of SC neurons or the manner in which they initiate and direct an overt motor response. This created two largely independent bodies of knowledge. The information gathered on the sensory organization and sensory properties of SC neurons (discussed previously) was most often obtained from anesthetized animals and emphasized the relationships between neural responses and the physical attributes of the stimulus. By comparison, studies that have dealt with SC motor function have more often been conducted in awake behaving animals, have employed more rudimentary sensory stimuli, and have focused more on the linkage between neural activity and the metrics of movements directed toward those stimuli. The vast majority of these studies have concentrated on saccadic eye movements (rapid movements of both eyes) or combined eye/head gaze shifts. Recently, however, there has been an emphasis on aspects of SC activity that resist the general classifications of sensory or motor, being attributed more often to mechanisms of attention, memory, target selection, movement selection, or motor intention—terms suggestive of more cognitive processes. These studies attempt to bridge the gap between the mainly sensory and motor studies of the SC and provide insights into the neural computations that are ongoing during the interval between the early sensory-evoked activity and later motor-related activity that precedes any goal-directed orientation. Thus, although this section deals primarily with the motor organization and motor-related properties of SC neurons, no discussion of the SC can be considered complete without some treatment of the more "cognitive" aspects of SC activity that have been the focus of many recent studies. Such a discussion will follow the consideration of the motor properties of the SC.

1. Motor Topographies

Unlike studies of sensory topographies in the SC, early efforts to reveal a systematic motor representation relied more on electrical stimulation than on single neuron recording. That the application of stimulating current to the SC can produce contralateral movements of both eyes has been known since the late 19th century. Although these and stimulation studies conducted in the 1940s demonstrated a topographic motor organization, the issue was revisited in the 1970s using modern methods of microstimulation and eye movement measurement. In his classic 1972 study, David A. Robinson systematically varied the position of a stimulating electrode within the SC of an alert monkey and demonstrated an orderly "motor map" wherein the amplitude of contralaterally directed saccades was represented along the rostrocaudal axis (small to large movement) and the upward–downward component of the movement was represented along the mediolateral axis of the SC (Fig. 6). Although first demonstrated in the monkey, analogous eye movement maps have been shown in the SC of other species (e.g., cat and rat). Furthermore, observations from a number of species have suggested the possibility of multiple motor maps in the SC. Indeed, a well-organized ear movement map has been demonstrated in the cat, and it has also been reported that stimulation of the SC can evoke movements of the limb (monkey), head (cat, rat, monkey, and owl), whiskers (cat and rat), and trunk (rat).

It is given that the motor topographies in the SC are tailored in a species-specific fashion (e.g., one would not find a detailed whisker representation in monkeys). With this in mind, it is interesting to note that despite early expectations to the contrary, the motor topographies controlling shifts of gaze in the two most intensely studied animals, cat and monkey, are quite similar despite the considerable phyletic differences of these species. Nonhuman primates, like humans, rely heavily on vision for maintaining an awareness of the environment. Accordingly, the range of ocular motility in monkeys rivals that of humans. In contrast, cats possess a more limited oculomotor range and consequently recruit head movements for all but the smallest changes in gaze. Unlike the cat SC, until very recently, the monkey SC was considered to be involved primarily in the generation of saccadic eye movements and not to be involved in producing combined eye/head gaze shifts. This notion of a significant species difference survived for some time without challenge because studies of nonhuman primates had traditionally been carried out in animals whose heads were restrained, thus precluding the possibility of evoking head movements with SC stimulation. However, in recent microstimulation and recording studies of monkeys, the head has been free to move, and these

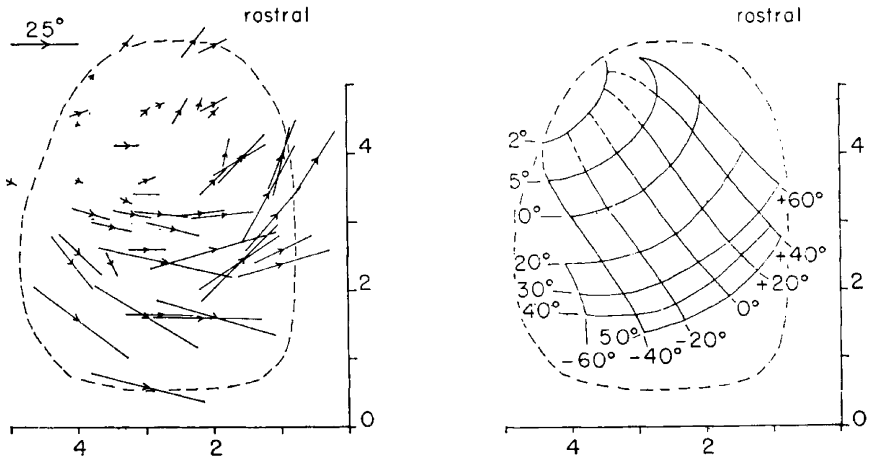

Figure 6 The motor map in the SC. (Left) Eye movements evoked by electrical stimulation at different SC sites are depicted by vectors (length represents amplitude and arrow orientiation represents direction) plotted onto a dorsal view of the SC. (Right) The data have been transformed to generate a map of eye movement amplitude and direction. Amplitude is represented from rostral (top) to caudal (bottom) and direction from medial (right) to lateral (left) within the SC. From rostral to caudal within the SC, the representation is from small movements to large movements. From medial to lateral, the representation is from movements with large upward (direction = $+60°$) components to movements with large downward components (direction = $-60°$). Thus, for example, microstimulation at the intersection of the $10°$ isoamplitude line and the $+20°$ isodirection line would evoke an eye movement of $10°$ in amplitude and inclined $20°$ upward (adapted with permission from Robinson, 1972).

studies have shown that the assumed differences between cat and monkey were, in large part, more apparent than real. Thus, although the relative contributions of eye and head movement to producing a gaze shift vary across species as well as circumstances (e.g., the position of the eye in the orbit at the start of the gaze shift), there seems little doubt that the motor map in the monkey SC, as in the cat, codes for changes in gaze and not simply changes in eye position.

Regardless of the specific kinds of movements one considers, it is thought that there are fundamental commonalities in the physiological characteristics of the neurons responsible for initiating an action. However, because the overwhelming amount of information available about the motor organization of the SC has been gathered in studies of eye and eye/head movements, this will be the focus of the following discussion.

Early studies established that an SC neuron that discharges in association with saccadic eye movements has a movement field. A movement field refers to the set of all saccade vectors (amplitudes and directions) that the neuron's activity contributes to producing. Consequently, SC movement-related neurons were found to discharge maximally for movements of a particular amplitude and direction (i.e., its preferred vector) and progressively less vigorously as a function of increasing deviation from the preferred vector (Fig. 7). Not surprisingly, experiments that have combined microstimulation and single-neuron recording have established that the vector of an electrically evoked movement agrees well with the preferred vector (and thus the movement field centers) of the neurons in the stimulated region.

2. Population Coding in the SC: Vector Averaging

Motor-related neurons are thought to provide a command signal to move the eyes and/or head. This signal plays a part both in initiating and in specifying the vector of a movement. Accordingly, saccade-related neurons are characterized by a high-frequency burst of action potentials that begins approximately 20 msec before the movement. Historically, the SC stands out as a model for understanding how information is represented within a topographic map. As discussed later, not only is it clear "what" the SC motor map encodes but also inferences can be made about "how" this information is "read out" by downstream circuits. In a series of elegant experiments, pharmacological blockade of small areas of the SC motor map provided significant insights into these issues and unexpectedly changed established views of how a motor map operates. These experiments demonstrated that the vector of SC-mediated saccadic eye movements is determined by the weighted *average* of activity across the motor map rather than by the activity of any

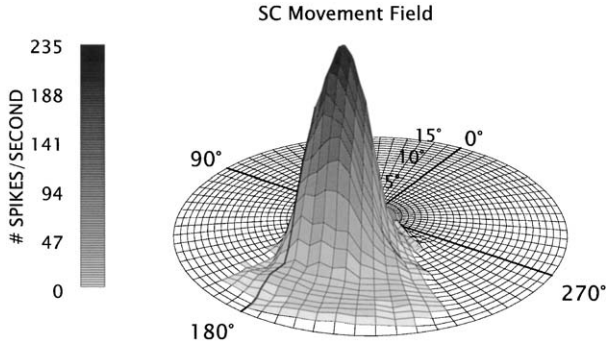

Figure 7 Motor-related neurons in the SC have movement fields that are defined by the relationship between the strength of motor-related activity and the vector (amplitude and direction) of movement. The 3D polar plot depicts a movement field for one saccade-related neuron in the right SC. Saccadic eye movement directions from 0 to 360° are represented on the graph. As a matter of convention, the 0 and 180° spokes represent saccadic eye movements that are straight right and left, respectively. Likewise, the 90 and 270° spokes represent movements that are straight up and down, respectively (note, however, that the plot is rotated and tilted for display purposes). Saccade amplitude is represented as the distance from the center of the plot (0 to 15°). Thus, each grid intersection (intersection of the amplitude and direction axes) corresponds to a vector, and the level of activity associated with making a saccade of that vector is given by the height of the plot at that point. For this particular neuron, most of the activity is associated with movements near 180° but biased toward the lower quadrant (i.e., toward 270°). Thus, this neuron discharged most vigorously for slightly down and left movements, with the peak rate corresponding to an amplitude of approximately 5–7°. Activity declines gradually for saccades that deviate from this vector (from Stanford and Sparks, unpublished).

restricted group of neurons within the topographic map. Although this conclusion seemed counterintuitive at first, it was the most reasonable conclusion that could be drawn from experiments in which deactivating a circumscribed region within the map did not render a trained monkey incapable of producing saccades that matched the preferred vector of neurons at the center of the now inactive population. In fact, these saccades were quite accurate, although they were slower to begin and, because of their lower overall velocity, took longer to reach their final position. That the appropriate vector can be computed in the absence of what would normally be the most active neuronal population indicated that the influences of surrounding neurons (i.e., those maximally responsive to different vectors) are averaged to produce the actual movement. On the other hand, the loss of the contribution of the deactivated population in the computation of other, *nonpreferred* vectors leads to a systematic pattern of movement errors, and this is also consistent with an averaging operation (Fig. 8).

It is typically stated that the *site* of activity within the SC motor map codes for the movement vector (e.g., of a gaze shift). Although true in a sense, it is also an incomplete explanation of how the movement vector of a gaze shift is programmed by the SC. The deactivation experiments referred to previously illustrate that there really is no singular correspondence between the *site* of activity in the SC and the actual movement vector produced because a vector-averaging scheme dictates that equivalent vectors can result from any number of activity patterns across the SC motor map. Thus, for example, gaze shifts of comparable metrics can be produced by activity tightly constrained around a particular locus in the SC, which we can refer to as A, or by a broad symmetrical swath of activity with point A at its center. More precisely, the desired change in gaze is represented by the spatial distribution of activity across a substantial fraction of the SC motor map. In this scheme, the contribution of any given neuron (whose preferred movement vector is determined by its position in the map) to the overall average (i.e., the ''weight'' of its contribution) is determined by the vigor of its discharge.

Interestingly, in the past decade there has been growing interest in understanding how the activity of the SC contributes to the time course of a gaze shift. Several proposals have been put forth in this regard. Although specific schemes differ substantially in detail, many have hypothesized that SC activity determines the moment-by-moment progress of a gaze shift by placing the SC within a feedback loop. The feedback loop compares the desired final gaze position with the current gaze position so that the appropriate signal can be generated to complete the movement. In other words, it is thought that at any given moment, activity in the SC reflects the difference between the current and desired gaze displacement, a ''motor error'' that must be progressively reduced in order to achieve the final desired gaze position. Some studies have suggested that somehow the nervous system represents motor error by the progressive changes in the peak *position* of activity on the SC motor map—a message that is predominantly spatial in nature. Others have suggested that the key index is the moment-to-moment changes in the firing rate of SC neurons during the gaze shift—a message that is predominantly temporal in nature. In neither case, however, has a causal relationship between SC activity and the progress of a gaze shift been established. As might be expected, this remains a topic of debate.

However, there seems to be little debate that the speed of a gaze shift depends on the overall vigor of SC

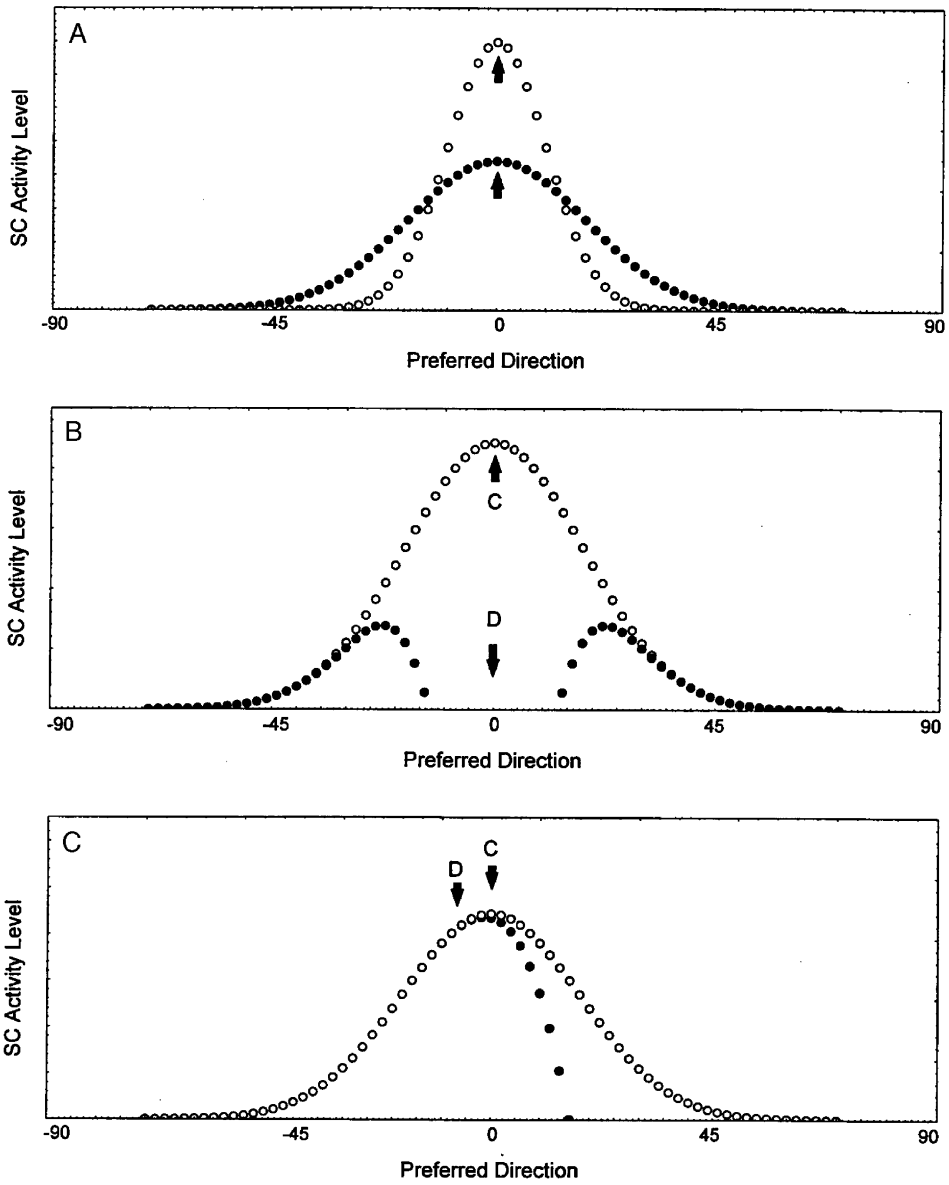

Figure 8 The vector of a saccadic eye movement or gaze shift is computed by averaging the contributions of active neurons within the SC motor map. To illustrate this concept, we show how hypothetical profiles of SC activity contribute to the computation of saccadic direction. For example, in A two different hypothetical activity profiles are shown. Consider each curve as representing the spatial distribution of activity across a lateral to medial slice through the SC (i.e., parallel to the direction axis). With this in mind, adjacent dots represent the activity of adjacent neurons (each with a slightly different preferred direction) within the motor map. Thus, in A, both activity distributions are centered about neurons having preferred directions of 0° (purely horizontal movements) with the activity profile declining symmetrically in both directions across neurons having progressively more upward (positive values) and downward (negative values) preferred directions. The key point of A is to illustrate how very different activity profiles (open and solid symbols) could result in a saccade of similar metrics. A vector-averaging algorithm for computing the direction of movement predicts an eye movement of 0° in each case. (Computed eye movement direction corresponds to the mean of each distribution, as indicated by an arrow in each case.) (B) A hypothetical deactivation experiment. Deactivation eliminates activity at the center of the population of SC neurons that would be active for a purely horizontal saccade (●). Nevertheless, computing the direction of the eye movement by averaging the contributions of the remaining active population of surrounding neurons predicts a saccade of the same direction (arrow D) as in the control condition (O; arrow C), (C) A hypothetical deactivation experiment that preferentially eliminates the activity of neurons with upward preferred directions (●). Loss of the "upward" neurons to the population average would lead to a "downward" bias on an attempt to make purely horizontal saccades. D, deactivation; C, control.

motor activity. The deactivation studies described previously are consistent with a positive relationship between the overall level of SC activity and the speed of the gaze shift that is produced. For example, local inactivation of regions of the SC, which reduces the overall average of activity in the SC, results in slower saccades. Similar results are obtained in electrical stimulation studies when the level or frequency of the stimulation is reduced. It is important to emphasize that changes in speed can occur without differences in movement vector. Consequently, a rule of thumb regarding an eye movement is that the spatial distribution of SC activity determines its vector, whereas the level of SC activity determines its speed.

3. SC Sensory Information Is Represented in Motor Coordinates

As discussed previously, some SC neurons discharge in response to sensory stimuli and some discharge in association with movements made for the purpose of orienting to sensory stimuli. However, many of the same neurons that respond to the onset of a sensory stimulus are later active in association with a movement directed toward that stimulus. Thus, the SC is at the interface of sensory and motor processing.

At first glance, the process of translating an incoming sensory signal into an outgoing motor command seems straightforward. Because the SC possesses both sensory and motor topographies, it is reasonable to assume that a simple point-to-point correspondence between the sensory and motor maps could support an accurate sensory-to-motor transform. This is certainly easy to understand if one considers gaze shifts to visual stimuli. Thus, for example, a visual stimulus 10° to the right (relative to the fovea) would require a gaze shift of 10° to the right to bring the image of the target onto the fovea. Because the fovea is used as a point of reference in each case, there is agreement between the position of a stimulus in retinal coordinates (retinal error) and the distance and direction of a gaze shift required to look at it (motor error); each is 10°. This reasoning formed the basis of the foveation hypothesis, a proposed mechanism for how the SC transforms a visual signal into a motor command for a saccadic eye movement. According to this scheme, visually driven activity among neurons in the topographically organized superficial layers leads to excitation in deeper layers where motor-related neurons are found. Although attractive in its simplicity, the foveation hypothesis cannot account for some recently demonstrated aspects of saccade programming. In particular, behavioral studies have shown that saccades can be accurate even in the absence of nominal agreement between retinal error and motor error. For example, saccades can be directed accurately to the *remembered* location of a previously flashed visual stimulus, even if an intervening saccade (e.g., the eyes are moved 5° upward) alters the required vector so that it no longer matches the original retinal error. To do so accurately requires that the intervening movement be taken into account and precludes a direct relationship between retinal error and initial motor error. Although dissociation between retinal error and motor error may not be the norm for visually guided saccades, these experiments demonstrate that saccades are not programmed on the basis of retinal coordinates. Rather, at the time (or before) the SC motor-related neurons become involved, the information about stimulus location has been transformed from sensory coordinates (e.g., retinocentric) to motor coordinates (oculocentric).

The issue of whether information is represented in a sensory versus a motor frame of reference in the SC is more readily appreciated when considering a *nonvisual* modality. For example, consider the problem of making a saccadic eye movement to an auditory or somatosensory target. Unlike the axes of visual space (centered on the retina), which are yoked to the position of the eye, the axes of acoustic space (head centered) and those of tactile space (body centered) are independent of eye position. Thus, there is no unique relationship between the position of a stimulus in either auditory or somatosensory coordinates and the vector of a movement that would be required to look at it. For example, the amplitude and direction of a gaze shift required to look at a stimulus on the forearm (or forepaw) depend on many factors, including the relative positions of the limb, the head, and the eyes. Similarly, the gaze shift required to look toward an auditory stimulus changes as a function of the position of the eyes in the orbit. Knowing the location of an auditory stimulus with respect to the head or a tactile stimulus with respect to the body surface (e.g., this knowledge is in terms of sensory coordinates) is not sufficient information to program a gaze shift to look at the stimulus; one needs to know where the stimulus is with respect to the current position of gaze. In other words, the referent must be eye centered or oculocentric. In fact, studies have shown that both auditory and somatosensory information in the SC have been translated from their native reference frames to a common motor coordinate frame. Rather than represent the position of a stimulus in auditory or somatosensory space, auditory- and

somatosensory-evoked activity represents stimulus location with respect to the current position of gaze.

F. A "Cognitive" Superior Colliculus?

In preceding sections, we focused on the sensory-related and motor-related aspects of SC function. In particular, we discussed how the SC represents information about sensory stimuli and how activity within the SC contributes to the programming of movements to orient to these stimuli. It may strike the reader that the majority of our discussion has been devoted to how the SC represents and guides simple actions to very simple stimuli. Whereas simple experimental paradigms afford the stimulus and behavioral control essential to addressing many fundamental issues, all would agree that the task of looking toward a bright spot of light in an otherwise dark environment does not approach the contextual complexity of orienting to stimuli in a natural setting. For example, given a complex scene, what factors dictate which of many potential targets becomes the goal of an orienting movement? Clearly, the choice of action is dictated by both the physical attributes of stimuli and the current set of circumstances (e.g., behavioral objectives). Recently, there has been a great deal of interest in investigating the neural basis of the decision processes that lead to a choice of a particular action among competing alternatives. Although the majority of these studies have focused on cortical structures, several have sought to determine if and how activity in the SC might reflect such higher order processes.

Although we briefly consider some of the recent developments concerning the influence of cognitive factors on SC activity, the fact that experimental context can modulate the responsiveness of SC neurons has been known for decades. Relatively early in the course of recording from awake behaving monkeys, it was noted that some SC neurons responded more vigorously to a visual stimulus if the stimulus was the anticipated goal of a saccadic eye movement (as opposed to being inconsequential to correct/rewarded performance on a behavioral trial). Although a clear-cut interpretation of this so-called response enhancement is difficult owing to the fact that many cognitive factors could be at play (e.g., anticipation of reward, allocation of spatial attention to a predictable location, and advance preparation of a predictable response), the important point is that the activity of these neurons was the joint product of the physical stimulus and behavioral context. In general, recent studies attempting to examine issues related to cognitive processes have used behavioral tasks designed specifically to manipulate behavioral context independently of sensory input or motor output.

As discussed in preceding sections, SC neurons may have activity that is temporally linked to the onset of a sensory stimulus and/or to the onset of a motor event (e.g., saccadic eye movement). Thus, temporal correlation is the main criterion for classifying activity as either sensory contingent or motor related. The focus of many cognitive studies has been on activity that cannot be so classified using a simple temporal criterion. In contrast to the transient, often high-frequency discharges closely associated with the occurrence of sensory or motor events, many SC neurons demonstrate a sustained, lower frequency discharge during the period that intervenes between early sensory and later motor-related bursts. Modulation of this low-frequency activity by contextual factors has been shown in a number of studies. Briefly, activity during the period has been linked to the maintenance of a stimulus in spatial memory, to the allocation of spatial attention, to the discrimination between relevant and irrelevant stimuli, to the likelihood of making a particular movement, and to the current state of response readiness. From these and other studies it is clear that processing within the SC is neither purely sensory nor purely motor, but the product of measurable events (e.g., stimulus onset and movement onset) and less tangible (and less readily quantified) internal factors.

Interest in the influence of cognitive factors on activity in the SC is a comparatively recent development and there remain many unsettled issues. As noted previously, low-frequency SC activity has been related to numerous covert processes. As noted by others, at least two caveats must be considered along with these findings. First, many of the factors mentioned previously are not mutually exclusive and are bound to covary in most experimental contexts (e.g., spatial attention and response readiness). Second, unlike the case for motor output, it is much more difficult with covert processes to establish a causal linkage between SC activity and overt behavior. With this in mind, it may be difficult to establish whether the SC activity is a significant contributor to the decision processes that lead to a specific action or simply reflects the outcome of computations carried out in higher centers.

VI. CONCLUDING REMARKS

The foregoing discussion has touched on many of the issues germane to the organization and functional role

of the SC. The history of research in this area has had obvious phases in which issues most closely tied to its sensory or motor roles appeared to dominate, and it is not difficult to predict that in the immediate future much of the SC scholarship will mirror the recent trend toward issues falling under the general heading cognitive neuroscience. The continued interest in this structure is prompted, in part, by its critical involvement in the immediate reactions to sensory stimuli that are so critical to survival and by the elegant simplicity of its sensory and motor roles. The SC is designed to process sensory cues so that motor commands can be generated to orient the organism to the very cues that began the process. Determining the degree to which the SC participates in the decisions that make these motor actions both timely and appropriate for a given circumstance is likely to remain a topic of interest for the foreseeable future.

Synapses and Synaptic Transmission and Integration

MICHEL BAUDRY
University of Southern California

GLOSSARY

active zones Specialized membrane structures in presynaptic terminals in which vesicles are docked and clustered and neurotransmitter is released.

long-term potentiation/long-term depression Long-lasting increase/decrease in synaptic transmission as a result of specific patterns of electrical activity.

neurotransmitter A molecule synthesized and released by an action potential and activating a postsynaptic receptor, thus producing a change in membrane potential.

receptor A transmembrane protein that is activated by a neurotransmitter and produces a modification of some postsynaptic function.

signal transduction Biochemical cascade that translates receptor activation by a neurotransmitter into a cellular signal.

synaptic dynamics Time-dependent modification of synaptic transmission.

The term synapse was coined by Sherrington to designate the points of contact between the terminals of a neuron and another cell or neuron. Synaptic transmission represents the process by which communication between neurons occurs—that is, when an action potential is propagated along the axon of one neuron and produces a postsynaptic response in the target cell or neuron. This process is a specialized form of intercellular communication and exhibits many unique features. In particular, it depends on a relatively large number of chemical messengers, or neurotransmitters, and their specific receptors and associated signal transduction systems. Synaptic transmission spans several time domains ranging from a few milliseconds to hours or days. Synaptic integration refers to the dynamics of synaptic transmission because the efficacy of transmission is dependent on the frequency of the signals in the presynaptic elements as well as the past history of activity. These characteristics, frequency dependency and activity dependency, form the basis for the adaptive properties of synaptic transmission and are responsible for the critical role of synapses in information processing and storage.

I. INTRODUCTION

Although transmission between nerve cells occasionally takes place at electric synapses, the most common form of neuronal communication involves chemical synapses. Synapses are structures specialized for interneuronal communication that have to satisfy a number of difficult requirements: (i) They have to be optimally designed for fast as well as slow synaptic transmission; (ii) they have to be modifiable for both

short-term and long-term periods of time as a result of activity; and (iii) once modified, they have to remain stable for very long periods of time. Because it is widely believed that learning and memory involve some forms of synaptic modifications, the extremely long duration of memories implies that such modifications could last one's lifetime. Recent data as well as computer models have emphasized the importance of the morphological characteristics of synaptic contacts in determining their functional properties. Synapses contain complex biochemical machineries on both the presynaptic and postsynaptic sides that perform the synthesis and release of specialized molecules (neurotransmitters and neuromodulators) as well as generate complex responses to these molecules that span many time domains (milliseconds, seconds, minutes, and hours). Furthermore, synaptic transmission at a number of synapses exhibits many adaptive features that are generally considered to form the basis of information processing and storage processes. In this article, I briefly describe the morphological features of synapses. The characteristics of neurotransmitters and neuromodulators are then presented, and the mechanisms of transmitter release are described. This is followed by a presentation of the properties and functions of neurotransmitter receptors as well as those of active channels located at synapses. The article concludes by discussing the mechanisms involved in synaptic dynamics and synaptic plasticity and the functions of these processes in synaptic integration.

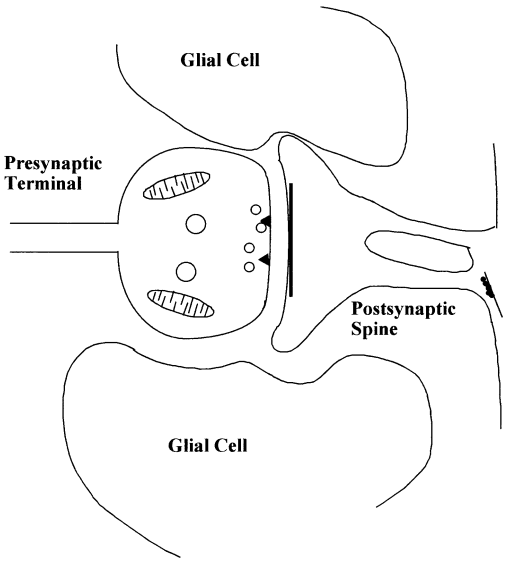

Figure 1 Morphological features of synapses. Schematic representation of an excitatory spine synapse. Note the presence of mitochondria in the presynaptic terminal, of small and large vesicles, and of active zones in the presynaptic membranes. A synaptic vesicle is depicted docked in an active zone. On the postsynaptic site, note the thickening of the postsynaptic membrane (corresponding to the postsynaptic density), the presence of a spine apparatus, generally thought of as a variant of the endoplasmic reticulum, and the presence of polyribosomes at the base of the spine. It is often assumed that signals originating from the postsynaptic density in response to neurotransmitter release might control the local translation of a small number of mRNAs present in dendrites. The whole synaptic complex is embedded in astrocytic processes.

II. MORPHOLOGICAL FEATURES

Synapses are highly specialized structures that are adapted to interneuronal communication. It was not until the advent of electron microscopy that the debate between Cajal and Golgi was definitely settled by showing the existence of numerous discontinuities between the axons and the dendrites of target neurons. Sherrington coined the term synapses to describe these points of contacts between one neuron and another cell or neuron. Synapses are characterized by a presynaptic element, generally loaded with small and large electron-dense vesicles (synaptic vesicles) that contain high concentrations of neurotransmitter and neuromodulator molecules, a postsynaptic element that exhibits a large variety of shapes, and a narrow synaptic cleft—a small 50-nm-wide space separating the pre- and postsynaptic elements. Synapses have been broadly categorized as asymmetric or excitatory and symmetric or inhibitory (Fig. 1). The presynaptic element often contains mitochondria, specialized membrane-associated structures believed to be the sites for neurotransmitter release (active zones), as well as various types of vesicles (small or large dense core vesicles). The postsynaptic element is characterized by a membrane thickening, the postsynaptic density, and occasionally by polyribosomes (especially at the basis of dendritic spines), which are believed to be a site for local protein synthesis. The postsynaptic density is assumed to contain numerous receptors for the presynaptically released neurotransmitters as well as associated transduction pathways and a whole set of anchoring proteins and the biochemical machinery required to regulate receptor properties.

Synapses exist in a variety of shapes and locations and include spine synapses, dendritic shaft synapses, cell body synapses, and axoaxonic synapses. Spine synapses are generally believed to be glutamatergic and excitatory (i.e., they use the excitatory amino acid

glutamate as a neurotransmitter), and recent results indicate that they also possess excitable channels, providing for a much more complex mode of functioning than previously thought. Axoaxonic synapses are less frequent and are presumed to provide for presynaptic regulation of synaptic transmission. A morphological feature that is becoming much more recognized is the close association of glial processes with synaptic contacts. Several functions have been attributed to such an association, including neurotransmitter metabolism, ion buffering, growth and trophic factor production, and morphological stabilization. Furthermore, it has been shown that glial cells exhibit several receptors for neurotransmitters, thereby providing for a much more active role for glial cells in the regulation of synaptic transmission. It is quite likely that the regulation of the shape of synaptic contacts as well as their stabilization involve complex interactions between cell surface adhesion molecules present in neuronal membranes and the extracellular matrix. Moreover, various types of enzymes, including proteases, lipases, and possibly protein kinases, have been shown to act extracellularly to regulate the interactions between neurons as well as between neurons and glial cells.

III. NEUROTRANSMITTERS AND NEUROMODULATORS

Synaptic transmission relies on a number of specialized molecules referred to as neurotransmitters and neuromodulators, which function in an anterograde direction—that is, from the presynaptic to the postsynaptic sites. In addition, neurotransmitters can also exert a presynaptic effect by stimulating receptors located in the presynaptic terminals (presynaptic receptors for the presynaptically released neurotransmitters are called autoreceptors). These molecules have to satisfy a number of criteria and have been divided into two major classes—classical neurotransmitters (mostly nonpeptidergic molecules) and peptide neurotransmitters. In addition, a small group of molecules have been identified that appear to function in a retrograde direction and influence the presynaptic site in response to postsynaptic activation. In all cases, neurotransmitters share a number of features with chemical messengers found in other forms of cellular communication. Not surprisingly, a number of neurotransmitters also participate in endocrine or paracrine communication.

A. Criteria

For a molecule to be considered a neurotransmitter, the following criteria should be satisfied: (i) The molecule should be present and/or synthesized in neurons that use it as a neurotransmitter; (ii) the molecule should be released as a result of an action potential (or as a result of depolarization), (iii) the molecule should produce appropriate pre- and postsynaptic responses, i.e., it should activate specific receptors, the activation of which by application of the exogenous molecules should mimic the effects of the endogenous neurotransmitter; and (iv) the molecule should be rapidly eliminated from the synaptic cleft. These criteria have been verified only rarely at synapses of the central nervous system (CNS), and a set of less stringent criteria has been developed to accommodate the technical difficulties of studying single synapses in the CNS.

B. Classical Neurotransmitters

The main feature of classical neurotransmitters is their local synthesis in the presynaptic terminals from precursor molecules provided by cellular metabolism or specialized transporters located in the plasma membrane. There are nine such molecules, amino acids or derivatives of amino acids, and acetylcholine, the neurotransmitter of the neuromuscular junctions in mammals. Local synthesis provides for a rapid and activity-dependent regulation of neurotransmitter availability in synaptic terminals. Specialized transport systems located in synaptic vesicle membranes are responsible for generating high neurotransmitter concentrations in synaptic vesicles. Once released in the synaptic cleft, neurotransmitters are rapidly inactivated by diffusion, reuptake in neurons or glial cells by potent transport systems, or by enzymatic inactivation. Several families of transporters for various neurotransmitters have been identified. Some are localized in neurons, whereas others exhibit mostly a glial localization. Transporters are generally responsible for the rapid elimination of neurotransmitters from the synaptic cleft and alterations in the function of transporters can result in dramatic modifications of synaptic transmission, as in the case of amyotrophic lateral sclerosis. In this disease, alteration in glutamate transport is responsible for the progressive degeneration of motoneurons.

C. Peptide Neurotransmitters

In contrast to classical neurotransmitters, peptide neurotransmitters are synthesized as large precursor proteins in the neuronal cell bodies; these precursors are transported down the axons by axonal transport and cleaved by appropriate peptidases in nerve terminals to generate the active neuropeptides. There are about 70 known neuroactive peptides and it is frequently the case that one or several neuropeptides are colocalized with a classical neurotransmitter. It has generally been proposed that neuropeptides are released under certain conditions along with the classical neurotransmitter and, as a result of activation of their postsynaptic receptors, modify the response to the classical neurotransmitter with which they are released. However, relatively little is known regarding the conditions under which neuropeptides are released and how their release affects synaptic transmission mediated by classical neurotransmitters. The peptide neurotransmitters belong to several families of peptides that sometimes share the same precursor protein. Several key differences exist between peptide neurotransmitters and classical neurotransmitters. First, as mentioned previously, peptide synthesis is nonlocal and the availability of neuropeptides has a much more limited local regulation than that of classical neurotransmitters. Second, neuropeptides are present in a much lower concentration than classical neurotransmitters, are released at a much lower concentration than classical neurotransmitters, and bind to postsynaptic receptors with high affinity compared to the low affinity of the classical neurotransmitters for their receptors. Finally, neuropeptides are stored and released from large, dense core vesicles as opposed to small secretory vesicles for classical neurotransmitters. They are degraded by a number of peptidases located extracellularly, and peptidase inhibitors have been found to alleviate a number of problems associated with disregulation of essential body functions. For all these reasons, neuropeptides are often considered to play a neuromodulatory role rather than a neurotransmitter function.

D. Retrograde Messengers

Recently, a small number of molecules have been identified and proposed to play the role of retrograde messenger at synapses; that is, these molecules are synthesized and released from the postsynaptic site, diffuse in the synaptic cleft, and act presynaptically to modify the properties of neurotransmitter release. In particular, arachidonic acid and certain derivatives of arachidonic acid could be produced as a result of postsynaptic phospholipase activation. Similarly, two diffusible gases nitric oxide (NO) and carbon monoxide, are produced postsynaptically and can affect neurotransmitter release. Whether these molecules qualify as neurotransmitters is a debated issue, and to many they belong to a broad category of chemical signaling molecules and have a limited role in synaptic transmission. In particular, these molecules could have a broader spatiotemporal domain of action and could influence many cellular types (e.g., glial cells and blood vessels).

IV. TRANSMITTER RELEASE

The mechanisms underlying neurotransmitter release represent a complex cascade of protein–protein interactions triggered by the influx of calcium resulting from the presynaptic activation of voltage-dependent calcium channels. A large number of proteins translate the influx of calcium into the fusion of synaptic vesicles to the so-called active zones of presynaptic membranes, which are presynaptic structures composed of voltage-dependent calcium channels and proteins required to dock synaptic vesicles against the presynaptic membranes. The majority of synaptic vesicle proteins and the proteins with which they are interact in the presynaptic terminal have been identified. One of the most remarkable features of transmitter release is its quantal nature, which originates from the storage of neurotransmitters in synaptic vesicles.

A. Quantal Release

Soon after electrophysiologists began investigating synaptic transmission, they realized that synaptic responses at individual synapses were not continuous but were distributed in a quantal fashion, representing multiple of a single size event, the quantal unit, which appears to be the amplitude of spontaneous potentials. In fact, when the distribution of evoked synaptic responses was analyzed statistically, the remarkable finding of Katz and colleagues was that this distribution followed a binomial law, with parameters n and p, where n is the number of quanta released and p the release probability. With the elucidation of the ultrastructure of presynaptic terminals, and the finding that synaptic vesicles were clustered near the active zones, it has been proposed that n could represent the number

of active zones. It is now clear that synapses in the CNS have different properties than those found at the neuromuscular junction. In particular, the majority of synapses in the CNS might have only one active zone, and the amplitude of postsynaptic potentials might reflect the number of postsynaptic receptors rather than the amount of transmitter released.

B. Release Machinery

A large number of vesicle-associated proteins have been identified and shown to participate in synaptic vesicle movement in presynaptic terminals, docking on the active zones, and fusing with presynaptic membranes. Several models of neurotransmitter release have been proposed to incorporate all these proteins and to account for all the salient features of transmitter release. One of the most recent models suggests that synaptobrevin and synaptophysin are bound to each other before synaptic vesicles fuse with the plasma membrane. Following an influx of calcium, synaptotagmin-1 (the calcium sensor of synaptic vesicles) interacts with two proteins from the plasma membrane, syntaxin and SNAP-25. Synaptobrevin dissociates from synaptophysin and interacts with the synaptotagmin-1–syntaxin–SNAP-25 complex. The interaction with SNAP dislodges synaptotagmin, and a new intermediate complex is formed. Subsequent steps leading to the fusion of the synaptic vesicle with the plasma membrane have not been completely identified. In addition, a family of vesicle-associated proteins, the synapsins, have long been identified and been shown to play a critical role in regulating the distribution of synaptic vesicles between two pools, the readily releasable vesicles and the reserve pool. Greengard and collaborators have shown that phosphorylation of synapsins is responsible for regulating the interactions between vesicles and actin filaments and thus for regulating the movement and the localization of synaptic vesicles in presynaptic terminals.

V. RECEPTORS AND SECOND MESSENGERS

All neurotransmitters exert their effects by activating membrane-associated proteins called receptors. When receptors are ligand-gated ionic channels, they are ionotropic receptors, whereas metabotropic receptors generally refer to receptors that are coupled to G proteins and produce a modification of the concentration of a second, intracellular messenger or the modulation of an ionic channel. Each neurotransmitter stimulates an array of receptors, thereby eliciting a number of postsynaptic responses (Fig. 2). Moreover, responses to a given neurotransmitter can be modified as a result of the simultaneous activation of receptors for another neurotransmitter on the same target cell or of the past activity of the target cell. Finally, transmitter receptors are not exclusively located on neuronal cells; they are also present on glial cells, thus establishing a direct communication between neurons and glia.

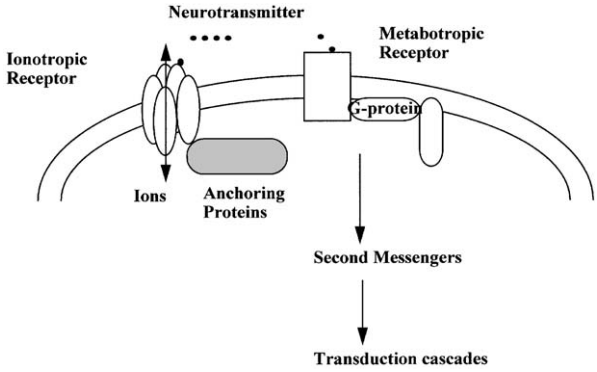

Figure 2 Schematic representation of neurotransmitter receptors. Both ionotropic and metabotropic receptors are schematically represented. Upon binding of the neurotransmitter, ionotropic receptors are activated and produce an increased permeability to specific ions, thereby resulting in a brief modification of the membrane potential. Activation of metabotropic receptors results in the activation of G proteins and their associated target ion channels or enzymes and the modification of the concentration of a variety of second messengers. This leads to the activation of transduction cascades that can modify the state of the neurons for minutes, hours, or weeks.

A. Ionotropic Receptors

The best known ionotropic receptor is the nicotinic receptor, which has served as the prototypical model for ionotropic receptors (this has occasionally led to some significant setbacks because some receptors were found to have properties distinct from those of the nicotinic receptors). It is a heteromeric pentameric protein, and each subunit is a transmembrane protein with four transmembrane domains. There are two binding sites for acetylcholine and binding of acetylcholine to the extracellular domain of the receptor results in a change of configuration of the channel domain and in a brief opening of a transmembrane ionic pore. This produces a brief modification of the membrane potential, the so-called postsynaptic potential. The same scenario seems to generalize to all

neurotransmitters, with hyperpolarization being produced by inhibitory neurotransmitters (generally due to the opening of chloride channels) or depolarization by excitatory neurotransmitters (generally due to the opening of sodium channels). This is generally followed by a desensitization phase during which the channel remains closed despite the binding of the ligand to its recognition domain. Numbers and kinetics for opening and closing of the receptor channels are critical parameters to determine the main features of synaptic transmission. A number of issues remain highly debated, particulary the saturability of the postsynaptic receptors by synaptically released neurotransmitter. In other words, are all the available receptors occupied following a release event? A number of laboratories have attempted to estimate the number of postsynaptic receptors for various neurotransmitters at different synapses. At glutamatergic synapses, recent studies estimate this number to be approximately 100 receptors. This obviously contrasts with the tens of thousands of nicotinic acetylcholine receptors found at the mammalian neuromuscular junction and emphasizes the point that synapses can have radically different properties in different structures. The answer to the question of postsynaptic saturability has obvious implications for mechanisms of synaptic plasticity. Furthermore, the mechanisms involved in the postsynaptic localization, anchoring, internalization, and turnover of the receptors remain the object of intense investigation. Recent studies have identified families of proteins that interact with the intracellular C-terminal domains of various receptors and channels and appear to anchor the receptors or channels in synaptic membranes as well as to link the receptors to various intracellular signaling processes. These proteins belong to a family of PSD-95 proteins, which are multifunctional proteins because they exhibit a guanylate kinase activity. In addition, members of the typical exocytosis machinery such as *N*-ethylmaleimide-sensitive factor and associated proteins have also been found to participate in receptor targeting and insertion mechanism. As discussed later, it is widely assumed that rapid regulation of receptor properties and numbers is an essential feature of synaptic modifications as a result of various patterns of activity.

B. Metabotropic Receptors

In addition to ionotropic receptors, neurotransmitters activate transmembrane receptors coupled with G proteins that generate a variety of cellular responses. These metabotropic receptors belong to a superfamily of proteins with seven transmembrane domains, with an extracellular ligand binding domain and an intracellular C-terminal domain that interacts with G proteins. Depending on the type of G proteins activated by these receptors, metabotropic receptor activation results in a variety of cellular responses, particularly in the modification of the concentration of several second messengers (e.g., calcium, cyclic AMP, cyclic GMP, inositol-triphosphate, and other phospholipid derivatives). Like ionotropic receptors, metabotropic receptors exhibit desensitization, generally mediated by phosphorylation reactions. Whereas ionotropic receptor-mediated responses generally last less than 1 sec, metabotropic receptor-mediated responses last for considerably longer periods of time, from seconds to minutes. Furthermore, some of these responses involve activation of transcriptional processes, resulting in the modification of specific proteins, and therefore produce functional modifications of neurons that last for hours to days (depending on the half-life of the newly translated proteins). As in the case of ionotropic receptors, several proteins involved in the targeting and anchoring of metabotropic receptors have been identified.

C. Second Messengers and Their Functions

Most second messengers activate enzymatic processes and are thus part of biochemical cascades that serve to amplify the responses to the first messenger. A number of protein kinases are the targets of second messengers, although protein phosphatases can also be activated by second messengers. As a result, a large variety of proteins can be functionally modified following the activation of metabotropic receptors. These include cytoskeletal proteins, neurotransmitter receptors, and ionic channels as well as transcription factors that regulate the expression of specific genes. Thus, the properties of ionotropic receptors can be regulated by phosphorylation reactions triggered by activation of a number of metabotropic receptors. In particular, channel kinetics, desensitization parameters, and even localization of a particular receptor can be modified as a result of the previous activation of metabotropic receptors for the same or a different neurotransmitter in its vicinity. As discussed later, some of these biochemical cascades have properties of biochemical switches and have been postulated to play important roles in synaptic plasticity processes. In any event,

second messenger-mediated cascades are highly regulated and provide for rich interactions between receptors for several neurotransmitters.

VI. SYNAPTIC INTEGRATION

It is well established that synaptic transmission at a given synapse is highly variable because it depends on a variety of parameters, including the state of the postsynaptic neuron (depolarized, hyperpolarized, firing, etc.) and the history of the synapse that influences both pre- and postsynaptic properties. These two properties, time- and state-dependent fluctuations and activity-dependent modifications of synaptic transmission, are considered the basis for most of the features of information processing and storage. It is generally agreed that synaptic dynamics regulate the efficacy of synaptic transmission on a short-term timescale, whereas synaptic plasticity operates on a longer timescale to modify synaptic strength.

A. Synaptic Dynamics

Synaptic transmission at CNS synapses is highly variable. This variability is the result of multiple processes that can alter any step involved in this highly complex and regulated mechanism (Fig. 3). The effectiveness of synaptic transmission depends on the frequency of stimulation and on the past activity of both pre- and postsynaptic elements. In general, repetitive high-frequency stimulation results in a rapid growth of postsynaptic potentials, a process called synaptic facilitation. A slower phase of increased transmission with a time course of several seconds follows facilitation and is called augmentation. A phase of decreasing transmission can also be superimposed to these processes and is referred to as synaptic depression. Other processes resulting from presynaptic feedback inhibition contribute to further regulate synaptic strength during a train of presynaptic action potentials. Several of these processes are due to the dynamics of $[Ca^{2+}]$ in the presynaptic elements and to the links between $[Ca^{2+}]$ and neurotransmitter release. Thus, synaptic strength is constantly modulated by the temporal pattern of presynaptic activity and the past history of the network in which the synapse is embedded. It is widely believed that this property of synaptic transmission results in the extraction of significant signals from noisy and variable temporal patterns. It has recently been recognized that dendrites and dendritic spines also

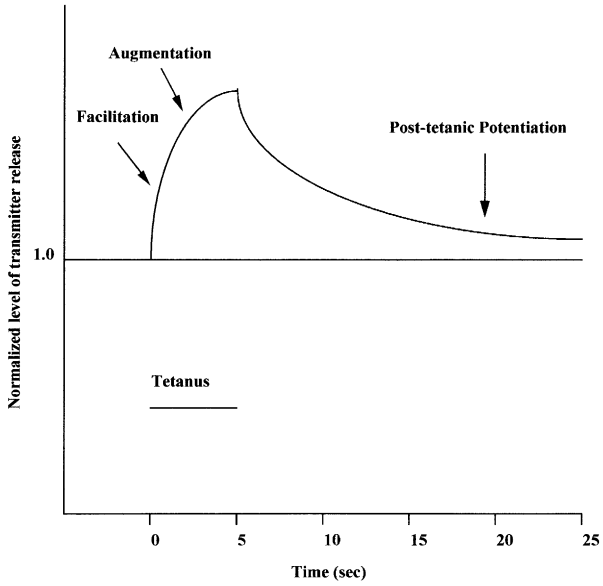

Figure 3 Multiple forms of synaptic modifications. Schematic representation of various forms of short-term synaptic plasticity due to changes in probability of release in response to a train of action potentials. Facilitation is a rapid increase in transmitter release occurring after a few pulses. Augmentation follows facilitation and has a longer decay period than facilitation. Finally, posttetanic potentiation is generally characterized by an increase in transmitter release lasting 20–40 sec.

contain active channels (in addition to neurotransmitter receptors), such as voltage-dependent sodium, calcium, and potassium channels. This means that firing of an action potential by the neuron can produce a dendritic action potential that is retrogradely propagated and thereby modifies the membrane potential of dendrites and their future responses to incoming signals. This property introduces additional complexities to synaptic transmission and integration. Numerous computer simulations of models of synapses incorporating rules of synaptic modifications based on experimental data have been developed and used to explore the computational properties of neuronal networks.

B. Synaptic Plasticity

In addition to the short-term variability of synaptic strength just described, several forms of long-term modifications of synaptic transmission, referred to as synaptic plasticity, have been described for a variety of synapses. Long-term potentiation (LTP) and

long-term depression (LTD) have received the most attention because they represent potential cellular models of information storage. LTP was first described in 1973 by Bliss and Lomo in rabbit hippocampus and has since been reported to occur in a wide range of structures and species. Its most common form is present at glutamatergic synapses, where stimulation of the NMDA subtypes of glutamate receptors triggers an influx of calcium and the activation of a complex intracellular cascade leading to increased responsiveness of the AMPA subtypes of glutamate receptors. Although much has been learned about the mechanisms involved in LTP during the past 10–15 years, several issues remain unanswered, particularly regarding the roles of gene expression and protein synthesis in LTP maintenance as well as the nature of the process involved in LTP stabilization. Two types of mechanisms by which synaptic activity could produce localized modifications of synaptic properties restricted to activated synapses have been proposed. In the first one, there is a small population of mRNAs constitutively present in dendrites; in response to an appropriate signal, these mRNAs are locally translated, and the newly synthesized proteins are incorporated into the activated synapses. Note that this process is rapid and does not require gene expression because it depends only on constitutively present mRNAs. In the second one, some locally generated signals are transmitted to the cell nucleus, triggering gene transcription and the synthesis of mRNA. This mRNA is targeted to the dendrites and is locally translated at the appropriate site. Note that this requires the existence of a signal or signals that remain present at activated synapses for a long period of time because the transcription of genes and their targeting to the dendrites necessitate a significant period of time. This mechanism is related to the synaptic tagging described by Frey and Morris. In their model, these authors propose that LTP induction is accompanied by the activation of signals they call "synaptic tags," which interact with plasticity-related newly synthesized proteins and stabilize the formation of LTP.

Many models of LTP propose that changes in synaptic efficacy are best accounted for by changes in synaptic structure. Although the issue is still highly debated, a large literature supports the notion that LTP is associated with modifications of synaptic structure and especially that an increased number of perforated synapses might represent an intermediate stage in the establishment of long-lasting potentiation. Again, various models have been proposed to incorporate changes in synaptic structure with changes in synaptic function, ranging from an increase in the number of functional synaptic contacts to an increase in axodendritic synapses. A popular version of these models is the notion of silent synapses, i.e., synapses with functional NMDA receptors but lacking functional AMPA receptors. Such synapses could become functional as a result of the coincidence of presynaptic activity with postsynaptic depolarization (conditions necessary and sufficient to activate the NMDA receptors) and the appearance of functional AMPA receptors due to their insertion in postsynaptic membranes from an intracellular pool or their redistribution from extracellular locations. Studies of simulation of transmitter release and receptor activation based on a synapse model that incorporates the geometry of synaptic contacts as well as the distribution of receptor proteins in postsynaptic densities have been performed to examine the role of various parameters in LTP. The results were quite astonishing because they indicated that the geometry of synaptic contacts has a much greater impact on synaptic function than previously thought. This is true not only on the presynaptic terminals, where geometry determines the probability of transmitter release, but also on the postsynaptic sites, where receptor location in concert with the location of neurotransmitter release determine the probability that a transmitter molecule activates a postsynaptic receptor. Thus, a silent synapse could simply represent a synapse for which the receptors are located too far from the site of transmitter release to be activated. Relocation of transmitter receptors closer to the release site could transform a silent synapse into an active synapse.

In contrast to LTP, LTD has a much shorter history and has only recently been studied extensively and incorporated into models of learning and memory. LTD at glutamatergic synapses between the parallel fibers and the Purkinje neurons in the cerebellum was proposed to account for the adaptation of the vestibuloocular reflex by Ito and colleagues. It was later proposed to account for learning of classically conditioned motor responses. Cerebellar LTD occurs when parallel fiber activation is closely associated with climbing fiber stimulation, and it appears to be due to a long-lasting decrease in AMPA receptor responsiveness at the parallel fiber to Purkinje cell synapse. Several second messengers have been proposed to participate in LTD induction, including cGMP and NO. LTD has also been found at hippocampal glutamatergic synapses and could represent the reversal of LTP and, in particular, the transformation of active synapses into silent synapses. Whether

cerebellar LTD and hippocampal/cortical LTD represent the same or different processes remains to be determined.

VII. CONCLUSIONS

Synaptic transmission is a highly complex and regulated process. Not surprisingly, numerous neurological diseases are thought to result from alterations in one or several steps involved in synaptic transmission. In particular, alterations in dopaminergic transmission are widely believed to contribute to schizophrenia, whereas abnormalities in biogenic amine transmission might contribute to affective disorders. Furthermore, learning and memory are generally considered to be due to activity-dependent modifications of synaptic efficacy along the networks involved in the processing of information. Although the roles of LTP/LTD in learning and memory remain highly debated, it is likely that multiple forms of synaptic plasticity are responsible for the rich variety of memory types exhibited by mammalian brains. Neuronal networks incorporating synaptic dynamics and synaptic plasticity rules derived from experimental neurobiology have been shown to exhibit rich computational capabilities, and silicon instantiation of such networks is being developed for performing human-like computational operations.

Synaptogenesis

FREDERIQUE VAROQUEAUX and NILS BROSE
Max Planck Institute for Experimental Medicine, Göttingen, Germany

GLOSSARY

active zone Presynaptic membrane specialization that the transmitter release process is restricted to; contains a scaffold of proteins involved in synaptic vesicle exocytosis.

cell adhesion Binding between cells, mostly mediated by cell surface molecules that interact homotypically or heterotypically with other cell surface proteins or with components of the extracellular matrix.

postsynaptic density Electron-dense postsynaptic membrane specialization containing a scaffold of receptors, ion channels, and signal transduction proteins.

synapse Contact between the sending nerve cell and target cell, typically formed by a presynaptic axon terminal that is specialized for transmitter secretion and a postsynaptic cell body or dendrite that is specialized for signal reception and transduction.

Synaptogenesis, the formation of functional chemical synapses between neurons, represents the climax of brain development. It results in the establishment of an ordered neuronal network that is later fine-tuned or remodeled to allow dynamic and flexible information processing in the brain. This article describes the characteristics of synaptogenetic processes with an emphasis on their possible molecular basis.

I. INTRODUCTION

Information processing in the brain is based on a complex and specific network of synaptic connections that in humans consists of approximately 10^{11} neurons connected by 10^{15} synapses. Synapses are asymmetric, strongly adhering, morphologically and functionally specialized contact zones where transfer of information takes place between a sending nerve cell and a receiving neuron, muscle fiber, or other target. The presynaptic axon terminal is specialized for the complex membrane trafficking mechanisms that underlie regulated secretion of transmitter. Many of the proteins it contains are highly specific for presynaptic structures. The axon terminal faces a postsynaptic structure that is uniquely specialized for signal reception and transduction. The postsynapse is typically built as a scaffold of proteins involved in clustering and anchoring neurotransmitter receptors, ion channels, and intracellular signal transduction molecules, many of which are specifically targeted to this structure and not present in other parts of the cell. The extraordinary specificity of connections in the adult brain is achieved by an elaborate developmental program that is regulated by a combination of genetic and epigenetic processes. Embryonic stem cells generate a population of neural precursor cells that proliferate and differentiate into glial cells and immature neurons. Immature neurons migrate to their final destination, where they form processes, axons, and dendrites, through which they are able to make synaptic contacts with target cells. Neurons can grow very long and ramified processes allowing them to connect with target structures over considerable distances. Once growing axons have reached their target areas, the process of brain development culminates in synaptogenesis, that is, in the formation and maturation of specific functional synapses between defined sets of neurons, resulting in an amazingly complex neuronal network. Even after

the network is formed, it retains its ability to undergo dynamic changes. Existing synaptic connections can be strengthened, weakened, or eliminated, and new synapses can be generated as a consequence of endogenous or environmental stimuli and experience, allowing the brain to adjust and optimize its responses and adapt to novel tasks throughout life. Similar to the situation in the brain, synapses in the periphery (e.g., at the neuromuscular junction) are generated with extreme accuracy, mature after formation, and can be modified or eliminated in response to various stimuli.

Centrally and peripherally, synaptogenesis and activity-dependent modulation of synaptic strength or connectivity are the final steps in the formation of a functional neuronal network. On an operational level, two temporally distinct synaptogenetic processes can be distinguished. First, a nascent axonal growth cone specifically recognizes its appropriate target neuron and make an initial contact. Second, pre- and postsynaptic proteins have to be recruited to the initial contact site in order to assemble a functional synapse. Accumulating evidence from convergent biochemical, morphological, electrophysiological, and genetic studies in model organisms (*Drosophila*, *Caenorhabditis elegans*, and mouse) indicates that both processes are mediated by a complex cascade of protein–protein interactions, involving cell adhesion molecules, intracellular adaptor proteins, and components of the secretory machinery or signal transduction cascades. Although the basic principles of synaptogenesis are similar for most synapses at the phenomenological level, ultrastructure and protein composition of synaptic contacts as well as molecular mechanisms of synaptogenesis differ strikingly between different types of synapses and seem to be only partially conserved during evolution. This suggests that multiple and, to a certain degree, redundant molecular mechanisms can contribute to the process of synapse formation.

This article discusses synapse structure and its synaptogenetic requirements, basic characteristics of synaptogenetic processes, and molecular mechanisms of synaptogenesis with respect to the four most prominent types of synapses: the excitatory glutamatergic synapse (type I), the inhibitory glycinergic synapse (type II), the inhibitory GABAergic synapse (type II), and the cholinergic neuromuscular junction.

II. STRUCTURE OF THE SYNAPSE

Neurotransmission at central nervous system and neuromuscular synapses occurs by the same basic mechanisms. In response to an action potential, the highly specialized presynaptic terminal releases neurotransmitter into the synaptic cleft by exocytotic fusion of synaptic vesicles. Transmitter then diffuses to the postsynapse, where an elaborate signal transduction apparatus mediates reception of the neurotransmitter and propagation of the signal. Synapses are asymmetric cell–cell contacts that consist of three core compartments: the presynapse, the synaptic cleft, and the postsynapse (Fig. 1).

The presynaptic compartment is morphologically very similar in all types of synapses (Fig. 1). Ultrastructurally, it is characterized by an accumulation of transmitter containing small (50 nm), clear synaptic vesicles. These are clustered near a thickened stretch of presynaptic plasma membrane, the active zone, to which synaptic exocytosis is restricted. Additional material protrudes from the active zone into the presynaptic lumen and partially fills the space between the vesicle cluster, suggesting that a dense network of scaffold molecules, together with components of the cytoskeleton and membrane skeleton, controls and optimizes vesicle trafficking at the active zone. In addition to small, clear vesicles, most presynapses contain large, dense-core vesicles (100 nm) as well as clathrin-coated vesicles, the latter reflecting the permanent membrane recycling activity in the presynaptic terminal. The high energy requirement of presynapses is reflected by the presence of numerous mitochondria.

In contrast to the similarities at the presynaptic level, different types of synapses differ dramatically in the structure and composition of the synaptic cleft and postsynaptic compartments. At central nervous system synapses (Figs. 1A and 1B), the synaptic cleft is formed by a regular parallel apposition of pre- and postsynaptic membranes. It is characterized by a widening of the intercellular space (20 and 30 nm in symmetric and asymmetric synapses, respectively, vs 15 nm outside of synaptic areas) that contains dense material but is devoid of a basal lamina and its molecular constituents. At the neuromuscular junction, a structured basal lamina ensheaths each muscle fiber and extends through the synaptic cleft and into the junctional folds, separating pre- and postsynaptic membranes (Fig. 1C). The synaptic part of the basal lamina has a specific molecular composition. At the postsynaptic level, structures are also diverse. Excitatory/glutamatergic type I synapses, the most abundant in the brain, are mostly located on dendritic spines. These represent a separate cellular compartment with autonomous biochemical activity that contains endoplasmic reticulum, polysomes, and mitochondria.

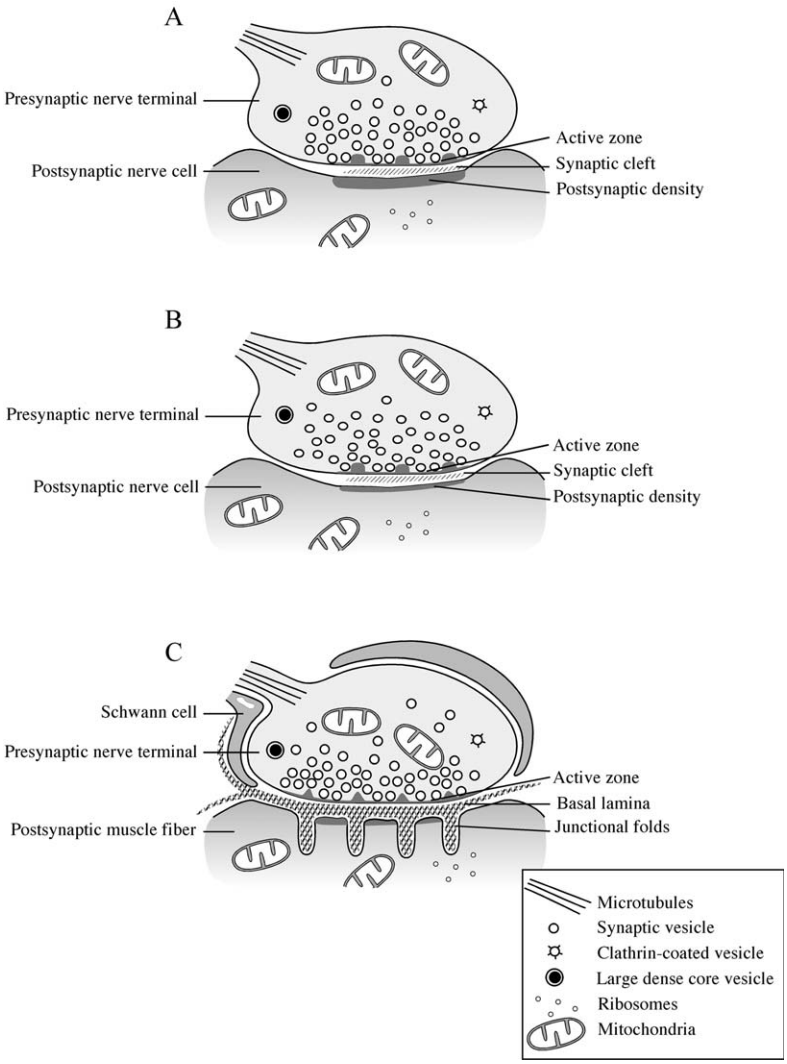

Figure 1 Morphology of chemical synapses. (A) Central asymmetric synapse (or type I); (B) central symmetric synapse (or type II); (C) neuromuscular synapse. Synapses in the central nervous system are established between two neuronal elements (A and B) and at the neuromuscular junction between a motor neuron and a muscle fiber (C). Asymmetric (or type I) synapses (A) use glutamate as major neurotransmitter. Symmetric (or type II) synapses (B) utilize GABA or glycine, whereas acetylcholine is the main chemical messenger delivered at the neuromuscular junction (C). All three types of synapses have developed a highly specialized and polarized presynaptic apparatus, where neurotransmitter-containing synaptic vesicles dock at the active zone of the presynapse and release their transmitter content into the synaptic cleft in response to an arriving action potential. At the neuromuscular junction only, this cleft is occupied by a dense organized network of material, the basal lamina. Facing the presynaptic release zone, the postsynaptic membrane is locally thickened and built differentially in the three synapse types. At central synapses, it is parallel to the release site and characterized by an intracellular accumulation of dense material, the so-called the postsynaptic density, characterized by an electron-dense appearance in electron microscopy. The postsynaptic density is prominent in asymmetric synapses (A) but barely detectable in symmetric synapses (B). At the neuromuscular junction, the postsynaptic membrane exhibits deep folds and intracellular accumulation of dense material in its uppermost area (C). Free or endoplasmic reticulum-linked ribosomes are observed in the proximity of the postsynapse. Under aldehyde fixation conditions with high osmolarity buffers, synaptic vesicles appear more ovoid or almost flattened in symmetric synapses, whereas they remain round shaped at asymmetric sites.

Type I postsynapses (Fig. 1A) are characterized by a prominent disc-shaped thickening underneath the membrane, the postsynaptic density, and by dense structures emanating from both sides of the junction, the puncta adhaerentia. Inhibitory/GABAergic or glycinergic synapses are mostly formed between axons and cell somata. They have a much less prominent postsynaptic thickening (Fig. 1B) and have therefore

been referred to as symmetric synapses (type II) in contrast to the prominent asymmetric appearance of the synaptic membranes in type I excitatory synapses. At the neuromuscular synapse (Fig. 1C), the postsynaptic membrane forms deep infoldings opposite to the active zone and exhibits thickenings at its uppermost portion.

The ultrastructural diversity of synapses reflects their fundamentally different molecular compositions, which will be discussed later. Their complex structure is based on an elaborate arrangement of a large number of proteins. During synaptogenesis, these have to be assembled in a coordinated and efficient manner—a task that is achieved by an interplay of cell adhesion molecules, scaffold proteins, and functionally relevant pre- and postsynaptic proteins.

III. RECOGNITION AND CONTACT FORMATION

A. The Problem of Specificity and Adhesion

Any given brain region contains multiple classes of neurons that can be distinguished on the basis of their localization, morphology, molecular composition, functional characteristics, and connectivity. In the case of the cerebral cortex, neuronal diversity may amount to approximately 500 different types of neurons. To produce specific connectivity despite this diversity, a cascade of pathfinding and recognition processes comes into play that allows a given neuron to find its partners.

Long before a nascent axonal growth cone establishes contact with its partner cell and synaptogenesis can commence, several classes of hierarchically organized cell surface and secreted proteins mediate and modulate axon extension and guidance, ushering the axon to its appropriate target area. In some cases, guidepost cells serve as temporary scaffold and transient synaptic targets in these processes. Such pathfinding mechanisms significantly reduce the specificity problem of synaptogenesis by confining possible partners of an ingrowing process to a defined compartment of the brain. However, the establishment of specific synaptic connections remains a daunting task because several levels of specificity have to be met by newly formed synapses. First, mechanisms of synaptogenesis have to mediate specificity at the cellular level, allowing an axon to distinguish between different cell types or even between individual cells of the same type. Second, mechanisms of synaptogenesis have to be specific at the subcellular level, identifying axon, dendrite, and soma of a target cell as functionally distinct input areas. Finally, mechanisms of synaptogenesis have to be specific for the different types of transmitter that will be used at the newly forming synapse.

Similar to axon pathfinding, synaptic recognition and synaptogenesis processes are thought to be mediated by cell adhesion molecules. In fact, different types of cell adhesion proteins must be present to mediate different levels of synaptic specificity, determining target region and target cell identity, subsections of the neuronal membrane surface, pre- and postsynaptic compartments, transmitter specificity of a synapse, or synapse strength, size, and stability. In addition to synapse specificity, cell adhesion molecules also fulfill the more mundane task of synaptic adhesion, keeping pre- and postsynaptic compartments in close apposition and register.

In contrast to synaptogenesis in the central nervous system, the specificity requirements during the formation of a neuromuscular junction are less complex. Once guided to the appropriate target area, the ingrowing axon of a motor neuron contacts its target structure near its site of entry into the muscle. This initial unspecialized contact is only capable of rudimentary neurotransmission, reflecting the absence of pre- and postsynaptic specializations, and matures into a functional synapse as the presynaptic compartment assembles and triggers postsynaptic clustering of acetylcholine receptors by secreting a soluble clustering factor. The fact that neuromuscular junctions contain a basal lamina while synapses in the central nervous system do not suggests that membrane–matrix interactions may predominate adhesion mechanisms at the neuromuscular junction, whereas typical cell–cell adhesion molecules may be more crucial in the brain. Such differences in adhesive mechanisms also imply that signals involved in target recognition and synapse maintenance may be different at neuromuscular junctions compared to synapses in the central nervous system.

B. Cell Adhesion Molecules in Synaptic Contact Formation and Specificity

Cell adhesion molecules form a diverse group of cell surface proteins that are specialized in mediating adhesion at the cell–cell and cell–substrate interface and play important roles in a variety of physiological processes, ranging from organogenesis to adhesion in cells of the immune system. In addition, many cell

adhesion molecules also serve signal transducing purposes. Although several hundred putative cell adhesion proteins have been described, only very few may be present in synapses. In fact, only five cell adhesion complexes have been found in electron microscopic studies to be unequivocally synaptic: cadherin/catenin, protocadherins/cadherin-litre neuronal receptors/(CNRs), neurexin/neuroligin, neural cell adhesion molecule (NCAM), and integrins (Fig. 2).

1. Cadherins

Cadherins were originally discovered as vertebrate cell surface molecules that mediate Ca^{2+}-dependent cell adhesion. They are expressed by almost all cell types in which, they are enriched in cell–cell junctions of different types (e.g., zonula adherens and desmosomes). Cadherins are essential for cell adhesion during development as well as in mature tissues. In addition to "classic" cadherins, the cadherin protein family contains desmosomal cadherins, protocadherins, and cadherin-related molecules. Classic cadherins (>15 isoforms) are composed of a large N-terminal extracellular domain containing five repeated subdomains (EC1–EC5), a single transmembrane domain, and a highly conserved C-terminal cytoplasmic region (Fig. 2). With few exceptions, cadherins interact homotypically, preferentially binding to proteins of the same subtype. This homotypic interaction and its specificity are mediated by multiple portions of the N-terminal domain. Intracellularly, classic cadherins interact with catenins, a group of proteins that attach the cytoplasmic domain of cadherins to the actin cytoskeleton and function as intracellular signaling molecules.

In the central nervous system, cadherins are involved in axon outgrowth, axon fasciculation, target recognition, and maintenance of neuronal connections in the adult brain. The differential region-specific and cell-type-specific expression patterns of certain cadherins was interpreted as a possible molecular basis for the specificity of synaptic connectivity in the brain, where the binding specificity of cadherins expressed on invading growth cones could determine synaptic partner choice. However, the number of classic cadherins expressed in the brain may not be high enough to account for the observed specificity in the synaptic network. Nevertheless, a synaptic role of cadherins is evident from the observation that neural (N) and epithelial (E)-cadherins are found on both sides of many synapses in the brain. Furthermore, their

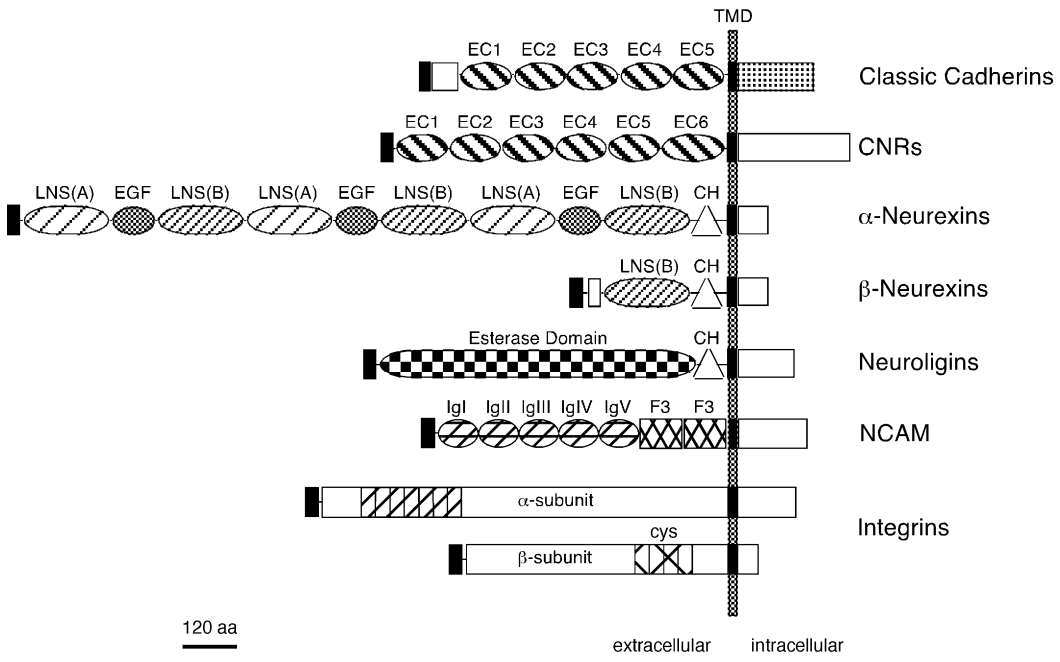

Figure 2 Domain structures of synaptic cell adhesion molecules. intracellular adaptor proteins, αN- and β-catenins, are present in asymmetric (type I) and symmetric (type II) synapses. In type I synapses catenin-containing regions are localized in a parasynaptic manner, flanking presynaptic release sites and postsynaptic densities, whereas in type II synapses catenin localization overlaps with release zones. The differential association of N- and E-cadherins with distinct synapses suggests that the homotypic binding preferences of different cadherin isoforms contributes to the specificity of synapse formation.

In addition to a role in synaptogenesis, functional cadherin-mediated synaptic cell adhesion appears to influence mature synapses as well in that it may be involved in the activity-dependent strengthening of synapses during memory formation by enhancing synaptic adhesion and efficacy.

2. Cadherin-like Neuronal Receptors and Protocadherins

The discovery of a novel family of cadherin-related proteins, the cadherin-like neuronal receptors (CNRs), has provided additional evidence for a synaptic function of the cadherin family of proteins. CNRs constitute a family of more than 50 different gene products. They are composed of a large N-terminal extracellular region containing six EC domains (EC1–EC6) with high homology to cadherins, a single transmembrane domain, and an intracellular C terminus that is highly conserved within the CNR family but has no homology with known cadherins and therefore does not bind catenins (Fig. 2). Some CNRs were shown to be present at the synapse, forming transsynaptic connections.

CNRs belong to the family of protocadherins whose common features are six or seven extracellular cadherin ectodomains and a divergent cytoplasmic region. Like CNRs, the initially identified protocadherins are highly expressed in brain, where they are localized mainly at cell–cell contact sites. One isoform, OL-protocadherin, was shown to be enriched in the synapse-rich glomeruli of the olfactory bulb, suggesting a role in synaptic adhesion. Recently, a large family of more than 50 human neural cadherin-like cell adhesion genes, including CNRs, was described. These genes are organized in three tandem linked clusters, in which the N termini of different cadherin-like proteins, containing all six cadherin ectodomains, are encoded by a large exon. In contrast, the C termini of all cadherin-like proteins are identical and each terminus is encoded by three exons located downstream from the tandem array of N-terminal exons. Although it is not known whether these cadherin-like genes recombine in an immunoglobulin-like manner, the genomic organization of protocadherin genes allows for a considerable combinatorial variability of gene products that may form the basis for the cell-specific expression of certain isoforms.

CNRs in the brain have multiple functional roles. Extrapolating from published data on classic cadherins, CNRs are likely to interact homotypically. Assuming that up to 100 different CNR and protocadherin genes are expressed in brain in a partially cell-type-specific manner, the CNR proteins may play a role in synaptic recognition, allowing an arriving growth cone to distinguish its appropriate partner cell from a large selection of possible candidates. Additionally, CNRs are likely to participate in Fyn-mediated intracellular signaling, suggesting an interesting functional parallel between CNRs and cadherins. Data on deletion mutant mice demonstrate that Fyn is critical for LTP induction and spatial learning; given that CNRs bind to Fyn, these novel cadherin-like proteins may also be instrumental in the induction of LTP, resembling functional characteristics of cadherins. Finally, members of the CNR family interact with reelin, a protein that is an essential cue during neuronal migration.

3. β-Neurexins and Neuroligins

Although homotypic cell adhesion molecules such as cadherins or CNRs may play a critical role in synaptic recognition and adhesion, the asymmetry of synapses is likely to be mediated in part by heterotypic transsynaptic signaling. In fact, heterotypic cell adhesion has to be postulated to explain certain aspects of synaptogenesis, such as the specific and differential recruitment of pre- and postsynaptic protein components to their respective subcellular compartments. The β-neurexin/neuroligin junction represents the only known heterotypic cell adhesion system present in synapses.

Neurexins constitute a family of brain-specific cell surface molecules. The mammalian genome contains at least three homologous neurexin genes (neurexins I–III). Each of these is controlled by two different promoters, resulting in the generation of two primary transcripts per gene (α and β isoforms). α-Neurexins are composed of a signal peptide, a large extracellular N terminus, a single transmembrane domain, and a highly conserved intracellular C-terminal tail. In addition to an O-linked sugar attachment sequence

close to the transmembrane domain, the extracellular region of α-neurexins is assembled from three overall LNS(A)–EGF–LNS(B) repeats, each of which carries a central epidermal growth factor (EGF)-like sequence flanked by two subdomains [LNS(A) and LNS(B)] with homology to repeats found in the G domain of laminin A, in sex hormone-binding globuline, agrin, protein S, and several other proteins (Fig. 2). β-Neurexins are truncated forms of the respective α variants, containing a unique signal peptide and short N-terminal sequence stretch that is spliced into the α-neurexin sequence after the third EGF domain (Fig. 2). Extensive alternative splicing of the six primary neurexin transcripts at five splice sites (that can carry 2–12 alternatively spliced inserts) results in a combinatorial polymorphism of neurexin gene products that is unparalleled in cell adhesion molecules. Because many of these neurexin variants exhibit differential expression patterns in the brain, it was suggested that a given neuronal subpopulation may express a unique set of neurexins, which in turn could contribute to the specificity of neuronal cell–cell contacts in the brain.

Neuroligins were originally discovered as isoform-specific and splice site-specific ligands of β-neurexins (Δ4) that constitute a family of three brain-specific type I membrane proteins (neuroligin 1–3). Their large extracellular, β-neurexin-binding N-terminal domain is homologous to serine esterases such as acetylcholine esterase but lacks catalytic activity. It is followed by a transmembrane segment and a shorter intracellular tail (Fig. 2). Several prominent homologs of neuroligins are involved in cell adhesion in *Drosophila*. In addition, the intracellular tail of neuroligin binds to PSD95, a PDZ domain-containing membrane-associated guanylate kinase that is thought to be involved in the assembly and organization of signal transduction complexes in postsynaptic densities by acting as a multifunctional scaffold protein. This suggests that neuroligins may not only serve as adhesion molecules between cells but also are able to influence the assembly of protein complexes involved in signal transduction.

The characteristics of β-neurexins and neuroligins gave rise to a model according to which the two proteins form intercellular junctions in the brain. In the rat central nervous system, neuroligin 1 resides in postsynaptic densities, its extracellular tail reaching into the synaptic cleft, placing the β-neurexin/neuroligin junction at the synapse. Like glutamate receptors, neuroligin 1 is specifically localized to excitatory synapses, suggesting that it may not simply serve to form transsynaptic contacts between pre- and postsynaptic compartments. Rather, it may be involved in the determination of synapse specificity, distinguishing excitatory from inhibitory contact sites and recruiting protein components that are specific for excitatory synapses. The highly specific localization of neuroligin 1 is paralleled by its interaction partner PSD95 and several other postsynaptic proteins. Given that all three neuroligins are coexpressed in almost all neurons of the rat brain, a role of the β-neurexin/neuroligin junction in the determination of cellular synaptic specificity is very unlikely. Rather, neuroligins may function in a late step of synaptogenesis and/or the modulation of mature synapses. Indeed, neuroligins may not be essential for axonal pathfinding or initial synaptogenesis *in vivo*, although they are sufficient to trigger the generation of synapse-like structures between neurons and "postsynaptic" fibroblasts that overexpress neuroligins.

4. Neural Cell Adhesion Molecule

NCAM is a member of the immunoglobulin superfamily. It is a glycosylated protein expressed in most cells of the central and peripheral nervous system, muscle, heart, and gonads. NCAM is concentrated at contact sites between cells and mediates cell adhesion and recognition by intercellular homophilic interactions. Three major isoforms of NCAM are expressed: NCAM-A, -B, and -C. The A and B isoforms are single-pass transmembrane proteins with different intracellular domains, whereas NCAM-C is attached to the extracellular membrane surface by a glycosylphosphatidylinositol anchor. The extracellular part of all NCAM isoforms is composed of five N-terminal immunoglobulin domains (IgI–IgV), followed by two fibronectin type III domains (Fig. 2). Alternative splicing and posttranslational modification generate additional structural and functional diversity. Particularly, glycosylation with polysialic acid is an important regulatory process in NCAM function.

NCAM is present at synaptic junctions in several areas of the brain. *In vitro* studies demonstrate that NCAM stimulates axonal growth. In contrast, NCAM is not essential for most axon pathfinding and synaptogenesis processes in the intact brain. Nevertheless, interference with NCAM function by various methods has interesting consequences for several aspects of brain function, most notably deficiencies in neuronal migration, axon pathfinding or fasciculation, and physiological (LTP) as well as behavioral correlates of learning and memory. Evidently, NCAM function is not central to synaptogenesis but does

influence dynamic changes in synaptic strength and adhesion.

With respect to a possible functional role in synaptogenesis, fasciclin II, a close *Drosophila* homolog of NCAM, exhibits unique characteristics. Like NCAM, fasciclin II is involved in axon fasciculation and sprouting. However, it has an additional role in synaptogenesis and synaptic plasticity. Fasciclin II likely forms transsynaptic contacts and associates with PDZ domain-containing proteins and receptors through their intracellular C terminus. During evolution, the fasciclin II system may have been replaced by other molecular processes.

5. Integrins

Integrins are cell surface proteins responsible for cell–cell and cell–matrix interactions. In addition to the families of Ig-like cell adhesion molecules, cadherins, and selectins, they represent one of the largest families of cell adhesion proteins. Integrins are heterodimeric transmembrane proteins consisting of an α and a β subunit. Each subunit has a large N-terminal extracellular domain, a single transmembrane region, and a cytoplasmic C terminus. In vertebrates, 15 α and 8 β subunits are known, which together can form more than 20 heterodimeric integrin complexes. The α subunits are characterized by seven homologous repeats in their N-terminal extracellular region, some of which have functional EF-hand regions that bind divalent cations. The β subunits carry a cation binding site in their N-terminal extracellular region that is followed by four cysteine-rich repeats (Fig. 2). Intracellularly, integrins bind to and recruit linker proteins and components of signal transduction modules that link the proteins to the cytoskeleton and allow integrin-mediated signaling to various subcellular compartments.

Depending on their subunit composition, integrins are essential for many physiological processes most commonly by mediating cell–matrix interactions. Binding of extracellular matrix components induces integrin-mediated signaling to regulate cytoplasmic kinases, growth factor receptors, or ion channels and to control cytoskeleton dynamics or cell cycle progression.

Several integrins are found to be specifically enriched in synapses, mostly at neuromuscular junctions. However, the role of integrins in synapses is only beginning to emerge. Recent studies suggest that they are involved in synaptogenesis and synaptic specificity at *Drosophila* and vertebrate neuromuscular junctions as well as in the formation, maintenance, or plasticity of central nervous system synapses. Signaling mechanisms that mediate these effects are poorly understood, particularly in synapses of the central nervous system. They may involve the regulation of the pre- and postsynaptic cytoskeleton as well as receptors and ion channels.

6. Hierarchical Organization of Synaptic Cell Adhesion Molecules

The synaptic expression of a large number of cell adhesion molecules from different protein families suggests that these proteins function, at least in part, in consecutive steps of synaptogenesis. The unusually large families of CNRs and protocadherins provide sufficient combinatorial diversity to serve as identifiers of neurons. They are good candidates for mediators of initial contact formation and synaptic specificity. On the other hand, cell adhesion systems such as the β-neurexin/neuroligin junction are linked to intracellular protein–protein interaction cascades that are thought to be involved in the specific recruitment of synaptic proteins and synapse maturation. Finally, cell adhesion molecules such as NCAM and integrins are likely to function in synapse maturation and plasticity by regulating synaptic adhesion and intracellular signaling cascades.

IV. ASSEMBLY AND MOLECULAR ARCHITECTURE OF THE SYNAPSE

Essentially supporting the operational view of two phases in synaptogenesis, initial contact formation and assembly, morphological and functional studies demonstrate that a nascent growth cone forms an immature synaptic structure on initial contact with its target cell, which then matures into a fully functional synapse (Fig. 3).

As mentioned previously, assembly is most likely initiated and regulated by synaptic cell adhesion molecules. Given the asymmetric character of synapses with morphologically, functionally, and molecularly distinct pre- and postsynaptic compartments, heterophilic transsynaptic interaction of adhesion molecules is likely to be an important contributor to synapse assembly.

Analysis of the molecular architecture of synapses has revealed an extremely complex cascade of protein–protein interactions that are thought to be the molecular basis of the synapse assembly process. It is

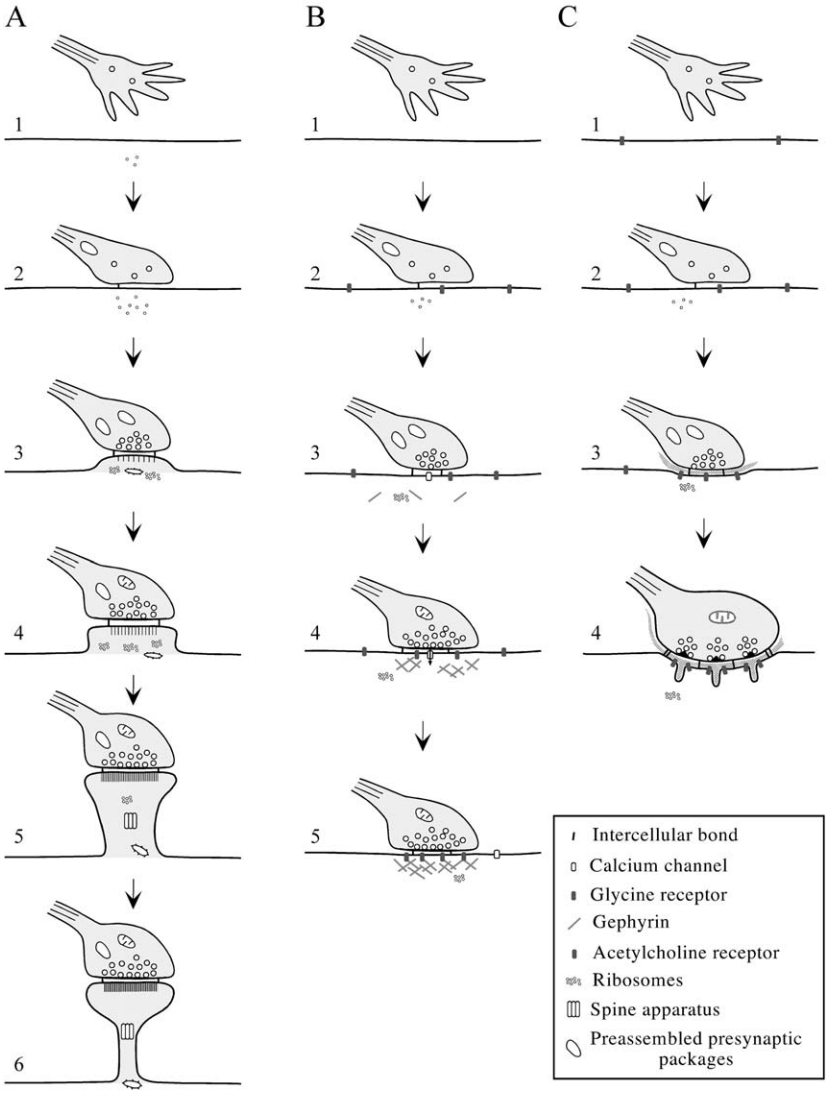

Figure 3 Formation of synapses. (A) Central asymmetric synapse (or type I) on a dendritic spine; (B) central symmetric synapse (or type II) on a cell soma; (C) neuromuscular synapse on a myotube. (A) Glutamatergic synapse. The growth cone approaches the membrane (1) and forms a specific but initially unspecialized contact (2), likely driven by a homotypic adhesion system (CNRs or cadherins). Presynaptically, putative preassembled active zones and scarce synaptic vesicles are present. Soon thereafter, Bassoon is recruited to the presynaptic site. A heterotypic adhesion system (β-neurexin/neuroligin) may coordinate and drive pre- and postsynaptic differentiation (3). Numerous polyribosomes may reflect high local protein synthesis. Progressively (4 and 5), functional presynaptic active zones are formed. Synaptic vesicles accumulate. The spine is taking shape, and a spine apparatus is organized. First-order scaffold proteins (e.g., SAP90/PSD95) accumulate at postsynaptic sites, followed by recruitment of specific receptors, ion channels, and second-order interaction partners. Glutamate receptors accumulate at postsynaptic sites (6). (B) Glycinergic synapse. The growth cone approaches the membrane (1) and forms a specific but initially unspecialized contact, possibly triggered by a homotypic adhesion system (CNRs and cadherins). At that point, glycine receptors are freely diffusing in the postsynaptic membrane (2). Calcium influx induced by presynaptic release triggers gephyrin accumulation (3). Gephyrin aggregates (4) and clusters glycine receptors at the subsynaptic membrane (5). (C) Cholinergic neuromuscular synapse. The growth cone approaches an already formed muscle cell (1) and forms an unspecialized contact capable of rudimentary neurotransmission. Acetylcholine receptors are diffusely distributed over the muscle cell membrane (2). The presynaptic terminal differentiates and accumulates synaptic vesicles. In parallel, the basal lamina forms and the muscle cell matures. Electric activity induces further synthesis of acetylcholine receptors near the synaptic input and suppresses synthesis in nonsynaptic areas (3). The junction matures, bonds between pre- and postssynapse induce the formation of folds, and different postsynaptic components are differentially distributed. In particular, acetylcholine receptors cluster at the edges of the folds (4).

likely that assembly of active zones and postsynaptic signal transduction systems is not just occurring at the level of the synapse. Rather, various protein complexes or even preassembled active zones may be put together at the level of the cell body and transported *in toto* to the developing synaptic contact, where they can be integrated into the newly forming synapse in response to the activity of an organizer protein or other stimulus.

Presynaptically, synapses of different types are very similar with respect to their protein composition, and only very few presynaptic proteins are known to be specifically expressed in only one type of synapse but not in others. This indicates that the assembly of presynaptic compartments follows the same general mechanisms, irrespective of the cell type under investigation. In contrast, the postsynaptic compartments of different types of synapses are composed of strikingly different sets of proteins, suggesting that alternative pathways of postsynaptic assembly are used.

A. Presynapse

In most cases studied, presynaptic differentiation precedes postsynaptic differentiation during synaptogenesis. Even before synapse formation, axonal growth cones exhibit vesicular fusion and irregular quantal release of transmitter from vesicles. This phenomenon likely contributes to growth cone extension during axon elongation. In addition, the resulting electrical activity may aid in early phases of synaptogenesis. However, mice with a completely dysfunctional synaptic secretion apparatus initially form a normal neuronal network that later degenerates. This suggests that sporadic neurotransmitter release from nascent presynaptic terminals/growth cones may not be required for synaptogenesis but instead be important for synapse maturation and maintenance. Upon contact between growth cone and target structure, a specific molecular adhesion reaction is thought to trigger synapse formation. Functional presynaptic boutons can form within 30 min of the establishment of an axodendritic contact, and 1 or 2 h may suffice to form a glutamatergic synapse.

Immature presynaptic compartments contain a small number of synaptic vesicles, cytoskeletal components, dense-core vesicles, tubulovesicular structures, and pleiomorphic vesicles. Some of the larger vesicular structures contain active zone and synaptic vesicle proteins. They are thought to represent preassembled presynaptic active zones that can be rapidly integrated into the presynaptic plasma membrane following contact formation between axon and target structure or an appropriate signal. Bassoon or Piccolo, two multidomain proteins of the presynaptic active zone, may function as organizers of active zone transport vesicles. As the synapse matures, synaptic vesicles accumulate, probably recruited from the cell soma or neighboring terminals (Fig. 3).

The physical contact between axon and target membrane appears to stabilize the presynapse and coordinate the development of pre- and postsynaptic specializations. Although the underlying coordinating signal is not known in central nervous system synapses, it is likely to involve cell adhesion molecules. Good candidates are cadherins and protocadherins as well as the β-neurexin/neuroligin system. The latter in particular is capable of coupling cell adhesion to intracellular protein interaction cascades that could ultimately lead to the assembly of presynaptic release sites or the integration of preassembled active zone complexes at the site of transsynaptic contact (Fig. 3A). β-Neurexins bind to the PDZ domain of calmodulin-dependent protein kinase, which is thought to serve as a first-order organizer molecule by recruiting/binding to components of the secretory apparatus via Mint1, Munc18, and Velis. Indeed, experiments using cocultures of neurons with neuroligin-overexpressing fibroblasts indicate that, at least *in vitro*, postsynaptically expressed neuroligin in fibroblasts may be sufficient to trigger presynaptic accumulation of synaptic vesicles in a contacting axon.

B. Postsynapse

1. Asymmetric/Type 1

Asymmetric synapses in the central nervous system are almost exclusively formed between axons and dendritic spines. Formation and maturation of synapses is concomitant with a striking morphological change. Most type 1 synapses are thought to be induced by contact between an axon and a dendritic filopodium. After retraction of the filopodium, a synapse onto the shaft of the dendrite is created. Spines are then formed from stubby protrusions emerging beneath the synapse (Fig. 3A). During growth of the protrusion and spine, polyribosomes accumulate in the postsynaptic compartment, indicative of local protein synthesis and its regulation by activity. The polyribosome number is reduced again in mature synapses. The mature spine

sometimes contains a spine apparatus that is a specialized form of smooth endoplasmic reticulum and also a prominent postsynaptic membrane specialization, the postsynaptic density, that is barely detectable in early shaft synapses and develops as the spine matures.

The postsynaptic specialization of asymmetric type 1 synapses contains a large number of proteins (Fig. 4). These include primary signal transduction molecules such as receptors and ion channels in the plasma membrane, secondary signal transduction proteins such as kinases and other components of intracellular signal transduction pathways, as well as organizer and scaffold proteins. This elaborate protein network is thought to be arranged in different organizational layers. CNRs and/or other protocadherins are believed to mediate the initial specific contact between axon and target membrane. Cell surface molecules of the cadherin family may then mediate synaptic adhesion and serve as cytoskeletal anchors. For example, N-cadherin and its intracellular catenin interactors are localized in a parasynaptic manner, flanking the presynaptic release sites and postsynaptic densities in type 1 synapses, compatible with a role in synaptic adhesion but not with a function in the formation and organization of the postsynaptic specialization. The β-neurexin/neuroligin system is thought to initiate the assembly of the postsynaptic signal transduction apparatus. Neuroligin 1, which resides in the postsynaptic density of type 1 synapses and is thought to form a transsynaptic connection with β-neurexin at the initial synaptic contact, could recruit a set of first-order organizing/scaffold proteins (PSD-95, S-SCAM, GRIP, and others). Their common feature is the presence of multiple PDZ domains that essentially serve as insertion sites for various postsynaptic proteins. PSD-95 and S-SCAM, for example, bind to neuroligins with one of their PDZ domains and to NMDA receptor subunits with another, thereby allowing the synaptic cell adhesion molecule neuroligin to recruit and aggregate NMDA receptors at the developing synaptic contact. Other domains of PSD-95 could recruit kainate receptors in a similar manner. Moreover, AMPA receptors may be recruited through their interaction with GRIP, although it is not clear whether GRIP can simultaneously bind to neuroligins. In addition to receptors, first-order organizing proteins of the PSD-95/S–SCAM/GRIP type bind to

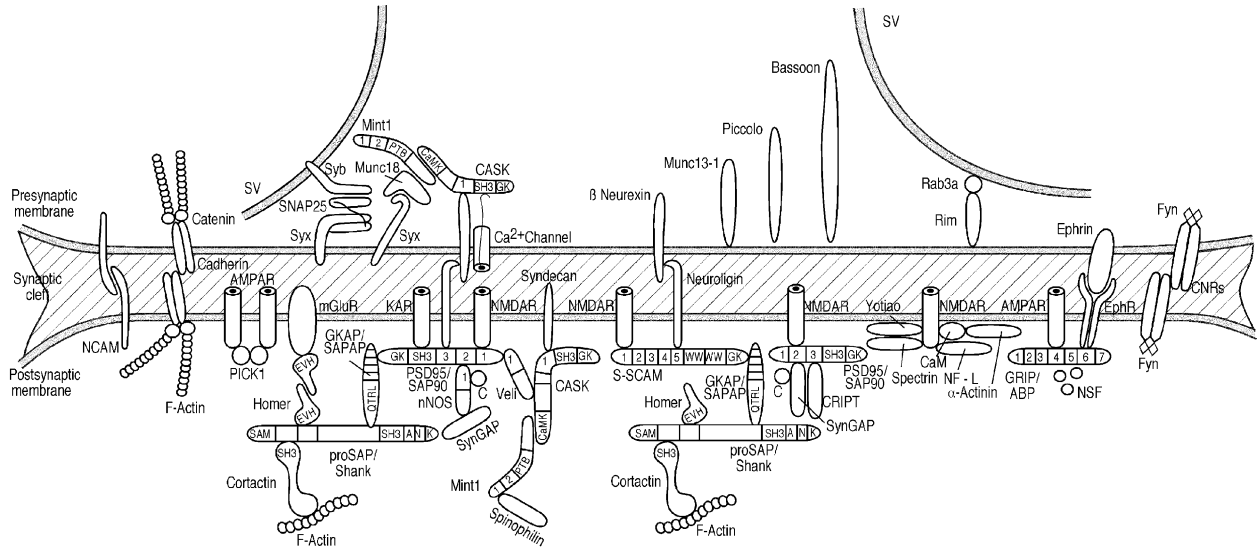

Figure 4 Molecular architecture of the glutamatergic synapse. Schematic representation of the major synaptic proteins with an emphasis on postsynaptic components. several cytoplasmic proteins, including scaffold proteins and components of signal transduction cascades. In turn, some of these interact with second-order organizing proteins such as ProSAP/SHANK, which provide a link to metabotropic glutamate receptors and the cytoskeleton.

In principle, the protein interaction cascades depicted in Fig. 4 provide a framework for recruitment processes that ultimately result in the assembly of the postsynaptic specialization. An important open question concerns the specificity of PDZ domain/target protein interaction *in vivo*. In many *in vitro* studies, these interactions are rather promiscuous, and as yet uncharacterized differences in affinities between PDZ domains and their respective targets as well as subcellular compartmentalization processes are likely contributors to an ordered assembly of the complex postsynaptic protein network. As with presynaptic active zones, it is possible that parts of this protein network are already assembled at the level of the cell body and transported to the developing synapse and inserted into the postsynaptic membrane *in toto*. Interestingly, the generation of asymmetric synapses appears to be dependent on and regulated by synaptic activity. The molecular mechanisms of such regulation are not known, but they may involve signaling through NMDA receptors.

2. Symmetric/Type 2

Symmetric synapses are mostly formed between axons and cell somata. In comparison to asymmetric synapses, they develop a much less pronounced postsynaptic thickening (Figs. 1B and 3B). These differences in morphology are paralleled by striking differences in molecular composition. Symmetric synapses exhibit a unique set of proteins in their postsynaptic compartment whose assembly into a functional postsynaptic specialization follows similarly unique molecular mechanisms.

Adhesion processes at developing symmetric synapses are likely to involve cadherins and related proteins. Catenins, for example, are found at symmetric synaptic contacts, suggesting that classic cadherins are acting as synaptic adhesion molecules in these synapses. Interestingly, the only characterized neuroligin isoform, neuroligin 1, appears to be specific for asymmetric synapses.

With respect to molecular mechanisms of assembly, glycinergic synapses are the best characterized inhibitory synaptic contacts. However, GABAergic synapses may be formed according to similar assembly mechanisms. Gephyrin, an intracellular scaffolding protein and enzyme cofactor, is essential for the formation of postsynaptic glycine receptor and GABA receptor clusters (Fig. 5). Gephyrin is thought to be recruited to synapses and assembled into a submembranous scaffold in response to glycine receptor activation and Ca^{2+} influx following presynaptic glycine release. Due to the altered Cl^- equilibrium potential, embryonic neurons respond to glycine with depolarization, resulting in Ca^{2+} influx through voltage-gated channels. An additional factor contributing to gephyrin recruitment may be activation of phosphatidylinositol 3-kinase through an unknown mechanism. This would lead to increases in membrane 3′-phosphorylated phosphoinositide (PIP_3) content and recruitment of collybistin and profilin, a regulator

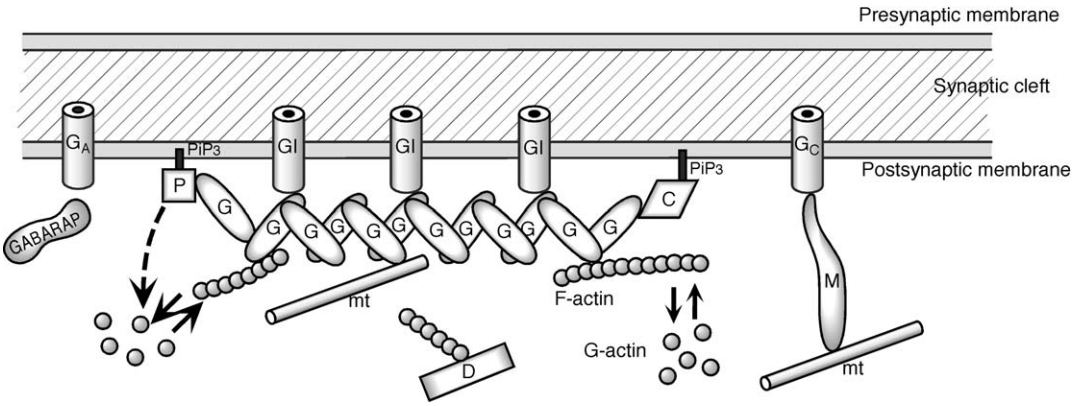

Figure 5 Molecular architecture of the GABA/glycinergic postsynapse. of the actin cytoskeleton, to the activated membrane domains. In turn, these induce cytoskeletal changes and apposition of gephyrin to the PIP_3-rich plasma membrane by binding to its PI-anchored interaction partners. Accumulation of gephyrin at activated postsynaptic membranes would then lead to recruitment and clustering of glycine receptors. A similar gephyrin-dependent mechanism may be active in $GABA_A$ receptor clustering, although direct interaction between $GABA_A$ receptors and gephyrin has not been demonstrated. In addition, a novel $GABA_A$ receptor binding protein, GABARAP, appears to be important in $GABA_A$ receptor transport to the synapse.

3. Neuromuscular Junction

The postsynaptic compartment of neuromuscular junctions undergoes significant structural changes as the synapse develops and matures. The most striking features are the presence of a basal lamina in the synaptic cleft and the formation of folds in the postsynaptic plasma membrane (Fig. 3C). Folds are created as the muscle fiber grows but is constrained by transsynaptic bonds between pre- and postsynaptic membrane via the basal lamina.

The specificity of neuromuscular connections is thought to be mediated by a combination of guidance, recognition, and synapse elimination/conversion mechanisms. Recognition and adhesion may involve ephrins and their receptors as well as integrins and NCAM. The assembly of a postsynaptic specialization at neuromuscular junctions, particularly the accumulation of acetylcholine receptors at subsynaptic sites, is influenced by three distinct signaling processes (Fig. 6).

Receptor clustering at the developing synaptic contact is induced by agrin, a proteoglycan that is synthesized by motor neurons, released from motor nerve terminals, and inserted into the basal lamina of the synaptic cleft. Agrin binds to a muscle-specific kinase (MuSK) in the subsynaptic membrane, most likely via an unidentified coreceptor (MASC). Activated MuSK leads indirectly (e.g., via a src family kinase) to the recruitment of a critical downstream effector, rapsyn, which contains domains responsible for membrane binding, oligomerization, and acetylcholine receptor binding. In turn, rapsyn is essential for receptor clustering. It associates with receptors in a 1:1 stoichiometry and accumulates them in the subsynaptic membrane. In addition, MuSK appears to be an important structural component of the primary synaptic scaffold.

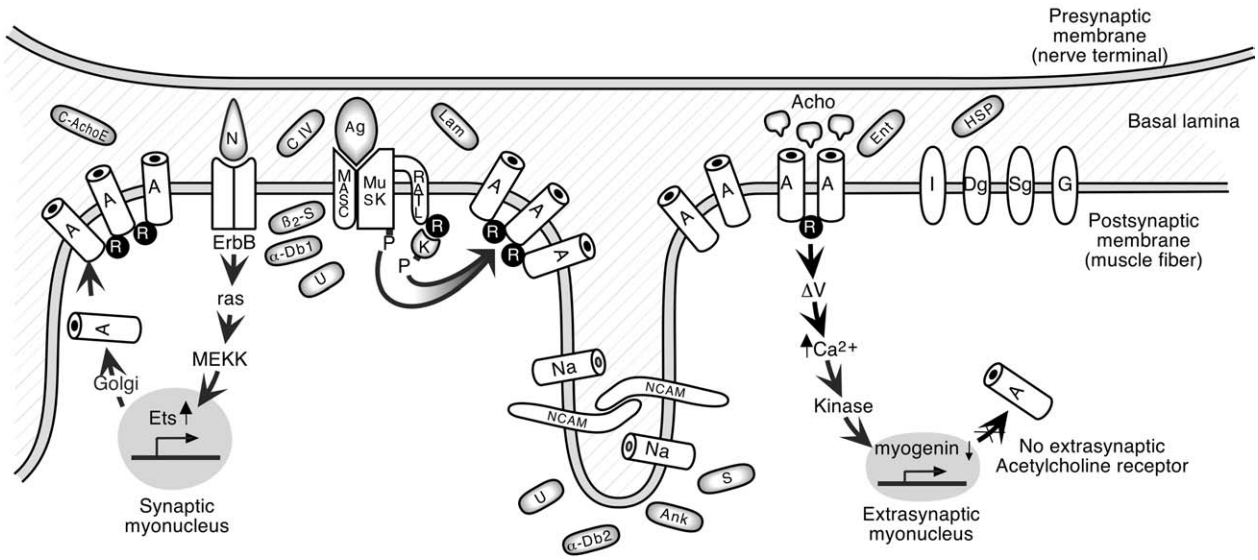

Figure 6 Molecular architecture of the neuromuscular postsynapse. A, acetylcholine receptor; Ach, acetylcholine; Ag, agrin; Ank, ankyrin; C-AchE, collagen-tailed acetylcholine esterase; C IV, collagen IV; α-Db1/2, α-dystrobrevin 1 and 2; D, dystrophin; Dg, dystroglycan; Ent, entactin; G, Gal *N*-acetyl transferase; HSP, heparan sulfate proteoglycans; I, integrin dimer; K, MuSK-activated src-like kinase; Lam, laminin; MASC, myotube-specific accessory component; MEKK, MAP/ERK kinase kinase; MuSK, muscle-specific kinase; N, neuregulin; Na, sodium channel; NCAM, neural cell adhesion molecule; R, rapsyn; RATL, rapsyn-associated transmembrane linker; β_2-S, β_2-syntrophin; Sg, sarcoglycan; U, utrophin.

Apart from agrin-mediated receptor clustering, the induction of synapse-specific transcription of acetylcholine receptors contributes to the development of postsynaptic specializations at neuromuscular junctions. In this context, the most important factor is neuregulin, which, like agrin, is released from motor nerve terminals and incorporated into the synaptic basal lamina. Neuregulin binds to receptor tyrosine kinases of the erbB family, some of which are enriched in the postsynaptic membrane. These receptor tyrosine kinases are the triggering components of an intracellular signaling cascade involving ras, raf, erk, PI_3 kinase, and transcription factors of the ets family. The latter are able to induce transcription of acetylcholine receptor subunit genes by binding to specific elements in the respective genomic sequence. The synapse specificity of this process results from the localization of ligands, receptors, and signaling molecules as well as additional transcriptional control mechanisms. Indeed, transcription of nicotinic receptor genes is restricted to subsynaptic nuclei.

In contrast to the synapse-specific induction of acetylcholine receptor gene expression, extrasynaptic receptor expression is repressed by a third regulatory mechanism at neuromuscular junctions. Here, the signaling molecule is acetylcholine. Binding of acetylcholine to its receptors leads to a depolarization of the muscle fiber and thereby triggers an action potential that is propagated. As a consequence of the action potential, Ca^{2+} levels increase in the cytosol mainly due to efflux from the sarcoplasmic reticulum. Apart from inducing muscle contraction, these Ca^{2+} ions are now able to repress acetylcholine receptor transcription. The key target is protein kinase C, which in turn inactivates/downregulates myogenic factors such as myoD, myf5, MRF4, and myogenin, resulting in reduced receptor expression.

V. CONCLUSION

The establishment of a functional neuronal network in the nervous system follows a complex developmental program that culminates in synaptogenesis, the formation of specific functional contacts between nerve cells. The specificity of synapse formation is thought to be caused by synaptic cell surface molecules that are responsible for appropriate target recognition and synaptic adhesion. Assembly of functional synapses at initial contact sites is most likely achieved by an interplay of several factors, including transsynaptic adhesion systems capable of recruiting pre- and postsynaptic proteins as well as input-dependent and activity-dependent clustering and recruiting mechanisms. Depending on the type of synapse, these processes follow strikingly different molecular principles.

During the development of the nervous system, synaptogenesis is paralleled by massive synapse elimination. Synapse elimination is, at least in part, regulated by exogenous stimuli and synaptic activity patterns. It results in the fine-tuning of the neuronal network. Furthermore, learning and memory storage processes in the central nervous system lead to the formation of new synapses and the modification or elimination of existing synapses. At the molecular level, these processes are likely to involve, among others, the same proteins that are necessary for synaptogenesis during development, including cell adhesion proteins such as cadherins, protocadherins, integrins, and NCAM, receptors and their trafficking or clustering, as well as scaffold and organizer proteins or cytoskeletal components. Thus, further molecular analysis of synaptogenesis will not only provide insights into the basic principles of nervous system development but also contribute to our molecular understanding of plastic processes in the brain.

Tactile Perception

CATHERINE L. REED
University of Denver

GLOSSARY

exploratory procedures Stereotypical hand movements used to extract distinctive object dimensions or qualities (e.g., pressure is used to identify hardness).

haptics Active touch; typically used for object recognition by touch.

homunculus Map of the body in somatosensory cortex; "little man."

secondary somatosensory cortex Cortical area located on the upper bank of the Sylvian fissure, ventrolaterally to primary somatosensory area, that processes information about touch, pain, and temperature.

somatosensory cortex Cortical strip located on the postcentral sulcus that receives input from the skin and is responsive to somatosensory stimulation.

somatosensory system Sensory system that includes the cutaneous senses, proprioception (the sense of limb position), and kinesthesis (sense of limb movement).

somatotopic map A map in somatosensory areas of the brain organized so neurons responsive to particular body parts are located next to neurons representing adjacent body parts.

Our sense of touch connects us physically with the external world. Tactile perception, or somesthesis, refers to our ability to apprehend information through touch. Not only do objects in the world touch us but also we explore our environment actively with our hands, fingers, and bodies. We use the motor capabilities of our hands to extract important characteristics necessary for identifying and using objects. Thus, tactile perception results from the stimulation of receptors in the skin and from proprioception. Our understanding of the neural bases of tactile perception is based on the study of perceptual and neurophysiological responses in animals and humans.

I. PSYCHOPHYSICS, ANATOMY, AND PHYSIOLOGY

A. Peripheral Somatosensory Receptors and Afferent Nerve Fibers

Tactile perception begins with the mechanical stimulation of the skin. Tactile information travels from cutaneous receptors to the afferent somatosensory pathways, the spinal cord and thalamus, and the brain. It is first collected and grouped by peripheral receptors in the skin, joints, and muscles. The hand is the primary organ for acquiring tactile information, although receptors are located throughout the body in both glabrous (nonhairy) and nonglabrous (hairy) skin. This article focuses on the receptors located in the glabrous skin of the hand that process nonnoxious information.

1. Psychophysics

To study the relationship between tactile perception and its neural mechanisms, psychophysical and physiological experiments have used several stimulating techniques designed to distinguish the response properties of the mechanoreceptors and their afferent nerve fibers. These techniques include the cooling of the skin and the presentation of masking vibrations to decrease

the sensitivity of one type of tactile channel to study another one. Electrophysiological studies using microneurography record the activity of the nerve fibers innervating the hand. Vibration has been applied perpendicularly and tangentially to the skin by pins and probes. Periodic and aperiodic gratings have been moved across the skin. Other stimuli include air puffs, embossed letters, steel wool, sandpaper, and cloth.

2. Mechanoreceptors and Afferent Nerve Fibers

Cutaneous mechanoreceptors transduce mechanical energy into electrochemical energy to create the neural signal. In glabrous skin, four major mechanoreceptors have been identified to respond to specific types of tactile information: Merkel disks, Meissner corpuscles, Pacinian corpuscles, and Ruffini cylinders. Each receptor corresponds to a specific type of afferent nerve fiber. The receptors and their associated nerve fibers respond selectively to certain types of mechanical stimulation, in that each has a lower threshold to a specific stimulus relative to the others.

Mechanoreceptors can be classified by the type of fiber, optimal stimulus, adaptation properties, and size of receptive field (Table I). Slowly adapting (SA) fibers signal the presence of stimulation and fire steadily while the stimulus is applied. Merkel discs and SA1 fibers respond best to 0.3- to 3-Hz frequencies that are perceived as pressure. They are slow to adapt and have small receptive field sizes. SA1 fiber activity is associated with the feeling of texture or fine detail. Ruffini cylinders and SA2 fibers respond best to 15- to 400-Hz frequencies that are perceived as buzzing. They are slow to adapt and have large receptive fields. SA2 fibers respond to the stretching of the skin or movements of the joints.

Rapidly adapting (RA) fibers signal stimulus onset by firing strongly and briefly when a stimulus is applied and when it is removed. Meissner corpuscles and RA1 fibers respond best to 3- to 40-Hz vibrations or taps on the skin that are perceived as flutter. They adapt rapidly and have small receptive fields. RA1 fiber activity is associated with rapid changes of pressure that occur when the hand feels a textured surface. Last, Pacinian corpuscles and RA2 fibers respond best to 10- to 500-Hz frequencies that are perceived as vibration. They adapt rapidly and have large receptive fields. RA2 fibers are specialized to respond to changes in stimulation.

3. Relationship between Nerve Fiber Response and Tactile Perception

How do the receptors and their nerve fibers give rise to our perceptions of touch? Although tactile perception is correlated with the properties of individual receptors and afferent fibers, it results primarily from activity across multiple nerve fibers. When we interact with common objects, such as a cold wet cup, different combinations of neural fibers tend to be activated. The brain combines these temporal and spatial patterns of impulses from a large number of different types of receptors to create complex tactile percepts.

4. Proprioception

In addition to cutaneous information, proprioceptive information is essential to tactile perception. Proprioception is signaled by specific receptors in muscles and joints to provide information about joint movement, position, and related forces. Without proprioception, the hand could not perform any exploratory procedures to determine the specific shape of an object or the size of a large object.

5. Temperature

Our perception of temperature also contributes to tactile object recognition. The perception of temperature is produced by the heating or cooling of the skin. Thermoreceptors respond to specific temperatures and changes in temperature but do not respond to

Table I
Properties of Mechanoreceptors and Afferent Nerve Fibers

Mechanoreceptor	Afferent nerve fiber	Optimal stimulus	Adaptation rate	Receptive field size
Merkel receptor	SA-I	Pressure	Slow	Small
Meissner corpuscle	RA-I	Taps on skin	Rapid	Small
Ruffini cylinder	SA-II	Skin stretch, joint movement	Slow	Large
Pacinian corpuscle	PC	Rapid vibration	Rapid	Large

mechanical stimulation. There are separate thermoreceptors for warm and cold.

B. Neural Pathways

Tactile signals from the body travel through the peripheral nerves to the dorsal root ganglia in the spinal cord. Once they enter the spinal cord, the nerve fibers go up the spinal cord in one of two pathways: the medial lemniscal pathway and the spinothalamic pathway. On the way to the thalamus, nerve fibers in both pathways cross over to the other side of the body so that signals originating from the left side of the body are represented in the right hemisphere of the brain and signals from the right side of the body are represented in the left hemisphere.

1. Medial Lemniscal Pathway

The medial lemniscal pathway consists of large fibers that convey information about aspects of touch and proprioception used to identify objects and surfaces (e.g., form, position, and temporal change). The neural signals travel via the medial lemniscal pathway to synapse in the ventroposterolateral thalamic nuclei. From the thalamus, signals travel to the post-central gyrus [somatosensory cortex (SI)], secondary somatosensory cortex (SII), and other higher order areas.

2. Spinothalamic Pathway

The spinothalamic pathway consists of smaller fibers that convey information primarily about pain and temperature. The neural signals travel via the spinothalamic pathway to the reticular formation, the intrinsic thalamic nuclei, and the SII.

3. Thalamus

All somatosensory signals are processed by specific thalamic nuclei. The ventroposteromedial nucleus receives cutaneous inputs from the face and the ventroposterolateral nucleus receives inputs from the rest of the body. These nuclei have precise somatotopy to maintain the stimulus' location on the body. The ventroposteroinferior (VPI) and the medial posterior nucleus (Pom) may also have functional importance for the processing of tactile information in that they have cutaneous receptive fields and project to cortical somatosensory areas.

C. Somatosensory Cortices

Much of our knowledge regarding the anatomy and function of cortical areas comes from research on animals and brain-injured humans. However, recently noninvasive neuroimaging techniques have permitted the investigation of the relationship between stimulus characteristics (e.g., frequency and amplitude) and physiological responses in the brains of non-brain-damaged humans. These techniques include magnetoencephalography/electroencephography, positron emission tomography, and functional magnetic resonance imaging. Brain activity is indexed by changes in cerebral blood flow, blood oxygenation levels, and magnetic field generation.

When the skin is touched, tactile information is sent to somatosensory areas of the brain (Fig. 1). If neurons in a particular cortical area have predominant or

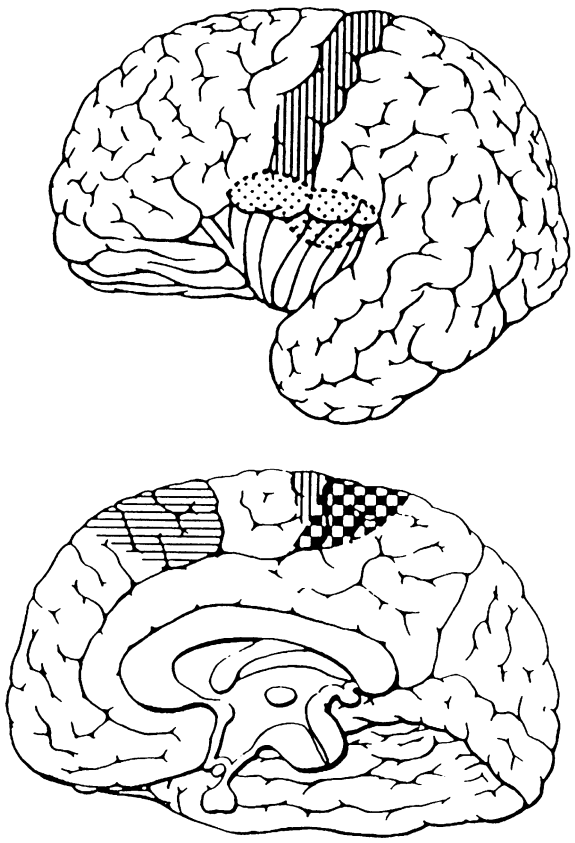

Figure 1 Schematic diagram of ventrolateral (top) and dorsomedial (bottom) somatosensory areas in the human brain. Vertical lines indicate SI, and small dots indicate SII, parietal operculum, and posterior insula. Checkerboards indicate SSA, and horizontal lines indicate SMA (from Caselli, R. J., 1997, by permission of Mayo Foundation).

exclusive responses to somatosensory stimuli, the area is considered to be involved in tactile perception. In monkey and human brains, the major cortical areas considered to be somatosensory cortices are SI, SII, parietal areas (areas 5 and 7b), the retroinsular cortex (Ri), and the insula.

1. Primary Somatosensory Cortex

Primary somatosensory cortex, or SI, is a region of postcentral cortex activated by tactile somatic stimuli. It includes Brodmann areas 1–3 (3a and 3b). These areas of cortex are activated almost exclusively from the contralateral side of the body. The neurons in primary somatosensory cortex are arranged in columns so that neurons with receptive fields processing information from like areas of the body are located together.

a. Somatotopic Organization Each of the four subdivisions of SI has a complete representation of the body, or a homunculus (Fig. 2). The homunculus has a medial-to-lateral organization, with the representations of the inferior limbs at the vertex, the upper limbs and mouth at the convexity, and the tongue at the bottom of gyrus. In the homunculus, adjacent body parts are represented primarily next to each other, but the cortical organization does not exactly match the body surface. For example, the representation of the hand lies between the back of head and the face.

b. Cortical Magnification There is a relative magnification of the amount of cortical area devoted to body parts with the highest tactile acuity and sensory specialization (Fig. 2). For example, the lips, fingers, and hands are the primary organs for extracting tactile information and they have proportionately larger representations. Cortical magnification means that there are many cortical cells for each afferent nerve fiber. This increase in the number of cells processing the same sensory input suggests that incoming

information may be elaborated and recoded. Higher level processes, such as object identification, may require information in a different format from which it was encoded.

c. Multiple Body Representations The different body representations are not just duplications of each other; areas 1 and 3b have two mirror-reversed body maps of cutaneous receptors. Areas 2 and 3a respond primarily to deep stimulation of the joints and muscles, although area 2 does receive cutaneous inputs. One reason for multiple body representations is that different areas within the somatosensory cortex have different functions.

d. Function To determine the function of SI, monkeys with damage to postcentral cortex have been studied. Lesions in area 3b affect all tactile discrimination, with the exception of crude touch. Lesions to area 1 impair texture discrimination. Lesions to area 2 impair the discrimination of shape and size as well as finger coordination. Supporting these functions, single-cell recording research has located orientation- and direction-selective neurons in area 2. In humans, damage to SI is rarely restricted to one area. Clinical data from extensive postcentral lesions suggest that damage to SI produces lasting impairments of pressure sensitivity, two-point discrimination, point localization, and the discrimination of object shape, size, and texture. In contrast, cortical lesions rarely affect the detection of touch, pain, and temperature.

2. Secondary Somatosensory Cortex

SI is bounded ventrolaterally by secondary somatosensory cortex (or the parietal operculum). In monkeys it is located in the parietal bank of the Sylvian sulcus behind the insula. In humans, SII includes the parietal operculum, and it appears to extend more posteriorally to the inferior parietal cortex. SII receives its peripheral inputs from SI and from the VPI thalamus. There are reciprocal connections between SI and SII. It has many direct connections with all somatosensory areas with the exception of area 5. Unlike SI, in which inputs are almost entirely contralateral, some proportion of SII neurons receive input from both sides of the body. Thus, SII can be activated bilaterally with unilateral stimulation.

a. Somatopic Organization SII also has somatotopic organization. Although the entire body is systematically represented in SII, the digits of hand and the face representations occupy most of the total area. According to cortical stimulation studies, human SII cortex has the face area in the most superficial part, the foot area in the most medial part, and the hand area in between.

b. Function The role of SII in tactile perception is not certain. Evidence suggests that SII is part of a higher-order association center for tactile object recognition and learning. In monkeys, damage to SII produces severe impairments of shape discrimination, impairments of learning, and altered size and roughness discrimination. In humans, lesions of SII impair texture and shape discrimination that require active haptic exploration. Another role of SII is to integrate tactile and motor actions. In humans, neural activity in SII can be modulated by concurrent somatosensory stimulation and finger movement. This modulation may reflect an improved analysis of tactile signals during movements.

3. Retroinsular Cortex and Somatosensory Insula

Ri and the posterior insula also have robust somatosensory properties. They are contiguous with SI and are located within the lateral Sylvian sulcus. Ri is adjacent to SII. In addition to SII and posterior SI, many neurons in Ri have bilateral receptive fields. Neurons in these areas respond primarily to contralateral tactile stimuli. Somatotopic representation is only rough. In primates, the majority of neurons in the insula (Ig) also have bilateral receptive fields. The insula may be involved in tactile learning and its role may be similar to the role of area TE in inferior temporal cortex for visual learning. In contrast to TE, which is purely visual, the insula is multimodal. In humans, lesions involving area 40 (putative area SII) and somatosensory insula can cause disorders of tactile object recognition.

4. Somatosensory Areas of the Posterior Parietal Cortex

In humans, SI is bounded dorsomedially by another somatosensory association cortex called supplementary sensory area (SSA) encompassing Brodmann's area 5 (inferior parietal cortex) and area 7b (supramarginal gyrus). The stimulation of supplementary motor area (SMA) during brain surgery sometimes elicits tactile sensations, suggesting that SMA may be a dorsomedial somatosensory association cortex. Posterior parietal cortex is believed to integrate sensory and motor processing and to combine tactile and proprioceptive information with other sensory

modalities. In monkeys, damage to area 5 affects proprioceptive inputs and impairs the nonvisual guidance of arm movements. In humans, damage to the right superior parietal lobe can produce similar impairments. Area 7b may have a role in higher order integration within the somatosensory system. The majority of neurons in area 7b have bilateral receptive fields. Furthermore, the area has multiple intra- and interhemispheric connections. They are activated by nonpainful tactile stimuli and, to a lesser extent, by visual and painful stimuli.

5. Summary

The multiple somatosensory cortical areas form a complex network. Somatosensory receiving areas are functionally involved with cortical areas subserving motor and spatial functions. The existence of such a complex system in the human brain is important for intentional, spatially guided motor movements that allow us to interact with tactile stimuli. The organization of the somatosensory system emphasizes the fact that perception is an active process.

II. PRIMARY AND COMPLEX TACTILE SENSATIONS

What parts of the neural system are involved in processing tactile information and our perceptions of touch? Primary tactile sensations refer to percepts arising from stimuli that vary along a single dimension. Often, primary somatosensory sensations can be elicited through passive stimulation. Complex tactile sensations arise from stimuli that vary along multiple dimensions. Typically, complex tactile sensations are enhanced by active exploration of the stimuli.

A. Primary Somatosensory Functions

1. Tactile Acuity and Two-Point Discrimination

The sensitivity of tactile perception depends on the relationship between mechanoreceptors and somatosensory cortex. Tactile acuity or sensitivity is typically defined as the ability to distinguish between two points of stimulation. Different parts of the body have greater sensitivity to tactile stimulation than others. For example, the fingertips and the lips are more sensitive than the back. Tactile acuity can be correlated with the properties of the afferent nerve fibers and of neurons in SI. At the afferent nerve fiber level, tactile acuity corresponds to parts of the body that have the greatest density of nerve fibers with both small and large receptive fields. However, better two-point discrimination is found for nerve fibers with small receptive fields (SA1 and RA1 channels): Two points of stimulation are more likely to fall in two separate receptive fields and be distinguished from each other. Thus, there are more small receptive field nerve fibers innervating the sensitive fingertips than the less sensitive palm. A similar relationship exists at the cortical level. Larger regions of the SI are devoted to sensitive parts of the body. The cortical area of the hand is relatively greater than that of the back, presumably to provide additional neural processing necessary for the perception of fine detail.

2. Light Touch

Light touch refers to the sensation of near-threshold tactile stimulation. Nerve fibers carrying light touch information are part of both the medial lemnescal system and the spinothalamic system. The exact contribution of different cortical areas to these sensory functions is not established, but 3- to 5-Hz pressure stimulation on various parts of the body produces contralateral activation in SI and bilateral activation in SII.

3. Vibration

Vibration activates most of the mechanoreceptors. Furthermore, it is easily manipulated experimentally and produces robust changes in cortical activity. Typically, neuroimaging experiments compare simple vibratory stimulation with no stimulation (i.e., a resting state). Stimulating either the hand or the foot with vibration produces bilateral activation in SII, the parietal operculum, and the insula. However, activation in SI is greater in the contralateral hemisphere. Vibration also activates contralateral motor cortex, supplementary motor area, and anterior parietal areas.

4. Summary

Primary somatosensory functions are largely processed by SI and, to some extent, by SII. Neuropsychological data support this conclusion. In patients who underwent surgery to relieve epileptic symptoms, the most severe disorders of tactile sensitivity, two-point discrimination, point localization, and position sense were produced by lesions in the contralateral, postcentral gyrus. The most severe defects occurred in patients whose lesions encroached the hand area of SI.

Furthermore, unilateral cortical lesions of SI produced clear bilateral sensory defects.

B. Complex Somatosensory Functions

Primary tactile perception varies along a single attribute and requires primarily passive touch. In contrast, most tactile experiences involve three-dimensional objects that vary on multiple attributes. The perception of complex objects is enhanced by active touch, or haptics, to help apprehend characteristic features that distinguish one object from another. When we explore objects, we use stereotypical hand movements called exploratory procedures. People use exploratory procedures to obtain particular types of information from objects. Lateral motion or rubbing is used to extract texture, pressure is used to extract hardness, and contour following is used for detailed shape. Enclosure, or a grasp, is often used to extract global shape and size. In addition, exploratory procedures are often executed simultaneously to extract multiple object features. Thus, the achievement of tactile object recognition results from the integration of information from cutaneous, motor, and cognitive systems.

1. Texture

The hand, with its mechanoreceptors and motoric abilities, is specialized to process information about an object's material substance. This information includes texture (roughness), hardness, and temperature. Sometimes, it is referred to as microgeometric information because it does not change the global shape of an object. Compared to vision, touch is superior for the discrimination of surface texture. When multiple object properties within an object are equated for perceptual discriminability, people prefer to categorize objects by touch on the basis of texture rather than shape. Furthermore, blind and sighted people are equally good at discriminating texture.

The perception of surface texture includes attributes such as roughness, hardnesssoftness, elasticity, and viscosity. The most widely examined texture dimension is roughness. To investigate roughness, studies use surfaces with regularly spaced ridges (gratings) and surfaces with raised dots to systematically and independently manipulate the relevant physical features. The spacing between the ridges (groove width) and the amount of force applied to the stimulus correlate highly with perceived roughness. The speed at which stimuli are moved across the skin, actively or passively, has little effect if the forces are equal. These results suggest that mechanoreceptors provide the signals for roughness perception independently of kinesthetic input.

However, roughness perception is not a simple function of any particular mechanoreceptor and its afferent nerve's response rate. Instead, roughness perception is related to spatial variation in responses between nerve fibers. Specifically, it is the between-fiber spatial variation in firing responses of the SA fibers that corresponds with perceived roughness. For example, in the fingertip, between-fiber spatial variation is the difference in the discharge rate over a distance of 1 or 2 mm.

At a cortical level, roughness perception can be associated with groove width and, to some extent, with force and velocity. In monkeys, strong responses in areas 1 and 3b of SI are produced from the active stroking of the fingertips over gratings with constant ridge and varying groove. In these areas, neurons respond differentially for rough stimuli, smooth stimuli, and combinations of the roughness, the force applied, and the velocity of stroking. In SII, neurons respond to the beginning, middle, and end of the strokes. Passive and active touching of the gratings activates different proportions of neurons. In humans, neuroimaging studies of passive roughness perception demonstrate corresponding SI and SII activation.

2. Complex Pattern and Shape

Shape and complex patterns can be considered part of an object's macrogeometry. In contrast to texture, the hand is less well suited for the extraction of these global properties. The tactile perception of pattern and shape involves the integration of input from multiple receptors in the skin and sometimes the integration of contour information over space and time. It appears that somatosensory cortex has specialized regions for processing different types of tactile information.

The identification of complex forms, such as Braille and alphabet letters, requires the recruitment of information from a number of afferent nerve fibers. Pattern perception appears to rely on the pattern of SA1 nerve fiber responses over a region of skin. The pattern of SA1 responses, often illustrated using spatial event plots, is similar to the stimulus pattern, indicating that they are important for the tactile perception of detail. Confusion in the perception of two patterns correlates with the similarity between their spatial event plots. For example, C's are confused with O's.

Pattern and shape information is processed by different areas of cortex from texture and hardness information. In monkeys, the discrimination of hardness, texture, and shape can be differentially impaired depending on which part of SI is ablated. Lesions of area 2 impair shape and contour discriminations but spare texture and hardness discriminations. The opposite pattern is found for lesions of area 1. Excisions of area 3b produce impairments in all aspects of tactile discrimination learning.

Neuroimaging studies in humans provide converging evidence that different areas of the somatosensory cortices are involved in the tactile perception of shape and size from texture and hardness. Contralateral activation of SI is produced by the discrimination of texture, shape, and hardness compared to a grasp. Although both shape and texture activate contralateral inferior temporal regions, texture differentially activates the parietal operculum. Shape and length discrimination activates the contralateral supramarginal gyrus, contralateral premotor cortex, and bilateral angular gyri. Thus, specific parts of the somatosensory cortices beyond SI are responsible for the perception of particular tactile properties. Global or macrogeometric features (shape and size) require additional integration of somatosensory information over space and time as well as more extensive somatosensory processing.

3. Object Recognition

The recognition of everyday, common objects through touch is fast and accurate, often requiring less than 2 sec. Haptic object recognition plays a frequent role in our lives. We use it every time we reach into our pockets for keys or coins. Real objects vary along multiple object dimensions and typically have characteristic features to help identify them. To determine the cortical areas involved in tactile object recognition, I turn to studies of patients with selective brain lesions and neuroimaging studies of normal individuals.

a. Astereognosia Tactile object recognition can be defective if primary sensory perception is impaired. Astereognosis is defined as the general inability to recognize objects by touch in the absence of vision. Although damage to higher level somatosensory regions can produce tactile object recognition deficits, astereognosis refers most commonly to tactile object recognition deficits resulting from severe primary somatosensory imperception. It reflects damage to any level of the somatosensory system from the peripheral nerves, spinal cord, brain stem, and thalamus to SI. Patients with astereognosis typically have difficulty perceiving light touch, vibratory sensation, proprioception, superficial pain, temperature, two-point discrimination, weight discrimination, texture, substance, double simultaneous stimulation, and shape. The impairment is usually restricted to one hand. SI is considered to be the cortical substrate of astereognosis.

Furthermore, when trying to identify objects by touch, patients with astereognosia do not tactually explore the object. This lack of appropriate exploration suggests that primary tactile functions are not adequately perceived or integrated with motor information during tactile object processing. Although sensorimotor integration and proprioception are important for tactile object recognition, it should be noted that tactile exploration is not necessary. Paralysis by itself does not produce defective tactile object recognition. In addition, objects can often be identified by touch if they are passively moved over a person's hand.

b. Tactile Agnosia Impaired tactile object recognition can arise from deficits in higher order tactile processing. In contrast to astereognosia, tactile agnosia is the inability to recognize objects by touch despite adequate primary somatosensory functions, intellectual ability, attentional capacity, and linguistic skill. Although patients with tactile agnosia cannot recognize objects by touch, they can often draw an accurate picture of an unrecognized tactually perceived object or match it to another object. The parietotemporal cortices, possibly involving SII, are considered to be cortical substrates for tactile agnosia. One patient with unilateral tactile agnosia had a left inferior parietal lesion involving the SII complex. She was able to discriminate and categorize objects on the basis of stimulus properties, but she was unable to recognize objects with the contralateral hand. It appeared that she was impaired in her ability to integrate information about the various object attributes to create a representation of the object as a whole.

Evidence from neuroimaging studies with non-brain-damaged individuals has also implicated SII as being important for tactile object recognition. When activation from exploration is subtracted, SII is activated bilaterally, with stronger activation on the contralateral side. Superior parietal and medial temporal cortices are also involved. Together, these cortical regions suggest that information about tactile features, spatial properties, and object identity is being integrated during tactile object recognition.

Tactile agnosia may also be produced from bilateral lesions in the subcortical part of the angular gyrus. The subcortical lesions presumably disconnect somatosensory association cortex from semantic memory stores located in the inferior temporal lobe.

III. CORTICAL ORGANIZATION OF TACTILE PERCEPTION

A. Plasticity and Reorganization of Somatosensory Cortex

Tactile perception can be influenced by changes occurring in somatosensory cortex as a result of trauma or experience. Several factors can influence the relative proportion of somatosensory cortex devoted to a particular body part or parts: the lack of sensory input due to the loss of a limb, the amount of stimulation or practice on a particular region of skin, and the active nature of the tactile task.

1. Changes in Sensory Input and Phantom Limbs

The somatosensory cortical maps can change when peripheral input changes or when signals from a specific part of the body no longer reach cortex. Signals can be prevented from reaching cortex due to the amputation of a body part or damage to the peripheral nerves conducting the signal from the skin. In monkeys, cutting nerves from the fingers eliminates responses in the corresponding SI region, but over time, stimulation of adjacent fingers may activate cortical cells in the lost digit's cortical area. The area of cortex devoted to that body part reduces over time.

The presence of phantom limbs provides good evidence for the plasticity of the human somatosensory cortex and how experience can change the functional organization of the brain. In humans, amputation often produces a phenomenon called the phantom limb; amputees experience sensations as if the limb existed. The plasticity of the synaptic connectivity of neurons in SI is one explanation for the cause of phantom limbs. For example, phantom sensation is related to changes in SI. Some studies support a remapping of somatosensory cortex in which the portion of SI devoted to the face (an active area) encroaches or is remapped into the adjacent area devoted to the absent limb (an inactive area). Some amputees can relieve an itch in their phantom limb by scratching the body region that is located in the homunculus next to the cortical area of the amputated limb. Neuroimaging experiments of patients with phantom upper limbs confirm an enlargement of the primary sensory field of the face.

2. Effects of Training

Somatotopic maps can be altered by increasing the stimulation to a particular body part location. Stimulating a specific region of skin can produce an expansion of the cortical area receiving its input. Furthermore, practice in the use of a particular fingertip can increase the cortical area representing that fingertip.

Evidence that training can effectively modify cortical representations comes from neuroimaging studies comparing string players and nonmusicians. Musicians had stronger cortical responses than nonmusicians when the fingers of their left hands were stimulated. Furthermore, the effect was strongest in musicians who began their careers early in life. It can also be demonstrated that the somatotopic cortical representations of the finger areas were altered in blind Braille readers who used three fingers of both hands to read. Instead of the typical homucular pattern observed in the neural responses of finger stimulation in sighted subjects, Braille readers had distorted organization in one or both hands. This disorganization had perceptual correlates. The same Braille readers also had difficulty identifying which finger was touched.

3. Activity of Body Part

The active nature of perception appears to influence cortical representation. Before surgery, patients with webbed hands had decreased cortical representations for the fingers and a reduced hand area in SI. After surgery, when the fingers functioned independently, the cortical hand area expanded and a greater distance was found between the representations of the thumb and little finger. Thus, somatosensory cortical maps are not static.

B. Dual Streams of Processing for Object Recognition and Localization in Somatosensory Cortices

When we recognize objects, not only do we have to identify the objects but also we must localize them in space. In visual cortical areas, two separate processing streams have been identified. The dorsal stream, leading from visual cortex to the parietal lobes,

conveys information about an object's spatial location ("where") and how to interact with it. The ventral stream, leading from visual cortex to the temporal lobes, conveys information about object identity ("what"). A similar dual stream of processing is proposed for the somatosensory system. Physiologic studies and behavioral studies suggest a functional distinction between ventrolateral ("what") and dorsomedial ("where") somatosensory association cortex (Fig. 1). Ventrolateral somatosensory association cortex includes SII, the parietal operculum, and the posterior insula. Dorsomedial somatosensory association cortex involves SSA and SMA.

1. The "What" Pathway

The ventrolateral stream processes somatosensory information regarding object recognition, tactual learning, and memory. Lesions of this pathway result in tactile agnosia, independent of other tactile or spatial abnormalities. Specific evidence for a distinction between somatosensory "what" and "where" systems in humans comes from a patient with unilateral tactile agnosia. Her selective impairment of tactile object recognition arose from a unilateral lesion involving the left inferior parietal lobe, thought to be part of the ventral pathway. She was unable to recognize objects with her right hand despite normal exploration procedures. In contrast, she was completely normal in her ability to perform visual and tactile spatial tasks. Thus, she was selectively impaired in "what" but not "where."

2. The "Where" Pathway

The dorsomedial stream is concerned with sensorimotor integration and tactile spatiotemporal functions. In particular, an apraxia–astereognosis syndrome has been identified in patients with damage to dorsomedial somatosensory association areas. Patients with extensive damage to SMA and SSA have moderate to severe impairment of primary and complex tactile functions. They have severe limb apraxia with extremely disordered tactile search strategies. In addition to the faulty spatial and temporal control of movement, they have an analogous spatiotemporal defect of tactile perception: They have difficulty localizing a stimulus within a limb or determining whether they have been touched once or twice. Other patients with damage to the superior parietal lobe have profound impairments in shape discrimination and spatial orientation without tactile sensory impairments. From these patients, it is suggested that there may be a nontactual, supramodal factor in tactile impairments. In summary, patient data suggest that the somatosensory "where" system can be differentially impaired.

C. Tactile Learning and Memory

Once tactile information is perceived, what parts of the brain are involved with its storage and retrieval? The hands feel object surfaces to sample and discriminate particular object properties. This information is sent to the brain so that it can be retrieved later. Most of our knowledge about tactile memory comes from experimental lesion studies of learning in the monkey, but recent functional neuroimaging studies have provided supporting evidence in humans. Tactile learning and recognition appear to be mediated by a circuit going from SI to SII, the insular granular cortex, the amygdala, hippocampus, and perirhinal cortex. This pathway is organized in a similar fashion as the visual learning pathway that accesses the limbic structures of the temporal lobe through inferior temporal cortex.

The anatomical organization of tactile learning in monkeys and in humans appears to be similar. Tactile learning and recognition activate areas involved in motor function (premotor areas, SMA, and the cerebellum) and in tactile perception (SI, SII, SSA, and superior parietal lobule). In addition, the tasks activate limbic and paralimbic structures (hippocampus, amygdala, insular cortex, orbitofrontal cortex, and cingulate gyrus), prefrontal areas, and the striatum. The major difference between tactile learning and recognition tasks is the relatively higher activation of the striatum and cerebellum during learning.

D. Selective Attention in Touch

Selective attention has been shown to influence tactile perception. It not only affects the ability to discriminate among stimuli but also appears to modulate the properties of somatosensory cortical neurons by either enhancing or suppressing their activity. In monkeys, the firing of neurons in SI and SII is dependent on whether the monkey is paying attention to a stimulus. Attention can increase the neuron's response to a stimulus. Relatively larger responses are found in somatosensory neurons when the animal is attending to the tactile stimulus than when it is not. Similarly,

neuroimaging studies in humans demonstrate that attention to vibratory stimulation can enhance signal processing in SI.

Attention can also change the signal-to-noise ratio in neuronal response. Attention may be a mechanism for reducing distractions through the suppression of signals from noncued channels. This produces a selective increase of signal magnitude in an attentionally cued channel. In monkeys, attending to one of several simultaneous vibrotactile stimuli suppressed firing rates in populations of neurons in SII and area 7b prior to the presentation of the target stimulus and enhanced activity during and after the target. A similar finding can be demonstrated in humans anticipating a stimulus. Behaviorally, individuals respond more quickly to a site when a vibratory stimulus is expected. Neurophysiologically, anticipation of either a focal touch or painful shock produces decreases in activation for regions of SI located outside of the representation for that skin area of the expected stimulus. Although the mechanisms underlying increases and decreases of activation of somatosensory cortical areas are not fully understood, it is clear that attention modulates the activity of the neurons.

E. Hemispheric Specialization

As noted previously, tactile perception is largely lateralized. Do both hemispheres equally process tactile information? To demonstrate hemispheric function and interhemispheric communication, two types of patients have been studied: patients with unilateral hemispheric lesions and "split-brain" patients who have undergone surgery dividing the cerebral commissures. Most interhemispheric transfer occurs via the corpus callosum (a large collection of nerve fibers that carry information from one side to the other).

In intact humans, it remains unclear whether hemispheric specialization exists for primary somatosensory functions (e.g., pressure sensitivity, vibration sensitivity, two-point discrimination, or point localization). However, unilateral SI lesions frequently result in severe and long-lasting defects in the contralateral hand. There is growing evidence from brain-damaged patients that the two brain hemispheres are specialized for certain higher tactile functions requiring the spatial exploration of objects or fine temporal analysis. The left hand–right hemisphere combination is better able to perform tasks with a spatial component, such as reading Braille or tactually determining the orientation of rods. The right hand–left hemisphere combination can perform these tasks if familiar stimuli are used, only a few objects are presented, or when linguistic processing is possible.

Given the lateralization of the tactile system, what information perceived by one hand is available to other if the two hemispheres cannot share information? The lack of interhemispheric transfer of tactile information (touch, pressure, and proprioception) can be demonstrated in the performance of split-brain patients. In a tactile task in which a set of objects are first felt using one hand and then retrieved from a larger set of objects, split-brain patients can accurately retrieve the objects with the same hand but not the other hand. Furthermore, these patients can name and describe objects explored tactually by the right hand but not by the left hand. In a tactile task in which the patient is touched on the fingertip of one hand and has to touch that fingertip with his or her thumb, the split-brain patient can perform the task with the same hand's thumb but not with the other hand's thumb. Last, in a tactile task in which the split-brain patient's hand is pressed into a posture, the patient can mimic the posture with the same hand but not with the other hand. In summary, tactile perception and proprioception are largely lateralized.

IV. CONCLUSIONS

The understanding of tactile perception requires an evaluation of tactile object recognition as well as an evaluation of basic tactile responses. Most tactile object recognition tasks contain sensory, spatial, proprioceptive, constructive, and motor components. As a result, tactile perception involves functional interconnections between SI, SII, premotor regions, and more posterior portions of the parietal cortex. There is still much to be learned about the neural bases of tactile perception. In particular, we need to know more about the roles of somatosensory cortices for the processing of complex tactile stimuli, such as real objects. Recent evidence suggests that the functional organization of the neural pathways is similar to that of vision.

GLOSSARY

branchiomeric nerves Nerves that innervate tissues derived from branchial (gill) arches.

best response Refers to the stimulus that elicits the highest spiking rate from a neuron and is used in defining classes of taste neurons, such as sucrose-best.

chemotopy Spatial separation of taste receptors within the oral cavity or taste neurons within an area of the central nervous system, according to chemosensory sensitivities.

common chemical sensation Elicited by activation of somatosensory pain pathways with a chemical stimulus.

dysgeusia A distorted, frequently unpleasant, taste perception, whereas aguesia is a loss of taste sensation.

flavor The combination of taste, smell, and other sensory aspects of food.

gastrointestinal malaise A feeling of illness that is attributed to a disorder of the gastrointestinal tract. It is the unconditioned stimulus that is associated with a conditional stimulus, the taste or smell of a food item, in learning a flavor aversion.

hedonic value Either positive or negative. A pleasurable experience has positive hedonic value; a repulsive experience has negative hedonic value.

iatrogenic Conditions caused by medical treatment, such as the mucositis associated with chemotherapy.

laterality of projections Refers to the side of the brain, left or right hemisphere, that is involved in the neural pathways. For example, touch is represented primarily on the opposite, contralateral hemisphere relative to the side of the body surface stimulated. The taste pathway is primarily ipsilateral, on the same side as the side of the tongue stimulated.

modality A sensation associated with one sensory system, such as vision, hearing, or taste. Multimodal responses are responses to stimuli that activate different sensory systems.

Old World primates Primates that evolved from the same progenitors as humans, not those living in the New World (North and South America).

prototypal taste stimuli Stimuli that represent taste qualities in relatively pure form, such as sucrose for sweet or quinine for bitter.

The sense of taste evaluates nutritional or harmful chemicals taken into the mouth and contributes to the pleasure of eating. Taste senses sources of nutrients, such as sugars, salts, and amino acids, as well as artificial sweeteners, which have been developed to satisfy the ''sweet tooth'' without causing health problems that come with overindulgence. Taste also senses poisonous and injurious substances. The brain associates an agreeable hedonic value to nutrients and a repulsive hedonic value to poisons. Nutrient sources are sought after and reflexively ingested. Poisons are reflexively expelled and their sources avoided. Internal physiological states and past experience influence the pleasure associated with taste sensations. The taste system, which is also known as the gustatory system, includes the taste receptor cells located in taste buds in the oral and pharyngeal cavities, the cranial nerves that innervate these receptors, and central nuclei and cortical areas that process the information transmitted by these nerves. The term ''taste'' here refers only to sensations mediated by this system. It should not be confused with flavor, the total experience of a food stimulus, which involves the senses of temperature, texture, common chemical, smell, and taste.

I. STIMULUS QUALITIES

Humans experience a limited set of taste qualities that each vary in perceptual intensity. The four elementary qualities are salty, sweet, sour, and bitter. *Umami* (savory), the meaty taste of monosodium glutamate (MSG), is considered to be a fifth taste quality. Complex tastes of various chemical stimuli can be thought of as combinations of the basic qualities. For example, potassium chloride is salty and bitter. Prototypical gustatory stimuli sodium chloride (salty), sucrose (sweet), citric acid (sour), quinine–HCl (bitter), and MSG (savory) each primarily evoke a single taste quality. However, particularly at just detectable or very high concentrations, the quality evoked by even these stimuli is perceived as a combination of qualities. At high concentrations, electrolyte stimuli activate the common chemical sense resulting in further perceptual complexity. A variety of chemicals can elicit the same taste quality. Chemicals having a number of hydrophilic molecular structures stimulate the sweet taste quality and include sugars, certain amino acids, and artificial sweeteners. Salty taste is elicited by sodium, lithium, potassium, and ammonium salts, although the latter two chemicals are also bitter. Acids have a sour taste. Chemicals with diverse chemical structures, such as salts, amino acids, and a variety of lipophilic compounds including alkaloids, thioureas, and bile acids, elicit the bitter taste.

II. PERIPHERAL TASTE SYSTEM

A. Taste Buds

Taste buds contain receptor cells and supporting cells that are both derived from epithelial cells. Taste receptor cells (TRCs) have an average life span of about 10 days and are replaced from a population of stem cells located within the taste bud. TRCs are depolarized by chemical stimuli that either enter the cells via channels (e.g., Na^+) or are bound by receptors located in the apical TRC membrane (e.g. sucrose, quinine, and glutamate). Peripheral axonal processes of neurons located in cranial nerve ganglia innervate the taste buds. The central axonal processes of the ganglionic neurons project to the brain. These neurons are mostly afferent; that is, they carry information to the brain. There is no purely efferent innervation of the taste buds. Efferent neurons modify peripheral receptors based on central commands. However, somatosensory afferent fibers and possibly gustatory fibers can release chemicals peripherally in response to stimulation and thus modify the response of TRCs. An example of a chemical released by somatosensory fibers is the peptide substance P. Taste papillae also receive efferent innervation from autonomic fibers, which could also influence gustatory responses. Finally, processing of gustatory information within taste buds may also be mediated by interactions between TRCs.

B. Taste Bud Fields and Innervation

The taste buds are located in a number of fields in the oral cavity. Taste buds in the several fields differ in distribution, morphology, sensitivity, and innervation. On the anterior two-thirds of the tongue, taste buds are located in fungiform papilla that are most dense at the anterior tip and are innervated by the chorda tympani branch of cranial nerve VII (cN-VII), the facial nerve. The greater superficial petrosal branch of cN-VII innervates palatal taste buds, found on either side of the border between hard and soft palates. The lingual and palatal branches of the trigeminal nerve (cN-V) provide somatosensory innervation to these regions and mediate the oral common chemical sense. Much of the epidermal trigeminal innervation of these areas is concentrated in or around the taste buds.

The lingual branch of the glossopharyngeal nerve (cN-IX) provides the gustatory innervation of taste buds that line the trenches of the foliate and circumvallate papilla located on the posterior one-third of the tongue. The superior laryngeal branch of the vagus nerve (cN-X) innervates taste buds located on the larynx. Nearby taste buds scattered on the surface of the epiglottis, pharynx, and uvula are probably also innervated by the cN-X, but the tonsilar branch of cN-IX may also contribute to the innervation of these as well as some palatal taste buds. Neuronal fibers for pain, temperature, and touch on the posterior third of the tongue and the pharynx and larynx are contained within cN-IX and cN-X.

C. Functional Differences among Taste Bud Fields

Prototypical taste stimuli can all be detected in any of the taste fields on the tongue or palate. Within the fungiform taste field there is little evidence for chemotopy, a mapping of chemical sensitivities based on spatial position. However, for NaCl and sucrose, perceptual intensity ratings are higher and detection

thresholds are lower for the anterior tongue and palate compared to other taste fields. For citric acid and particularly quinine, intensity ratings are higher and thresholds are lower for the posterior tongue. Stimulus sensitivities of the laryngeal and pharyngeal taste receptors are not well-known in humans or primates. In other mammals, they appear to play a role in airway protection and other reflexes. Many of the receptors are sensitive to water.

D. Afferent Nerve Physiology

Electrophysiological recordings have been made from single nerve fibers in the chorda tympani and glossopharyngeal nerves in a variety of species, including some Old World primates. The gustatory afferent neurons have low spontaneous rates and respond to taste stimulation with an increase in spiking (action potential) rate. The neurons are slowly adapting; the initial phasic response is followed by a tonic response that slowly decays over the course of stimulation. The response latency is longer for stimuli that bind to apical receptors, such as sucrose, than for ionic stimuli such as NaCl. Stimulus intensity is encoded by rate of neuronal response because spike rates are directly correlated with stimulus concentration. The firing pattern is not regular, and in response to sweet chemicals it often consists of irregular bursts of spikes. It is not known if this temporal information is utilized by the nervous system. Rather, the primary mechanism of taste quality coding is thought to be present in the differential response of neurons. Some classes of afferent taste neurons are specific in that they respond only to chemical stimuli that elicit one taste quality (Fig. 1). S fibers, a class of neurons in the chorda tympani nerve of the chimpanzee, respond to all compounds known to be sweet to humans, and they show little response to other stimuli. N fibers, which show a best response to NaCl, are not as specific as a group. However, there are subsets of N fibers specific for sodium or lithium salts, others responsive to NaCl, KCl, and other salts, and still others that respond to NaCl and Na-glutamate. A class of chorda tympani fiber with a best response to acids is found in macaques but not in chimpanzees. Quinine-best Q fibers are the least specific class of afferent taste neuron in the chimpanzee chorda tympani. In contrast, the glossopharyngeal nerve contains quinine-best neurons quite specific for stimuli that taste bitter to humans. In

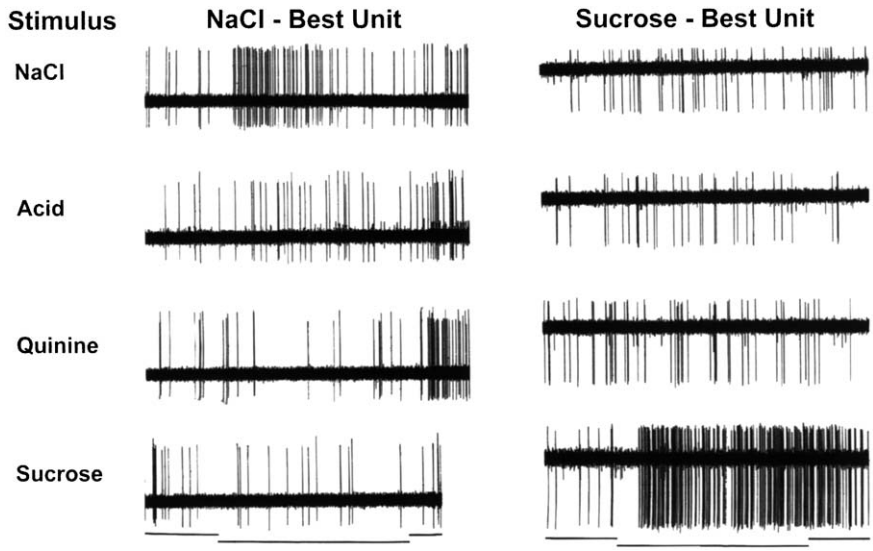

Figure 1 Response of two nerve fibers (units) in the chimpanzee chorda tympani nerve to the application of taste stimuli to the anterior tongue. Each unitary excursion from the baseline represents a single action potential. The stimuli were 70 m*M* NaCl, 5 m*M* quinine–HCl, and 0.3 *M*, sucrose for both units. For the (sour) stimulis, 50 m*M* aspartic acid was used for the unit on the left, and 40 mM citric acid was used for the unit on the right. The stimuli were applied to the anterior tongue for 8 sec as indicated by the displaced line at the base of the figure, followed by an artificial saliva rinse. The delay in the response is partially due to the time it took the stimulus to reach the taste buds on the tongue. Note that the NaCl-best unit appears to be inhibited by quinine. This is because, unlike the other stimuli, quinine was dissolved in water rather than the artificial saliva. Thus, the NaCl-best fiber was excited by the 10-m*M* sodium content of the saliva rinse following quinine (courtesy of Viktoria Danilova and Göran Hellekant).

addition, there is a group of glossopharyngeal fibers that responds best to MSG and glutamate and another group that responds best to stimuli that are sweet to humans. Although there are quantitative regional differences in taste sensitivities, there is significant overlap. Loss of any one receptive field does not seriously impair discrimination among prototypal taste stimuli in humans.

III. CENTRAL TASTE SYSTEM

The location of central processing of taste information in the brain reflects the distribution of taste bud fields in the peripheral taste system and their relationships to other sensory systems (Fig. 2). Taste buds are located in the oral and pharyngeal cavities. The oral cavity marks a transition between the external sensory world, which is largely conscious, and the internal sensory world of the pharyngeal cavity and more internal parts of the body, which is reflexive and largely unconscious. Thus, gustatory information is processed in regions of the brain that are transitional between areas that process exteroreceptive versus interoreceptive inputs. Peripherally, the taste buds are closely associated with receptors for pain, temperature, and touch. The processing of taste and these somatosensory modalities in adjacent or overlapping central nuclei occurs throughout the central nervous system (CNS). On the other hand, olfactory information is not integrated with taste and somatosensory information until they converge within association areas of the cerebral cortex, the amygdala, or hypothalamus. It is also in these areas that taste information is integrated with information on internal states, such as the state manifested as satiety.

A. Functional Anatomy of Taste Pathways

1. Nucleus of the Solitary Tract

The central axonal processes of primary afferent gustatory neurons enter the brain via three cranial nerves: cN-VII, cN-IX, and cN-X. All of these are mixed branchiomeric nerves, which contain gustatory and nongustatory sensory and motor components. The cell bodies of the sensory nerve fibers are located in cranial nerve ganglia as shown in Fig. 2. Gustatory afferent fibers terminate in the superior part of the ipsilateral nucleus of the solitary tract (NST) in the medulla. Nongustatory primary afferent fibers in the facial, glossopharyngeal, and vagus nerves terminate more caudally in the NST as well as in other nuclei, including the caudal spinal trigeminal nucleus and even the dorsal horn of the spinal cord. These nuclei are involved in somatosensory processing from areas including the oral cavity and may influence gustatory processing. The spinal trigeminal nucleus projects to the NST as well as to higher order gustatory nuclei including the thalamic gustatory nucleus.

Primary afferent gustatory fibers from the greater superficial petrosal and chorda tympani nerves enter the pons between the vestibulocochlear (cN-VIII) and motor cN-VII nerve roots via a separate rootlet of cN-VII, the intermediate nerve of Wisberg. The fibers course posteriorly and medially and descend over a short distance through the pons, trapezoid body, spinal trigeminal tract, and interpolar spinal trigeminal nucleus to reach the solitary tract. Fibers descend in the solitary tract or ascend for a few millimeters to terminate in the NST superior to the tract. Glossopharyngeal primary afferent fibers enter the medulla in the cN-IX cranial nerve root and course posteriorly and medially through olivocerebellar fibers, the descending trigeminal tract, and interpolar nucleus to reach the solitary tract, where they may ascend or descend. More inferiorly, vagal afferent fibers course posteriorly and medially through the inferior cerebellar peduncle and trigeminal tract and nucleus to reach the solitary tract. Within the NST, gustatory fibers terminate largely in the interstitial nucleus, which wraps around the solitary tract and forms most of the NST superior to the tract. The interstitial nucleus extends from the level of the accessory motor trigeminal nucleus to just inferior to the obex. It is characterized by dense acetylcholinesterase staining, which is associated with the extracellular surface of primary afferent terminal fibers. Acetylcholinesterase is an enzyme that hydrolyzes the neurotransmitter acetylcholine, but its function in the NST is unknown. The sequence of projections of gustatory afferent axons into the solitary tract is from superior to inferior: facial, glossopharyngeal, and vagal. However, there is substantial overlap and all three nerves have projections into the superior pole of NST. The oral and interpolar sections of the descending trigeminal nucleus lie immediately anterolateral to the solitary tract (Fig. 2, inset). Trigeminal axons penetrate the NST at midsuperior levels where glossopharyngeal axons terminate most heavily. The trigeminal terminal fields overlap with more lateral glossopharyngeal and vagal axonal terminal areas that contain neurons responsive to somatosensory stimuli. The clearly separate medial areas contain taste-responsive

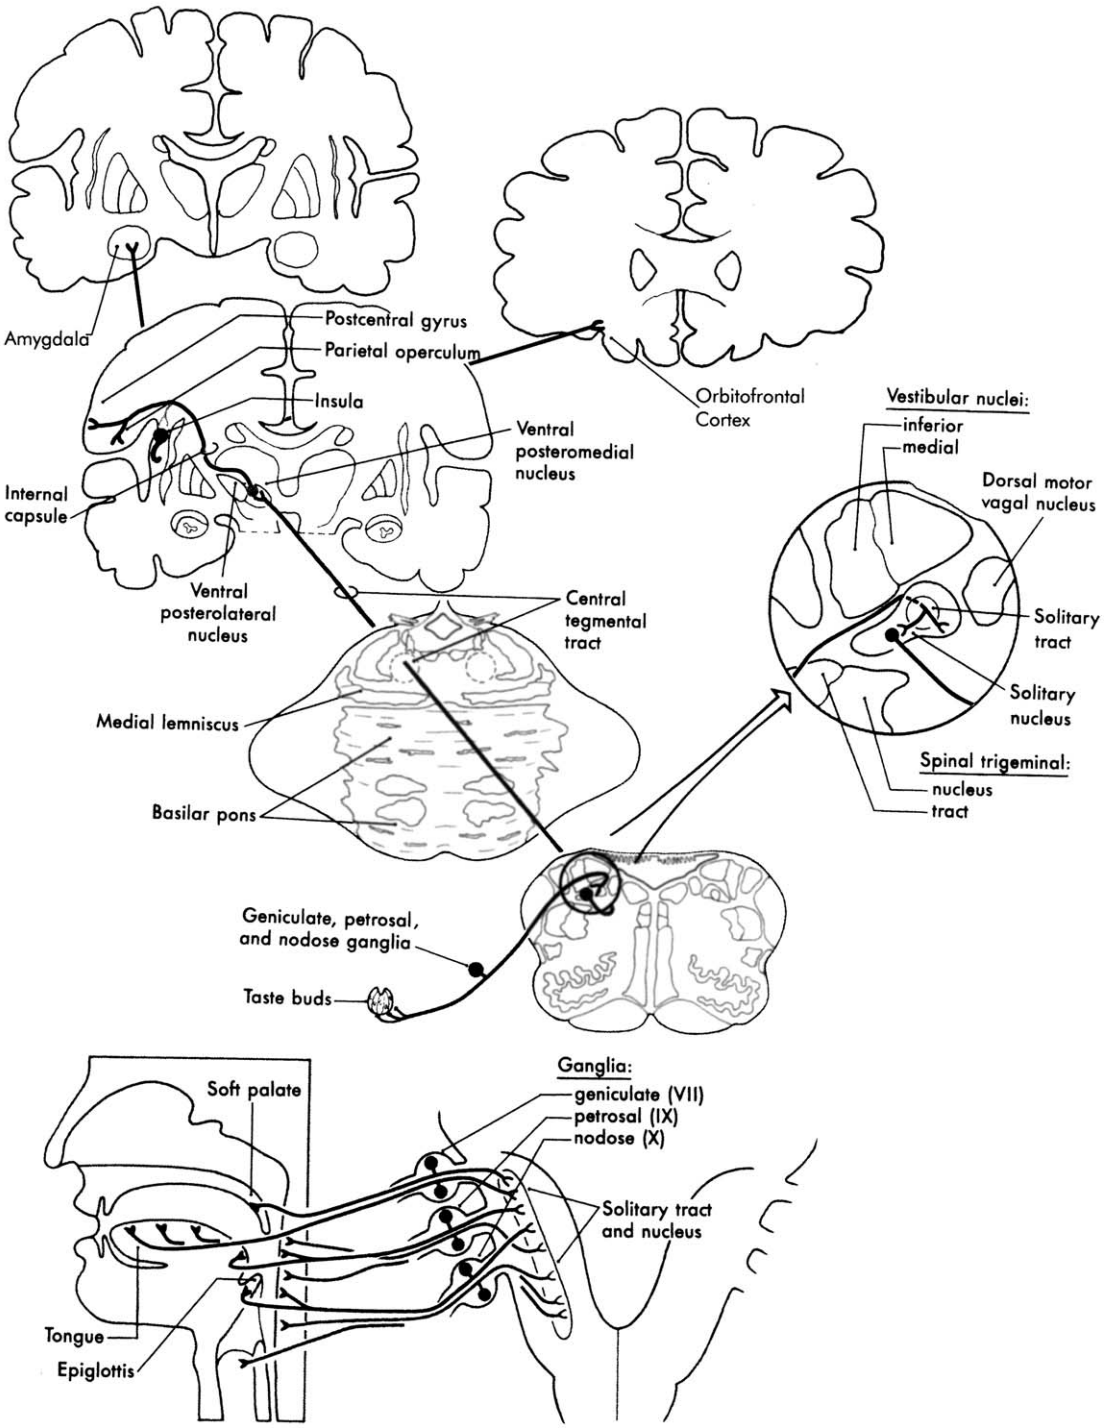

Figure 2 Summary of peripheral and central taste pathways. Gustatory, afferent fibers terminate in the superior part of the nucleus of the solitary tract, whereas general visceral afferent fibers terminate in the inferior portion of the nucleus. Gustatory neurons in the nucleus of the solitary tract project to the parvicellular part of the ventral posteromedial nucleus in the thalamus. Thalamic gustatory neurons project to the insular cortex and parietal operculum. Gustatory neurons in the insular cortex project to the amygdala and orbitofrontal cortex [modified with permission from Sweazy, R. D. (1997), Olfaction and taste. In *Fundamental Neuroscience* (D. E. Haines, Ed.), pp. 321–333. Academic Press, San Diego].

neurons. In primates, responses to stimulation of the tongue with taste stimuli are found primarily in the superior part of the afferent projection zone within the interstitial nucleus.

Primary afferent axonal endings form synapses on dendrites of NST neurons in the gustatory zone and release the excitatory neurotransmitter glutamate. Many small intrinsic NST neurons use the inhibitory neurotransmitter γ-aminobutyric acid (GABA) to mediate inhibitory interactions among primary afferent and other inputs. Other neurotransmitters that influence NST gustatory neurons include substance P and possibly enkephalins. Inputs to the gustatory zone include projections from trigeminal nuclei, other parts of NST, the reticular formation, pons, amygdala, and insular cerebral cortex. NST neurons project to sites such as oromotor centers in the reticular formation, implying involvement in oral reflexes. The brain stem, including NST and pontine parabrachial nucleus, without involvement of higher neural centers, can generate behavioral motor responses, such as sucking and rejection, and exocrine responses, such as salivation, in response to taste stimulation.

Ascending projections from the gustatory zone of NST course in the ipsilateral central tegmental bundle and terminate in the ipsilateral small-celled [parvicellular (pc)] portion of the ventral posteromedial nucleus (VPMpc) of the thalamus. In rodents and lagomorphs, NST thalamopedal projections terminate in the parabrachial nucleus of dorsal pons. This nucleus surrounds the brachium conjunctivum, also known as the superior cerebellar peduncle. In Old World primates, and probably humans, there is apparently no projection from the NST gustatory zone for the anterior lingual taste buds to the pons. There may be pontine projections from NST gustatory zones for posterior tongue or pharynx. The pontine parabrachial nucleus projects to the thalamus and to brain regions that process visceral information, such as the hypothalamus and amygdala. Destruction of the thalamic gustatory relay has little effect on taste preferences for taste stimuli by primates. This observation might be explained by indirect pathways that may bypass the VPMpc, such as those that utilize the pontine parabrachial nucleus.

2. The Parvicellular Ventral Posteriomedial Thalamic Nucleus

The gustatory pathway to the thalamus is largely ipsilateral; VPMpc thalamic neurons respond only to stimulation of the tongue on the same side in most species. However, the situation in humans is not as clear. In the few available clinical cases, ipsilateral gustatory losses usually follow pontine or midbrain lesions, but there are some contradictory examples and some experimental studies suggest that projections from the NST to the thalamus are bilateral. VPMpc lies immediately medial to the VPM and is contiguous with the facial–oral somatosensory representation in VPM. Neurons in VPMpc are smaller than in the VPM. VPMpc neurons respond to taste stimuli, but unlike the taste part of the NST, neurons that respond to somatosensory stimuli or somatosensory and taste stimuli are also present. General viscerosensory information may also be processed in VPMpc. Thus, unlike somatosensory, visual, and auditory thalamic nuclei, VPMpc, the thalamic nucleus that processes taste information, also processes information from other modalities.

3. Primary Gustatory Cortex

By definition, a primary sensory cortex is the cortical area that receives most direct projections from the specialized sensory relay nucleus in the thalamus. Thus, the primary gustatory cortex (PGC) receives direct projections from the thalamic gustatory relay, VPMpc. In Old World monkeys, the most extensive VPMpc projections are to the dorsal (superior) part of the anterior insular cortex and adjacent frontal–parietal lobes covering the insular cortex, the opercula. The projection zone is centered on granular insular cortex but extends ventrally (inferiorly) into the dysgranular insular and dorsally and laterally into dysgranular opercular cortex. Granular cells are small neurons that are most prominent in cortical layer IV in granular cortex, but in dysgranular cortex the granule cell layer is thinner and contains fewer cells. The VPMpc projection area is characterized by increased cytochrome oxidase staining, but it is not as dense as it is in regions receiving primary thalamocortical inputs for other sensory modalities. Cytochrome oxidase is a mitochondrial enzyme. Increased levels of this enzyme are indicative of increased capacity for oxidative metabolism. A second projection area from the VPMpc is more lateral, at the convexity of the parietal operculum in somatosensory cortical area 3b, just anterior to the area where the tongue is represented.

Cortical neurons that respond to gustatory stimulation are found in both of these areas and in adjacent opercular and insular cortical regions not receiving direct projections from VPMpc. These areas, such as the inferior agranular insula, are secondary or higher

order gustatory areas. Less than 10% of neurons in PGC respond to taste stimuli; many others respond to other intraoral stimuli, but most are unresponsive to these stimuli. Thus, the PGC and adjacent higher order areas sensitive to gustatory stimuli cover a large region of cortex, but gustatory neurons contribute to but do not dominate the processing taking place in these regions. As in VPMpc, the thalamic relay, taste-responsive neurons in the primary gustatory projection zone in the cerebral cortex are intermingled among nontaste neurons, unlike in other sensory modalities.

Much of what is known about the primary gustatory cortex is based on studies of nonhuman Old World primates. Although the insular and adjacent opercular cortex is similarly organized in humans, the exact location of PGC is unknown. PGC and adjacent taste-responsive areas occupy large regions of cortex and precise tracing of VPMpc projections has not been possible in humans. Clinical cases with lesions have placed the PGC in the insular cortex, anterior temporal lobe, or parietal operculum (i.e., the inferior part of the post-central gyrus). The parietal operculum is adjacent to the somatosensory representation of the tongue, which is shifted posteriorly in humans compared to Old World monkeys.

Modern imaging techniques localize human cortical gustatory areas in the general region of the insular cortex and adjacent parietal or frontal operculi (Fig. 3). Specifics differ depending on recording technique and stimulus paradigm.

Magnetoencephalography identifies the posterior insula and adjacent parietal operculum as the first cortical site of activation in humans, which is consistent with a posterior shift of the homunculus compared to monkeys. Functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) also detect insular activation anteriorly in positions similar to the PGC of Old World monkeys.

Neurons in the VPMpc project to the ipsilateral PGC, but the laterality of gustatory processing in the PGC is not established. As is the case for the brain stem, the results of most studies of gustatory loss following insular lesions in humans suggest that taste information is initially processed ipsilaterally to the stimulus. However, the initial wave of the electroencephalogram evoked by a unilateral taste stimulus occurs in both hemispheres of the cortex simultaneously, suggesting projections to PGC are bilateral. Many PET and fMRI studies localize activation (or a stronger activation) to the right superior and anterior insular cortex following whole tongue stimulation.

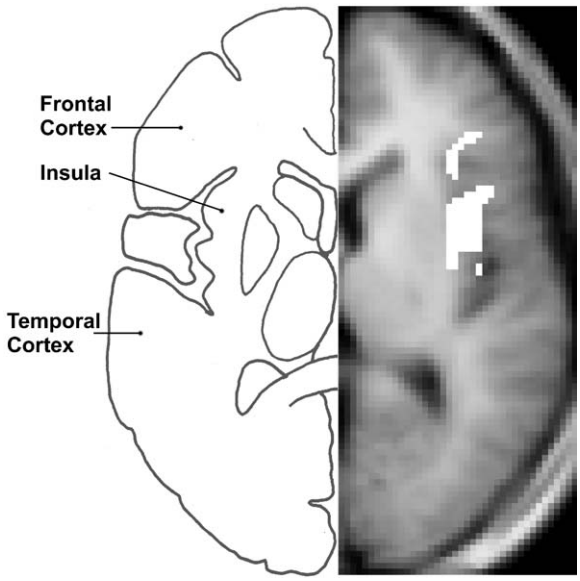

Figure 3 Response of the human cerebral cortex to electric-taste stimuli applied to the anterior tongue. The right hemisphere of a horizontal section is shown. Areas with a significantly ($p<0.01$) elevated hemodynamic response are shown superimposed on an anatomical image. The activation and anatomical images represent the average of 11 subjects. The activated regions at this level are in the insular cortex and adjacent frontal cortex. Electric taste is a phenomenon in which small currents applied across the tongue mucosa activate taste receptor cells and produce a metallic/sour taste sensation.

Thus, cortical taste processing occurred predominantly in the nondominant hemisphere of the right-handed subjects studied, but more work is needed to clarify lateralization of taste function.

The many taste-responsive neurons in the insular and opercular cortices that do not receive direct projections from the VPMpc by definition comprise gustatory association areas, which also lie outside this periinsular region, mostly in the limbic system. Neurons in the PCG project to the amygdala, entorhinal cortex, perirhinal cortex, superior temporal sulcus, secondary somatosensory area, and frontal cortex. The connections are reciprocal because neurons in these regions project back to the PGC. Gustatory association areas in the amygdala, a precentral frontal opercular area, and orbitofrontal cortex have been electrophysiologically verified. PET imaging has revealed taste-evoked activation in the orbitofrontal cortex bilaterally and right anterior medial temporal cortex, including the amygdala. Epileptic patients who are treated with right temporal lobectomy have difficulty with taste quality recognition but have normal taste thresholds.

In turn, orbitofrontal and amygdalar neurons project to other nuclei, including the striatum and lateral hypothalamus, in which responses to gustatory stimuli have been recorded. These secondary and tertiary association areas are multimodal limbic centers in which information about internal state, taste, and smell may be integrated. Activation of other limbic centers, such as the hippocampus or anterior cingulate cortex, by gustatory stimuli depends on the hedonic value of the stimulus.

B. Gustatory CNS Physiology

Neurons in the rostral (superior in humans) part of the NST in mammals respond to gustatory stimulation of the ipsilateral tongue and palate. Excitation and inhibition are seen, but due to low spontaneous rates inhibition is clearer in response to stimulus mixtures. NST neurons are less specific for stimuli of one taste quality than peripheral neurons but show quality tuning across stimulus classes. Additional taste information may be provided by differences in the locations of neurons processing gustatory stimuli of different perceptual qualities along the long superior–inferior NTS axis, an organizational plan known as chemotopy. There is a rough chemotopy imposed on the NTS by the rostral to caudal (superior to inferior in humans) projection pattern of the intermediate, glossopharyngeal, and vagal nerves, which have characteristic sensitivities to taste stimuli, as noted previously. In addition, NTS neurons that are most sensitive to sour acids are located more caudally than neurons tuned to stimuli with other taste qualities. This chemotopy is not seen in the gustatory thalamus and cortex, in which there are few neurons that respond best to acids. Unlike taste-responsive NTS neurons, many thalamic and cortical neurons respond to both gustatory and nongustatory stimuli. Neural response patterns across different taste stimuli at brain stem, thalamic, or cortical levels take on one of four or five general response patterns that show correspondence to the four or five perceptual taste qualities. Neuronal responses to mixtures of taste stimuli are more complex. Insular cortical neurons respond less to a mixture of several prototypal stimuli, including the best stimulus, than to the best stimulus alone. This result suggests that primary cortical neurons do not identify a specific mixture, such as lemonade, but are tuned to detect a single taste quality, such as sweet; their responses are inhibited if the mixture contains stimuli with other qualities.

Responses of neurons in gustatory association areas are modifiable by internal states. Taste information is used for making decisions on acceptance/rejection of food, the hedonic value of which depends on general internal state (i.e., hunger) and even specific nutritional deficits. In monkeys, satiety modifies responses of neurons in gustatory association areas, such as orbitofrontal cortex, amygdala, and lateral hypothalamus. For example, neurons in the amygdala respond to taste stimuli only if the monkey is hungry. In the association areas, taste information is combined with the olfactory, visual, and somatosensory information about foods. Thus, many of the neurons respond in effect to the flavor of foods, and it is the response to flavor that is influenced by satiety. In the orbitofrontal cortex, the responses of single neurons can show specific, satiety-related decreases in firing rates that occur only for the stimulus for which the monkey is satiated and not for other stimuli. In Fig. 4, the response of a single orbitofrontal neuron to the taste of glucose decreases as the monkey is fed to satiation with a glucose solution. However, the firing rate in response to black currant juice is unchanged. In other experiments in which monkeys were fed to satiation with black currant juice, neurons were found that showed a decreased response to the juice but not to glucose.

In addition to being multimodal, neurons in the orbitofrontal cortical gustatory association area often respond more strongly to complex taste mixtures (e.g., black currant juice) than to any single stimulus (e.g., the sweet sugar) contained therein. This is in contrast to PGC neurons that respond more to a best single taste stimulus than to a taste mixture containing that stimulus. The tuning of multimodal association neurons to a mixture may simply reflect an additive response to the taste, olfactory, and textural stimuli that activate the neurons. Most natural taste stimuli have smells and textures as well as tastes that contribute to flavor perception.

Neurons in the lateral hypothalamus are also excited by specific gustatory stimuli, which suggests that they may be involved in taste discrimination. However, there are also neurons in this nucleus that respond nonspecifically to taste stimuli and may influence other aspects of taste processing besides discrimination. The nonspecific neurons have high spontaneous spiking rates, which are reduced in response to taste stimuli. They are (i) spatially separated from the taste-excited neurons; (ii) sensitive to the internal milieu, as demonstrated by an increase in spiking rate when glucose is locally applied; and (iii) involved in sensorimotor integration.

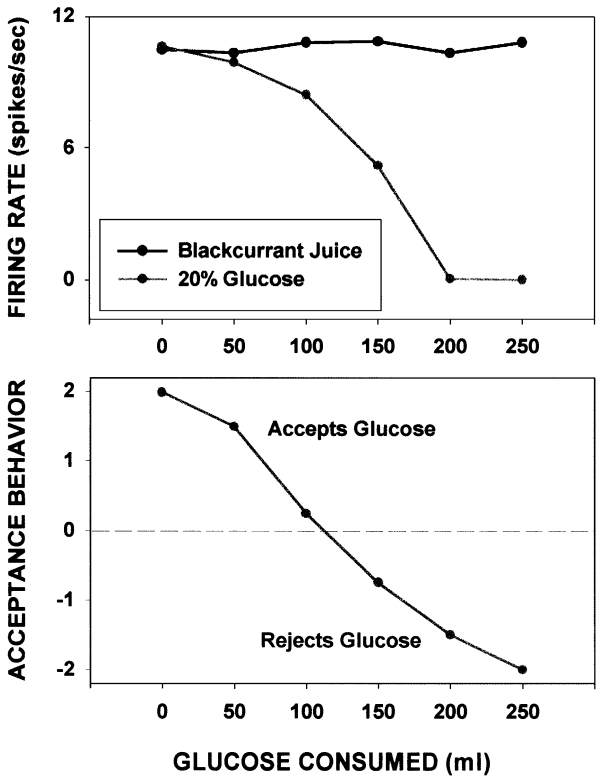

Figure 4 (Top) The effect of feeding to satiety with a 20% glucose solution on the response of a neuron in the orbitofrontal cortex to the taste of glucose and black current juice. (Bottom) The acceptance or rejection of the glucose solution on a scale from 2 to −2, respectively; a value of 0 indicates neither acceptance or rejection. The monkey was fed 50 ml of the glucose solution at each stage, as indicated along the abscissa, until he was satiated as shown by whether or not he rejected the solution [modified with permission from Rolls, E. T. (1997). Taste and olfactory processing in the brain and its relation to the control of eating. *Crit. Rev. Neurobiol.* **11,** 263–287].

IV. TASTE PSYCHOPHYSICS

A. Spatial Localization

Much of what we know about human tastes derives from psychophysical studies, which scientifically demonstrated fundamental taste qualities as noted previously. Precise localization of a taste stimulus was thought to require specific, associated somatosensory cues in humans. In contrast, goldfish have an exquisite ability to separate food pellets that have taste from inorganic particles, such as sand or pebbles, within the mouth. Although this ability may not be as developed in people, we can easily tell which side of the tongue a taste stimulus is on without specific touch cues. Thus, location-specific taste information is available to humans.

B. Integration of Information from Several Peripheral Fields

As noted previously, taste buds located on the anterior and posterior tongue have different sensitivities to prototypal taste stimuli in humans. Thus, whole-mouth perception of taste stimuli is the result of CNS integration of information from the various taste fields. For example, specificity of neurons mediating responses to salts and *umami* in the glossopharyngeal and chorda tympani nerves differs and thus provides different information about taste quality to the CNS from anterior and posterior lingual sites. However, because stimulation of either site with sweet stimuli elicits a similar response profile, in this case, stimulation of a second field provides added intensity and not new quality information. People rarely report deficits in whole-mouth taste following unilateral loss of a single peripheral taste field, which may be related to the poor localization of taste noted previously or central compensatory mechanisms. For example, if CNS neurons that are excited by posterior tongue stimulation are inhibited by anterior tongue stimulation, eliminating the inhibitory inputs would result in heightened responses to posterior tongue stimulation. For the bitter taste of quinine, there is evidence for such compensation. When the chorda tympani nerve was anesthetized, the perceived intensity of quinine applied to the posterior tongue increased.

C. Variability in Human Taste Abilities

In any human population, there is a unimodal normal distribution of taste detection thresholds or ratings of perceived suprathreshold taste intensity for many taste stimuli. This variation may be correlated with anatomical variation, such as the number of fungiform taste buds on the anterior tongue. For the bitter-tasting thioureas, such as propylthiouracil (PROP) or phenylthiocarbamide (PTC), there is a bimodal (or trimodal) distribution of sensitivities. Subjects are divided into tasters and nontasters of 1 m*M* PROP or PTC. Individual differences in sensitivity are hereditary and the ability to taste PROP is mediated by an autosomal-dominant allele.

V. PHYSIOLOGICAL AND DEVELOPMENTAL EFFECTS

Internal states and drives, such as hunger, modify preference for foods with specified taste qualities. For

example, after ingesting untasted NaCl tablets, humans on a low-sodium diet add less salt to unsalted tomato juice, demonstrating decreased salt preference. They also show an increase in NaCl recognition threshold, the concentration at which its taste is correctly identified. Thus, based on internal NaCl levels, physiological mechanisms, which likely involve the CNS, modify salt intake and salt recognition. As noted previously, lateral hypothalamic neurons respond to internal levels of glucose and oral taste stimuli. These neurons may form part of the pathway mediating effects of internal states on taste function. In contrast to physiologically adaptive mechanisms, increased habitual tasting and consuming of salted foods results in decreased salt intensity ratings and increased salt preference and consumption. Similar effects of habitually satisfying the sweet tooth lead to increased sugar consumption. Such eating habits establish a tolerance that exacerbates common health problems, such as hypertension and tooth decay.

Human newborns are very responsive to sweet stimuli. Their appetitive hedonic responses are readily observed in their sucking rates, preferences, facial expressions, and heart rates. Newborns' rejection of MSG, acid, and quinine is just as clear, demonstrating negative hedonic value on many of the same measures. However, sensitivity to the taste of some bitter compounds and NaCl may develop during the first 3 or 4 months after birth. Newborns hardly detect the taste of NaCl, but if detected it has negative hedonic value. However, sensitivity increases rapidly; by the time they are 4 months of age, NaCl is readily detected and preferred over water. The earlier development of sensitivity for sweet compared to salty stimuli may reflect differential development of taste bud receptors. Changes in preference during early postnatal development may reflect developing physiological controls involving the CNS.

VI. TASTE DISORDERS AND AGING

Dysgeusia is a distorted, frequently unpleasant taste perception. A "metallic" perception, perhaps the most common taste quality reported for dysgeusia, is a side effect of many medications, including antibiotics, antipsychotics, antiarthritics, and antihypertensives. Dysgeusia accompanies illnesses such as gastroesophageal reflux disease, oral yeast infections (candidosis), and burning mouth syndrome (BMS), a pain disorder primarily affecting postmenopausal women. Dysgeusia is also an iatrogenic result of treatment of head and neck cancer with radiation or chemotherapy, which also causes oral mucositis. Distorted unpleasant tastes may also result from treatment of oral infections with antiseptic mouth rinses that contain chlorhexidine. Taste-quality distortions may have peripheral or central origins. BMS dysgeusia, which is often eliminated by topical anesthesia of the tongue, may be due to a malfunction of the taste buds and peripheral nerves. Radiation-induced dysgeusia may encompass learned flavor aversions involving the CNS; food may be associated with the gastrointestinal malaise accompanying radiation therapy.

Taste losses without distortions also accompany illnesses or medical procedures and may indicate injuries to the taste nerves. The symptoms of BMS, for example, include loss of taste, which can be verified by clinical taste testing. High (1 *M*) concentrations of sweet sucrose and salty NaCl are rated weaker by BMS patients than by normal people. Also, extraction of the third molar teeth may result in weakened taste perceptions. The amount of taste loss is correlated with severity of tooth impaction and likelihood of nerve damage from the oral surgery. Losses are associated with damage to the chorda tympani nerve for lower third-molar extractions and with damage to the greater superficial petrosal nerve following upper third-molar extractions. Increases in taste detection thresholds and decreases in taste intensity ratings are also associated with aging. However, age-related losses in taste function are generally less severe than those for olfaction, audition, or vision.

Medications that many elderly people use result in taste losses, complicating the question of the effect of aging on taste. For example, antiarthritic, antihypertensive, and antineoplastic drugs have been implicated in taste loss. Nonetheless, aging has been shown to affect detection thresholds for taste stimuli, as well as ratings of perceptual intensity of taste stimuli that are well above threshold, in healthy adults. Average threshold increases are significant; for example, the NaCl detection threshold is about 2 m*M* NaCl at 25 years but about 4 m*M* NaCl at 65 years. It may be argued that the minimal concentration detected is not that relevant to "real-world" taste and thus the ratings for above-threshold stimuli are of greater importance. Again, there are significant decreases with age, but they are smallest for sweet sucrose and largest for bitter quinine. The intensity of 0.56 *M* sucrose is rated 10% weaker by those older than 70 years compared to those younger than 40 years. The intensity of 0.1 m*M* quinine–HCl is judged 40% weaker by those older than 70 years. The physiological mechanisms by which

aging affects taste perception are unknown. In rodents, aged individuals have about 10% fewer taste buds in their fungiform papillae on the anterior tongue than the young, but this trend has not been verified in humans. It is possible that taste buds remain but the function of this regenerating epithelial population is compromised with age.

Temporal Lobes

HENRY A. BUCHTEL
Ann Arbor VA Health Care Center and University of Michigan

GLOSSARY

Klüver–Bucy syndrome Behavioral changes after bilateral damage to mesial temporal lobe tissues.

material-specific memory The lateralization of memory functions such that the learning of different kinds of materials depends on different degrees of left or right temporal lobe mechanisms.

temporal lobe syndrome A concept that patients with temporal lobe pathology have a particular way of behaving, usually involving a personality change with religiosity or sexual dysregulation.

The temporal lobes are important brain structures comprising about 20% of the total volume of the cerebrum. This part of the brain is important for complex visual and linguistic analyses and for the formation of new memories.

I. INTRODUCTION

The temporal lobes are readily recognizable brain structures with a thumb-like appearance when viewed from the side (Fig. 1). Their name simply reflects their location beneath the temporal bone on the side of the head. The temporal bone, in turn, receives its name from the fact that this is the place in which graying of hair starts, indicating aging with the passage of time (*L. tempus*). In some ways, the temporal lobes are more a convenient fiction than anatomical entities. They share borders with the occipital and parietal lobes, but the precise boundaries are not clearly defined by landmarks. A better definition of the anatomical limits of the temporal lobe would come from thalamic and intracortical projections and a functional analysis of the various subunits within the lobe. Because excision of the anterior temporal lobe is often used to help control medically intractable seizure disorders, much of our knowledge of the effects of damage to (or stimulation of) this area comes from studies of persons with epilepsy.

II. CYTOARCHITECTURE, PATHWAYS, AND CONNECTIONS

The posterior limit of the inferior and inferior-lateral temporal lobes is defined by the anterior border of area 19 of the occipital lobe. The Sylvian fissure (sometimes called the lateral cerebral fissure) defines the dorsal limit, whereas the posterior border at this dorsal level is defined by the beginning of parietal lobe Brodmann areas 39 and 40. Areas 22 and 37 (laterally) and 27 and 36 (mesially) belong within the temporal lobe, whereas areas 39 and 40 (inferiorally and laterally) and areas 23, 26, 29, and 30 (mesially) belong within the parietal lobe. There are three lateral gyri, delineated by the *superior, middle, and inferior sulci*, that parallel the Sylvian fissure. In the left hemisphere, Wernicke's area, which includes temporal lobe area 22 (as well as parietal areas 39 and 40), lies at the posterior end of the superior temporal gyrus where it meets the parietal lobe. Just in front of this region, bilaterally, is Heschel's gyrus (primary auditory cortex).

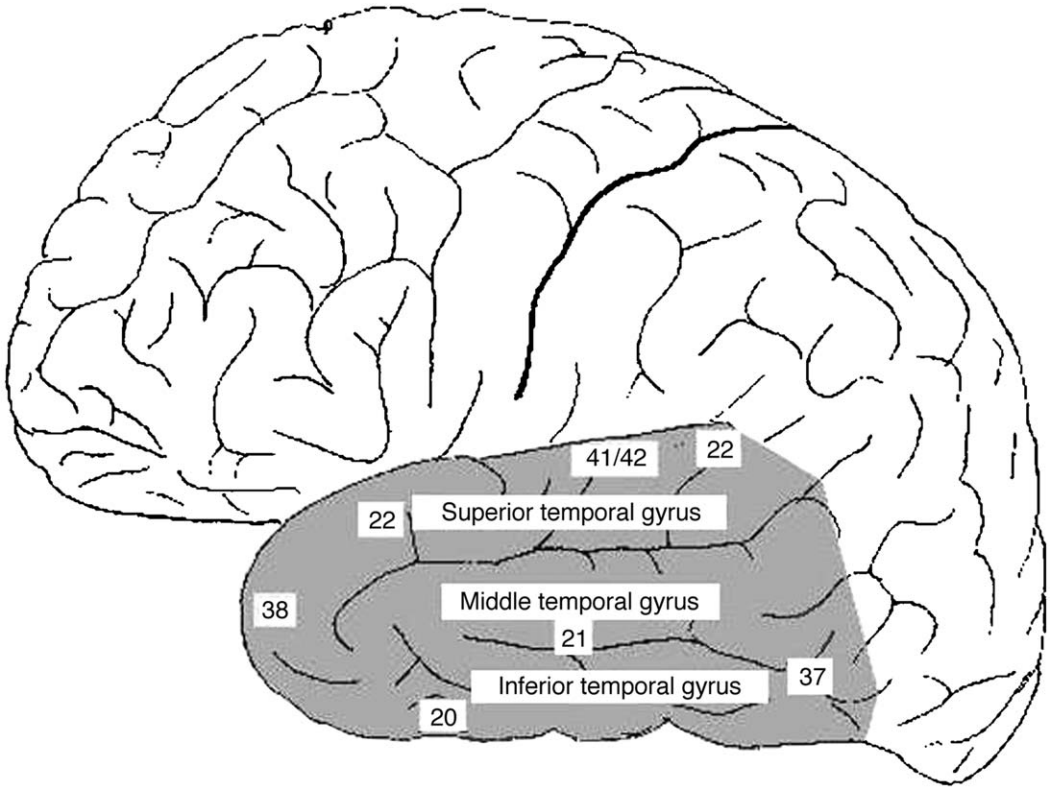

Figure 1 Side view of the brain showing temporal lobe (shaded) and Brodman areas.

III. HEMISPHERIC SPECIALIZATION

In humans, the functions of the temporal lobe can best be understood through the organizing principle of lateralization of function. It has been clearly established that the temporal lobes make important contributions to memory and perception, but the types of materials that are optimally handled by right and left temporal lobe mechanisms depend on the side being considered. In order to simplify the description of these functions, references to the right and left hemispheres in the following discussion are based on a typical representation, as seen in the majority of both right- and left-handers. In other words, for the purposes of this article, the left cerebral hemisphere will be assumed to be the one responsible for most speech functions and the right cerebral hemisphere to be the one responsible for most visual–spatial functions. There are clear exceptions among both right- and especially left-handed individuals, and even the designations visual–spatial functions and speech functions are not simple and unidimensionally lateralizable. This needs to be stated because for the temporal lobes, as well as for significant portions of the frontal and parietal lobes, many of the functions subserved need to be discussed in the context of the functional organization of the hemisphere within which the lobe is located. Evidence for this assertion comes from observations of patients with brain damage, from the effects of direct electrical stimulation during brain surgery, and from functional imaging studies [e.g., positron emission tomography (PET) and functional Magnetic resonance imaging (fMRI)]. In terms of gross anatomical structure, the striking differences between the functions of the right and left temporal lobes are not reflected in equally striking morphological differences. The Sylvian fissure rises more sharply on the left than on the right, but this pattern is by no means invariable and its probable underlying cause (the size of the planum temporalis) is only weakly correlated with the side of speech mechanisms (about 60% of right-handers have a larger planum temporalis on the left, but more than 97% of normal right-handers appear to have left hemisphere speech mechanisms). Interestingly, these morphological differences between the hemispheres appear to have predated the acquisition of speech abilities. Higher apes show the same pattern of morphological asymmetry and possess lateralized

differences in the motor system (preferring the right hand for manipulation tasks and the left for spatial localization), but it is clear that speech is not developed in these animals and "true" language abilities in nonhuman primates remain controversial.

IV. CLINICAL AND FUNCTIONAL ASPECTS

Functionally and neuroanatomically, the posterior parts of the inferior temporal lobe (especially the fusiform gyrus, area 37) can be considered to be extensions of the occipital lobe visual system. Microelectrode recordings from this region in animals in visual tasks and functional brain imaging findings with humans show that cells in these regions are actively involved in the analysis of visual images: In animals, cells have been found that are particularly sensitive to the presence of faces and other body parts.

Because of its position in the cranium, the temporal lobe is vulnerable to damage from closed-head injuries and increased intracranial pressure (sometimes induced during the process of vaginal delivery); its proximity (vascular and linear distance) to the face and to openings into the cranium from the nose leads to a major involvement in diseases such as herpes simplex virus. Most of what we know about the functional significance of temporal lobe mechanisms comes from the effects of lesions on behavior. Although much of this knowledge comes from animal studies, the higher cognitive skills subserved by the temporal lobes mean that it has been more rewarding to work with humans who, in addition to having psychometric deficits, can report their subjective impressions of the changes brought about by the damage. Cognitive changes occurring after damage to the temporal lobes are mainly seen in the domains of memory and perception. Again, the concept of hemispheric specialization is relevant because of the material-specific nature of some of the deficits.

A. Memory

Mesial structures of the temporal lobe (*amygdala, hippocampus*, and *rhinal cortex*) all have demonstrated roles in some aspects of the establishment of new memories. The relative roles of these portions of mesial temporal lobe are being worked out; however, interpretation is difficult because it is unusual for one region to be damaged without a disturbance of the functions of the others, and animal studies, in which precise lesions are possible, do not have exact analogs to the kinds of memory tasks given to humans.

B. Religiosity

There is a clinical impression that some patients with right hemispheric temporal lobe lesions undergo an increase in religiousness, sometimes to the extent that the term "hyperreligiosity" is applicable. The theoretical basis for such a change has resisted definition, but if the phenomenon does exist, its origin may lie in an attempt by the patient to explain the presence of unusual and "unworldly" feelings that arise from the effects of his or her lesions or seizure activity, especially if arising from the right hemisphere.

C. Emotion

The hemispheric organization of emotion has received renewed attention since the strengthening of the biological revolution in psychiatry, and the limbic system has traditionally been accorded a role in the experience and expression of emotion. The amygdala, in particular, has been seen as contributing to normal and abnormal emotional responses and experiences (leading, in extreme and misguided cases, to psychosurgical excision of these structures in individuals who are seen to have unacceptable emotionally driven behavior). Bilateral amygdaloid destruction causes a severe disturbance of normal affective behavior (Klüver–Bucy syndrome); damage in humans is usually unilateral and often incomplete, but even unilateral amygdaloid damage has led to changes in emotional experience. Recently, the amygdala has been implicated in the manifestations of schizophrenia and bipolar disorder.

D. Visual Perception

The contribution of the temporal lobe to visual perception has been clarified by the division of visual projections from the occipital lobe in two directions or "streams": a dorsal route into parietal lobes that is involved in spatial localization and a ventral route into the temporal lobe that is involved in the appreciation of the qualities of objects (and their identification) in the visual scene (Fig. 2). Early and controversial evidence from single-cell recordings that neurons in the inferior temporal lobe of monkeys respond to complex visual stimuli has thus been confirmed and extended.

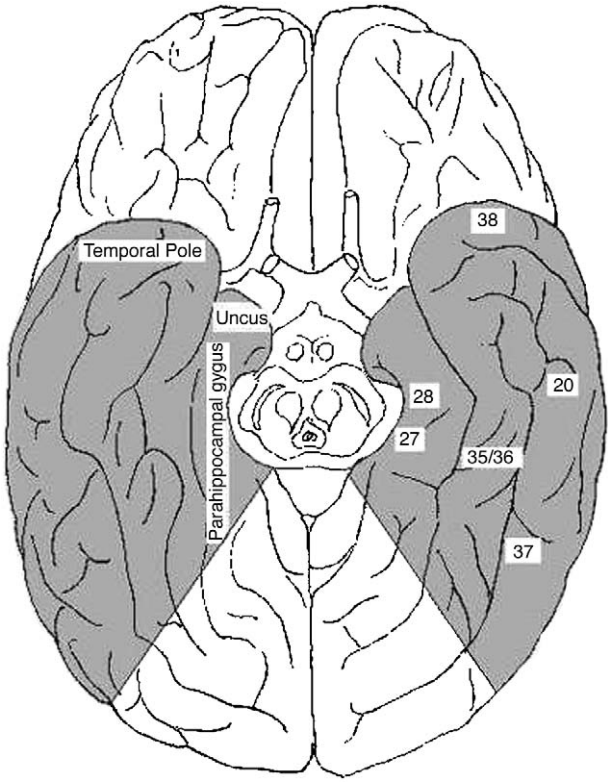

Figure 2 Base of the brain showing temporal lobe (shaded) and Brodman areas.

E. Face and Object Recognition

Damage to posterior inferior temporal (IT) lobe, especially when bilateral and when portions of inferior areas 18 and 19 are involved, can lead to a condition called *prosopagnosia*. Patients with this disorder can see a face but do not recognize the person from the face alone. This affects the recognition of friends, relatives, and famous persons alike. Interestingly, as soon as the person speaks, his or her identity may be immediately recognized. Prosopagnosics can usually recognize and correctly interpret facial expressions, and they may also be able to recognize a person from other visual but nonfacial cues, such as gait or posture. It is clear that the disorder caused by IT lesions has to do with conscious recognition: Recordings of galvanic skin conductance (which reflect emotional reactions) show that emotional responses occur with presentations of photographs of relatives and friends but not of photographs of strangers, despite the prosopagnosic's claim that all faces are equally unknown. Persons with prosopagnosia are usually also unable to learn new faces, at least when tested using conscious recognition. The disorder may be accompanied by difficulty recognizing (naming) famous buildings, and such individuals may also have difficulty with texture discriminations and color perception. In addition, attempts to name objects may result in the use of a general category rather than the object's unique name (e.g. "bird" rather than the more specific "robin" or "peacock"), with some kinds of objects appearing to be affected more than others (e.g., the naming of tools may be relatively good compared to the naming of natural things such as vegetables or animals). Prosopagnosia has also been seen with unilateral IT lesions, but the nature of the disorder appears to be different, depending on the side of the damage. When the damage is on the left, the person may identify the face incorrectly but still give an answer in the correct category (e.g., naming a different figure in politics or entertainment). This is called "deep" prosopagnosia, in analogy with "deep" dyslexia in which the person reads a word semantically related to a word on the page. When the damage is on the right, the person may be slow and erratic at recognizing faces but not profoundly prosopagnosic. The conjunction of prosopagnosia and other recognition deficits has been taken as evidence that faces and other complex visual stimuli share neurological substrates. However, it has been found that the regions responsible for these different categories of perceptual recognition are close neuroanatomically and thus it is difficult to damage one while leaving the other intact.

F. Language

The *superior temporal sulcus* lies above the *superior temporal gyrus* and electrical stimulation of this gyrus (especially in the posterior half) in the left hemisphere of typical right-handers often causes speech arrest or other alterations of language abilities. PET findings show bilateral activation of Heschel's gyrus and unilateral activation of Wernicke's area (left hemisphere only) when typical right-handed subjects listen to a verbal material such as a narrative.

The *middle temporal gyrus* lies between the middle and superior temporal sulci. Speech-related areas are occasionally found here, although it is possible that such unusual patterns of speech representation might be found predominantly in patients with preexisting brain damage (e.g., the patients described previously who were being evaluated for seizure surgery).

Damage to the anterior parts of the inferior and lateral portions of the temporal lobe of the speech

Table I
Effects of Temporal Lobe Damage

Region	Damaged hemisphere		
	Left	Right	Both
Lateral (inferior and/or inferior lateral)	Mild deficits in naming object categories; "deep" prosopagnosia	Mild deficits in naming object categories; brief prosopagnosia	Severe deficits in naming object categories; severe persistent prosopagnosia
Anterior	Deficits in finding proper names; anomia or restricted naming	Difficulty naming facial expressions	Anomia; retrograde memory deficits
Medial	Poor memory for new verbal information	Poor memory for new nonverbal information	Severe memory deficit for all new information

hemisphere causes problems with confrontational naming (e.g., naming pictures of common objects), but repetition and grammar are usually unaffected. An inferior speech area has been seen in some patients (speech arrest following electrical stimulation) and surgeons have usually assumed that these areas can be removed without significant loss of language ability. The existence and persistence of naming deficits after temporal lobectomy despite the sparing of the posterior speech zone raise the possibility that some patients need this inferior language area. Some patients have isolated naming deficits (e.g., proper names) with unilateral lesions of the anterior and lateral tip of the temporal lobe. Damage to the anterior parts of the inferior and lateral portions of the temporal lobe of the right hemisphere has been associated with memory for autobiographical episodes, although other retrograde memory functions may remain intact (Table I).

V. FUNCTIONAL IMAGING AND FUTURE DIRECTIONS

Most of the studies detailing the perceptual functions of the temporal lobes have been carried out in primates using microelectrode recordings and lesions, but new studies using functional activation with PET or fMRI have confirmed the hypothesis that visual analysis extends into the inferior portions of the temporal lobes. The activation appears to be bilateral in most cases, but there is a predominance of left-sided activation if the object's name is being sought. In animal studies, posterior lesions of IT lobe tissue disturb visual discrimination, whereas more anterior lesions disturb visual recognition. In this context, it is worth mentioning that one of the disadvantages of functional brain scans is that patterns of activation reveal what is activated, not what must be activated for successful completion of the task. For example, if a subject finds a task difficult, portions of the brain associated with frustration and discontent may be activated even though they are not a part of the neural substrate for the task. The design of control tasks is even more crucial than usual in such tasks.

Thalamus and Thalamic Damage

CHIHIRO OHYE
Hidaka Hospital

GLOSSARY

cytoarchitecture Morphology based on a cellular component.

gamma knife A medical device used to treat deep-seated brain lesions by gamma-ray from 201 cobalt sources focused on a pinpoint.

lamellar distribution Distribution of cell dendrites directed in an anteroposterior direction to form a parallel thin layer.

microrecording Recording of neuronal activity by a microelectrode.

myeloarchitecture Morphology based on a myelin component.

positron emission tomography scan Computerized imaging of the living brain by detecting energy emitted by positrons from injected or inhalated short-lived radioactive substances.

stereotactic surgery Neurosurgical technique used to locate a given deep cerebral point using three-dimensional coordinates.

The thalamus is a mass of neurons that receives external and internal information and sends it to the cerebral cortex or basal ganglia after selection or modulation. Thus, the inner environment of human life is kept in harmony. If the thalamus is damaged, sensory, motor, or mental disorders may result depending on the site of thalamic damage.

I. INTRODUCTION

The thalamus is a mass of various types of neurons located in approximately the center of the brain underneath the cerebral cortex. It is covered completely by the cortical hemisphere, and therefore it is not visible from the surface of the brain. Its shape is ellipsoid, like a rugby ball, separated by the third ventricle in the middle except for small connecting fibers of massa intermedia. Thus, in relation to the third ventricle, it is symmetric, with a half ellipsoid on each side (Fig. 1). In a normal adult, its longer axis is about 30 mm, the maximum width of one side is about 20 mm, and the height about 20 mm. It contains approximately 10^7 neurons, and anatomists classified them into about 50–80 nuclei. However, this kind of classification is more or less artificial, depending on the diifferent methods and criteria used. Therefore, the same area could be divided or joined to make a new percellation. In fact, recent progress due to new staining techniques has shed new light on this field, delineating new boundaries previously not obvious by other methods.

Because the fundamental function of the thalamus is to relay and modulate peripheral information to the cerebral cortex and to the basal ganglia, keeping the somatosensory, mental, and emotional activity of a living individual in harmony, the ideal parcellation probably depends on the input–output relation from periphery via thalamus to higher centers. However, in the human thalamus, it is difficult to apply many modern methods, and most of the thalamic nuclei are still poorly understood. Thus, this article describes neurological findings correlated with restricted thalamic damage, stereotactic surgery with microrecording (even though it is biased to the ventral tier nuclei), and some relevant data in nonhuman primates.

The term thalamus, which was used by Galen approximately 1700 years ago, originated from the

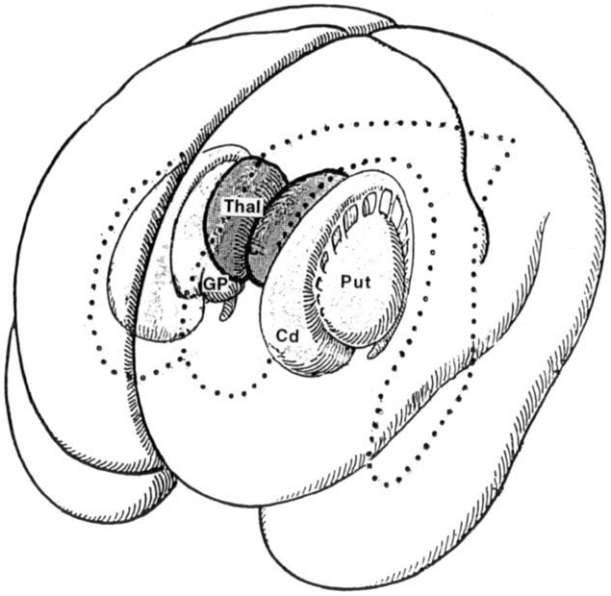

Figure 1 Transparent overview (anterolateral view) of the thalamus (Thal) (hatched area) in the brain. Cd, caudate nucleus; GP, globus pallidus; Put, putamen; dotted line, lateral ventricle. (modified with permission from Duus, 1989). Copyright George Thieme Verlag.

Latin or Greek word that means "inner chamber." The corresponding French word, *couch optique*, may be related to the fact that the optic tract can be traced by gross anatomy to the thalamus; in fact, the optic tract is the only visible input pathway from the periphery to the thalamus that can be recognized from the base. The term optic thalamus has also been used as a synonym for thalamus in old English literature. It is interesting to note that in Japanese terminology, thalamus is called *shisho*, which means "optic bed."

II. ANATOMY

A. Development

The thalamus is derived from the rostral part of neural tube together with the cerebral hemisphere. In the course of the early embryonic developmental stage, the first bending of the rostral neural tube toward the ventral side (flexura cephalica) separates the prosencephalon and mesencephalon. In the second bending, the flexura cervicalis further separates the caudal part of the neural tube into the rhomencephalon and spinal cord. From the rostral neural tube (prosencephalon), the telencephalon (future cerebral hemisphere) and diencephalon (future thalamus) develop. At an early stage of 6 mm crown–rump length (CRL), when the optic vesicle becomes visible from the outside, a swelling or thickening of the wall of the neural tube at the level of the diencephalon occurs (origin of the thalamus), together with a swelling of the neural tube canal (origin of the third ventricle) (Fig. 2A). In this stage, the diencephalon consists of four main parts: the epithalamus, dorsal thalamus, ventral thalamus, and hypothalamus (from dorsal to ventral). Each part is separated by the sulcus diencephalica dorsalis, medius, and ventralis, respectively. At the stage of 18 mm CRL (about 6 weeks gestational age), rapid growth of the dorsal thalamus with migration of the neuroblast of the dorsal thalamus surpasses that of the ventral thalamus, thus changing the relative portion and size (Figs. 2B–2D). The dorsal thalamus becomes larger, and the ventral thalamus is displaced and compressed to the lateral and ventral part. Further cellular differentiation at 25 mm CRL (about 7 weeks) induces nuclear primordis in each dienephalic part. For example, the pineal body, habenula, and posterior commissure originate from the epithalamus; the lateral part of the lateral geniculate body originates from the dorsal thalamus; the nucleus reticularis thalami, zona incerta, nucleus reuniens ventralis, and so on originate from the ventral thlamus; and the subthalamic nucleus and probably globus pallidus originate from the hypothalamus. As anticipated, the dorsal thalamus finally becomes the so-called thalamus, the main part.

Most thalamic cells migrate from the wall of the third ventricle at an early stage untill about 10 weeks gestation. Then, the path of migration is more active from the ganglionic eminence, which is a huge mass of highly proliferating cells located on the floor of the lateral ventricle–ditelencephalic border. This supplies cells to the caudate, putamen, and amygdala, and from 16 to 37 weeks of gestation the telencephalic part of the ganglion eminence (corpus gangliothalamicum) becomes a source of cells in pulvinar, which develops late in the gestation stage. It is interesting to note that the cells in the largest nucleus of the thalamus, the pulvinar, are telencephalic in origin.

Until approximately the 50-mm CRL stage, cellular differentiation is relatively poor in the dorsal thalamus. One can distinguish only lateral and medial geniculate body, parafascicular nucleus, and pulvinar. At the 100-mm CRL stage (about 15 weeks), various nuclei and fiber tracts develop. Also, the internal medullary lamina separates the dorsal thalamus into three the dorsal, ventral, and lateral parts. Thus, from the dorsal part originates centrum medianum and nucleus medialis, from the ventral part embryonic

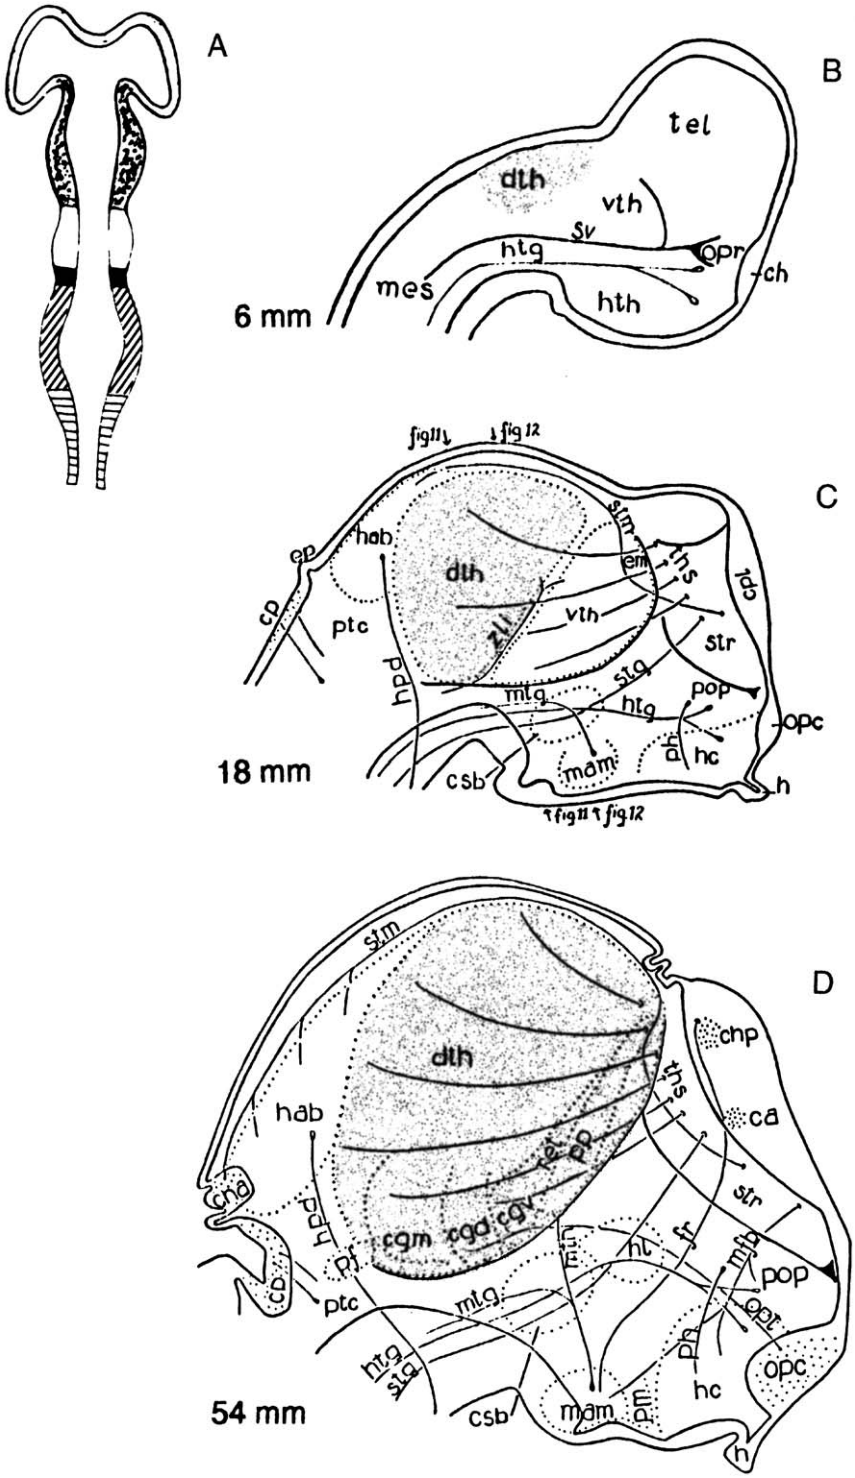

Figure 2 Schematic illustration of embryonic development of the human thalamus. (A) Axial section of the neural tube showing the origin of the main element of the central nervous system. From top to bottom, telencephalon (bilateral swellings), diencephalon (dotted area), mesencephalon (white zone), isthmus of rhombencephalon (black area), metencephalon (hatched area), and myelencephalon (horizontal bars). (B–D) Sagittal views of diencephalon at 6 mm (B), 18 mm (C), and 54 mm crown–rump length (D). Abbreviations are given only for relevant parts: dth, dorsal thalamus; vth, ventral thalamus; hth, hypothalamus; ep, epithalamus; htg, tractus hypothalamicus tegmentalis; ch, chiasmatic plate; opc, optic chiasma. Lines inside the thalamus are several fiber bundles (modified from Gilbert, 1934).

nucleus ventralis and arcuate nucleus, and from the lateral part lateral geniculate body (pars lateralis), medial geniculate body, and nucleus lateralis including pulvinar. Therefore, at about 4 months genstatinal age, most of the main thalamic nuclei and fibers are very similar to the complete form. Further cytoarchitectural differentiation of the diencephalon is essentially completed at birth. On the other hand, the development of the telencephalon is remarkable, and in a fully developed state each thalamus locates almost at the center of each hemisphere, sandwiching the third ventricle but completely covered by the cerebral cortex.

B. Gross Anatomy

The coronal section (a vertical plane through the two ears) has been used since the early era of anatomy of the human thalamus. However, horizontal or sagittal sections can clearly demonstrate nuclei that are not easily distinguished in coronal section. Furthermore, for practical purposes, a stereotactic section using an intercommissural line (an imaginary line connecting the anterior and posterior commissures through the third ventricle) is now widely used for intervention into the thalamus, which lies just adjacent to the third ventricle. Therefore, a three-dimensional (coronal, sagittal, and horizontal) stereotactic atlas is commonly used. Today, in the era of computerized three-dimensional imaging, the idea of the stereotactic method is receiving increasingly more important meaning.

Looking at a horizontal section of the brain shown in Fig. 3, the large ellipsoid mass of gray matter in the center is the thalamus. It is surrounded by the basal ganglia, with the intermediate of the internal capsule: anteriorly by the canudate nucleus and laterally by the lenticular nucleus. Within the thalamus, one can easily

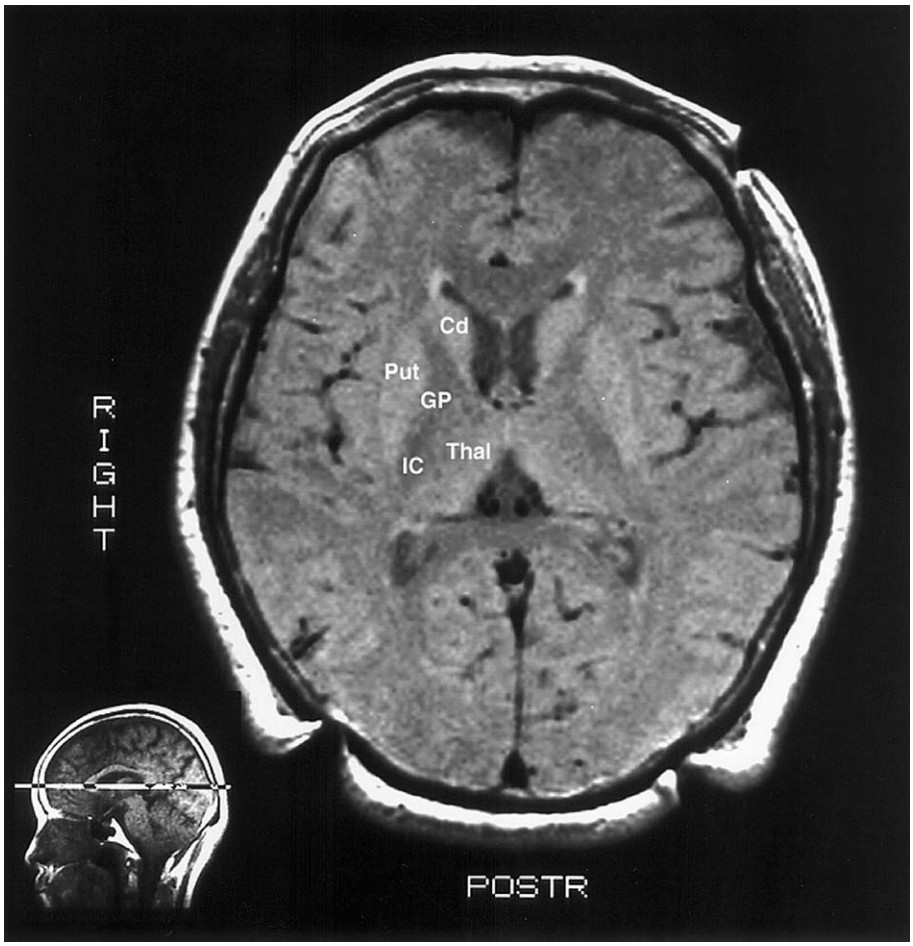

Figure 3 MR axial image showing the thalamus (Thal) and its surroundings. Cd, caudate nucleus; GP, globus pallidus; IC, internal capsule; Put, putamen. (Bottom left) A scout view for cutting level.

identify the fiber-rich longitudinal structure named the internal medullary lamina, which separates the thalamus into three parts—anterior, lateral, and medial groups. Therefore, the internal medullary lamina is a good landmark for orientation in the thalamus, and the thalamic nucleus is generally named after the relative geographic location: anterior nucleus, posterior nucleus, medial nucleus, midline nucleus, intralaminar nucleus, dorsal nucleus, and ventral nucleus.

In reality, however, the nomenclature of the human thalamus is complicated. Traditionally, there are at least two different streams, German and Anglo-American; the former depended on myeloarchitecture and the latter on cytoarchitecture. Moreover, it is often the case that each anatomist uses his or her own naming, and there is no uniform system for the nomenclature of animal thalamic nuclei. Therefore, this confusion has resulted in further misunderstanding and controversy. One should be careful in reading the literature or in referring to an atlas of the human thalamus. In this article, one of the most prevalent styles in the field of human stereotaxy since the publication of *Stereotactic Atlas of the Human Thalamus*, the German style of Hassler's naming, is used, especially for the ventrolateral part. An example of the stereotactic atlas for three different sections (horizontal, coronal, and sagittal) is shown in Fig. 4.

The whole thalamus is surrounded by a thin wall of reticular nucleus, which is more conspicuous anteriorly. Also, the internal medullary lamina is easily distinguished. The most anterior is the lateropolar nucleus. The lateral group consists of (from anterior to posterior) the ventral anterior, ventral oral, ventral intermediate, and ventral caudal nucleus. Each nucleus is usually further divided into several subparts. The main medial group consists of the dorsomedial nucleus, center median nucleus, and parafascicular nucleus. The internal medullary lamina has its own nuclear group, centralis lateralis together with the previously mentioned center median–parafascicular

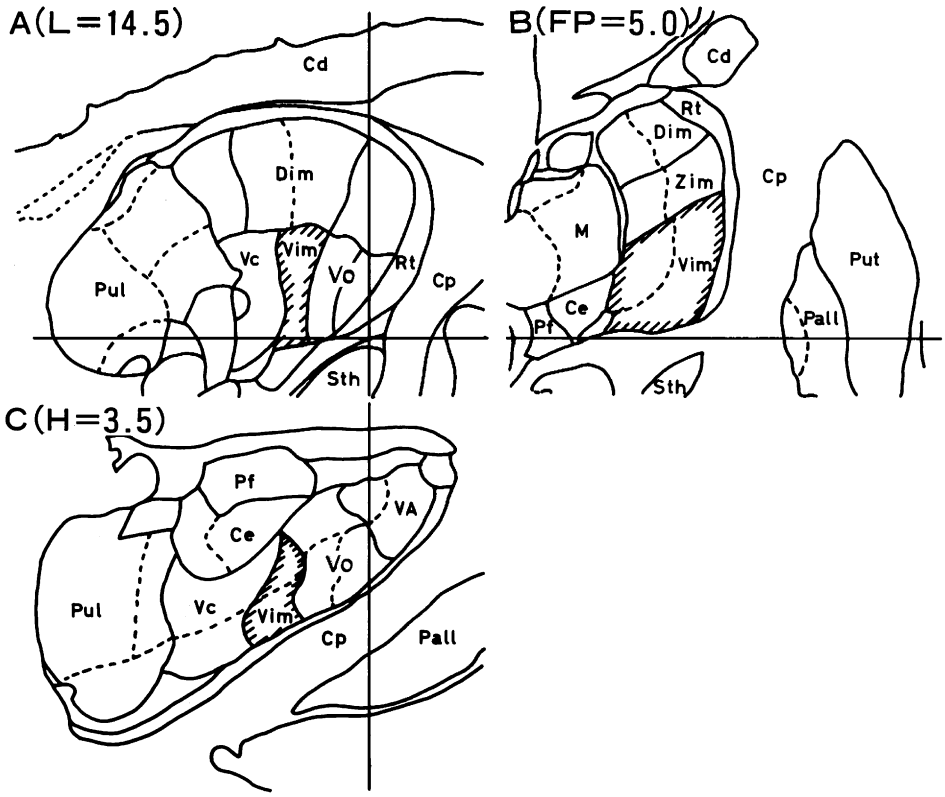

Figure 4 Examples of the stereotactic atlas in common coordinates, with main nuclei. A, sagittal section; B, coronal section; C, axial section. Horizontal line is drawn at the level of the intercommissural (IC) line. Vertical line is drawn at the midpoint of the IC line. complex. The most posterior part is occupied by the pulvinar, the largest nucleus in the human thalamus.

C. Thalamic Cells

Each thalamic nucleus consists of characteristic cellular components, neurons. The morphology of neurons is variable; for example, angular, round, spherical, or oval in shape and large, medium, and small in size. Usually, the similar types of neurons gather together in one nucleus, providing the basis for drawing a line at the frontier to classify subnuclei. It is generally the case that the larger neurons are relay neuron, transmitting peripheral information to the higher centers, and the smaller neurons are intrinsic interneurons connecting intranuclear neurons.

Precise cytometric studies have determined the characteristics of the various nuclei. For instance, in the ventral oral nucleus, medium-sized and small neurons are densely packed, with the cell density being about 110 cells/mm^2/50 μm thickness. The subdivisions of the nucleus, ventral oral anterior and posterior, are almost the same in cytoarchitecture but the ventral oral internus is composed of larger neurons with a less dense distribution. The ventral intermediate nucleus is characterized by large cells and by an area in which cells are sparse (Fig. 5). The cell size peaks at 600–700 μm^2, the largest neuron group in the human thalamus, and at 400 μm^2. The cell density is about 60 cells/mm^2/50 μm thickness, contrasting to that of the rostral nucleus of ventral oral group. The ventral caudal nucleus, located further caudally, consists of a mixture of large and small cells. The histogram of cell size shows a different distribution according to subnuclei (anterior, posterior, externus, and internus), varying from 100 to 550 μm^2. The mean cell density is approximately 120 cells/mm^2/50 μm thickness. These histological findings correlate well with electrophysiological findings discussed later.

D. Chemical Anatomy

Recent advances in neuroscience have opened a new horizon to visualize particular chemical substances, proteins, or peptides related to synapse, receptor, etc. on the cell membrane or in the cell content. For instance, dopamine, acetylcholine, peptides, calcium-binding proteins, and so on are visualized by immunochemical and histochemical staining methods or by radioimmunoassay. In the literature, however, most animal experiments have been performed in the rat, and only a small amount of direct study on human thalamus has been performed. Figure 6 shows an example of a histological section of the human thalamus stained by acetylcholine estelase legant. By this method, a new parcellation of the ventrolateral nuclei was proposed.

In Table I, the distribution of chemical substances in the human thalamus collected from 15 different sources is shown. From these results obtained using techniques, there emerge several interesting hypotheses about the function of the particular thalamic nucleus, which was hitherto unable to be seen.

III. PHYSIOLOGY

Physiological understanding of the human thalamus is limited. Only restricted areas such as ventrolateral tier nuclei (ventral anterior, ventral oral, ventral intermediate, and ventral caudal) and nuclei of the medial group (central lateral, centromedian, and parafascicular) are explored in the course of stereotactic thalamotomy for treating various kinds of involuntary movement and intractable pain. Electrodes are guided into the specific parts, and the signals from neurons responding to stimulation of peripheral body areas are recorded. The electrical stimulation of the specific thalamic point elicits sensation or movement at the periphery.

Because the subjects are inevitably in a more or less abnormal state, one should exercise caution in interpreting the results. For convenience, here description will be made from caudal to rostral.

A. Ventral Caudal Nucleus or Nucleus Ventralis Caudalis

This nucleus is one of the most thoroughly explored, probably because it gives the same sensory response as that obtained from animal experiments. Light touch on a small contralateral body part gives rise to a sharp response of spike discharges (Fig. 7), which is the same as the well-known thalamic sensory response in animal experiment.

The peripheral receptive field is very small, usually several square millimeters in the distal extremity, especially at the finger tip and face and lip. In the proximal parts, the receptive field is relatively large, sometimes several square centimeters. Once a response to natural stimuli is found, another response in an

Hirai).

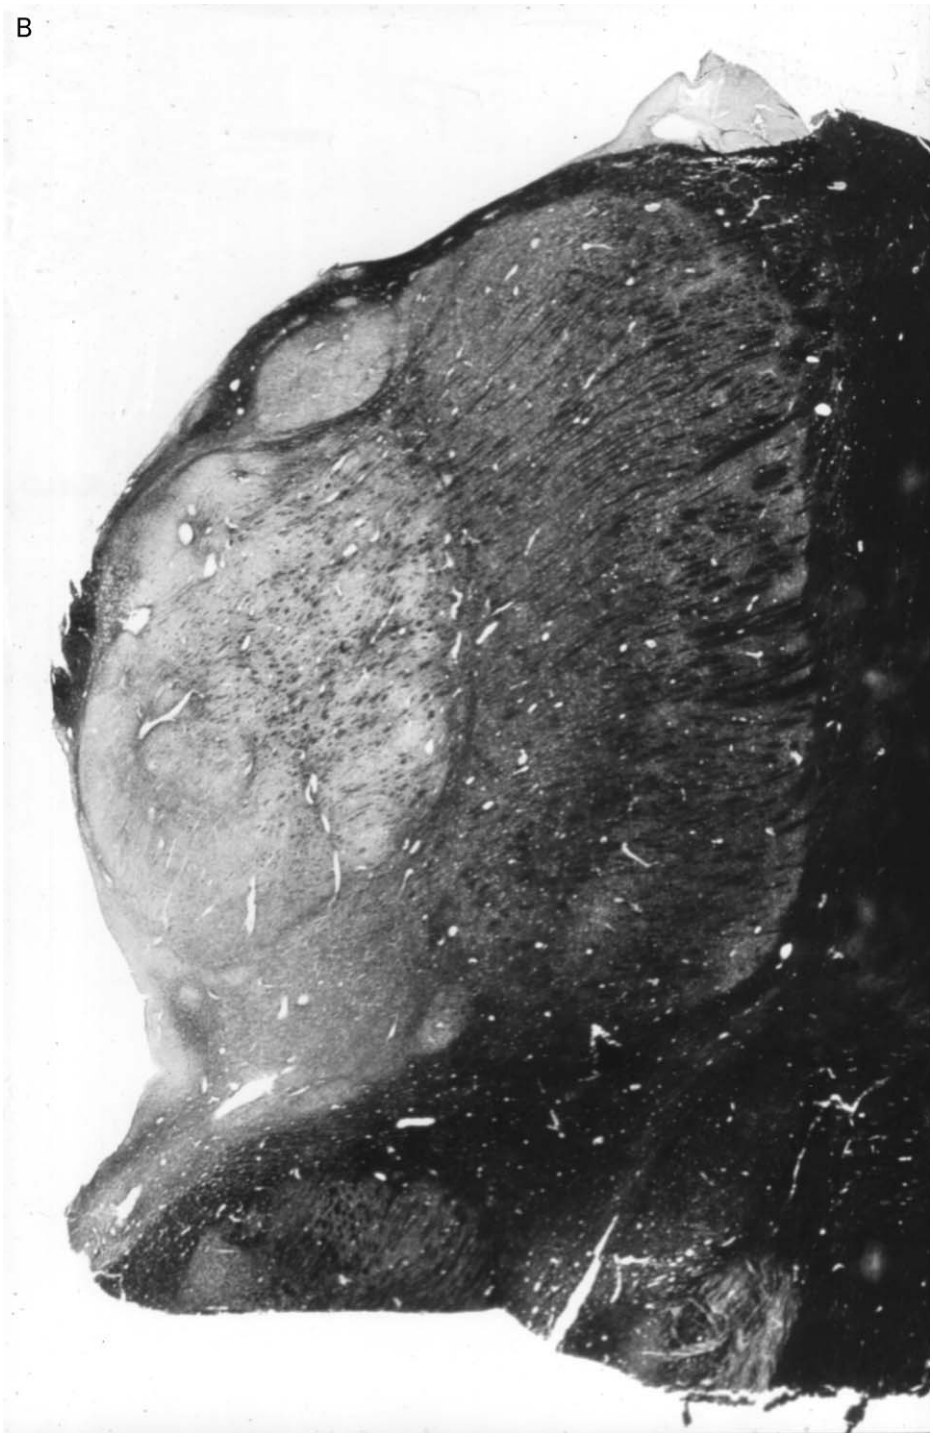

Figure 6 *(continued)*

adjacent area of a given receptive field follows as the electrode descends. For example, if the first response is to light touch on the chin area, the next response is from the buccal area, followed by responses from the nasal labia, along several millimeters of descent. In this sense, there is a topographic representation within the ventral caudal (VC) nucleus. Generally, the leg area is represented in the dorsolateral part of the nucleus, the

Table I
Distribution of Chemical Substances in the Human Thalamus

Classification	Substance	Location	Remarks
Acetylcholine	CHAT	All thalamic nuclei	Affiliation with limbic structure and influence of ascending reticular system
		CHAT-positive axons and varicosities	
		Medial habenula	
		CHAT-positive perikaria	
		Some intralaminar nuclei	
		Dorsomedial N	
		Patch dense, matrix weak	
	[^{3}H] Nicotine	Anteroventral N and dorsomedial N	Heterogeneous distribution
	[^{3}H] Ach		
	[^{3}H] Nicotine	Lateral dorsal N, medial and lateral geniculate bodies	Different from animal
		Anterior nuclei	
Monoamines	Norepinephrine	Medial group, intralaminar nuclei-high pulvinar-low level	
			Dopamine (-)
	Serotonin	Similar as above but pulvinar- considerable increase	
Amino acids	GABA	Local circuit neurons in thalamic visual domain	Species difference
		Dorsal thalamus	
		Reticular N	
	Glutamate	Caudal part of medial group	
		Rostral part of pulvinar	
	Asparate	Middle part of the thalamus	
Gut–brain peptides	Cholecystokinin	Dorsal thalamus, intralaminar nuclei	
	Neurotensin	Periventricular nuclei	Widespread in CNS
	Neuropeptides Y	Periventricular zone	Fiber reaction
	Tachykinin	Immunoreactive fiber	Related to pain
		Posterior group (posterior nucleus, limitans nucleus, suprageniculate nucleus)	
		Intralaminar nuclei	
		Submedius nucleus	
Hypophysiotropic peptide	Somatostatin	Reticular nucleus, dorsal nuclei	
	DO	Anterior nuclei	Wide distribution
	Somatostatin		Septum
			Corpus striatum
Calcium binding proteins	Calbindin D-28	Central lateral nucleus, paracentral nucleus, central medial nucleus, parafascicular nucleus	All intralaminar nuclei
	Calretinin	DO Central lateral nucleus, paracentral nucleus, central medial nucleus parafascicular nucleus	
	Palvalbumin	Centromedian nucleus	
	Calretinin (gene)	Reticular nucleus, dorsomedial nucleus, intralaminar nucleus (rostral)	Heterogeneous
	Calretinin (immunohistochemical)	Very intense: submedius nucleus	Related to emotional and motivational state
		Strong: midline group	
		Moderate: reticular nucleus and anterior medial and lateral group	
		Weak: medial and lateral geniculate bodies	

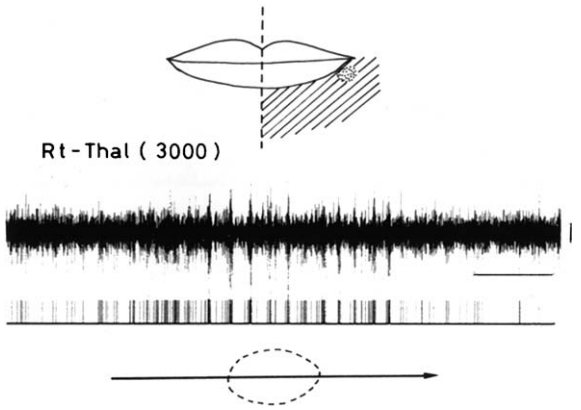

Figure 7 Cutaneous response of a thalamic VC neuron. (Top) Peripheral receptive field just under the left lower lip is illustrated. The small dotted area is the most sensitive. (Bottom) Thalamic responses are shown. Repetitive light touch is applied passing through the most sensitive area (dotted circle) from left to right (arrow).

hand area in the medioventral part, and the face area in the most medial part. No neuron has been shown to respond to different receptive fields or to different modalities (such as joint movement, heat, or pain). Inhibitory responses including so-called lateral inhibition that could be revealed by suppression of spontaneous spike discharge seem to be very rare.

When a stable response to natural tactile stimuli is recorded, electric stimulation on the same skin surface elicites the same spike response in the thalamus, with a fixed latency of approximately 10 msec (conduction velocity about 40–50 m/sec) in a given case. In analogy with animal experiments, this response is mediated via the lemniscal pathway and further projects to sensory cortex of Brodmann's area 3–1–2 although there is no direct evidence in humans.

In certain cases, at the thalamic point at which a cutaneous response is recorded, electric stimulation is given to test the sensations thereby elicited. Subjective perceptions are paresthesia, numbness, tingling, or electric sensation in the receptive field. Such unique observations may be realized only in human cases. However, it is not known how and where touch sensation arises. Also, it is noteworthy that destruction of a part of the VC nucleus results in paresthesias in the contralateral corresponding receptive field. Therefore, VC nucleus is an area that cannot be invaded for therapeutic purposes.

Anteroposterior lamellar distribution of dendrites of a sensory relay cell demonstrated by single cell staining in experimental animals has not been anatomically determined in human thalamus. However, a recent physiological study in the human thalamus demonstrated a possibility of similar lamellar organization in this nucleus.

B. Ventral Intermediate Nucleus or Nucleus Ventralis Intermedius

Rostral to the VC nucleus, between the ventral oral (VO) and VC nuclei, there is a wedge-shaped zone named the ventral intermediate (Vim) nucleus that contains clusters of large cells, scattered throughout. This fact is related to electrophysiologically very high spontaneous background activity. Also, recent histochemical staining revealed a cholinesterase-poor characteristic, in contrast to the cholinesterase-rich nature of VO and VC nuclei neurons.

In this zone with particularly high spontaneous activity, rhythmic grouped discharge time locked with contralateral tremor was found in Parkinson's disease in the early 1960s. It was a remarkable discovery made by French investigators and subsequently confirmed by many who used microrecording during the course of stereotactic surgery.

The early assumption was that the rhythmic discharge might be of a tremorogenic nature (origin of tremor); however, it is mainly the results of afferent impulse originating from trembling muscle. The most pertinent evidence is that the same unit discharge involved in rhythmic discharge also responds to passive stretch of the corresponding muscle and compression on that muscle can produce the same spike discharge (Fig. 8).

The peripheral receptive field is strictly contralateral, and there is no convergence from a different receptive field or different modality. In this sense, it is termed a "kinesthetic" response. The distribution of kinesthetic cells is mostly confined within the anatomically defined Vim nucleus or slightly extends caudally and dorsally. They are always found among a very high background activity zone (suggesting a zone of large cells) and the recorded points on X-ray film correspond well to the Vim nucleus zone in the stereotactic standard atlas. However, it should be noted that only the most lateral part of the nucleus is involved.

The most posteroventral area of the kinesthetic zone may extend slightly into the anteriormost part of the VC nucleus, namely the ventrocaudalis externus anterior, but there is no mixture of cells responding to kinesthetic and cutaneous stimuli, the former always located anterior to the latter. This fact is very important for practical, operative purposes because a

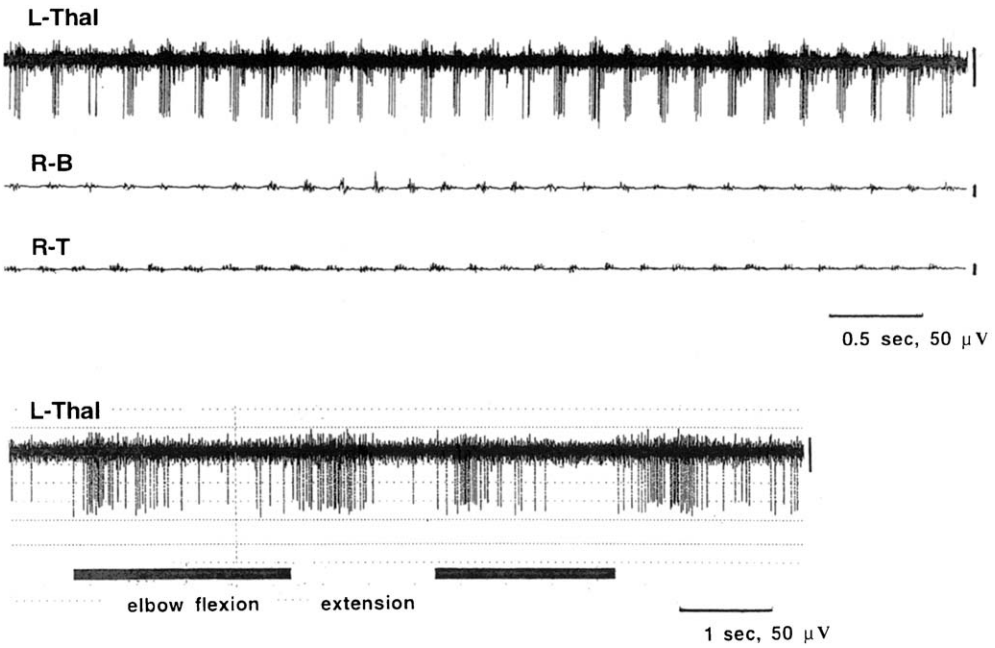

Figure 8 Rhythmic grouped discharge time locked with the contralateral peripheral tremor (top) and kinesthetic response (bottom) in the thalamic Vim, recorded in a case with Parkinson's disease. In the top set of recordings, the first trace is from the left thalamic Vim nucleus, and the second and third EMG traces are from the right upper arm. B, biceps muscle; T, triceps muscle. In the bottom set of recordings, the first trace is from the left thalamic Vim (the same neuonal activity as above), the thick lines depict the moment of elbow flexion, and spaces between thick lines depict the moment of elbow extension. The Vim neuron responded at both flexion and extension.

final therapeutic lesion (minimal effective volume is about 40–60 mm^3) including this kinesthetic region results in complete arrest of tremor, irrespective of its cause, without affecting cutaneous sense. It seems plausible that a point-to-point correspondence exists between peripheral tremor and thalamic kinesthetic cells.

Like the thalamic cutaneous cell in the VC nucleus, the kinesthetic cell in the Vim nucleus responds to electric stimulation given to the contralateral peripheral nerve innervating its receptive field. The shortest latency is about 10–12 msec from upper limb stimulation, and there is slightly faster conduction velocity than that of cutaneous origin (60 m/sec). The spinothalamic tract is postulated to be a possible ascending pathway mediating kinesthetic sense, but another possibility via the cerebellum cannot be denied. From Vim, it is thought to project to the cotical 3a area (Brodmann). However, there is no direct evidence in humans; hence, this should be clarified.

Acute electric stimulation of this kinesthetic point usually suppresses tremor. This fact is used widely for the treatment of parkinsonian tremor and other types of tremor. For this purpose, stimulation is applied through the chronically implanted electrode. The tremor stops only during repetitive (approximately 100 Hz) electric stimulation while the voluntary movement is maintained normally. Because this method is reversible in one sense, it is accepted for therapeutic purposes.

Careful observation on electric stimulation revealed that it often elecits a sensation of numbness or electric sensation at the peripheral receptive field. Also, stimulation of the medial part induces a turning sensation or elevator feeling, suggesting vestibular activation. It is claimed that the vestibular system projects to the medial part of Vim, the so-called Vim internus. In this regard, it can be argued that the main, medial part of the Vim nucleus (kinesthetic zone is only the lateral part) may be the receptive area of the cerebellar afferent, being the equivalent area of the so-called VL nucleus relay station of dentatothalamocortical motor area.

C. Ventral Oral Nucleus or Nucleus Ventralis Oralis

Early attempts (in the 1960s) to make a stereotactic therapeutic lesion in the VO area [ventralis oralis

anterior (Voa) and ventralis oralis posterior (Vop) of Hassler] were based on anatomical knowledge that pallidal fibers terminate in this thalamic area of Voa and cerebellar projection in Vop. The coagulative lesion was in fact large enough to cover the whole VO and may include the Vim nucleus. As a result of using microrecording techniques during the course of stereotactic surgery, the functional organization of this particular part is now fairly well understood.

Myeloarchitecturally, the VO nucleus is divided into two parts, anterior (Voa) and posterior (Vop), the former being more darkly stained. The Voa nucleus is believed to receive fibers originating from the internal segment of the globus pallidus and to project to the premotor cortex of Brodmann's area (BA) 6; the Vop is considered to receive cerebellar projection fibers and to send axons to motor cortex of BA 4, although direct evidence is lacking. Currently, however, there is ample evidence against the classical idea. Namely, as mentioned previously, both Voa and Vop consist of small-sized angular neurons; cell density is almost homogeneous. Moreover, VO neurons as a whole receive projections from the striatum, from the internal segment of globus pallidus. In an awake state, this nucleus exhibits low spontaneous background electrical activity superimposed by small-amplitude spike discharges. There is no sensory response to natural stimuli given to the contralateral body part, but activity related to voluntary movement occurs, as mentioned later. These features are recognized as characteristics of the VO nucleus, in marked contrast to its caudal nuclei, Vim and VC.

In the VO nucleus, so-called voluntary movement units exist, as shown in Fig. 9. The unitary spike activity increases firing only to an active movement of a part of the contralateral extremity and not to passive movement or to light touch on the corresponding skin surface. Response initiation time analysis revealed that the thalamic unit started firing before execution of the contralateral muscle contraction. The voluntary movement unit may transfer the signals to motor cortex. However, there remains a delicate problem of initiation of voluntary action.

In this region, other complex responses have been reported, including bilaterally activated cells, multi-unitary activity associated with arousal responses, and activation of cells of a complex polyfunctional type.

Electrical stimulation of the VO nucleus also produces changes in tremor rhythm in the contralateral extremity, if tremor exists. However, the response is variable; sometimes there is an increase of tremor and sometimes a suppression of tremor, suggesting that the VO nucleus is not directly related to tremor mechanism. Other motor effects, such as arrest of ongoing speech, errors in naming objects, and a kind of perseveration (repetition), were also noticed.

Clinically, a small stereotactic coagulation restricted to the VO nucleus results in alleviation of rigidity (muscle tone) but not of tremor in Parkinson's disease. Thus, the same procedure is effective for the treatment

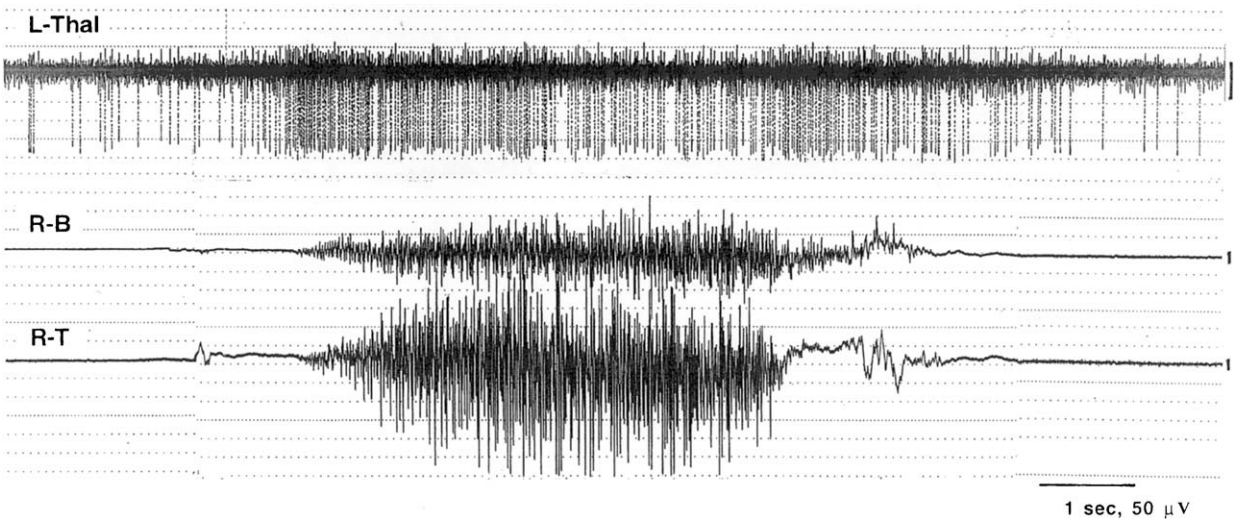

Figure 9 A left thalamic VO neuron related to voluntary action. The neuronal discharge increased (first trace) slightly before the start of elbow movement (attempt to raise arm) against examiner's resistance, indicated by EMG discharge of the contralateral upper arm. B, biceps muscle; T, triceps muscle.

of partial dystonia, several kinds of dyskinesia, especially DOPA-induced dyskinesia, and choreic movement. It should be noted that these disorders are related, more or less, to abnormal muscle tone.

Finally, the Voa and Vop nuclei have been regarded (according to Hassler's concept) as different components in the motor thalamus; curiously, however, both are considered to have almost the equivalent structure as the well-known motor thalamic nucleus in experimental animals, the ventrolateral (VL) nucleus. However, it would be reasonable to revise this concept: Voa and Vop nuclei are homogeneous with one of the thalamic motor nuclei, receiving striatal input. We assume that the majority of the Vim nucleus (except the lateral part) may correspond to the VL nucleus.

To summarize the current understanding of the input–output relations in the main ventral tier nuclei of the human thalamus, a simplified schema is shown in Fig. 10.

D. Other Nuclei

Apart from the previously mentioned ventral nuclei that have been investigated extensively because they are the target of choice for stereotactic surgery, there are several other thalamic nuclei that have attracted attention.

1. Ventral Anterior Nucleus

The ventral anterior (VA) nucleus located just rostral to VO, divided at least in two parts: VA magnocellular (VAmc) and VA parvocellular (VApc). VAmc receives projection from the substance nigra reticulata and probably sends fiber to the prefrontal cortex of areas 8–10, whereas VApc receives the pallidal projection and sends fiber to the cerebral cortex of area 6. It should be noted that there is some discrepancy in the naming of the pallidal projection nucleus. Experiments in monkeys showed that the pallidothalamic projection fiber terminates in two part of VA: VApc and VA densicellular (VAdc). According to this classification, VAdc may correspond to VLo of Olszewski or Voa of Hassler, a member of the VO nucleus.

Few physiological studies on these nuclei have been conducted. A Canadian group found rhythmic discharge time locked to the contralateral tremor in the VA zone (subdivision not defined) and a coagulation in this area was also effective for parkinsonian tremor. If

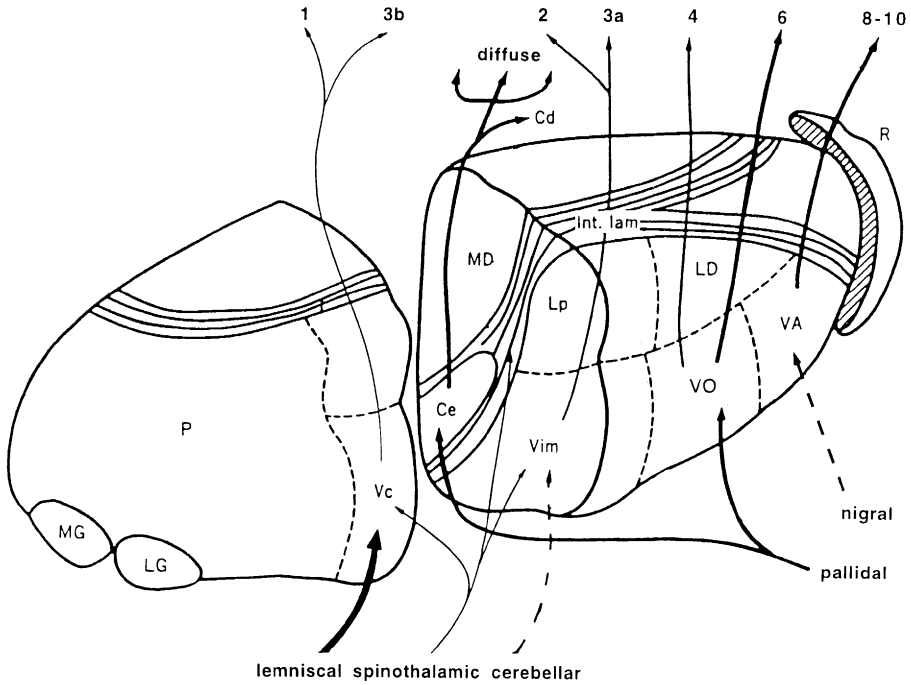

Figure 10 Simplified schema of input–output relations of the thalamic ventral tier nuclei. Numbers indicate Brodmann's cortical numbers. Cd, caudate nucleus; Ce, centromedian nucleus; Int. lam, internal medullary lamina; LD, lateral dorsal nucleus; LG, lateral geniculate body; Lp, lateral posterior nucleus; MG, medial geniculate body; P, putamen; R, reticular nucleus; VA, ventral anterior nucleus; Vim, ventral intermediate nucleus; VO, ventral oral nucleus.

pallidal surgery is effective for tremor as recently claimed, for coagulation of the VA nucleus, a part of which receives pallidal projection, it is not surprising to find tremor rhythms in VA. Unfortunately, there are no follow-up studies.

2. Reticular Nucleus

The reticular nucleus wraps around the thalamus. As described previously, it originates from the ventral thalamus embryologically, being differnt from other neurons of the so-called dorsal thalamus. It has a wide network with the other thalamic nuclei as well as cerebral cortex and brain stem reticular formation. This nucleus is considered to be related to arousal, attention, cognitive function, etc. Also, as discussed later, it plays a role in maintining cortical activity in a disease state of epilepsy.

A Russian group studied the human thalamus using microrecordings during stereotactic thalamotomy for dyskinesia and found verbal command neurons in this nucleus and adjacent area. They classified three types of neurons: A-type neurons exhibited irregular sporadic spikes that were usually activated by imperative verbal command, B-type neurons showed spontaneous rhythmic burst that was inhibited during the command presentation, and C-type neurons showed aperiodic long-lasting burst discharge without responding to verbal command. They discussed a possible role for a basic regulatory mechanism allowing the performance of speech-mediated voluntary movements.

3. Noxious Neurons

It has long been debated whether there is a particular group of neurons responding solely to noxious or thermal stimuli in human thalamus as well as in animals. Such nociceptive neurons have been discovered. Neurons of the nucleus submedius located under the VC nucleus are activated by noxious stimuli.

Recently, exploring the human VC nucleus during the pain surgery, a Canadian group discovered a small restricted zone, microstimulation of which evoked pure cold sensation and neurons there responded to innocuous cooling. They claimed that it is the first direct electrophysiological evidence for a human thalamic relay site for the cold sense pathway. This nucleus may correspond to the ventral medial posterior (VMpo) nucleus situated just ventral to the centromedian parafascicular (CM–Pf) complex and caudal to CM and ventral posteromedial nucleus (VPM). The VMpo was described in 1996 by American investigators as a parvalbumin-rich zone in rat and monkey. The VMpo neurons responded solely to noxious and thermal stimuli. The clinical significance of this nucleus is not clear.

4. Pulvinar

Pulvinar is the largest nucleus in the thalamus, located most caudally. On the philogenetical scale, it is a newly developed nucleus, simultaneously developing with an increase in association cortex in the primate. Therefore, interspecies difference is marked. In primate and human, it is roughly divided into four parts: oral (or superior), medial, lateral, and inferior pulvinar. Several different functions have been suggested, but recently it has been considered to be related more to the visual system, playing a role as the secondary visual system or extrageniculate visual system. Especially in the inferior pulvinar of experimental animals, there is a direct connection from the contralateral retina (not via lateral geniculate body). Also, there are close reciprocal connections between visual cortex (BA 17), superior colliculus, prefrontal cortex, parietal association cortex (angular gyrus and supramarginal gyrus), and temporal lobe, being involved in the higher cognitive functions such as symbolic experession. Pulvinar is correlated with attention behavior; therefore, if it is damaged, visual neglect often occur.

Using stereotactic surgery, a group tried to make a lesion here in cases with intractable pain or a kind of involuntary movement. While microrecording during the course of surgery, several pulvinar neurons fired synchronously with the rhythmic electroencephalogram of the pulvinar. Also, some pulvinar neurons increased firing during voluntary action or during combined stimuli, such as voluntary action plus visual or auditory stimuli.

5. Dorsomedial Nucleus

This nucleus is a large mass located medial to the internal medullary lamina. It is divided into different subdivisions, but probably its medial part, the magnocellular part of the nucleus, is relatively well-known because it receives direct input from the rhenal cortex and amygdala, both related to cognitive memory function. It also has connections from the prefrontal cortex, temporal lobe, and basal forbrain area. Hence, it may play an important role in higher nervous function. Clinically, it is well-known that damage to this area induces personality changes and memory disturbance known as antegrade amnesia.

In this connection, it should be remembered that the first human stereotactic surgery was performed to destroy a part of this nucleus in a patient with mental illness by Spiegel *et al*. in the mid-20th century. Their original idea was to eliminate the uncertainty of frontal lobotomy frequently used at that time and to avoid undue damage of overlying healthy brain structures by open surgery.

6. Intralaminar Nuclei

This nucleus, embedded in the internal medullary lamina, consists of centralis lateralis, paracentralis, central medial nuclei (anterior group), and centromedian and parafasciculus nuclei (posterior group). The latter is often called the centromedian–parafascicular complex. The anterior group receives diverse projections from the spinothalamic tract, deep cerebellar nucleus, brain stem reticular formation, etc. The posterior group has a reciprocal connection with the basal ganglia. The efferent connection with the cerebral cortex is very wide and was once thought to be a diffuse projection. However, it is now known that each intralaminar nucleus has its own topographic projection area and projection pattern is somewhat heterogeneous.

The intralaminar nuclei has been a main focus of anatomophysiological investigations on the organization of the thalamocortical system. It was classified as a representative of the ''nonspecific system'' rather than the ''specific system,'' such as the thalamic relay station for the visual, auditory, or somatosensory system with definite modality-specific peripheral input. Due to many multidisciplinary studies performed during the past 50 years, the meaning of nonspecific system has changed because the morphological understanding of the thalamocortical connection is far advanced and the physiological mechanism of recruiting response, for example, has been precisely analyzed into synaptic events. Functionally, on the basis of this recent knowledge, the mechanism of sleep–wakefulness, the dual behavioral basis of animal life including humans is gradually becoming clearer.

IV. THALAMIC DAMAGE

There are several different kinds of thalamic damage that induce particular clinical symptoms. Vascular damage, thalamic tumor, and degeneration are the most common causes. The clinical features are closely related to the site of affected thalamic nucleus. Therefore, precise clinical study, especially clinicopathological analysis, has contributed greatly to understanding the function of the particular thalamic nucleus thus involved. It can be understood that medial thalamic damage leads to disturbance of consciousness, cognitive function, personality, etc. more or less related to higher nervous activity, whereas the lateral thalamic damage results in the disturbance of somatosensory function.

A. Thalamic Syndrome

At the end of the 19th century, a particular syndrome with sensory disturbance, movement disorder, and often severe pain in one side of the body without any damage to the affected area attracted the attention of German neurologists and thalamic vascular damage was suspected as the responsible pathology. Later, French neurologists Dejerine and Roussy described its exact pathological lesion: the thalamic ventralis posterior lateral nucleus (VC of Hassler).

The core symptoms of thalamic syndrome are (i) mild hemiparesis, ususally without contracture, and early recovery; (ii) continuous hypesthesia of superficial sense, sometimes replaced by hyperesthesia of superficial sense, always accompanied by disturbance of deep sense; and (iii) slight hemiataxia and astereognosia. These symptoms are often accompanied by continuous severe pain developing later on the paretic side (it is intolerable but there is no effective remedy) and choreoathetotic movement developing on the side of motor paresis.

The previously mentioned clinical description has been accepted and the vascular damage (either hemorrhage or infarction) in the VPL (VC) was established, as the responsible pathology, together with its responsible artery, the so-called thalamogeniculate artery.

Regarding the developmental course of thalamic syndrome, it was found that the major vascular impact was ususally not related to the later development of thalamic pain but rather minor damage induced pain after several months to 1 year after stroke (Fig. 11). This may be due to the fact that a large lesion destroys the main sensory nucleus of VC and surrounding area concomitantly, whereas a small lesion affects only a part of VC and causes irritaion in the adjacent area. In fact, microrecording during the course of stereotactic thalamotomy showed many abnormal irregular burst discharges in and around the VC nucleus and Vim nucleus as well (Fig. 12). Within the supposed VC

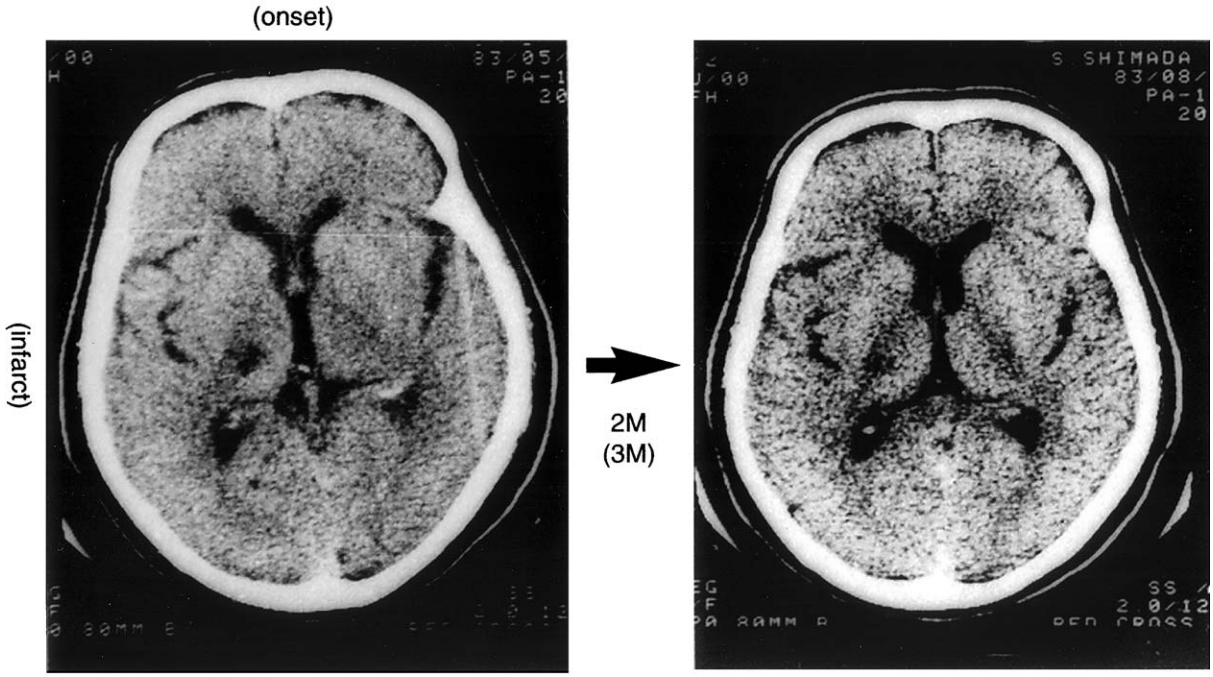

Figure 11 Vascular damage that caused typical thalamic pain. (Left) CT image of the infarction (low-density area) in the right posterior thalamus just after the stroke (onset). (Right) Follow-up CT image in the same patient 2 months (2 M) after stroke. Thalamic pain gradually developed after 3 months (3 M) in this case. The remaining responsible lesion (infarct: low-density area) was much reduced.

nucleus, the background activity was low and the sensory response to cutaneous stimuli was disorganized, with the usual topographic representation being lost and often the face area occupying a wider distribution than that of the usual VC nucleus. Moreover, it was often the case that convergent response to peripheral stimuli was encountered. Therefore, in cases with thalamic pain syndrome, the thalamic VC nucleus is disorganized after vascular damage and some plastic change may take place during the recovery course, leading to the reorganization. Microstimulation of the VC nucleus in the thalamic pain patient induces pain sensation of the patient's own pain. This is noteworthy because usually stimulation of the thalamic VC nucleus results in the sense of paresthesia but not pain.

Clinically, we tried to make a coagulation including the abnormal VC area and a part of Vim where the neuronal activity was also different from that in the usual Parkinson's disease. As mentioned previously, Vim neurons are assumed to receive muscle sense; this operation is more effective for the thalamic pain patient with deep pain than the patient with predominant superficial pain.

The mechanism of the thalamic pain has not been clarified. Dejerine and Roussy discussed the possible abnormal excitation at the level of terminal ascending fibers and terminal neurons of the pain system. There are other hypotheses, for this mechanism, including the released corticothalamic inhibitory system, a disorder of the filter function of the thalamus, and the problem of isolation in the damaged pain conducting fibers. It is interesting to note that a recent study put forward the possible upregulation or downregulation of transmitter receptors (probably noradrenaergic). We assume that the abnormal irregular burst activity of the viable VC neurons caused by the adjacent affected part of the VC nucleus is certainly responsible for production of the chronic pain, but there is no reasonable explanation. Because the development of pain takes time after stroke (often several months), the strong influence from these abnormal zones over the central nervous system, directly or indirectly connected, may cause unusual neural networks to be established in due course.

B. Other Vascular Disorders

Apart from the well-known thalamic syndrome described previously, other types of thalamic hemorrhage and infarction may occur. Using computerized three-dimensional imaging, different kinds of vascular

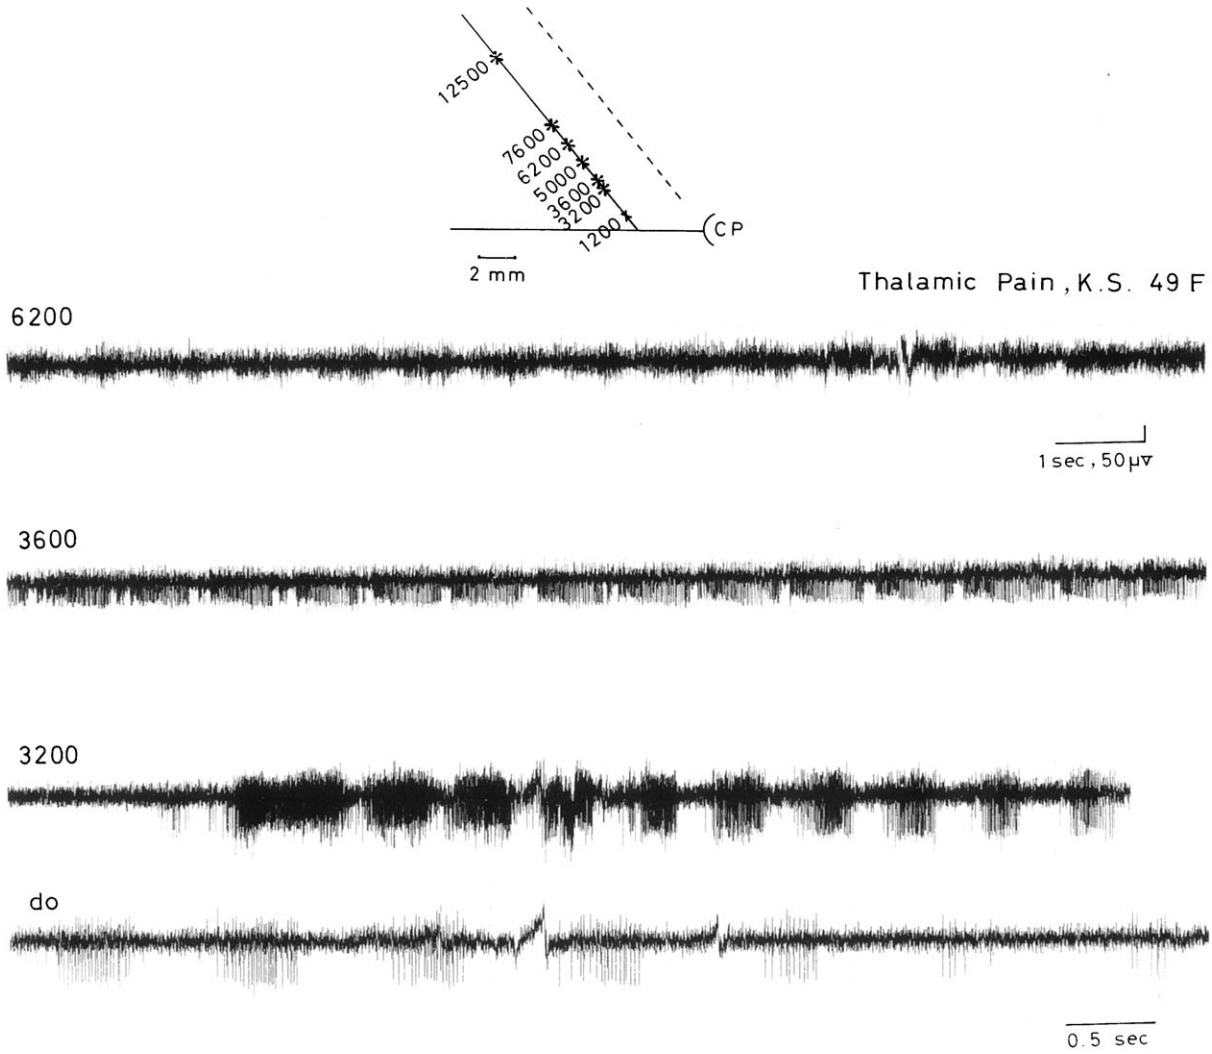

Figure 12 Abnormal irregular burst discharges recorded in a case with thalamic pain. (Top) A lateral view of recording track (an oblique line) referring to the intercommissural (IC) line (a horizontal line) to show the recording site (asterisks) along the anterior track. There was no recording from the posterior track (dotted line) in this case. CP, posterior commissure; Numbers indicate distance in micro meters from zero at the level of the IC line.

damage are easily visualized and these lesions are correlated with clinical symptoms. Thus, it is reasonable to understand thalamic vascular damages with respect to the specialized blood supply to the thalamus. However, there are problems of nomenclature of blood vessels and the variety of blood vessels (origin and course of small thalamic vessels). Therefore, one should be careful to refer to the literature. There are at least five main vessels. Here, the most common naming and synonyms are listed with location of blood supply.

- Anterior choroidal artery, originating from carotid artery

  — Posterolateral part of thalamus
- Tuberothalamic artery (anterior thalamoperforating artery, polar artery), originating from posterior communicating artery (this artery is often lacking)

  — Reticular nucleus, part of VL, dorsomedial nucleus, mammillothalamic tract
- Paramedian artery (posterior thalamosubthalamic paramedian artery, posterior thalamoperforating artery), originating from P1 part of posterior cerebral artery (PC)

  — Internal medullary lamina, dorsomedial nucleus, VPL and VPM (internal side), upper mesencephalon

- Thalamogeniculate artery (principal inferolateral artery), originating from P2 part of PC
  — VPL and VPM, VL, pulvinar
- Posterior choroidal arteries (medial and lateral branch), originating from P2 part of PC
  — Lateral and medial geniculate body, pulvinar, subthalamic region, part of substantia nigra

In Fig. 13, these arteries are illustrated schematically with their respective main locations.

Recent clinicopathological studies of cases with thalamic hemorrhage have demonstrated its clinical features in relation to the responsible artery. Results are summarized in Table II. In cases with infarction, the clinical features are essentially the same as those in cases with hemorrhage but usually less severe because of more restricted damage compared to that of hemorrhagic lesion.

It should be mentioned that contrary to the classical thalamic syndrome, analgesia and thermoanesthesia of thalamic origin have been observed clinically. These clinical symptoms have been known since the early 20th century as poststroke symptoms but their pathophysiological analysis was somewhat behind that for the thalamic pain. As mentioned previously, the recently reported group of specific nociceptive and thermoceptic neurons of VMpo may be responsible for these symptoms, although no direct evidence has been provided.

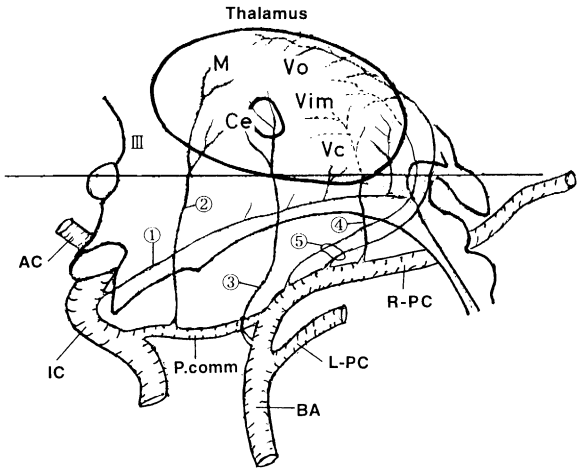

Figure 13 Schematic illustration of the blood supply (1–5) in the thalamus. Right thalamus and the third ventricle are viewed from the medial side. In the thalamus, only representative nuclei are marked. M, dorsomedial nucleus; Ce, centromedian nucleus; Vo, ventral oral nucleus; Vim, ventral intermediate nucleus; Vc, ventral caudal nucleus; 1, anterior choroidal artery; 2, tuberothalamic artery; 3, paramedian thalamic artery; 4, thalamogeniculate artery; 5, posterior choroidal arteries. AC, anterior cerebral artery; IC, internal carotid artery; P. comm, posterior communicating artery; L-PC, left posterior cerebral artery; R-PC, right posterior cerebral artery. Dotted parts of the small arteries indicate lateral, hidden side of the thalamus. Horizontal line is the intercommissural line.

C. Movement Disorder

Contrary to the previously mentioned sensory disturbances caused by damage in and around the VC nucleus, the pathophysiology of movement disorders of thalamic origin is not always clearly understood. Although mild motor paresis, ataxia, choreoathetotic movement, and dystonia are claimed to occur after thalamic damage (by vascular, tumoral, or degenerative lesion), it is doubtful that a restricted lesion in the thalamus produces such motor disturbance. Because these symptoms are otherwise caused by capsular, cerebellar, and basal ganglia and brain stem lesion, they could be explained as secondary symptoms due to the disruption of a specific neural loop connected with one of the thalamic ventral tier nuclei (VA, VO, Vim, and VC).

Moreover, it should be remembered that the stereotactic intervention in certain thalamic nuclei (mainly VO and/or Vim) is useful for the treatment of movement disorders such as tremor and rigidiy of Parkinson's disease and other kinds of tremors, dyskinesia, choreic movement, dystonia, etc.

D. Thalamic Tumor

The incidence of thalamic tumor is low, about 1% of all intracranial primary tumors. In fact, thalamic tumor is usually classified as an item of tumor of rostral brain stem and basal ganglia. There is no specific primary brain tumor that develops within the thalamus, but glial tumors (e.g., astrocytoma, oligodendroglioma, and glioblastoma often in children or adolescents) and malignant lymphoma may grow in the thalamus.

Often, the thalamic tumor grows to a large size, occupying mass without noticeable signs and symptoms. With the progress of tumor size, headache and nausea caused by obstructive hydrocephalus due to compressed foramen Monro are the most common symptoms (Fig. 14). Some specific symptoms indicate the possible location of the tumor. For example, movement disorder is caused by damage or compression of the VO area and invasion into the internal

Table II
Types of Thalamic Hemorrhage and Responsible Arteries

Type	Responsible artery	Main symptoms	Prognosis
Anterior	Tuberothalamic artery	Acute behavioral abnormality	Benign prognosis
Posteromedial	Paramedian artery	Marked hydrocephalus due to bleeding into the third ventricle	Worst prognosis
Posterolateral	Thalamogeniculate artery	Large hematoma	
		Marked sensory motor signs	
		Dejerine–Roussy syndrome	Common
		Right-side hemineglect; left, language problem	
Dorsal	Posterior choroidal artery	Moderate hematoma	Excellent recovery
		Sensorimotor signs	
Global	Combined	Massive hemorrhage	
		Severe sensorimotor signs	Death
		Conscious disturbance	

capsule; sensory disturbance is caused by VC invasion; and mental confusion, personality change, and memory disturbance are related to the medial nuclei and internal medullary lamina. Diagnosis is easily made by computed tomography (CT) scan or magnetic resonance imaging, and malignancy is suspected by positron emission tomography (PET) scan when higher uptake of glucose metabolism or methionin is found. An example is shown in Fig. 15.

As the secondary brain tumor that emanates from other organs besides the brain, the metastatic tumor is increasingly found and the thalamus is also involved. Tumors of the third ventricle (plexus papilloma, ependymoma, and astrocytoma) or basal ganaglia can compress or invade the thalamus.

Because the thalamus is deep in the brain, direct attack for removal of the tumor is a challenging strategy. A stereotactic approach with the aid of three-dimensional imaging and microscope is one a possible procedure. As adjuvant therapies, stereotactic radiosurgery by Gamma Knife or LINAC irradiation often with some kind of chemotherapy are performed. Complete remission is almost impossible and the prognosis is generally poor.

E. Degeneration

Degenerative disease specific for the thalamus is rare. In the literature, only approximately 10 cases have been reported since the first description by Stern. In these cases, the most characteristic clinical symptoms were progressive dementia and conscious disturbance often accompanied by the cerebellar symptom involuntary movement. In most cases, in the thalamus, anterior group and dorsomedial nucleus were symmetrically affected, showing severe cell loss and gliosis. Once, this disease was considered to be a thalamic type of Creuzfeld–Jacob disease (Stern–Garcin syndrome), but now it is recognized as primary thalamic degeneration (without spongiosis). Even in these cases, mild degeneration was noticed in other nucleus, especially in the inferior olivary nucleus. Similar primary degenerative changes in certain thalamic nuclei were reported in Japan. In cases with rapidly progessing mental deterioration (amnesia and dementia) and movement disorder, autopsy revealed symmetric degeneration in the thalamus, especially in the dorsomedial nucleus, lateral posterior and dorsal posterior nuclei, and pulvinar. It was emphasized that these nuclei were a relatively late developing group in the ontogenetic course.

Some of the systemic degenerative process involves thalamic neurons as well. For example, it was noticed that smaller neurons of the VL nucleus (not defined clearly) decreased in Huntington's chorea, in which degeneration of the smaller neurons of the caudate nucleus is essential. Also, a similar change was observed in the VA nucleus. In a particular type of amyotrophic lateral sclerosis, eosinophilic inclusion body was found in the thalamus. Also, in pallido–nigro–Luysian atrophy, Lewy body-like inclusion was found in the thalamic parafascicular nucleus and the centromedian nucleus, in addition to other parts of the central nervous system. Other types of systemic degenerative disease, such as Pick's disease, olivopontocerebellar atrophy, and Friedleich's ataxia, are also known to exhibit thalamic degeneration

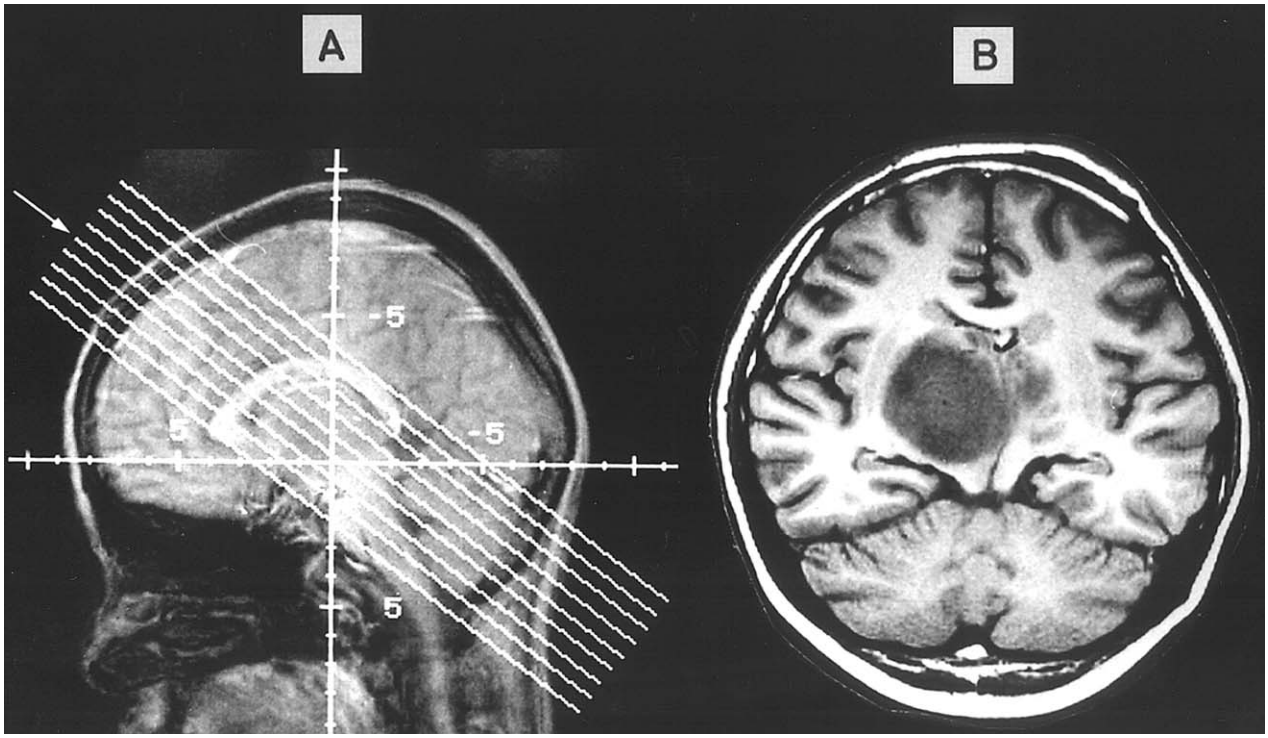

Figure 14 MRI of the right thalamic tumor (malignant glioma) in a young girl. (A) Scout view showing the direction of the brain slice. Arrow indicates the semiaxil slice corresponding to the image in B. (B) A large thalamic tumor in the right thalamus, compressing the lateral ventricles.

concomitantly. In the literature, however, description of the degeneration in the thalamus is not frequent.

F. Others

In certain conditions of thalamic damage by vascular, tumoral, or degenerative effects as mentioned previously, several types of abnormal state are recognized.

1. Thalamic Amnesia

When the anterior part of the thalamus is destroyed, so-called thalamic amnesia (antegrade type) may occur. Precise analysis (lesion that may cause amnesia vs lesion that may not cause amnesia) of such cases using CT scan revealed two important elements. One is the mammillothalamic tract connecting the mammillary body and the thalamic anterior nuclei, forming a loop from hippocampal formation to mammillary body and anterior thalamic nucleus. The latter tract is also known as Vic d'Azur. The other is the amygdalothalamic projection (ventroamygdalofugal pathway), connecting amygdala and thalamic dorsomedial nucleus. In the anteromedial thalamic area, the latter pathway runs adjacent to the mammillothalamic tract. Therefore, it is interesting to note that only when these two tracts are interfered does thalamic amnesia occur; if one of them is spared, no amnesia is noticed.

Therefore, the essential element for thalamic amnesia is not a lesion of the thalamic nucleus but fiber tract connecting extrathalamic components related to the memory system. Hence, if the thalamic damage is repaired, amnesia may disappear.

2. Thalamic Aphasia

As in the case of cortical aphasia, it is the posterior part of the left thalamus that may cause thalamic aphasia. Language disturbance of primary thalamic origin has been discussed for a long time; if it really exists, what nucleus is responsible? Although recent imaging and autopsy studies list a part of the dorsomedial nucleus, the centromedian–parafascicular complex, a part of the VL nucleus (VO), the pulvinar, etc. as the responsible thalamic lesion, the exact lesion has not been clarified. For example, the role of the dorsomedial nucleus was strongly suspected, but there were cases without aphasia in which the dorsomedial nucleus was damaged.

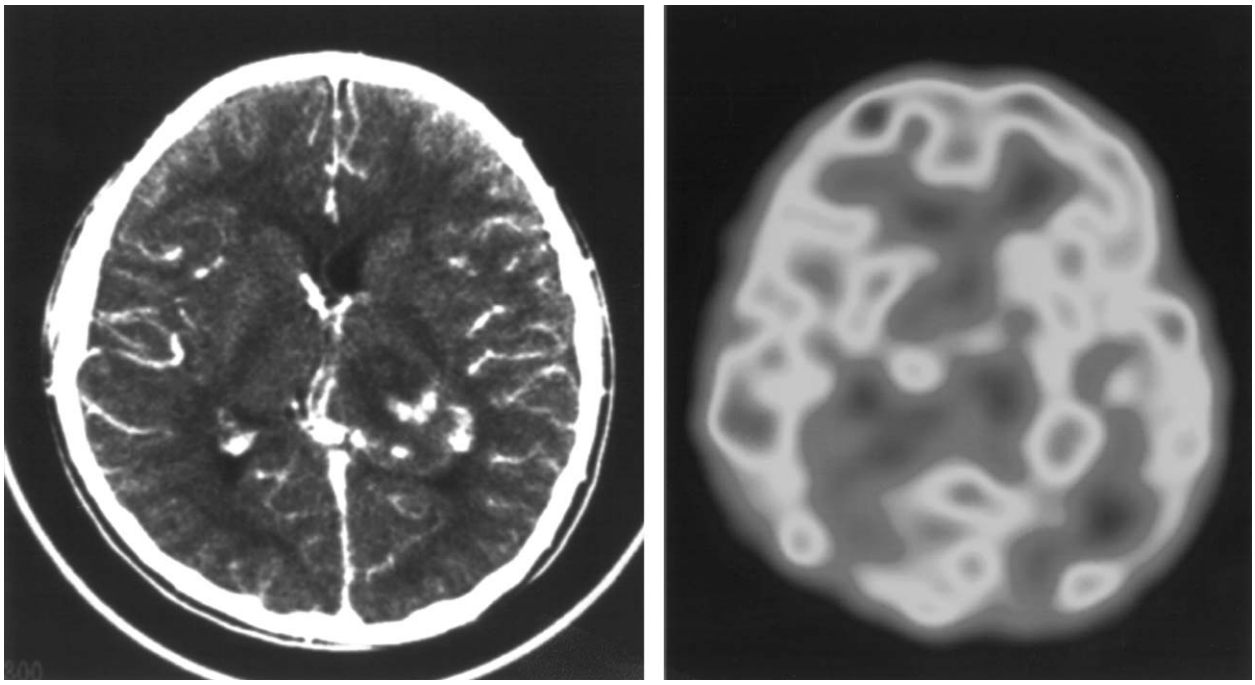

Figure 15 A left thalamic tumor demonstrated by CT image (left) and PET scan (right). The thalamic tumor is seen in the posterior part of the left thalamus as a low-density shadow with an irregular high-density area at its caudal end, the latter showed high uptake of FDG in the right PET image. Diagnosis was anaplastic astrocytoma in this 11-year-old boy. (courtesy of Dr. T. Shibasaki).

Another possible explanation for thalamic aphasia is the decreased thalamic influence on the related cortical area. In fact, cortical blood flow measurement by PET or single photon emission computerized-tomography has often revealed a marked decrease of blood flow in the left cortical area in cases of thalamic damage with aphasia. In such cases, thalamic damage causes a decrease in excitatory input to the cortical activity, which in turn reduces its blood supply. Further analytical study is expected.

The thalamic aphasia is similar to a type of so-called transcortical aphasia. In this category, repetition is preserved, although other language functions, such as spontaneous speech, comprehension, reading, and writing, are more or less disturbed.

It is relevant to mention studies of stereotactic thalamotomy on language function. The arrest of speech by electrical stimulation of the VO area was reported several times. It occurs only during repetitive electrical stimulation, for example, when a patient is counting numbers or telling a story. Whether it is due to an effect on the specific language mechanism or just tremor arrest on movement in general is not clear.

Also, it is well-known that bilateral thalamotomies (not in one procedure) induce speech disturbance, often referred to as dysarthria and dysphasia (mild aphasia). Sometimes, only one-sided thalamotomy results in the same kind of speech disturbance (left side is dominated). However, with the aid of microrecording to identify the exact target point in the Vim nucleus for tremor surgery, for example, postoperative speech disturbance is much reduced even after bilateral operation. Probably, a relatively large lesion including the thalamic pharyngial representative zone is responsible for inducing such speech problems.

3. Epilepsy

Among various epileptic seizures, petit mal or absence is considered to be closely related to the thalamus, in the sense that projection neurons of the thalamus play an important role in cortical seizure activity. According to basic studies, the thalamocortical triangular circuit that consisted of cortical neurons of the superficial layer, thalamic reticular neurons, thalamic diffuse projection neurons of the intralaminar nucleus, is the essential element. The synaptic events in this thalamocortical reciprocally connected loop maintain the seizure activity.

Clinically, absence seizure is characterized, in a typical case in children, by abrupt (no aura) arrest of movement or behavior, with head drop posture or upward gaze in vain with eyes open. Within a few second, consciousness returns completely to the normal level without any postictal deficit. The patient has no memory of the seizure. During epileptic seizure, bilaterally synchronized and generalized (but frontal dominant) "three-cycle spike and wave" in EEG is well-known and has diagnostic value. Also, three-cycle spike and wave synchronized with cortical EEG has been recorded from the thalamic depth. Thus, it was once called a centroencephalic seizure, which includes the generalized type of epileptic seizure.

V. CONCLUSION

Anatomy, physiology, and disease of the human thalamus were described briefly. Although the modern techniques of neuroscience are limited to use in humans, meticulous clinical observation and stereotactic surgery experience with microrecording provide useful information about the structure and function of the human thalamus. Many problems remain to be solved, but with the development of new techniques the future of thalamic study is promising.

GLOSSARY

basal ganglia A group of nuclei situated in the internal portion of each cerebral hemisphere. The definition of basal ganglia varies but typically includes the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and substantia nigra. Different terms are applied to various subdivisions of the basal ganglia. The putamen and globus pallidus comprise the lenticular nucleus. The caudate nucleus and putamen comprise the striatum.

Brodmann areas Neuroanatomically distinct areas of the cerebral cortex derived by Korbinian Brodmann, a German neurologist, based on the organization of cells or the cytoarchitecture of the human brain. Functional distinctions of brain regions correlate remarkably well with this neuroanatomic differentiation.

cerebellum The cerebellum is attached to the posterior surface of the brain stem by fiber bundles called cerebellar peduncles. The midline of the cerebellum forms the vermis and the larger portions on each side are the lateral hemispheres. The cerebellum receives sensory input from most of the cerebral cortex, which then projects back from the deep cerebellar nuclei by way of the brain stem and thalamus. The deep cerebellar nuclei consist of the dentate nuclei in the lateral hemispheres, the emboliform and globus nuclei, which are medial to the dentate, and the fastigial nuclei, which are the most medial of the nuclei.

dopaminergic neurons Most dopaminergic neurons are located in the midbrain, including the dorsal portions of the substantia nigra. Fiber pathways from the substantia nigra project to the caudate and putamen. In Parkinson's disease there is neuronal loss in the substantia nigra, which reduces activity in receptors that terminate in the caudate and the putamen.

frontal lobes The frontal lobes are located anterior to the central sulcus and consist of four major areas: the primary motor cortex, the premotor area, Broca's area, and the prefrontal cortex. General functions subserved by the frontal lobe included movement initiation, the production of language, executive processes involved in working memory, and aspects of personality.

functional imaging methods Scientific methods for investigating brain–behavior relationships. Two main functional imaging techniques are positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). PET techniques involve intravenously injecting various short-lived radioactive agents and then imaging subjects in a specialized detector system to examine biochemical or physiological processes involved in cerebral blood flow and metabolism. Like PET, fMRI techniques are noninvasive and produce images of brain activation by detecting the indirect effects of neural activity on local blood volume, flow, and oxygenation. The most common fMRI technique for brain mapping involves blood oxygen dependent-level contrast that detects endogenous changes in local concentrations of paramagnetic deoxyhemoglobin associated with local increases/decrease in neural activity. Relative to PET, fMRI has superior temporal and spatial resolution.

lesion method A scientific method for investigating brain–behavior relationships by studying patients with focal brain lesions or neurodegenerative disorders that primarily affect a specific brain region.

long-term memory A repository where information can be stored for long periods of time and retrieved or recalled in accord with current goals.

parietal lobes The parietal lobes are located posterior to the central sulcus and are divided into the primary somatosensory, the

superior parietal, and the inferior parietal lobes. The inferior parietal lobe is further subdivided into the supramarginal gyrus and the angular gyrus. These structures are important for many functions, including processing sensory information, language comprehension, attention, and spatial perception.

prospective timing A term used to describe estimation of current time.

temporal lobes The temporal lobes are located inferior to the lateral sulcus and are divided into the superior, middle, and inferior temporal gyri. Various portions of the temporal lobe are important for memory, higher order processing of visual information, language comprehension, and audition.

timekeeper mechanisms Explicit control of prospective timing is thought to be implemented by a hypothetical timekeeper mechanism. A clock metaphor is used to describe the timekeeper, which represents subjective time through the accumulation of periodic pulses, possibly generated by oscillators.

working memory A short-term repository where information is temporarily stored before it is transferred to long-term memory. Working memory is composed of two main processes. Rehearsal processes repeat information to maintain it in working memory. Executive processes manipulate information in accord with current goals (e.g., comparing two intervals of time).

Psychologists' long fascination with the study of time is evident from the immense body of research that has grown over the years. In our daily life, we are so accustomed to experiencing time that frequently there is no conscious awareness of it. For example, the perception of time in the range of tenths of milliseconds is necessary for detecting formant changes in speech, but we have no awareness of these intervals. Longer intervals are more easily accessible to consciousness, but their processing differs depending on whether time perception is retrospective or prospective. Our memory for time in the past is thought to be estimated using information in the environment to reconstruct elapsed time. Therefore, for example, when reflecting on how much time has gone by since last seeing a close friend, one might use notable events such as a holiday or a place of encounter to reconstruct the passage of time. This contrasts with our subjective perception of the present in which events in the hundredths of milliseconds up to about 3 sec appear to require a central timekeeping or pacemaker mechanism. A clock metaphor is commonly used to describe the timekeeper mechanism, which represents subjective time through the accumulation of periodic pulses within a particular physical time. This article focuses on prospective timing of these relatively short intervals because they are thought to structure actions and our perception of objects and events, both of which can be abnormal in patients with central nervous system damage. In view of the extensive literature on temporal processing, this article is further confined to the study of time perception, except to briefly note that although support exists for analogous timekeeper mechanisms in movement, timing can also emerge from properties of movements, such as their force or trajectory.

I. INTRODUCTION

In this article, we explore the mechanisms by which the brain times events and stores them in memory for later use. This is of great interest to neuroscientists not only because there are a variety of neurological disorders in which the timing of behaviors appears abnormal (e.g., Parkinson's disease, Huntington's disease, and cerebellar damage) but also because insight into the underlying neural substrate(s) has important implications for understanding everyday perceptual and motor activities (e.g., playing a musical instrument and driving an automobile) that depend on timing precision. A prevailing model of temporal processing is first reviewed, along with a description of paradigms commonly used for investigating these phenomena. We then discuss the insights into the neural underpinnings of time perception provided by studies of patients with neurological disorders. Although significant contributions have been gained from this line of investigation, the emergence of functional neuroimaging technologies has offered a converging methodology, which may help clarify some of the issues in this area. This literature is discussed, including a recent study in which we charted the evolution of brain activation patterns during time perception using event-related functional magnetic resonance imaging (fMRI). Although important research has also been conducted using electrophysiological and pharmacological approaches, this relevant work is acknowledged only in brief due to necessary limitations in the scope of this article. Our current understanding of the neural systems that modulate time perception from converging lines of research will then be integrated into a framework that we hope will be useful for guiding future investigations.

II. COGNITIVE MODELS OF TEMPORAL PROCESSING

Many theories have been put forth to explain prospective timing, but most embody similar processes

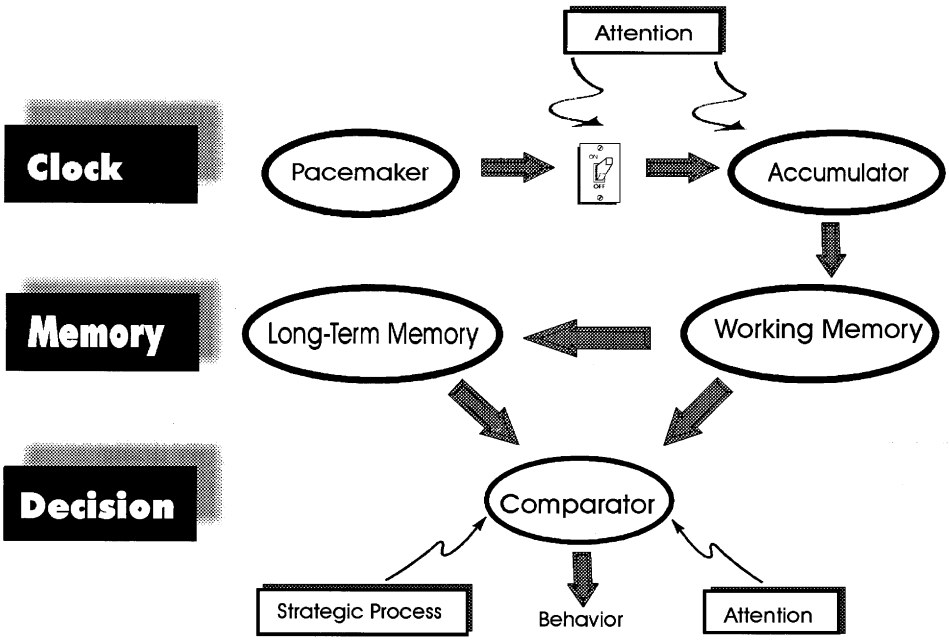

Figure 1 Diagram of the key components of temporal processing. The clock component consists of a pacemaker, which represents time through the accumulation of internal pulses. Pulses are turned on and off by a switch and then passed into an accumulator to be counted. Accumulated pulses are passed on or encoded into working memory, where interval representations are temporarily maintained and manipulated in accord with current goals. Over time, more enduring interval representations are stored in long-term memory. Decision process compares pulse counts from the accumulator with ones in memory to determine when or how to respond.

and there is a remarkable resemblance among them in their predictions. Figure 1 illustrates the key component processes of an influential theory of John Gibbon and colleagues, scalar timing theory, which was derived from an impressive series of animal studies. In this theory, central control of timing is implemented by a pacemaker mechanism that represents time through the accumulation of internal pulses, possibly generated by oscillators. Subjective perception of time, however, is intimately related to the interplay between the pacemaker and the level of attention given to the passage of time. Attention affects the switch that controls the flexible starting and stopping of pulses from the pacemaker, enabling anticipation of predictable events. The cost of this flexibility, however, is less accurate and more variable timing than is found, for example, with circadian timing mechanisms. Attention also appears to play a role in the accumulation of pulses because when attention is diverted there is a systematic shortening of subjective duration, suggesting that pulses from the pacemaker may be lost. Once a representation of time is formulated, it is passed on to working memory, which is a short-term repository in which interval representations are maintained and manipulated in accord with current goals. Over time, more enduring interval representations are stored in long-term memory. Subjective perception of time can therefore be altered in working or long-term memory. In some renditions of the model, the representation of time in memory is also determined by the rate by which the pulse count in the accumulator is transferred or encoded into memory. Finally, a decision process compares pulse counts from the accumulator, which represents current time, with ones in memory to determine when or how to respond. Strategic or attentional factors can influence decision processes by biasing response thresholds that determine when the current time is sufficiently close to the remembered time. The coupling of these different component processes gives rise to our perception of time.

The three component processes depicted in Fig. 1 have been studied using a variety of procedures, which vary in their ability to test the finer points of scalar timing theory. Figure 2a illustrates one widely used paradigm for investigating time perception—the comparison procedure. In this procedure, a standard interval to be timed is presented on each trial followed by a comparison interval, which the subject then judges as longer or shorter than the standard. Typically, subjects are not given feedback about their

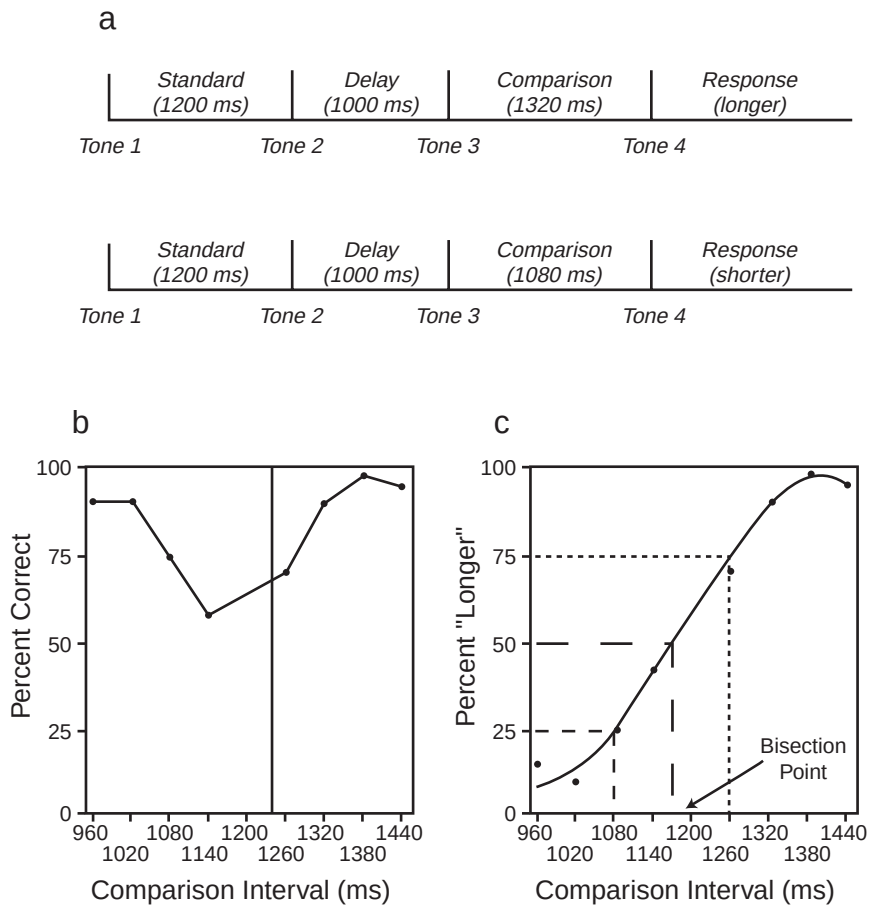

Figure 2 Diagram of a time perception paradigm and hypothetical results. (a) The time perception paradigm using the comparison procedure. In this procedure, a standard interval to be timed is presented on each trial followed by a comparison interval, which the subject then judges as longer or shorter than the standard. (b and c) Hypothetical data generated from this method. (b) The percentage correct responses as a function of the duration of the comparison interval. (c) The percentage of "longer" responses as a function of the duration of the comparison interval. The bisection point (dashed line) is derived through interpolation of the point at which approximately 50% of the trials are classified as longer. The difference limen is the difference between the intervals classified as longer in 75 and 25% of the trials (dotted lines) divided by 2.

response. Some procedures utilize a fixed set of comparison intervals wherein half are longer and half are shorter than the standard interval.

Figure 2b shows hypothetical data generated from this method. Here, a standard interval of 1200 msec is represented on the graph by a vertical line intersecting the *x* axis. The *y* axis designates the mean percentage correct responses, which are plotted for each of eight comparison intervals on the *x* axis. This graph illustrates a classic discrimination function wherein accuracy is worse the closer the comparison interval is to the standard. In this example, accuracy tends to be better for longer than shorter comparison intervals, which implies that the duration of the standard is underestimated. This is more evident in Fig. 2c, in which the same data are plotted as a function of the percentage of "longer" responses for each comparison interval. Here, time perception accuracy is designated by the bisection point, which is most directly derived through interpolation of the point at which approximately 50% of the trials are classified as longer. In this example, the bisection point is approximately 1170 msec, indicating underestimation of the 1200-msec standard interval. Asymmetrical discrimination functions are common because perception of the standard interval can be biased by various circumstances. For example, we tend to perceive an interval as being shorter than its actual physical duration when it is maintained for a longer period of time in working memory. Hence, as time passes our memory for a

standard interval will be more difficult to distinguish from shorter than longer comparison intervals. Another measure of time perception performance is the difference limen, which is the difference between the intervals classified as longer on 75 and 25% of the trials divided by 2. In the example in Fig. 2c, this would be calculated by subtracting 1080 msec from 1260 msec and then dividing this quantity by 2, which yields a difference limen of 90 msec. Larger values reflect greater variability in time perception performance. When the difference limen is divided by the bisection point, this produces a coefficient of variation, which represents processing sensitivity or efficiency. Finally, the precision or consistency by which intervals are judged over trials is reflected in the residual variance, which is the portion of variance unexplained by changes in the comparison interval.

A similar paradigm for studying time perception is the time bisection method. Here, subjects are first trained to discriminate two standard intervals, one short and one long. Once this is mastered, both standard intervals are randomly presented along with other intervals that fall in between the two standards. The subject's task is to classify intervals in terms of whether they are more similar to the short than the long standard or vice versa. There are many variations on this approach, including those in which subjects judge whether a comparison interval is longer, shorter, or the same as the standard. Unlike the comparison procedure, subjects must remember the standard intervals over trials such that subjective perception of time can be more influenced by working and long-term memory. Although the time bisection method generates data similar to those shown in Fig. 2c, in humans the bisection point is typically closer to the arithmetic than the geometrical mean of the two standard intervals. The bisection point is also sensitive to the spacing of intervals, which suggests that the difficulty of the discrimination task can influence accuracy.

Other variations on these procedures employ step-down approaches to estimate time perception acuity. This is commonly done in comparison paradigms by systematically reducing the difference between the standard and comparison intervals by small increments (e.g., 7 msec) to assess the least amount of time an individual can reliably perceive between two intervals. This method generates lower and upper thresholds for shorter and longer responses, respectively. The main measure of interest is the difference threshold, which is computed by subtracting the lower from the upper threshold and dividing the difference by 2. Difference thresholds computed from step-down methods are highly accurate measures of perceptual acuity for time, but the data do not easily lend themselves to computations of variability that are equivalent to those described previously (Fig. 2c). Rather, the variability of time representations is implicit in the difference threshold because the threshold estimate is set based on a predetermined number of standard deviation units (e.g., 1 standard deviation) from the interval at which an individual is equally likely to respond shorter or longer.

These and other methods reveal two fundamental properties that are thought to regulate the timing of behaviors by the internal clock. One property is mean accuracy, which is assumed to reflect a representation of time close to the actual physical time. The second is called the scalar property, which specifies that the standard deviation of time representations grows linearly with the mean of the interval being timed. This is a form of Weber's law and indicates that the precision of the timekeeper mechanism is constant irrespective of the duration being timed.

Scalar timing theory predicts that clock, memory, and decision processes should be represented by specific patterns of accuracy and variability. Perhaps some of the most compelling evidence for a distinction between clock and memory components comes from pharmacological investigations in animals conducted by Andres Maricq, Russell Church, Warren Meck, and colleagues. In these studies, animals were first pretrained to discriminate a standard interval(s) and then administered either a dopaminergic (DA) agonist (e.g., methamphetamine) or antagonist (e.g., haloperidol) to observe the effect on timing performance. Timing variability (coefficient of variation) remained scalar, but accuracy (e.g., bisection point) was abruptly altered. DA antagonists produced an *immediate* overestimation of time, which was attributed to the clock slowing down so that the pulse count from the pacemaker accumulated later in physical time relative to pretraining. In contrast, DA agonists produced an underestimation of time presumably due to the clock speeding up so that the pulse count accumulated earlier in physical time. Interestingly, when animals were given feedback about their timing performance, these distortions gradually disappeared over trials because the clock can be recalibrated to adjust a slower or a faster pulse count to the values stored in memory. This pattern of results contrasts with those produced by manipulating cholinergic activity, which is thought to affect memory processes. Cholinergic challenges alter timing accuracy and variability, and the effects are gradual because it takes time to establish new pulse

counts in memory. Cholinergic agonists (e.g., physostigmine) produce an underestimation of time and reduced variability presumably because they speed up the encoding of the pulse count into memory (Fig. 1). Cholinergic antagonists (e.g., atropine) have the opposite effect, causing an overestimation of intervals and increasing variability because encoding of the pulse count into memory is ostensibly slowed down. These effects are long-lasting because memory cannot be recalibrated quickly.

These findings are intriguing and suggest that scalar timing theory and other similar models may be conceptually useful for understanding temporal processing. Still, in most research it has proven difficult to isolate the independent effects of the clock from other component processes in Fig. 1 because they interact to bring about timed behaviors. Experimental manipulations of attention or working memory, pharmaceutical challenges, or the use of neurological patients can alter variability in one or more component processes. The reasons for changes in variability, however, are often difficult to determine because there are subtle differences in the behavioral patterns predicted for clock, memory, and decision processes. Still, this remains a prevailing model and has been a springboard for investigations into the neural underpinnings of temporal processing. The remainder of this article discusses investigations in this area that have used focal lesion and functional imaging methods in humans, which to date are the predominant neuroscience approaches. Although few of these studies are able to directly specify the source of behavioral changes resulting from manipulations of brain states (i.e., clock, memory, or decision processes), a picture of the distributed neural systems that give rise to precisely time behaviors is beginning to emerge. This work, combined with a preliminary understanding of the functional significance of different neural systems, extends current models and points to new approaches for dissecting the component processes underlying timed performance and their neural substrates.

III. LESION STUDIES OF TIME PERCEPTION

In humans, one approach to investigating the role of a neural site in a behavior is to study patients with focal brain damage as a consequence of a stroke, tumor resection, or neurodegenerative disorder. This approach can validate areas essential for a behavior by showing, for example, that damage to a particular site disrupts the clock but not memory or decision processes. This is a definite strength of the lesion method compared to others because there is a direct link between brain dysfunction and specific behavioral consequences of theoretical significance. In practice, however, caution must be taken in interpreting these studies because it is possible that a distant site interconnected with the damaged area is the neural system primarily responsible for sustaining a particular behavioral process. Additionally, inferences about brain–behavior relationships can be complicated by recovery of function and the fact that brain damage often affects multiple sites. For these reasons, it is important to cross-validate findings with converging methods.

Despite these cautionary remarks, the results from studies of time perception using the lesion method have been remarkably consistent with those derived from other methods. The basal ganglia and the cerebellum have been most studied because they are logical candidates for timekeeper operations. Damage to these brain regions commonly disrupts behaviors that depend on precise timing, such as rhythmic movements in Parkinson's disease (PD) and regulation of agonist–antagonist muscle activity (e.g., dysmetria) after cerebellar damage. Although these movement abnormalities could be attributed to a disruption of more generalized motor execution functions classically attributed to these systems, the basal ganglia and cerebellum mediate the perception of time as well. The role of interconnected cortical sites in temporal processing has been less well studied, but an emerging literature indicates that our perception of time is also regulated by various regions of the cerebral cortex.

A. The Role of the Basal Ganglia

The previously mentioned pharmacological studies in animals provided some of the first evidence for the regulation of timekeeper operations through DA neurotransmission in the striatum. Subsequently, Warren Meck showed that the physiological effect of DA agents on pacemaker operations was due to their binding affinity for dopamine D2-type receptors rather than type D1, noradrenergic, or serotoninergic receptors. These studies implicated the basal ganglia in timekeeper operations because DA receptors are abundant in the caudate, putamen, and substantia nigra (SN).

PD has been the dominant model of dopaminergic dysfunction in humans. In PD, dopaminergic neuronal loss in the SN reduces activity in receptors that

terminate in the caudate and the putamen, which increases inhibitory output from the striatum. The hallmark symptoms of PD include tremor, postural rigidity, and slowness in movement (bradykinesia). Additionally, the disorder is commonly associated with bradyphrenia or a slowing in cognition. One proposal is that cognitive slowing is due to the reduction in rhythmic neuronal firing of basal ganglia–thalamocortical circuits, causing a disruption in the timing of behaviors. This has been studied by comparing performance on timing tasks when PD patients are withdrawn from dopaminergic replacement therapy (''off'' medication) to their performance when therapy is reinstated (''on'' medication). Although the study of unmedicated patients offers a more sensitive appraisal of basal ganglia dysfunction, withdrawal of medication for sufficient periods of time is often difficult or impractical. For this reason, studying medicated patients has advantages because normal dopaminergic functioning is not fully restored by replacement therapy.

Several studies have shown that PD disrupts the timing of movements, but this could be due to the motoric functions traditionally ascribed to the basal ganglia. For this reason, time discrimination procedures have advantages because the motor requirements are minimal. Relatively few studies, however, have used these procedures. In 1989, Richard Ivry and Steven Keele were the first to report that time perception was normal in PD patients who were on medication. This was surprising given previous work in animals, and it raised the possibility that a sensitive assessment of basal ganglia functioning may not always be obtained in patients on medication. Julio Artieda, Maria Pastor, and colleagues reexamined this issue in 1992 using a temporal discrimination threshold (TDT) paradigm, which measured the least amount of time subjects could discriminate between two successive auditory, visual, or somaesthetic stimuli in order to perceive them as separate. They reported prolonged TDTs in PD patients tested off medication, irrespective of the stimulus modality. Moreover, reinstatement of dopaminergic replacement therapy substantially reduced TDTs, although whether performance actually returned to normal levels was not evaluated. These findings were not easily explained by possible primary sensory deficits because indices of such deficits, including sensory nerve action potentials from the wrist and cortical evoked potentials recorded over the parietal lobe, were normal in PD patients. Although the results implied that dopamine neurotransmission in the striatum regulated time perception competency, arguably this task may not be a pure measure of explicit timing because subjects made decisions about whether they perceived one or two stimuli rather than about the length of time between presentation of two stimuli. Additionally, impaired time perception in this study could be due to a disruption in other processes that interact with the timekeeper mechanism.

We attempted to address these and other concerns in a study of medicated PD patients using the comparison procedure. Our study employed a step-down approach, in which the difference threshold was the measure of perceptional acuity for time. Unlike previous studies using the comparison procedure, we employed two different standard intervals (300 and 600 msec) to assess whether time perception acuity remained scalar in patients. When variability is nonscalar, especially due to reduced processing efficiency for longer time intervals, this is sometimes attributed to the role of memory or decision processes in timing performance rather than to changes in clock speed, which are thought to alter timing accuracy in proportion to the interval being timed (i.e., scalar). However, because patterns of accuracy and variability are not understood well with respect to specific mechanisms, we also controlled for the effect of memory and decision processes on discrimination performance using a pitch perception task. In this task, the trial events were the same as in the time discrimination task, except that subjects judged the pitch of the comparison tone pair relative to the standard tone pair. We found that PD patients were impaired on the time (i.e., larger difference thresholds) but not the pitch perception task. Timing performance was also scalar, suggesting that timing sensitivity remained constant across the two standard intervals despite the elevated difference thresholds in PD patients. Moreover, these same patients were impaired on a converging measure of clock processes from a motor timing task. Together, these results suggest that timekeeper operations, rather than other cognitive processes required for the performance of temporal processing tasks, are disrupted in PD patients.

Although the previously mentioned studies support the basal ganglia's role in timekeeper operations, surprisingly few studies have directly examined whether basal ganglia dysfunction compromises processes that interact with timekeeper mechanisms to bring about representations of subjective time. To investigate this possibility, research will be required that analyzes patterns of performance as a function of manipulating memory, decision, and other processes

that may be regulated by the basal ganglia. For example, the time perception paradigms utilized in most human neuroscience studies minimize long-term and working memory demands so that their effect on performance may not be as evident as in other paradigms, such as the time bisection procedure. This avenue of research will be essential for more critical tests of the basal ganglia hypothesis of timing. It is also worth considering that diminished timing competency could also arise from the effect of basal ganglia dysfunction on interconnected cortical sites, some of which are strongly associated with working memory and attention functions. Specifically, the basal ganglia project via separate pathways of the thalamus to at least five prefrontal cortical areas: the supplementary motor area, premotor cortex, dorsolateral prefrontal cortex (DLPFC), anterior cingulate cortex, and the frontal eye fields. Fiber pathways also connect the basal ganglia with the parietal and the temporal cortex. Consequently, performance could be altered by abnormalities in the functioning of any of these systems due to reduced basal ganglia output.

B. The Role of the Cerebellum

Human lesion studies also support the role of the cerebellum in temporal processing. Patients with cerebellum damage due to a variety of etiologies, including cerebellar atrophy, soft signs of cerebellar damage (e.g., clumsy children), tumor resection, and stroke, have been studied. These cerebellar disorders can produce a variety of motor symptoms that impair gait (ataxia), accurate reaching to targets (dysmetria), postural stability, tremor, slowed or slurred speech (dysarthria), and eye movement abnormalities (nystagmus and ocular dysmetria). Interestingly, damage to focal structural regions of the cerebellum, such as the vermis or lateral hemispheres, does not correlate strongly with the manifestation of specific symptoms. Additionally, patients with cerebellar damage sometimes show cognitive deficits on clinical testing resembling those classically associated with cortical damage. This is consistent with mounting evidence from cognitive neuroscience investigations, which implicate the cerebellum in cognitive operations.

Many studies have documented disruptions in the timing of movements after cerebellar damage; however, as in PD, this could be attributed to the motor functions of this system. Nonetheless, several studies have reported that cerebellar damage also impairs performance on time perception tasks. In 1989, Richard Ivry and Steven Keele reported that time perception performance was impaired (i.e., larger difference threshold) in patients with cerebellar damage due to stroke, tumor, or degenerative disease. These patients also showed impairments in timing movements. In another study, these investigators reported that patients with focal damage to the lateral cerebellum and its primary output, the dentate nucleus, showed deficits in timing movements that appeared independent of potential motor implementation deficits. This contrasted with damage to the medial aspect of the cerebellum (vermis) that produced motor implementation problems, but the timing of movements was normal. Although these findings implicated the lateral cerebellum in timekeeper mechanisms of motor timing, a similar lesion analysis has not been conducted for time perception competency. Additionally, whether motor timing competency was scalar could not be assessed since only a single standard interval was used in these studies.

In 1996, Paolo Nichelli and colleagues studied time perception in patients with cerebellar degenerative disorders using the time bisection method, wherein subjects classified intervals as short or long after exposure to two standard intervals. Time perception was studied in four different conditions, each of which used different standard intervals (100 and 325 msec, 100 and 600 msec, 100 and 900 msec, and 8 and 32 sec) that varied in interval range. To control for possible deficits in discrimination processes unrelated to explicitly timing stimulus events, subjects also performed a spatial bisection task in which they classified horizontal lines as short or long relative to two previously practiced standard line lengths (6 and 54 mm). These investigators reported that spatial bisection performance was normal in patients with cerebellar degeneration, despite deficits in time perception in some but not all of the experiments. Specifically, processing efficiency was diminished (i.e., larger coefficient of variation) in cerebellar patients relative to the normal control subjects for the long-interval discrimination condition (8 and 32 sec). It was speculated that this finding was due to deficits in sustaining attention or the use of different strategies to maintain temporal information over long periods of time. Processing efficiency was also diminished in one of the short-interval discrimination conditions (100 and 600 msec), but in another condition (100–900 msec) only accuracy (bisection point) differed between the groups, such that patients underestimated intervals. The investigators concluded that the results for short-interval conditions supported the

cerebellum's role in clock processes. Although these findings were intriguing, the type of deficits (bisection point and coefficient of variation) in patients depended on the range of intervals used in each experiment in ways that were not necessarily predicted by scalar timing theory.

This issue was revisited in 1998 by Jennifer Mangels, Richard Ivry, and colleagues in a study of nine patients with focal lesions of the cerebellum. A step-down comparison procedure was adopted to estimate perceptional acuity for time using two different standard intervals (400 msec and 4 sec). Cerebellar patients showed impaired time perception (i.e., larger difference thresholds). Their deficits also appeared greater for the longer than the shorter standard interval, which might imply deficient working memory or attention. Alternatively, strategic processing deficits could also be an important factor if patients fail to employ normal strategies for sustaining information in working memory, especially over longer intervals. This latter possibility was investigated by examining the role of counting strategies in time perception because counting helps to divide longer intervals into a series of shorter ones, which improves timing accuracy. Subjects performed a time perception task with and without strategic support (i.e., a 4-sec interval was divided into 10 subintervals using auditory clicks) and with and without instructions to use the subintervals to count out time. Time perception acuity was impaired in the cerebellar patients irrespective of the condition and could not be attributed to counting deficits. Although the authors concluded that the cerebellum regulates clock processes, this is arguable because patients used explicit counting strategies, which involve timing, as efficiently as the control subjects to improve their performance. Moreover, patients with cerebellar damage also showed significant deficits on a pitch perception task, which raised the possibility that their time perception impairments might be explained by deficits in other processes that interact with pacemaking operations. A recent study by Laurence Casini and Richard Ivry indicates that working memory deficits do not explain timing impairments after cerebellum damage. In this study, seven patients with focal cerebellar damage and one with cerebellar atrophy showed impaired time perception (i.e., larger difference thresholds). However, performance deteriorated to the same extent in the healthy control and the cerebellar groups when performing under dual-task conditions, which places a greater demand on working memory. Nonetheless, pitch perception was still impaired in patients, raising the possibility that deficits in other undefined processes might explain impaired time perception after cerebellar damage.

The previous studies indicate that cerebellar damage usually disrupts time perception performance; however, the specificity of this system for explicit timing operations is questioned by findings of impairments in other types of discrimination that are not time dependent. More work is necessary to tease out the fundamental mechanisms of time perception deficiencies in these patients. Abnormalities could be due in part to a disruption in the functioning of cortical systems, given that reciprocal fiber pathways interconnect the cerebellum to most regions of the frontal, temporal, and parietal cortex. This is especially likely inasmuch as most research has studied cerebellar degenerative disorders, which are rarely focal and typically involve the cerebral cortex. For this reason, studies of patients with focal cerebellar lesions more directly assess the function(s) of the cerebellum. To critically evaluate the cerebellar timing hypothesis, it will also be important to further validate whether the lateral hemispheres and the vermis play functionally different roles in building representations of subjective time. Most functional imaging investigations of time perception challenge this proposal.

C. The Role of the Cerebral Cortex

Relatively limited attention has been given to the role of specific cortical systems in time perception, despite the multiple interconnections of the cerebral cortex with the basal ganglia and the cerebellum. Richard Ivry and Steven Keele first investigated the role of the frontal cortex in time perception in 1989. They employed a step-down comparison procedure to estimate perceptual acuity for time using a 400-msec standard interval. Eight patients with lesions in undefined areas of the frontal cortex were studied and these investigators reported normal time perception performance. Recent studies, however, indicate that the frontal cortex is involved in time perception processes. Paolo Nichelli and colleagues studied time perception in 11 patients with frontal lesions in undefined and heterogeneous regions of the frontal lobe using the time bisection task. Time perception was studied in short-(100–900 msec) and long-interval (8–32 sec) discrimination conditions. In both conditions, patients with frontal lobe damage were as accurate as controls in estimating intervals but processing efficiency (i.e., larger coefficient of variation) was diminished. Additionally, patients demonstrated less

precision or consistency for the long- but not the short-interval discrimination condition relative to the control subjects. Although this pattern of results could be attributed to impairments in many processes, the investigators speculated they were due to the role of the frontal lobes in memory or sustained attention since time perception deficits were more striking for long-interval discriminations.

The discrepant results from the previous two studies could be due to a variety of factors, including differences in patients (e.g., lesion location or size) or the use of time perception tasks that differed, especially in their memory requirements. However, recent studies using procedures similar to those of Richard Ivry and Steven Keele provide convincing support for the frontal lobe's role in working memory functions, including the short-term maintenance of intervals and executive processes involved in comparing intervals, both of which modify subjective representations of time. Jennifer Mangels and Richard Ivry used a step-down comparison procedure for estimating perceptual acuity for time in seven patients with frontal lobe damage. They reported impaired time perception acuity (i.e., larger difference threshold) when the standard and comparison intervals were separated by 4 sec but not 400 msec. Likewise, pitch perception acuity was impaired in these patients only when the standard and comparison pitches were separated by 4 sec. Thus, frontal lobe damage produced deficits related to maintaining information in working memory over longer periods of time, irrespective of whether the auditory events were explicitly timed. In another study, Laurence Casini and Richard Ivry reported that executive functions of working memory are also impaired in patients with frontal lobe damage. In their study, subjects made time or pitch discriminations in a comparison procedure that had a single- and a dual-task condition. Perceptual acuity for time and pitch deteriorated in the five patients with frontal lobe damage, whereas only time perception acuity declined under dual-task conditions in the normal control group. Hence, frontal lobe damage disrupts the division of attentional resources in working memory, irrespective of whether events are explicitly timed and even when the demands on working memory resources are minimal.

Although most of the previously mentioned studies implicate the frontal lobe in various functions of working memory during temporal processing, the specific frontal sites supporting these functions were not delineated. Importantly, the role of other cortical areas was not examined. In particular, the parietal cortex might be expected to support timing operations because of its interconnectivity with the basal ganglia and the cerebellum. The inferior parietal cortex has abundant, bilateral projections to the putamen and caudate nucleus in monkeys and there are also cerebellar–thalamic projections to the inferior and the superior parietal cortex. Moreover, damage to the right parietal cortex often produces neglect, a disorder in attention, which might interrupt communication between timekeeping and attention processes.

To address these issues, we investigated the role of the cerebral cortex in time perception in a study of a large sample of patients with unilateral cortical lesions in the left ($n = 19$ patients) or the right ($n = 20$ patients) hemisphere. Patients and control subjects were studied using time and pitch perception tasks (comparison procedure), and the interval separating the standard tone pairs was either 300 or 600 msec. We also investigated whether time perception competency correlated with an independent measure of attention to determine whether timing deficits were related to diminished attention. This task required subjects to switch their attention between one of two key presses when a preceding cue did not match the impending response. Right or left hemisphere damage compromised attention to a similar degree. Pitch perception was also impaired after left or right hemisphere damage, but the incidence of deficits was considerably higher in patients with left frontal lesions (67%) than in the other patient groups (20% or less), suggesting a left hemispheric bias for processing frequency information. When deficits in pitch perception were controlled by including only subjects with normal pitch perception, only the right hemisphere-damaged group showed time perception deficits (larger difference thresholds), which were greater for the 600- than the 300-msec interval condition (nonscalar). Poorer time perception acuity also correlated with more severe deficits in attention in the right but not the left hemisphere group, despite similar attention deficits in both groups. Interestingly, attentional capacity did not correlate with pitch perception acuity in any patient group, implying that its relationship to discrimination performance was more specific to explicitly timing events.

We then examined whether damage to specific regions of the cerebral cortex was associated with time perception deficits. Patients' lesions were reconstructed from MRI scans onto computerized templates, which portrayed the neuroanatomy for different horizontal (axial) sections of the brain. Next, the templates from each patient were overlaid to

examine the extent to which lesions overlapped in patients with and without time perception deficits. Figure 3 displays the lesion overlap in patients with damage primarily anterior or posterior to the central sulcus, who exhibited impaired or normal time perception. The left and right halves of the brain show the lesion overlap for patients with left and right hemisphere damage, respectively. The section displayed in Fig. 3 showed the greatest lesion overlap in patients with impaired time perception, and the lower right side of the figure gives the location of this section on a lateral view of the brain. All patients with right anterior lesions in the vicinity of the middle and the superior frontal gyri [Brodmann areas (BA) 8 and 46] exhibited time perception deficits. In contrast, time perception deficits were not found when this same region was damaged in the left hemisphere. All right hemisphere patients with posterior damage and time perception deficits had lesions involving the supramarginal (BA 40) and the angular gyrus (BA 39). Time perception was normal in three patients with right posterior lesions; one had occipital damage (not shown in Fig. 3) and although the other two had lesions involving BA 40, performance was borderline normal in one of these patients.

Together, these results implicate a right prefrontal–inferior parietal network in time perception, which is associated with the right hemisphere's bias for controlling attention. Moreover, our results suggest that the right inferior parietal cortex is not limited to spatial attention, as commonly reported, but also participates in attentional functions involved in formulating representations of time. Attention is intimately associated with working memory functions, which presumably are required to compare intervals in time perception tasks. Others have implicated the middle and superior prefrontal cortex in working memory, which may explain the behavioral basis for impaired time perception in patients with damage to this system. It is worth mentioning that we failed to uncover evidence of a common left hemisphere network for time perception when carefully inspecting lesion sites in patients with left hemisphere damage who exhibited both impaired time and pitch perception. Nonetheless,

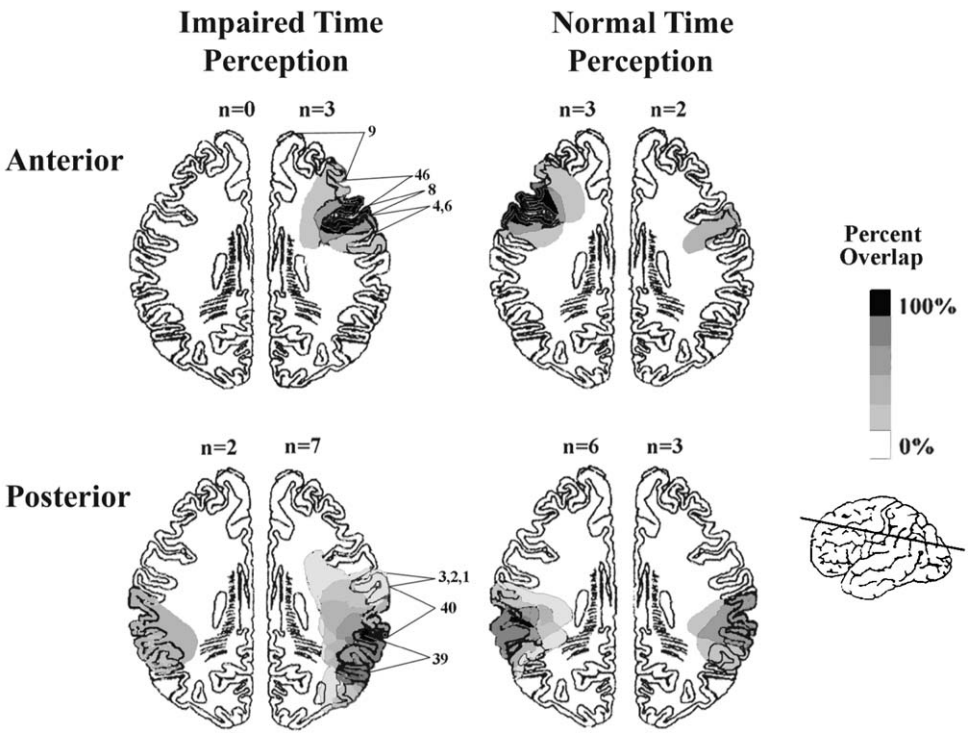

Figure 3 Lesion overlap in stroke patients with damage anterior or posterior to the central sulcus. The axial sections show the overlap for patients with left (left side of brain) and right (right side of brain) hemisphere damage with impaired and normal frequency perception. (Bottom right) The location of this section on a lateral view of the brain. The bar designates the percentage of patients with damage to a particular area.

it remains possible that the left hemisphere supports representations of time by way of other processes that were not identified in our study.

The previous work is consistent with clinical neuropsychological views of the functions of the frontal and the parietal lobes. This avenue of research, however, will be strengthened by further studies that directly manipulate variables presumed to alter clock, memory, and decision processes, with the goal of better delineating the functional significance of neural systems that regulate temporal processing. It also appears that there may be a right hemispheric bias for attending to temporal information, at least for intervals in the range of hundredths of milliseconds. Electrophysiological recordings in humans have also shown a right hemisphere bias for temporal processing, especially in the parietal cortex. In the next section, we discuss converging results from a recent functional imaging study that are in agreement with this proposal.

IV. FUNCTIONAL IMAGING INVESTIGATIONS INTO TIME PERCEPTION

Recently, the neural substrates of time perception have been studied using functional imaging tools in healthy individuals. Positron emission tomography (PET) and fMRI are widely used methods for examining hemodynamic changes in blood oxygenation, flow, and volume associated with regional increases or decreases in neural activity in the brain. PET scanning involves injection of a short-lived isotope produced in a cyclotron. PET scanners, which have rings of crystal detectors arranged around a central bore, create images by identifying areas of increased radioactivity in the brain. The most commonly used isotope for conducting brain mapping experiments, ^{15}O-water, has a relatively short half-life (2.1 min) and provides a measure of both global and local changes in cerebral blood flow. ^{15}O-water is injected into a subject while he or she performs a task for approximately 40–60 sec. In a typical brain mapping experiment, a subject may receive 4–10 injections per session. Subtraction techniques are used to compare images obtained in response to contrasting tasks in order to identify brain regions critically involved in each task.

fMRI comprises a wide range of techniques for imaging brain function. The most commonly used technique for brain mapping experiments, referred to as blood oxygen level-dependent (BOLD) imaging, involves a high-speed, T2-weighted echo-planar pulse sequence capable of generating an image in 40–100 msec. The endogenous BOLD technique involves collection of a series of images to detect decreases in local concentration of paramagnetic deoxyhemoglobin, reflected in an increase in magnetic resonance signal intensity. These signal changes take approximately 5–7 sec to reach a peak; with cessation of the activation task, the signal returns to baseline in 7 or 8 sec. In addition to not having to inject agents, BOLD imaging offers advantages in temporal and spatial resolution relative to PET imaging. Whereas PET experiments typically examine the cumulative activity associated with a block of trials administered over a 40- to 60-sec interval, BOLD experiments can examine changes associated with a single trial as brief as 1 sec and, as shown later, can image the evolution of brain activity in trials that span several seconds. With spatial resolutions that can approach a cubic millimeter, BOLD imaging, unlike PET, can pinpoint activity resulting from relatively small subcortical structures, such as distinguishing between putamen versus globus pallidus activation in the basal ganglia.

The first PET experiment to examine time perception was conducted by Jueptner and colleagues in 1995. Three conditions were imaged: a relatively easy temporal comparison procedure (standard tone pair interval = 300 msec; test tone pair = 200 or 400 msec), a control condition with two isochronous tone pairs, and a rest condition. Greater activation in time perception task was observed in the superior parts of the lateral cerebellum bilaterally and in the vermis when compared to the control condition. The authors argued that their data supported a cerebellar timing process, despite the fact that greater activation in the basal ganglia (right caudate and bilateral putamen/globus pallidus), bilateral thalamus, and cingulate cortex (BA 24) was also observed in the timing condition. It should also be noted that this study was limited by the lack of an active comparison control task (e.g., pitch perception). The low-level sensorimotor control task cannot determine whether the activated structures were specific to time perception or were associated with more generalized encoding, memory, and decision processes involved in any discrimination task. Finally, the limited coverage of the PET camera was focused on examining activity in the cerebellum; as a result, potential activation of superior cortical structures (dorsolateral prefrontal and parietal regions) was not measured.

Two PET studies by Maquet, Lejuene, and colleagues were subsequently reported in 1996 and 1997. In

the 1996 study, three conditions were contrasted: (i) a visual time-bisection procedure with a 700-msec standard and 490- to 910-msec comparisons, (ii) a visual intensity bisection procedure, and (iii) a sensorimotor control task. The contrast comparing the first and third conditions resulted in greater activation in the time discrimination task in the right DLPFC (BA 44, 45, and 47), right inferior parietal (BA 40), anterior cingulate areas, and the cerebellum (vermis and left lateral cerebellar hemisphere). However, no significant differences were observed between the first (time bisection) and second (visual intensity) conditions, suggesting that time and visual discriminations were supported by similar neural systems. In the 1997 study, subjects were required to judge the duration (2.7-sec interval) separating successive illumination of a light stimulus. The sensorimotor control task consisted of responding to a light stimulus that appeared on average every 2.7 sec (range, 2–3.4 sec). Four regions demonstrated greater activation in the duration than control task: right insula/inferior prefrontal (BA 47), right inferior parietal (BA 40), anterior cingulate (BA 32), and the cerebellar vermis. The authors also performed a meta-analysis that examined conjointly activated regions associated with both PET studies. In addition to the regions noted previously, they also observed activation in the right DLPFC (BA 46) and the left putamen.

Taken together, these three PET studies provide evidence for cerebellar and basal ganglia involvement in time perception. In addition, primarily right-sided cortical activations were observed in the middle and inferior prefrontal and inferior parietal regions. Unfortunately, the temporal resolution of PET scanning is limited to blocked-trial designs that cannot disentangle timekeeper and attention operations from working memory and response implementation processes. In a recently completed study, we exploited the finer temporal resolution of event-related fMRI to study the time course of brain activation patterns associated with different stages of a time perception task. Specifically, our study was designed to isolate patterns of brain activation that correlated with encoding time intervals from those associated with comparing two time intervals and implementing a response. Timing theory suggests that activation should develop earlier in systems integrally involved in encoding or formulating a representation of time (i.e., timekeeper and attention operations) and later in systems concerned with manipulating information in working memory (i.e., comparing intervals) and implementing a response.

fMRI scans were obtained for three different tasks. In the time discrimination condition, two tones (50 msec) separated by 1200 msec (standard tone pair) were presented, followed by a 1 sec delay and then a comparison tone pair. Subjects indicated whether the comparison tone pair was longer or shorter than the standard. To better separate neural systems specific to timing operations, subjects also performed a pitch discrimination condition in which the auditory events were similar except that subjects indicated whether the fourth tone was higher or lower in pitch than the first three tones. Imaging runs in each discrimination condition were contrasted with a sensorimotor control condition in which subjects responded after the presentation of two isochronous tone pairs of identical pitch. Figure 4 (top) illustrates the temporal relationship among the trial events, the acquisition of images, and the expected hemodynamic response function. The first scan was acquired at the onset of the first tone (T1). The fourth tone (T4) was presented an average of 3.4 sec post-trial onset. The typical key press response occurred 4.5 sec post-trial onset. Idealized early and late MR signal changes pegged to T1 and T4 are modeled using a gamma variate distribution to allow for the delay in the rise and fall times of the hemodynamic response. The time and pitch conditions were compared to the control condition at each of four post-trial onset scanning intervals or epochs (2.5, 5.0, 7.5, and 10.0 sec). Allowing 5 sec for the hemodynamic response to peak, we hypothesized that the 2.5- and 5.0-sec post-trial onset intervals should reveal brain activation patterns specific to encoding time intervals. In contrast, the 10.0-sec scanning interval should also include activations associated with contrasting the standard and comparison intervals and implementing the response. Overlap between these processes should be particularly evident during the 7.5-sec scan.

Figure 4 (bottom) shows that time discriminations produced unique and relatively early subcortical activations within the right putamen (2.5 sec), the head of the caudate nucleus bilaterally (5.0 and 7.5 sec), and the right centromedian and ventroanterior thalamic nuclei (5.0 and 7.5 sec). In contrast, cerebellar activation, which was located in the posterior vermis (tuber) of lobule VII, occurred relatively late (7.5 and 10.0 sec) in the time discrimination condition. During the first two epochs (2.5 and 5.0 sec), cortical foci specific to the time condition included the right intraparietal sulcus (IPS; BA 40), right inferior frontal gyrus (BA 44/45), bilateral dorsal and left ventral premotor (BA 6; not shown in Fig. 4

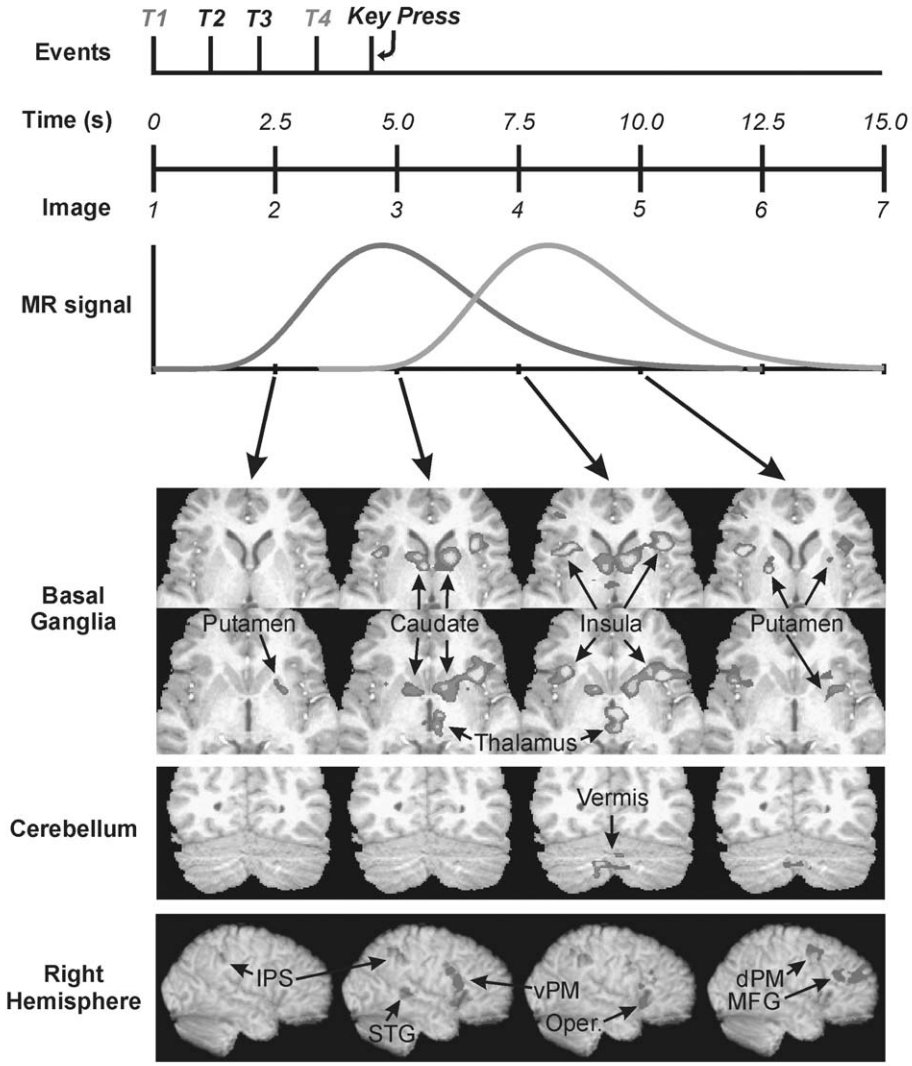

Figure 4 Illustration of the temporal relationship among the trial events, the acquisition of images, the expected hemodynamic response function, and the patterns of brain activation. (Top) The first scan was acquired at the onset of the first tone (T1). The fourth tone (T4) was presented an average of 3.4 sec post-trial onset. The typical key press response occurred 4.5 sec post-trial onset. (Middle) Idealized early and late MR signal changes pegged to T1 (left function) and T4 (right function) are modeled using a gamma variate distribution to allow for the delay in the rise and fall times of the hemodynamic response. These functions indicate that the 2.5- and 5.0-sec scans are influenced by the encoding of the standard interval, whereas the 10.0-sec scan reflects decision and response preparation processes. Overlap between these processes is evident during the 7.5-sec scan. (Bottom) The patterns of activation that were unique to the time perception task. Significant activation foci ($p < 0.001$) indicate greater activation for the time and pitch discrimination conditions relative to the control condition at 2.5, 5.0, 7.5, and 10.0 sec post-trial onset. dPM, dorsal premotor cortex; IPS, intraparietal sulcus; MFG, middle frontal gyrus; Oper, frontal operculum; STG, superior temporal gyrus; vPM, ventral premotor cortex.

for the 2.5-sec epoch), and bilateral lateral temporal (BA 21 and 22) regions. No such foci were observed in the pitch condition. Unique activations of the right DLPFC and right dorsal premotor areas also occurred in response to the time condition during the 7.5- and 10.0-sec epochs. Common activation foci (time and pitch conditions) were observed within the left hemisphere and included the inferior frontal gyrus (BA 44/45), IPS (BA 40), superior parietal lobule/precuneus (BA 7), and DLPFC (BA 9, 10, and 46). In addition, common areas were observed in the anterior supplementary motor area (pre-SMA; area 6), anterior cingulate (BA 32), and anterior insula/frontal operculum (BA 47).

From this fMRI investigation, we concluded that early sustained activation in the bilateral basal ganglia and right inferior parietal cortex during the encoding of time intervals suggests that these systems may regulate the hypothetical timekeeper and attentional operations put forth by theories of timing. Activation was also observed in regions commonly associated with various working memory functions, including the right premotor cortex and right DLPFC. However, the time course of activation in these two systems was remarkably different. This finding suggests that the two regions serve different purposes in temporarily storing time information. PET and fMRI studies have implicated the premotor cortex in the temporary maintenance of information, whereas the DLPFC subserves comparative processes that involve manipulation of information in working memory. Contrary to Ivry's theory, the lateral cerebellum was not associated with temporal processing. We did observe relatively late activity specific to the temporal processing condition in the vermis, suggesting that this structure is not critical to timekeeper or attentional factors associated with time perception. This study, as well as the three previously mentional PET studies, provides additional support for a right hemispheric bias for attending to temporal information.

Clearly, more research is needed to directly specify the proposed brain–behavior relationships we suggest account for our fMRI findings. It is also important to note that the interpretation of functional imaging results is often indirect, frequently relying on findings from other methods (e.g., lesion, pharmacological, and electrophysiological), in which brain function is more directly associated with behavioral measures that represent different hypothetical processes. Functional imaging approaches also currently depend heavily on the subtractive logic, wherein the subtraction of two tasks is understood to reflect brain activity unique to a particular mental operation. Unfortunately, this assumption is often not tenable or difficult to test, such that interpretations of causal linkages between brain structure and behavior may not be valid. Hence, findings from functional imaging approaches need to be weighed and verified by studies using other converging methods.

V. CONCLUSIONS

An understanding of the neural systems that give rise to our perception of time is beginning to emerge from converging lines of research. There is mounting evidence from lesion, pharmacological, and functional imaging studies for the basal ganglia's role in regulating hypothetical timekeeper operations. It also appears that this system supports prospective timing of intervals as short as hundredths of milliseconds and as long as many seconds, although more work is clearly needed to verify this conclusion. Although timing functions have been attributed to the cerebellum in some very influential work, the findings are weakened by reports that the cerebellum also participates in discrimination processes and working memory functions that do not depend on explicit prospective judgments of time. Likewise, our fMRI study suggests that the cerebellum is activated at a point in time closely correlated with selecting a response. Taken together, these findings are compatible with the proposal that the cerebellum is involved in monitoring and adjusting cognitive and sensory input from the entire cerebral cortex rather than performing a specific mental operation per se.

The right inferior parietal cortex is also intimately involved in regulating our perception of the passage of time. The strong association of this system with attention functions in lesion studies, combined with coupled activation in the basal ganglia, raises the prospect that this region may be crucial for controlling the flexible starting and stopping of pulses from the hypothetical timekeeper mechanism. There is also consensus that the frontal cortex is important for temporal processing. The specific role it plays needs clarification because different regions likely sustain different processes. Some insight into this issue was provided by our finding that the time course of activation differed in the premotor cortex and the right DLPFC during time discriminations. Based on other work, we speculated that this may be due to the role of the premotor cortex in maintaining an active representation of the time interval in working memory and the role of the DLPFC in manipulating or comparing interval representations in working memory. Other functional imaging work has reported activation of the inferior–prefrontal superior–temporal network during temporal processing. However, we and others have also shown that this network is activated during pitch discriminations, silent rehearsal of letter strings, and auditory imagery. Hence, this system appears to support a more general function, perhaps in the retrieval and rehearsal of auditory information. This is compatible with our lesion work showing that damage to this network does not disrupt time perception competency, indicating that it is not

essential for formulating or maintaining representations of subjective time.

It is particularly striking that lesion, electrophysiological, and fMRI studies report a right hemispheric bias for processing current time. This is not to say that the left hemisphere does not participate in prospective timing. We found activation in left frontal, temporal, and parietal regions during time perception in our fMRI study, but similar regions were also activated during pitch discriminations. Likewise, both time and pitch perception performance were abnormal after left hemisphere damage. Thus, unidentified processes common to both forms of discriminations appear to be biased for left hemispheric processing.

The previously mentioned research illustrates the many potential ways in which neural systems might come to regulate different component processes implicated in prospective timing. Nevertheless, more research is needed to directly test some of the ideas put forth in this article. Differentiating the reasons for impaired timing in focal lesion or functional imaging studies will require more refined paradigms that are capable of isolating clock mechanisms from those involved in working memory or decision processes. This endeavor should facilitate an understanding of how timing accuracy and variability are reflective of manipulations in some but not all component processes of time perception. This approach combined with investigations of the time course of brain activation should prove enormously beneficial in furthering an understanding of how the brain processes time.

MARY M. ROBERTSON
University College, London

GLOSSARY

dopamine An amine neurotransmitter; the dopaminergic system is the pathway.

genotype Genetic makeup of an individual.

noradrenalin A catecholamine neurotransmitter; the noradrenergic system is the pathway.

perfusion The amount of blood that is used to supply a certain area of the brain per unit of time in order to supply oxygen, glucose, etc. Hypoperfusion refers to a decrease in perfusion, whereas hyperperfusion refers to an increase in perfusion.

phenotype Physical expression or observable characteristics of the individual. The striatum and pallidum are parts of the basal ganglia. The thalamus, limbic system, anterior cingulate, medial temporal, prefrontal, and midbrain are all specific areas of the brain.

serotonin (5-hydroxytryptamine) An amine neurotransmitter; the serotonergic system is the pathway.

Gilles de la Tourette syndrome (TS) is a movement disorder characterized by multiple motor tics (involuntary muscle twitches) and one or more vocal tics (involuntary noises) that have been present for more than a year, with age of onset before 18 years. The *International Classification of Diseases*, 10th version, and the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (*DSM-IV*), define obsessive–compulsive disorder (OCD) as a condition characterized by recurrent obsessions or compulsions that cause marked distress, are time-consuming (take more than 1 hr a day), or significantly interfere with the person's normal routine functioning, social activities, or relationships. Obsessions are recurrent, intrusive, and unwelcome ideas, thoughts, images, or impulses, which are recognized by the individual as absurd. Compulsions are repetitive purposeful behaviors performed in response to an obsession. The diagnosis of OCD as per *DSM-IV* also incorporates an additional criteria that "at some point during the course of the disorder, the person has recognized that the obsessions or compulsions are excessive or unreasonable; however, this does not apply to children." The occurrence of OCD in the context of TS has received a great deal of attention and research in the recent past. Although there is increasing evidence from epidemiological, phenomenological, neurobiological, and genetic research about the association between TS and obsessive–compulsive behaviors (OCB), the exact nature of such an association is still debated.

I. HISTORY

The occurrence of obsessive–compulsive symptoms in the context of TS was first recognized by Gilles de la Tourette. While describing the case of Marquise de Dampierre, a French noblewoman, he reported that in addition to the tics and vocalizations, obsessive thoughts tormented her. Subsequently, Charcot identified involuntary "impulsive" ideas, such as arithmomania (counting obsessions), doubting, checking, and touching in the context of TS. Subsequent writings by other authors referred to the presence of obsessions as an accompaniment of the tic disorder, representing psychical tics. These early clinicians documented the psychopathology of people of "convulsive tic disorder" with special reference to OCB, such as checking, arithmomania, folie du doute, delire de toucher (forced touching), and folie du pourqoui (the irresistible habit of seeking explanations for the most commonplace insignificant facts by asking perpetual questions). It has been speculated with some conviction that Dr. Samuel Johnson, the 18th century literary figure, had TS, and in a book on the life of Dr. Johnson it was noted that "he often had convulsive starts and odd gesticulations." Furthermore, Johnson felt compelled to measure his footsteps, perform complex gestures when he crossed the threshold of a door, and involuntarily touch specific objects, thus suggesting that he also had OCB.

In the early 20th century, experts in the field began to note that "the frequency with which obsessions, or at least a proclivity for them, and tics are associated, cannot be a simple coincidence" and acknowledged a relationship between tics and OCD: "No feature is more prominent in tics than its irresistibility.... The element of compulsion links the condition intimately to the vast group of obsessions and fixed ideas." Robertson and colleagues documented in detail the historical aspects of the link between TS and OCD.

II. EPIDEMIOLOGY

TS is no longer considered to be rare. The accepted prevalence rate for some time has been 0.5/1000, but recent studies have suggested that it affects between 1 and 8 of every 1000 boys and between 0.1 and 4 of every 1000 girls. Even rates of up to 3% have been reported, with higher rates reported in children with special educational needs (approximately 25%) and autism (approximately 6%). Similarly, OCD was considered an uncommon psychiatric disorder until recently, but it is now recognized to be a more common psychiatric illness affecting approximately 1–3% of population. To date, nine population surveys have been conducted using the Diagnostic Interview Schedule and the lifetime risk of OCD has been estimated to be 1.9–3.2%, with a 6-month prevalence rate of 0.7–2.1%; furthermore, the British National Survey of Psychiatric Morbidity gave a 1-month prevalence of 1% in males and 1.5% in females. Other community-based studies have noted that the prevalence estimates are similar for males and females, whites and blacks, and across different socioeconomic status. However, the central issue in epidemiological research in OCD is that of case definition. Even if there were a reasonable consensus regarding case definition, difficulties would remain because of comorbid conditions, such as generalized anxiety disorder, depressive disorder, and TS. This is further complicated by the lack of consensus as to whether a separate diagnosis of OCD is justified in these situations. Although different solutions have been proposed, none has gained sufficient acceptance to dispel ambiguity from epidemiological studies.

Robertson and associates, reviewing the prevalence of OCB in the context of TS, mention that high rates of OCB have been reported by several investigators, with the rates ranging from 11 to 90%. It has also been shown that these symptoms vary based on the severity of TS; the frequency of echolalia has been reported to be 9.3% in grade 1 (mild) TS and 48.3% in grade 3 (severe) TS. It has been suggested that OC symptoms are more pronounced and severe in older TS patients, and in a study of 30 patients with TS older than 21 years of age, 27 patients (90%) were found to have OCD. Other investigators, however, have failed to find any relationship between age and OC symptomatology. Thus, the variations in the reported frequencies of OC symptoms in TS may well be due to a bias in sample selection.

Earlier empirical studies in the 1960s based on clinic samples reported that 12–35% of patients with TS also had OCB. However, these estimates have been considered to be underestimates since the absence of a report of symptoms could not be equated with the absence of the symptoms. Higher rates of 55–80% were reported in the 1980s, with one study documenting that 37% of 90 TS patients not only reported OC behavior but also obtained higher scores on standardized rating scales than normals. In the early 1990s, Robertson and colleagues interviewed 85 members of a multiply affected TS family and reported that distinction between cases and noncases could be made on the

basis of OC features and the trait score of the Leyton Obsessional Inventory. Similarly, in an interview of an Arab family, 4 TS cases were found, all of whom had OCB. In a study in a New Zealand cohort of 40 TS cases, 20 of whom were evaluated in detail, half of the cases were found to have OCB. Pauls and associates also reported that OCB occurs in approximately 40% of TS cases.

In this context, only few studies have included control groups. Fifty-two percent of TS patients in one study were found to have OCB compared to 12.2% of the controls; another study found 45% of TS patients had OCB compared to 8.5% of controls. In yet another controlled study, TS patients were found to be disproportionately obsessional, which was not accounted for by depression. Similarly, it has been documented that TS patients have significantly more obsessionality than controls. Given that the population prevalence of OCD is between 1 and 3%, the prevalence of OCD in TS patients seems to be much greater than is expected by chance.

While examining epidemiological evidence, it is equally important to consider the relationship from the other perspective, i.e., the occurrence of tics and TS among OCD patients. In this regard, open studies in the 1980s reported a rate of 5% for TS among OCD patients, whereas in a controlled study of 16 TS, 16 OCD, and 16 normal subjects, 37% of the OCD subjects were found to have a tic disorder compared to only 1 subject from the normal controls. In the 1990s, an epidemiologic sample of 861 Israeli adolescents found 40 individuals with OC spectrum disorders. After reviewing the literature on OCD, Rapoport and colleagues suggested that approximately 20–25% of OCD patients have tics.

III. PHENOMENOLOGY

It has been observed that TS and OCD share some clinical features, such as waxing and waning of symptoms, early age of onset, lifelong course, egodystonic behavior, and worsening of symptoms with stress and anxiety. However, despite some overlap in clinical features, available evidence suggests that the two conditions are not phenomenologically identical and that OCD may well be a heterogeneous entity, with one subtype related to TS.

Several investigators have tried to identify OC symptom subtypes in an attempt to find homogeneous subgroups of OCD patients. In this regard, four factors have been described using the Maudsley Obsessive Compulsive Inventory (MOCI): checking, cleaning, slowness, and doubting in descending order of variance. However, use of the MOCI has an inherent problem of item selection bias in that although checking (9 items) and cleaning (10 items) symptoms are well represented, others, such as aggressive obsessions (2 items), symmetry, ordering, and hoarding compulsions (no items), are underrepresented. In another cluster analysis of 410 OCD patients assessed using a checklist with similar symptom selection bias as the MOCI, five symptom subgroups were reported; checking, washing, the past, death, and sex.

The Yale–Brown Obsessive Compulsive Scale (YBOCS) symptom checklist overcomes the symptom selection bias of the MOCI and provides a comprehensive list of more than 50 obsessions and compulsions, comprising 15 general symptom categories. Using this checklist, it has been found that in a series of 250 OCD patients, 60% had multiple obsessions, whereas 48% had multiple compulsions. Another study using the same instrument assessed 79 children and adolescents with OCD and found that 47% had both washing and checking compulsions at some time and that none maintained the same symptom constellation at follow-up 2–7 years later. This calls into question the validity of categorizing patients into mutually exclusive subgroups, such as cleaners or checkers, based on symptoms at a given point.

It has also been reported that nearly 80% of the patients could be correctly classified as having TS or primary OCD diagnosis based on two items of the Hamburg obsessive–compulsive inventory, namely "fearful obsessive thoughts" found in 90% of OCD patients and echophenomenon present in 56% of TS patients. Differences between OCD and TS patients were evident on the MOCI subscales checking and slowness/repetition as well as on the total scores. Although TS patients scored higher than controls, they reported fewer symptoms when compared to OCD patients.

Although several studies have attempted to define the precise phenomenology of OC symptoms in TS, few have attempted to compare them to the symptomatology that occurs in OCD patients without a tic disorder. It has been documented that certain kinds of compulsions, such as touching and symmetry behaviors, occurred more often in TS patients than in the OCD group and that TS patients had more counting compulsions and impulses to hurt themselves, whereas OCD patients had compulsions to do things in a specified order and to arrange things; other symptoms,

however, showed an overlap between the two disorders. These clinicians also noted that the symptoms changed with age, with the younger patients exhibiting compulsive behaviors related to impulse control, whereas the older patients had more checking and arranging compulsions. Furthermore, it was suggested that the frequency of OC symptoms increases with the duration of TS. The role of gender and comorbid OCD on the phenomenology of TS has also been studied, and it was found that probands with OCD were more likely than those without OCD to onset with complex tics, and that females onset with compulsive tics more often than do males. In a study of TS children and adolescents with TS, it was observed that the presence of comorbid obsessions contributed to the prediction of learning problems, perfectionism, and antisocial behavior, whereas compulsions contributed to the prediction of hyperactivity, psychosomatic symptoms, and muscular tension.

Robertson and associates noted that coprolalia and echolalia were significantly related to OCB and that self-injurious behaviors in TS were associated with obsessionality. However, nonobscene complex socially inappropriate behaviors occurring in TS were not found to be associated with obsessions or compulsions. In another study by the same group comparing 10 OCD patients to 15 TS patients with comorbid OCD, it was found that violent, sexual, and symmetrical obsessions, as well as forced touching, counting, and self-damaging compulsions, were more common in comorbid OCD/TS subjects. On the other hand, obsessions concerning dirt or germs and cleaning compulsions were more commonly encountered in OCD subjects. Furthermore, the TS group reported that the compulsions occurred spontaneously or *de novo*, whereas in the OCD group this was preceded by guilt or worry. Other studies comparing TS patients with and without OCB found that, in contrast to OCB-free TS patients, TS + OCB patients had a higher incidence of volatile temper, compulsive tics, perinatal disorders, and brain wave changes, as well as a higher prevalence of developmental disorders and a higher severity of TS. They suggested that TS + OCB may be more strongly associated with organic cerebral disorders.

Eapen and colleagues compared the distribution of OC symptoms in 16 patients with OCD and 16 patients with TS and associated OCB. Among the obsessional symptoms, sexual and violent themes were more common in the TS group, whereas concern about contamination and fear of something going wrong or something bad happening were more common among the OCD group. With regard to compulsions, symmetry/evening up behaviors, saying or doing things "just right," and forced touching were more prevalent in the TS group, whereas washing and cleaning were more common in the OCD group. Sex of the proband did not account for any of these differences. Other investigators reported that patients with a history of tic disorder had significantly more touching, repeating, self-damaging, counting, and ordering compulsions. Similarly, in an epidemiological study of OCD, it was reported that OCD subjects with tics had significantly more touching, ordering, repeating, counting, violent, sexual, and aggressive behaviors. In yet another study, TS patients were found to have obsessions concerning harming self or others, intrusive nonsense words, music, or sounds, thoughts about something bad (fire, death, and illness) happening, and compulsions such as checking, excessive washing and tooth brushing, cleaning rituals, counting, and hoarding or collecting things. It was also found that TS patients with comorbid OCD were significantly more likely to report obsessions involving nonviolent images, need for symmetry and excessive concern with appearance, and compulsions such as touching, blinking or staring, and counting. The authors suggested that the differences in symptomatology between TS and primary OCD may be linked to putative differences in pathophysiology.

Thus, it has been suggested that there are at least two subtypes of OCD: one associated with abnormal risk assessment, high levels of anxiety, and pathologic doubt involving worry that something terrible might happen that may be relieved by checking and washing compulsions, and the other type associated with incompleteness and sense of imperfection that is relieved when a compulsion is performed just right. The latter was often associated with tics, TS, onychophagia, and trichotillomania. It has also been proposed that all these conditions belong to a family of OCD spectrum disorders, with the TS subtype having predominantly impulsive features.

However, a problem inherent in this approach of comparing OCD patients with or without tic disorder is the disagreement regarding whether certain symptoms should be classified as compulsions or complex motor tics. Furthermore, Leckman and colleagues reported considerable overlap between TS and OCD symptoms; 93% of their 135 subjects with a tic disorder reported experiencing premonitory urges before performing tics. Thus, it seems that the common distinction based on the involuntary nature of tics compared to OC symptoms is not entirely valid. It has been

reported that intentional repetitive behaviors in OCD differ from those in TS in that the former is preceded by cognitive phenomena and autonomic anxiety and the latter by sensory phenomena. In another study by the same investigators, it was found that, like the TS group, the OCD + TS group reported more sensory phenomena and fewer cognitions than did the OCD group.

An alternate approach to distinguish TS + OCB subjects from pure OCD individuals is to search for a symptom profile rather than individual symptoms. By identifying such phenomenological similarities and differences, it may be possible to gain a better understanding of the underlying etiology and pathogenesis of both TS and OCD. Thus, in a factor analysis of symptom subtypes, three factors (symmetry/hoarding, contamination/cleaning, and pure obsessions) were found, of which only the first factor was associated with a lifetime history of tics or TS. In a cluster analysis of OC symptoms, Eapen and associates found that the TS cluster was characterized by fear of harming self/others, obsessions with violent/aggressive themes, symmetry/evening up, saying/doing things just right, forced touching, and arranging, whereas the OCD cluster was characterized by obsessions about dirt, germs, and contamination as well as the need to tell/ask/know, fear of something bad happening, the need to be neat and clean, and excessive washing and cleaning. In addition to such differences in the symptom profile, both research and clinical experience suggest that the OCB occurring in the context of TS is ego-syntonic, causing less distress to the patients, and is often associated with lesser levels of anxiety. Primary OCD, on the other hand, seems to be ego-dystonic, causing considerable distress to the patients, is preceded by obsessive cognitions, is associated with higher levels of autonomic anxiety, and has fewer or no prior sensory phenomena.

IV. NEUROBIOLOGY

The role of serotonin in the etiology of OCD and that of dopamine in the etiology of TS have been well documented. The strongest body of evidence favoring the serotoninergic and dopaminergic basis of OCD and TS, respectively, comes from studies indicating the effectiveness of selective serotonin reuptake inhibitors (SSRIs) in OCD and dopamine antagonists in TS. Reviewing the available neurobiological and pharmacological data in OCD and TS, Eapen and Robertson mention that the basal ganglia and its frontal cortical circuits are the prime anatomic loci that are implicated in TS and OCD. Furthermore, there is growing evidence of the existence of anatomic and functional interactions between 5-hydroxytryptamine (5-HT) and dopaminergic systems, especially in the basal ganglia areas. 5-HT neurons are believed to maintain a tonic inhibitory influence on dopaminergic function in some regions of the brain, especially the midbrain and brain stem projections to the forebrain. Thus, the neuroanatomic hypothesis that the basal ganglia and its orbitofrontal connections may form the neuronal circuit that subserves TS and OCB, and the available evidence about the interaction between 5-HT and dopamine, is compatible with the role of the previously mentioned structures and neurotransmitters in the pathophysiology of TS spectrum OCB.

Additional evidence for the previously mentioned hypothesis comes from pharmaclogical data on the beneficial effects of neuroleptic augmentation in the treatment of OCD with SSRIs, especially when there are comorbid tics/TS. It has also been suggested that although there may be abnormalities in the serotonergic system in primary OCD patients, both serotonergic and dopaminergic systems may be involved in those with TS + OCD. Furthermore, Leckman and associates suggested that noradrenergic mechanisms are also involved in the pathobiology of TS, and that alterations in the balance of noradrenergic, dopaminergic, and serotonergic systems may be involved in the pathobiology of OCD.

Although no definitive abnormalities have been found, there is a tentative consensus regarding the brain areas involved in TS and OCD, and particularly implicated are the striatal and frontal areas. There is growing evidence of the role of multiple parallel neuronal circuits involving cortex, basal ganglia, and thalamus (fronto-striato-pallido-thalamo-frontal circuits) in the pathophysiology of TS and OCB, and that a failure of inhibition in these circuits may be the cause of inappropriate release of fixed action patterns and OCB. The central role of the basal ganglia in the storage and regulation of complex motor schemas and the existence of contiguous projection areas within the striatum from both the motor and sensorimotor cortical areas suggest that these projections are involved in TS. Leckman and colleagues reviewed the evidence for the previous hypothesis from animal immunohistological studies, postmortem studies of TS patients, as well as neuroanatomical, neurochemical, and neuroimaging studies. Neuroimmunological studies have also suggested that Sydenhams chorea, TS, and OCB might occur following streptococcal

infection through a mechanism of molecular mimicry whereby antibodies are produced that mistakenly recognize cells within the basal ganglia and cause an inflammatory response. Neuropsychiatric manifestations occuring as a result have been termed pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS) by Swedo and associates. However, there is continuing debate about the exact role of such a mechanism in TS and OCD.

Complex processes, such as generation, maintenance, switching, and blending of motor, mental, or emotional sets, take place at the cortical level, whereas the planning and execution of these behaviors are coordinated in the basal ganglia. Given the diversity and complexity of activity within the basal ganglia, the consequence of disruption will depend largely on the site of the lesion and the associated interplay of neurochemical factors. Thus, the anatomical distribution of tics as well as the theme and content of obsessions and compulsions in OCB may be determined by these aspects of the basal ganglia circuitry and the site and extent of its involvement. It is known that an abnormality in the function of dopamine in the basal ganglia structures could affect wide areas of corticostriatal loops modulating and integrating both limbic and frontal motor circuits, thus influencing the clinical presentation and symptom profile in TS. Furthermore, Leckman and colleagues suggested that other modifying factors, such as age, gender, and other environmental factors including perinatal events and exposure, may play a role in determining the final symptom expression in TS.

It has been proposed that the previously mentioned basal ganglia cortical circuits may be hyperactive in OCD as evidenced by the hyperperfusion and increased metabolic changes in the orbitofrontal cortices and basal ganglia in OCD patients. Furthermore, it has also been suggested that the frontal hyperperfusion seen in OCD may be linked to increased arousal and anxiety in these cases. Although limited, the available literature on perfusion patterns in TS suggests hypoperfusion rather than increased blood flow. For example, increased relative metabolic activity and regional cerebral blood flow in certain frontal cortical areas have been documented in OCD when compared to TS. Preliminary studies in TS suggest involvement of caudate, anterior cingulate, medial temporal, and dorsolateral prefrontal areas in the form of hypoperfusion. In a family study using single photon emission computed tomography imaging, Moriarty and colleagues noted that the ''affected'' family members of TS probands showed hypoperfusion irrespective of whether they had tics, TS, or OCD. None of the affected members, including those who had only OC symptoms, showed hyperperfusion. Furthermore, the affected family members were noted to have lower anxiety scores. This, coupled with the finding by other investigators of a correlation between improvement in anxiety and a reduction in the orbitofrontal metabolism in OCD subjects, suggests that the difference in perfusion findings between OCD subjects and TS + OCD patients may be related to the difference in anxiety levels, which in turn may be determined by the specific OC symptom profile in these two groups of patients. Thus, it seems that even at a functional level, there are differences between primary OCD subjects and those with TS spectrum OCB.

V. GENETICS

In addition to the clinical and neurobiological relationship between TS and OCB, studies by Pauls and associates have suggested that OCB may be genetically related to TS. Family studies have shown that TS and OCB are genetically related, with the frequency of OCD in the absence of tics among first-degree relatives (FDRs) being significantly elevated in families of both TS + OCD and TS−OCD probands. The rate of OCD among FDRs was significantly increased compared to estimates of the general population and a control sample of adoptive relatives. The rates of TS, tics, and OCD were the same among relatives of TS probands with OCD (TS + OCD) when compared with families of probands without OCD (TS−OCD). Other family studies by Comings and colleagues also found that many relatives of TS patients have OC symptoms even in the absence of motor and vocal tics.

Segregation analyses studies of TS families by the previously mentioned groups of researchers found that TS and OCB may be an alternative expression of the putative TS gene(s). Furthermore, in a TS twin study, both twins were reported to be obsessional, and in a study of triplets, one was reported to be obsessional.

Genetic mechanisms have been found to be important in OCD as well, with a heritability rate of 44% for OC traits and 47% for OC symptoms, thus suggesting that genetic and specific environmental factors were both important for the manifestation of OCD. In a study on identical twin pairs who were separated prior to the onset of symptoms, neither being aware of the other's problems, it was found that the OC symptoms started at similar ages and followed a similar course in

both pairs. It is interesting that the fathers of both sets of twins had obsessional traits. Furthermore, one of these twins had childhood tics and two of the four sets of identical twins with OCD had TS. However, in all the twin data reported, the concordance for MZ twins was less than 1.0 and heritability estimates were consistently less than 1.0. In addition, an analysis of OC traits in twins has shown a strong interaction between genetic and environmental factors. Thus, although genetic factors are important in the expression of OC symptomatology, these behaviors are also influenced by environmental factors.

Based on evidence from two twin studies, it has been suggested that although genetic factors are important for anxiety disorders in general, this contribution is obscured by the grouping of anxiety symptoms into specific disorders. In this regard, in a study of FDRs of 32 adult OCD probands and 33 psychiatrically normal controls, it was found that the morbid risk for anxiety disorders was increased among the relatives of OCD subjects when compared to the relatives of controls, but the risk for OCD was not. Risk for a more broadly defined OCD was increased among the parents of OCD probands but not among the parents of controls (16 vs 3%). These findings suggest that an anxiety disorder diathesis is transmitted in families with OCD but that its expression within these families is variable.

When compared to population prevalence estimates, several family studies have reported significantly higher rates of OCD in parents and siblings of OCD probands, with rates among parents being 5–10 times higher. Two family studies found remarkably similar risk rates in FDRs of young OCD probands. One study of 145 FDRs of 46 children and adolescents with OCD reported an age-corrected morbid risk of 35% in FDRs when subclinical OCD was included. Another study examined families of 21 children and adolescents with OCD and found that 35.7% of parents received a diagnosis of clinical or subclinical OCD. In yet another study of 92 adult OCD probands, it was found that the rate of OCD among FDRs was only 3.4%. However, when probands were separated into two groups based on whether the age of onset was before or after 14 years, it was noted that the morbid risk for OCD among relatives of the early onset probands was 8.8% compared to 3.4% among the relatives of probands with a later age of onset.

However, the results from these investigations do not suggest that all subjects with OCD have a disorder that is genetically determined. It has been suggested that there are subgroups within OCD: those with a family history of OCD and those without such a history. Furthermore, there may be a familial subgroup that is genetically related to TS. Available evidence suggests that the OC symptoms observed in members of families with TS comprise a milder form with less distress and anxiety, and that the range and character of symptoms are somewhat different and specific when compared to those observed in clinical patients with OCD in the absence of tics or TS. Further evidence for heterogeneity in OCD comes from descriptive studies of childhood OCD and family studies. Although some investigators did not find an increased incidence of tic disorders among adult OCD patients, others, such as Riddle and colleagues, suggested that childhood-onset OCD may be different from adult-onset OCD and that the childhood-onset subtype may be more closely related to TS.

In a recent segregation analysis study of OCD families, a dominant model of transmission was suggested. When the phenotype was widened to include TS and chronic motor tics, an unrestricted model of transmission became the best fit, and it was proposed that the OCD phenotype probably presents a higher level of heterogeneity than the TS phenotype. Furthermore, the clinical and phenotypic heterogeneity may be linked to genetic heterogeneity, with some individuals having inherited the TS + OCD genotype and others the classic OCD genotype. In a family study of OCD probands and TS + OCD probands, Eapen and colleagues found that all the OCD probands who shared a similar symptom profile to that of TS probands had at least one first-degree relative with OCD, whereas none of the OCD probands with classic OCD symptoms had a positive family history. These authors concluded that the latter could be regarded as sporadic or nonfamilial cases. These observations may be consistent with genetic heterogeneity within both OCD and TS. In this regard, it is interesting to note the findings of a recent segregation analysis study by Pauls and colleagues, who used factor-analytic symptom dimensions to subset the family sample based on probands' symptom factor scores. They found that families with a high symptom score of symmetry and ordering had a higher risk of OCD in relatives and suggested that this may constitute a genetically significant subtype of OCD. This is in keeping with the findings of another study that reported that OCB is less prominent in sporadic than in familial TS, perhaps reflecting a more restricted pathophysiology in this subgroup. These investigators also found that although bilineal transmission of tics is relatively infrequent in consecutive TS pedigrees, cotransmission of OCB from an otherwise unaffected parent is

common and significantly influences the development of OCB and self-injurious behaviors, but not tics, in the offspring.

Thus, according to the collective knowledge, it seems that although there is little doubt about a familial relationship between OCD and TS, not all cases of OCD are either familial or etiologically related to TS. In this regard, three subtypes of OCD have been described by Pauls and associates: a familial type related to tic disorders, a familial type unrelated to tics, and a nonfamilial type. It is hoped that further refinements at various levels of diagnostic hierarchies will ultimately lead to an improved definition of what constitutes the genetic spectrum of TS. Furthermore, molecular genetics offers a promising method for exploring the underlying etiologic heterogeneity of TS and related conditions such as OCD.

GLOSSARY

allograft Transplant consisting of cells or tissues from a donor of the same species.

apoptosis Cell death occurring due to a specific series of genetically orchestrated intracellular reactions.

autograft Transplant consisting of cells or tissues from the recipient's own body.

neurotrophic factor Molecules in the environment of central nervous system cells that support their survival and growth.

plasticity The capacity of nerve cells to alter their structure and function.

rejection The response of the immune system that coordinates the destruction of transplanted cells or tissues.

stereotaxic surgery Procedure that allows accurate targeting of deep brain structures within a system of three-dimensional coordinates.

xenograft Transplant consisting of cells or tissues from a donor of a different species.

We generally think of transplantation as a surgical approach for the treatment of diseases in which an entire organ is transferred from one body to another. As applied to the brain, however, transplantation refers to the surgical replacement of specific cells or clusters of cells of the brain, instead of the whole organ. Thus, this approach replaces brain cells that have died or stopped functioning due to injury or disease. This article reviews the theoretical background of neural transplantation, its history, current and future applications to the treatment of brain damage as developed from studies of animals and human patients, and the societal issues associated with the procedure.

I. WHY TRANSPLANT BRAIN CELLS?

Most of the organs in our body are made up of cells that are capable of constantly repairing and renewing themselves, maintaining the vital functions of the organs. For example, when your skin is damaged the cells can multiply and migrate to form new skin; thus, healing occurs over a short period of time. The cells lining the digestive system are constantly being renewed as old cells succumb to the harsh environment of digestive enzymes. However, there are certain types of cells in the body that exhibit little or no ability to multiply in order to renew the population. These include muscle cells of skeletal muscle and heart and the cells of the brain that process and transmit information—the neurons. Therefore, when neurons die there exists an extremely limited capacity for neuronal replacement. When neurons die in large

numbers due to injury or disease, permanent problems arise in the normal function of the brain. In Alzheimer's disease, for example, problems arise in the ability to learn and remember information. In Parkinson's disease, movement and balance are disturbed. These problems, and others associated with other types of brain injury or disease, can be related directly to death of specific populations of neurons that normally function to produce the mental or physical activities that become disturbed.

Given that the brain has a limited capacity to repair itself, how can brain disorders be treated? For some problems, there is no treatment currently available. For problems that can be linked to depletion of the chemicals used by neurons to transmit information, the "neurotransmitters" of the brain, the traditional treatment has been to replace lost activity by administering drugs that produce a similar effect. However, treating brain disorders with drugs can be problematic. Some potentially therapeutic substances may never gain access to the brain. Instead, they either are rapidly broken down by enzymes in other parts of the body or are unable to pass the physical barrier that exists between the blood supply and the brain, the so-called blood–brain barrier. In addition, it currently is not possible to restrict the action of a drug to the particular problem in the brain that needs treatment. Neurotransmitters used by neurons to perform their functions often exist in other systems of the body, where they perform different functions. Thus, although a drug might be administered to treat a problem in the brain, it circulates through the rest of the body and may act at other organs to produce side effects, for example, changing blood pressure or affecting digestion. Even within the brain a given neurotransmitter often exists in many different parts of the brain, each subserving a different function. Consequently, a drug that gains access to the brain will affect all neural systems that use the chemical, again producing side-effects that may be undesireable, such as confusion, anxiety, or sedation. Finally, the effects provided by drugs usually are not long-lasting. Even if a drug can be identified that treats the problem in the brain effectively and with acceptable side effects, the effects of the drug vary with its amount present in the body over time. Thus, high levels and strong effects occur immediately after ingestion, whereas low levels and loss of effect are seen several hours later as the drug disappears from the body.

Transplantation is a treatment strategy that aims to replace the function of neurons that die by replacing the neurons. With a combination of surgical skill and an understanding of brain anatomy and physiology, new cells can be placed into the specific location they are needed, become part of the brain, replace neurotransmitters, and function for the lifetime of the individual (Table I).

II. HISTORY OF NEURAL TRANSPLANTATION

For many years, neural transplantation was used in biological research as an experimental tool for understanding the development of the nervous system. Beginning in the 1920s, a number of now classic studies employed transplantation, removal and reimplantation, and transposition of nervous tissue to study the specificity of the developing interconnections of the nervous system and the capacity of this tissue for regeneration. Nearly all this work was done in amphibians, fish, and birds. Indeed, the robust growth capacity of nervous tissue in cold-blooded vertebrates, coupled with the limited success of early neural transplantation experiments in mammals, probably

Table I
Comparison of Neural Transplantation to Drug Therapy

Transplantation	Drug therapy
Targeted delivery: Replacement of neurotransmitter/other molecules at the specific site in brain required	Diffuse delivery: Effects produced throughout the body; side effects potentially problematic
Biological replacement: Multiple actions of natural cell products possible	Synthetic replacement: Highly specific drug action
Regulated delivery: Cellular release of molecules potentially controlled by surrounding cells	Delivery based on pharmacokinetics: Variable concentrations over time due to ingestion/absorption/circulation
Lifetime replacement: Cells integrate with host, becoming part of the tissue	Temporary replacement: Drug response varies over time

contributed to the scientific bias of the time that the regenerative properties of central nervous system (CNS) tissue were fundamentally different among species and deficient in mammals. In fact, it can be argued that the most important concept that has emerged from neural transplantation studies is an appreciation of the considerable capacity for regeneration, growth, and functional integration that can be exhibited in the complex CNS of mammals.

The first neural transplantation experiment reported in the scientific literature appeared in 1890. The study by W. G. Thompson at New York University examined the survival of pieces of cerebral cortex from adult cats transplanted into cortical cavaties of adult dogs. By 6 weeks after grafting essentially no transplanted neurons were observed to survive. In 1917, Elizabeth Dunn at the University of Chicago published the first study to convincingly demonstrate survival of transplanted CNS cells. Earlier, in 1909, S. Walter Ranson of Northwestern University successfully grafted neurons from the peripheral nervous system into the CNS of rats, documenting a form of morphological plasticity associated with younger tissue. In Dunn's experiments, cortical tissue from 9- and 10-day-old rats was grafted into cortical cavaties of littermates. At survival intervals of as long as 66 days, Dunn reported that grafts retained some of their normal cellular architecture. In addition to providing the first indication that CNS tissue could survive transplantation, the study provided more evidence that the developmental stage of the tissue was related to graft survival, and that transplantation of tissue in contact with a rich vascular bed may improve transplant outcome. In the 1940s, W. E. LeGros Clark at Oxford University began to report studies of embryonic CNS tissue transplants in rabbits that indicated that tissue from donors of even earlier developmental stage had greater capacity for survival and integration with the host nervous system. In 1945, Harry Greene and Hildegarde Arnold at Yale University provided the first report of successful transplantation of human embryonic CNS tissue to the anterior eye chamber of guinea pigs. Comparison of grafts of embryonic tissue from humans, rabbits, and guinea pigs revealed comparable excellent survival from all donors for periods of up to 2 years. With the demonstration that transplanted human tissue behaved similarly to transplants derived from other mammalian species, the slowly emerging concepts being developed in experimental animals became directly applicable to the human nervous system.

Although the roots of neural transplantation can be traced back to 1890, the approach largely remained a scientific curiosity until the late 1960s. At this time, a variety of new techniques were developed that enhanced the ability of scientists to study transplanted tissue. Interest in transplantation experienced a resurgence, with the number of research articles dealing with the topic that were published in 1983 alone equaling the number published in the entire century preceding 1970. In rapid succession, experimental findings documented the conditions that favored transplant survival and demonstrated that transplanted neurons exhibit a variety of important characteristics of mature neurons including manufacture and release of specific neurotransmitters, normal patterns of electrical activity, expression of cell surface receptors, the capacity to establish appropriate synaptic connections with the host brain, and influence the behavior of the host organism in a manner consistent with the biology of the transplanted cells.

Although transplantation experiments in animals have yielded several findings important to our current understanding of the capacity of neurons to alter their structure and function, properties termed "plasticity," transplantation as applied to the human brain exists in the realm of evolving medical therapies. The remainder of this article focuses on the development of neural transplantation as a treatment strategy for CNS injury and disease in humans.

III. WHICH CELLS CAN BE TRANSPLANTED TO THE BRAIN?

In animal experiments, many different types of cells have been transplanted into the brain or spinal cord with varying degrees of success. For treatment of disorders of the human CNS, the majority of transplantation trials to date have used nervous tissue or paraneural cells such as the chromaffin cells of the adrenal gland. However, there is reason to believe that many types of cells could be transplanted successfully to the brain. This contention is based on what is known about the interactions between the immune system and the CNS.

One problem associated with transplantation of tissues and organs is the potential for rejection. This is because the immune system functions to distinguish foreign organisms, cells, and tissues from those associated with one's own body. Cells of the immune system can identify "self" and "nonself" and coordinate the destruction of foreign substances. Transplants are classified as autografts when the cells or tissues are taken from other parts of the transplant recipient's

own body, homografts or allografts when taken from an individual of the same species, and heterografts or xenografts when taken from a member of a different species. Autografts tend to survive transplantation well. These transplants consist of cells that are genetically identical to the host and recognized by the immune system as self. In contrast, allografts and xenografts are composed of cells that are detected as foreign by the immune system, triggering rejection.

As neural transplantation experiments progressed, it became clear that transplant rejection was not as serious a problem as originally anticipated when tissues were transplanted to the CNS. As early as 1921, evidence was beginning to emerge that suggested that xenografts survived for relatively long periods of time in the brain while the same tissue implanted in muscle was actively rejected in a short period of time. Findings such as these led to the concept of the brain as an immunologically privileged site. Recently, this concept has been revised to incorporate research findings that indicate the brain is a site of reduced surveilance by the immune system, but that immunological responses can be provoked in brain, albeit often delayed and less vigorous than those that occur in other parts of the body. Part of this diminished immune surveilance may be attributable to the blood–brain barrier. The same barrier that shelters the brain from organisms and substances circulating in the bloodstream that are potentially toxic or damaging reduces the ability of immune cells in the circulation to access the brain. Although this barrier is physically opened by transplant surgery, it is reestablished relatively rapidly over a period of several days. This allows physicians to treat patients receiving neural transplants with drugs that suppress the immune response for a relatively short time after surgery, until the blood–brain barrier can be reestablished, whereas recipients of transplants in other parts of the body often take drugs for immune suppression for the rest of their lives.

Although the brain as a site for transplantation presents fewer problems than other parts of the body with respect to rejection, in theory making it possible to successfully transplant a variety of types of cells, most success has been achieved with implants of neural tissue taken from embryonic donors. From a commonsense perspective, the best cell to replace the function of a neuron is another neuron. It became clear in early neural grafting experiments that transplantation of adult CNS tissue seldom yielded surviving neurons, whereas implants of neonatal or embryonic tissue exhibited much better results. This is probably due at least in part to the anatomy of neurons. Neurons consist of a cell body that extends a number of fine cytoplasmic processes that serve as sites for transmitting, receiving, and integrating neurochemical/electrical signals from other cells in the CNS. In particular, the neuron's axon, the process subserving signal transmission, can extend for long distances in the CNS, intermingling with large numbers of processes of other neurons and glial support cells. This anatomical complexity of mature CNS tissue presents a problem for the harvest of neural tissue for transplantation. During dissection of donor tissue, mature neurons inevitably will be damaged by severing their long processes from the cell body, inducing molecular events leading to cell death. Neural tissue in the early stages of development does not present this problem. In fact, it has been found that neurons collected at a time during development just prior to extension of processes provide the best chance of optimal transplant survival. Thus, the appropriate time interval for collection of neurons for transplantation varies with the specific regional development of the neurons of interest. Knowledge of the timing of neural development and the landmarks and architecture of the immature brain becomes crucial to the collection of appropriate donor cells for transplantation. The features of embryonic neural cells considered optimal for transplantation are listed in Table II.

IV. HOW CELLS ARE TRANSPLANTED TO THE BRAIN

In comparison with many types of neurosurgery, transplantation surgery is a relatively straightforward procedure. In general, collection of embryonic neural tissue for transplantation is the most technically challenging aspect of the approach. In surgery using this type of donor tissue, the appropriate region of the developing CNS, from donors of an appropriate developmental stage, is collected via microdissection. Working with the aid of a microscope, the surgeon removes the region of brain containing the appropriate population of neurons for transplantation by utilizing the external and internal landmarks of the brain as reference points. Once the donor tissue is collected, it is usually prepared in one of two ways for transplantation into the host brain: either as small pieces of tissue (i.e., so-called solid tissue grafts) or as a physically and enzymatically dispersed solution of cells in the form of a "cell suspension." Tissue pieces or suspensions are held in an oxygen-rich fluid medium that can be

Table II
Optimal Characteristics of Neural Cells for Transplantation

Characteristic	Description
Postmigratory	Cells have reached their specific anatomical location in the developing brain that allows reproducible dissection and collection
Postmitotic	Neurons have reached a stage of maturity in which they no longer divide; provides a measure of safety against tumor formation by transplants
Differentiation	Cells have reached a stage of maturity in which they express the chemical machinery specific for production of neurotransmitters or other molecules needed for therapeutic replacement following transplantation
Prior to neurite extension	Neurons have not yet extended long processes making them prone to injury during collection, but they are poised for rapid growth of processes, which facilitates integration with the host brain following transplantation

supplemented with other ingredients that promote the health of the cells. Implantation of tissue or cells occurs by drawing the material into sterile syringe needles, or cannulae, and slowly infusing the material into the appropriate brain site of the host. The target for transplants can be determined with medical imaging techniques, such as magnetic resonance imaging, and the infusion cannulae can be accurately positioned using stereotaxic surgery—a method of accurately locating deep brain structures within a three-dimensional system of coordinates (Fig. 1). After surgery, drugs are administered to prevent infection and suppress the immune response in the case of allografts or xenografts.

The major problem in transplant surgery is not the delivery of donor cells to the appropriate location but survival of the transplanted cells. Transplanted cells are under assault at every stage of the procedure. The issue of cell survival has been studied in greatest detail for embryonic neurons making the neurotransmitter dopamine transplanted as an experimental therapy for Parkinson's disease. Factors influencing survival of these developing neurons are summarized in Fig. 2 but may be generalized to other donor cells. It is estimated that 80–95% of immature dopamine neurons harvested for transplantation die within 4 days of implantation into the host brain. As indicated in Fig. 2, factors influencing cell survival probably occur during three main stages of the transplantation procedure.

Stage 1 includes the time during which donor tissue is collected and prepared for implantation. It has been found that a significant proportion of cell death following transplantation is triggered during the preparation of tissue prior to transplantation. Among the potential triggers of cell death occurring during this interval are (i) physical trauma to the tissue as a consequence of dissection and handling; (ii) anoikis, a type of genetically programmed cell death triggered by detaching immature neural cells from the matrix of extracellular molecules in which they are embedded; (iii) ischemia—disruption of the supply of blood-borne oxygen and nutrients; (iv) oxidative stress—exposure to oxygen radicals that damage cell membranes and are generated by cells undergoing metabolic stress; and (v) withdrawal of trophic factors, molecules that exist in the environment of the developing brain that are known to promote survival and growth of immature neural cells. Stage 2 includes the 4 days immediately following transplantation. In this stage many of the same triggers of cell death exist but are in part generated by the environment of the host brain, not just removal of immature tissue from the developing brain. For example, withdrawal of trophic factors for the immature neural cells is compounded by the markedly lower concentrations of these molecules in the environment of the mature or aging host brain. Ischemia is likely to exist for several days for neural transplants. Unlike organ transplantation in the periphery, which often includes meticulous reconnection of the vascular supply of the transplanted organ, tissue transplants in brain are entirely dependent on growth of new blood vessels connecting the transplant with the host. This process takes place over 4–7 days, leaving the transplanted tissue dependent on diffusion of oxygen and nutrients from nearby host brain blood vessels for an extended time. Stage 3 includes the time after the first few days following transplantation. Most death of transplanted cells has already occurred, but delayed death of cells can be triggered by continued deprivation of trophic molecules and a delayed rejection response.

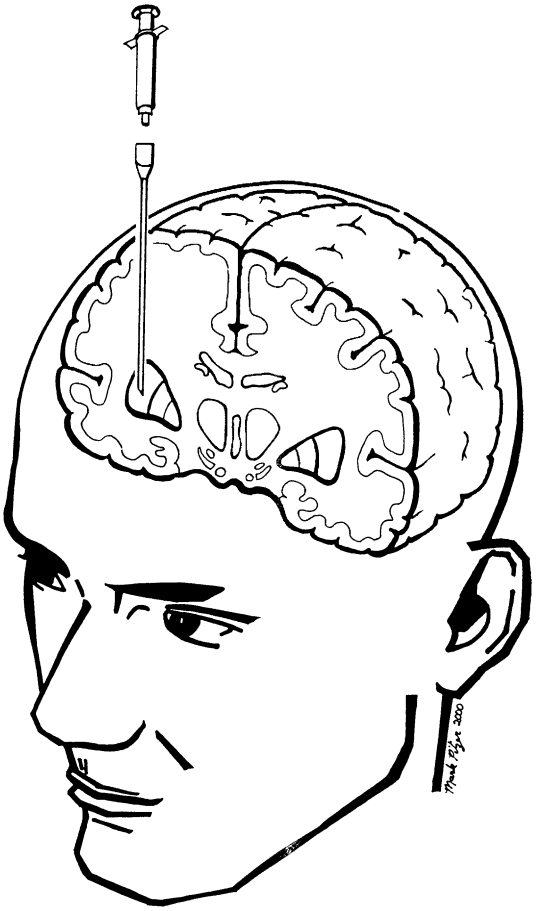

Figure 1 Diagram illustrating the principles of stereotaxic implantation of cells into the brain. Medical imaging techniques, such as MRI, provide visual cross sections through the brain, providing a map from which measurements are made that allow localization of deep brain structures for placement of transplants. The cross section shown approximates the detail provided by MRI and shows the putamen being targeted for transplantation. The putamen is a structure in the striatum and is a target of transplants for treatment of Parkinson's disease. A hollow cannula is lowered into position using stereotaxic surgery, a method for accurately locating deep brain structures within a three-dimensional system of coordinates. Cells for transplantation are slowly infused via the cannula, the cannula is withdrawn, and the surgery is completed.

Taken together, these elements present a formidable obstacle to graft survival. Thus, development of strategies designed to prevent death of cells transplanted to brain represents one of the keys to more widespread therapeutic application of this technique. Increased understanding of the triggers and mechanisms of cell death provides clues to potential methods for augmentation of survival of transplanted cells. For example, the appreciation that many cells are dying via the type of genetically programmed cell death observed during development of the nervous system, apoptosis, provides a framework for designing interventions. The molecular events participating in apoptosis have been defined, first by studies in invertebrates and then in mammals. Accordingly, strategies aimed at

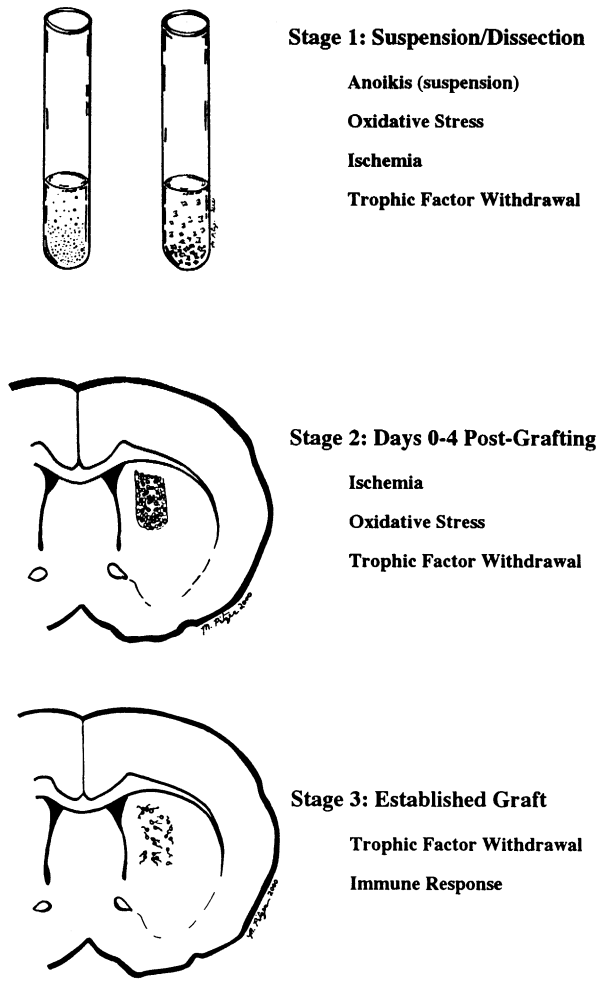

Figure 2 Factors associated with the transplantation procedure that may negatively affect survival of immature neural cells. The transplantation procedure has been divided into three stages. Factors that challenge cell survival for each stage are discussed in the text. Stage 1 covers the process of dissecting, collecting, and preparing the cells for transplantation. The diagram depicts a dissociated cell solution or small pieces of neural tissue held in test tubes prior to transplantation. Stage 2 covers the first few days after transplantation of cells. The diagram depicts a cross section through the rat brain at the level of the striatum. A newly implanted group of cells is shown as a cylindrical deposit on the right side of the brain. Stage 3 covers long-term survival of transplanted cells. Again, a cross section through the rat striatum is shown, with transplanted cells, now more integrated with the host brain, on the right side of the diagram.

interfering with this molecular cascade, such as pharmacological blockade of the action of the ultimate executioner molecule, caspase, have been demonstrated to enhance grafted cell survival in animal experiments. Similarly, approaches that increase the blood supply to transplanted cells, buffer environmental free radicals with antioxidants, and recapitulate the trophic environment of the developing nervous system by local replacement of survival- and growth-promoting molecules all show promise in ongoing studies.

V. TRANSPLANTATION AS A TREATMENT FOR PARKINSON'S DISEASE

In large part, the history of neural transplantation in humans is the history of transplantation as a treatment for Parkinson's disease (PD). PD is the human neurodegenerative disease most amenable to a neural transplantation approach for several reasons: (i) Symptoms of the disease are mainly due to loss of a single population of neurons, the dopamine-producing cells of the substantia nigra; (ii) death of these neurons depletes dopamine in specific locations of the brain, of which the regions of the striatum appear to be most important for the disruptions of movement that debilitate patients; and (iii) dopamine release in these brain regions is widespread and relatively constant, requiring no reconstruction of highly specific point-to-point connections that characterize some other systems of the brain. Thus, cell transplants that replace dopamine in the striatum, in a relatively nonspecific manner, have a high likelihood of being therapeutic in PD.

Additional support for considering transplantation therapy for PD is provided by the history of treating the disease with drug therapy. In the early 1960s, scientists and physicians began developing a drug therapy for PD consisting of the precursor molecule of dopamine, levodopa, which was known to cross the blood–brain barrier. Levodopa was administered in combination with carbidopa, which prevented breakdown of levodopa in the body, allowing it to access the brain. This combination of drugs revolutionized treatment of PD and remains an effective treatment of symptoms for several years early in the progression of the disease. However, with continued degeneration of dopamine neurons and long-term use of the drugs, therapeutic benefit decreases and undesireable side effects increase. Patients with advanced PD are left with unmanageable symptoms for most of their daily lives. The transplantation approach is an attractive alternative, potentially providing a cellular source of dopamine, implanted directly into the striatum to deliver dopamine locally to the structure important for the movement disorders and lasting for the lifetime of the individual.

Clinical application of neural transplantation to PD was preceded by more than 15 years of studies in rodents and nonhuman primates. These studies demonstrated that immature dopamine neurons could survive transplantation into the model environment of the anterior eye chamber of rats, with subsequent verification of survival of grafted dopamine neurons and the dopamine-producing paraneural cells, chromaffin cells, of the adrenal gland transplanted into the brain ventricles and striatum of rats. These studies documented that grafted cells produced and released dopamine and could ameliorate behavioral symptoms of dopamine depletion in rodent models of PD. In the case of transplants of immature dopamine neurons, it was also documented that cells extended processes into the host brain, made appropriate contacts with other neurons in the host, and maintained electrical properties typical of dopamine neurons. With the notable successes of rodent studies, investigations were carried over to nonhuman primates exposed to the neurotoxin 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which produced specific degeneration of substantia nigra dopamine neurons highly reminiscent of PD. Systematic study of transplants in this setting allowed development of parameters applicable to clinical trials by approximating the complexity of neural circuitry of the motor system in a species more closely related to humans.

The first neural transplants performed as a therapy for PD were undertaken in the early 1980s. Although transplants of embryonic dopamine neurons showed promise in animal experiments, the first tissue transplants in humans consisted of chromaffin cells of the adrenal gland implanted into the striatum. These cells normally produce small amounts of dopamine and larger amounts of the chemicals norepinephrine and epinephrine, which are synthesized from dopamine. However, when removed from the regulatory influences of other cells in the gland, chromaffin cells increase production of dopamine. In addition to making the appropriate neurochemical, chromaffin cells can be collected from the patient's own gland as an autograft, minimizing the chances of rejection. The use of chromaffin cells for transplantation was also not encumbered with the ethical issues associated with the use of tissue from embryonic donors. In 1985, the first

report of chromaffin cell transplants for the treatment of PD was published by investigators from Sweden, followed soon after by reports of trials conducted in Mexico. During the next few years, hundreds of patients received these transplants worldwide. Careful evaluation of 126 patients operated on in the United States revealed only modest improvements in symptoms, often lasting only 1 or 2 years after surgery, accompanied by significant medical or surgical complications in more than 40% of the cases. Of the cases that came to autopsy, most reported no surviving transplanted chromaffin cells expressing the biochemical signs of dopamine production. Studies of chromaffin cell transplants in animals demonstrated that despite poor survival of these cells, there was evidence of stimulation of surviving host dopamine neurons, perhaps via release of neurotrophic molecules by transplanted cells. This transplant-associated stimulation may account for the modest improvements in symptoms observed in some patients. In 1990, chromaffin cell transplants for the treatment of PD were discontinued in the United States.

With support for the therapeutic efficacy of chromaffin cell transplants waning, initial reports of human embryonic dopamine neuron transplants in patients with PD appeared in the literature in 1988. All of these initial clinical studies were performed outside of the United States because links between the issue of abortion and the use of embryonic tissue for transplantation sparked a societal debate in the United States that lasted for nearly 4 years. By 1996, published articles accounted for approximately 200 patients receiving embryonic tissue grafts worldwide. It is likely that many more patients have received transplant therapy and have not been accounted for in the scientific literature. Reports of effects on PD symptoms have been highly variable. In general, modest improvements have been observed, primarily expressed as a reduction in so-called "off time," the time during which medication provides no benefit for PD patients, and a reduction in dyskinesias, which are involuntary movements that are a side effect of medications for PD. In general, reports suggested that transplants failed to replace sufficient dopamine innervation to allow significant reduction of levodopa intake by patients to manage their symptoms. However, it is noteworthy that considerable variation existed around this average outcome, with some patients showing dramatic improvements.

Transplantation of embryonic dopamine neurons in PD patients continued at a cautious pace as animal experiments sought to inform physicians about strategies to optimize the transplantation approach. In 1992, an article was published by Scandinavian scientists indicating much greater therapeutic effects than previously had been reported following dopamine neuron transplants in two patients suffering from PD-like symptoms produced by exposure to the neurotoxin MPTP. In 1995, a group of scientists in the United States published a similar report of improved outcome following transplantation of immature dopamine neurons in PD patients, followed in 1996 by autopsy findings from two patients providing the first demonstration of good survival of large numbers of transplanted dopamine neurons over an 18-month period following surgery. In 1999, a report was published by the Scandinavian group on positron emission tomography imaging of a PD patient that suggested survival of transplanted embryonic dopamine neurons and continuous replacement of dopamine activity over a period of 10 years after surgery. A common feature of these studies was a revision of the transplant procedure to implant tissue from several donors into each patient. Animal experiments had begun to describe the problems associated with survival of transplanted immature neurons and the need for an initial strategy for compensating for loss of cells by increasing the amount of tissue transplanted. Although the relatively poor survival of transplanted neurons remained problematic, it is clear that when more cells were implanted a sufficient number survived to produce a better therapeutic effect.

The exchange of information between experimental findings and issues raised in animal studies and clinical trials has been one of the defining characteristics of neural transplantation as an experimental therapy. To date, every important variable associated with the transplantation procedure has been accurately predicted by animal experiments. The sequential examination of the properties of immature neurons grown and maintained in tissue culture, followed by animal experiments with transplantation in rodents and ultimately tests of safety and feasibility with transplants in the best model of the human brain, the nonhuman primate, has directly led to therapeutic application of neural transplantation and continues to provide strategies to improve the current approach. The microscopic photographs of dopamine neuron grafts presented in Fig. 3 illustrate the similarity of outcome that has been achieved in animal studies and human clinical trials. Some of the important issues for transplants of embryonic neurons that have been studied in animals and confirmed in patients are listed in Table III.

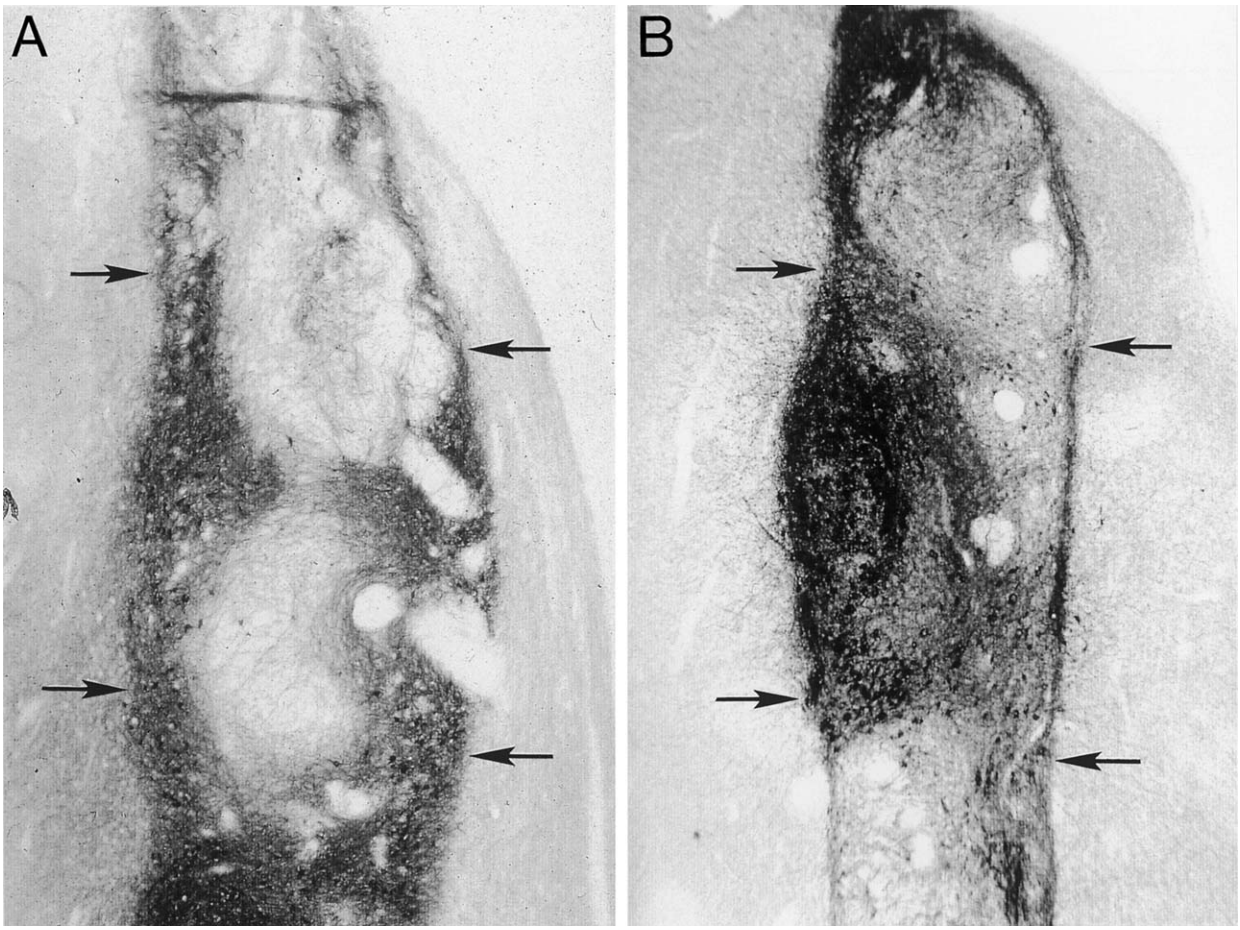

Figure 3 Comparison of transplants in human and monkey. Photographs of transplanted dopamine neurons visualized postmortem in the striatum of a human patient with Parkinson's disease at 18 months after transplantation (A) and in an MPTP-treated monkey 7 months after transplantation (B). Transplants (arrows) appear as similar cylindrical deposits of cells. Dark staining is for the enzyme tyrosine hydroxylase, which is necessary for the synthesis of dopamine and a characteristic marker for dopamine neurons. Note the nearly identical appearance of the transplants, illustrating one aspect of the predictive value that animal experiments have had for the development of transplant procedures for clinical application.

VI. THE SOCIOLOGY OF TRANSPLANTATION

The use of transplantation as a treatment for human neurological disorders carries with it a variety of ethical and societal concerns. At an abstract level, manipulations involving the brain as the organ of being human, the source of intellect and personality, may give rise to ethical and religious concerns. However, individuals afflicted with neurological disorders are often faced with desperate circumstances in which any hope of treatment overwhelms such philosophical issues. The more difficult societal issue for neural transplantation revolves around the current understanding that the best therapeutic results are provided by implants of embryonic tissue. In this context, the medical therapy is confronted with issues surrounding abortion.

This debate between science and ethics spilled over into politics with a request by scientists of the United States National Institutes of Health for permission to implant human embryonic dopamine neurons into patients with PD. In a climate of political conservatism, a moratorium of indefinite duration was placed on the use of federal research funds for transplantation of human embryonic tissue obtained from elective abortions into human patients in March 1988. The moratorium did not preclude the study of human embryonic tissue not used for transplantation in humans, and it did not target embyronic tissue obtained from spontaneous abortions. During the

Table III
Issues in Neuron Transplantation

Issue	Description
Donor age	Relatively narrow range (a few days) based on stage of development when specific characteristics of neuron type are expressed, but large-scale extension of neurites has not occurred
Amount of tissue	Currently, relatively poor survival of transplanted embryonic neurons requires implantation of tissue from multiple donors.
Target/distribution of tissue	In general, transplanted embryonic neurons extend neurites for short distances (2–3 mm) in the adult host brain. Thus, cells are transplanted within the brain region targeted for replacement therapy, and multiple transplants spaced close together provide the most complete replacement.
Form of transplant (pieces, suspensions)	Both have advantages. Both have been effective in human clinical trials.
Tissue storage (culture, hibernation, cryopreservation)	Storage of tissue prior to transplantation is desireable to allow testing for infection/contamination, best tissue type match, and transportation/distribution of tissue. Cryopreservation allows storage for very long periods of time (years), but cells are lost with freezing and thawing. Hibernation for short periods (2–3 days) does not reduce cell survival. Storage in tissue culture for short periods (4–8 days) with rotary motion and exposure to antioxidants and/or neurotrophic factors does not reduce cell survival
Immune suppression	Rejection is reduced in the CNS. Drugs for suppression of immune response have been administered for up to 6 months after transplantation, then discontinued, with no detected adverse effects
Pharmacotherapy	Patients receiving transplants often take medications to manage symptoms. For PD, animal experiments indicate mixed findings regarding whether levodopa therapy reduces survival or function of transplanted neurons. No conclusions have been drawn from human trials
Disease progression	Will transplanted cells be attacked by the neurodegenerative disease process existing in the patient? Studies using medical imaging techniques in PD patients indicate stable survival of transplanted neurons 10 years after implantation
Age of transplant recipient	Advanced age in the transplant recipient reduces therapeutic efficacy of transplanted neurons

moratorium, a government-appointed panel on human fetal tissue transplantation research met to assess both the science and the morality of using tissue from deceased aborted embryos. The panel, consisting of members representing a range of views on abortion, religion, and research, concluded by a vote of 17 to 4 that embryonic tissue transplantation was morally acceptable and that the issue of abortion and the use of tissues after death of the embryo were separable. In consensus agreement with similar debates that were carried out in Sweden, the United Kingdom, The Netherlands, Canada and elsewhere, it was believed that research of potential benefit to so many people should proceed as long as important safeguards were in place. Among these were prohibition of the sale of tissue and procedures for isolating the decision to have an abortion from consent to use the tissue for research.

Despite the recommendations of the panel, no immediate action was taken to change the moratorium. During this time, first reports of neural transplantation for PD were published by investigators in Sweden, Mexico, the United Kingdom, and China. Progress in embryonic tissue transplants for PD and promising work on transplantation of embryonic pancreatic islet cells for treatment of diabetes were slowed in the United States and moved forward only to the extent that private funds could be garnered to support the research. In January 1992, 2 days after a change of administration in Washington, DC, the government lifted the moratorium on human embryonic tissue transplantation research. The research is now governed by strict guidelines that borrow from those already accepted as the standard for acquisition of other organs for transplantation from human cadavers. Although work in the area of embryonic tissue transplants proceeds, the association of this approach with abortion remains a contentious issue that will remain unacceptable to some individuals. Accordingly, one challenge for the field of neural transplantation is the development of approaches that take advantage of the important characteristics of immature cells but move away from a continuing need

for tissue derived from aborted embryos. Several approaches are being explored, including (i) the use of gene transfer techniques to alter adult cells, such as skin fibroblasts, to express therapeutic molecules and allow them to be maintained in cell culture for an indefinite period of time, providing a continuous source of cells for transplantation; (ii) the use of neural stem cells or progenitor cells—cell types that are more immature than embryonic neurons and glia currently used for transplantation—that maintain the capacity to proliferate in cell culture as a source of cells for transplants and potentially can respond to specific chemical cues to differentiate into the cell type of therapeutic choice; and (iii) the use of viral vectors, a strategy to "infect" the nervous system with therapeutic molecules carried in the genetic material of experimentally manipulated viruses.

VII. OTHER USES OF TRANSPLANTATION

Experimental evidence suggests that neural transplantation will be most effective in neurodegenerative diseases or injury that involves the focal loss of neurons. It appears that in the environment of the adult or aging host brain, molecular cues may not be present in sufficient quantity to provide for complete long-distance reconstruction of neural circuits or the establishment of highly specific, complex, point-to-point connections by implanted neurons. Transplantation of neural stem cells may represent an exception to this, as discussed later. Use of nonneuronal cells for transplantation requires an even less demanding set of conditions in which mere secretion of a chemical in the local environment of the transplant could be expected to be therapeutic. Given these constraints, some types of disease or injury remain reasonable candidates for transplantation therapy. We have described the characteristics of PD that make this disease particularly appropriate for transplant treatment. Another neurodegenerative disease that has been studied in this context is Huntington's disease. In this fatal disease, neurons localized within the striatum die in large numbers, yielding significant atrophy of this brain region accompanied by abnormal body movements and psychological disturbances. The replacement of lost tissue by transplantation of embryonic striatal cells into the striatum appears to be another logical application of the transplantation approach. Replacement of striatal neurons via transplantation has been studied with some success in animal models, and initial trials in patients have been reported. Although establishing the feasibility and safety of the transplant surgery, these trials are too recent to provide results relevant to therapeutic outcome.

Transplantation to correct neurological deficits relevant to Alzheimer's disease has also been studied in animal models. Problems associated with learning and remembering new information that can be linked to loss of neurons that secrete the neurotransmitters norepinephrine and acetylcholine have been individually corrected with transplants of embryonic neurons in both young and elderly rodents. Replacement of the function of acetylcholine neurons with transplants has also been successful in monkeys. Although these therapeutic effects have sometimes been dramatic, Alzheimer's disease affects multiple brain regions and populations of cells, making it difficult to treat with the transplant approach. While the relatively diffuse actions of norepinephrine and acetylcholine have been successfully replaced in animal models, the more complex restoration of point-to-point connections that characterize the cells of the cortex and hippocampus, which are also affected by the disease, has been less successful in transplant experiments.

One recent option for the neural transplantation approach is the implantation of neural stem cells. As mentioned previously, these cells are more immature than the primary embryonic neurons and glia that have been employed in most neural transplantation therapy to date. Stem cells are self-maintaining, self-renewing, and multipotential. Accordingly, they provide a continuously available source of cells for transplantation, limiting the continuous need for embryonic tissue, and they may respond to specific molecular cues to mature into multiple types of neurons and/or glial cells that may be of therapeutic importance. Of particular interest is the finding that stem cells can migrate away from the site of implantation, be attracted to injured brain regions, and mature into the types of neural cells required to repopulate the damaged area. For example, following induction of experimental stroke in mice, transplanted stem cells were found to repopulate the damaged area of cerebral cortex and mature into neurons and oligodendrocytes, the primary cells lost following interruption of the blood supply. Similar transplantation of stem cells into the spinal cord of mice with peripheral nerve damage that leads to degeneration of lower motor neurons yields maturation of stem cells into cells with characteristics of motor neurons. These early studies are consistent with the view that local environmental signals generated during injury and degeneration of CNS regions may attract and cause site-specific maturation of implanted

stem cells in a manner consistent with reconstitution of the injured neural region.

Cell transplants have also been used as a vehicle for local administration of neurotrophic factors in the CNS. For this approach, cells are modified in tissue culture, using gene transfer techniques, to produce and release molecules that support survival and growth of specific neurons that are endangered by disease or injury. The cells that have been used most frequently are skin fibroblasts or baby hamster kidney cells. Following insertion of genes coding for growth factor production, the cells are either implanted directly into the brain site of interest or encapsulated in a semipermeable membrane prior to grafting. This approach has been successful in rescuing vulnerable neurons in animal models of Alzheimer's disease using nerve growth factor (NGF)-secreting cells and in animal models of Huntington's disease using cells engineered to produce either NGF or ciliary neuronotrophic factor.

VIII. CONCLUSIONS

During the past 25 years, cell transplant therapies for the treatment of neurological injury and disease have moved from science fiction to science fact. The safety, feasibility, and efficacy of transplant therapies have been firmly established by detailed, systematic studies in animal models of injury and disease and confirmed in clinical trials, primarily in the treatment of PD. Serious limitations and concerns still exist that have prevented more widespread clinical application of neural transplantation. These include limited survival and growth of immature neural cells transplanted into the adult and aged nervous system and the sometimes highly polarized views concerning the morality of using embryonic cells for transplants. As the intricate cellular mechanisms of life, death, and growth are better understood, it is likely that graft survival will not be an issue. With the emerging inquiry into neural cell lineage, including the study of stem cells, progenitor cells, and the cues necessary to drive differentiation into specific neural cell types, the possibility of a safe, dependable, and virtually inexhaustable supply of cells for transplantation may become an acceptable resource for medicine and society. If these problems can be successfully addressed, the original promise of the neural transplantation approach can be realized: replacement of neurotransmitters or other cell products lost or compromised by disease or injury at exactly the site required by replacing the cells themselves, which integrate with the host CNS, providing therapeutic benefit for the lifetime of the individual.

GLOSSARY

automatic processes Perceptual–cognitive operations that are initiated involuntarily, executed outside phenomenal awareness, and consume no attentional resources.

dichotic listening A technique in which different auditory messages are presented over separate earphones; the subject is instructed to repeat (shadow) one message but ignore the other.

dissociation A statistical outcome in which one variable, either a subject characteristic (such as the presence of brain damage) or an experimental manipulation (such as the direction of attention), has different effects on two dependent measures (such as free recall or priming). In psychiatry, the "dissociative disorders" include psychogenic amnesia, psychogenic fugue, and multiple personality disorder: All three disorders involve disruptions in consciousness involving memory and identity.

explicit memory Conscious recollection, as manifested in a person's ability to recall or recognize some past event. Explicit memory is the model for the definition of explicit perception, learning, thought, emotion, and motivation.

functional magnetic resonance imaging A brain-imaging technique using magnets to measure blood oxygenation due to brain activity.

Implicit memory Any effect on task performance that is attributable to a past event, independent of conscious recollection of that event. Implicit memory is the model for the definition of implicit perception, learning, thought, emotion, and motivation.

limen From the German, "threshold." In classical psychophysics, the threshold referred to the minimum amount of energy required for an observer to detect the presence of a stimulus (the absolute threshold) or a change in a stimulus (the relative threshold). Processing of stimuli, which are undetected, is referred to as subliminal. In modern signal-detection theory, the concept of the threshold has been replaced by that of zero detectability ($d' = 0$).

preattentive processing Perceptual–cognitive operations occurring before attention has been paid to a stimulus.

priming The facilitation of perceptual–cognitive processing of a target stimulus by prior presentation of a priming stimulus. "Negative" priming refers to the inhibition of processing occurring under the same conditions.

Consciousness has two aspects: (i) monitoring ourselves and the world around us so that percepts, memories, thoughts, and other mental states are represented in phenomenal awareness and (ii) controlling ourselves and the environment so that we are able to voluntarily initiate and terminate behavioral and cognitive activities. In psychology, the unconscious refers to the idea that cognitive, emotional, and motivational states and processes can influence ongoing experience, thought, and action outside of phenomenal awareness and voluntary control.

I. CONSCIOUSNESS IN PSYCHOLOGY

In the last twenty-five years of the 19th century, as the new science of psychology began to emerge from its roots in philosophy and physiology, consciousness was at the center of the enterprise. Beginning with Wilhelm Wundt and E. B. Titchener, the whole structuralist school of psychology attempted to analyze conscious mental states in terms of their constituent sensations, images, and feelings. Its preferred method of introspection assumed that people had accurate

introspective awareness of their own mental states. In 1927, E. G. Boring summarized the achievements of structuralism with a monograph titled *The Physical Dimensions of Consciousness*.

Even William James, opposed as he was to the doctrines of structuralism, embraced a version of introspection as his preferred research method (he had a collection of brass instruments, but he hated using them). James began his *Principles of Psychology* with the assertion that "psychology is the science of mental life." By this he meant *conscious* mental life, as he made abundantly clear in the *Briefer Course*, in which he adopted G.T. Ladd's definition of psychology as "the description and explanation of states of consciousness as such."

II. THE INITIAL DISCOVERY OF THE UNCONSCIOUS

At the same time, both James and the structuralists understood that there was more to mental life than was accessible to introspection. The notion that unconscious processes are important elements of mental life is commonly ascribed to Sigmund Freud, the founder of psychoanalysis, but in fact it was an old idea, originating before Freud was born.

A. The Unconscious in Prepsychological Philosophy and Physiology

At the beginning of the 18th century, long before psychology split from philosophy and physiology, the German philosopher Leibniz wrote that our conscious thoughts are influenced by sensory stimuli of which we are not aware. At the close of that century, Immanuel Kant's *Anthropology from a Pragmatic Point of View*, the philosopher's last work and arguably the first comprehensive textbook of psychology, devoted a major section to a discussion of "the ideas which we have without being conscious of them."

In the 19th century, Johann Friedrich Herbart, drawing on the views of Gottfried Wilhelm von Leibniz, defined the "*limen*," or sensory threshold, as a mental battleground where various perceptions, themselves mostly unconscious, competed for representation in consciousness. In the *Treatise on Physiological Optics*, Hermann von Helmholtz argued that our conscious perceptions are determined by unconscious inferences.

The pre-Freudian analysis of unconscious mental life reached its apex with Eduard von Hartmann and his *Philosophy of the Unconscious* (1868), an extremely popular work whose three volumes, comprising more than a 1000 pages, went through a total of 12 editions. For Hartmann, the universe was ruled by the unconscious, a highly intelligent dynamic force composed of three layers: the absolute unconscious, accounting for the mechanics of the physical universe; the physiological unconscious, underlying the origin, evolution, development, and mechanisms of life; and the relative unconscious, which Hartmann considered to be the origin of conscious mental life. Hartmann's relative unconscious is what we nowadays call the psychological unconscious—a term referring to those mental states and processes that influence our experience, thought, and action outside phenomenal awareness and independent of voluntary control.

We owe to Hartmann the Romantic notion, still with us in some quarters today, that the unconscious possesses capacities and powers that are superior to those available to consciousness. As Hartmann stated, "the Unconscious can really outdo all the performances of conscious reason." In the end, however, Hartmann's ideas proved to be too speculative for the first generation of scientific psychologists. Hermann von Ebbinghaus, in discussing Hartmann's book, concluded that "what is true is not new, and what is new is not true." William James also offered a warning that would reverberate throughout the 20th century exploration of the unconscious: "The distinction … between the unconscious and the conscious being of the mental state … is the sovereign means for believing what one likes in psychology, and of turning what might become a science into a tumbling-ground for whimsies."

B. The Psychoanalytic Unconscious

Nevertheless, all of this activity, from Leibniz and Kant to Helmholtz and Hartmann, laid the foundation for what Henri Ellenberger, the great historian of psychiatry, called the discovery of the unconscious. This discovery was consolidated with what Ellenberger called a new dynamic psychiatry—the psychiatry of Sigmund Freud and his sometime compatriots, C. G. Jung and Alfred Adler.

Based on their clinical observations, for example, Freud and collaborator Josef Breuer concluded that the symptoms of hysteria were produced by unconscious memories of traumatic events. They stated, "Hysterics suffer mainly from reminiscences," with the proviso that these memories are unconscious,

emerging only after skilled intervention by a therapist. In *The Interpretation of Dreams* (1900), Freud proposed a topographical division of the mind into conscious, preconscious, and unconscious compartments. Later, he proposed that our conscious experiences, thoughts, and actions are determined by the interaction between unconscious sexual and aggressive impulses, on the one hand, and defense mechanisms such as repression arrayed against them in order to ward off anxiety caused by the conflict between these primitive motives and sociocultural demands and strictures, on the other hand.

C. The Impact of Behaviorism and the Revival of Consciousness

Unfortunately, just when the concept of the psychological unconscious was gaining support, the behaviorist revolution occurred. Interest in consciousness disappeared virtually overnight, and interest in the psychological unconscious went with it. For John B. Watson and comrades in arms, the only way to make psychology truly scientific was to abandon the mental. It was bad enough to try to explain behavior in terms of mental states that could not be publicly observed; it was even worse to try to explain behavior in terms of mental states that could not be privately observed. Of course, psychological interest in consciousness did not die completely with the triumph of behaviorism. So, too, some psychologists maintained an interest in the psychological unconscious. Still, a full-scale revival of academic interest in consciousness had to wait until behaviorism was overthrown by the cognitive revolution.

Ironically, the early cognitive psychologists rarely used the term consciousness. This is a reflection of two tendencies described by the philosopher Owen Flanagan: On the one hand, there is a positivistic reserve reflecting our persisting reluctance to use mentalistic language, and on the other hand, there is a piecemeal approach that assumes that major problems such as consciousness can be solved by working up from the bottom. However, consciousness was there anyway, in the guise of such topics as selective attention, primary or short-term memory, and mental imagery.

III. THE REDISCOVERY OF THE UNCONSCIOUS

A revival of interest in unconscious mental life followed shortly thereafter. The seeds for this revival had been planted at the very beginnings of the cognitive revolution, when the linguist Noam Chomsky argued that human language was mediated by "deep" grammatical structures that are inaccessible to conscious introspection and can be known only by inference. Along the same lines, the philosopher Jerry Fodor argued that many mental functions, such as visual perception, were mediated by dedicated structures that were impenetrable by conscious awareness and voluntary control. Cognitive approaches to perception, as exemplified by the work of Irvin Rock on visual illusions, entailed a version of Helmholtz's notion of unconscious inference. Finally, the classic multistore model of memory invoked a concept of preattentive, or preconscious, information processing.

We are now at a point, however, where interest in the psychological unconscious runs wide and deep within psychology. This happy state of affairs is the end-product of at least four independent strands of investigation, which together converge on our modern conception of the psychological unconscious: automaticity, cognitive neuropsychology, subliminal perception, and hypnosis.

A. Automatic and Controlled Processes

One research tradition contributing to the modern interest in the psychological unconscious is the distinction commonly drawn between "automatic" and "strategic" cognitive processes. Skilled reading provides one example of automaticity: We recognize certain patterns of marks on the printed page as letters and certain patterns of letters as words, and we decode the meanings of words in light of the words near them, but we rarely have any conscious awareness of the rules by which we do so. It just happens, as an automatic consequence of having learned to read.

The power of these processes is illustrated by the color–word effect discovered by J. R. Stroop. In the basic "Stroop" experiment, subjects are presented with a list of color names printed in different colors and are asked to name the color in which each word is printed. This task is easy if the ink color matches the color name (e.g., the word yellow printed in yellow ink), but if the word and its color do not match (e.g., yellow printed in green ink) it is very difficult. Despite the subjects' conscious intention to name ink colors and to ignore the words, they cannot help reading the color names, and this interferes with naming of the colors. It just happens automatically.

According to traditional formulations, automatic processes are inevitably engaged by the appearance of

specific environmental stimuli, regardless of the person's conscious intentions. Once invoked, they proceed inevitably to their conclusion, and (in theory at least) their execution consumes no attentional resources. Because they consume no attentional resources, automatic processes leave no traces in conscious memory. Some automatic processes are innate, or nearly so, whereas others are automatized only after extensive practice of a task. Recently, some of these properties have been called into question by revisionist, memory-based views of automaticity. It is no longer clear that ostensibly automatic processes are really executed involuntarily and really consume no attentional resources. However, even these revisionist views concur that some mental processes, represented in procedural memory, are unconscious in the strict sense of the term: They are inaccessible to phenomenal awareness in any circumstances and can be known only by inference from task performance.

B. The Rise of Neuropsychology

Both traditional and revisionist approaches to automaticity assume, at least tacitly, that the mental contents on which these processes operate are accessible to conscious awareness. However, it is now clear that our experiences, thoughts, and actions can be influenced by mental contents—percepts, memories, thoughts, feelings, and desires, of which we are unaware. Compelling evidence for this proposition began to accumulate about 30 years ago, as cognitive psychology turned into cognitive neuropsychology and researchers began to obtain evidence of the psychological unconscious in the behavior of brain-damaged patients.

Pride of place in this history goes to studies of the amnesic syndrome resulting from bilateral damage to the hippocampus and related structures in the medial temporal lobe or, alternatively, to the diencephalon and mammillary bodies. On clinical observation, such patients show a dense anterograde amnesia: After only a few moments of distraction, they cannot consciously remember events that occurred recently. However, as the study of these patients shifted from clinical description to controlled laboratory investigation, it became apparent that the events apparently covered by the amnesia nonetheless influenced the patients' ongoing experience, thought, and action.

For example, Elizabeth Warrington and Lawrence Weiskrantz showed that amnesic patients who could not remember having studied a list of words were nonetheless biased to complete ambiguous word stems or fragments with items from the previously studied list. Past experience influenced their subsequent task performance, even though they had no conscious recollection of the experience. Based on "priming" effects such as these, Daniel Schacter and others drew a distinction between two expressions of memory, explicit and implicit. Explicit memory refers to one's conscious recollection of the past, as manifested on tasks such as recall and recognition. In contrast, implicit memory refers to any change in experience, thought, or action that is attributable to a past event, regardless of whether that event is consciously remembered.

Priming effects in which prior exposure to a word such as "assassin" makes it easier to complete a fragment such as "a__a__i_" than one such as "t_p__r_" are good examples of implicit memory because the priming effect obviously depends on memory, but the task does not, logically, require conscious recollection of any past event. The subject must only generate an acceptable word that fits in the spaces provided. The sparing of implicit memory in amnesia shows that some representation of a prior event has been encoded and stored in memory and influences ongoing experience, thought, and action, even though that event cannot be consciously remembered. Implicit memories are unconscious memories.

Neuropsychological research has also revealed unconscious influences in the perceptual domain. Perhaps the most dramatic example is the phenomenon of blindsight documented in some patients with damage to the striate cortex of the occipital lobe. Such patients experience a scotoma—a portion of the visual field where they have no visual experience. When a stimulus is presented to their scotoma, they see nothing at all. However, when encouraged to make guesses about the properties of the stimulus, their conjectures about the presence, location, form, movement, velocity, orientation, and size prove to be more accurate than would be expected by chance.

Something similar occurs in at least some cases of visual neglect arising from lesions in the temporoparietal region of one hemisphere (usually the right) that do not affect primary sensory or motor cortices. These patients appear to neglect the corresponding portion of the contralateral sensory field (usually the left). Thus, a patient asked to bisect a set of horizontal lines may ignore the ones on the left side of the page; and for the remainder, the pencil strokes tend to be located about one-fourth of the way in from the right. It is as if the left half of the page, and the left half of each line, is

not seen at all. However, in some cases, it can be shown that these patients respond to information available only in the neglected field. For example, pictures presented in the neglected portion of the visual field prime lexical decisions concerning semantically related words presented in the intact portion. Preserved visual functioning in blindsight and in neglect is unconscious perception.

C. The Subliminal

Perception without awareness can also be observed in neurologically intact subjects in the form of "subliminal" perception. Before World War II, the question of subliminal perception was raised mostly in regard to psychoanalysis; after the war, the notion was revived as part of Jerome Bruner's "New Look" in perception, only to be shot down by the withering critiques of Israel Goldiamond and C. W. Eriksen. However, in the early 1980s Anthony Marcel presented solid evidence of subliminal semantic priming effects on lexical decision: Presentation of a word such as "doctor" primed lexical decisions of a semantically related word such as "nurse," even though an intervening mask prevented subjects from consciously perceiving the prime.

Other investigators soon confirmed and extended Marcel's findings, but his studies raised a firestorm anyway, with a number of critics essentially repeating the criticisms that Goldiamond and Eriksen had made of Bruner and colleagues. A major reason for this response may have been the association of subliminal perception with psychoanalytic theory. However, another reason was the simple fact that the cognitive theories of the time tended to describe cognition in terms of a series of ever more complicated processes and had no room for the possibility that the meanings of words could be analyzed unless conscious attention was paid to them. The criticisms had the character of the apocryphal entomologist who found a bug he could not classify so he stepped on it.

In any event, things are vastly different now. Signal detection theory has replaced the notion of an absolute limen, or threshold, with the statistical concept of zero sensitivity (where $d' = 0$). A wealth of evidence now supports the validity of subliminal perception, defined broadly as the influence of stimuli that are too degraded by their conditions of presentation to be accessible to conscious perception. The debate now is not so much over whether subliminal perception (so defined) occurs as over the extent of subliminal processing.

D. The Role of Hypnosis

The fourth line of research contributing to the rediscovery of the unconscious was hypnosis, a social interaction in which the subject acts on suggestions for experiences involving alterations in perception, memory, and the voluntary control of action. As William James recognized more than a century ago, many of these phenomena involve a division in consciousness such that memories, percepts, and the like influence experience, thought, and action outside of phenomenal awareness.

Consider posthypnotic amnesia, the phenomenon that gave hypnosis its very name. After receiving appropriate suggestions, many highly hypnotizable subjects come out of hypnosis unable to remember the events and experiences that transpired while they were hypnotized. For example, subjects who studied a list of animal names while hypnotized will be unable to remember them afterward. However, these unremembered items will also give rise to priming effects: If asked to generate names of animals, subjects will be more likely to give the names they studied while under hypnosis. Moreover, after the amnesia suggestion has been canceled by a prearranged reversibility cue, the subject will regain perfect conscious memory for the studied list. The reversibility of amnesia indicates that, in contrast to the organic amnesias associated with hippocampal damage, posthypnotic amnesia reflects a deficit in retrieval rather than encoding. However, the preserved priming effects show that the retrieval deficit affects explicit, but spares implicit, expressions of memory.

Hypnotic suggestion can also affect perceptual functions. When given hypnotic suggestions for blindness, many hypnotizable subjects have the subjectively compelling experience that they no longer can see. However, Richard Bryant and Kevin McConkey presented subjects with cards on which were printed homophones (i.e., words that have the same sound but two different spellings, such as "pain" and "pane") together with disambuguating words (e.g., "body" or "window"). The hypnotically blind subjects did not see the cards, but on a subsequent test they spelled the homophones in accordance with the disambiguating associates with which the words had been paired. This is another kind of priming effect, and it clearly indicates that the words in question were perceptually processed outside of awareness.

A third example of unconscious processing in hypnosis is provided by posthypnotic suggestion—the phenomenon that, our mythology tells us, gave Freud

his first good insight into the psychological unconscious. In some sense, posthypnotic suggestion is a special case of implicit memory because subjects act on a suggestion given during hypnosis, despite the fact that they cannot remember the suggestion. Posthypnotic behavior is typically experienced as an involuntary, quasi-automatic response to the cue, but it has had no opportunity to be automatized by extensive practice, and detailed experimental analysis shows that it does not fit the conventional criteria of automaticity. Despite consuming considerable attentional resources, posthypnotic suggestions are executed, outside of awareness, thus extending the boundaries of the psychological unconscious beyond the automatic.

IV. IMPLICIT COGNITION

The rediscovery of the unconscious may have gotten a late start, but it is now well along.

A. The Automaticity Juggernaut

The concept of automaticity has proved to be particularly popular across a wide variety of fields within psychology. For example, a set of articles in the July 1999 issue of *American Psychologist*, published under the title of "Behavior—It's Involuntary," illustrated the increasingly powerful role played by the concept of automaticity in personality, social, and clinical psychology. The general argument is that some attitudes, impressions, and other social judgments, as well as aggression, compliance, prejudice, and other social behaviors, are typically mediated by automatic processes, which operate outside phenomenal awareness and voluntary control. To some extent, what might be called an automaticity juggernaut seems to represent a reaction to a cognitive view of social interaction, which some consider inappropriately emphasizes conscious, rational, and cognitive processes at the expense of the unconscious, irrational, emotive, and conative. In addition, the popularity of automaticity seems to represent a reversion to earlier, precognitive, situationist views within social psychology.

After all, the concept of automaticity is at least tacitly modeled on innate stimulus–response connections, such as reflexes, taxes, and instincts, as well as those acquired through classical and instrumental conditioning. The automaticity juggernaut is not exactly a reversion to Skinnerian behaviorism because it entails internal mental representations and processes intervening between stimulus and response, but it is close: If the cognitive processes underlying social cognition and social behavior are indeed largely automatic, then not too much thought has gone into them.

B. Implicit Memory

Like automaticity, the concept of implicit memory has received a huge amount of attention in the field. A whole industry has developed around implicit memory, involving amnesic and demented neurological patients; dissociative disorders such as psychogenic amnesia, fugue, and multiple personality; children and the healthy aged; depressed patients receiving electroconvulsive therapy; surgical patients receiving general anesthesia or conscious sedation; hypnotized subjects (but apparently not sleepers); and even college students who have all their wits about them.

However, there are some important issues that have to be addressed by further research. For example, almost all the evidence on implicit memory has been collected within a single narrow paradigm, repetition priming, leading to theories of implicit memory that emphasize relatively low-level perceptual processes. However, semantic priming also occurs, not just in posthypnotic amnesia but also in organic amnesia, suggesting that these perception-based theories are not adequate for the phenomenon. Similarly, although explicit and implicit memory are dissociable, they also interact, requiring revisions in theories that hold that these two expressions of memory are mediated by separate memory systems in the brain.

Despite these and other persisting questions, the general acceptance of the distinction between explicit, conscious and implicit, unconscious expressions of memory opens the door to extensions of the explicit–implicit distinction to other domains of mental life.

C. Implicit Perception

By analogy to implicit memory, implicit perception may be defined as the influence of a current event, or an event in the very recent past (what William James called the specious present), on experience, thought, or action, in the absence of conscious perception of that event. Implicit perception subsumes so-called "subliminal" perception, involving the processing of stimuli that are degraded beyond conscious perception by low intensities, brief durations, or masking stimuli. However, it goes beyond the subliminal to include neurological syndromes such as blindsight and neglect,

where the stimuli are in no sense subliminal: They are perfectly visible to everyone but the brain-damaged subject. This is also the case for the conversion syndromes of "hysterical" deafness, blindness, and anesthesia. Similarly, in hypnotic blindness, deafness, anesthesia, and analgesia, the subjects would be clearly aware of the stimuli in question were it not for the hypnotist's suggestion. On the fringes of consciousness are cases of so-called preattentive processing, in which the stimulus in question is nominally supraliminal but escapes focal awareness by virtue of parafoveal presentation or presentation over the unattended channel in the dichotic listening or shadowing paradigm. Thus, the term implicit perception captures a broader range of phenomena than is covered by the term subliminal perception because it covers the processing, outside of conscious awareness, of stimulus events that are clearly perceptible in terms of intensity, duration, and other characteristics. It also has the advantage of skirting the difficult psychophysical concept of the limen.

What all these phenomena have in common is a dissociation between explicit and implicit perception, analogous to the dissociation between explicit and implicit memory: The subject's experience, thought, and action are affected by some event in the current stimulus environment, in the absence of conscious perception. The distinction between implicit perception and implicit memory is not always easy to make because both phenomena are revealed by postexposure priming effects (i.e., by performance on a nominal test of implicit memory). Arguably, however, the term implicit memory should be reserved for cases in which the stimulus event was consciously perceived at the time of encoding; where there is no conscious awareness at the time of encoding, we can consider priming effects as evidence of implicit perception. Thus, on the assumption that adequately anesthetized patients are really unaware, during their procedures, of what our medical colleagues disarmingly call "surgical stimuli," evidence collected in the recovery room of priming effects attributable to events presented during surgery constitutes evidence of implicit perception, not just implicit memory. In contrast, priming effects observed in conscious sedation, in which subjects are fully aware of the study trials, are pure implicit memory effects.

Adopting the implicit–explicit distinction may help resolve a persisting controversy over the scope of unconscious perception. For example, Anthony Greenwald and colleagues asserted that subliminal perception is analytically limited: Some semantic processing of a subliminal stimulus is possible, but not too much. On the other hand, advocates of subliminal symbiotic stimulation—the "mommy and I are one" experiments—assume more processing than Greenwald's arguments would predict; so do those who employ subliminal techniques in advertising and psychotherapy. Most arguments for the analytic power of subliminal processing appear to be based on Romantic or psychoanalytic notions of the unconscious. On the other hand, there are many ways to render percepts implicit, and how this is done may make a major difference in regard to what one can do with them. Philip Merikle and colleagues distinguished between the objective threshold, where all responses to the stimulus decrease to chance levels, and the subjective threshold, where the subject simply does not experience the stimulus consciously. Greenwald's experiments take subjects as close to the objective threshold as possible, and with such degraded presentations it is not surprising that perception, and memory encoding, is analytically limited. When subjects get closer to the subjective threshold, more extensive analyses, still outside awareness, might be possible. In hypnosis, in which the stimulus is in no sense degraded, the possibilities for analysis might be unlimited.

D. Implicit Learning

Continuing the elaboration of the explicit–implicit distinction to other domains, implicit learning can be defined as the acquisition of new knowledge and patterns of behavior through experience, in the absence of awareness of the knowledge or behavior so acquired. As it happens, the term implicit learning antedates implicit memory, having been coined by Arthur Reber in 1967. Reber demonstrated that subjects who studied a set of letter strings generated by a Markov process artificial grammar could distinguish between new grammatical and ungrammatical strings without being able to articulate the grammar in question.

In some respects, the learning of artificial grammars appears similar to the acquisition of syntax in natural language. After all, we are perfectly fluent speakers and interpreters of our native language long before we learn the rules of grammar in elementary school. However, implicit learning has also been observed in a wide variety of other paradigms, including classical and instrumental conditioning, control of complex systems, and the learning of categories and sequential relationships. In each of these cases, the claim is that people's behavior is shaped by prior experience (the

classical definition of learning), even though they are unaware of what they have learned.

As with implicit perception, however, the border between implicit learning and implicit memory is vague. Of course, this is as it should be: Memory provides the cognitive basis for learning in the first place, and whatever is learned has to be stored in memory. However, the problem goes deeper than that. When normal subjects learn an artificial grammar, they certainly remember being asked to study the sample strings, and they may even remember the strings themselves, even if they are unaware of what they have evidently learned about the structure of the grammar. In contrast, when brain-damaged amnesic patients acquire new patterns of behavior from experience, as exemplified by mirror tracing and pursuit-rotor learning in patient H.M., they are amnesic for the whole learning experience. In amnesia, the occurrence of implicit learning also provides evidence of preserved implicit memory, but as in the case of implicit perception the term implicit memory is best reserved for effects that occur in the absence of conscious memory for the original experience. By the same token, implicit learning refers to abilities and patterns of response that are acquired through learning experiences, in the absence of conscious awareness of what has been learned.

A small industry has developed around implicit learning, culminating in the 1998 publication of an entire handbook devoted to the topic. However, the claim of implicit learning remains controversial even after more than 30 years of work. There is continuing debate over whether implicit learning is really unconscious in any meaningful sense of the term. It may be too much to expect subjects to be able to articulate an entire Markov process artificial grammar, but subjects might be consciously aware of enough of the rule to permit them to discriminate at above chance levels between grammatical and ungrammatical strings. Perhaps this debate will be resolved if we pay more attention to the format in which the newly acquired knowledge is represented. Perhaps, as implied by the original artificial grammar studies, the subject acquires a whole system of ''if–then'' productions and this procedural knowledge, like all procedural knowledge, is inaccessible to conscious introspection.

On the other hand, perhaps the knowledge acquired during implicit learning is not procedural at all, but declarative in nature. For example, subjects might abstract from the learning trials a prototype of a grammatical string; alternatively, they may simply memorize the instances on the study list. In either case, they may make relatively accurate grammaticality judgments by consciously comparing test items to the summary prototype or to the specific exemplars they have memorized. In any event, amnesic patients can learn from their experience without remembering the learning experience, and in this sense, at least, implicit learning provides evidence of unconscious influence.

E. Implicit Thought

If the concept of implicit learning is more controversial than those of implicit memory or implicit perception, the concept of implicit thought is even more so. However, the literature contains some favorable evidence. For example, Kenneth Bowers and associates found that subjects can choose which of two problems is soluble without knowing the answer to the soluble one. In a variant on Sarnoff Mednick's Remote Associates Test (RAT), called ''Dyads of Triads,'' subjects were presented with two RAT-like items. The task in the traditional RAT is to generate a fourth word that is associatively linked to the other three. In Bowers's modification, one triad coheres on a common (if remote) associate, and the other does not (at least barring psychotically loose associations). Bowers *et al.* found that subjects could choose the coherent triad at better than chance levels, even when they could not say what the solution was.

Subsequent research has found that soluble RAT items primed their solution words for lexical decision, even when the subject failed to produce the solution. This priming effect, and the effect on choice observed by Bowers, seem to reflect the preconscious activation of a mental representation of the solution to the problem. However, this mental representation is not a percept, and it is not a memory. The mental representation in question is an idea or an image or, more broadly, a thought.

Accordingly, implicit thought may be defined as the influence of some cognitive representation, itself neither a percept nor an episodic memory, on experience, thought, or action in the absence of conscious awareness of that representation.

Implicit thought may well underlie some of the most interesting facets of creative thought. In this view, intuition reflects a priming-based ''feeling of knowing'' similar to what we commonly see in studies of memory, incubation reflects the gradual accumulation of strength of this primed idea, and insight reflects the emergence of the preconscious idea into the full daylight of consciousness.

V. IMPLICIT MOTIVATION AND EMOTION

Along with automaticity, implicit memory, implicit perception, implicit learning, and implicit thought comprise the cognitive unconscious. However, cognition is not all there is to mental life, and so we are led to ask whether there is an affective unconscious and a conative unconscious as well. Of course, emotional and motivational states may arise automatically and in this sense result from unconscious processes. However, can motives and emotions be unconscious in the same way that implicit memories can?

In fact, the late David McClelland and associates articulated a concept of implicit motives—interestingly, without overt reference to the concept of implicit memory. Explicit motivation might be defined as the conscious representation of a conative state or the desire to engage in some particular activity, as represented by a craving for food, yearning for love, and the like. In contrast, implicit motivation refers to any change in experience, thought, or action that is attributable to one's motivational state in the absence of conscious awareness of that state. We are admittedly on the verge of Freudian territory here, but the motives in question are not seething sexual and aggressive impulses arising from the id; they are motives for achievement, power, affiliation, and intimacy.

Moreover, McClelland and colleagues keep us on a firm empirical base. For them, explicit motives are self-attributed: The person is aware of the motive, can reflect on it, and can report its presence in interviews or on personality questionnaires. Implicit motives, in contrast, are inferred from the person's performance on such tasks as the Thematic Apperception Test. On the basis of an extensive program of empirical research, McClelland and associates concluded that explicit and implicit motives influence different classes of behavior and respond to different types of social influence. More work needs to be done, but the evidence indicates that explicit and implicit motives are indeed dissociable, in much the same way that explicit and implicit memories are dissociable.

Regarding the affective domain, it is possible that dissociations occur between explicit and implicit expressions of emotion, just as they occur between explicit and implicit expressions of memory. Again paralleling the vocabulary of the cognitive unconscious, we define explicit emotion as the person's conscious awareness of an emotion, feeling, or mood state; implicit emotion refers to changes in experience, thought, or action that are attributable to one's emotional state in the absence of conscious awareness of that state.

Note that conscious emotional responses can serve as expressions of implicit memory and perception. Most of the relevant studies make use of the mere exposure effect documented by Robert Zajonc, in which exposure to an object increases one's preference for that object on a subsequent choice task. According to one theory, the mere exposure effect is a variant on the priming effect familiar from studies of implicit memory and implicit perception. On the memory side, it seems that brain-damaged, amnesic patients show the mere exposure effect, even though they cannot recognize the objects to which they had previously been exposed. With respect to perception, normal subjects show mere exposure effects even when the exposures in question were subliminal and thus not consciously perceived. In both cases, the subjects preferred previously exposed objects to new ones, even though they had no conscious perception, much less conscious recollection, of the visual stimuli.

With respect to the proposition that people can be unaware of emotional states, which nonetheless influence their ongoing experience, thought, and action, the empirical evidence is regrettably sparse. However, there remain good theoretical reasons for thinking that it might be true. For example, Peter Lang's multiple-systems theory of emotion postulates that every emotional response consists of three components: verbal–cognitive, corresponding to a subjective feeling state such as fear; overt motor, corresponding to a behavioral response such as escape or avoidance; and covert physiological, corresponding to a change in some autonomic index such as skin conductance or heart rate. These three components or systems usually covary, but in some circumstances they can move in different directions—a state that Stanley Rachman and colleagues labeled desynchrony.

Of special interest in the current context is a particular form of desynchrony in which explicit emotion, as represented by the conscious, subjective feeling state, is absent, but behavioral and somatic signs of emotion persist. Currently, most evidence for this desynchrony comes in the form of clinical anecdote rather than controlled experiment, but it is comforting that just such a desynchrony is predicted by a neuropsychological model of fear recently presented by Joseph LeDoux. LeDoux proposes that environmental stimuli are first processed by sensory centers in the thalamus that then pass information about emotional events to the amygdala, which in turn generates appropriate behavioral, autonomic, and

endocrine responses. Information about these responses is also passed to cortical centers supporting working memory, where it is integrated with information provided by thalamic centers about the fear stimulus, thus generating the full-blown subjective experience of being afraid of something. However, if a disconnection between thalamus and cortex prevents the fear-eliciting stimulus from being represented in working memory, the person will experience fear without being aware of the fear stimulus. In this case, emotion will serve as an implicit expression of perception or memory, as described earlier. Alternatively, if there is a disconnection between the amygdala and the cerebral cortex, the person will behave in a fearful manner without feeling fear or anxiety. In this case, there will be a dissociation between explicit and implicit emotion.

Neuroscientific theory aside, a potentially interesting approach to implicit emotion has been offered by Anthony Greenwald and Mahzarin Banaji in their application of the explicit–implicit distinction to the social–psychological concept of attitude. Attitudes are affective dispositions to like or dislike certain things; like motives, they are usually measured explicitly by self-report scales. However, Greenwald and Banaji suggested that people may possess positive and negative implicit attitudes about themselves and other people, which can affect ongoing social behavior outside of conscious awareness. Like McClelland's implicit motives, implicit attitudes are assessed in terms of task performance rather than self-report. When implicit attitudes diverge greatly from their explicitly expressed counterparts, this indicates a dissociation between explicit and implicit emotion. Unfortunately, the experimental literature on implicit attitudes rarely offers a direct contrast between explicit attitudes, so it is unknown whether such dissociations actually occur, in what kinds of people, and in what circumstances. However, this experimental approach to implicit emotion is very promising.

VI. THE UNCONSCIOUS AND THE BRAIN

In the 19th century, Hartmann distinguished between the relative (psychological) unconscious and the physiological and physical unconscious, and we can make a similar distinction between unconscious mental life and unconscious physiological and biochemical processes. Most of our bodily functions proceed unconsciously, without any direct introspective awareness of them or direct voluntary control over them, and this is as true of the nervous system as it is of the other systems in the body. At the molecular and cellular levels of analysis, we have no awareness of the depolarization of cell membranes, the transmission of action potentials down the axon, or the processes of synaptic transmission. We are not aware of the transmission of neural impulses up and down the spinal cord or of the patterns of neural activity that constitute the cortical representation of experience, thought, and action afferent.

We are not aware of the saccades by which we refresh our retinal images or of the opponent processes that allow us to see various combinations of red, yellow, green, and blue. Spinal reflexes are spared in neurological patients who have been rendered paraplegic or quadriplegic by virtue of a complete break in the spinal cord. However, the patients have no direct awareness of these responses, no ability to voluntarily inhibit them, and no ability to initiate similar actions, at will, in the absence of effective stimuli. In the absence of biofeedback technology, we have no awareness of our blood pressure or whether our brains are generating alpha, beta, delta, or theta activity. These physiological and electrochemical processes in the body are as unconscious as photosynthesis and cell division, the tides, and plate tectonics. However, these things are not what "the unconscious" is all about. To refer to them as unconscious, as Hartmann did, is to make what the philosopher Gilbert Ryle called a category mistake—the error of ascribing to one domain a feature attributable only to another. Consciousness belongs to the domain of the mental, and so does the psychological unconscious. It makes no sense to apply the distinction to anything other than mental life.

The revival of interest in consciousness among psychologists and other cognitive scientists has led to a revival of interest in its physiological substrates. A number of neural correlates of consciousness (NCCs) have been proposed, such as activity in the reticular formation or the left hemisphere. However, the reticular formation appears to be responsible for maintaining cortical arousal, which is not the same as consciousness, and careful studies of split-brain patients make it clear that the right hemisphere has a consciousness of its own, even if lacks the ability to communicate its experiences verbally. Recent proposals have similar problems. For example, Francis Crick and Christof Koch proposed that the NCC consists of synchronized firings (e.g., at 40 Hz) of different various cortical neurons representing features of an object; however, it may also be that such firings serve merely to

bind various features of an object together to form a unified mental representation, and that other neural processes determine whether that representation will be consciously accessible. Giulio Tononi and Gerald Edelman proposed that consciousness results from the firings of neurons distributed widely over the thalamocortical system; however, this may be true of any mental representation, conscious or not.

The 19th-century phrenologists did not assign the "faculty" of consciousness to any portion of the brain, perhaps because they viewed consciousness as an intrinsic property of mental life. However, documented dissociations between explicit and implicit cognition, emotion, and motivation offer the possibility of finding portions of the brain that are involved in conscious but not unconscious, or unconscious but not conscious, mental life. For example, Schacter hypothesized the existence of a conscious awareness system (CAS), a brain module that supports conscious awareness in various domains, such as perception and memory. Connection between a module supporting memory and the CAS would render memories accessible to conscious awareness; a disconnection (to use a term coined by Norman Geschwind) between these modules would impair conscious recollection but spare implicit expressions of memory.

Schacter's proposal is congruent with a general principle of the modularity of the mind and brain, but some considerations suggest that there might be multiple CASs, each supporting conscious awareness in different mental domains. Thus, although it appears that the hippocampus plays a special role in explicit memory, it plays essentially no role in conscious vision. The striate cortex (area V1) mediates conscious visual experience but plays no special role in conscious recollection. As noted earlier, LeDoux proposed that conscious emotional experiences (or at least the experience of fear) are mediated by connections between the amygdala and cortical structures supporting working memory, whereas unconscious behavioral and physiological expressions of emotion are mediated by connections between the amygdala and subcortical structures. Perhaps newly emerging brain imaging techniques applied to patients or subjects who display a dissociation between explicit and implicit memory, or the like, will be able to reveal cortical structures that are differentially involved in conscious and unconscious mental life.

On the other hand, it may be that brain imaging approaches will not reveal the neurophysiological differences between conscious and unconscious mental life. For example, it has been proposed that all conscious mental states refer to the self as the agent or patient of some action or the stimulus or experiencer of some state; unconscious mental states lack this kind of self-reference. If so, then conscious awareness is not a matter of the activity of one or more brain modules but rather of a connection of some sort between the mental representation of the action or state in question and a mental representation of the self. It is now believed that such knowledge representations are generated by ensembles of neurons distributed widely across the cortex rather than by specific cortical loci (e.g., "grandmother" cells). If this notion is correct, then brain imaging techniques such as functional magnetic resonance imaging, which are designed to identify specific neural loci involved in one kind of mental activity or another but cannot discriminate between neural representations of specific mental contents, cannot reveal the NCC.

VII. WHITHER THE UNCONSCIOUS?

The initial discovery of the unconscious, which was consolidated at the turn of the 20th century, has been revived, and the process of rediscovery is well along at the beginning of the 21st century. There is incontrovertible evidence for automatic mental processes and for implicit memories. Implicit perception is perhaps less convincingly established, and implicit learning remains controversial as well. However, the evidence favoring both concepts cannot be dismissed out of hand. Research on implicit thought is admittedly immature, but the evidence in hand is quite provocative. Based on the evidence for the cognitive unconscious, implicit motivation and implicit emotion cannot be dismissed out of hand, but we still require convincing evidence that they can be dissociated from their explicit counterparts. However, it is clear that the paradigms developed in the study of implicit memory provide a vehicle for exploring all aspects of the psychological unconscious. In response to Immanuel Kant, we can say that priming and other methodologies do in fact enable us to infer that that we have ideas, even though we are not conscious of them. Also, in response to William James, we can say that these same methodologies, rigorously applied, will prevent us from believing whatever we like about the unconscious mind.

In that respect, it must be emphasized that the scope of the psychological unconscious, broad as it is, does not appear to be so broad as to encompass the unconscious of psychoanalytic theory. There is no

evidence favoring Freud's view that the unconscious is the repository of primitive, infantile, irrational, sexual, and aggressive impulses, repressed in a defensive maneuver to avoid conflict and anxiety. Nor is there any evidence to support the more extreme clinical lore concerning unconscious representations of trauma or the excesses of the recovered memory movement in psychotherapy. In this case, as James warned, the unconscious does indeed seem to be a tumbling ground for whimsies.

GLOSSARY

agnosia Loss of comprehension at the level of the central nervous system of any of the senses; the sensory sphere is intact but the patient is unable to assimilate the meaning of the sense.

dyslexia A disorder, occurring more frequently in males, characterized by the inability to read, spell, and write words despite the ability to see and recognize letters; a typical manifestation is the reversal of letters within a word.

somatosensory of or relating to bodily sensations not necessarily associated the eyes, ears, tongue, and other primary sense organs.

Neglect is a deficit in spatial distribution of attention or exploration that is manifested in the failure to report, consciously respond, and/or orient to novel or meaningful stimuli, when this failure cannot be attributed to either sensory or motor defects. Neglect may be spatial or personal: One may be neglecting stimuli in space or on the person and one may fail to act in a portion of space, in a spatial direction, or on a portion of one's body. The neglected stimuli are usually situated in the side of space that is opposite a brain lesion (contralesional) but might be on the same side (ipsilesional). This disorder was first described in the last 25 years of the 19th century. Most of the early reports were clinicoanatomical studies of unilateral horizontal right/left, and many of the behavioral manifestations of neglect were defined throughout this period. During the past 25 years, neglect has been the subject of a multitude of studies. It is difficult to integrate all these observations into a unified model. In this article, we first discuss the elementary behavioral components of neglect and related disorders. We will then introduce some recent observations, and finally we attempt to integrate these observations into a unified model.

I. THE CLINICAL SYNDROMES

The major behavioral manifestations of neglect include the syndromes discussed in the following sections.

A. Sensory Neglect

Sensory neglect, or inattention, refers to a deficit in awareness of contralesional stimuli that is not related to afferent defects. Inattention might be found in one or more sensory modalities—visual, tactile, and

auditory. Sensory neglect must be differentiating from sensory disorders. This is easier for auditory inattention because the auditory pathways ascend to the cortex bilaterally, and unilateral brain lesions cannot impair hearing in one ear. Thus, the inability to hear stimuli on one side is usually due to inattention. Inattention is more difficult to discriminate from sensory deficits in the visual and tactile modalities. Visual hemiinattention may be dissociated from hemianopia by having subjects move their eyes to the ipsilesional side of space. Similar methods can be used to distinguish tactile inattention from a true sensory defect.

B. Motor Neglect

Motor neglect (action intentional) is often seen in patients who are aware of contralesional stimuli but fail to respond normally to these stimuli (exo-evoked akinesia). Even in the absence of weakness, patients may have aspontaneity of the contralesional arm. Motor neglect might present not only as a failure to initiate movement (akineia) but also as a delay, slowing of initiation (hypokinesia), or inability to sustain (impersistence) of a movement. The body parts that are involved in the motor neglect might differ between patients and include the eyes, the head, a limb, or the whole body. The akinesia might be directional (e.g., there is a reluctance to move in a direction that is contralateral to the lesion) or spatial (e.g., the contralesional arm is more akinetic in the contralesional hemispace independent of the direction of movement).

C. Personal Neglect

Patients with this syndrome might not interact with the contralesional parts of their body. For example, they do not dress or groom one side (e.g., shaving or combing only the ipsilesional side of the face and hair). A patient might only put the right half of his or her body on a chair. Patients with personal neglect might have asomatognosia, which is the failure of a patient with personal space neglect to accept ownership of his or her contralesional limbs. Patients might think that their limbs are owned by someone else, even when confronted with objective evidence that they are mistaken (e.g., following the course of the limb from its distal end toward the point where it is attached to the patient). In severe cases, the limb might be personified (e.g., related to as a person or a thing) or be the object of hatred (misoplegia). More frequently, in milder forms of personal neglect, patients will be aware that their extremities belong to them, but they still refer to them as though they were objects. Contralesional supernumerary limbs have also been described with this syndrome.

D. Spatial Neglect

Spacial neglect is a failure to respond to stimuli in hemispace. Contralesional hemispace is most often involved. Spatial neglect may occur in all three directions of space; horizontal, radial, and vertical.

E. Imagery Neglect

When asked to image an object, scene, or part of the body, some patients fail to image one half. Although patients with imagery neglect often have hemispatial neglect or asomatagnosia, imagery neglect and spatial or personal neglect can be dissociated. Imagery neglect, like spatial neglect, can be viewer, environmentally, or object centered. For example, patients might have difficulty spelling from memory the neglected side of a word, both forwards and backwards.

F. Memory Neglect

In memory neglect, patients who can recognize contralateral stimuli may have difficulty recalling them.

G. Extinction

In this disorder, patients detect and respond to the contralesional stimuli when they are presented alone, but the patients are unaware of these stimuli when presented simultaneously with ipsilesional stimuli. Extinction might be sensory (e.g., failure to detect a contralesional stimulus during bilateral simultaneous stimulation in the visual, tactile, auditory, and even olfactory modalities). Extinction might be found either in patients who recover from inattention or in patients who never had inattention. Patients with motor extinction can detect bilateral simultaneous stimuli but cannot move both sides of the body simultaneously.

II. EVALUATION PROCEDURES

As a result of the number and heterogeneity of the behavioral deficits associated with the neglect syndromes, there are an enormous the number of possible tests. In the following sections, we describe the most important evaluation procedures.

A. Observation of Spontaneous Behavior

Spontaneous directional orienting of the eyes, head, or body should be observed to determine if there is a directional bias. There may be a decreased amount of movement of the limbs on one side. Daily activities are usually very informative. For example, patients might be able to communicate with visitors and family only from one side. They might eat and drink only from one side of the tray or plate. Patients might neglect dressing and grooming (e.g., shaving and combing) in this same side.

B. Tests for Sensory Inattentional Tasks

Inattention is tested by asking the patient where he or she was stimulated. This should be done in the visual (either in bedside confrontation tests by using a cotton-tipped applicator or a moving finger or in the laboratory by perimetry or a tangent screen), auditory (either by rubbing or snapping the fingers or by audiometric techniques), and somesthetic (either by touching with a finger or a cotton applicator or by Von Frey hairs). Stimuli of other somatosensory modalities (pin, temperature, etc.) can also be used.

C. Motor Intentional Tests

Hypo- or akinesia in one or more body parts (eyes, head, body, or limbs) should be examined by observing spontaneous behavior and behaviour in response to commands. Failure to move or a delay in movement in the face of relatively preserved motor strength suggest motor neglect. Crossed-response tasks might be used to differentiate motor-intentional neglect from elemental sensory disorders and sensory inattention.

D. Extinction Tasks

If the patient responds normally to unilateral stimuli, he or she is intermittently presented with bilateral stimuli and asked either to verbally report the side of the stimuli or to move the stimulated body part (e.g., hand or arm). The bilateral stimuli should be randomly mixed with unilateral stimuli to the right and left sides. Correct response to the unilateral stimuli with contralesional unawareness in the bilateral stimulation suggests contralesional sensory extinction. A failure to move or a delay in moving the contralesional limb with preserved verbal reports of bilateral stimulation is a sign of motor extinction.

E. Spatial Neglect Tasks

The following are among the many tests that can be used to assess spatial neglect:

1. Cancellation tasks: Lines circles, letters, or stars are drawn in random positions on a sheet of paper and presented to patients who are asked to cancel or cross out all the targets. Spatial neglect patients may fail to cancel targets on the contralesional side.
2. Line bisection task: Patients are asked to bisect or find the middle of lines 6–10 in. long. Patients with spatial neglect make their mark to the ipsilesional side of the real midline. When copying a figure, patients with neglect might omit the contralesional parts of the figure (e.g., omitting the contralesional petals while copying a daisy).
3. When drawing spontaneously, a patient with spatial neglect might omit the contralesional parts of the drawing (e.g., in drawing one half of a daisy). When given a frame to fill with typically related data, such as numbers on an empty clock face or cities and states on an empty map, the patient might omit the contralesional data or draw all the data on the ipsilesional side. Norms are available for a few of these.

F. Representational Neglect

Representational neglect can be detected by asking the patient to recall details of mental images (e.g., places, geographical areas, or familiar routes) from a specific point of view and comparing the recalled details on each side. The same might then be done from oppositely located points of view.

III. EPIDEMIOLOGY OF NEGLECT SYNDROMES

The following data in this section concern patients with acute stroke.

Contralesional neglect: The frequency of contralesional visual spatial neglect has been investigated

extensively. Recent studies have shown: the frequency of visuospatial neglect to be significantly higher after right (70–82%) compared to left (40–65%) hemispheric lesions. These rates are higher than those indicated by previous studies, probably because of better definition of the syndrome.

Extinction: The frequency of visual extinction was found to be 23% with right and 2% with left hemispheric lesions. Tactile extinction was found in 65 and 35% of patients with right and left hemispheric stroke, respectively. Another study found the rate of visual extinction after right hemispheric stroke to be 9% and that of tactile extinction to be 14%. An additional 6% had combined visual/tactile extinction. The difference in the rates between the two studies seems to be related to the differences in the criteria of extinction, but in both studies the frequency of tactile extinction is higher than that of visual extinction.

Ipsilesional neglect: The rate of ipsilesional neglect was found in one study to be approximately 16% of right hemispheric lesioned patients.

Clustering of the neglect phenomena: It was found that between 49% and 73% of neglect patients present three or four coexisting neglect features. In addition, many double dissociations were found between these features. For example, hemiinattention was dissociated from all other components of neglect.

IV. HETEROGENEITY OF BEHAVIORAL DEFICITS ASSOCIATED WITH THE NEGLECT SYNDROME

Previously, we discussed many of the behavioral deficits associated with the neglect syndrome. Several studies have revealed that although some patients may have all or most of these deficits, others have only one or some deficits but not others, suggesting that many of these behavioral deficits are dissociable. In the following sections, we present these clinical dissociations.

A. Hemineglect Syndromes

1. Representational/Non-Representational Neglect

Most of the patients that manifest representational neglect also have some other hemispatial perceptual deficits. Thus, they do not fully show that representational and perceptual neglect are dissociated. However, recent studies report cases in which patients had representational but not perceptual neglect or the opposite.

2. Attentional/Intentional Neglect

The failure to cancel contralesional stimuli and the error toward the ipsilesional space in bisecting a line may be related to either a failure to allocate attention to contralesional hemispace, with a resulting failure to fully perceptually process the sided stimulus (a sensory-attentional deficit), or a failure to initiate or execute movements toward or in the neglected hemispace (a motor-intentional deficit).

Several methods have been used to test this dissociation in patients with neglect. Tests for motor interference reduce the need for blindfolded manual exploration and also reduce measuring time to initiate movement (moving a handle along a track with the right hand) as well as other indirect time measurements. Investigators have tried to create conditions in which attentional and intentional conditions are dissociated. Such paradigms include using a pulley device, a mirror, or closed-circuit TV. For example, a recent study evaluated 10 patients with right hemispheric injury and left hemispatial neglect in both line bisection and cancellation tasks while they viewed stimuli on closed-circuit TV. The patients could only view the stimuli and their hands indirectly through a closed circuit TV monitor. Direct viewing was precluded by a drape. Manipulation of the video camera created two different conditions. In the direct condition the left and right sides of the paper in actual work space were on the left and right sides of the monitor scan. Hand movements on the table (work space) were congruent with those displayed on the monitor (perceptual space). Inverting the camera 180° created the indirect condition, in which the left side of the paper projected to the right side of the monitor and vice versa. Consequently, leftward movements in the work space appeared as rightward movements in perceptual space and vice versa. In the direct condition of the line bisection task, all subjects bisected, as anticipated, to the right of the midline. The critical condition for discriminating between attentional and intentional factors is a comparison between indirect conditions. If the patient has primarily an attentional deficit or bias, then in the direct condition this would have a rightward bias but in the indirect condition the bias would reverse and be leftward. Rightward deviations on the actual line during both conditions suggest a failure to move leftward (intentional deficit). Whereas patients with temporoparietal posterior lesions had primarily attentional deficits, patients with frontal lesions had primarily intentional deficits. Patients with primarily

attentional or intentional deficits often had secondary intentional or attentional deficits. The attentional–intentional dissociations were also found in the auditory modality.

3. Personal vs Extrapersonal (Spatial) Neglect

Personal space refers to the body and extrapersonal space refers to the space outside the body. Extrapersonal space is divided into near (peripersonal) and far. Personal and spatial neglect were found to double dissociate. Whereas spatial neglect in the absence of personal neglect is common, the opposite is less common.

4. Domains of Spatial Neglect

Neglect might occur in different spatial domains. Several dissociable subtypes have been reported. First, hemineglect is commonly reported in the horizontal direction (right/left axis); however, neglect has also been observed in the radial (near or far) and vertical (high or low altitudinal) directions of space. Horizontal neglect may also be related to the position of the stimulus in the peripersonal versus extrapersonal space. For example, some patients will fail to correctly bisect horizontal lines in near space but perform correctly in far space and vice versa. In diagonal neglect, patients frequently fail to cancel targets primarily in the left part of the page nearest the body. This seems to be related to a combination of horizontal and near radial neglect. Second, neglect is reported in different reference frames. In the egocentric reference frame, neglect is relative to the body of the viewer (i.e., left or right of the viewer). Within the body-centered coordinates, there might be a dissociation between retinotopic; head- and trunk centered-neglect. An allocentric or environmental reference frame locates an object in relation to its spatial environment. For example, the stimulus might be located in the left of a scene, independent of the viewer reference frame. Egocentric and allocentric neglect can be dissociated by changing the position of the patient relative to the environment. An object-centered reference frame codes intrinsic spatial aspects of the object relative to the object's principal axis. The object-centered reference frame remains stable when the stimulus is moved in relation to the body or environment. By manipulating the relative position of the patient's body, visual scene, and object neglect could be shown in each of these reference frames. Third, some types of neglect are stimulus specific. For example, neglect was shown to the left side of the face or to either the right or left side of a word. Complex objects or scenes have global and local features. In Navon's figures, a larger (global) form is composed of smaller (local) forms (e.g., a large "H" and small "o"s). There are patients with left hemispatial neglect who might fail to recognize either the global or the local elements on the neglected side.

a. Auditory Neglect Although auditory spatial neglect is not uncommon, there is a paucity of reports in the literature on the subject. Also, most of the reports are of auditory extinction (with its unresolved connection with neglect).

b. Tactile Neglect The dissociable described subtypes are those that are related to orthogonal axes of neglect. Here also, near and far radial and high and low altitudinal neglect are seen.

c. Olfactory Neglect This was reported in right parietal lesioned patients. Olfactory detection was comparable to that in controls. Both lateralization and identification of unilaterally presented odorants were decreased on the left contralesional nostril.

d. Motor Neglect The following dissociations have been reported for motor neglect:

1. Orthogonal axes of neglect: These dissociations might be attentional, representational, or intentional. In order to show a specific dissociation of motor neglect along the orthogonal axes, specific paradigms should be used. Using a fixed-window paradigm, a near radial intentional neglect was identified.
2. Involved part of the body: This might be eyes, head, limbs, or the whole body.
3. Type of action: For example, writing (producing errors on the contralesional side of the word), reaching with the ipsilesional limb, and manual exploration.
4. Direction of movement: Directional or spatial deficit.
5. Part of movement: There might be difficulty in initiating (akinesia and hypokinesia) or in maintaining (impersistence) a movement.

e. Contra/Ipsilesional Neglect Whereas most patients with viewer-centered or environmental-centered neglect fail to be aware of or act on contralesional stimuli, some patients with neglect fail to recognize or act on ipsilesional stimuli.

B. Extinction Syndromes

Neglect and extinction are clinically related phenomena. They frequently coexist in the same patient. Also, extinction appears when there is an improvement in the signs of neglect. There is even a tendency to view extinction as "mild neglect." Although these syndromes are related, there are significant differences between them. The main similarity is the failure to report, respond, or orient to a contralesional stimulus, with the difference being the bilateral stimulation condition in the extinction syndrome. Many of the dissociations found in spatial neglect have counterparts in the extinction syndrome, but dissociations as representational/nonrepresentational and personal/extrapersonal have not been reported in extinction, maybe because extinction is of stimuli in space and not of space. The following dissociations have been reported:

1. Motor/sensory: Showing extinction in either sensory or motor tasks.
2. Within/between modalities: Usually, extinction is reported to be between two stimuli of the same modality. Recently, cross-modal extinction was reported between visual and tactile stimuli.
3. Orthogonal axes Vertical extinction has been reported. That the distinction between near and far peripersonal spaces is also relevant for extinction is suggested by the observation that modulation of visuotactile cross-modal extinction is found when both stimuli are in the near peripersonal space but not when only one of them is in the near peripersonal space and the other is in the far peripersonal space.
4. Reference frames: The previously mentioned ego/allocentric distinction is not described in the extinction literature. However, it seems that there is a place for such a dichotomy. For example, double simultaneous tactile stimuli were given to the ipsilesional thumb and little fingers of the ipsilesional hand, in the ipsilesional hemispace, when the palm was up or down. In the two cases the medial contralesional stimulus was extinguished. This means that some allocentric reference frame is affecting the extinction. Also, posterior truncal tactile extinction was found in parkinsonian patients.
5. Hemispatial location of stimuli: Extinction might occur not only when stimuli are presented in both hemispaces but also when they are in the ipsilesional hemispace. This was shown for visual and for tactile domains.
6. Type of stimuli: For example, patients with visual extinction were found not to extinguish stimuli presenting motion.

V. ISSUES WITH SIGNIFICANCE FOR THE MECHANISMS OF NEGLECT SYNDROMES

A. Variability of Neglect Due to Task-Specificity

In addition to the previously mentioned variability of the different syndromes of neglect, its appearance and degree are affected by the demands of the task by which it is evaluated. For example, the line bisection and cancellation tests, both used to diagnose neglect, may show a double dissociation. In a study that investigated 120 patients with neglect after right hemispheric infarcts, 14 of 83 patient who were impaired in a letter cancellation task had no neglect on line bisection, whereas 29 of 37 patients who cancelled normally showed signs of neglect in a bisection task. Interestingly, the side of the neglect relative to the side of the lesion was also found to dissociate with these tasks. Some patients were reported to show contralesional hemineglect on cancellation and ipsilesional hemineglect on line bisection tasks. These task-specific dissociations are explained by specific task demands (e.g., in terms of needed computations of target location or for intention, moving attention, etc.) and locations.

Several factors were found to affect the degree of neglect even within the same task, including location of the target (lesser neglect in ipsilesional bisection), length of the line (more neglected on longer lines), higher discrimination demands (e.g., in cancellation), levels of perceptual parsing (e.g., in copying complex drawings), hand used for accomplishing the task, its starting point, and the type of response (e.g., pointing vs grasping the midline).

Drawing tasks were also found to be affected by general factors, such as verbal IQ and simplification of instruction. Fluctuations in visual neglect were related to fatigue, time of day, and other nonspecific factors. This variability suggests that neglect is not a unitary syndrome, and that its components in a specific patient reflect the specific neuroanatomical injury.

B. Amelioration of Neglect

Neglect can be temporarily ameliorated by a number of procedures. These treatments can be generally

classified according to their approach and possible mechanism. The first group includes vestibular (by irrigation of the left external ear with cold water or the right ear with warm water, inducing nystagmus movements of the eyes, with the slow phase to the left), optokinetic (by horizontally moving bars to the left, also inducing nystagmus with the same features), posterior neck proprioceptive (by vibratory stimulation to the left side), and transcutaneous somatosensory electrical (to the left side of the neck) stimulation. Such stimulations were found to improve visuospatial, motor, and personal neglect, anosagnosia, and representational neglect. The time range of the improvement is between the duration of the stimulation and about 20 min. The exact mechanisms of the effects of these manipulations are not understood.

Other procedures include altering perceptual components (e.g., perceptual cueing) and moving stimuli from the neglected to the normal side by using prisms, reorienting attention to the neglected side by motor–intentional manipulations (e.g., looking to the neglected side, limb activation, both contra- and bilateral, and provoking an intention to act; changing the relative positions of the body-centered and environmental-centered reference frames; and increasing arousal), and transcranial magnetic stimulation of the unaffected hemisphere. These procedures altered performance in a variety of neglect tasks and their effects cannot be explained by a single mechanism.

C. Neuroanatomical Correlates

Neglect is often associated with right than with left hemisphere lesions. The mechanisms for this asymmetry might be related to right hemispheric dominance for arousal, space representation, and attentional and intentional computations.

Analysis of anatomical correlations reveals that left hemispatial neglect can be associated with both cortical and subcortical lesions. The cortical lesions are mainly posterior (e.g., inferior parietal) or both anterior and posterior (e.g., frontal and inferior parietal). However, neglect might be associated with isolated anterior (frontal) lesions. The subcortical structures that neglect when injured include the basal ganglia, the thalamus, and subcortical white matter. Lower diencephalic and upper mesencephalic lesions were also reported to cause neglect both in human and in animals. The size of the lesion does not always correlate with the degree of the neglect. Specific behavioral deficit may be associated with specific brain lesions. Near radial and lower vertical neglect were found after bilateral posterior parietal, whereas far radial and high vertical neglect were found after bilateral inferior temporal lesions. Neglect on the cancellation task is more likely to be associated with frontal lesions and that on line bisection with parietal lesions. Intentional (motor) neglect and ipsilesional neglect are also more frequently associated with frontal than parietal lesions. Sensory-attentional neglect is more likely to be associated with parietal lesions. Whereas spatial hemineglect is associated with inferior parietal lesions, visual extinction seems to be more associated with superior parietal lesions.

VI. UNAWARENESS OF NEGLECTED/EXTINGUISHED STIMULI

When extrapersonal or personal hemispatial neglect are severe, unawareness seems general, as if the contralateral sides of the world or of the body do not exist. In less severe cases, the picture is usually mixed: The unawareness is more variable. The patient might be aware of certain stimuli but not others. The picture is even more surprising in extinction since the general behavior of the patient (if having only extinction) does not include any signs of unawareness except during double simultaneous stimulation. Although most patients insist on seeing only a single stimulus, some observations suggest that in some circumstances the ''extinguished'' stimulus is perceived. The unawareness of neglect/extinction syndrome should be differentiated from other disorders associated with unawareness, including blindsight and simultanagnosia. Blindsight refers to the ability to perform some visual (e.g., detecting movements) and visuomotor tasks (e.g., pointing or grasping a target) in the areas of visual scotoma that resulted from damage to the primary visual cortex. The patient does not have a visual experience of the stimulus on which he or she acted. In simultanagnosia, the patient has difficulty simultaneously perceiving more than a single object.

Another type of deficit of awareness in some patients with neglect might be described as ''hyperawareness,'' in the form of completion phenomena. The patient copies or draws from memory only the ipsilesional half of a drawing (e.g., a butterfly with only the left wing) but believes that what he or she drew is the complete picture (e.g., a butterfly with two wings). Directing his or her attention to the neglected side or to the missing parts might not help. This

phenomenon might provide an indication of the veridicality of the patient's visual experience despite the deficit of awareness.

A. Implicit Processing of Contralesional Stimuli in Neglect

To be aware of contralesional stimuli does not mean that these contralesional stimuli are not processed. Several studies report that even in the presence of unawareness there may be a significant contralesional processing.

The processing of contralesional stimuli in hemineglect was suspected in patients with left neglect dyslexia who make errors that affect the left side of the word but maintain the length of the misread word (e.g., "pillow" for "yellow"), showing an implicit detection of the full word. Using a forced-choice paradigm, patients were able to correctly select between two pictures that were identical on the normal side but different on the neglected side (e.g., two identical houses with red flames coming out of the left side of one house). Patients were aware of the right but not the left side of stimuli (e.g., only the kangaroo in a picture that was contained a deer on the left and a kangaroo on the right side) even after correctly tracing on command, the silhouette of the whole picture. Patients who neglected pictures of objects on the left side of a display claimed to have already seen a significant number of them when these pictures were later presented intermixed with foils in a forced-choice paradigm. The presence of a significant context in the neglected contralesional side of a visual scene increased the range of exploratory eye movements toward the neglected hemifield, despite unawareness of that side. Electrophysiological and psychophysiological measurements indicated that contralesional visual and somatosensory stimuli were perceived, although the patients were unaware of these stimuli.

These observations raise the following question: What is the level of processing that the contralesional stimulus of which the patient is unaware is achieving? The study of patients with visual object agnosia and patients with naming disorders has helped to identify two levels of processing that are essential for recognizing and naming visual stimuli. The first and more elementary is the perceptual level, in which the sensory components of the presented stimulus are determined (e.g., color and form). The output of the perceptual level is transferred to the semantic level, which attaches the meaning to the stimulus based on the knowledge represented in the brain. An appropriate specific response to the stimulus (e.g., naming and motor act) as well as full awareness to it are dependent on the completion of the processing in these two levels. These principles are also valid for the auditory and the somatosensory stimuli.

Several studies have been performed to define the level of processing that is achieved by the contralateral stimulus of which the patient is unaware. Perceptual presemantic processing was reported in some studies. For example, the mere presence and the number of contralesional stimuli were found to affect ipsilesional reaction time and the degree of neglect. The segregation of figures from their background was found to occur on the neglected side. These studies indicate that the stimulus of which the patient is unaware is perceived to a level that it can modulate the severity of the neglect. Semantic processing was also reported in the neglected hemifield in semantic priming (e.g., where the contralesional stimulus should be processed to a semantic level in order to modify the response to an ipsilesional stimulus) and other tasks.

Reports of extinction indicate that it mainly occurs on the perceptual level. They include modulation of extinction by contralesional identical and similar stimuli and also contralateral stimuli that affect grouping processes. Perceptual processing of extinguished stimuli was shown by other paradigms. The anatomical level of processing of the extinguished stimulus was investigated by event-related functional magnetic resonance imaging (fMRI) in a patient with right inferior parietal lesion and left–sided extinction. Even when the left object was extinguished in the double simultaneous presentation, fMRI showed activation of the striate and early extrastriate cortex of the extinguishing hemisphere. In another study, it was shown that the contralesional processing of the extinguished stimulus occurs to the level where it affects motor responses to the ipsilesional stimulus, namely, an advanced perceptual level. Contralesional processing was also reported to extinguished somatosensory stimulus.

In summary, both in neglect and in extinction, there is a significant processing of the neglected stimulus. Any hypothesized mechanism (e.g., attentional or representational) for these syndromes should relate to the phenomenon of unawareness in the face of an advanced level of processing of the neglected stimulus.

VII. MECHANISMS OF NEGLECT AND EXTINCTION

Many mechanisms have been hypothesized to explain the neglect/extinction syndromes, including perceptual, specific representational, attentional, and executive mechanisms. Although neglect and extinction impair awareness, to some extent they might have different mechanisms because they are dissociable both clinically and anatomically.

The clinical heterogeneity of the syndromes and the abundance of related observations have resulted in a multitude of possible mechanisms. Although many of the posited mechanisms are supported by research and can explain several clinical observations, their relation to the core deficit of the neglect/extinction syndromes, which is the unawareness of contralesional stimuli, is not always explicit. Therefore, the suggested mechanisms should be understood as parts of a modular system that creates awareness in general, explain the spatial localization of the deficit, and offer a basis for the heterogeneity and specific dissociative features of the relevant syndromes.

Awareness, as a phenomenon of subjective consciousness, is associated with several cognitive domains, including arousal, the nature of the perceived stimuli and its processing, binding, space representation, selective attention, and working memory. Unawareness of unilateral stimuli might result from a deficit in any of the previously mentioned domains or a combination of them.

A. Explanations of Extrapersonal Hemineglect

The main explanations of the hemispatial unawareness in neglect include attentional, intentional, and representational mechanisms. These mechanisms are not mutually exclusive, and they might even be related or interact with each other.

1. Mechanisms Associated with Asymmetric Deployment of Attention

The attentional deployment bias mechanisms are based on the assumption that the unawareness is caused by a difficulty in allocating the appropriate level of attentional resources to process the presented stimuli. There are two main theories to explain the nature of these deficits. The attention-arousal theory claims that each hemisphere is responsible for orienting responses to the contralateral hemispace. In addition, the right hemisphere has dominance in mediating bilateral cerebral activation and arousal. In left-sided neglect, the lesioned right hemisphere is less aroused than the nonlesioned left hemisphere. As a result, there will be hypoorienting to the contralesional hemispace. Evidence supporting this theory includes the effect of the increased arousal procedure to ameliorate neglect, the effect of contralesional novel stimuli, hypometabolism of the contralesional left hemisphere in neglect patients, and the failure of right neglect patients to show pupilary dilation when they look at the nonneglected stimuli in the ipsilesional left hemispace. The ipsilesional attentional bias theory claims that each hemisphere activates contralateral orienting through corticotectal connections. Each hemisphere inhibits the opposite one through callossal connections. When one hemisphere is injured, the other (the left, in the case of left hemispatial neglect) becomes hyperactive and attention is biased contralaterally (to the right hemispace in this case). This mechanism is indicated by the "magnetic attraction" of gaze to the right, the exacerbation of neglect by general activation of the left hemisphere (e.g., by a language task), amelioration of neglect by decreasing saliency of right-sided stimuli (e.g., when canceling by erasing and not by drawing over), detecting rightmost targets faster than controls, the lack of effect of dimensions of distribution of attention (e.g., entire display vs rightmost position), and the presence of a steep gradient from left to right (as opposed to sharp discontinuity) in a visual search task.

2. Mechanisms Associated with Asymmetry of the Spatial Distribution of Intention

The process of acting on stimuli requires setting the goal of the action and preparing, initiating, executing, and monitoring the action. Patients with intentional hemispatial neglect fail to act on contralesional stimuli of which they are aware. Some methods used to differentiate between intentional and attentional neglect were discussed previously. Spatially directed intention is an integrative process that incorporates multimodal extroceptive stimuli, internal drives, and goal selection and develops coordinated output programs. The patient with the intentional deficit does not have the normal level of mental effort to support these action-related processes. The intentional deficit might affect the different components of the action-producing processes. It might be presented either in simple (e.g., pointing) or in complex actions, in highly

voluntary or automatic actions, or when the intentional demands are phasic or tonic.

Neglect intentional deficits are associated with lesions in dorsolateral and medial (SMA and anterior cingulate gyrus) frontal lobe, inferior parietal lobe, thalamic (ventrolateral, anterior lateral, and medial nuclei), and basal ganglia (striatum and substantia nigra) regions of the ipsilesional hemisphere. Based on the transmodal gateway approach, every region should have a specific role in the intentional system (these roles are not known). Although the net result of the deficit is a decrease in the level of contralesional deployment of intention, it is not known whether this bias is related to the hypointentional level of the stimulus in contralesional space or the hyperintentional level of the stimulus in ipsilesional space.

3. Mechanisms Associated with Disturbance of Shifting Spatial Attention

These mechanisms are based on the three-stage model of attention. According to this model, in order to shift attention from one spatial location to another, one first disengages attention from a currently attended stimulus, moves attention to the new stimulus, and engages that stimulus. These stages can be dissociated using a valid/invalid cueing paradigm, and disengagement deficit was found in patients with right parietal lesions.

In addition to the spatially asymmetric attentional operations described previously, some nondirectional attentional deficits have also been reported in neglect, including a smaller floodlight for distributed attention, a smaller attentional focus, and a nonspatial attention deficit (reflected by a strong relationship between the degree of neglect and digit span discrepancy). A global effect was found in a patient with left hemispatial neglect. The patient was requested to cancel targets of a standard cancellation task in the left and right side alternatively. The patient was able to overcome her right-sided spatial bias, but she did not cancel more targets even though she was successful in overcoming the bias. These results suggest a limited capacity system that might be either attentional (e.g., rapid habituation) or intentional.

4. Mechanisms Associated with Space Representation

The syndrome of representational neglect is based on the assumption that the environment is internally represented as a spatial map in the brain. This mental map enables the brain to calculate spatial coordinates for both perceiving (attending) and acting (intending) on our environment by relating stimuli to spatial referent. A critically localized brain lesion might damage specific parts of these space representations. As a result, selected locations for mental processing will be impaired (representational scotoma). Neglect of left hemispace after right posterior parietal lesion might be caused by a representational deficit.

During the past decade, neuropsychological research both in animals and inhumans has advanced our understanding of the role of the parietal cortex in constructing multimodal distributed representations of space. Such representations should be able to supply the subject with a stable spatial representation for daily functioning. Paradoxically, the parts of space to which we are exposed are continuously changing during normal perceptual experience. For example every movement of our eyes while making saccades toward stimuli in the environment activates different retinotopic neurons. However, the space around us remains stable. The posterior parietal cortex has the processing mechanisms to solve this paradox. Studies in monkeys indicate the following:

1. Multiple modalities are converged in the parietal cortex, including visual, somatosensory (e.g., neck, arm, and eye positions), auditory, vestibular, and efference copies of motor commands. A high proportion of its neurons response to bimodal stimulation [e.g., visual/tactile in the ventral intraparietal area and visual auditory in the lateral intraparietal area].
2. Specific areas are associated with spatial neuronal computations of specific activities (e.g., the LIP area, related to space exploration by eye movements, and the medial intraparietal area, related to space associated with reaching).
3. Posterior parietal neurons encode the locations of stimuli in specific reference frames (e.g., retinotopic, eye centered, head centered, body centered, and world centered). An area might encode in a single reference frame, and a stimulus might be coded in more than a single reference frame. There is debate whether a single neuron can simultaneously encode spatial location of an object in multiple reference frames. This combinatorial multiple reference frame encoding might permit high-efficiency processing of spatial information relevant to selection of stimuli and actions on them.
4. Parietal areas execute transformations of spatial information between specific reference frames (e.g., from retinotopic to head centered) and between modalities and reference frames (e.g., auditory and visual signals to eye-centered coordinates).

5. The parietal cortex contains mechanisms for shifting attention, stimulus selection, and movement planning.

Relevant spatial reference frames and locations are selected according to their salience and relevance to specific sensori motor transformation.

B. Explanations of Extinction

The mechanisms of extinction have been investigated much less intensively than those of neglect. The main reason for this seems to be that the understanding that extinction is a syndrome on its own and not a ''mild neglect'' is relatively new. As a result, only recently have independent mechanisms been sought. Thus, for example, a dichotomy such as attentional/intentional extinction does not exist as it does in spatial neglect. Therefore, we are able to give only a general view of the subject.

The main mechanisms suggested to account for extinction are either sensory or attentional. The sensory theories claim that pure contralateral deafferentation might cause extinction. Although this can be the mechanism for some patients, it seems unlikely to explain the syndrome in most patients, mainly because of recent reports suggesting that the extinguished stimuli is processed to an advanced level. Also, sensory deficit cannot explain extinction of the left stimulus of a pair that is presented in the basically intact ipsilesional hemifield. An attentional explanation seems to be more adequate.

The unique feature of extinction is that it appears only upon bilateral double simultaneous stimulation. This raises the hypothesis that there is a competition between the stimuli—that in the patient, because of an attentional deficit, there is a failure of the contralesional stimuli to successfully compete for limited processes resources. In fact, an effect of competition can even be found in normals. In a position emission tomography study of normals, it was shown that simultaneous bilateral visual stimulation reduced the activation of bilateral striate and extrastriate cortices compared to the level at which each side was activated in the single stimuli condition. Interestingly, an extinction-like phenomenon appeared on one of the sides that was not attentively prioritized (e.g., the subject was instructed to begin the report either from the left or the right side of the array of stimuli). Thus, with the bilateral stimulation, there is a hemispheric rivalry. The extinction appears because there is an attentional bias to the ipsilesional hemifield, with a resulting suppression of the lesioned hemisphere. The two main hypotheses used to explain this attentional bias are the same as those used to explain spatial neglect. The limited capacity theory claims that the lesioned hemisphere cannot fully attend to the contralateral stimuli. The capacity of the remaining attention is generally limited and thus results in extinction of the less attended stimulus. In support of this theory is the finding that patients report bilateral stimulation in conditions in which only the ipsilesional arm was touched but not vice versa, and also the fact that the reaction times to visual stimuli in extinction patients were higher than those of normals even in the intact hemifield. The other explanation is that an ipsilesional bias is caused by the release of the left hemisphere contralateral-orienting system from the right hemisphere inhibitory influence. In support of this theory is the gradient of increased efficiency of stimulus detection from left to right and the improvement of the extinction by nonverbal report in right-handed patients.

In contrast to neglect, much less is known about the possible dissociation between attentional and intentional features of extinction. A recent study of extinction in parkinsonian patients who had an anterior flexed posture and were simultaneously stimulated on the anterior and posterior surfaces of the upper part of the trunk revealed that they extinguished the posterior stimuli. This might suggest an intentional effect on attentional bias.

A disengagement deficit was described in patients with visual extinction. However, this cannot explain contralesional extinction when the contralesional stimulus was presented before the ipsilesional one. An effect of specific spatial reference frames on extinction is suggested by some studies for both visual and tactile extinction in a way similar to neglect. It seems that in extinction there is also a deficit in computations of reference frames that are needed for various tasks, but the representations are not abolished.

C. The Relation between Mechanisms of Neglect and Unawareness

Each of the mechanisms mentioned previously might interfere with awareness of perceptual experience in the neglected contralesional hemispace. For example, although the exact role of selective attention in visual awareness is not fully understood, some of its effects seem to be correlated with awareness (to visual

stimulus in this case). Among them are binding components of the visual scene, increasing activity in the different visual areas, and linking information from the ventral and dorsal streams. Selective attention was found to have a powerful effect on recognition potentials. Intentional processes are part of motor planning. It was suggested that visual awareness is associated with motor programming. Thus, an intentional deficit might be related to unawareness. The feedforward theory of motor-intentional deficit in anosagnosia to hemiplegia is also related to the intention–awareness relationship.

A deficit in the representation of a portion of space might cause a deficit in perceptual awareness by more than a single mechanism. For example, with a degraded representation one may be unable to compute the spatial coordinates that are needed to spatially direct attention. Another possibility is a deficit in visuospatial working memory. Such a deficit will prevent the incorporation of the spatial background that is needed for the short-term storage and processing of newly perceived and already represented information. Interestingly, working memory activity is needed for perceptual awareness.

Recently, it was shown that the use of nonverbal response in testing for extinction reduced visual extinction. Conscious awareness is deepened by language and by activation of language-bound representations. It might be that there was a disconnection of language networks in the left hemisphere from the visual presentation of the extinguished stimulus in the right hemisphere. This of course will not explain extinction of contralesional stimulus of double stimuli that are presented in the ipsilesional hemifield.

Clearly, the spectrum of the hypothesized mechanisms of neglect and extinction reflects the better understanding of these syndromes. There is no doubt that further study of the relation between phenomena such as attention, intention, and awareness will enable an integration of many of these mechanisms into a more comprehensive model of spatial awareness and its deficits.

VIII. CLINICALLY IMPORTANT ISSUES

A. Course

In stroke patients, neglect usually improves in weeks to months. The rate of recovery is fastest in the first 10 days. Left hemispheric/right hemispatial neglect improves at a faster rate and to a higher level than does right hemispheric/left hemispatial neglect. Intentional deficits, extinction, and anosodiaphoria might be present for long periods of time. The natural history reflects the spontaneous recovery of the brain, but the severity of neglect can also be influenced by training.

B. Rehabilitation

Rehabilitation of neglect means improving the patient's awareness and orienting to the neglected hemispace beyond that expected by its natural recovery. The improvement should be prolonged and should generalize to real–life situations. Some studies provide evidence for such an effect. Until recently, three main approaches were used to get patients to direct their attention to the neglected side; cueing, the use of salient stimuli, and contralesional limb activation. Altering a spatial attention bias was achieved by training visuospatial scanning, sometimes with addition of optokinetic stimulation, by turning the head to look to the neglected side, by using Fresnel prisms to shift images from the neglected side toward the normal side, and by feedback procedures. Increasing nonspatial attention was achieved, for example, by training vigilance by a self–alerting procedure.

Rehabilitation procedures are associated with functional improvement of lesioned brain areas. A recent PET study in neglect patients after right hemispheric lesions showed that in the acute phase, hypometabolism was found in both the ipsi- and contrahemispheres. The degree of this transhemispheric diaschisis was correlated with the size of the involvement of the right cortical and subcortical regions and with the degree of improvement in the chronic phase. A recent single photon emission computerized tomography (SPECT) study investigated cerebral blood flow changes in seven patients with left hemineglect from right hemispheric lesions who had rehabilitation for 2 months, beginning 4 to 14 months post-CVA. The training included visual scanning, reading and copying, copying line drawings on a dot matrix, and descriptions of a scene. SPECT was done before and after rehabilitation. Increased perfusion was found in the posterior parts of the lesioned right hemisphere and in the anterior areas of the nonlesioned left hemisphere. This increment in perfusion was correlated with the behavioral improvement shown by the patients in a visual exploration task. These results suggest that the training of space exploration helps patients to develop strategies to increase attention and exploration of the left hemispace. Although in normals attending and exploring to left hemispace involves the

right prefrontal areas, these areas were either destroyed or disconnected in the neglect patients. Consequently, the contralesional left hemisphere prefrontal areas might have taken over this function. In addition to intrahemispheric and interhemispheric effects, behavioral improvements might also be achieved by subcortical mechanisms. For example, a study in the cat showed that neglect associated with cortical lesions was reduced by destroying the ipsillateral superior colliculus or the intercollicular commissure. Recent studies have improved our insight into the plasticity of brain changes that are related to the rehabilitation of neglect. For example, an ipsilesional gaze-related enhancement in blood flow in the lesioned hemisphere was recently reported. This enhancement was broadly distributed and reflected an increase over normal values, suggesting the involvement of generalized diffuse synaptic activity in functional inprovement. The observation that the effect of prisms in reducing neglect is maintained for at least 2 hr after removal of the goggles also suggests that treatment can induce changes in synaptic connectivity.

The understanding of neglect as a heterogeneous deficit in specific computations of components of spatial behavior enables better understanding and development of potential rehabilitation strategies. A recent study aimed to analyze whether the improvement of line bisection errors in neglect is due to improvement of the causative sensory-attentional mechanism (defined by the Landmark task) or because of a learned behavioral strategy to counteract these mechanisms. In the two studied patients, it was shown that despite marked recovery on line bisection, they still showed a significant sensory-attentional deficit. Thus, they adapted some other mechanisms to overcome the deficit. The fMRI finding that in normals there is an activation of the cerebellum as well as other cortical areas in line bisection judgments (in addition to the inferior parietal area) supports the possibility of other task-related areas taking over the inferior parietal function. Another study reported a patient who had right frontotemporal CVA, with resulting ipsilesional neglect. The deficit was primarily motor intentional with a motor-action bias to the left and a secondarily sensory-attentional bias for stimuli to the right (defined by the video apparatus described previously). Rightward motor-intentional cue (touching the end of the bisected line) improved the primary left-sided intentional bias, and the leftward sensory-attentional cue improved the secondary right-sided attentional bias. Using such methods to define the exact deficient mechanism according to the model of spatial behavior might help in designing rehabilitational-specific strategies and increase the efficiency of the treatment.

C. Pharmacology

Although only very little is known about the neurochemistry of spatial attention, several observations suggest that deficits in some neurochemical systems, especially the dopaminergic, might be related to the syndrome of spatial neglect. The effect of dopamine might be either specific (to improve the hemispatial intentional deficit by enhancing the ability to intend to act) or more general (to increase the modulatory effect of dopamine on the brain distributed network that moderates spatial distribution of attention). A recent study reported an improvement in neglect behavior in a patient who was treated with the dopamine agonist bromocriptine. However, the same agent was found to increase the ipsilesional attentional bias. Thus, the effect of dopamine to improve the behavior of neglect might be more specific to the attentional and not to the intentional component of the deficit.

In addition to dopamine, an effect of norepinephrine has been suggested to improve spatial neglect, but there is no direct clinical evidence. Clomethiazole, a modulator of the GABA(A)ergic system, has been reported to specifically reduce the severity of neglect behavior in monkeys that had an experimental unilateral stroke. It seems that a pharmacological treatment for hemispatial neglect should be actively searched for.

Ventricular System

DAVID E. SCOTT
Eastern Virginia Medical School

GLOSSARY

cuboidal ciliated ependymal cells Involved in the dynamics of local formation and flow of cerebrospinal fluid.

ependymal cells Subtypes that line the cerebral ventricular system.

tanycyte Specialized cells that constitute the lining of circumventricular organs.

The cerebral ventricular system is regarded as the core of the mammalian central nervous system and plays multiple physiological roles. It is important in the physical support of the brain through buoyancy effects; it is a trophic mediator for the global distribution of a broad array of neuromodulators, neuropeptide hormones, and neurotransmitters. The cerebral ventricular system also harbors the choroid plexus, which is responsible for the production of cerebrospinal fluid. The mammalian cerebral ventricular system possesses specialized regions called circumventricular organs that allow the brain not only to perceive the peripheral endocrine and physiological milieu but also to respond by changing it with precision.

I. HISTORICAL INTRODUCTION

It is certain that we are not the first to inquire or analyze the mammalian cerebral ventricular system, which has been regarded for centuries as the core of the central nervous system. Alexandrian anatomists associated the cerebral ventricles with various mental functions. In 1487, Leonardo DaVinci turned his attention to the mammalian cerebral ventricular system. Employing the brain of an ox and his skills as a sculptor, he injected the cerebral ventricular system with hot wax using a syringe after making two vent holes in the anterior horns of the lateral ventricle. When the wax cooled, he carefully dissected away the overlying gray and white matter to reveal a relatively accurate waxen cast of the mammalian cerebral ventricular system. He regarded the cerebral ventricular system as a repository for fantasy, cognition, and memory. In 1503, a Carthusian scientist named Gregor Reich asserted that the freely communicating cavities of the cerebral ventricular system possessed different functions. His thesis inculcated the idea that the first ventricle (the anterior horn) sequestered imagination. The second cavity (the rest of the lateral cerebral ventricle) was the seat of higher associations and the midline third cerebral ventricle was the repository for memory. In his *Treatise on Man*, (1624), Rene Decartes suggested that the ''spirits'' from the body entered the brain via the pineal gland and were distributed throughout the cerebrospinal fluid (CSF) to various regions of the brain in a global fashion. Despite the fact the these early scientists–philosophers did not posses the high-tech imaging equipment and biochemical technology of today, it is surprising how close they came to modern thinking about the

structure and function of the cerebral ventricular system.

This article focuses upon current knowledge that deals with the development (Table I), regional organization, specializations, and structural and functional changes that occur in the normal mammalian cerebral ventricular system or following pathophysiological events as observed with scanning or transmission electron microscopy and immunocytochemistry.

II. EMBRYOGENESIS OF THE CEREBRAL VENTRICULAR SYSTEM

From a structural standpoint, the cerebral ventricular system can be considered the functional core of the brain and begins to make its appearance during the 18th day of life. The flattened neural plate, no more than 70 μm in diameter, appears at approximately 18 days postcoitus (PC). At 20 days PC, the neural groove and folds appear rostrally. Exuberant growth of the neural folds forms a complete neural tube with closure of the caudal neuropore by 25 days in the normal developing brain. The neural tube exhibits three enlargements along its linear axis. The most rostral of these is the prosencephalon, which is destined to differentiate into the telencephalon and diencephalon. The telencephalon expands rapidly and by 12 weeks there is further differentiation into the forerunners of the cerebral cortex, basal ganglia, and the more complex limbic structures. At this time, the corpus callosum begins its inexorable caudal migration, forcing the hippocampus ahead of it into each newly forming temporal horn of the lateral ventricle. The diencephalon, whose walls constitute much of the third cerebral ventricle, begin its differentiation into the epithalamus, thalamus, and hypothalamus during the 12th week of gestation. The mesencephalon is slow to differentiate and does not develop into its definitive derivatives, the corpora quadrigemina and the crus cerebri, until the 20th week of gestation. The cerebral aqueduct (iter) is surrounded by the aforementioned structures and is continuous with the third cerebral ventricle rostrally and the fourth cerebral ventricle caudally, whose dorsal and ventral surfaces are formed by the metencephalon and myelencephalon. The metencephalon differentiates into the cerebellum and the pons by the 16th week of gestation and the myelincephalon differentiates into the medulla oblongata by 18 weeks PC. Despite the fact that the outer surface of the mammalian brain remains lissencephalic for 28 weeks PC, the cerebral ventricular system is fully formed and lined by various types of ependymal cells that exhibit an unusually broad array of functional and structural differences.

Although this article focuses on the three-dimensional topography of the cerebral ventricular system, it is important to discuss the pleuripotential neuroepithelial cells that constitute the simple neural tube and particularly the neuroblasts that give rise to neurons

and the spongioblasts (gliablasts) that evolve into glia and ependymal cells. Many types of ependymal cells exist, and although their lineage is poorly understood, certain data point to the fact that they may be derived from wandering neuroblasts. In the adult definitive brain, they represent a population of postmitotic cells that lack the capability of renewing themselves and reepithelializing their surfaces of the ventricular wall, which may become denuded by various pathological processes and remain so permanently.

III. NEUROANATOMICAL ORGANIZATION OF THE ADULT CEREBRAL VENTRICULAR SYSTEM

A. The Lateral Cerebral Ventricular System

The lateral cerebral ventricular system is the most expansive part of the mammalian cerebral ventricular system. It consists of an anterior projection, with the anterior horns bounded by the septum pillucidum medially, the genu of the corpus callosum rostrally, and the head of the caudate nucleus laterally. It is continuous with the body of the lateral ventricle, whose medial and lateral walls are composed of the body of the caudate nucleus and the lateral aspect of the thalamus. A thick veil of overlying choroid plexus, which is derived from the germinal matrix of the choroidal fissure during the seventh week *in utero*, commonly obscures both of these structures. The body of the lateral cerebral ventricle is continuous, with the posterior horn and the beginning of the temporal horn, an area that is collectively referred to as the collateral trigone. The posterior horn is quite variable in mammals and particularly in the human brain. The most distinct feature of the temporal horn is the presence of the massive hippocampus, with the alveolus of the fornix arising from it as a flattened filet of fibers. Both the hippocampus and the fornix are commonly obscured by a thick felt work of chord plexus, which is highly vascularized and irrigated in large part by the anterior choroidal artery coupled with some branches of the posterior cerebral artery. The lining cells of the lateral cerebral ventricle are chiefly cuboidal ciliated ependymal cells (Figs. 1 and 2). The cilia that constitutes the surfaces of these ependymal cells beat in a metachronal fashion and are regarded as a mechanism that alters the local flow and dynamics of CSF, which is produced in large part by the choroid plexus. It should be noted, however, that cilial density alters from region to region and if a region is denuded of ciliated ependymal cells, no reepithelization will occur. Hence, ciliated ependymal cells of the lateral cerebral ventricle are regarded as postmitotic.

B. The Third Cerebral Ventricle

The mammalian third cerebral ventricle is bounded dorsally by the thalamus. The lower walls and floor are formed by the endocrine hypothalamus. The actual floor of the hypothalamus is formed by the dorsum of the median eminence (Fig. 3), which is a major component of the neurohypophyseal system. The third cerebral ventricle functionally interconnects with the lateral cerebral ventricular system via the two interventricular foramina. The leading edge of both foramina is formed by the columns of the postcommissural fornix that are heavily myelinated fibers that arise from neurons in the hippocampus. The roof of the third cerebral ventricle is formed by the velum interpositum, which separates the body of the fornix from the cavity of the third cerebral ventricle below. The two internal cerebral veins pass through the velum interpositum to fuse as the great vein of Galen over the pineal gland caudally. The velum interpositum gives rise to choroid plexus, which is continuous with that found in both lateral ventricles and courses through the interventricular foramen. The interventricular foramen is a critical area because of its small size and can be easily obstructed by pathological changes in ependymal cells that constitute the choroid plexus, such as ependymal choroid plexus papillomas or ependymomas. Due to the narrowness of this foramen, obstruction can trigger the development of a noncommunicating hydrocephalus and the buildup of CSF in either one or both lateral cerebral ventricles.

Ependymal cells that line the dorsal aspect of the hypothalamic wall are heavily ciliated and posses gap junctions; they are strikingly similar to those found in the lateral cerebral ventricular system. However, as one descends toward the floor of the third cerebral ventricle (dorsum of the median eminence), there is a gradual transition with increasingly fewer ciliated ependymal cells (Figs. 3–5). As one reaches the lateral recess of the third cerebral ventricle, there is a replacement of cuboidal ciliated cells with a specialized type of ependymal cells called tanycytes. These specialized ependymal cells have relatively few cilia, if any, but instead exhibit a rich nap of microvilli that form distinct hexagonal arrays (Fig. 6). On the floor of the third cerebral ventricle, which is the dorsum of the median eminence, beneath these arrays of microvilli there exist tight junctions referred to as zonulae

Figure 1 Scanning electron microgram (SEM) of ependymal surface of the head of the caudate nucleus forming the lateral wall of the anterior horn of the lateral ventricle. Both cilia (CL) and micro villi (MV) are notable in this region of the cerebral ventricular system. × 8000.

occludentes (Fig. 7), that prevent even the smallest proteins or macromolecules from migrating interstitially from the blood vascular system into the cerebral ventricular system from the median eminence below. The barrier properties of tanycytes are discussed later.

C. The Cerebral Aqueduct

The mammalian cerebral aqueduct is clearly one of the most critical regions of the cerebral ventricular system. Through this narrow channel, only 2 mm in diameter, more than 500 ml of CSF must pass in a 24-hr period in the human brain. Pathophysioloical changes in the ciliated ependymal of this region due to fetal infections or teratogens can cause atresia and/or obstruction with the formation of a noncommunicating hydrocephalus. Lining cells of the cerebral aqueduct (Fig. 8) are uniformly ciliated and demonstrate regular metachronal synchrony in their movement.

D. The Fourth Cerebral Ventricle

The roof of the fourth cerebral ventricle is formed by the cerebellum (Figs. 9 and 10). The rostral floor is formed by the pons, whereas the caudal floor is formed by the medulla oblongata. From the opening of the cerebral aqueduct to the caudal portion of the obex of the fourth ventricle, the ependymal cells that line the surfaces of the fourth cerebral ventricle are uniformly ciliated, even in the central depression, which is linear

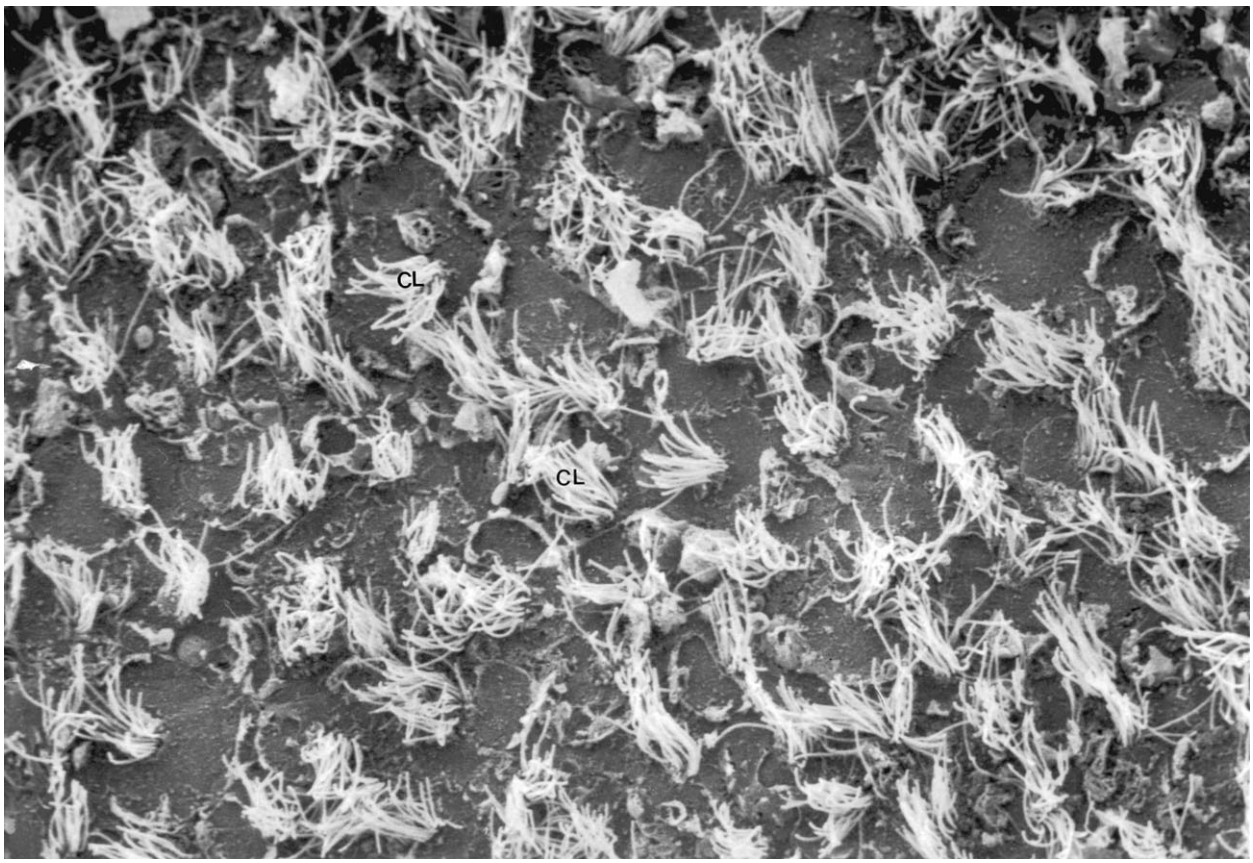

Figure 2 SEM of cerebral ventricular wall of the human hippocampus 28 days postcoitus. Ependymal cells demonstrate patchy cilia (CL) interspersed by areas devoid of any membranous modification. × 6000.

and is referred to as the medial eminence of the fourth ventricle. Frequently, isolated populations of cells can be observed on the surface of these ciliated ependymal cells. Careful analysis has revealed them to be histocytes (Fig. 9).

E. The Choroid Plexus

The choroid plexus arises from the choroid fissure at approximately 7 weeks *in utero*. It is normally found in all the cavities of the cerebral ventricular system, with the exception of the anterior horn and posterior horn of the lateral ventricle, the cerebral aqueduct, and the rostral component of the fourth ventricle. The choroid plexus is formed by a bilayer of ependyma and pia, which is referred to as a tela. The tela is invaded at 7 weeks *in utero* by primitive mesodermal elements, which are the forerunners of noncontinuous fenestrated capillaries. The pia eventually becomes atrophic, leaving a residuum of collagen and fibroblasts sandwiched between an inner layer of porous fenestrated capillaries and an outer ventricular layer of cuboidal ependymal cells covered by dense microvilli and sparse cilia in contact with the CSF of the ventricular system (Figs. 9 and 10). An important neuroanatomical specialization occurs between the apical surfaces of choroid plexus ependymal cells. The apposed apical membranes of adjoining cells posses zonula occludentes (tight junctions), which prevent the passage of even the smallest protein or metabolite from the blood vascular system, through the fenestrated capillaries, into the CSF. Hence, unlike the rest of the brain, the choroid plexus has a blood–CSF barrier rather than a blood–brain barrier and is more similar to the specialized regions of the brain that constitute the unique circumventricular organs where the barrier has been shifted from the vascular to the ventricular side. The fetal choroid plexus is significantly larger during development, than in the adult definitive brain. This

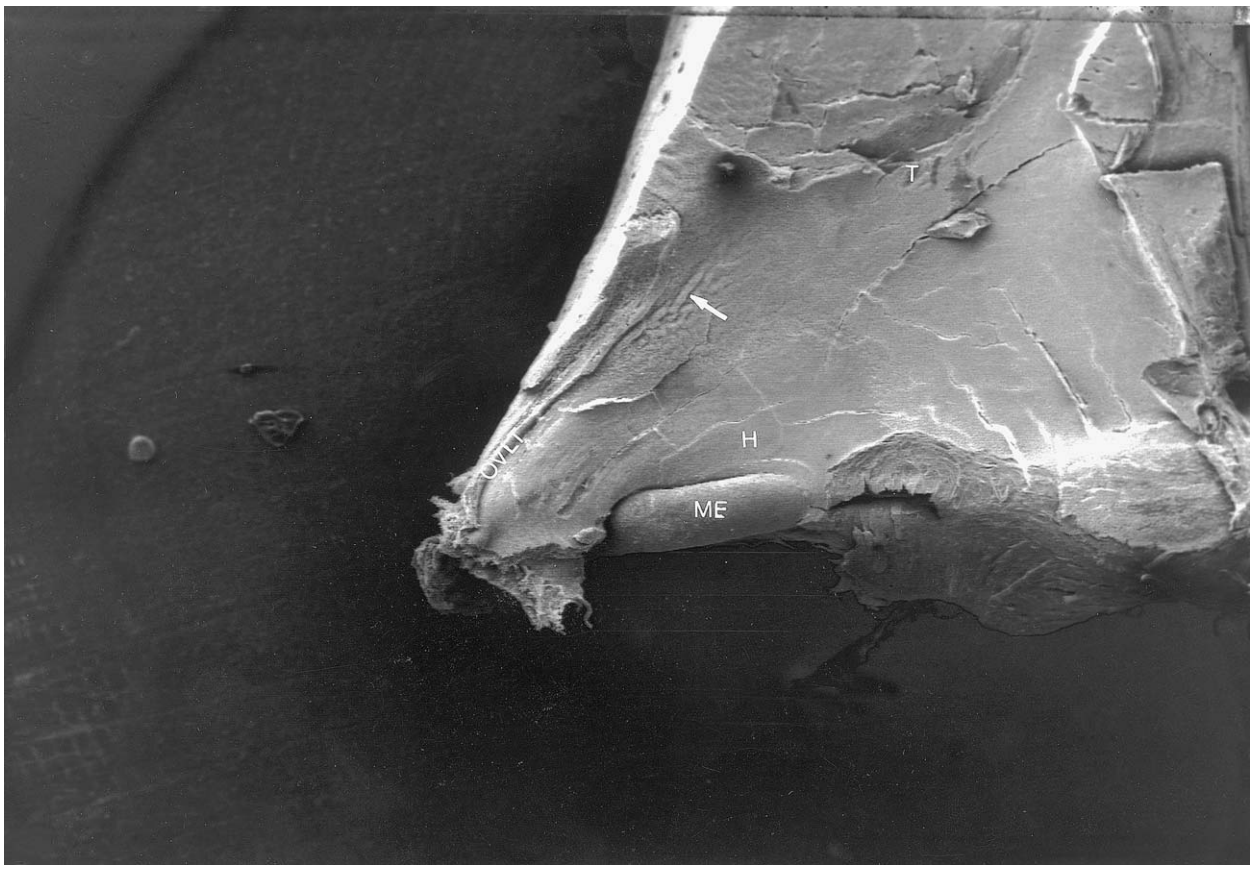

Figure 3 Low magnification SEM of the entire wall of the thalamus (T) and endocrine hypothalamus (H). There is a distinct transition in the neuroanatomical organization of the thalamic ependymal cells versus hypothalamic ependymal cells that line this expansive region of the diencephalon. Rostrally, the thalamic region is lined by heavily ciliated cuboidal ependymal cells that are thrown up into ridges (arrow) and possess gap junctions. As one descends toward the floor of the third cerebral ventricle, there is a transition toward less ciliated ependymal cells with more microvilli (compare with Fig. 4). Upon reaching the median emience (ME), which forms the floor of the third cerebral ventricle, ciliated ependymal cells are essentially replaced by tanycytes that possess apical tight junctions, have relatively few cilia, and whose foot processes stretch through the entire parenchyma of the basomedial hypothalamus to terminate in large numbers on fenestrated capillaries of the hypophyseal portal system. OVLT, organum vasculosum of the lamina terminals. $\times 280$.

relative enlargement and rich vascularity suggest the concept of early prenatal function for this critical organ system within the developing brain and connote a trophic and nutritional contribution during fetal growth and development. The structural organization of human fetal ependymal cells, as observed with scanning electron microscopy, makes it clear that they are aptly suited for the bidirectional transport of a variety of ions and other solutes that comprise normal CSF, which plays a multipotential role in the developing brain. Because the parenchyma of the central nervous system has the same specific gravity as CSF, CSF may act as a buoyancy control mechanism and provide the brain with a certain degree of protection against sudden forces of trauma. In addition, CSF is thought to play a nutritive role for developing glia, ependyma, and neurons in the fetal brain. Since the mammalian cerebral nervous system has no lymphatic drainage system, it is speculated that CSF production, movement, and reabsorption may serve as a mechanism for the removal of cerebral metabolites back into the blood vascular system at the level of the arachnoid granulations that penetrate into the superior sagittal sinus. Since the extracellular space of the developing and adult brain freely communicates with the CSF, this may allow for the constant control of ionic composition of both compartments, with the exception of circumventricular organs. The immense array of biologically active factors, such as neurotransmitters, neuromodulators, and neuropeptide hormones, that may arise from the periventricular neuropil, as well as the established presence of intraventricular

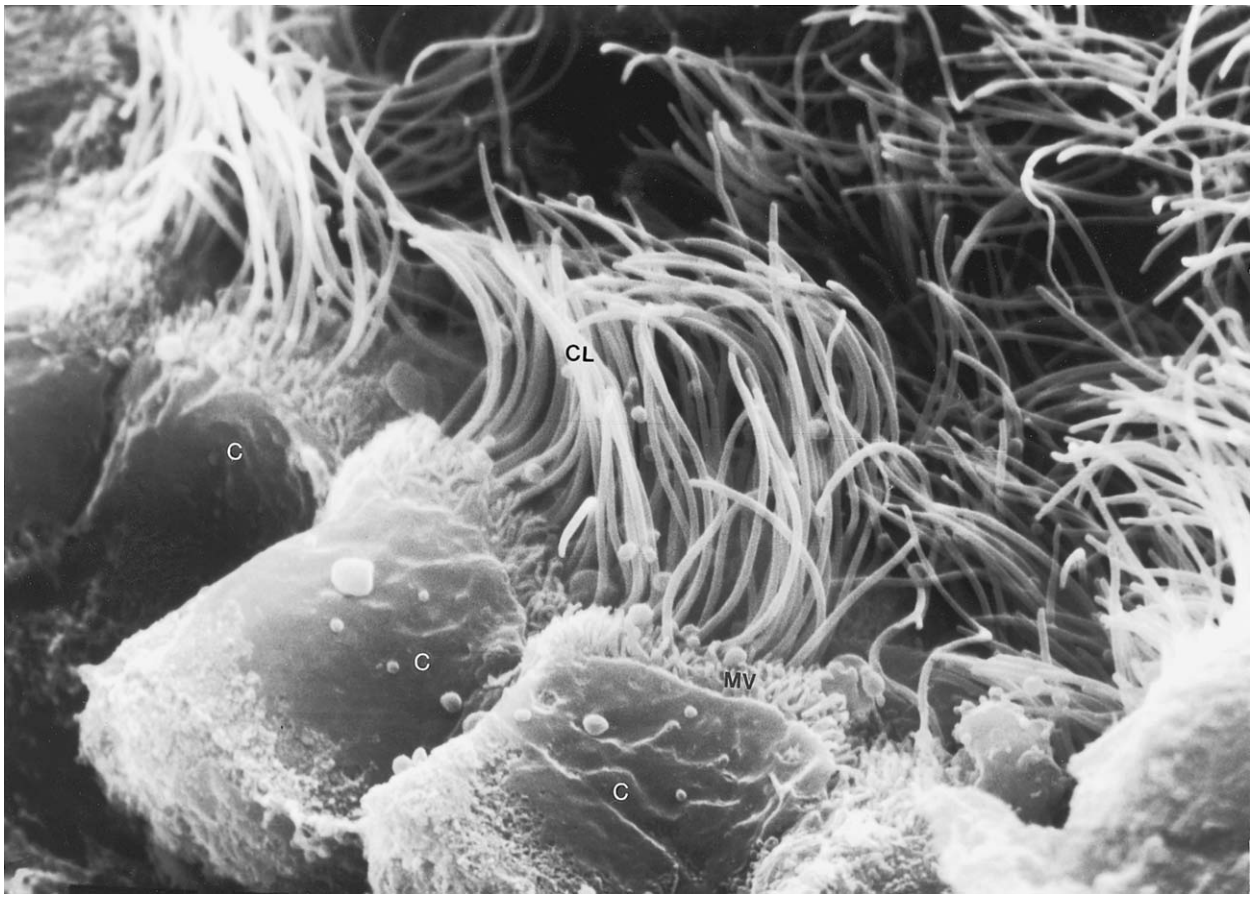

Figure 4 Midrange SEM of dorsal thalamic wall. Cuboidal ependymal cells (C), which lack tight junctions, exhibit a rich nap of cilia (CL) and microvilli (MV). × 6800.

axons and neurons in the cerebral ventricles, has triggered consistent speculation that the CSF may function as a trophic mediator for the distribution of such around the mammalian brain. Due to its strategic location and the lack of intrinsic enzyme systems in the CSF, this makes such an hypothesis very attractive. Finally, because of its predictable composition as well as its chemical and cellular consistency, any alteration in the CSF becomes an excellent diagnostic tool to demonstrate a wide spectrum of pathophysiological changes that can occur within the mammalian central nervous system.

IV. CIRCUMVENTRICULAR ORGANS (THE WINDOWS OF THE BRAIN)

The mammalian central nervous system would be a relatively useless organ if it were not capable of constantly assessing the peripheral physiological and endocrine milieu of the body that it exercises such precise control over. However, despite the fact that most of the brain and spinal cord possess a blood–brain barrier that consists of continuous capillaries with tight junctions protecting brain parenchyma from a variety of blood–bourne compounds that may be toxic to it, there are a small number of highly specialized areas found chiefly around the third cerebral ventricle and in the caudal region of the fourth cerebral ventricle that are unique with respect to their neuronal, glial, and ependymal organization. These specialized regions of the brain are referred to as circumventricular organs and, like the choroid plexus, their barrier properties have been shifted from the vascular to the ventricular side of the brain, which allows them the capacity to assess the peripheral physiological changes by their parenchyma, which is in direct contact with molecular components carried in the bloodstream. They are collectively referred to as circumventricular organs or the windows of the brain

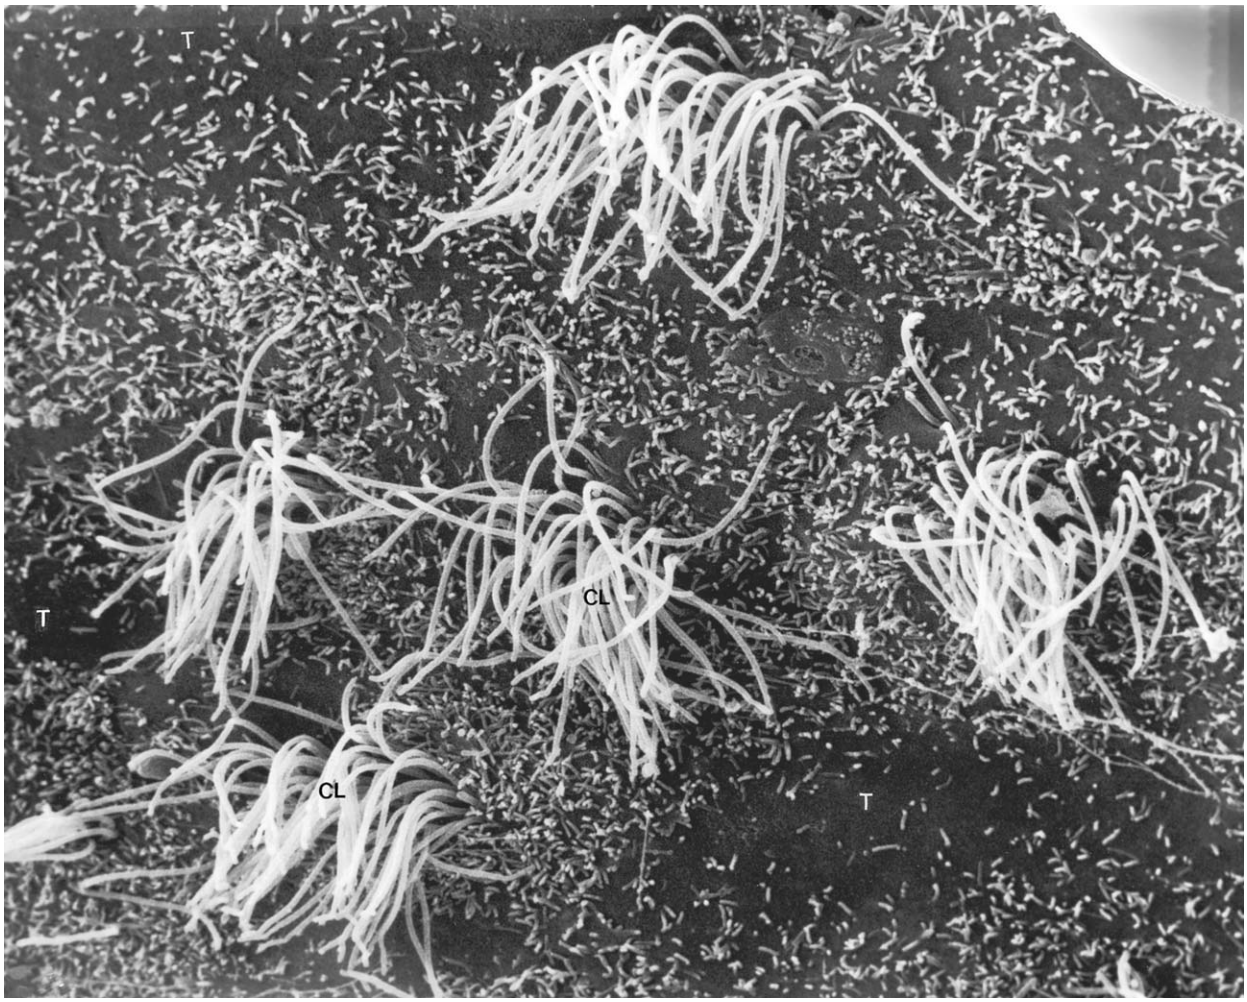

Figure 5 Transitional zone of lower thalamic–upper hypothalamic wall as observed with SEM. Ependymal cells with small amounts of cilia (CL) are being replaced by tanycytes (T), which exhibit microvilli on their apical (ventricular) surfaces. × 7500.

and are composed of the organum vasculosum of the lamina termialus, the median eminence (ME), the neural stem (NS) and neural lobe (NL), the subfornical organ (SFO), the pineal gland (PG), and the area postrema (AP) of the fourth cerebral ventricle. The organization of these specialized areas is unique from that of the rest of the brain. The barrier properties of these areas are fundamentally different and allow for the diffusium of bioactive macromolecules, peptides, and other blood-borne signals to enter their parenchyma in order to integrate homeostatic mechanisms, such as water balance, hypovolemia/hypervolemia, and changes in the peripheral endocrine milieu. With the exception of the PG, NS, and NL, all these circumventricular organs posses a highly specialized type of ependymal cell, the so-called tanycyte (Figs. 6 and 7). Tanycytes posses zonulae occludentes (tight junctions) between their apical zones, which face the ventricular lumen, and much like the ependymal cells of the choroid plexus, these tight junctions act as a blood–CSF barrier to prevent the transport of metabolites from the bloodstream into the cerebral ventricular system. Despite the fact that the lineage of tanycytes is not well understood, like pituicytes of the NS and NL, they are all regarded as highly specialized ependymal cells. Compelling evidence suggests that these unique ependymal cells are neurally innervated and exhibit synaptic specializations. Moreover, these specialized ependymal cells may produce specific neurotrophic factors that serve to attract both hypothalamic and extrahypothalamic neurites. Recent data also strongly suggest that transected supraoptic and

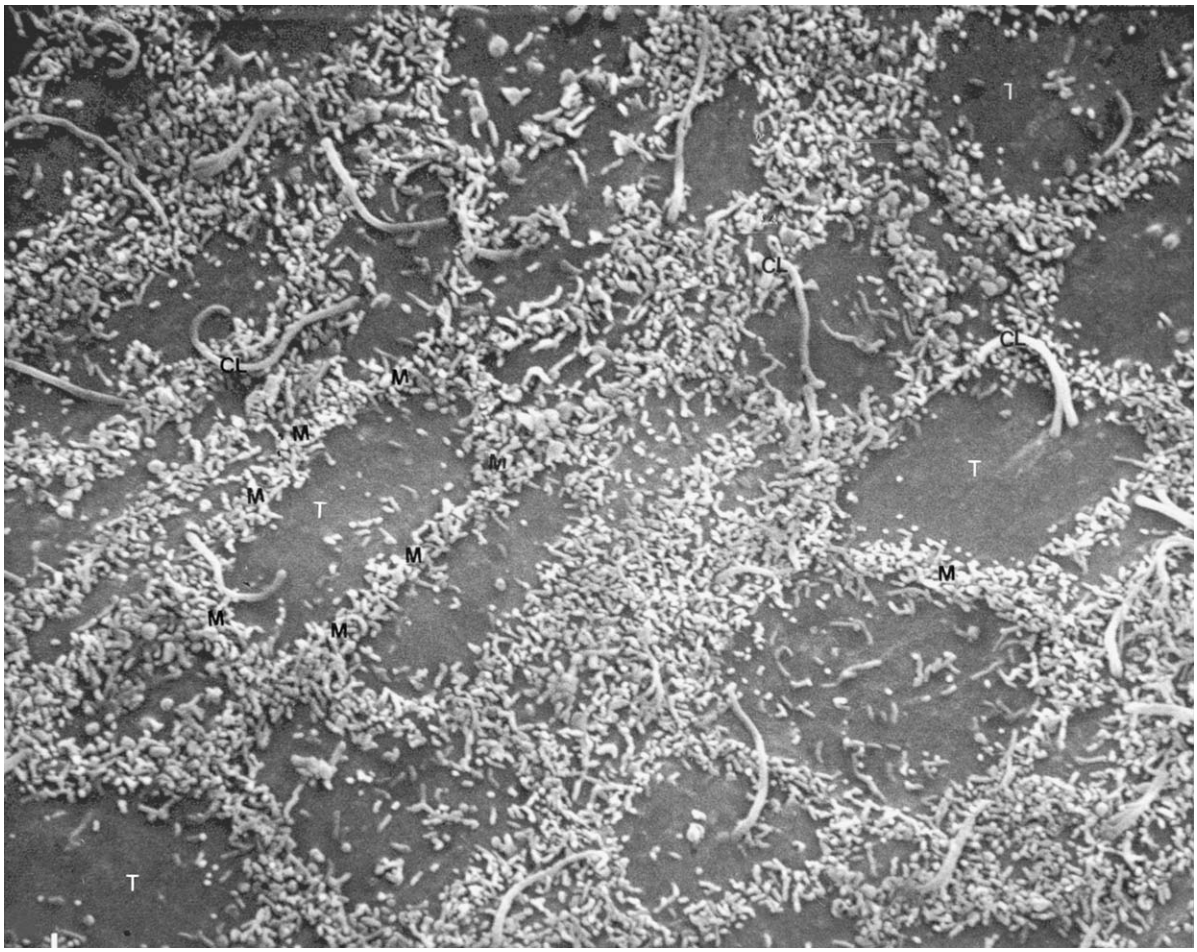

Figure 6 SEM of floor of the third cerebral ventricle (dorsum of the median eminence). Notable are the apical (ventricular) surfaces of tanycytes (T) that are rimmed by ridges of microvilli (M). This gives a hexagonal mosaic appearance to the surface of this circumventricular organ. A few isolated cilia (CL) are notable. This region of the brain is regarded as a target area for the absorption of biologically active molecules from the CSF into the parenchyma of the median eminence. $\times$ 6000.

paraventricular neurits regenerate along tanycyte processes employing them as a template for growth and regeneration. Tanycytes of the ME consistently demonstrate the accumulation of dense core vesicles and microvesicles in their terminal foot processes that abut upon the fenestrated capillaries of the hypophyseal portal plexus. This observation has led to speculation that this specialized ependymal cell type may release various macromolecules into the portal plexus and may directly influence adenohypophyseal metabolism. In control animals sparse numbers of neuritic processes can be observed on the surface of the median eminence (Fig. 11). Although relatively rare in normal animals, these neurites are considered to harbor catecholemines.

It appears that circumventricular organs have a great deal of functional connectivity and integration and not only contribute to the composition of the CSF but also to the composition of the blood. Also, along with other areas of the brain, they posses a high degree of plasticity and germinal potential.

A. The Median Eminence–Neurohypophyseal System

The ME, NS, and NL play an important role in the release of both arginine vasopressin (AVP) and oxytocin (OXY) into the blood vascular system. Both these occtopeptide hormones are noncovalently bound to a carrier molecule neurophysin. However, in the case of the ME, hypothalamic releasing factors from the surrounding endocrine hypothalamus enter a unique capillary bed called the primary hypophyseal

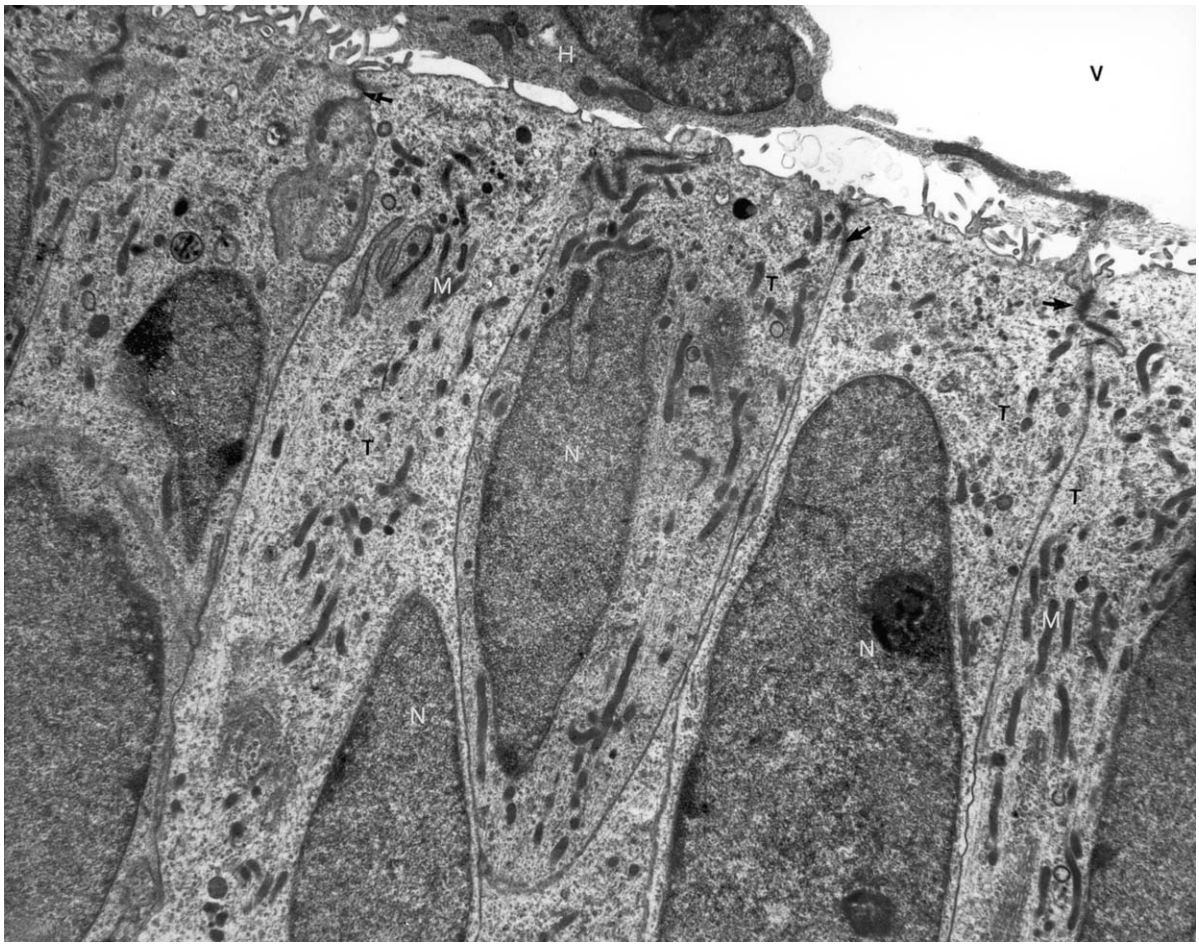

Figure 7 Transmission electron micrograph (TEM) of tanycytes (T) that constitute the floor of the third cerebral ventricle (dorsum of the median eminence). These specialized ependymal cells posses tight junctions between the apical cell collars that face the lumen of the ventricle (V) and, like other circumventricular organs, are regarded as a blood–CSF barrier to the movement of proteins and other macromolecules. H, histiocyte; N, nuclei; M, mitochondria. × 12,500.

portal plexus, which is found at the base of the ME. These delicate capillaries ultimately become the long portal veins that recondense to form the portal sinusoids, which are the sole and exclusive blood supply of the anterior pituitary gland. The anterior pituitary gland is a source of trophic hormones that serve to maintain the integrity of the peripheral endocrine milieu that feeds back on both the pituitary and the median eminence and other portions of the brain and endocrine hypothalamus. Modified glial cells, the so-called pituicytes, exercise dynamic control over NS and NL axons that sequester AVP and OXY during states of hypovolemia or during lactation and suckling. In their passage from the supraoptic (SON) and paraventricular (PVN) neurons of the endocrine hypothalamus, axons that pass through the median eminence (which are destined to terminate in the NS and NL) become myelinated as they enter it. When SON and PVN axons ultimately leave the median eminence to enter the NS and NL, where they form neurovascular zones for the systemic release of neuropeptide hormones, they again become unmyelinated. Although not fully understood, the myelinization of neurohypophyseal axon fibers in the median eminence may serve to confer a degree of protection in a region that otherwise lacks a bona fide blood–brain barrier and instead possesses a blood–CSF barrier. All of the circumventricular organs posses a blood–CSF barrier and all exhibit axon terminals that abut upon fenestrated capillaries for the quantal release of various bioactive hormones and neuropeptides into the blood–vascular system. This concept of a neurovascular

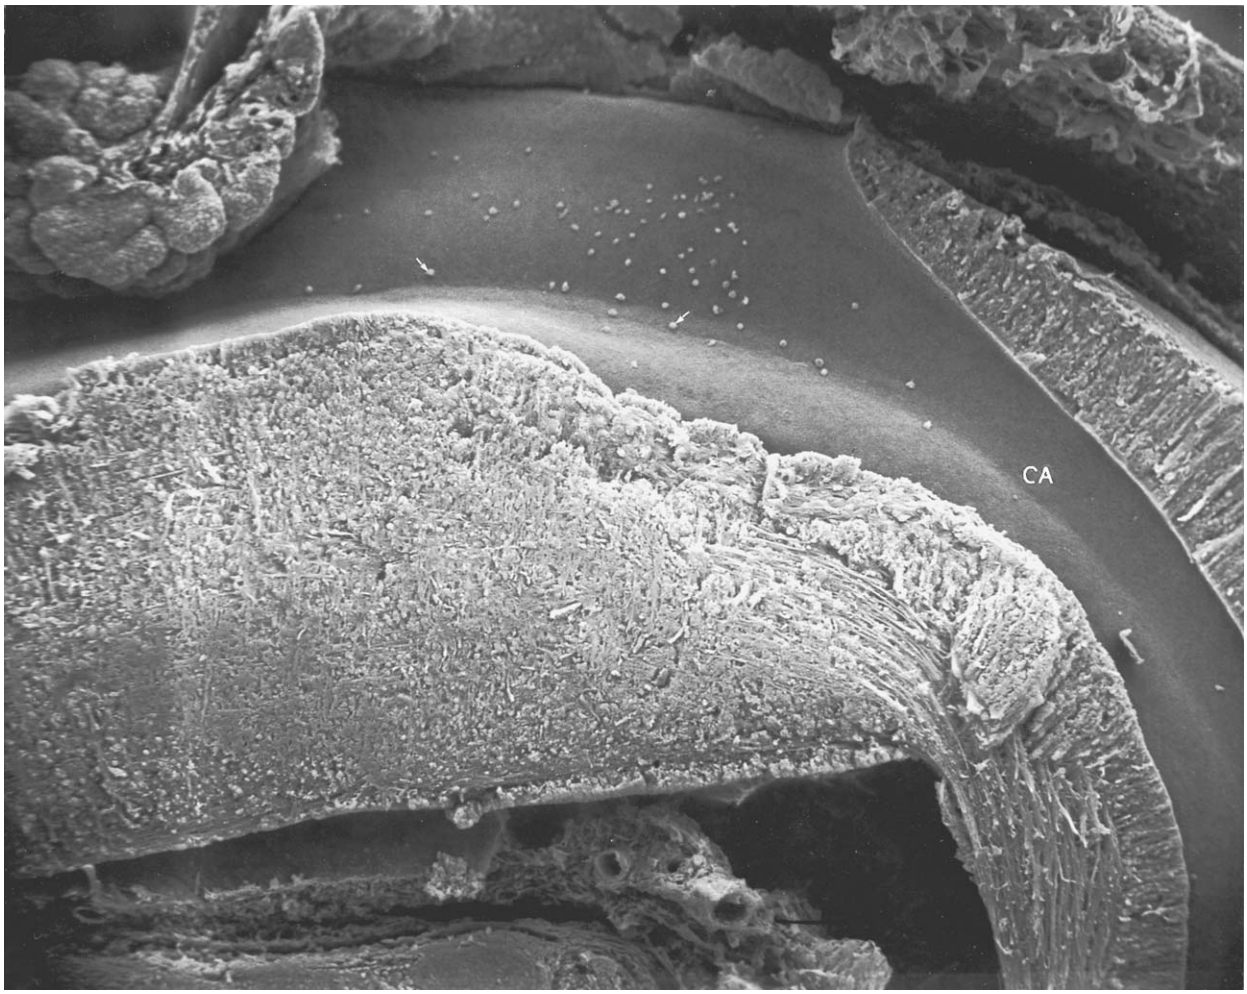

Figure 8 Low-magnification SEM of cerebral aqueduct (CA). The ependymal cells are uniformly ciliated. Numerous macrophages (arrows) stud the rostral end of the fourth cerebral ventricle. × 600.

(neurohemal) function is a pivotal concept in neuroscience and has been described as the mechanism of neurosecretion. This fundamental concept enunciated more than 69 years ago by Ernst Scharrer suffered a long apprenticeship of skepticism and doubt before it was finally accepted as a major tenent of neuroendocrinology in the early 1950s.

B. The Subfornical Organ

Unlike other circumventricular organs (CVOs), the subfornical organ possesses a variety of different neuronal types, which are integrated with other regions of the hypothalamus to include the SON and PVN. There are essentially four different types of neurons that reside within the subfornical organ. Two types are in contact with the cerebral ventricular lumen and the CSF and the other two types are deep within the parenchyma of the SFO. Consistent with the neuronal subtypes are axonal subtypes that are found in the SFO. A number of glial subtypes are also found in the SFO, including tanycytes, whose apical surfaces face the ventricular lumen and whose end feet terminate on perivascular spaces that surround fenestrated capillaries. Like other CVOs, the SFO possesses a blood–CSF barrier. Numerous investigations have firmly established that neurons of the SFO in the third cerebral ventricle function as central dipsogenic receptors. These investigations have shown that the intraparencymal injection of a number of substances, including carbacol, acetylcholine, and physiostigmine, triggers drinking behavior. Conversely, ablation of the SFO inhibits chemically induced drinking behavior.

Figure 9 Caudal end of the fourth ventricle (V) just ventral to the area postrema (AP). The roof of this part of the ventricle is formed by the developing choroid plexus (CP). The floor exhibits numerous isolated histiocytes. Compare with Fig. 5. × 550.

Such conclusions are simply reinforced by the finding of rich reciprocal innervation that exists between the SFO and the SON and PVN of the endocrine hypothalamus.

C. The Pineal Gland

The PG, common to all mammalian species, is a relatively simple circumventricular organ with respect to its histological organization. It is routinely found at the dorsal–caudal region of the third cerebral ventricle just above the posterior commissure and medial to both habenular nuclei. The PG possesses essentially one predominant cell type, the so-called pinealocyte. The basic function of the normal intact, PG is antigonadotrophic and it actively synthesizes and releases the indole, melatonin. The neural regulation of the normal intact PG has been well investigated. Primary control of the PG is exerted by the prevailing light–dark environmental photoperiod acting through the suprachiasmatic nuclei (SCN). Environmental information perceived by the eyes is transferred to the PG over a complex series of neuronal pathways, which include the SCN and the PVN of the hypothalamus, pregangionic sympathetic neurons in the upper thoracic spinal cord, and postgangionic sympathetic neurons in the superior sympathetic ganglion. Direct innervation of the PG is from the superior cervical sympathetic ganglion. Production of the pineal hormone melatonin is cyclic, with high levels of synthesis occuring at night (dark environment) and low levels occuring during the day (light environment). This cyclic synthesis is controlled by the neural pathways mentioned previously coupled with direct retinohypothalamic pathways. The synthesis of melatonin at

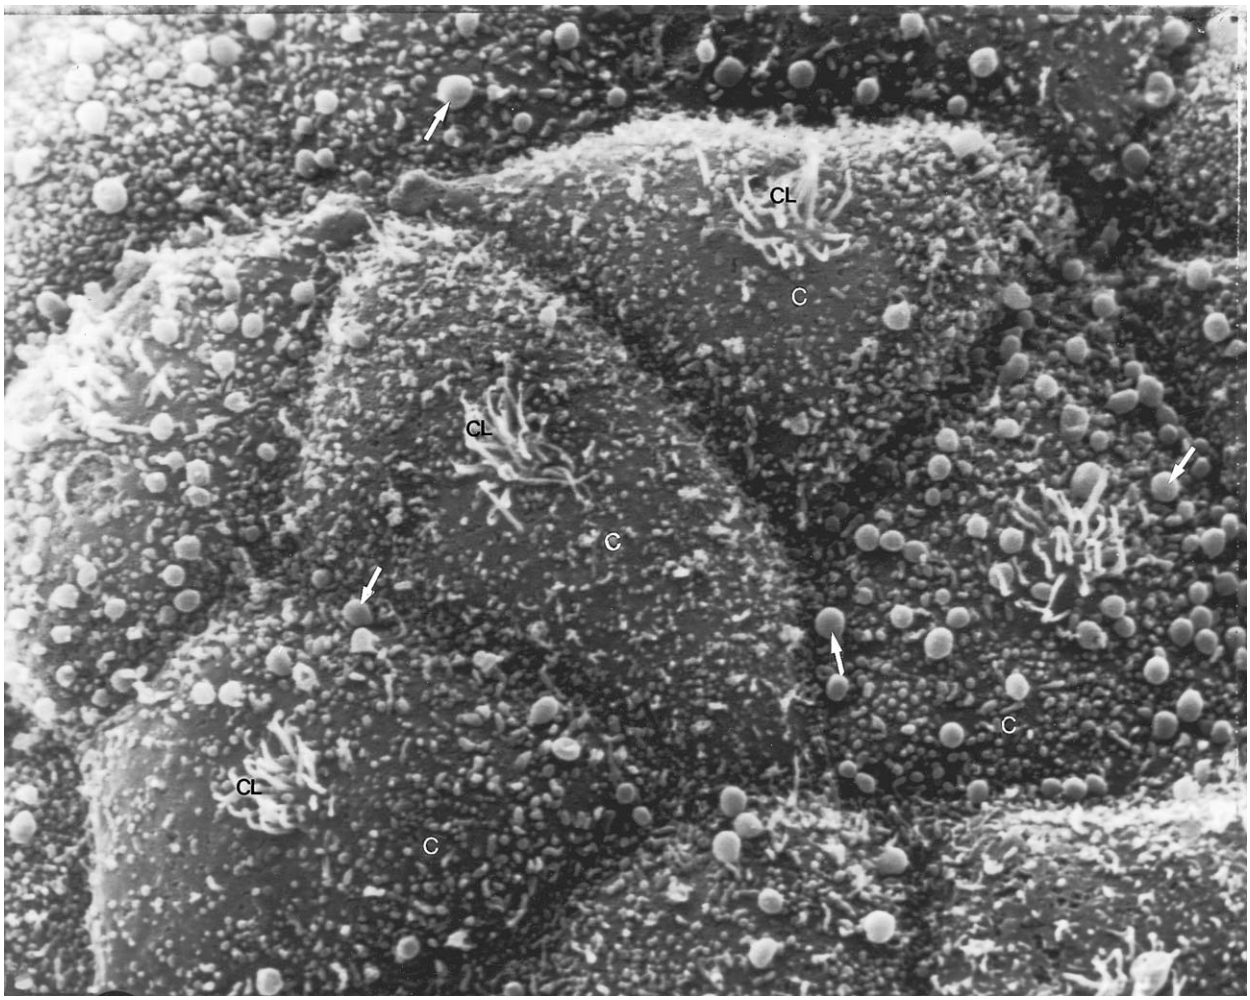

Figure 10 High-magnification SEM of the choroid plexus in the fourth cerebral ventricle. Note a distinct separation of the apical surfaces of the choroid ependymal cells (C) that in the living state are bathed by the cerebrospinal fluid and to which they contribute numerous bioactive molecules ions and peptides. These choroidal ependymal cells exhibit numerous apical secretory blebs (arrows) and populations of isolated cilia (CL). Also evident on the surface of these secretory cells are numerous microvilli. × 7000.

night is a consequence of norepinephrine (NE) released from postganglionic sympathetic nerve endings that terminate in the vicinity of the pinealocyte processes. The PG possesses a pineal recess, which is continuous with the lumen of the third cerebral ventricle. This recess is lined by ependymal cells and occasional small axonal varicosities can be seen on their surfaces. These varicosities have been interpreted to be monoaminergic.

D. The Area Postrema

The AP is found in the caudal end of the fourth ventricle just rostral to the obex. The cerebral ventricular lining of this CVO is composed of tanycytes that have relatively short cell bodies and terminate on underlying fenestrated capillaries. The apical surfaces of these cells lack cilia and posses a rich nap of microvili; they are also quite uniform in their organization (Fig. 9). The AP is rich in both serotimergic and noradrenergic fibers, some of which penetrate between lining tanycytes and sequester both clear and dense core vesicles that measure between 20 and 40 nm in diameter. Large numbers of neuronal elements can be noted in the parenchyma of the AP. Many of these are in close physical contact with the abluminal basal lamina of perivascular spaces that surround fenestrated capillaries. This close neuroanatomical juxtaposition of neurons with fenestrated capillaries suggests a

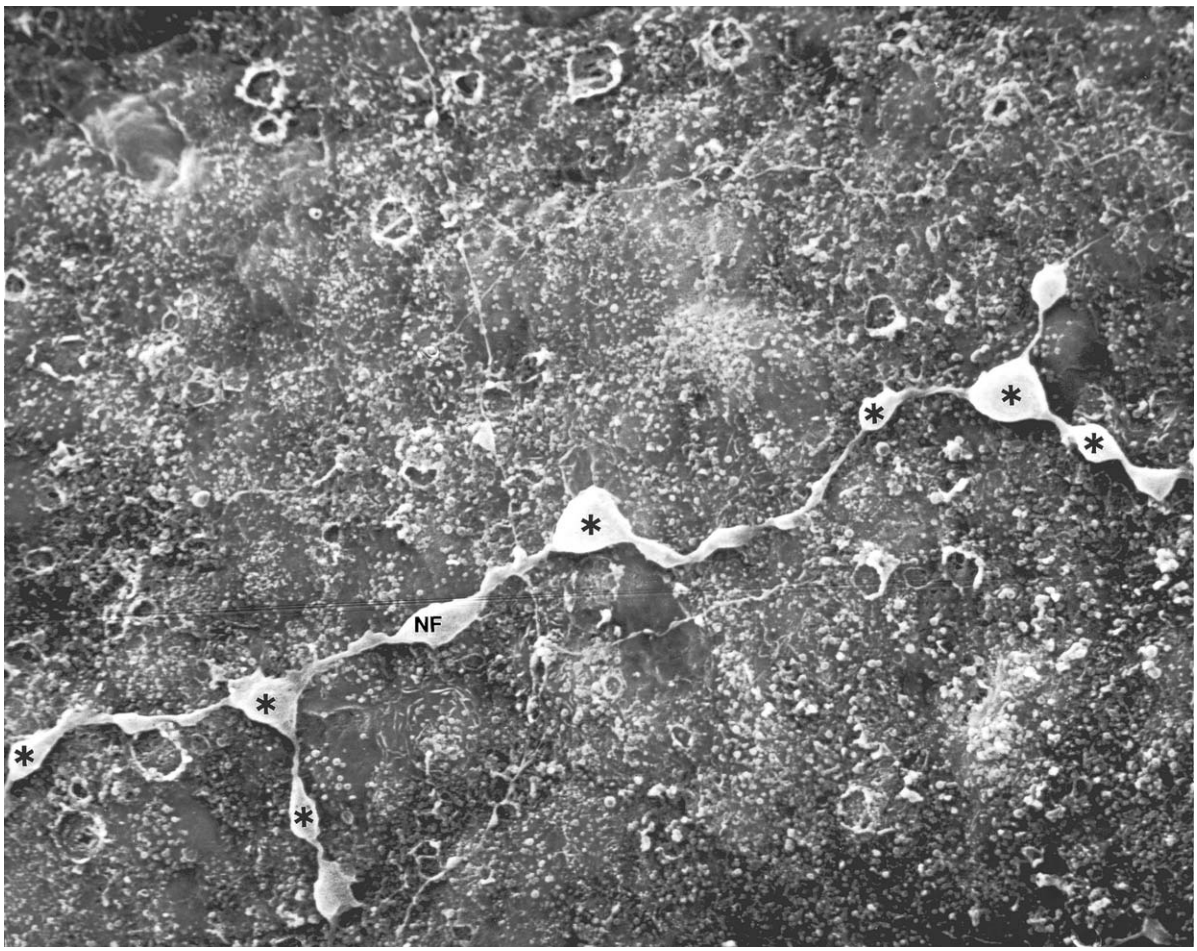

Figure 11 High-magnification SEM of a nerve fiber (NF) on the floor of the third ventricle. This fiber demonstrates distinct enlargements or varicosities (asterisks) along its linear axis. Such fibers are occasionally observed on the ventricular surface of circumventricular organs in the third and fourth ventricles and are regarded to be serotinergic in nature. × 15,000.

neurosecretory function for these neurons of the AP. The AP is regarded as a center of the brain that is a chemoreceptor trigger zone involved in body fluid homeostasis and may play an important role in the physiology of emesis, water balance, and blood pressure due to its critical location and the presence of a blood–CSF barrier.

V. STRUCTURAL–FUNCTIONAL CHANGES IN THE CEREBRAL VENTRICULAR SYSTEM

A. Influence of Neural Transplantation

During the late 20th century, there were many reports dealing with the neural transplantation of various fetal and adult tissue types into the central nervous system. Many of these studies focused on the transplantation of normal tissue into the brains of both humans and other mammals that suffered from neurodegenerative disorders such as Parkinson's disease, or, in the case of animals, autosomal homozygous diabetes insipidus (the Brattleboro rat). A large number of human patients underwent steriotaxic surgery for the placement of their own adrenal medulla into the region of the corpora striata of the telencephalon. The rational for this approach was based on the concept that the cells of the adrenal medulla, derived originally from the neural crest, would, in the environment of the central nervous system, undergo phenotypic differentiation and revert back into neural elements. By doing so, these autografts could secrete sufficient amounts of dopamine to overcome the deficit of Parkinson's disease due to the loss of the nigrostriatal

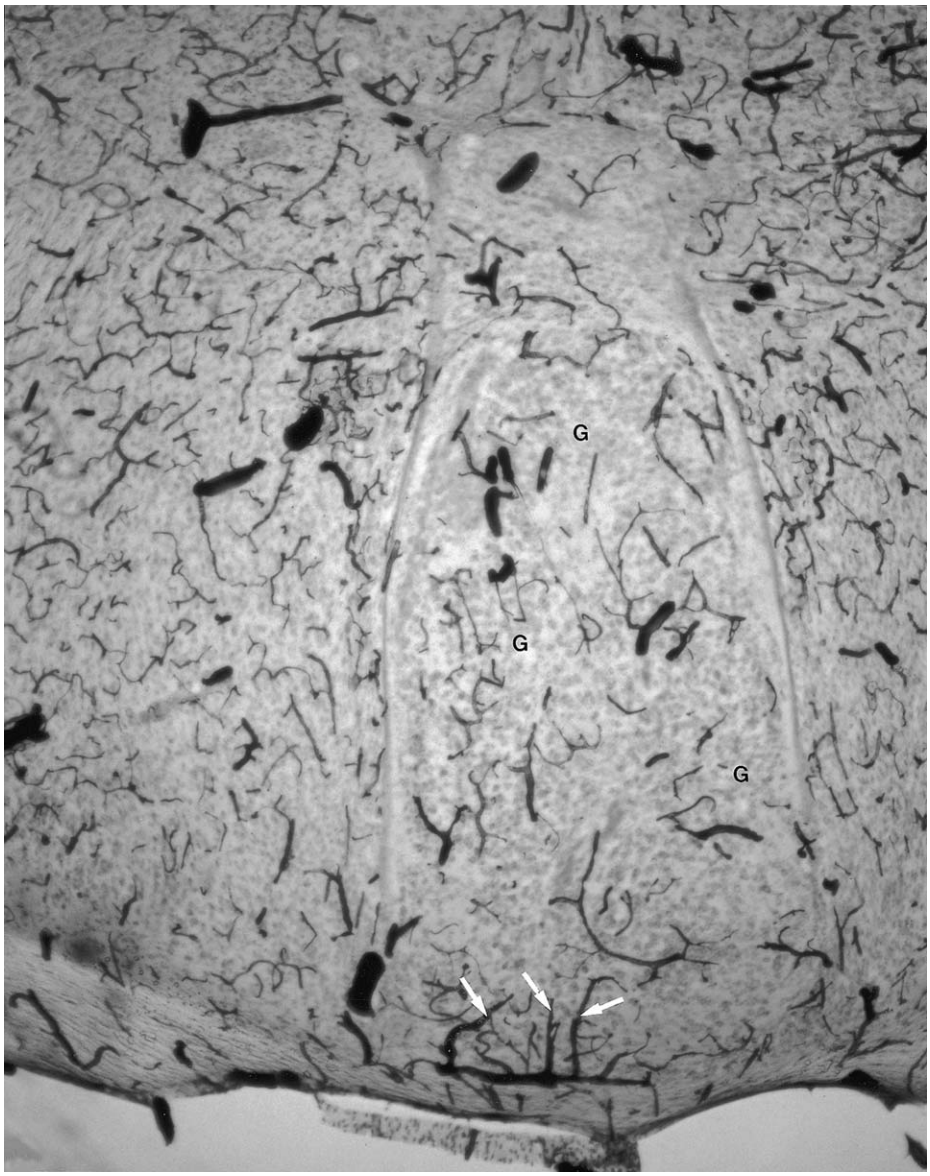

Figure 12 Fifty-micro meter-thick vibratome section of a 20-day-old fetal neural graft (G) in the hypothalamus of a Brattleboro rat with autosomal homozygous diabetes insipidus. The host–graft preparation was stained with methylene blue and reacted for endogenous peroxidase in blood vessels with diamino benzadine. Note especially how delicate branches of the primary portal plexus (arrows) make entry into the base of the graft parenchyma. $\times 400$.

dopaminergic input in parkinsonian patients. Most, if not all, of these procedures failed to produce any positive long-term effects. However, in certain species of monkeys, whose dopaminergic nigrostrigal systems were destroyed chemically, the stereotaxic placement of fetal neurotransplants into the ventricular region of the caudate–putamen proved successful and long lasting.

In the early 1980s, a number of experiments were conducted in which adult rats with homozygous autosomal diabetes insipidus were utilized. These rats received stereotaxic placement of fragments of normal fetal supraoptic hypothalamus. The SON of the Brattleboro rat is incapable of producing viable AVP because it's carrier molecule, neurophysin, contains a mutant cystine end terminal residue that fails to project AVP against enzymatic degradation. Hence, these rats suffer with profound polyuria and polydypsia, produce large amounts of

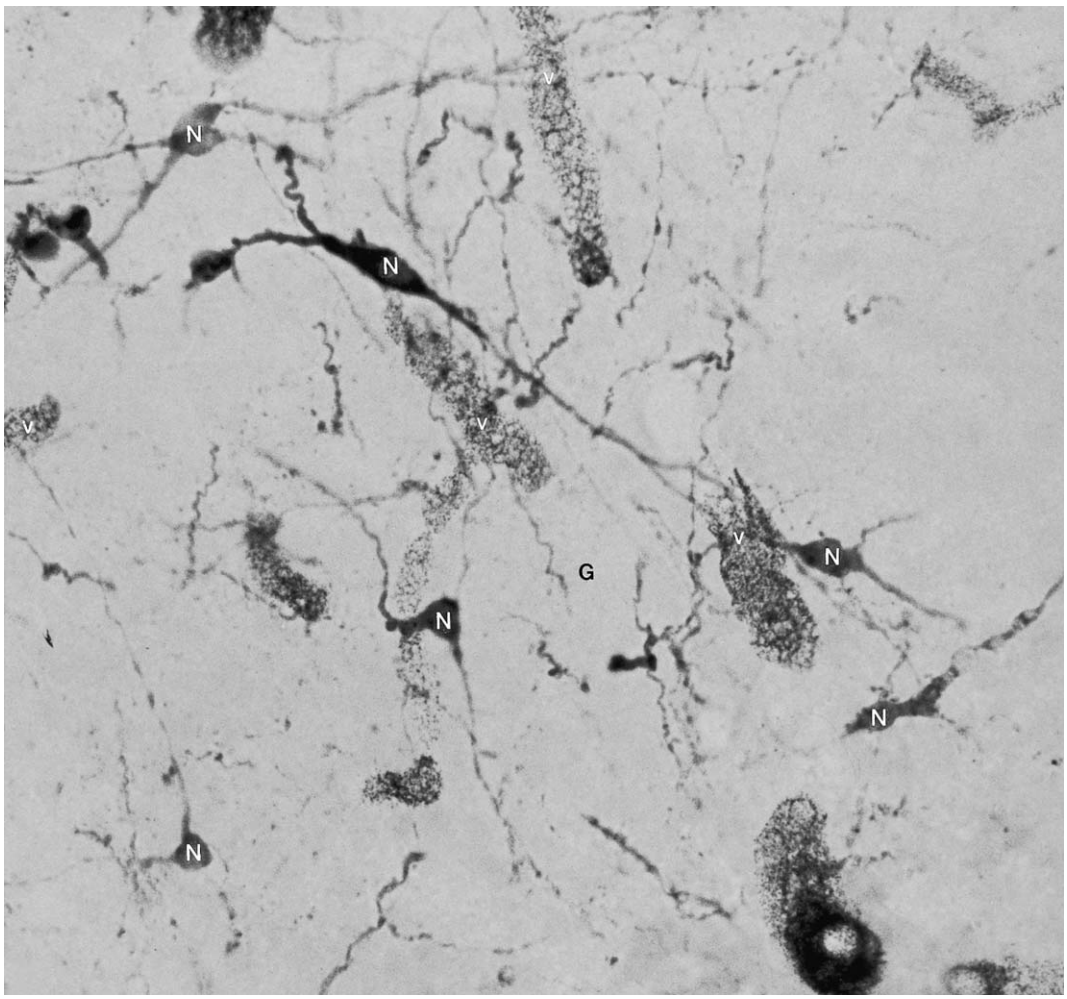

Figure 13 Immunohistochemical preparation of a fetal neurograft 20 days post-transplantation into the third cerebral ventricle of a Brattleboro rat with diabetes insipidus. Neurons (N) and their neurites that are reactive to antisera against AVP appear dark and are observed anatomically juxtaposed to blood vessels (V) that have been infused with the polymerized silastic microfil. × 700.

low-molecular-weight urine, and commonly can consume their own body weight of water in a 24-hr period. Without AVP, they are incapable of absorbing water through the epithelium of the renal distal convoluted tubules and loops of Henle. When adult Brattleboro rats received viable normal fetal hypothalamic implants via steriotaxic surgery into the third cerebral ventricle, several notable events took place. Approximately 40% of the adult Brattleboro rats began to demonstrate normal water balance properties, with a decrease in polyuria and polydipsia. By 20 days post-transplantation, many of these grafted animals had returned to normal. Upon histologic examination, a large proportion of recovering rats demonstrated the invasion of capillaries from the surrounding host parenchyma, which became anastomotic with vessels of the transplanted fetal hypothalamic fragment. These vessels commonly arose from the underlying hypophyseal portal plexus in the median eminence below that formed the floor of the third cerebral ventricle (Fig. 12). Furthermore, surviving neurons that stained positively with antisera against AVP in the fetal transplant were observed to grow their axonal processes toward capillaries of the host portal system (Fig. 13). At the ultrastructural level, these appeared to establish bona-fide neurovascular zones (Fig. 14). Hence, new neurosecretory zones were established for the transport of viable AVP from normal fetal transplants into the vasculature of adult hosts with diabetes insipitus.

Transplantation of the pineal glands also met with similar success. After adult rats were pinealectamized, all cyclic melatonin secretion was inhibited. However,

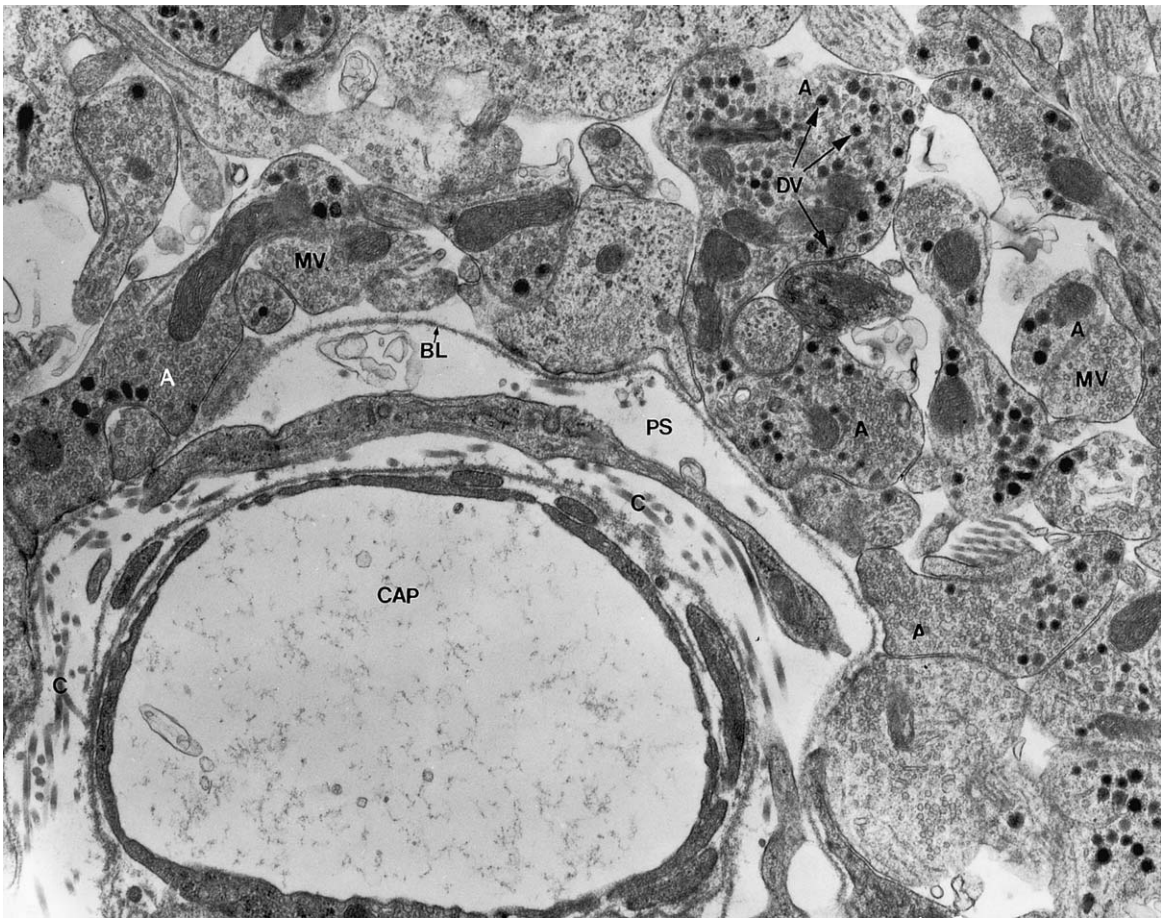

Figure 14 TEM of neurovascular zone at the base of a neural graft 20 days following neural transplantation into the third cerebral ventricle of a Brattleboro rat. Notable are numerous axon terminals (A) with dense core (DV) and microvesicles (MV) that terminate near or on the abluminal basal lamina (BL) of a large perivascular space (PS). This space is filled with collagen fibrils (C) and fenestrated capillaries (CAP) and constitutes a bonafide neurovascular zone for neurosecretion and the delivery of AVP to the host circulation of the adult Brattleboro rat. $\times$ 24,000.

when pineal glands from neonates were transplanted into pinealectomized adults, these grafts became well vascularized by fenestrated capillaries surrounded by large perivascular spaces. Two secretory processes were observed to occur in these grafted pineal transplants. The first type was neurosecretory-like, involving the formation of dense core vesicles in axon terminals. The second was ependymal in origin, involving vacuoles formed by specialized ependymal cells. Neonatal pinealocytes survived transplantation and exhibited the ultrastructural correlates of active neurosecretary processes. The synthesis and release of melatonin was reestablished in pinealectomized adults following transplantation of neonatal pineal glands into the third cerebral ventricle.

During the past 25 years, in all the transplantation paradigms involving the cerebral ventricular system little attention was ever paid to the incidence of mechanical trauma and perturbation that occurred to the cerebral ventricular wall when various fragments of normal brain tissue were stereotaxically placed into the third or fourth lateral cerebral ventricles of diseased brains. Little was mentioned about structural changes or alterations of ependymal surfaces of the cerebral ventricle in which the transplants were stereotaxically placed. In the early 1980s, a number of studies demonstrated that by 20 days following the steriotaxic transplantation of fetal hypothalamic fragments, large numbers of axon fibers and neuron-like cells were observed to emerge on the surface of the third cerebral ventricle following transplantation (Figs. 15–18). Cerebrospinal fluid contacting neurons had been previously described in a variety of vertebrate species. However, the numbers reported were far less

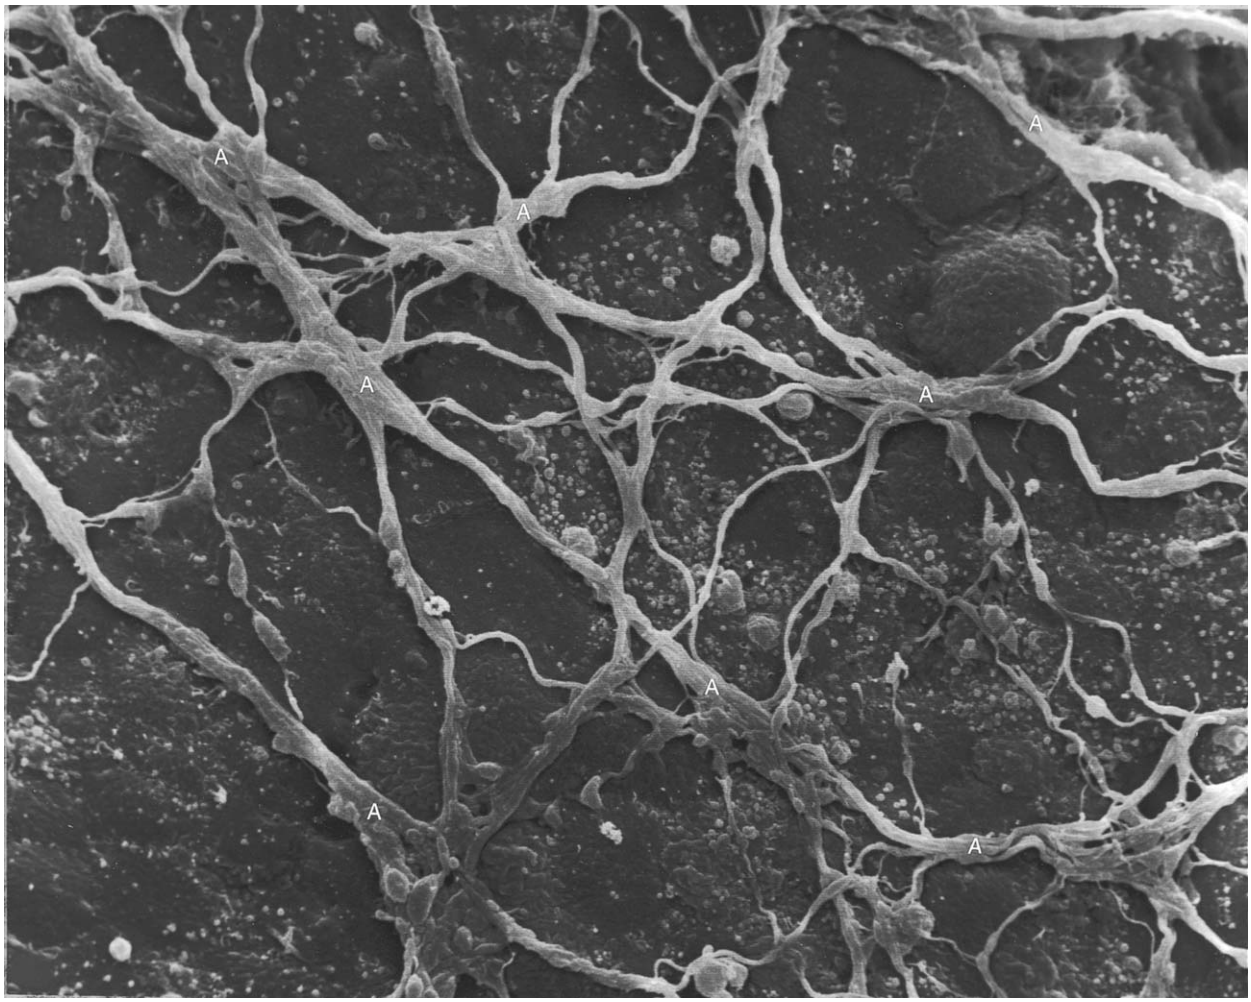

Figure 15 SEM of the third ventricular floor (median eminence) of a rat 20 days posthypophysectomy (axotomy). Numerous axon fibers (A) carpet the floor of this circumventricular organ in response to the upregulation of NOS due to trauma to the neural stalk from axotomy. Unlike the axon fiber in Fig. 11, these axon fibers are immunoreactive for antisera against AVP and are regarded as supraoptic or paraventricular in origin. × 10,500.

than those observed following transplantation or operative manipulation. Investigation of neonatal rats also described limited numbers of CSF contacting neurons that emerged by Day 3 postpartum, only to disappear by Day 7. This phenomenon was regarded as a part of the critical period of sexual differentiation in the rat, and their disappearance by Day 7 postpartum was due to a process of dying back or apoptosis. Large sample sizes were available through the use of scanning electron microscopy coupled with transmission electron microscopy on the same tissue sample, which made it easy to identify the phenotype of this supraependymal neuron. It was hypothesized that upon stereotaxic transplantation, there might have occurred mechanical perturbation and injury to the cerebral ventricular walls and floor. Such a mechanical insult or stimulation was thought to have led to the release of tissue injury factors, neuronotrophic factors, or other powerful cytokines that stimulated the migration and emergence of axonal and neuronal elements to the ventricular surface. However, other factors had to be considered. For example, it was demonstrated that in acute stress models, neuron-like cells emerged upon the surface of the third cerebral ventricles, which are ordinarily devoid of surface cells, with the exception of scattered macrophages. These neurons appeared in large numbers and were never observed prior to the stress stimulus. It was also

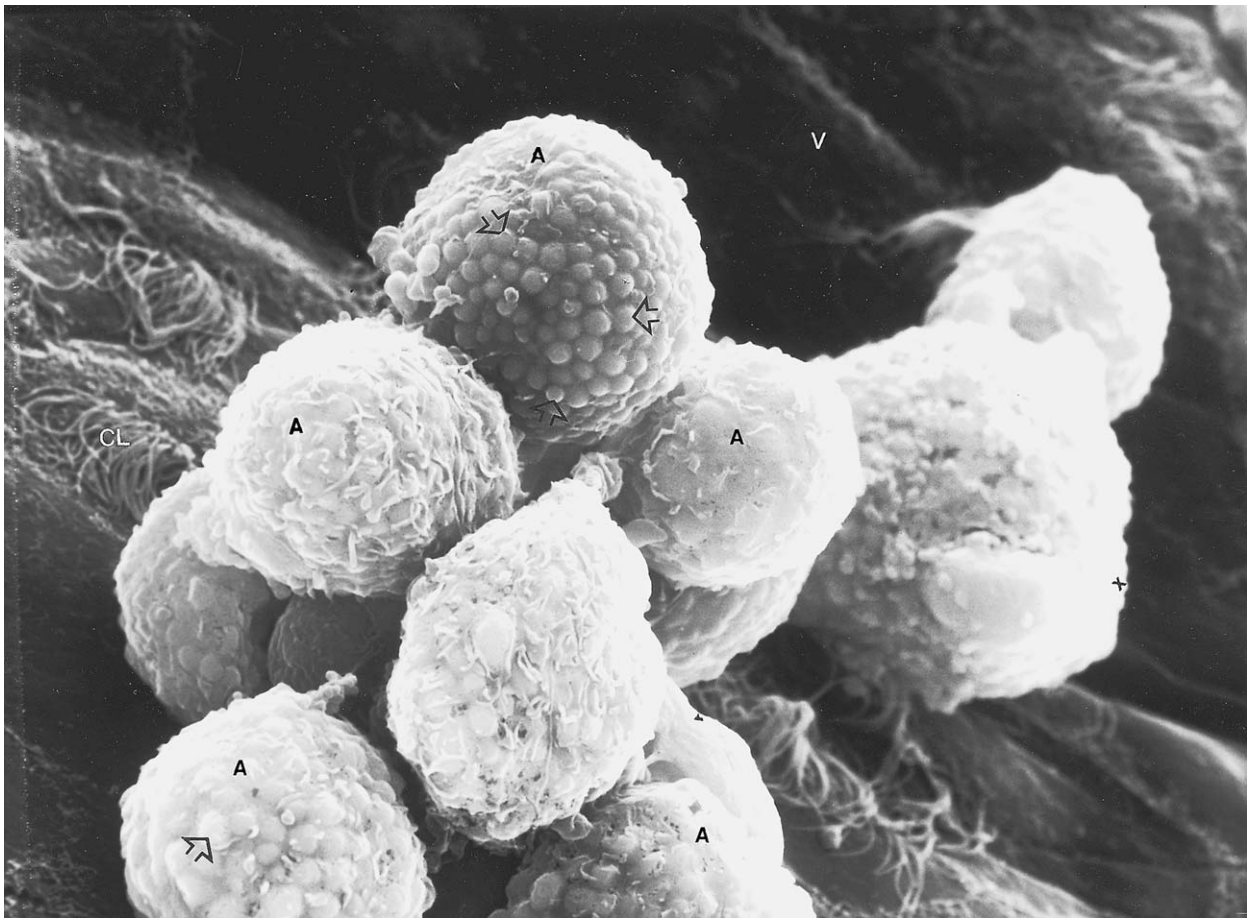

Figure 16 SEM of the cerebral ventricular floor of a rat that received the intraventricular grafting of a normal fetal hypothalamic fragment containing functional supraoptic neurons. Individual axon fibers (A) appear to contain uniform vesicular components (arrows) beneath the plasmalemma, which has shrunk from technical processing. These vesicles measure from 130 to 180 nm in diameter and fall into the size range for neurohypophyseal peptide hormones. CL, cilia; V, cerebral ventricular lumen. × 13,500.

demonstrated that following ovariectomy or the infusion of dopamine into the third cerebral ventricle, these two procedures stimulated the emergence of supraependymal neurons in large numbers coupled with numerous axonal arrays. By the mid 1990s, new techniques were being employed to assess the role of trauma and its effect on the walls of the cerebral ventricular system.

B. Trauma-Induced Changes in Ventricular Ultrastructure

In By mid-1990s, a number of investigations reconfirmed the hypothesis that the neurohypophyseal system (ME, NS, and NL) was capable of regeneration following high stalk section due to parapharyngeal hypophysectomy. Investigations employing *in situ* hybridization demonstrated that there was a significant upregulation of nitric oxide synthase (NOS) in SON and PVN following high stalk section (axotomy). NOS is the enzyme that catalyzes arginine to the ubiquitous gas nitric oxide (NO). Ordinarily, regeneration of the neurohypophyseal system took approximately 4 weeks in otherwise normal rats. The regeneration process involved the proliferation of pituiticytes, modified glial cells that acted as a structural template for the regrowth of SON and PVN axons, much as Schwan cells do for regenerating axons in the peripheral nervous system. However, the entire process of neurohypophyseal regeneration was completely inhibited by the infusion of the NO antagonist nitroarginine. This became a pivotal finding in light of the fact that during upregulation of NO,

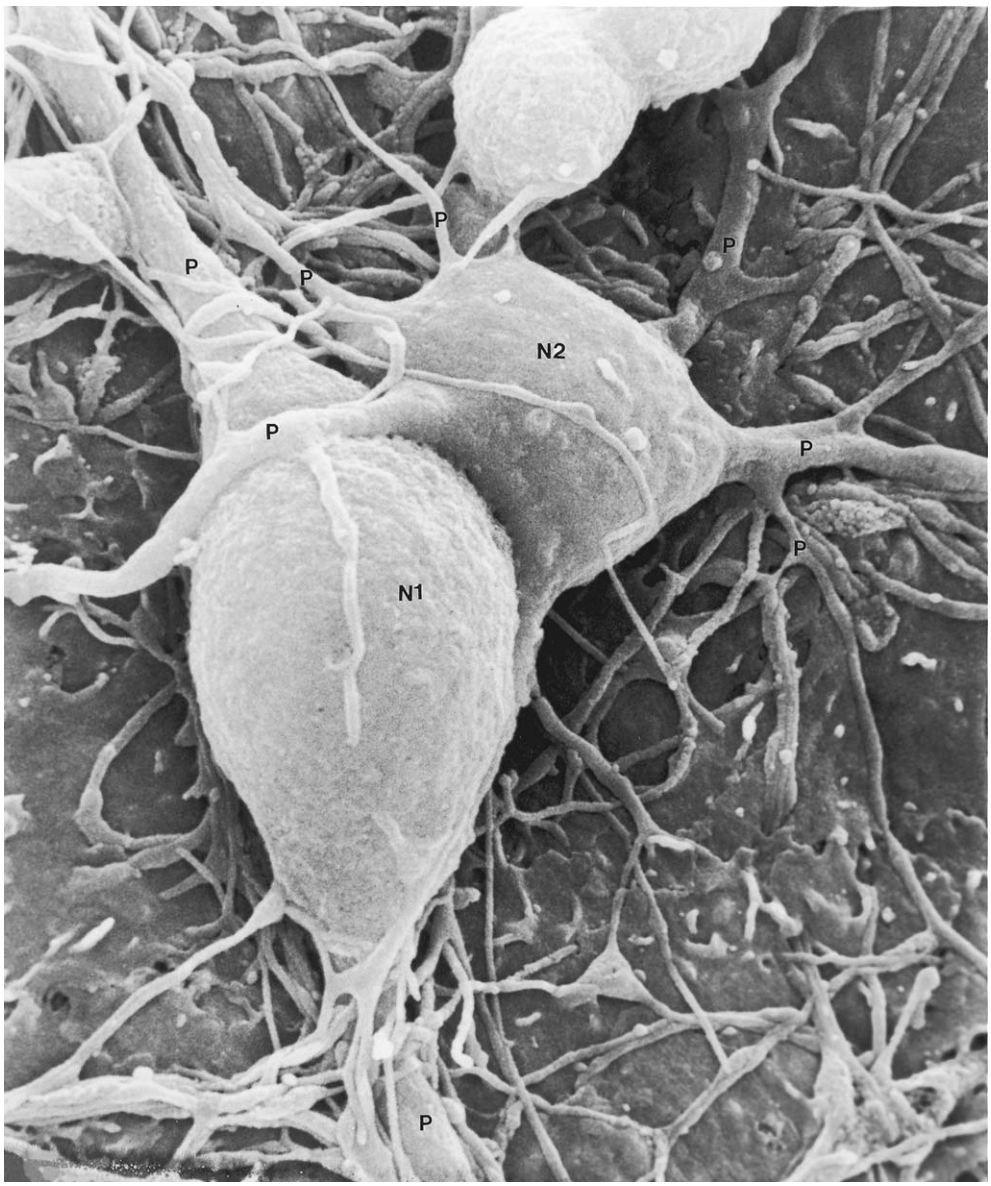

Figure 17 High-magnification SEM of two supraependymal neurons (N) that have just migrated to the cerebral ventricular surface of the median eminence. Both are relatively featureless, but both are distinctly different from one another. Cell type 1 is a bipolar neuron with two main processes (P) arising from its cell body. Cell type 2 is a multipolar neuron with numerous neuritic processes. Neither cell has undergone synaptogenesis. × 21,000. [From Scott, D. E. *Front. Horm. Res.* **9,** 15–35. By permission of S. Karger AG, Basel].

following the trauma of hypophysectomy, there was a remarkable degree of migration and appearance of supraependymal neurites (Fig. 15) and neurons on the ventricular surface of the adjacent median eminence (Fig. 19). Hundreds of axons and nerve cell bodies emerged within 5 days after hypophysectomy (Figs. 20 and 21). This appeared to be driven by the upregulation of NO. Furthermore, as in the case of neurohypophyseal regeneration, when the antagonist of NO (nitroarginine) was employed in the same animal model, these migratory neuroblasts and axonal arrays were inhibited from emerging onto the floor of the third cerebral ventricle (dorsum of the median eminence), which retained its relatively barren appearance and mimicked the picture observed in control rats. The current hypothesis being tested by a number of laboratories throughout the world is that these neuroblasts may arise from pluripotential neuronal stem

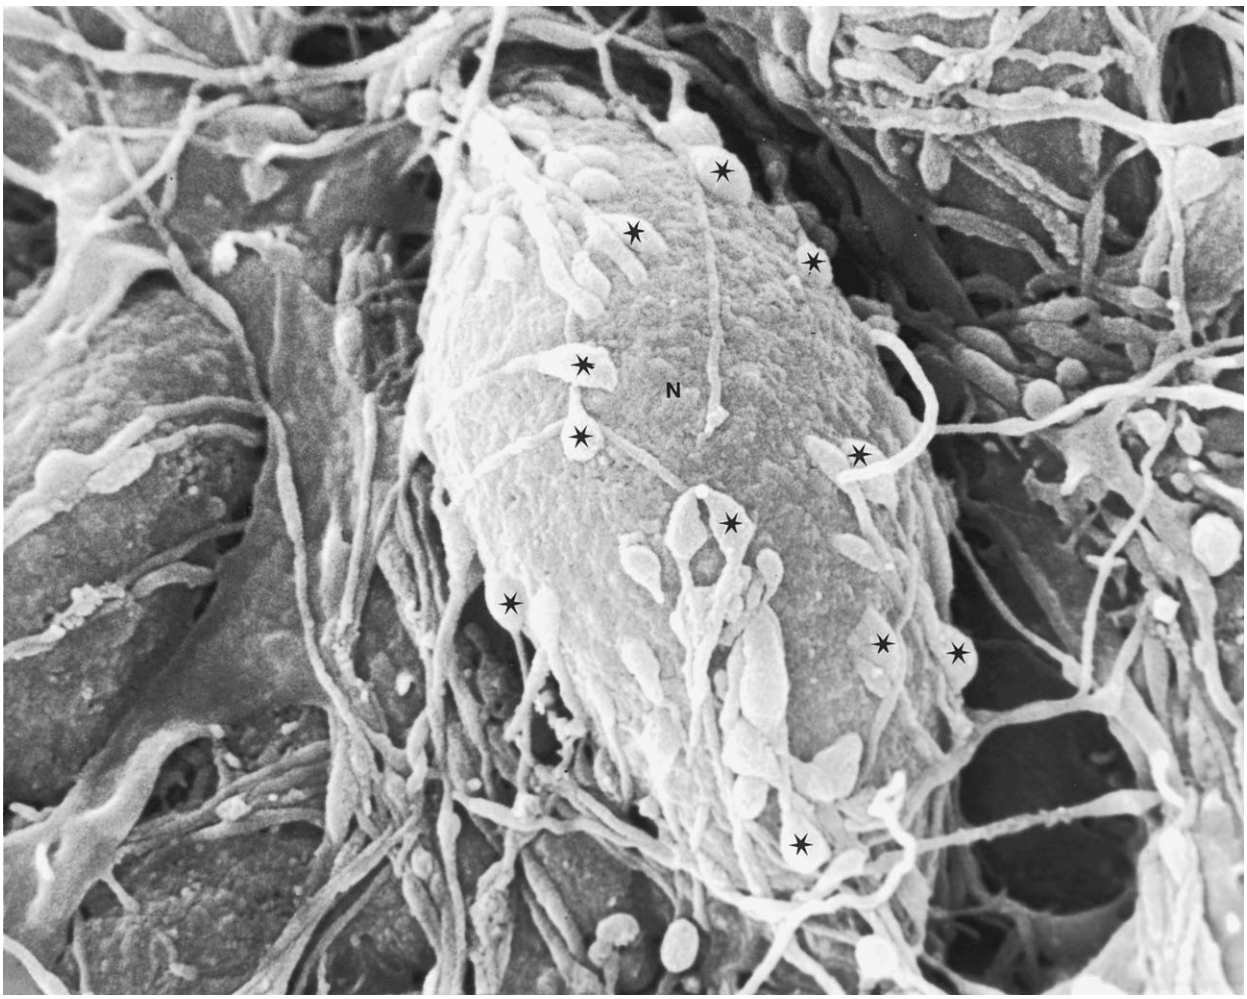

Figure 18 High magnification SEM of a supraependymal neuron (N) that has migrated and has been on the surface of the median eminence for 20 days posttransplantation. This neuron has not migrated any further. Instead, it has undergone synaptogenesis characterized by numerous axosomatic synapses (stars) on its cell body. If this population of migratory neuroblasts fail to migrate any further after the injury of axotomy, then invariably they will remain on the surface of the ventricle and undergo compensatory synaptogenesis. × 20,000. cells, which are found in germinal matrix regions throughout the adult mammalian brain.

C. Neuronal Stem Cell Migration in the Cerebral Ventricular System

The lineage and formation of neural stem cells and their relationship with the cerebral ventricular system can be traced to scientific observations in the early 1980s. However, at that time, NO, the ubiquitous central nervous system molecule, was not recognized as a mechanism that controlled migration of neuroblasts (or daughter cells) from these neural stem cells. Clearly, NO was inculcated in a diverse number of other physiological events. In the case of spinal cord injury, the presence of NO was viewed as a harbinger of apoptosis of alpha motor neurons and widespread neuronal death. Studies performed in the early 1990s revealed that it served as a powerful endothelial-relaxing factor. However, its role and upregulation in post-traumatic alterations in the third cerebral ventricle of the endocrine hypothalamus became well established as a beneficial mechanism surrounding regeneration of the neurohypophyseal system and recovery of function.

In the early 1960s, a body of evidence began to accumulate that neurogenesis persisted through

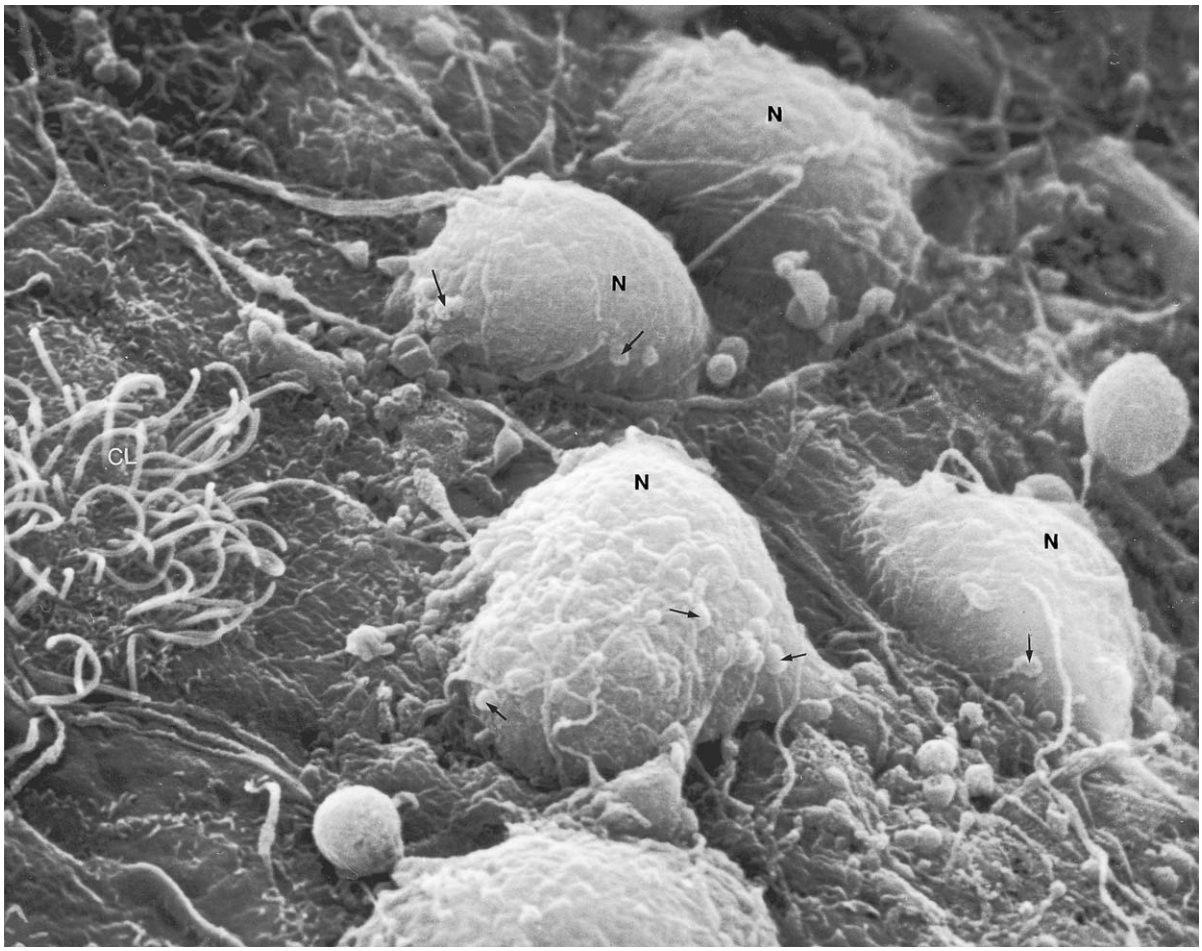

Figure 19 SEM of four supraependymal neurons (N) on the surface of the ventricle 8 days following hypophysectomy. Early signs of synaptogenesis have become apparent, with small axosomatic bouton-termineaux (arrows) beginning to appear on their cell bodies. × 6500.

adulthood in the central nervous system. Recent evidence has demonstrated that neural stem cells in the subventricular zone of the lateral ventricle of both rats and mice give rise to daughter cells (neuroblasts). In the rat model, these stem cells are stimulated to emerge by the intraventricular infusion of brain-derived nerve growth factor. In the murine model, these stem cells give rise to neuroblasts that reportedly stream rostrally beneath the ventricular ependymal cells of the lateral ventricle and ultimately replace cells that have been lost to natural turnover processes in the olfactory region. The emergence of migratory nerve cell bodies to the surface of the ventricle has recently been described following the placement of lesions in the underlying median eminence (the floor of the third cerebral ventricle). These elegant studies served to confirm early observations following neural transplantation as well as those following the high stalk neural sections done in the early to mid-1990s. Migrating neuroblasts that emerge from putative stem cells following lesions placed in the median eminence express neural cell adhesion molecules such as PSA-NCAM and B-50/GAP43, which are regarded as mechanisms that serve to expedite their migratory dynamics through the neuropil of the endocrine hypothalamus to the surface of the third cerebral ventricle above. Recent evidence strongly supports the presence of stem cells in the subventricular zone of the lateral cerebral ventricle in the adult primate brain. These newer data simply confirm earlier investigations in the murine model that daughter cells derived from stem cells migrate to the olfactory system and replace nonfunctional cells. Finally, it has recently been shown that when human neural stem cells are introduced into

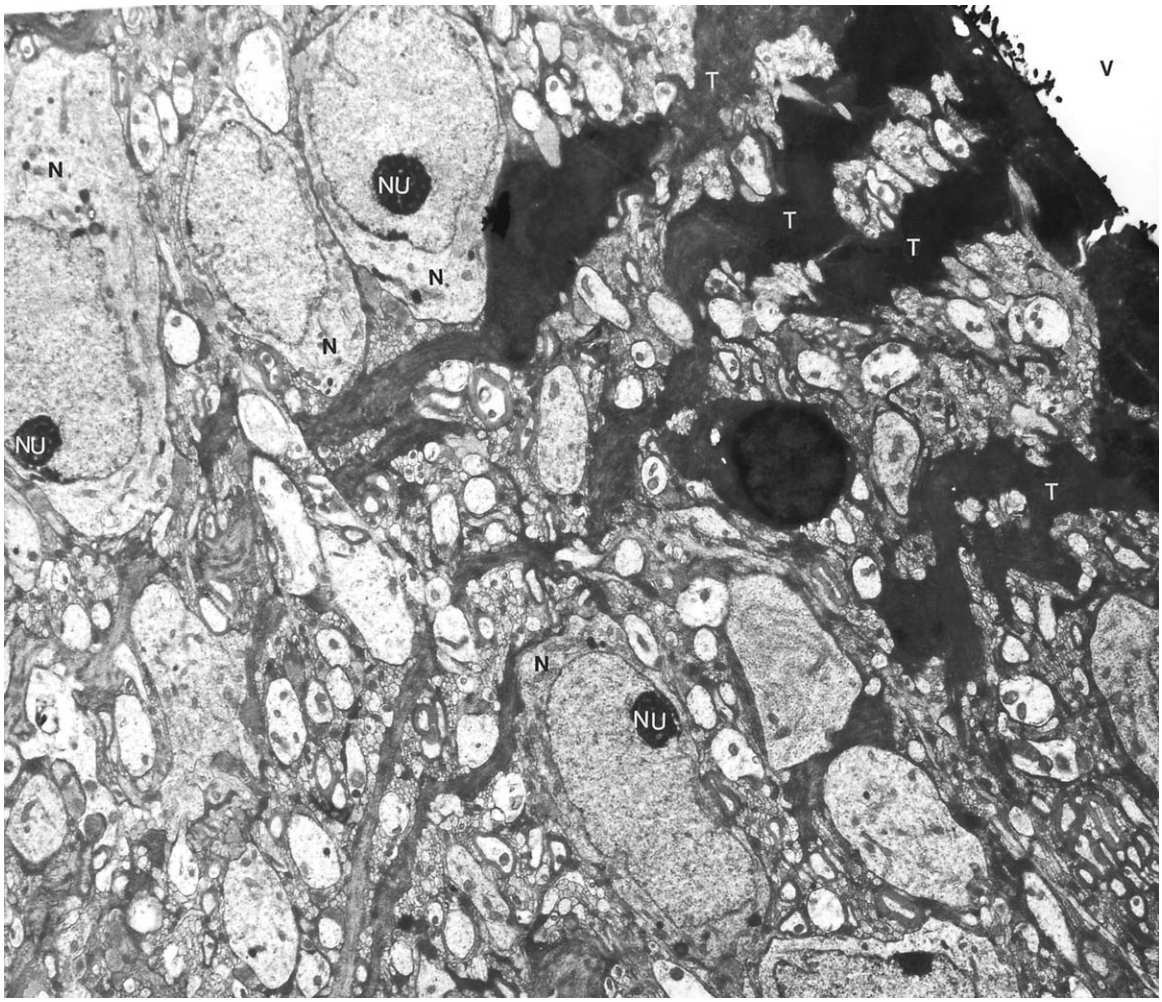

Figure 20 TEM of previously scanned median eminence 5 days following hypophysectomy (axotomy). Notable are numerous neuroblasts (N), with distinct nucleoli (NU), relatively clear nucleoplasm, and rudimentary organelles and inclusions. This sort of ultrastructural picture supports the concept of neuroblast migration from germinal zones in this circumventricular organ toward the ventricular surface above (V). T, tanycyte cytoplasm turned dark due to technical elution from previous scanning electron microscopy. × 6000.

the cerebral ventricular system of the neonatal Shiverer mouse, these cells distribute globally and use the cerebral ventricular system as a low-resistance pathway for migration to many different regions of the mouse brain. It is of interest that these human stem cells, regarded at first to be "neuronal," differentiated into oligodendroglial cells in these transgenically dysmyelinated mice. Sixty percent of the mice that received intraventricular infusion of human neuronal stem cells remained normal and exhibited none of the neurological deficits associated with the Shiverer syndrome. If indeed these were neuronal stem cells to begin with and not an earlier, more primordial undifferentiated type of human stem cell, then the concept of molecular recognition due to the lack of oligodendroglia and its product basic myelin protein must be considered.

VI. THE CEREBRAL VENTRICULAR SYSTEM AS A NEUROENDOCRINE TRANSDUCER

Since the early 1960s, the mammalian cerebral ventricular system has been regarded as a neuroendocrine transducer and its fluid contents, the CSF, a trophic mediator and delivery system for a vast array of hormones to target sites around the brain. Lines of evidence supporting such a supposition include (i) mechanisms of entry of bioactive molecules into the CSF, (ii) the transmission of such throughout the CSF,

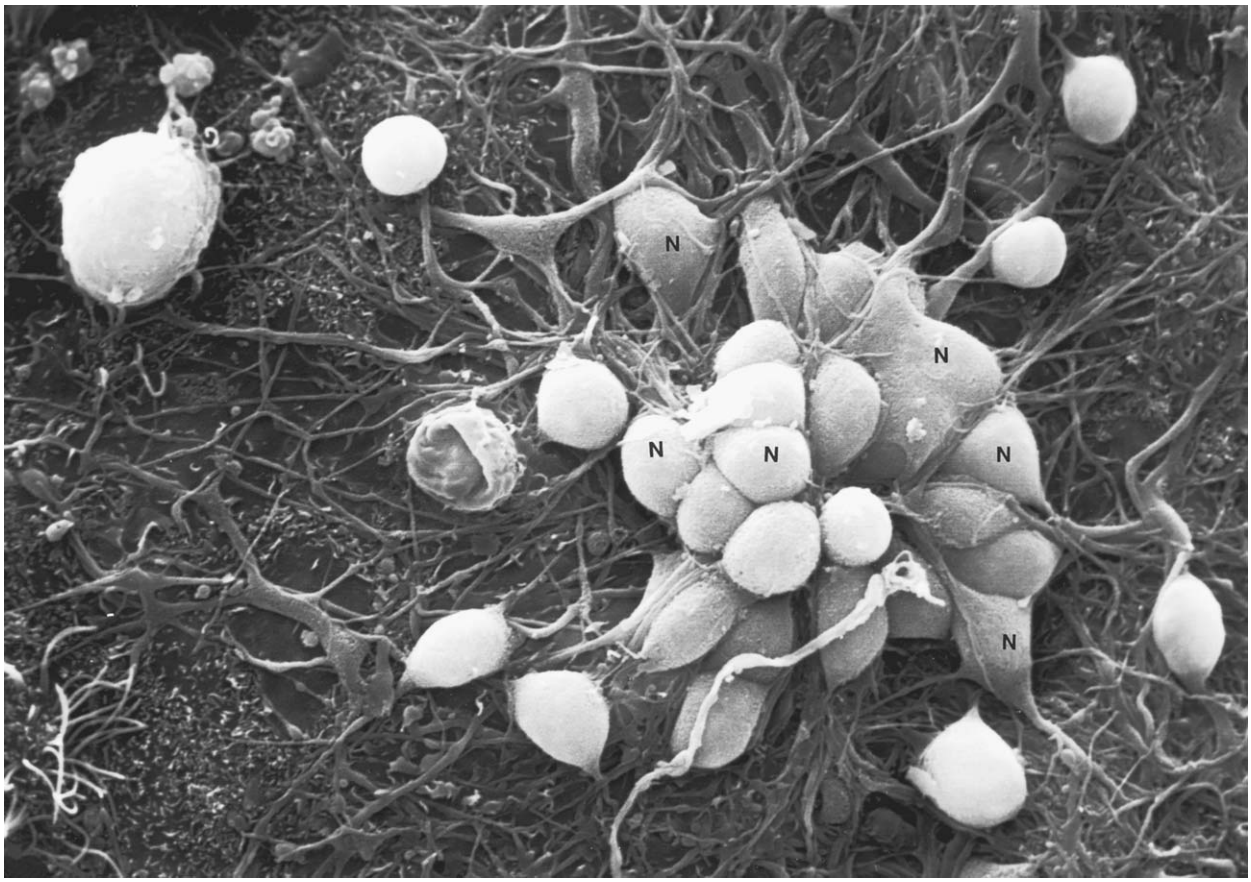

Figure 21 SEM of the surface of the median eminence 7 days posthypophysectomy. Notable is a cluster of what are regarded as juvenile neuroblasts (N) newly emergent into the third ventricular lumen. These juvenile cells are smooth but possess distinct neuritic processes. × 4000. [From Scott, D. E. (1999). Post-traumatic and emergence of a novel cell line upon the ependymal surface of the third cerebral ventricle in the adult mammalian brain. *Anat. Record* **256,** 233–241. Copyright 1999 Wiley-Liss Inc., a Subsidiary of John Wiley & Sons, Inc.]

and (iii) mechanisms of exit or delivery to specific target areas responsive to biologically active molecules. There is ample evidence that there is a wide range of biologically active factors that can be found in the CSF of normal mammals using a variety of techniques, including radioimmunoassay and other molecular techniques. The appearance of these bioactive substances may in large part be due to direct secretion by supraependymal nerve terminals from brain stem neurons of the brain stem raphe nuclei, which are known to secrete serotonin into the CSF. Others may be derived from the choroid plexus, which actively secretes AVP, angiotension, T3, and T4 as well as IGF2. However, perhaps the most important contributors to the CSF are all the CVOs that secrete a variety of neuropeptide hormones, catecholeamines, and indoleamines into the CSF. CVOs as well as the choroid plexus are also the target organs for their various bioactive molecules, which they secrete; hence, they may function in a paracrine fashion to alter the internal biochemical milieu of the brain and the CSF that bathes it. Hence, the cerebral ventricular system is not only the neuroanatomical core of the brain but also it becomes the physiological basis for the control of the internal neuroendocrine milieu of the mammalian central nervous system.

Vigilance

MARTIN SARTER and JOHN P. BRUNO
Ohio State University

GLOSSARY

acetylcholine A neurotransmitter in the peripheral and central nervous system. Acetylcholine is released in all cortical areas and layers by neurons originating in the basal forebrain. This neuronal projection represents a crucial component of the circuitry mediating sustained attention or vigilance.

anterior attention system A term proposed by Posner and Petersen and now used to conceptualize the results from mostly blood flow studies indicating that right medial–frontal and prefrontal areas are consistently activated in subjects performing vigilance tasks. The anterior attention system is also thought to act downstream via the posterior (parietal) attention system to facilitate sensory processing, particularly visual information processing.

arousal Desynchronization of forebrain activity or, functionally, a general increase in the state of mental and physical activity has usually been associated with the term arousal. Although arousal has never been well defined as a psychological construct, it is used here, and thereby dissociated from attentional processes, to describe the general activational effects of novel, stressful, or emotionally strong stimuli on forebrain information processing. Recent imaging studies in humans support the role of ascending noradrenergic projections in mediating arousal and suggest that the noradrenergic activation of the thalamus represents a critical link mediating the interactions between attentional processes and states of arousal.

basal forebrain A region in the forebrain that refers to cholinergic neurons originating in the nucleus basalis of Meynert and the substantia innominata and that project to the cortex.

noradrenaline A neurotransmitter in the peripheral and central nervous system. Noradrenergic neurons originating in the locus coeruleus and terminating in widespread telencephalic and diencephalic regions are conceptualized to mediate arousal.

positron emission tomography A functional imaging method that generates images of the distribution of a radionucleotide (such as $H_2\ ^{15}O$ or [^{18}F]-2-fluoro-2-deoxy-D-glucose) to detect changes in blood oxygenation or regional cerebral metabolic rates. Positron emission tomography is also used to monitor the distribution of more selective radiotracers for receptors and other markers of neurotransmission.

posterior attention system A component of the attentional network as conceptualized by Posner and Petersen consisting mainly of the posterior parietal lobe and thalamic and collicular circuits and mediating the spatial orientation of attention.

vigilance A component of attention, also termed sustained attention, that describes the subject's readiness to detect rarely and unpredictably occurring signals over prolonged periods of time.

The psychological construct vigilance, or sustained attention, describes a fundamental component of attention characterized by the subject's readiness to detect rarely and unpredictably occurring signals. Human imaging studies revealed frontal and parietal cortical activation associated with vigilance performance. Converging animal research has focused on cortical afferent systems, particularly on the cholinergic inputs originating in the basal forebrain, as a crucial component of the neuronal network mediating vigilance performance. Collectively, the findings from human and animal studies provide the basis for the description of the main components of the neuronal circuits mediating sustained attention.

I. INTRODUCTION

Beginning with Mackworth's experiments in the 1950s, the assessment of vigilance has typically utilized

situations in which an observer is required to keep watch for inconspicuous signals over prolonged periods of time. The state of readiness to respond to rarely and unpredictably occurring signals is characterized by an overall ability to detect signals (termed vigilance level) and, importantly, a decrement in performance over time (termed vigilance decrement). The psychological construct of "vigilance" (or "sustained attention") has been greatly developed in recent decades and provides the basis for recent studies on brain mechanisms mediating vigilance performance in humans and laboratory animals.

Vigilance represents a fundamental attentional function that determines the efficacy of the "higher" aspects of attention (selective attention and divided attention) and of the overall cognitive capacity in general. Although impairments in the ability to detect and select relevant stimuli or associations are intuitively understood to tremendously affect modern living skills (e.g., driving a car), cognitive abilities (e.g., acquiring novel operating contingencies of automatic teller machines or detecting social cues important to communicate effectively), and possibly even consciousness, psychological research on vigilance has largely focused on parametric, construct-specific issues and only rarely addressed the essential significance of vigilance for learning and memory. In fact, the evidence in support of the fundamental importance of sustained attention for general cognitive abilities has largely been derived from studies in neuropsychiatric populations. Thus, determining the brain networks mediating vigilance or sustained attention represents a crucial step in the development of cognitive neuroscience-inspired theories of neuropsychiatric disorders.

II. VIGILANCE: COMPONENTS OF A PSYCHOLOGICAL CONSTRUCT

A. Vigilance versus Arousal

Because the terms vigilance and arousal have been used interchangeably, particularly in clinical contexts and in interpreting electroencephalographic data, the specific attentional meaning of vigilance needs to be stressed and dissociated from the more global classification of brain states that includes arousal. Obviously, the ability to perform in monitoring tasks requires an activated forebrain and thus depends on arousal. Likewise, the "arousing" consequences of novel, emotional, or stress-like stimuli interact with vigilance performance. However, the operational definition of vigilance and the measures generated to describe vigilance performance are specific and unrelated to the concept of arousal. Although changes in vigilance typically are deduced from electroencephalograph (EEG) data, an interpretation of data in terms of vigilance or sustained attention is necessarily based on performance data, and the validity of hypotheses about the neuronal mediation of vigilance depends on the validity of the behavioral measures of vigilance employed to study the mediating brain mechanisms.

B. Variables Affecting Vigilance

1. Variables Taxing Vigilance Performance

Similar to other attentional capacities, the capacity to sustain attention has been considered to represent a limited resource. Several variables have been demonstrated and conceptualized as taxing vigilance performance. First, the successive (as opposed to the simultaneous) presentation of signal and nonsignal features taxes vigilance performance. Second, high (as opposed to low) event rate (i.e., the frequency of signal events) combined with unpredictability of the time of the presentation of the event (event asynchrony) and of the event type (e.g., signal vs nonsignal) enhance the demands on vigilance performance. High event rates also represent a critical variable in the manifestation of a vigilance decrement. Third, spatial uncertainty (as opposed to certainty) about the locus of event presentation also promotes the manifestation of vigilance decrements. Fourth, the use of dynamic (as opposed to static) stimuli, such as signals with variable luminance or presentation time, also fosters the manifestation of a vigilance decrement, partly because presentation of dynamic stimuli is associated with decreased discriminability. Fifth, demands on working memory (as, for example, occur in tasks with successive event presentation) tax vigilance performance. Finally, using signals with conditioned or symbolic significance, thus requiring additional processing to report detection (as opposed to pure detection of signals), is thought to foster the exhaustion of the vigilance capacity. Such signals are considered to increase the demands for the controlled processing of signals and thus to increase the allocation of resources consumed by the vigilance task.

2. Practice

In experiments using human subjects, practice of vigilance tasks typically is kept at a minimum in order to limit the degree to which the task performance is mediated by highly automated attentional processing. Prevention of the disappearance of the vigilance decrement is a related reason for allowing only minimal practice in many studies. However, practice also serves to produce stable measures of performance and, in interaction with the variables listed previously, does not necessarily attenuate the vigilance decrement. Different levels of practice may account for a substantial proportion of conflicting data in the literature, and although the issue is widely recognized, the effects of practice on vigilance performance remain insufficiently investigated. Extensive practice and the resulting high level of automatism may not decrease the demands on processing resources to the extent assumed in earlier theories. Recent conceptualizations of sustained attention as a process in which an attentional supervisory system maintains target schemata that correspond with the actual detection requirements predict that the functions of this system consume processing resources even in well-practiced vigilance tasks.

3. Reaction Time versus Number of Detected Signals and False Alarms

In highly practiced vigilance tasks in which subjects exhibit high levels of detections of signals and low levels of false alarms, reaction time may become the critical measure of performance and performance change. Increased reaction times usually correlate with decreased detection rates, supporting the hypothesis that the former measure also indicates vigilance decrements. In humans, reaction times may increase more than several hundred milliseconds during monitoring tasks that last more than 1 hr. In animals, reaction times have been analyzed and interpreted with great caution, especially following manipulation of neuronal functions, because they are potentially confounded by a multitude of sensory and motor variables and competing behavioral activities.

4. Changes in Sensitivity versus Shift in Criterion

Data generated by traditional vigilance tasks have been routinely analyzed using signal detection theory, to the extent that vigilance and signal detection theory have been considered interchangeable terms and ignoring the fact that the latter in essence represents a statistical method. However, an analysis of vigilance performance data using signal detection theory may provide the quantitative basis for an interpretation of the changes in vigilance performance. Specifically, the number of signals detected is a combined result of signal detectability (or sensitivity) and the subject's criterion or "willingness" to report detection of a signal. The former depends largely on the psychophysical characteristics of the signals relative to nonsignals, whereas the latter is a more complex function of the subject's general strategy, task instructions (e.g., performing in accordance with a conservative versus a risky criterion), and task parameters such as cost/benefit considerations for reporting signals and false alarms, respectively. For example, a decline in the number of hits (i.e., the correct detection of signals) over a prolonged period of time may be due to an increasingly conservative criterion. Experimentally induced increases in the probability for a signal typically result in a decrease in the criterion that is reflected by increases in hits and false alarms. Conversely, changes in the performance in high event rate, successive discrimination paradigms may be due to a decline in sensitivity. Signal detection theory-derived analyses potentially assist in dissociating the contribution of shifts in sensitivity and criterion to changes in vigilance performance.

III. MACROANATOMICAL CORRELATES OF VIGILANCE PERFORMANCE

A. General Heuristic Issues

Macroanatomical correlates of vigilance performance have been determined mainly by two lines of research. First, findings from neuropsychological studies have identified areas of brain damage or degeneration that are correlated with impairments in vigilance performance. Second, recently, functional imaging studies have located areas in the intact brain in which changes in metabolic activity correlate with vigilance performance. The interpretation of these findings in terms of neuronal systems mediating vigilance performance is limited by several issues. Complexities in the interpretation of brain damage in terms of determining the normal functions of the brain region of interest, although a persistent topic in the literature, deserve continued and careful scrutiny. Typically, the

functional consequences of the absence of a brain region routinely have been interpreted as indicating this area's functions in the intact brain, ignoring the more appropriate view that residual functioning reflects the processing maintained by the residual brain. This interpretational concern arises in part from, and is further convoluted by, the often implicit conception of a particular brain region as a functionally distinct unit rather than representing a functionally critical "knot" or intersection of multiple neuronal networks. For example, the prominent (and almost compulsory) involvement of prefrontal cortical areas in diverse cognitive functions may be due to their central position within cortical associational, limbic, and paralimbic neuronal networks rather than, or at least in addition to, the cognitive operations mediated via intraprefrontal neuronal circuits.

Although the assumption that attentional (or other cognitive) functions can be localized is considered to be valid, attempts to map complex functions to brain structures assume, often implicitly, that the psychological function of interest (e.g., vigilance) represents a relevant functional unit that maps on, or is isomorphic with, a traditionally defined neuroanatomical region or a neuronal system of interest. Usually, however, such an assumption is without basis (for illustration, consider the historical ideas versus the actual conceptualization of the analyses of visual information by the primary visual cortex). Neuropsychological evidence or data from imaging studies that suggest that vigilance maps onto macroanatomical correlates (such as the prefrontal or parietal cortex) will have to converge with experimental evidence to allow "strong inference" in concluding that vigilance is mediated via these structures. The evidence discussed later focuses on such converging avenues of research and presents the view that such converging evidence forms the basis for a theory that attributes vigilance performance to defined neuronal projection systems and their afferent circuits rather than to the activity within macroanatomically defined regions of the cortex.

B. Vigilance Following Brain Damage and Degeneration

Damage to the frontal cortex (anterior to the central sulcus and dorsal to the Sylvian fissure), in particular, as well as lesions in the (inferior) parietal lobe result in decreases in the number of hits, increases in reaction time, and in the manifestation or augmentation of a decrement in performance over time. The detrimental effects of distractors on sustained attention performance appear to be particularly prominent in patients with right frontal lobe damage, whereas the performance of patients with parietal lesions is generally more sensitive to the effects of high event rates. Experiments in split-brain patients support the hypothesis that vigilance processes are primarily mediated via right hemispheric mechanisms. The specificity of interpretations of the effects of right frontoparietal damage in terms of vigilance impairments has been supported by studies that excluded the possibility that increased fatigue, differential effects of practice, or differences in motivational processes significantly confound impairments in vigilance performance in these patients.

Aged humans and, more dramatically, patients with age-related dementias exhibit lower detection rates in continuous performance tasks and other standard neuropsychological tests that assess an insufficiently defined blend of arousal and vigilance functions. Because the majority of the available studies conducted in patients with Alzheimer's disease did not selectively assess sustained attention, the reliability of demonstrating a vigilance decrement in these patients has remained unsettled. Most likely, the demonstration of such effects depends on the degree to which tasks demand the sustained and effortful monitoring and processing of stimuli, thereby presumably taxing frontoparietal functions. Likewise, the extent to which impairments in sustained attention can be demonstrated, similar to impairments in selective and divided attention, in early stages in Alzheimer's disease is unclear. In general, the determination of such early attentional impairments may provide a neuropsychological measure that assists in the determination of initial pathological processes that set off the accelerating and escalating cognitive decline in these patients.

Assumptions concerning the neurobiological bases for the attentional impairments in Alzheimer's disease, including the decline in sustained attention, have generally followed the frontoparietal conceptualizations of attentional functions. It must be noted, however, that impairments in sustained attention in neurodegenerative disorders have been reflexively attributed primarily to frontal cortical degeneration, based on a circular logic that considers attentional performance to depend on the integrity of frontal cortical supervisory attentional systems and thus attributes impairments in attentional abilities in patients with neurodegenerative disorders to frontal dysfunction.

C. Macroanatomical Correlates Determined by Functional Neuroimaging Studies

The degree of agreement of evidence from lesion studies and functional imaging studies is remarkable. Anterior cingulate and dorsolateral prefrontal as well as parietal cortical regions, primarily but not exclusively in the right hemisphere, have been consistently found to be activated in subjects performing sustained attention tasks, irrespective of the modality of stimuli used in these tasks (Fig. 1). Furthermore, decline in activity in fronto-parietal-temporal regions in the course of task performance has been suggested to mediate vigilance decrements. The findings from functional neuroimaging studies have suggested that the neuronal circuits mediating the necessary arousal for proper sustained attention performance can be dissociated from those correlated with sustained attention, and that the former may be mediated via activation of the thalamus, presumably including thalamocortical projections.

In addition to the modality-independent activation of right frontoparietal regions during sustained attention, demands on monitoring and discriminating stimuli of a particular modality secondarily activate sensory cortical regions as well as sensory associational areas. These findings correspond with increases in responsiveness and selectivity of single cell firing activity observed in sensory associational areas, predominately in extrastriate regions of nonhuman primates, under conditions of increased demands on attention.

Collectively, the findings from functional imaging studies have supported a general model that describes sustained attention as a "top-down" process that begins with the subject's general readiness to detect and discriminate information, mediated largely via right frontoparietal regions, and that enhances the spatial and perceptual processes contributing to vigilance performance via activation of posterior parietal areas and facilitation of the processing of sensory inputs in primary and secondary sensory and sensory-associational regions. The available data generally support Posner and Petersen's conceptualization of a right hemispheric anterior attention system mediating modality-independent aspects of vigilance and recruiting the more posterior and temporal cortical areas to mediate relevant spatial processes and modality-specific components of vigilance performance.

IV. NEURONAL CIRCUITS MEDIATING VIGILANCE PERFORMANCE

A. "Bottom-Up" Research Approaches

The determination of neuronal circuits mediating vigilance or sustained attention is typically based on

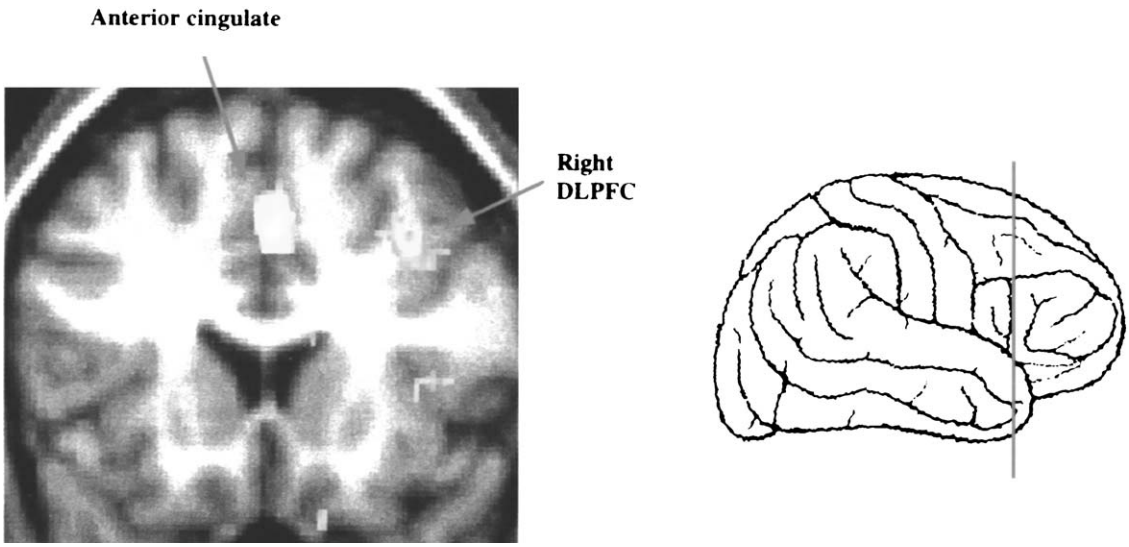

Figure 1 Regional cerebral blood flow in subjects performing a rapid visual information processing task. Right dorsolateral prefrontal cortex (DLPFC) and anterior cingulate were activated in subjects required to respond to target stimuli but not to distractors, compared to nonselective responding to all stimuli. The data from this study generally support the concept of a right frontoparietal network mediating sustained attention performance (reprinted from *Prog. Neurobiol.* **55,** J. T. Coull, Neural correlates of attention and arousal: Insights from electrophysiological, functional neuroimaging and psychopharmacology, 343–361. Copyright 1998, with permission from Elsevier Science).

(bottom-up) research approaches that manipulate the functioning of defined neuronal circuits and assess the consequences for attentional performance or record from neurons constituting such circuits in subjects that perform tasks designed to tax attentional abilities. As already mentioned, evidence from such approaches ideally converges with the evidence from human (top-down) neuropsychological and imaging studies to allow robust formulations about the neuronal mechanisms mediating sustained attentional abilities. In actual terms, experimental evidence from bottom-up research approaches is expected to explain the prominence attributed to frontal cortical and parietal regions in neuropsychological studies on sustained attention. Such reductional explanations are expected to specify the nature of the processing mediated via frontoparietal cortical areas in sustained attention, and they are intended to determine the specific neuronal circuits responsible for the activation of these areas observed in imaging studies or for the impairments in sustained attention as a result of damage or degenerative processes in these areas. Although the focus of the current discussion is the neuronal mechanisms mediating vigilance in the human brain, evidence from animal experimental approaches represents a necessary component of such an analysis.

B. Animal Behavioral Tests of Sustained Attention

Animal experimental approaches to the study of the neuronal mechanisms of attention have only recently become viable as tasks for the measurement of different aspects of attention have become available. These tasks were designed and demonstrated to be valid in accordance with the criteria constituting the psychological construct. Two tasks for use in rats have been extensively used for the study of sustained attention. First, Robbins, Everitt, and coworkers employed the "five-choice serial reaction time task" that requires animals to monitor the location of a briefly presented light in one of five spatially arranged target areas. This task combines aspects of the continuous performance tasks used in human studies and primarily tests sustained spatial attention. Second, an operant task requiring rats to detect signals and to discriminate between signals and nonsignals was designed to generate a complete set of response categories (hits, misses, false alarms, and correct rejections). Importantly, a false alarm in this task represents a discrete "claim" for a signal in a nonsignal trial, therefore overcoming the limitations of the response rate-confounded calculation of false alarm rates in more traditional signal detection tasks used in animal research. Among the parametric manipulations shown to vary task performance as predicted by the construct "sustained attention," the effects of distractors and variations in event rate or the probability for signals supported the validity of the measures of performance generated by this task in terms of indicating sustained attention. Similar to tasks used in human research, significant vigilance decrements in intact animals were not always reliably observed but usually emerged in interaction with detrimental neuronal manipulations.

C. Ascending Noradrenergic Projections: The Arousal Link?

Although noradrenergic projections originating from the locus coeruleus (LC) have been traditionally considered to mediate increases in arousal and aspects of attentional processing, their specific roles in sustained attention and arousal have remained less well defined. Psychopharmacological studies in humans and animals traditionally did not dissociate between the effects of systemic manipulations of noradrenergic neurotransmission, particularly the effects of the administration of the α_2 receptor agonist clonidine, on arousal and attention. However, findings from recent studies support the hypothesis that rather than mediating specific attentional functions, ascending noradrenergic projections regulate the more general activation or arousal of the forebrain that is required for proper sustained attention performance. Anatomically, this noradrenergically mediated foundation for attentional performance may be attributed primarily to thalamic mechanisms. Furthermore, Coull and coworkers demonstrated that the administration of clonidine in humans performing a rapid visual information processing task resulted in the reduction of thalamic activity at baseline but not during performance. The data from these studies collectively support the hypotheses that the attentional effects of clonidine depend more on the state of arousal rather than revealing a primary noradrenergic component mediating sustained attention and that thalamic circuits mediate the interactions between arousal and attention.

Aston-Jones and coworkers developed a comprehensive model of the noradrenergic contributions to attentional processes. Based largely on the sympathoexcitatory afferents of the LC, noradrenergic

projections are proposed to serve as the cognitive limb of a rapid response system. Thus, the attentional processing triggered by emotional, novel, or stress-related stimuli is "initiated" via ascending noradrenergic projections, but it is not mediated by this system. For example, the privileged attentional processing of fear- and anxiety-related stimuli has been theorized to depend on the noradrenergic activation of basal forebrain corticopetal projections. Evidence in support of regulation of the LC excitability by the prefrontal cortex indicates a top-down control of such gating mechanisms mediated via ascending noradrenergic projections. This hypothesis suggests that the attentional functions triggered, but not mediated, by noradrenergic ascending activation refer more to selection of stimuli and associations and to the reallocation of processing resources for the processing of selected stimuli, whereas sustained attention performance may less critically depend on variations in activity in ascending noradrenergic projections. This hypothesis is also supported by results from several studies indicating that lesions of the dorsal noradrenergic bundle, which deplete cortical noradrenaline contents, do not affect the performance of animals in well-practiced vigilance tasks unless the state of arousal is manipulated by the presentation of salient, stressful stimuli.

D. Basal Forebrain Corticopetal Cholinergic Projections: Sufficient Neuronal Mechanisms Mediating Sustained Attention

For several decades, human and animal psychopharmacological experiments on the effects of nicotine and muscarinic receptor antagonists (such as scopolamine and atropine) have strongly implicated cholinergic systems in sustained attention. Beginning with the

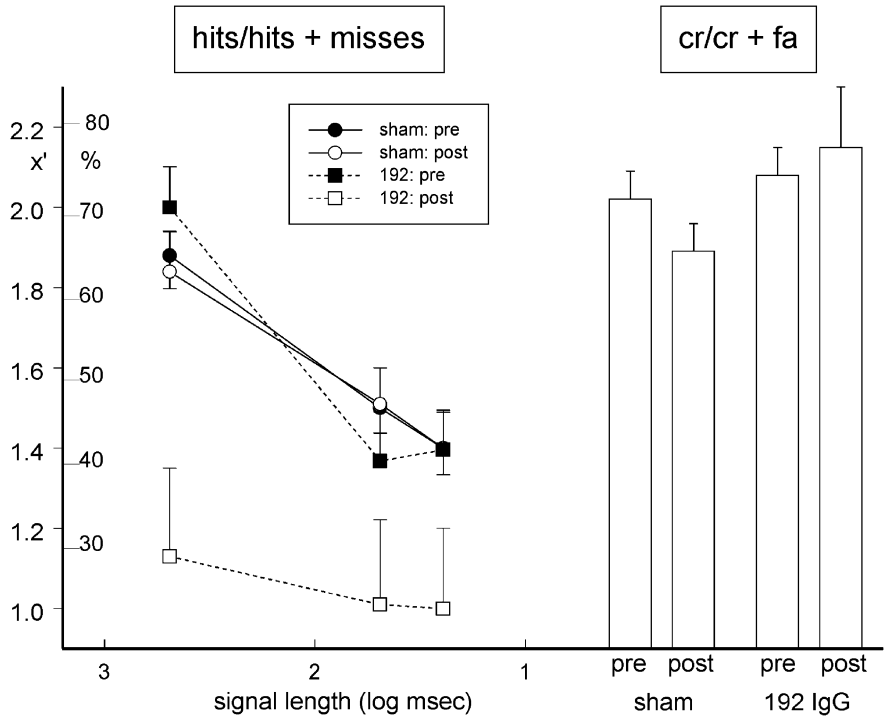

Figure 2 Effects of ^{192}IgG–saporin-induced lesions of basal forebrain cholinergic projections on the performance of rats in an operant sustained attention task. The figure depicts the effects of the lesion and the sham lesion on the relative number of hits and correct rejections (cr). The ordinate depicts the transformed percentage values (x') that were used for statistical analyses (mean $\pm$ SEM). To improve readability, the ordinate also shows percentage values assigned to appropriate transformed values. The right part of the abscissa depicts log signal length (signals were presented for 500, 50, or 25 msec). The relative number of correct rejections (i.e., the correct response in nonsignal trials) could not vary with signal length. fa, false alarms; pre, preoperative baseline; post, postoperative baseline. Preoperative baselines did not differ between the groups, and the lesion did not affect the animals' ability to correctly reject nonsignals (right). However, the lesion decreased the relative number of hits across all signals. The effects of the lesions correlated highly with the loss of cholinergic inputs to frontal and frontodorsal cortical areas (from McGaughy *et al.*, 1996. *Behav. Neurosci.* **110,** 253. Copyright 1996 by the American Psychological Association, Reprinted with permission).

demonstration of the effects of excitotoxic lesions of the basal forebrain on animals' performance in the five-choice reaction time task, the crucial dependency of attentional abilities on the integrity of this system has been extensively explored. Collectively, the available evidence demonstrates the following: First, selective lesions of the basal forebrain corticopetal cholinergic projections, produced by infusions of the cholinoimmunotoxin ^{192}IgG–saporin into the region of the nucleus basalis of Meynert and the substantia innominata in the basal forebrain, are sufficient to produce profound impairments in sustained attention. Second, the lesion-induced impairment in performance is restricted to signal trials, whereas correct rejections remain unaffected (Fig. 2). Moreover, such lesions decrease the vigilance levels as well as augment the vigilance decrement. Third, loss of cortical cholinergic inputs alone, as opposed to loss of all basal forebrain cholinergic efferents, suffices to produce such impairments. Fourth, the impairments in sustained attention observed following cortical cholinergic deafferentation are persistent and do not recover, not even following extended periods of daily practice of performance. Finally, the extent of the impairments in sustained attention correlates highly with the degree of loss of cortical cholinergic inputs, particularly in frontodorsal cortical areas.

Numerous experiments have provided strong and consistent support for the hypothesis that loss of cortical cholinergic inputs, or neuropharmacological manipulations of the excitability of basal forebrain corticopetal cholinergic projections, may represent a sufficient and possibly even necessary neuronal manipulation to affect sustained attention performance. The focus on cortical cholinergic inputs in the mediation of sustained attention is not based solely on the effects of lesions or of manipulation of the excitability of corticopetal projections. Recent studies demonstrated that acetylcholine (ACh) release in the cortex in animals performing a sustained attention task is correlated with demands on sustained attention. The hypothesis that distractor-induced increases in the demands for sustained attention are mediated via cortical cholinergic inputs has also been supported by electrophysiological studies that observed distractor-induced increases in neuronal activity in the medial prefrontal cortex that were cholinergically mediated. It should also be noted that the fact that higher forms of attention (selective and divided) also depend on the integrity of cortical cholinergic inputs is not in conflict with the hypothesis that this neuronal system primarily mediates sustained attention, because the selection of relevant and the rejection of irrelevant stimuli as well as the allocation of available processing resources to these tasks depend fundamentally on the ability to sustain attention.

The basal forebrain corticopetal cholinergic projections terminate in practically all areas and layers of the cortex. The question of whether the cholinergic inputs into a particular cortical region(s) are more crucial than inputs to other cortical regions in mediating sustained attention has remained unsettled. It is important to keep in mind that although mechanical and excitotoxic damage to medial prefrontal areas impair sustained attention performance, such effects were suggested to be due to more fundamental executive problems rather than specifically reflecting sustained attentional impairments, and they cannot be attributed primarily to the loss of cholinergic inputs. Data from studies on the consequences of loss of cortical cholinergic inputs to defined, restricted cortical regions (produced by intracortical infusions of ^{192}IgG–saporin) suggest that more widespread loss in frontal and frontodorsal areas is required to produce reliable and persistent impairments in sustained attention.

Assuming that sustained attention performance is mediated, minimally, by cholinergic inputs to widespread areas of the cortex, the issue of how the specific functions of ACh in these areas mediate sustained attention performance requires further comment. Electrophysiological recordings from neurons in sensory cortical areas following the local application of ACh or the stimulation of the basal forebrain have uniformly suggested that ACh amplifies the processing of sensory inputs. For example, such manipulations result in an increase in the responsivity of sensory cortical neurons to stimuli, an enhancement of their response selectivity to sensory stimuli, and generally in a facilitation of the detection and discrimination of sensory inputs. In the visual cortex, evidence in support of a cholinergically mediated enhancement of intralaminar transfer of information between cortical columns suggests that the effects of ACh go beyond primary sensory processes and include facilitation of higher perceptual processes. Thus, the enhanced processing of information in sensory cortical areas may not depend solely on the top-down regulation of these areas by the anterior attention system but may reflect the direct effects of ACh in sensory regions that occur in parallel and in interaction with the ACh-mediated activation of the anterior attention system (Fig. 3). It must be stressed that loss of cholinergic inputs, for example, to primary and secondary visual cortical areas alone does not result in an impairment in

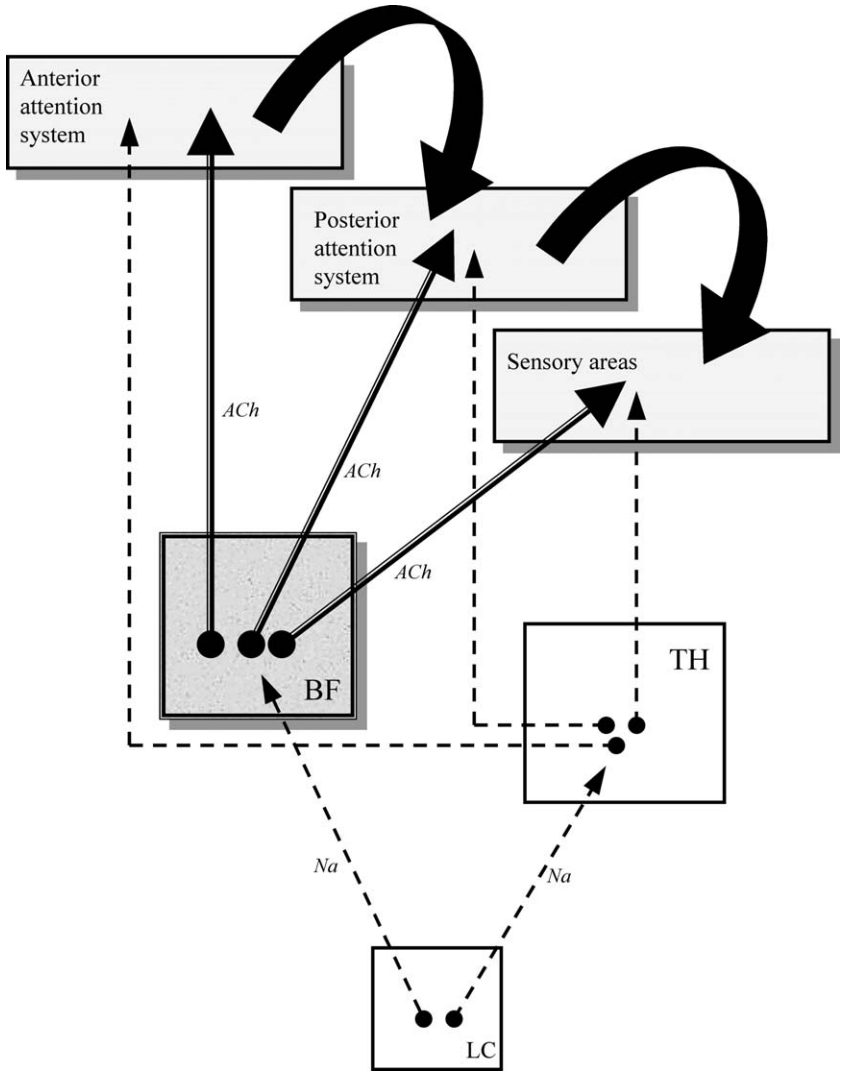

Figure 3 Schematic illustration of the major components of a neuronal network mediating sustained attention performance. The figure combines anatomical and functional relationships and represents a conceptual summary of the evidence from human neuropsychological and imaging studies and animal experimental approaches. Neuroimaging studies demonstrated consistent activation of right medial frontal and dorsolateral prefrontal cortical regions as well as parietal cortical regions in subjects performing sustained attention tasks. Activation of the anterior attention system has been suggested to modulate the functions of the posterior attention system, thereby supporting selective and spatial attentional processes, and sensory information processing in primary sensory through sensory-associational regions, thereby enhancing the sensory components of vigilance performance (curved arrows). Animal experiments determined the crucial role of cortical cholinergic inputs in sustained attention (ACh). Activation of basal forebrain (BF) corticopetal cholinergic projections is necessary for sustained attention performance, and these cortical inputs may mediate, or at least critically contribute to, the activation of frontoparietal regions. Cholinergic inputs also mediate the facilitation of sensory information processing in sensory cortical regions and may do so in interactions with the downstream modulation of sensory information processing by the anterior attention system. The necessary arousal for proper sustained attention performance is mediated largely via noradrenergic (Na) projections originating in the locus coeruleus (LC) and terminating in the thalamus (TH) and the basal forebrain. Aberrations in the crucial cholinergic activation of the anterior attention system are thought to mediate the attentional dysfunctions in major neuropsychiatric disorders (see text).

visual sustained attention performance, supporting the view that the significance of the direct sensory effects of ACh in mediating sustained attention performance depends on the converging activation of the anterior attention system and its downstream modulation of the ACh-mediated enhancement in sensory information processing. These necessary interactions between ACh-activated anterior cortical attention systems and sensory cortex (Fig. 3) may also explain the observation that loss of cholinergic inputs into single

cortical areas does not suffice to impaire sustained attention performance.

Compared to the effects of ACh in sensory cortex, information about the effects of ACh on the firing properties of individual neurons in associational areas is scarce. Generally, however, ACh appears to produce a combination of intrinsic cortical inhibition and postsynaptic increases in excitability that collectively enhance the ability of cortical neurons to process subcortical or associational inputs and thus the processing of conditioned or behaviorally significant stimuli. These cellular effects in associational areas, combined with the enhanced sensory processing, may form the basis for a cholinergic mediation of the subject's readiness to monitor the source(s) of signals, to detect such signals even if they occur rarely and unpredictably, and to initiate the higher cognitive processes that result in a decision for, and the execution of, a response that indicates detection and processing of a signal.

The prevailing focus on the cholinergic system in sustained attention should not be confused with the suggestion that sustained attention is "localized" within this neuronal system. Rather, the anatomical and electrophysiological characteristics of this neuronal system make it an ideal mechanism for gating information processing in the entire cortical mantle. Thus, in terms of localizing sustained attention, sustained attention is more adequately described as being mediated via the activation of the cortex by cholinergic inputs, specifically anterior–parietal circuits, and the interactions between the modulation of sensory processing by the downstream projections of anterior attention system, including the recruitment of interhemispheric circuits, the direct cholinergic stimulation of sensory areas and thalamic input to these regions (Fig. 3). Thalamic inputs import sensory information and, activated via noradrenergic afferents, a general state of arousal that is a prerequisite for proper attentional performance. Thus, sustained attention is a function based on distributed, parallel circuits, with the cortical cholinergic inputs being most selectively involved in the mediation of sustained attention (whereas, for example, prefrontal regions are involved in a multitude of cognitive operations) and representing a necessary limb of these circuits.

E. Convergence of Bottom-Up and Top-Down Evidence: Predictions and Gaps

The hypothesis that the activation of the frontoparietal areas observed in humans performing sustained attention tasks reflects cholinergic stimulation of these regions is attractive but remains unsubstantiated. The hypothesis would predict more widespread areas of cortical activation than reported in most of the available studies, although the relative selectivity of the activity changes reported in these studies may in part by due to the methods used to isolate regions of interest. Furthermore, the predominant role of the right hemisphere for sustained attention observed in human studies has not been addressed in the experimental literature on the functions of cortical cholinergic inputs. However, right cortical lesions produce greater sensory neglect in rats than do left lesions, and lateralized cortical muscarinic receptor densities have been reported, raising the possibility that the prominent right hemispheric involvement in sustained attention is associated with lateralized cholinergic function. Alternatively, evidence in support of a cortical lateralization of sustained attention may be associated with the type of tasks used because spatial, nonverbal sustained attention tasks by default may foster the demonstration of right hemispheric dominance in the mediation of sustained attention. As radiotracers for the visualization of presynaptic cholinergic activity and muscarinic and nicotinic receptor stimulation become available for human PET studies, future experiments will be capable of testing the hypothesis that sustained attention performance is associated specifically with increases in cholinergic transmission in the cortex.

V. ABERRATIONS IN VIGILANCE AND THE MANIFESTATION OF DEMENTIA AND SCHIZOPHRENIA

A. Sustained Hypo- and Hyperattention and Escalating Cognitive Consequences

Impairments in sustained attention detrimentally impact other aspects of attention and higher cognitive functions. For example, impairments in the ability to monitor traffic or the functions of common interfaces (such as automatic teller machines) not only acutely diminish everyday skills and performance but also, if persistent, result in the weakening of operational routines and their underlying mnemonic processing that rapidly escalates into the reduction of behavioral competence in complex situations. Because it is likely that impairments in the ability to sustain attention generalize to associational capabilities (such as the

ability to sustain chains of associations for proper processing), impairments in sustained attention proficiently and directly advance cognitive dysfunction, particularly if such impairments converge and interact with other limitations in executive functions (as is the case, for example, in aging and dementia).

In addition to impairments in the detection of signals, impairments in sustained attention may result from diverse behavioral and cognitive aberrations and manifest in a variety of changes in performance. Specifically, overattentional processes that can be explained in terms of a pathological shifts toward a "riskier" criterion, a biased monitoring of a particular source of information (e.g., anxiety-related stimuli), or an excessively comprehensive monitoring of the environment, including the subjects' own proprioceptive inputs and associational processes, may yield tremendous impairments in sustained attention. Such sustained hyperattentional impairments effectively contribute and interact with abnormalities in executive functions in human neuropsychiatric disorders, such as the exhaustion of processing resources for the unconstrained monitoring of all potential sources of information. Impairments in sustained attentional functions, broadly classified into sustained hyper- or hypoattentional impairments, represent the core symptoms of several neuropsychiatric disorders and, as discussed later, may be attributed in part to aberrations in the integrity and/or the afferent regulation of corticopetal cholinergic projections.

B. Senile Dementia

The significance of impairments in sustained attention in senile dementia, specifically Alzheimer's disease, and the sufficiency of a loss of cortical cholinergic inputs to disrupt sustained attention performance were previously addressed. The so-called cholinergic hypothesis of senile dementia—that is, the hypothesis that loss of basal forebrain cholinergic projections represents the main neuronal event mediating the emergence of dementia—continues to be debated. The available evidence strongly supports the assumption that degeneration in this system is primarily responsible for the attentional impairments in these patients that at least contribute to, and possibly initiate, the development of dementia.

Morphological as well as neurochemical measures of the loss of basal forebrain cholinergic neurons, and specifically the loss of cholinergic inputs to cortical areas, have consistently revealed significant correlations with the intellectual status of patients with Alzheimer's disease. Such correlations have not been obtained concerning the activity or density of other cortical input systems, such as noradrenergic or serotonergic inputs. Recent *in vivo* PET mapping studies of cerebral acetylcholinesterase activity confirmed the early widespread loss of cholinergic inputs in the entire neocortex in patients with Alzheimer's disease. The experimental evidence discussed previously indicates that profound impairments in attentional functions are the primary result of the cortical cholinergic deafferentation in these patients. Although treatments of patients with Alzheimer's disease with drugs that inhibit the metabolizing enzyme acetylcholinesterase have yielded heterogeneous results, including the enhancement of attentional functions, it is important to understand that traditional cholinomimetics have only a very limited capacity to "replace" the functions of absent presynaptic cholinergic neurons. Because the phasic nature of the cholinergic signal encodes crucial cognitive information, and because traditional agonists at postsynaptic cholinergic receptors and (indirectly) cholinesterase inhibitors result in excessive stimulation of these receptors that is largely unrelated to the activity of presynaptic (residual) cholinergic neurons, it is unlikely that such drugs effectively replace a partly degenerated presynaptic cholinergic system. Therefore, the limited therapeutic significance of such drugs may not serve to reject the hypothesis that the attentional impairments in senile dementia are primarily due to loss of cortical cholinergic inputs.

C. Schizophrenia

Impairments in the attentional functions, including sustained attention, have been hypothesized since Bleuler's early descriptions to constitute the core cognitive symptoms of this disorder. Unfortunately, clinical research has focused on the demonstration of impairments in standard neuropsychological tests such as the continuous performance test and only rarely attempted to identify the nature of the attentional dysfunctions in schizophrenia. The frequently used description of the breakdown in filtering functions of schizophrenics and the resulting indiscriminate monitoring of multiple sources of information (i.e., the sustained hyperattention), combined with the resulting exhaustion of processing resources, yields a diminished ability to reject irrelevant sources from being monitored in these patients (e.g., patient 13 in McGhie and Chapman stated, "If I am talking to

someone they only need to cross their legs or scratch their heads and I am distracted and forget what I was saying''). The assumption that sustained hyperattention represents a component of the fundamental cognitive impairments in schizophrenia predicts that, if sources of information are experimentally restricted, schizophrenics should show higher detection rates and reduced vigilance decrements when compared to normal people. Accumulating evidence supports the hypothesis that the sustained hyperattention in schizophrenia is mediated via a disinhibition and thus an increased excitability of cortical cholinergic inputs.

Schizophrenia is generally believed to result from developmental dysmorphogenesis. Results from recent PET studies strongly support the long-standing hypothesis that increases in dopaminergic transmission in ventral striatal regions represent a hallmark of the brains of schizophrenics. Although the cognitive dysfunction of schizophrenia has frequently been attributed to the aberrations in mesolimbic dopaminergic systems, particularly in the nucleus accumbens (NAC), neuropharmacological studies support the hypothesis that NAC dopaminergic receptor stimulation disinhibits basal forebrain corticopetal cholinergic projections via projections to the basal forebrain. The resulting overactive cortical cholinergic inputs system represents a prime candidate for a neuronal mechanism mediating the greater activation of cortical areas in response to sensory stimuli observed in functional imaging studies and, cognitively, for the hyperattentional dysfunctions in schizophrenia. Evidence from animal studies supports this assumption because sustained hyperattention, indicated by increases in the number of false alarms, was demonstrated to result from manipulations that disinhibit or even sensitize the excitability of corticopetal cholinergic projections. It should be noted that studies that assess traditional neurochemical measures indicating static levels of cholinergic transmission or that test the acute effects of traditional cholinergic drugs on schizophrenic symptoms may have very limited power in testing this hypothesis. A direct test of the hypothesis of hyperattentional dysfunctions in schizophrenic patients awaits PET studies using markers that provide sensitive indications of the phasic nature of cholinergic transmission.

VI. CONCLUSIONS

Sustained attention represents a fundamental component of the cognitive capacities of humans. Aberrations in the ability to properly monitor significant sources of information rapidly develop into major cognitive impairments. Human neuropsychological and functional imaging studies have indicated frontoparietal areas, particularly in the right hemisphere, as being prominently involved in the mediation of sustained attention or vigilance. Animal experimental evidence strongly supports the basal forebrain corticopetal cholinergic projection as a major component of the neuronal circuits mediating sustained attention performance. Future research will test the prediction that sustained attention performance-associated increases in cortical acetylcholine release mediate the activation of the anterior attention system and, in parallel, sensory cortical areas, and that the interactions between the direct effects of acetylcholine in sensory regions and the top-down modulation of sensory processing by the anterior attention system are required for proper sustained attention performance. Furthermore, hypotheses suggesting that aberrations in the integrity or afferent regulation of corticopetal cholinergic systems mediate the alterations in sustained attention as they contribute to schizophrenia, dementia, as well as other disorders, require investigations in humans, particularly using PET combined with radiotracers for markers for cholinergic transmission and muscarinic and nicotinic receptor function, as well as the generation of valid animal models on the long-term attentional effects of changes in cortical cholinergic inputs. Such studies will also clarify the significance of the hypothesis that the right frontoparietal circuits dominate over left cortical areas in the mediation of sustained attention performance.

Given the close theoretical relationships between different aspects of attention (sustained, selective, and divided), it should not be surprising that the available data from neuropsychological, functional imaging, and animal experimental studies suggest extensive overlaps in the circuits mediating different aspects of attention. For research purposes, it is important to maintain clear definitions of the aspects of attention studied. However, with respect to real-life performance, and to the underlying brain mechanisms, those differentiations may turn out to be of more limited significance. Monitoring a particular source of information requires the selection of such a source and the rejection of competing sources and also the allocation of processing resources to this task. Obviously, such tasks cannot be performed without mnemonic processing, taxing additional executive functions. Likewise, impairments in attention are difficult to conceive as

remaining restricted to a particular aspect of attention, and suggestions for such specific impairments in patients have overly relied on dissociations in performance on standardized tests. Thus, the current reductional attempts to determine the neuronal circuits mediating specific aspects of attentional functions represent a first step toward a more comprehensive understanding of the multiple circuits that allow us to effectively attend to our environment and our cognitive operations.

Violence and the Brain

KAREN E. ANDERSON
University of Maryland

JONATHAN M. SILVER
Lenox Hill Hospital

GLOSSARY

catastrophic reaction Unusual behavior, usually seen after left hemispheric strokes and often seen in those individuals with aphasia. Patients may display anxiety, aggression, and extreme agitation.

explosive No gradual buildup; instead, sudden and unpredictable outburst.

ictal Behavioral changes occurring during an epileptic seizure.

interictal Behavioral episode occurring between seizure episodes.

nonreflective Does not involve planning; is not premeditated.

postictal Behavioral change occurring between seizure periods.

Explosive and violent behavior can occur with focal brain lesions as well as with diffuse damage to the central nervous system. In this article, we review neuroanatomical structures implicated in violence and the neurotransmitters believed to modulate aggressive behavior. We then discuss common neurological and medical conditions related to aggressive behavior.

I. NEUROANATOMY OF AGGRESSION

Many brain areas are involved in the production and modulation of aggression (Fig. 1). Damage due to a particular condition may be diffuse, as seen in traumatic brain injury or infection, or focal, as may occur in a small stroke, tumor, or herpes encephalitis.

A. Limbic System

The limbic system is composed of a complex set of structures, including the temporal lobes, frontal lobes, thalamus, hypothalamus, and amygdala, with extensive and far-reaching connections in the brain. The temporal lobes, especially in the amygdaloid complexes, are involved in regulation of response to basic emotions, such as fear and anger, and to drives, such as hunger, pain, and sexual behavior. The limbic system has an important role in the incorporation of sensory experience into memory so that previously unpleasant experiences can be avoided and pleasurable ones sought out.

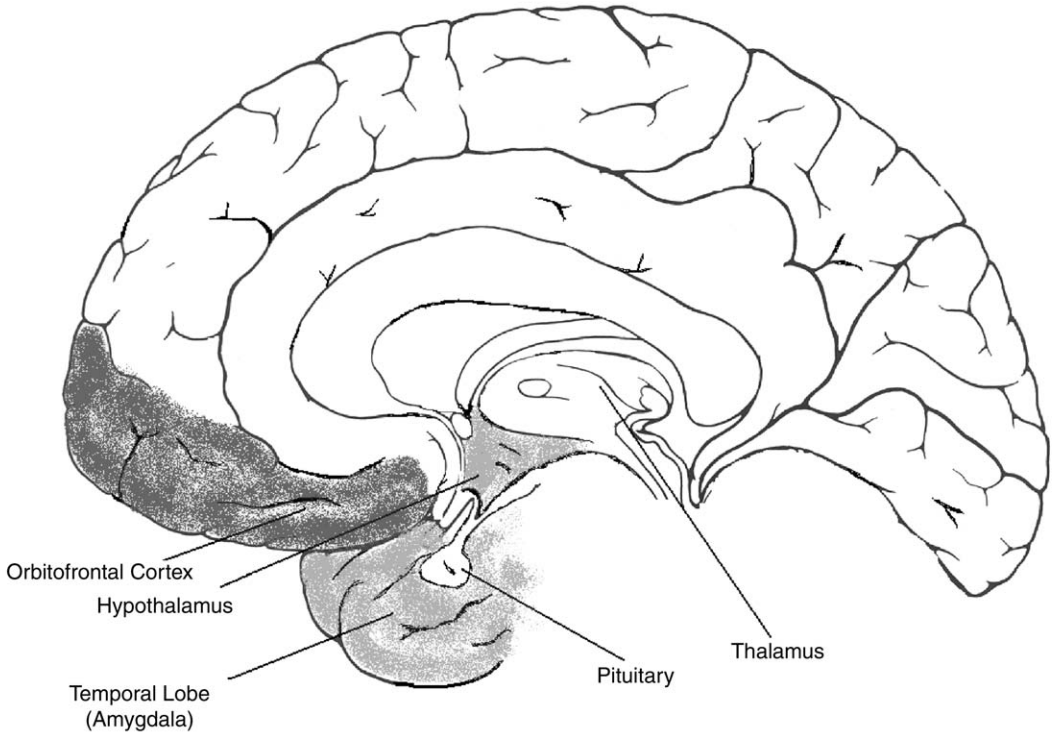

Figure 1 Regulation of aggression by brain regions: Orbitofrontal cortex modulates decreases in aggression. Limbic regions and hypothalamus modulate increases in aggression.

Early studies with animals indicated that the amygdala provides a mediating response on aggressive behavior. Klüver and Bucy first demonstrated that bilateral lesions of the amygdala produced passive behavior in untamed animals. Their work delineated the Klüver–Bucy syndrome of hyperorality, hypersexuality, the absence of fear response, increased touching (hypermetamorphosis), and visual agnosia in monkeys that had undergone bilateral temporal lobectomy. The animals could not identify which objects were associated with which drives, and they would, for example, attempt to eat nonfood items, including feces. Later work revealed that amygdalectomy in submissive monkeys could result in aggressive behavior, which concurs with the modulatory role of the amygdala on other brain functions rather than acting as a simple "aggression center."

Humans with bilateral temporal lobe damage can display behaviors similar to those seen in monkeys with Klüver–Bucy syndrome. They show placidity, apathy, bulimia, and aphasia but may also become quite aggressive at times. Temporal lobe damage in humans may occur as part of surgery or in traumatic brain injury.

Some medical conditions also cause disruption of temporal lobe function. The herpes simplex virus (HSV-1) can produce a severe form of encephalitis that, for unclear reasons, localizes in the temporal lobes. These patients often have severe neurological sequelae, including profound behavioral disturbances. They may display a Klüver–Bucy syndrome in which they are hyperoral, hypersexual, and hypermetamorphic.

Although Klüver–Bucy syndrome generally produces passive behavior, some patients with temporal lobe damage from the encephalitis are aggressive. Since aggression does not occur in Klüver–Bucy monkeys, the aggression in some patients with herpes simplex encephalitis may be due to only partial involvement of limbic areas in these cases, whereas patients with a classical Klüver–Bucy syndrome have complete involvement of both temporal lobes.

Recent functional studies using positron emission tomography (PET) or single photon emission computerized tomography (SPECT) indicate that particular aggressive individuals may have focal abnormalities in the temporal lobes, often on the left side. Some data suggest that the amygdala may be particularly prone to

kindling, in which repeated stimulation of a neural pathway leads to a lower threshold for activation of those areas. Animal models of temporal lobe epilepsy have shown evidence of kindling phenomena. Some authors have suggested that a kindling effect is responsible for the emotional outbursts seen interictally (between seizures) in a few patients with temporal lobe epilepsy.

Damage or dysfunction in the limbic area, and not temporal lobe epilepsy per se, is the significant factor in predisposing to violent behavior. Therefore, temporal lobe epilepsy may be related to aggression as a result of pathological abnormalities or dysfunction of the temporal lobe.

Numerous studies with experimental animals have demonstrated that damage to particular areas of the hypothalamus can result in rage. Decorticate cats display "sham rage" when all areas rostral to the hypothalamus are lesioned. The posterior lateral hypothalamus is a site that, when stimulated, causes the decorticate animals to hiss, extend their claws, and display other signs of aggression. Ventromedial hypothalamic stimulation may inhibit aggressive behavior in some instances, and its removal or injury have been associated with an increase in aggression, even in previously tame animals.

Several similar case reports of patients with hypothalamic damage and aggression are also cited in the neurological and psychiatric literature. In the early 20th century, tumors of the hypothalamus were found to be associated with unpredictable rage outbursts in a few patients who eventually came to postmortem. Some authors proposed that these aggressive behaviors are actually in response to heightened perception of internal stimuli, such as hunger, rather than completely unprovoked actions. With the advent of neuroimaging as a common diagnostic tool, it is now rare for patients with dramatic personality change not to undergo brain imaging early on so that tumors are discovered and treated.

B. Prefrontal Cortex

The prefrontal cortex regulates both limbic and hypothalamic activity. Thus, damage to this area may cause aggression due to lack of limbic inhibition. This area evaluates social cues and mediates an individual's judgment concerning behavior. Lesions of the prefrontal cortex may result in an exaggerated response to seemingly minor irritations. These patients may exhibit little remorse over their aggressive acts, in contrast with temporal lobe epilepsy patients, who often are quite apologetic when they have acted violently. Many people with violent or antisocial behavior have had damage to the frontal areas of the brain.

Damage to specific areas of the prefrontal cortex produces varying behavioral changes. Dorsal prefrontal lesions generally cause apathy and inability to plan. Orbital frontal lesions result in impulsive behavior. Patients with these lesions respond to environmental stimuli without evaluating the possible consequences. The most famous case of this syndrome is Phineas Gage, a railroad worker whose left orbitofrontal lobe was severely injured when a tamping iron was driven through his skull in an accidental explosion. Whereas he had previously been a sober, diligent employee, after the accident he was disruptive, rude, and garrulous. A recent case series of murderers demonstrated poor behavioral performance on classical "frontal" psychological tests and a high incidence of frontal lobe abnormalities, both structurally, [on magnetic resonance imaging (MRI) or computed tomography (CT)], or functionally (on PET or SPECT). Preliminary neuroimaging data indicate that some murderers, especially those with histories of poor impulse control, have decreased prefrontal glucose metabolism.

C. Brain Stem

Animal studies indicate that the brain stem may mediate some parts of aggressive display but does not seem to modulate complex aggressive actions. Threatening facial expressions have been seen in subhuman primates when brain stem nuclei are stimulated. Humans rarely display more than fragments of aggression resulting from brain stem lesions. Patients with rapid eye movement (REM) sleep behavior disorders are an exception to the rule that the brain stem does not mediate aggressive action.

D. Diffuse Injury/Dysfunction

Although aggressive behavior can be localized to injury or activation of some particular brain areas, confusion, delirium, and psychosis produced by general medical conditions such as anoxia or infection can also potentiate aggression. Both acute cerebral hypoxia, a deficiency of oxygen in tissue, and hypoxemia, deficiency of oxygen in the blood (usually resulting from cardiac or pulmonary compromise), may also

cause delirium. As with any delirious state, these patients may become combative. Numerous other medical conditions, such as hypertensive encephalopathy, hypoglycemia, or intracranial bleeding, can also cause delirium, occasionally with concomitant aggression.

II. NEUROTRANSMITTER MODULATION OF AGGRESSION

A. Serotonin

Serotonin exerts an inhibitory influence over aggression in animal studies. Low serotonin levels are associated with higher rates of shock-induced fighting in rats and aggression in rhesus monkeys. Studies in humans reveal an association between decreased serotonin and both aggression and impulsivity. Low serotonin has a strong association with self-destructive acts such as suicide attempts, particularly of the violent type. The serotonin system projects to the frontal cortex and thus may be particularly susceptible to damage from traumatic brain injury. However, studies after traumatic brain injury fail to show consistent decreases or increases in serotonin.

Levels of 5-HIAA, the primary serotonin metabolite, considered to be a reflection of presynaptic brain serotonergic activity, correlate with central serotonin activity. Studies of cerebrospinal fluid (CSF) 5-HIAA levels in prisoners accused of murder or attempted murder found that murderers whose acts were more impulsive had lower CSF 5-HIAA levels. Prisoners who had a history of suicide attempts or repeated violent acts had lower CSF 5-HIAA levels than those without these factors. Low serotonin levels have also been reported in persons with personality disorders who have a long-standing history of violent behavior. Thus, low serotonin may lower the threshold for impulsivity, which can lead to violence.

B. Norepinephrine

Animal studies suggest that norepinephrine enhances aggressive behavior, including sham rage and shock-induced fighting. The major norepinephrine tracts in the brain originate in the locus ceruleus and lateral tegmental system and continue to the forebrain. They are thus among the neuroanatomical regions most vulnerable to traumatic brain injury, as discussed later. Indeed, some studies have demonstrated markedly elevated norepinephrine levels after traumatic brain injury. Some, but not all, humans who exhibit aggressive or impulsive behavior have been shown to have increased levels of norepinephrine metabolites.

Monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT) are two of the major enzymes involved in breakdown of norepinephrine and other catecholamines. Low levels of these enzymes may reflect high norepinephrine activity since catabolism is reduced. Animal studies implicate low MAO levels in aggressive behavior since MAO knockout mice, which lack the MAO-A gene, show increased aggression. Low MAO activity has been found in platelet studies of violent criminals. Data on COMT levels are less conclusive. Male knockout mice that lack COMT are more aggressive, but this increase is not seen in female COMT knockouts. Human studies are inconclusive with regard to the role of COMT and violence.

C. Dopamine

Dopamine pathways course through mesolimbic and mesocortical regions. Increases in dopamine have been shown to lead to aggressive behavior in animal studies. Dopamine increases in the prefrontal cortex have been linked to stress in humans (e.g., in studies of posttraumatic stress disorder). Chronic stress may increase dopamine in other brain regions. Agitation and, at times, aggression may be seen in schizophrenia, which is treated with antidopaminergic medications.

III. MEDICAL AND NEUROLOGICAL ILLNESS ASSOCIATED WITH AGGRESSION

Numerous conditions may cause or exacerbate violent behavior. Characteristic behavioral features occur in many patients with brain pathology who are violent. Typically, violence seen in these patients is reactive (i.e., triggered by modest or trivial stimuli). It is nonreflective, in that it does not involve premeditation or planning, and nonpurposeful, in the sense that the aggression serves no obvious long-term aims or goals. The violence is periodic, with brief outbursts of rage and aggression interspersed between long periods of relatively calm behavior. The aggression is ego-dystonic, such that patients are often upset or embarrassed by it. Finally, it is generally explosive, occurring suddenly with no apparent buildup.

Some relatively common conditions appear to have a relationship to aggressive behavior but have not been

studied empirically. Other illnesses may have a strong association with violence but occur too infrequently to permit large case studies. Studies of aggression often vary greatly in the reported frequency of this behavior in various populations. There are several factors that may influence these findings. Definitions may differ as to requirements of frequency or severity for inclusion in criteria of aggression. Some studied separate self-injurious behavior from aggression. Also, cutoff rates vary for inclusion of behavior such as damage to property or injury to others in studies of aggression. We can report which populations are more likely to show aggressive behavior and can predict some situations in which violence is more likely to be provoked in these patients. However, risk of violent behavior for an individual patients can be difficult to anticipate.

A. Dementia

Behavioral disturbances are common in individuals with dementia. Up to 70–90% of patients with Alzheimer's disease have some form of emotional or behavioral problem. Families are able to tolerate their relative being forgetful; it is more difficult to manage the sudden episodes of anger. Aggressive behavior is one of the main factors that lead to placement of a demented person in a nursing home.

In a study of agitation and cognitive impairment in nursing home residents, Cohen-Mansfield studied 408 residents of a large suburban nursing home. Impairment of activities of daily living (ADL) and cognitive impairment were associated with increased aggression. Aggressive behavior was associated with the individual being a married man, having poor social interactions, being more likely to fall, and exhibiting more aggressive behavior before admission to the nursing home. Most of the aggressive behavior was directed at caregivers and often occurred consistently around morning assistance with ADL.

Several predictors of aggressive and violent behavior have been found in Alzheimer's disease. Greater functional impairment, but not severity of cognitive decline, is a predictor of aggressive behavior in Alzheimer's patients. Delusions and misidentifications (e.g., inability to recognize one's self in a mirror or believing that someone else is living in the house) are both associated with an aggressive episodes. In a recent multicenter study of 235 outpatients with Alzheimer's disease, Devanand and others found physical aggression to be an uncommon symptom of Alzheimer's disease, persisting in only 2.8% of the sample for over 2 years. However, if physical aggression was reported during one visit, there was more than a 50% probability that it would be reported by a caretaker at the next visit. The authors concluded that physical aggression may become a more persistent problem at later stages of Alzheimer's disease since the patients became more demented as the study progressed. Changes in multiple neurotransmitter systems, including serotonin and norepinephrine, may play a role in the development of aggressive behavior in patients with Alzheimer's.

Behavioral disturbances in a subcortical dementia (Huntington's disease) and a cortical dementia (Alzheimer's disease) have been compared. Huntington's patients are significantly more aggressive than Alzheimer's patients. It is possible that damage to deep subcortical structures, such as the hypothalamus and limbic system, may result in aggression and behavioral dyscontrol.

B. Traumatic Brain Injury

Aggression and agitation commonly occur after traumatic brain injury (TBI). These behaviors, which occur during the acute stages of recovery from brain injury, can endanger the safety of the patients and their caregivers. In the acute phase after brain injury, patients often experience a period of agitation and confusion that may last from days to months. Agitation usually appears in the first 2 weeks of hospitalization and resolves within 2 weeks. Restlessness may appear after 2 months and may persist for 4–6 weeks. Subsequently, patients may develop low frustration tolerance and explosive behavior that can be set off by minimal provocation or occur without warning. These episodes range in severity from irritability to outbursts that result in damage to property or assaults on others. In severe cases, affected individuals cannot remain in the community or with their families and often are referred to long-term psychiatric or neurobehavioral facilities.

Studies of mild TBI have evaluated patients for much briefer periods of time; 1-year estimates from these studies range from 5 to 70%. Other work has examined the relationship between the number of TBIs associated with loss of consciousness (LOC) and various symptoms and has demonstrated that irritability increases with subsequent injuries. Of those men who did not have head injuries with LOC, 21% reported irritability, whereas 31% of men with one

injury with LOC and 33% of men with two or more injuries with LOC admitted to having this symptom.

C. Congenital Brain Disorders and Developmental Disorders

People with intellectual deficiencies who engage in aggression toward others or self-injurious behavior are more likely to require intensive supervision and management. Aside from the severity of intellectual impairment, aggression is the most important reason why patients are institutionalized. The mounting costs of caring for such individuals makes improved understanding of such behavior a crucial concern.

1. Inpatient Populations

Several recent studies reviewed rates of aggressive behavior among institutionalized people with intellectual disabilities. Linaker compared 57 people in an institution who had shown violence in the past year with 57 people in the same institution who had not shown violence. The groups were matched for age, sex, and level of retardation. The aggressive residents had significantly more resources allocated to them and more space available per client on the wards. Communication skills and the ability to care for themselves did not differ between the two groups. Neuroleptic drugs were given in a higher percentage in the assaultive group, and a higher level of psychopatholgy was found in this group. The number of patients with specific organic brain disorders, such as Down's syndrome or infantile autism, did not differ significantly, except that Down's syndrome tended to be more common in the control group.

Sigafoos and others studied a population of 2412 people with intellectual disability in Queensland, Australia. Of the sample, 48% were severely to profoundly mentally retarded, whereas 24% were moderately impaired and 9.6% were mildly impaired. Most individuals (59%) were male, and 16% of this population lived in institutions. Aggressive behavior was rated by a questionnaire given to those who cared for the patients. For the entire sample, hitting others with a closed or open hand was the most common aggressive behavior (68%), followed by pushing others (64%). Three or more forms of aggression were displayed by 80% of those who were violent (e.g., hitting others, kicking, verbal abuse, and pinching others). Persons who were identified as aggressive had more profound levels of retardation and lower verbal abilities. Self-injurious behavior was less common than aggression toward others.

2. Outpatients

Those people with severe intellectual impairment are more severely and frequently aggressive. In a study by Sigafoos and coworkers, aggressive behavior occurred in 17% of those in group homes and 3% of those in community-based facilities. The remainder of those studied were either in family care or living independently or semi-independently. Intake evaluations, historical data from agency records, and medical records were reviewed as sources of data on aggressive behavior. After the cohort was sorted by the presence or absence of primary referral involving explosive or assaultive behavior toward property or other individuals, 131 individuals were classified as aggressive at the time of the study. This study found that aggressive and nonaggressive patients had similar neurological histories and medical status. Central nervous system disorders, including seizures, were seen with a similar prevalence in both groups. The authors concluded that current aggressive behavior was best predicted by past aggressive behavior when found in males with lower cognitive functioning who might have been previously institutionalized. Consistent with these findings, studies of prison inmates with intellectual disabilities suggest that they have a higher incidence of offenses such as fighting and destruction of property when compared with inmates without documented intellectual deficiencies.

D. Epilepsy

Epilepsy has long been believed to be a cause of, or at least a contributor to, acts of violence. There has been substantial use of the "epilepsy defense"—persons who claim they are not guilty of certain crimes, usually violent in nature, because they were seizing or in a period of confusion following a seizure (i.e., "postictal confusion"). An examination of 75 cases in the United States, reviewed by state or federal courts and in which the epilepsy defense was used by an offender charged with commission of a violent crime ranging from rape to murder, showed that the defense was successful in only 1 case.

Estimates of interictal aggressive acts vary from 5 to 50% of individuals with epilepsy. There are several possible explanations for this variability. Many

studies of general populations of epileptics are performed at large teaching hospitals, where the patients who are referred likely have more severe disorders than those seen in a general population of people with epilepsy. Aggressive behavior can result from structural lesions that cause seizures. Medications used to treat epilepsy can alter mood and behavior. Lastly, many reports of violent behavior in persons with epilepsy are anecdotal and do not rely on standardized rating scales.

In analyzing the occurrence of aggressive behavior in individuals with epilepsy, it is important to note when the behavior occurs. Aggressive acts can be ictal (during a seizure), postictal (immediately after a seizure), or interictal (in the period between seizures).

1. Ictal Aggression

Ictal aggression occurs most often during attempts to assist or restrain a patient during a seizure. Resistive violence has also been observed in animal seizure models. Ictal aggression is rarely directed. Delgado-Escueta and colleagues reported that on video electroencephalograph(EEG) recordings of ictal behavior in 5400 patients, only 19 showed aggression. Only 1 of these 19 demonstrated actual aggression directed toward another person. The others yelled loudly, spat, or destroyed property.

2. Postictal Aggression

Postictal aggression involves violent acts that occur when a patient is still confused following a seizure. Postictal aggression is commonly seen following a general tonic–clonic seizure, and it occurs less often following a complex partial seizure. Attempts at restraint are the most typical cause of aggression during this time. Postictal psychosis is another likely cause of aggression that occurs during this period, especially if the patient experiences frightening hallucinations or paranoia during that time.

3. Interictal Aggression

The occurrence of aggressive behavior between seizures is more controversial than ictal or postictal aggression because there is no direct relationship between the aggression and the seizure event. Most epileptologists agree that the majority of patients with epilepsy are psychologically normal between seizures. It is unclear whether a small subset of persons with epilepsy behave differently between seizures as a result of brain alterations caused by the ictal events. Interictal violence is associated more with underlying psychopathology, such as schizophrenia or mental retardation, than with seizure activity.

4. Temporal Lobe Pathology

Although studies that examine general populations of individuals with epilepsy do not find a significant correlation with aggressive behavior, there is a large body of literature that links the interictal behavior of individuals with temporal lobe epilepsy to aggression. This may be due to the association of the "limbic lobe" with emotion and aggression. Patients with temporal lobe epilepsy may exhibit emotional lability, impairment of impulse control, and suspiciousness.

It was found that male sex, early seizure onset, and a history of long-standing behavioral problems were associated with aggression. Aggression was not associated with a history of psychosis.

Stevens, in reviewing several large, older studies of aggression in temporal lobe epilepsy, concluded that people with temporal lobe epilepsy are not, as a group, more violent than those with other forms of epilepsy. Damage or dysfunction in the limbic area, and not temporal lobe epilepsy per se, were the significant factors in predisposing to violent behavior. Therefore, these studies suggest that temporal lobe epilepsy may be related to aggression as a result of pathological abnormalities or dysfunction of the temporal lobe.

E. Encephalitis

The influence of viral and other forms of encephalitis on behavior was first noticed during the pandemic of encephalitis lethargica during World War I. Also known as Von Economo's encephalitis, the illness was noted to produce a plethora of psychiatric symptoms, including behavioral changes such as aggression in previously normal persons. Other forms of encephalitis, most notably herpes encephalitis, are now also known to result in aggressive behavior.

1. Encephalitis Lethargica

Encephalitis lethargica was first described in detail by Constantine von Economo in 1917. The agent that causes encephalitis lethargica has not been isolated. Besides producing physical symptoms of an acute central nervous system infection, encephalitis lethargica can, at times, progress to coma or death. Survivors were sometimes afflicted with parkinsonism or with

bizarre behavioral disturbances. Some survivors, mostly adolescents, suffered pseudopsychopathic states. In a review of early work on the illness, children who had been normal became uninhibited, damaging property and attacking strangers in the street. Few neurological abnormalities were seen in these cases. Sporadic cases of encephalitis lethargica are still seen throughout the world.

2. Herpes Simplex Encephalitis

The herpes simplex virus (HSV-1) can produce a severe form of encephalitis. It is probably the most common cause of nonepidemic encephalitis in temperate zones. Mortality rates are as high as 70%. However, with new antiviral treatments, many patients are living longer. These people often have severe neurological sequelae, including profound behavioral disturbances. For unclear reasons, the herpes virus tends to specifically destroy the temporal lobes. This can produce a Klüver–Bucy syndrome in which patients are hyperoral, hypersexual, and may have an abnormal desire to explore objects (hypermetamorphosis).

3. Other Forms of Encephalitis

Since herpes simplex encephalitis is the only encephalitis known to localize to a particular brain area, it is the only encephalitis in which neuropsychiatric symptoms may be predictable. Other types of encephalitis produce more diffuse central nervous system damage.

a. Autoimmune Deficiency Encephalitis Autoimmune deficiency syndrome (AIDS) causes numerous behavioral deficits, including dementia. Another common behavioral disturbance associated with agitated behavior in AIDS patients is AIDS-related mania. Patients can display symptoms seen in typical mania, including irritability and psychosis. AIDS encephalitis has been reported to cause depression and psychotic symptoms in some patients.

b. Limbic Encephalitis Paraneoplastic syndromes, a remote effect of malignancy generally believed to be autoimmune in nature, are the most common cause of limbic encephalitis. Due to its involvement with the limbic system, aggression can be seen as a result of the condition.

F. Movement Disorders

Movement disorders often present with behavioral changes (Table I). Increased irritability and angry outbursts are reported in many movement disorders. Psychotic symptoms, which exacerbate underlying aggression, are also seen.

1. Gilles de la Tourette Syndrome

Gilles de la Tourette syndrome is a condition in which patients display both verbal and motor tics. These tics change over time in localization and presentation. Patients with Tourette's may display coprolalia (obscene speech) and copropraxia (obscene gestures). Numerous authors have cited behavioral problems as part of the clinical picture in some cases of Tourette's syndrome. Indeed, Tourette mentioned behavioral problems in his original description of the syndrome. Although obsessions, compulsions, and disorders related to attention deficit hyperactivity disorder are generally the most commonly described psychiatric symptoms in Tourette's, aggressive outbursts have also been described. Aggressive behavior was significantly associated with symptoms of being forced to touch and with copropraxia. There was no significant association between aggression and age of onset, personal or family history of psychiatric illness, EEG or neurological abnormalities, medication, distribution of tics, hyperactivity, or difficulty in concentration or attention as a child.

2. Wilson's Disease

Wilson's disease, or hepatolenticular degeneration, is an autosomal-recessive disorder involving dysregula-

Table I
Movement Disorders Associated with Aggressive Behaviors

Disorder	Comments
Tourette's syndrome	Aggression often associated with attention deficit or thwarting of urge to touch/manipulate
Wilson's disease	Psychiatric symptoms may be presenting complaint, including changes in personality and temperament
Huntington's disease	Irritability in more than 40% of patients, often associated with rigid behavioral patterns
Parkinson's disease	Aggression rare, generally associated with confusion or psychosis due to anti-Parkinson's medications

tion of copper metabolism by the liver. Psychiatric symptoms in Wilson's disease were recognized as early as 1912 by Samuel Alexander Kinnier Wilson in his description of the disorder. Neurological, renal, and hepatic abnormalities are the usual findings in the disease. Kaiyser–Fleischer rings can often be seen on fundoscopic examination. All symptoms are caused by abnormal deposition of copper in organ systems. Some studies have reported that more than half of all Wilson's disease patients have psychiatric symptoms as their presenting complaint. Personality changes are generally the most common psychiatric complaint and may include aggressive behavior. Family members may describe a patient as having more "temper" than usual or yelling and throwing things when angry. Psychosis, which could contribute to aggression, may also occur. There may be an association between incongruous behavior, aggression, and personality change and certain neurological symptoms, such as dysarthria, dysphagia, drooling, and rigidity.

3. Huntington's Disease

Huntington's disease is an autosomally dominant disorder that can present with choriform movements and/or psychiatric symptoms. Aggression and irritability may be seen in these patients and are frequently reported to be among the most common psychiatric features of the illness. Violence may occur in these patients due to degeneration of frontal–striatal pathways and subsequent behavioral disinhibition. Psychosis is also occasionally seen in Huntington's patients.

4. Parkinson's Disease

Although aggression may not be a common manifestation of Parkinson's disease, it can develop as a result of treatment with dopaminergic medications, which may precipitate psychosis.

G. Brain Tumors

Aggression secondary to intracerebral malignancy has long been a part of the differential diagnosis considered by psychiatrists. However, it is rare for violent behavior to manifest itself as the first symptom of a brain tumor. We believe that the more frequent use of brain imaging techniques has resulted in earlier detection of tumors, resulting in less frequent behavioral presentation. To date, there have been few studies of central nervous system malignancies as a cause of aggressive behavior. Generally, behavioral symptoms attributed to brain tumors can be difficult to correlate with location since tumor growth, especially when rapid, can cause widespread edema, bleeding, and large mass effects. Often, patients present with lethargy as the predominant behavioral problem. There are a few case series, especially in the older literature, in which attempts have been made to correlate tumor location with manifestation of behavioral disturbance.

Patients with tumors in the temporal lobe may have irritable, angry, or actual assaultive episodes during their clinical courses. Tumors causing aggression vary in histological type but are all relatively slow growing, disrupting mainly limbic system structures, and not causing rapid shifts in intracranial pressure. Limbic system tumors may cause seizures, and these patients' psychiatric symptoms may be related to the behavioral disturbances seen in temporal lobe epilepsy. Numerous studies with experimental animals have demonstrated that damage to the ventromedial hypothalamus can result in hyperphagia and, occasionally, rage.

H. Stroke

Mood disorders following stroke have been reported in numerous case studies and reviews. Robinson's extensive studies on the relationship between lesion location and depression or mania suggest that patients with left hemisphere lesions are more likely to become depressed, whereas those with right-sided lesions are more likely to be unusually cheerful or even manic.

Catastrophic reaction to stroke is a relatively rare mood disorder seen most commonly after left hemispheric strokes, although it is also described in other types of brain damage. It is often seen in those individuals with aphasia. Patients may display anxiety, aggression, and extreme agitation. Some authors attribute this to frustration at not being able to communicate due to the aphasia.

I. Hypoglycemia

A series of studies conducted in Finland examined biologic correlates of aggression in a group of violent prisoners. One consistent finding was that this group is

prone to hypoglycemia, and they have an increase in irritability during these episodes.

The main criticism of studies of violent populations is the confounding effect of alcohol. Since many of these patients have a history of extensive alcohol abuse, especially while perpetrating violent acts, it is unclear what contribution alcohol makes to the overall picture of violence. Some authors have questioned the usefulness of the oral glucose tolerance test as a measure of blood glucose levels in these circumstances. The differences in diet of patients compared with that of controls can be quite disparate for institutionalized persons. Currently, these results are not useful predictors of violent behavior in the general population.

J. Sleep Disorders

There have been a few reports of aggressive behavior during parasomnias, including violent attacks. Patients often seem to be fleeing from imaginary pursuers and may assault family members who happen to be in the room with them. Formal sleep studies can help determine the cause of this sleep-related behavior, which includes non-REM parasomnias, sleep-related seizures, REM behavior disorder, or psychogenic dissociative phenomena.

K. Endocrine Disorders

In addition to systemic effects, several endocrine disorders are known to produce behavioral symptoms and often have psychiatric symptomatology as the presenting complaint.

1. Thyroid Disorders

Hyperthyroid states can produce agitation and psychosis. Thyrotoxicosis is caused by increased production of thyroid hormone by the thyroid gland, inflammation of the thyroid, or sources of thyroid hormone from outside the gland (i.e., exogenous thyroid hormone consumption or tumor production of thyroid hormone). Neuropsychiatric symptoms of thyrotoxicosis include anxiety, insomnia, and intense dysphoria. Memory and concentration can be impaired. Psychosis is sometimes present; when it is, violence generally occurs since patients may react dramatically to perceived threats or command hallucinations. When psychosis is seen, it may be a sign that the patient is progressing toward the more serious state of thyroid storm.

Thyrotoxicosis in children can present in numerous ways, including an attention deficit hyperactivity disorder-like picture, affective symptoms, and psychosis. Severe aggression is rarely reported in children with thyrotoxicosis.

Hypothyroidism is usually primary; pituitary or hypothalamic disease causing hypothyroidism is rare. In psychiatric patients, lithium can cause hypothyroidism. Patients with hypothyroid conditions are usually characterized as depressed, apathetic, and lethargic. Elderly patients may look demented. However, there are case reports of agitation leading to violent behavior in persons with hypothryroidism.

Approximately half of the patients with hypothyroidism will have some affective disturbance, and a small percentage of these cases will show signs of psychosis. Long-standing hypothyroidism can lead to myxedema. Patients with myxedema psychosis (or "myxedema madness", as severe psychiatric disturbance in hypothyroid states was once termed) can become quite agitated.

2. Parathyroid Disorders

It has long been recognized that parathyroid disorders, and the resulting calcium abnormalities, can cause psychiatric symptoms. Since calcium is involved in neurotransmission, it is not surprising that hypercalcemia can have many psychiatric manifestations. Primary hyperparathyroidism can be caused by a tumor of the parathyroid or by parathyroid hyperplasia. The condition usually causes depression, fatigue, and confusion. However, psychosis has been reported in rare cases and can lead to violent behavior. Patients with hypercalcemia are also more likely than those with other endocrine disorders to display psychiatric symptoms with concomitant fully intact consciousness. There is some indication that patients with higher calcium levels are more likely to have psychotic symptoms.

Hypoparathyroidism can cause hypocalcemia. Hypoparathyroidism is usually associated with autoimmune disorders or other destruction of the parathyroid. Hypocalcemia has not been reported to cause violence. Patients with this disorder are often anxious and demented.

3. Cortisol Disorders

Patients with Cushing's syndrome due to adrenal tumors or adrenocorticotropin hormone (ACTH) secreting tumors have high levels of cortisol, which

can cause metabolic encephalopathy and various psychiatric symptoms. Psychotic symptoms can be precipitated by hypercortisolism. Older literature cites an example of homicidal psychosis after exogenous ACTH use. Patients with Addison's disease, who have abnormally low cortisol levels, are generally depressed.

IV. MEDICATIONS AND DRUGS

Drug effects and side effects can result in disinhibition or irritability. In any individual with brain dysfunction, there is increased susceptibility to adverse behavioral effects of medication. By far the most common drug associated with aggression is alcohol, during both intoxication and withdrawal. Stimulating drugs such as cocaine and amphetamines, as well as stimulating antidepressants, may produce agitation. Antipsychotic medications often increase agitation through anticholinergic side effects, and agitation and irritability usually accompany severe akathisia. Many other drugs may produce confusional states, especially anticholinergic medications that cause agitated delirium. Other drugs that may produce aggressive behavior include steroids, analgesics (opiates and other narcotics), and anxiolytics (barbiturates and benzodiazepines).

V. SEX HORMONES

A. Testosterone

High testosterone levels are often blamed for aggressive behavior in men, although the actual relationship between testosterone levels and violence is far from clear. Several controlled studies of testosterone levels in serum, saliva, and spinal fluid have attempted to correlate these values with various measures of violence.

Several groups have examined testosterone levels in male prisoners who committed violent acts, finding some correlation between elevated testosterone and aggression. Some studies have found higher serum testosterone levels in continuously violent groups of prisoners. The socially dominant prisoners have also been shown to have higher testosterone levels than the nondominant, nonaggressive prisoners.

In contrast, other studies found no correlation between plasma testosterone and incidences of fighting and verbal aggression in prisoners. Those prisoners with a more prominent history of violent crime in adolescence did have a higher level of testosterone than those without a significant early history of violence. The authors propose that high levels of testosterone may have a permissive effect on aggression early in life in some individuals who are more prone to commit crime in the first place. However, it is unclear whether high testosterone levels in adulthood correlate with increased testosterone early in life. Testosterone may exert a modulatory effect in decreasing the threshold for violent crimes. However, most violent crime is not directly correlated with testosterone levels. Future studies using saliva or CSF testosterone may be more conclusive.

B. Premenstrual Dysphoric Disorder

Popular wisdom has linked the menstrual cycle to mood swings and unusual behavior since the early 1900s. However, there are few controlled studies that address the question of whether violence in women is linked to a certain phase or phases of the menstrual cycle.

The term premenstrual syndrome, which has been replaced with the term premenstrual dysphoric disorder, is used to describe a number of physical and/or mood changes observed in a small percentage of women in association with their menstrual cycles. The psychiatric symptoms include tiredness, depression, and, in some women, irritability and anxiety.

Several studies have examined the relationship between stage of menstrual cycle and commission of a crime. These studies, which rely on retrospective self-report by women, may be confounded by popular opinion, which may cause women to falsely recall that they were paramenstrual at the time a crime was committed as an explanation or excuse for the behavior.

Thus, the relationship between the menstrual cycle and aggression is unclear. Women who commit crimes may be more likely to do so during the premenstrual or menstrual phase of their cycle. However, these data may be influenced by suggestibility because women may retrospectively attribute their actions to a particular phase in their menstrual cycle.

C. Prenatal Exposure to Exogenous Hormones

Prenatal exposure to androgens occurs mainly when synthetic androgens are used to prevent abortion. It has been suggested that the exposure to androgens would masculinize females and could lead to higher

levels of aggression. Fortunately, these cases are quite rare. Exposed children were compared with their same-sex siblings, who had not been exposed, using questionnaires about aggression. Both exposed boys and girls scored higher on the questions that predicted potential for aggression. However, no actual observation of whether the children displayed more aggression than their siblings was reported. Prenatal diethylstilbestrol exposure was examined No increase in verbal or physical aggression was found in exposed females when compared with controls. In summary, human studies on prenatal exposure to sex hormones do not provide conclusive evidence that exposure to androgens leads to an actual increase in violent behavior.

VI. NUTRITIONAL FACTORS

Vitamin deficiencies generally present with apathy as the foremost behavioral symptom, but some nutritional deficiencies are reported to cause agitation and violence, usually as a result of psychosis (Table II). Pyridoxine (B_6) deficiency due to homocystinuria may cause psychosis. Folic acid deficiency in homocystinuria and hypomethioninemia may cause a schizophrenia-like syndrome.

There are a few case reports of dietary vitamin deficiencies causing agitation. Niacin deficiency can cause depression with psychotic features, including hallucinations and thought disorder. Patients with more severe psychotic symptoms may become agitated. As the disorder progresses, patients will become more demented and, ultimately, stuporous.

B_{12} deficiency leading to pernicious anemia causes psychotic symptoms in approximately 16% of patients. It is also reported that 30–80% of patients with pernicious anemia may have an organic brain syndrome including paranoia, violence, and depression. These symptoms all respond to correction of vitamin deficiencies. Psychiatric symptoms can be seen without neurological deficits or anemia.

VII. ELECTROLYTE IMBALANCE AND HYPOXIA

Electrolyte imbalance can precipitate delirium and confusional states. Patients may become acutely agitated and aggressive as a result of various electrolyte abnormalities. Sodium and calcium are probably the most common abnormalities to cause agitation since either state can result in disturbance of cell membrane equilibrium in the central nervous system.

Both acute cerebral hypoxia, a deficiency of oxygen in tissue, and hypoxemia, a deficiency of oxygen in the blood (usually resulting from cardiac or pulmonary compromise), may also cause delirium. As with any delirious state, these patients may become combative. Patients with chronic cerebral anoxia may compensate for the condition at baseline but can become quite confused and aggressive if the anoxia is worsened by infection or other systemic illness. Numerous other medical conditions, such as hypertensive encephalopathy, hypoglycemia, or intracranial bleeding, can also cause delirium, occasionally with concomitant aggression.

VIII. TOXINS

Toxins will generally cause stupor and lethargy with acute intoxication. However, numerous toxins have

Table II
Nutritional Deficiencies Associated with Aggressive Behavior

Deficiency	Comments
Pyridoxine (B_6)	Due to homocysteinuria; causes psychosis that may lead to violence; also seen in patients treated for tuberculosis with isoniazid who are not given pyridoxine supplementation
Folic acid	Due to homocystinuria and hypomethioninemia; may cause schizophrenia-like syndrome with agitation
Cobalamin (B_{12})	Irritability, emotional lability, and suspiciousness may lead to violence; neuropsychiatric symptoms occasionally present without peripheral neurological signs
Niacin	Deficiency can cause pellegra, seen commonly in alcoholics; depression, psychosis (hallucinations and thought disorder), more severe psychotic symptoms may cause agitation

Table III
Toxin Exposures That May Cause Violent Behavior

Toxin	Typical source
Mercury	Felt manufacture (past), hat makers
Organophosphates	Pesticides
Lead	Adults exposed occupationally (e.g., construction workers), children by ingesting paint
Manganese	Usual exposure is in miners, processors of manganese; parkinsonsonian symptoms with agitation
Arsenic	Chronic exposure may cause encephalopathy, confusion, agitation

been reported to cause irritability and even aggression in extreme cases, especially when exposure is gradual (Table III). As with general medical illnesses discussed previously, encephalopathy and psychosis are the main reasons for aggression. Chronic mercury exposure produces the most well-known neuropsychiatric side effects, leading to the expression "mad as a hatter" since it was formerly used in the manufacture of felt hats. Afflicted persons have mood lability and are shy, with decreased sleep and memory problems. Actual violence has not been reported. Organophosphates act by binding to acetylcholinesterase and inactivating the enzyme. The immediate effect is accumulation of large amounts of acetylcholine in the synapse. Organophosphate toxicity, usually following pesticide use, commonly presents with neuropsychiatric symptoms. Aggression has been described in rare cases, including one incidence of a man and his pet cat who both became quite violent after organophosphate exposure in their home. The aggression resolved after the pesticides were discontinued.

Lead has been reported to cause mood disorders and irritability, among other neuropsychiatric symptoms, but aggression per se has not been reported. Adults are usually exposed to lead through occupational contact, whereas children commonly ingest lead paint. At highly toxic levels, lead intoxication causes encephalopathy. Encephalopathy is seen most commonly in children since they absorb lead more readily. Encephalopathy can progress to psychosis. Chronic arsenic poisoning can also cause encephalopathy and, in some case, psychotic symptoms. "Manganese madness" occurs most often in miners and processors of manganese. Besides parkinsonian symptoms, patients may have behavioral disturbances, including psychosis.

IX. TREATMENT

In establishing a treatment plan for patients with agitation or aggression, the overarching principle is that diagnosis comes before treatment. It is essential to determine the mental status of the patient before the agitated or aggressive event, the nature of the precipitant, the environment in which the behavior occurs, the ways in which the event is mitigated, and the primary and secondary gains related to the problem behaviors. We suggest utilizing the *Consensus Guidelines for the Treatment of Agitation in the Elderly with Dementia* as a framework for the assessment and management of agitation and aggression. After assessment of possible etiologies of these behaviors, treatment is focused on the occurrence of comorbid neuropsychiatric conditions (depression, psychosis, insomnia, anxiety, and delirium) (Fig. 2). Evaluation and documentation with objective measures such as the Overt Aggression Scale and the Overt Agitation and Severity Scale are often helpful. Other factors that influence the choice of medications include whether the treatment is in the acute (hours to days) or chronic (weeks to months) phase and the severity of the behavior (mild to severe). Table IV presents an overview of medications used to treat aggressive behaviors.

Although no medication has been approved by the Food and Drug Administration specifically for the treatment of aggression, medications are widely used (and commonly misused) in the management of patients with aggression. We divide the use of pharmacological interventions for aggression to two major categories: (i) the use of the sedating effects of medications, as required in acute or severe situations so that the patient does not harm him- or herself or others, and (ii) the use of

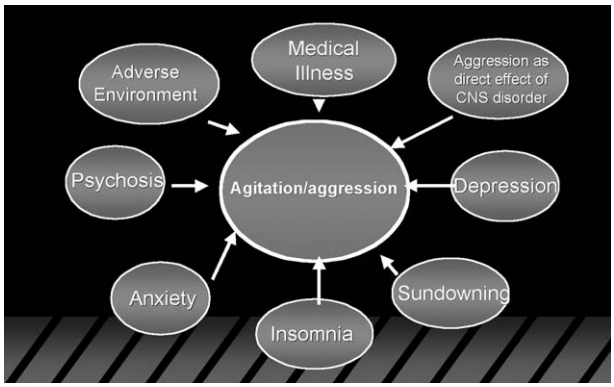

Figure 2 Neuropsychiatric factors associated with agitation and aggression.

nonsedating medications for the treatment of chronic aggression.

A. Acute Aggression and Agitation

Medications that are sedating may be indicated for the treatment of agitation and for treating severe episodes of aggressive behavior. Because these drugs are not specific in their ability to inhibit aggressive behaviors, however, there may be detrimental effects on arousal and cognition. They may also cause seriously disabling side effects including tardive dyskinesia. Unless aggressive behavior is clearly related to psychosis, we prefer to limit the use of both antipsychotic agents and benzodiazepines for ''sedating'' aggression to a maximum time period of 4 weeks. Beyond this time, the clinician must consider whether or not the aggression is chronic and alter the treatment plan accordingly to use medications recommended in the following sections for chronic treatment.

1. Antipsychotic Drugs

Antipsychotics are the most commonly used medications in the treatment of aggression. Although these agents are appropriate and effective when aggression is a derivative of active psychosis, the use of neuroleptic agents to treat chronic aggression is often ineffective and entails significant risks for the patient. Often, patients develop tolerance to the sedative effects of the neuroleptics and therefore require escalating doses. As a result, especially with the older neuroleptics, extrapyramidal and anticholinergic-related side effects occur. Paradoxically (and frequently), because of the development of akathisia, the patient may become more agitated and restless, especially when a high-potency antipsychotic such as haloperidol is administered.

Evidence from studies of injury to motor neurons in animals indicates that haloperidol decreases recovery. It is possible that the effect on decreasing dopamine and inhibiting neuronal function, which may be the mechanism of action to treat aggression, may have other detrimental effects on recovery. Whether this finding is generalizable to humans remains unclear. However, these studies raise important potential risk/benefit issues that must be considered in the management of aggression.

In patients with acute aggression, we recommend starting a high-potency neuroleptic such as risperidone

Table IV
Medications to Treat Aggressive Behavior

Class (Examples of Agents)	Indications	Side effects/Considerations
Antipsychotics (atypicals include: risperidone, olanzapine, quetiapine)	Psychosis, need for sedation, hallucinations	Multiple side effects (decrease in extrapyramidal side effects with atypicals)
Benzodiazepines (lorazepam)	Acute management	Extremely sedating; may be cause of violence by paradoxical disinhibition and rage
Anticonvulsants (carbamazepine, valproate)	Seizure disorder, bipolar disorder	Bone marrow suppression (CBZ), hepatotoxicity (VPA) May be very sedating
Buspirone	Chronic anxiety/depression	Long onset to therapeutic action
Antidepressants (fluoxetine, paroxetine, citalopram, sertraline)	Depression, anxiety, or labile mood	Selective serotonin reuptake inhibitors may be most useful
Beta blockers	Chronic or recurrent aggression	4–6 weeks to onset of efficacy; high doses needed may cause blood pressure effects in some patients

at low dosages of 0.5 mg orally with repeated administration every hour until control of aggression is achieved. If intramuscular medication is required, haloperidol should be utilized. If, after several administrations of risperidone the aggressive behavior does not improve, the hourly dose may be increased until the patient is so sedated that he or she no longer exhibits agitation or violence. Once the patient is not aggressive for 48 hr, the daily dosage should be decreased gradually (i.e., by 25%/day) to ascertain whether aggressive behavior reemerges. In this case, consideration should then be made as to whether it is best to increase the dose of risperidone and/or to initiate treatment with a more specific antiaggressive drug.

2. Sedatives and Hypnotics

There is an inconsistent literature on the effects of the benzodiazepines in the treatment of aggression. The sedative properties of benzodiazepines are especially helpful in the management of acute agitation and aggression. Most likely, this is due to the effect of benzodiazepines on increasing the inhibitory neurotransmitter GABA. Paradoxically, several studies report increased hostility, aggression, and the induction of rage in patients treated with benzodiazepines, possibly due to disinhibitory effects. However, this phenomenon is rare. Preexisting memory dysfunction can be exacerbated by the use of benzodiazepines.

For treatment of acute aggression, 1 or 2 mg of lorazepam may be administered every hour by either oral or intramuscular route until sedation is achieved. Intravenous lorazepam is also effective, but caution must be taken with intravenous administration, and it should be injected in doses less than 1 cc (1 mg) per minute to avoid laryngospasm. Intravenous lorazepam does not have faster onset of action than intramuscular administration. As with neuroleptics, gradual tapering of lorazepam may be attempted when the patient has been in control for 48 hr. If aggressive behavior reoccurs, medications for the treatment of chronic aggression may be initiated. Other sedating medications, such as paraldehyde, chloral hydrate, or diphenhydramine, may be preferable to sedative antipsychotic agents.

B. Chronic Aggression

If a patient continues to exhibit periods of agitation or aggression beyond several weeks, the use of specific antiaggressive medications should be initiated for prevention.

1. Antipsychotic Medications

If, after thorough clinical evaluation, it is determined that the aggressive episodes result from psychosis, such as paranoid delusions or command hallucinations, then antipsychotic medications will be the treatment of choice. Risperidone has been used to treat agitation in elderly patients with dementia with good results. Olanzapine appears to be more sedating, and quitiepine may have fewer extrapyramidal side effects (EPS) than does risperidone. Clozapine may have greater antiaggressive effects than other antipsychotic medications. However, the decrease in seizure threshold must be carefully assessed, along with the need for monitoring blood counts.

2. Antianxiety Medications

Serotonin appears to be a key neurotransmitter in the modulation of aggressive behavior, as discussed previously. In preliminary reports, buspirone, a 5-HT 1A agonist, has been reported to be effective in the management of aggression and agitation for patients with head injury, dementia, and developmental disabilities and autism. Rare cases of paradoxical increase in aggression have been reported with buspirone use. We usually initiate buspirone at 7.5 mg bid for 1 week and then increase the dosage to 15 mg bid. Dosages of 45–60 mg/day may be required before there is improvement in aggressive behavior, although we have noted dramatic improvement within 1 week.

Clonazepam may be effective in the long-term management of aggression, although controlled, double-blind studies have not been conducted. We use clonazepam when pronounced aggression and anxiety occur together or when aggression occurs in association with neurologically induced tics and similarly disinhibited motor behaviors. Doses should be initiated at 0.5 mg twice daily bid and may be increased to as high as 2–4 mg bid, as tolerated. Sedation and ataxia are frequent side effects.

3. Anticonvulsive Medications

Carbamazepine has been proved to be effective for the treatment of bipolar disorders and has also been advocated for the control of aggression in both epileptic and nonepileptic populations. Several open studies have indicated that carbamazepine may

be effective in decreasing aggressive behavior associated with TBI, dementia, developmental disabilities, schizophrenia, and patients with a variety of other organic brain disorders.

In our experience and that of others, valproic acid may also be helpful to some patients with organically induced aggression. For patients with aggression and epilepsy whose seizures are being treated with anticonvulsant drugs such as phenytoin and phenobarbital, switching to carbamazepine or to valproic acid may treat both conditions. Gabapentin has been used effectively for the treatment of agitation in patients with dementia.

4. Antimanic Medications

Although lithium is known to be effective in controlling aggression related to mania, many studies suggest that it may also have a role in the treatment of aggression in selected, nonbipolar patient populations. Included are patients with TBI as well as patients with mental retardation who exhibit self-injurious or aggressive behavior, children and adolescents with behavioral disorders, and patients with other organic brain syndromes. Reports also suggest that lithium is useful in reduction of aggression in prisoners. Because of lithium's potential to cause neurotoxicity and dehydration, and its relative lack of efficacy in many patients, we limit the use of lithium in those patients whose aggression is related to manic effects or recurrent irritability related to cyclic mood disorders.

5. Antidepressants

The antidepressants that have been reported to control aggressive behavior are those that act preferentially (amitriptyline) or specifically (trazodone and the SSRIs) on serotonin. Trazodone has also been reported to be effective in the treatment of aggression. Sertraline and fluoxetine have been used in numerous cases of aggression due to neurological and psychiatric disorders. We have used selective SSRIs with considerable success in aggressive patients with brain lesions. The dosages used are similar to those for the treatment of mood lability and depression.

We emphasize that for many patients it may be necessary to administer these medications at standard antidepressant dosages to obtain full therapeutic effects, although response may occur for others within days of initiating treatment at relatively low doses. In select patients with obsessions and compulsions due to organic disease, aggression is seen when the patients are prevented from acting on these symptoms. In these cases, higher doses of SSRIs, such as those used in the treatment of obsessive–compulsive disorder, may be more effective (e.g., 60–80 mg of fluoxetine).

6. Antihypertensive Medications: Beta Blockers

Since the first report of the use of β-adrenergic receptor blockers in the treatment of acute aggression in 1977, more than 25 articles have appeared in the neurological and psychiatric literature reporting experience in using beta blockers for more than over 200 patients with aggression. Most of these patients had been unsuccessfully treated with antipsychotics, minor tranquilizers, lithium, and/or anticonvulsants before treatment with beta blockers. The beta blockers that have been investigated in controlled prospective studies include propranolol (a lipid-soluble, nonselective receptor antagonist), nadolol (a water-soluble, nonselective receptor antagonist), and pindolol (a lipid-soluble, nonselective beta receptor antagonist with partial sympathomimetic activity). The effectiveness of propranolol in reducing agitation has been demonstrated during initial hospitalization after TBI. When a patient requires the use of a once-a-day medication because of compliance difficulties, long-acting propranolol (i.e., Inderal LA) or nadolol (Corgard) can be used. When patients develop bradycardia that prevents prescribing therapeutic dosages of propranolol, pindolol (Visken) can be substituted using one-tenth the dosage of propranolol. Pindolol's intrinsic sympathomimetic activity stimulates the beta receptor and restricts the development of bradycardia.

The major side effects of beta blockers are a lowering of blood pressure and pulse rate. Because peripheral beta receptors are fully blocked in doses of 300–400 mg/day, further decreases in these vital signs usually do not occur, even when doses are increased to much higher levels. Despite reports of depression with the use of beta blockers, controlled trials and our experience indicate that it is a rare occurrence. Because the use of propranolol is associated with significant increases in plasma levels of thioridazine, which has an absolute dosage ceiling of 800 mg/day, the combination of these two medications should be avoided.

X. SUMMARY OF PHARMACOTHERAPY AGGRESSION

Table V summarizes our recommendations for the use of various classes of medication in the treatment of

Table V
Pharmacotherapy of Agitation

Acute agitation/severe aggression	
High-potency antipsychotic drugs (haloperidol, risperidone)	
Benzodiazepines (lorazepam)	
Chronic agitation	
Drug	**Primary indication**
Atypical antipsychotics (risperidone, olanzapine, quetiapine, clozapine)	Psychosis
VPA, CBZ,? gabapentin	Seizure disorder, severe aggression
Serotonergic antidepressants (SSRI, trazodone)	Depression, mood lability
Buspirone	Anxiety
Beta blockers	Aggression without concomitant neuropsychiatric sequelae

acute and chronic aggressive disorders. If partial response without undue side effects is seen with adequate dosing of one agent, augmentation with a second agent should be considered. Control of aggression with the lowest dose of the medication (or medications) with the fewest potential unwanted side effects should be the goal of pharmacotherapy.

XI. CONCLUSIONS

Aggressive and violent behavior may result from many disorders of the central nervous system. These problems are common and constitute a major source of morbidity and mortality. Disruptive behavior is often the largest barrier to reintegration into the community for those with severe neurological illnesses. Many medications are effective in the treatment of aggression, although accompanying side effects must be weighed carefully for each particular patient (Table IV).

Lesions that involve the limbic lobes may be more frequently associated with aggression, but violent behavior is also seen with diffuse cortical disease. Patients with central nervous system disease may be violent in an unpredictable manner, but aggression often occurs when others attempt to restrain or assist a patient. This resistive aggression is reported frequently in studies of demented patients, those with intellectual deficiency, and those with epilepsy who are postictal. Aggression is also seen as a result of severe medical illness, especially in individuals with chronic illness. Encephalopathy as a result of a medical condition can lead to agitation and aggression. Systemic medical illness can also cause psychosis, which may lead to violent behavior in response to paranoid ideation.

Although aggression may appear to be unpredictable in these populations, patterns are evident in many forms of disruptive behavior. If a sudden change in behavior occurs, neurological or medical illness should be ruled out as a cause of the aggression. This may require a fairly extensive workup and consideration of uncommon conditions. Description and evaluation of aggression in the aggressive behavior is the first step toward treatment and prevention.

In treating aggression, the clinician, when possible, should diagnose and treat underlying disorders and use antiaggressive agents specific for those disorders. When there is partial response after a therapeutic trial with a specific medication, adjunctive treatment with a medication with a different mechanism of action should be instituted. In all cases, the clinician should attempt to treat aggression with the lowest effective dose of medication and to avoid using treatments with severe potential side effects.

Vision: Brain Mechanisms

ROBERT SHAPLEY and NAVA RUBIN
New York University

GLOSSARY

magnetic resonance imaging Imaging of the internal structure of body tissue by the observation of magnetic resonances induced in them.

occipital cortex Cerebral cortex belonging to the occiput or back part of the head.

retinotopic map A map that preserves the spatial relations of the sensory receptors of the retina.

segmentation The process of division into segments.

stereopsis The ability to perceive depth and relief by stereoscopic vision.

temporal cortex The lowest lobe of the brain lying below the Sylvian fissure.

Vision appears to be a simple matter, which does not require any mental effort: We open our eyes and see. However, the subjective ease of seeing masks a tremendous amount of brain processing required to allow us to perceive the world through the visual sense. The most direct evidence for this is the large portions of cortex that are devoted to visual processing. The entire occipital lobe, as well as parts of the temporal and parietal lobe, is concerned with interpreting the image impinging on the retina. The operations done by the numerous visual cortical areas are understood only partially. Part of the difficulty stems from the lack of good theoretical understanding of visual processing. For example, research on artificial vision has not been able to produce "seeing machines" that would perform visual tasks that humans perform effortlessly, such as navigating through a crowded room or recognizing a familiar face. Better theoretical understanding would have allowed to map the various brain processes onto known computational stages of visual processing. Instead, the study of the brain mechanisms of vision and research on the computational aspects of vision have progressed in parallel, each field drawing inspiration from findings in the other. In this article, we survey some of the major findings on the function of the various areas of the visual cortex.

I. INTRODUCTION

The visual cortex takes signals about the retinal images that are relayed to it through the lateral geniculate nuclei (LGN) and seeks to recognize objects and navigate in the world based on vision. Visual signals are processed in V1 (also known as the striate cortex) and V2, the primary and secondary visual cortical areas. From V1 and V2, signals are sent to multiple visual areas anterior and lateral to these early visual areas in the brain. Some of these extrastriate visual areas seem to be very specialized for certain aspects of the visual image, such as motion or color. How these different areas contribute to visual perception has become much clearer in recent years.

Knowledge about the visual system's functional anatomy has expanded tremendously in the past decade through the use of brain imaging techniques.

Optical imaging of the upper layers of the cerebral cortex in nonhuman primates, using activity-dependent changes in reflectance, can be used to study structure on the scale of several square millimeters. Magnetic resonance imaging (MRI) both in nonhuman primates and in human subjects allows scientists to study the structure of the visual system noninvasively. Functional MRI (fMRI) enables researchers to study changes in the brain's blood oxygenation that are caused by variations in neuronal activity, thus enabling noninvasive functional mapping of human brain activity. Most of the results we cite about human brain activity correlated with perception are derived from fMRI experiments. fMRI has lower spatial resolution than optical imaging, but it allows the experimenter to study brain volumes from 100 to 1000 ml and reflects activity not only from the cortex's superficial layers but also through the depth of the cortex.

It appears that the brain must find meaningful patterns in order to compute visual attributes correctly as well as to be able to place these attributes in and around perceived objects in a scene organization that is consistent with the visual image. This view is based on experimental observations by, among others, Hans Wallach that visual attributes of perceived objects, such as color, shape, and motion, are linked, and they all need to be computed by the brain. Thus, we are compelled by the evidence from human perception, from fMRI, and from physiological experiments on animals to conceive of perception as an active process in which visual image information is combined with memory to compute "why things look as they do." This is most easily understood when visual images are ambiguous—for example, when selected visual images produce figure/ground reversals or binocular rivalry. Then it becomes clear that there are multiple states of brain activity corresponding to multiple "interpretations" that are consistent with the visual image. What one sees in this situation changes with time and the state of the brain and must involve time variations in the computations that the visual system is doing based on the visual image.

The first neural computation we consider is the mapping of the visual world onto the cortex in V1 and adjacent visual cortex.

II. V1–V*n* AND RETINOTOPY

In order to understand appearance, we must account for the location of perceived objects in the world. Perceived location depends on the mapping from location in the world to location on the cortex. A schematic diagram of human visual cortex is depicted in Fig. 1. This diagram emphasizes the visual field

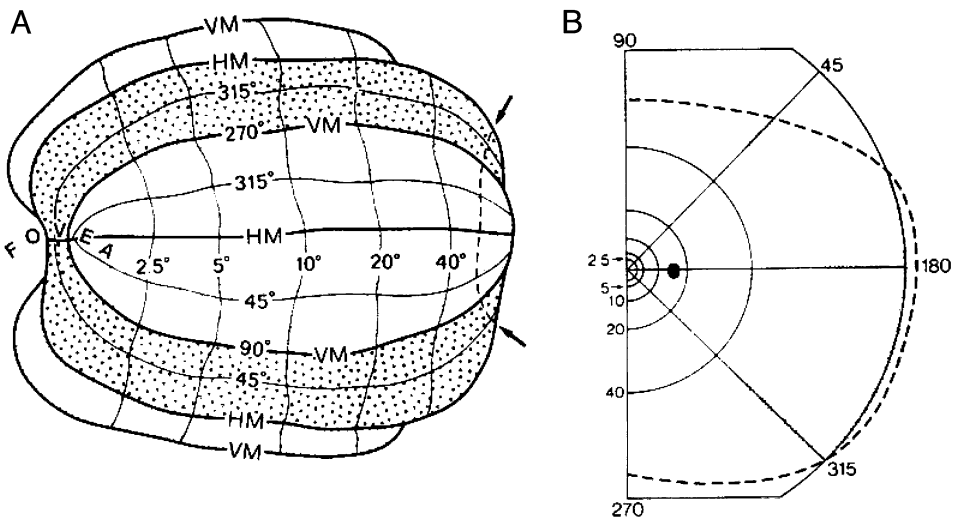

Figure 1 (A) Retinotopic mapping in human V1–V3. Mapping of the visual field on an artificially flattened human visual cortex. V1 is the central clear zone, V2 is marked by the small dot stippling, and V3 is the outermost zone. (B) Visual field coordinates corresponding to those drawn in A. Note that V2 and V3 are split along the representation of the horizontal meridian into separate upper field and lower field halves (reproduced with permission from Horton and Hoyt, 1991). Quadrantic visual field defects. A Hallmark of lesions in extrastriate (V2/V3) cortex. Brain **114,** 1703–1718.

mapping onto different brain regions, V1–V3. Human primary visual cortex V1 is located deep in the calcarine fissure, and it extends slightly onto the cortex around the posterior pole. Most of the visual cortex located on the posterior surface of the human cerebral cortex is in fact extrastriate cortex; that is, V2, V3, V4, and up to V*n*. V1 is continuous above and below the calcarine fissure and forms a continuous boundary with V2, which surrounds it completely. V2 is composed of two disjoint cortical regions, upper and lower V2, as is the case for V3 and V4. From lesion studies we know that the upper half of V1 receives LGN input that is looking only at the lower visual field, whereas lower V1 is looking at the upper visual field. This is true also of V2, V3, etc. It is well-known that the early, retinotopic areas V1–V3 represent the visual field contralateral to the cerebral hemisphere in which they are located. Thus, a lesion in the upper region of V2 will cause a visual field defect only in the lower contralateral quadrant of the visual field.

The map of the visual field in V1 was demonstrated elegantly in the monkey visual cortex by Roger Tootell and colleagues. They used the 2-deoxyglucose activity-labeling technique as illustrated in Fig. 2. The stimulus used was a "ring and ray" pattern presented for approximately 1 hr while the radioactively labeled 2-deoxyglucose circulated through the bloodstream of the monkey. Active cells picked up the label and appear dark in the autoradiograph in Fig. 2. The center of the ring and ray pattern was placed where the foveae of the eyes were looking, and the pattern in the contralateral hemifield (Fig. 2) activated the neurons in the hemisphere that is imaged in the figure. The cortex was flattened physically to enable the flat two-dimensional (2D) image of the cortical map to be made. The mapping of the ring and ray pattern is smooth and relatively precise onto V1 cortex. The circular rings were spaced at distances that grew geometrically larger, and their map onto V1 is approximately onto lines that are approximately equidistant from each other. This means the mapping is approximately logarithmic, as has often been noted. The stimulus rays also map into approximately straight lines that are separated from each other by a fixed distance. The vertical meridian is mapped into the V1/V2 border, whereas the horizontal meridian divides V1 in half, with the upper field mapped to lower V1 and vice versa. Figure 2 is a succinct summary of the main facts about retinotopic mapping in primate V1 cortex.

Retinotopic mapping in the human V1 cortex, and in extrastriate visual areas as well, has been demonstrated with fMRI. The technique developed by Engel and colleagues is shown in Fig. 3. The basic idea is to use a periodic stimulus, such as an expanding ring or a rotating wedge. Then neurons that are functionally connected to the retinal region excited by the stimulus will be activated only during one phase of the stimulus cycle. Location will be encoded in the phase of the fMRI response with respect to the stimulus cycle. This technique is therefore called phase mapping. The phase of fMRI response with respect to the expanding ring's cycle encodes radial distance from the point of expansion (usually the fovea). The phase of fMRI response with respect to the rotating wedge encodes the azimuth of the response location in the frontoparallel plane. From Fig. 2, one might expect that the active regions of V1 excited by a given azimuth should lie along straight lines in a flattened map of the cortex since this is what was observed in the 2-deoxyglucose maps. Also, one should expect that regions of a given retinal eccentricity in flattened-cortex phase maps should lie along straight lines that are approximately perpendicular to the cortical projection of the vertical meridian, as demonstrated by the monkey 2-deoxyglucose data.

Data on the retinotopic map in human visual cortex are given in Fig. 4. Here, the representation of the visual cortex as a flat sheet was not achieved by physical flattening as in the monkey experiments since these were *in vivo*, noninvasive measurements and the cortex was not available for physical flattening. Rather, the cortex was virtually flattened by computer image processing of the 3D image of the cortex obtained from MRI measurements, using an algorithm that preserved local distances. Separate eccentricity and azimuth maps were measured to create the mapping in the figure. As shown, only azimuth is coded by color. The V1 map is consistent with the monkey V1 map in terms of both eccentricity and azimuth. The map indicates that human V1 also represents only the contralateral hemifield, consistent with the effects of lesions on human visual cortex.

The results summarized in Fig. 4 also reveal important facts about the mapping of visual space in extrastriate cortex for example, V2 cortex adjacent to V1. Also, there is a retinotopic map in V2. The V1 and V2 maps are separated by the representation of the vertical meridian in each cortical area, so the vertical meridian projection serves as a marker for the V1/V2 boundary. This also means that V2, like V1, is only receiving visual input from the contralateral visual hemifield. Furthermore, the boundary between V2 and V3, a distinct visual cortex region more lateral than V2,

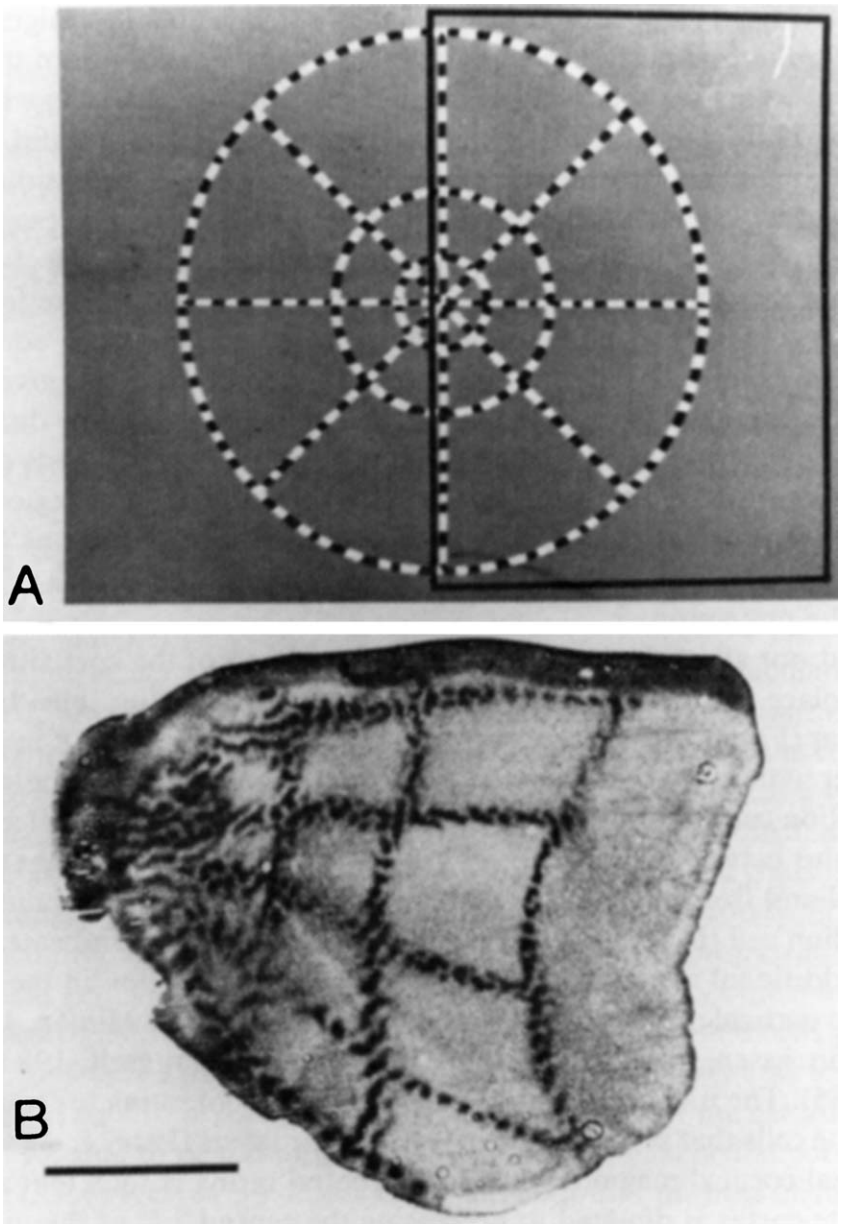

Figure 2 Retinotopic mapping of macaque monkey V1 cortex measured with radioactively labeled 2-deoxyglucose. (Top) The ring and ray pattern was presented to an anesthetized monkey for a long duration. The pattern that was exposed to the left visual cortex is shown. (Bottom) Autoradiograph of V1 showing the regions of V1 that took up the labeled 2-deoxyglucose (dark regions). This shows the mapping of the rings and rays into straight lines on the cortical surface (reproduced with permission from Tootell *et al.*, 1982). Deoxyglucose analysis of retinotopic organization in primate striate cortex. *Science* **218,** 902–904.

is the projection of the horizontal meridian. It is important that the projection to V2 (and also V3) of visual image regions just above and just below the horizontal meridian projects to cortical subregions that are widely separated. This means that local circuits that may compute spatial linking between local stimuli encounter a wide chasm in extrastriate cortex at the horizontal meridian; therefore, it is likely that visual signals from upper and lower visual fields are processed separately in extrastriate cortex. This does not apply to V1, in which neurons are mapped smoothly across the horizontal meridian. This can be

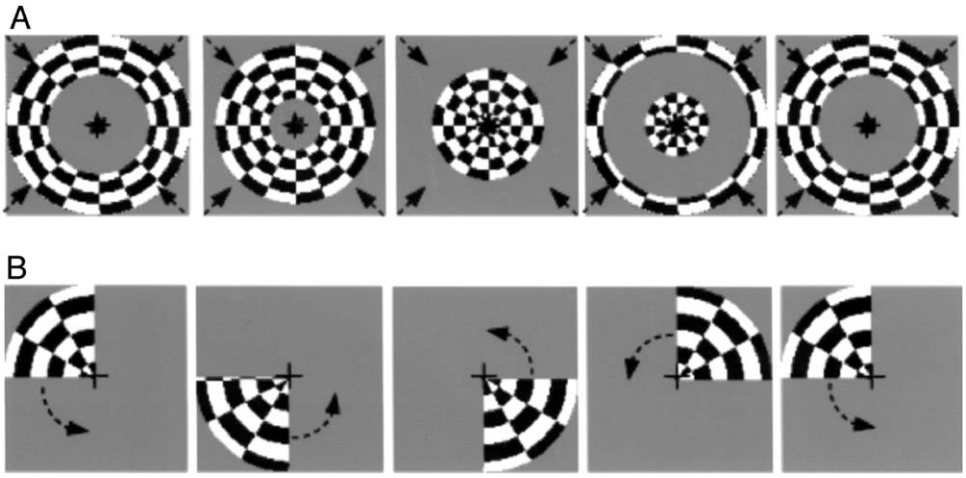

Figure 3 Diagram of the stimuli used in the phase mapping technique for fMRI. Radial checkerboards are the basic stimuli. In A, used for eccentricity mapping, rings of the underlying checkerboards are propagating inwards to a focus of contraction. In B, a rotating wedge of checkerboard is shown, and the wedge's azimuth varies with time [reproduced with permission from Wandell (1999). Computational neuroimaging of human visual cortex. *Annu. Rev. Neurosci.* **22,** 145–173.]

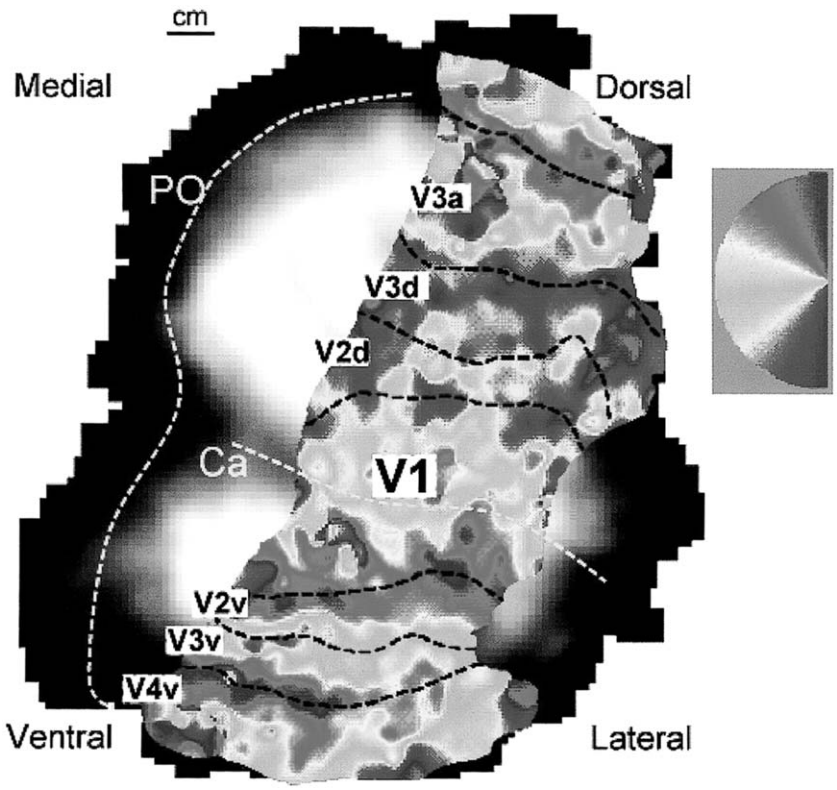

Figure 4 Retinotopic mapping in the human cortex measured with fMRI. Phase mapping as in Fig. 3 was used. In this example, only azimuth is mapped, as indicated in the inset, which gives the key to angle. The map is onto a mathematically flattened cortex and shows the transitions between retinotopic areas along the meridians [reproduced with permission from Wandell (1999). Computational neuroimaging of human visual cortex. *Annu. Rev. Neurosci.* **22,** 145–173.] (See color insert in Volume 1).

seen best in Fig. 1. The continuous mapping in V1 and the discontinuous mapping in V2–V4 are likely to have functional consequences for vision.

In the human visual cortex, mapping experiments such as those in Figs. 3 and 4 indicate that the right and left hemifields are kept distinct through several extrastriate regions, including V1–V4. Signals from the right and left visual fields are not combined until one reaches the lateral occipital cortex (LOC), an area discussed later. Therefore, there are two "seams" in the mapping of the visual world onto early visual cortical processing areas from V1–V4 and possibly beyond. One seam is the vertical meridian that separates the right and left visual fields. The second seam is the horizontal meridian that separates the upper from the lower visual fields. Our visual perception appears to be seamless, subjectively. The unified worldview we have must be the result of a combination of visual signals across these seams in the mapping in a manner that remains to be discovered. The interhemispheric mapping of the visual world in LOC and anterior visual areas is likely to be significant in producing the seamless appearance of the visual world.

III. SEGMENTATION

There is a great transformation that takes place in visual perception between the analog representation of the visual image in V1 and the symbolic representation of surfaces and objects as they appear to us. In V1, as in the retina, there seems to be an analog map of the brightness and colors in the image. However, when we perceive a meaningful natural image, we see a countable number of surfaces and discrete objects that are segregated from the background and from other objects. There are probably many stages of this transformation, but one stage of this process is known to be of great importance: visual segmentation. Segmentation is a process that involves the grouping of object parts together in a separated figure that is distinct from what is around or near it. Often, this process must group together parts of an object in an image that are separated from each other by an occluding object in front of the object to be segmented. Segmentation is necessary for correct organization of a scene because it allows the organizing process to know which are the surfaces that must be ordered in depth. Also, the action of segmentation could contribute to the scene organization computation because it needs to resolve occlusions that are a strong clue to depth order and therefore, scene organization.

As with many brain computations, we can understand segmentation better by observing its action when it deals with an exceptionally difficult task. Usually, segmentation is so smooth and efficient that we are unaware it is happening. However, for certain special visual images, the segmentation process becomes evident. This is the reason for the fascination with these special images, the so-called illusory contours (ICs). An example of such a visual image is shown in Fig. 5, which presents an image that is referred to as a Kanizsa triangle, named after the Italian Gestalt psychologist Gaetano Kanizsa. In Fig. 5, the perception of a bright white triangle is very strong, but if one scrutinizes the boundaries of the triangle it becomes evident that there is no difference in the amount of light coming to the eye from the regions inside and outside the perceived triangle. However, we see the inside as a bright surface segmented from its background by sharp contours along the boundary of the triangle. In this sense, the boundary between inside and outside the triangle is an illusory contour. This image is a classic example in favor of the basic concept of the Gestalt psychologists—that the brain is searching for meaningful patterns. In this case, the brain manufactures a perceptual triangle from fragmentary information because a meaningful pattern, an occluding triangle, is consistent with the available image information even

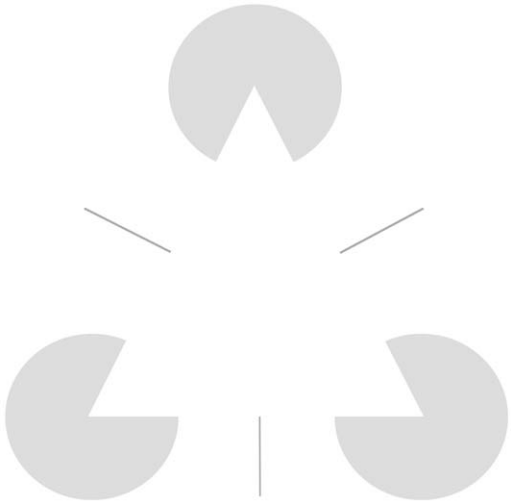

Figure 5 Kanizsa triangle. The occluding triangle that appears in front of the three circles and the three line segments is of the same physical brightness as the surroundings. However, it appears brighter and appears to be a solid surface in front because of perceptual processes.

though other perceptions are possible. It is reasonable to believe that the segmentation computations that the visual system performs on these exceptional Kanizsa images are the same as for more typical images.

From electrophysiological single-cell recordings in awake monkeys, von der Heydt, Peterhans, and colleagues found that Kanizsa-type images and other illusory contour images could excite spike activity in neurons in early visual cortex. An example of one of their experiments is shown in Fig. 6. They recorded from a single neuron in area V2 of the macaque visual cortex. The neuron's activity is depicted as a raster plot of spikes vs time during repeated presentations of the stimuli. The neuron responds with excitation to a luminance contour that crosses its receptive field. When an illusory contour (as perceived by us) crosses its receptive field, the cell produces a slightly delayed excitatory response resembling the response to a real contour. As a control that the response is not merely a weak response to the remote features of the IC stimulus, the investigators made a small image manipulation (closing the inducing boundary) and this eliminated the neuron's response. Von der Heydt and Peterhans also performed several quantitative studies on these IC-responsive V2 neurons, particularly the measurement of the orientation tuning for illusory and real contours on the same population of V2 neurons; they found that real and illusory contours produced similar orientation tuning in IC-responsive neurons in V2. Thus, these neurons seem to be a candidate neural substrate for illusory contour perception. There have also been reports of IC responses in neurons in V1. This is a controversial issue since von der Heydt, Peterhans, and colleagues maintained that they observed very few V1 neurons that produced IC responses. The discrepancy may occur in part perhaps because of the use of different stimuli and in part because of different views of what constitutes an illusory contour. For present purposes, it is enough to conclude that IC responses can be observed in

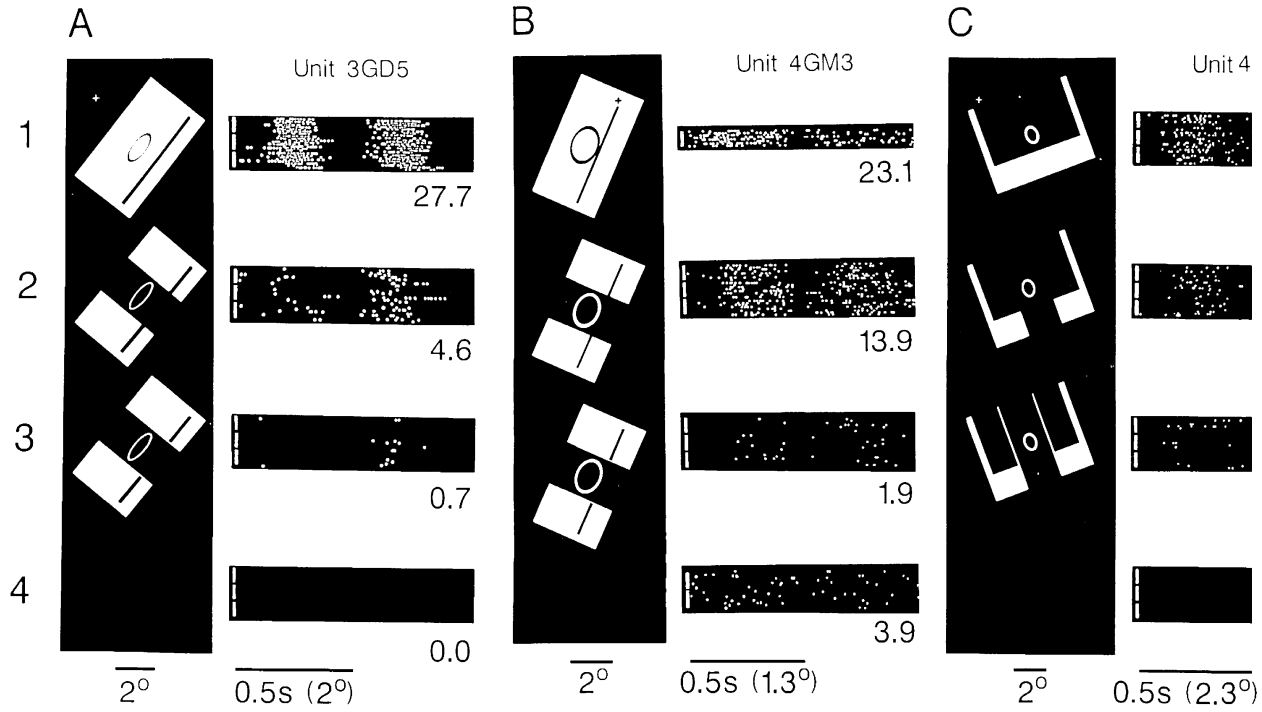

Figure 6 Responses of three macaque V2 neurons to ICs. Stimuli are shown in the insets next to raster plots of neuronal responses, in which each white dot is a nerve impulse. The raster shows multiple repeats of the same stimulus swept over the receptive field repeatedly. The crosses indicate the fixation point, and ellipses mark the classical receptive field of each neuron. In each case, row 1 is a conventional luminance stimulus, row 2 is the IC stimulus, and row 3 is a control stimulus, where a small image manipulation destroys the IC percept. Row 4 is a blank control to show the spontaneous firing rate [reproduced with permission from Peterhans and von der Heydt (1989). Mechanisms of contour perception in monkey visual cortex. II. Contours bridging gaps. *J. Neurosci.* **9,** 1749–1763.]

retinotopic areas in the monkey's brain—areas that are traditionally thought of as stimulus driven.

The connection of the monkey V2 neurons with IC perception in humans needs to be established more firmly. We do not know the nature or quality of IC perception in these animals because there are insufficient animal data from rigorous experiments to test for IC perception. Once we know whether monkeys can exhibit behavior that proves they see illusory contours in Kanizsa-type images, further experiments would be necessary to determine whether or not the V2 neurons have the same sort of parameter dependence on size, contrast, and retinal location as the behavior. How do the V2 neurons respond to an illusory contour that crosses the horizontal meridian? Humans respond as well to such illusory contours as they do to ICs that do not cross the horizontal or meridian. The reader can observe this for himself or herself by fixating the middle of the Kanizsa triangle in Fig. 5 and observing the robust lateral ICs that traverse the horizontal meridian in his or her visual field. However, in V2, there is a marked separation between neurons that represent the visual field just above and just below the meridian. Therefore, one might expect some deleterious effect on IC responses for meridian-crossing ICs in V2 neurons. If that decrease in IC sensitivity in V2 neurons were observed, it might cast doubt on the role of V2 alone in IC perception. Moreover, as discussed later, the human data point to other brain areas as the major processing sites for ICs. The monkey results could be interpreted to indicate that similar IC-related activity is occurring in human V2, but fMRI and other techniques used on humans are too insensitive to measure it. A second possibility is that the V2 activity seen in monkeys is related to IC perception but is not the central mechanism involved in the percept. Another possibility is that human and monkey perception and neural mechanisms are fundamentally different at this midlevel stage of visual processing.

Human responses to ICs have been measured with fMRI techniques. Most fMRI studies have involved the measurement of the activation of Kanizsa squares or diamonds compared with the same pacman-shaped inducers rotated outwards or all in the same direction. Pacman is a term that refers to the shape of an agent in a video game from the early 1980s. The shape of "Pacman" was exactly the same as the cut-off circles used by Kanizsa in the IC figures he originated. Early studies by Hirsch and colleagues and by Ffytche and Zeki found that there was activation of the occipital cortex lateral to V1 by Kanizsa-type figures, but they could not pinpoint the cortical location because the IC experiments were not combined with retinotopic mapping. Therefore, these studies established that signals related to segmentation were present in occipital cortex, but further work was needed to determine more precise localization.

The extensive research of Janine Mendola and colleagues established that IC-related signals were observed in retinotopic area V3 and also in LOC, the lateral occipital area previously discovered by Malach and colleagues. Figure 7 is an fMRI image indicating the large region of cortical activation evoked by the Kanizsa diamonds used as stimuli in Mendola's study. The early retinotopic areas V1 and V2 did not produce statistically significant activation. Mendola and colleagues also used different inducers for ICs, such as aligned line endings, and found a similar pattern of brain activation in V3 and LOC. These results are important in implicating extrastriate cortex in the process of visual segmentation in humans.

Although ICs are often chosen for studying visual segmentation, other visual phenomena can lead us to an understanding of this very important process. The assignment of an image region as figure or ground, is one such phenomenon. As Edgar Rubin, the famous perceptual psychologist, pointed out in 1921, such assignment is automatic and inescapable. However, ambiguous figures exist in which figure and ground assignments flip back and forth, and perception changes when that happens. The familiar face/vase figure from E. Rubin is the most reproduced example, but there are other examples from Rubin that illustrate the consequences of figure/ground assignments even better. One of these is the Maltese cross figure shown in Fig. 8. This example is described in Koffka's 1935 book but not depicted in it. The diamond-shaped arms of the cross can appear grouped in fours, with a vertical and horizontal pair grouped together as figures in front (resembling a propeller in shape) and then two diagonal pairs grouped together as figures in front (and the vertical–horizontal pairs are then in back). The contrasts in the figure are arranged such that the vertical–horizontal propeller shape looks darker in front than it does when it is perceived "in back," appearing as a light gray diamond behind the white tilted propeller. This is because of the enhanced effect of brightness contrast across borders that define a figure and on the regions to which such borders are attached, as Rubin noted. Similar effects can be seen in color. This is only one of many illustrations of the deep consequences of figure/ground assignment. For instance, another consequence of the importance of

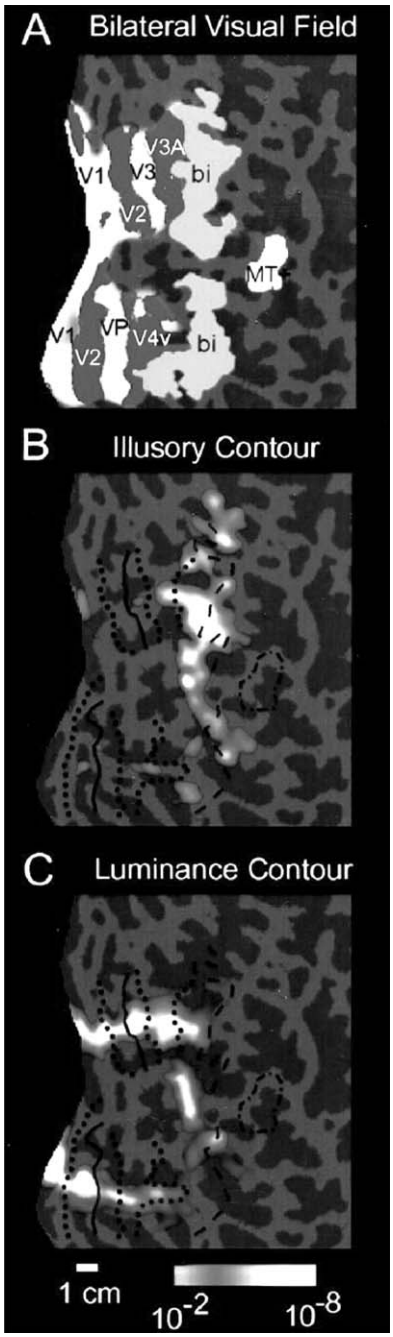

Figure 7 Mapping of IC responses in human cortex with fMRI. (A) Map in human visual cortex of retinotopic visual areas and also the interhemispheric region as obtained by use of phase mapping as in Figs. 3 and 4. (B) The region of differentially high activity when Kanizsa illusory contours are compared with activation produced by the unorganized pacman inducers. The main activation is in V3A and in the interhemispheric region. (C) Activation produced by a square defined by luminance contours [reproduced with permission from Mendola *et al.* (1999). The representation of illusory and real contours in human cortical visual areas revealed by functional magnetic resonance imaging. *J. Neurosci.* **19,** 8560–8572.]

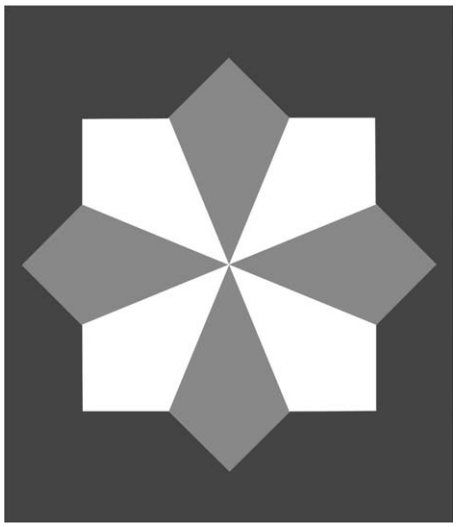

Figure 8 Maltese cross figure from E. Rubin. There are two sets of vanes, white and gray. They group together to produce "propeller" figures that alternate front and back. When the propeller of a given color is seen in back, it tends to complete into a gray diamond or a white square, respectively. Some observers report that the perceived value of the gray changes, becoming darker when the gray regions form a propeller in front and lighter when they form a diamond in back (drawn from a description in Koffka, 1935).

figure/ground is that people remember the shapes of figures, not grounds. Therefore, understanding the neural basis for this phenomenology is an important clue to the function of the visual system.

Figure/ground assignment is a special case of a more general problem in vision—the assignment of border ownership. Assignment of a region as figure or ground is all one has to do if there is only one figure surrounded by the background. However, if there are many figures, and if one is in front of another so that it partly occludes the shape of the second figure in the visual image, then the visual system must decide on the basis of image information which surface is in front along the boundary between the two figures in the image. Briefly, the brain has to decide which figural region owns the border between them (i.e., the front surface). Assignment of border ownership is a problem that must be solved for almost every visual image.

There have been only a few investigations of neural mechanisms for border ownership and figure/ground assignments. Zhou and colleagues studied single cells in V1 and V2 cortex of macaque monkeys. By keeping local edge contrast the same but varying the global stimulus so that different regions own the boundary between them perceptually, Zhou *et al.* tested

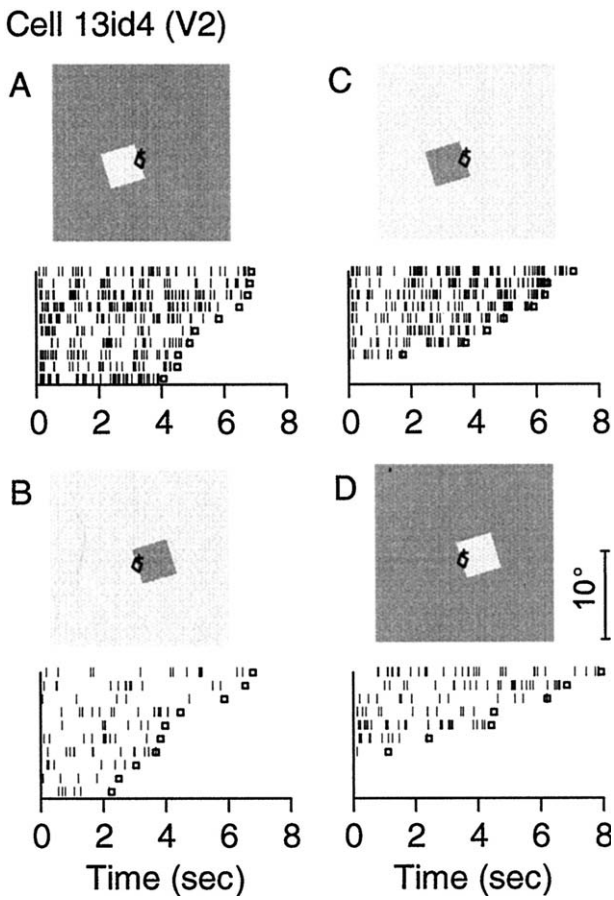

Figure 9 This is a representative neuron from V2 cortex in a macaque monkey that reveals sensitivity to border ownership. The same polarity edge border is in the pairs A and B and C and D, but the cell responds most strongly when the border "belongs" to a figural region down and to the left of the cell's receptive field (black line). Each vertical stroke in the raster plots stands for a nerve impulse [reproduced with permission from Zhou *et al.* (2000). Coding of border ownership in monkey visual cortex. *J. Neurosci.* **20,** 6594–6611.]

sensitivity to border ownership in single cortical neurons. The experimental design and results in an archetypal border ownership cell are shown in Fig. 9. A substantial number of cells such as this are encountered in monkey V2 cortex. Baylis and Driver reported that many neurons in monkey inferotemporal (IT) cortex respond differentially to figure or ground; thus, these also must reflect signals about border ownership. Since the IT cortex is supposed to be involved in object recognition, it is reasonable that neurons in this area should be affected by border ownership that is necessary for accurate object recognition in the real world.

Studies by Kleinschmidt and colleagues of figure/ground reversals in human cortex using fMRI revealed activation over a number of areas in occipital, temporal, parietal, and even frontal cortex. The involvement of temporal, parietal, and frontal cortex seems to imply that activation of top-down influences from "high-level" cortical areas could be necessary for figure/ground reversal of border ownership. However, as in the case of ICs, it is also possible that there may be signals associated with figure/ground assignment in "early" retinotopic areas, such as V1 or V2, that are undetectable with fMRI.

An important part of segmentation in human visual perception is the phenomenon of amodal completion—that is, completion and grouping together of the parts of a partially occluded object that are visible. This completion process is crucial for normal object perception in the real world. Evidence that amodal completion affects the firing rates of V1 neurons in macaque V1 was obtained by Y. Sugita by manipulating apparent occlusion using stereopsis (Fig. 10). Only a small fraction of V1 neurons were affected by amodal completion, but it is still a significant result.

IV. MT AND MOTION

Two of the strongest stimulus cues for segmentation are motion and color. This makes sense ecologically since it is unlikely that separate things will move together for any length of time, and similarity in color is associated with similarity in surface properties. The visual cortex appears to agree with this reasoning because it devotes a large amount of specialized cortical processing for motion and for color. We first consider motion processing in the middle temporal area MT (or V5). This brain area was initially defined by Zeki in his early work in the macaque extrastriate visual cortex. Zeki noted the large number of directionally selective cells in what he called V5, the middle temporal area later called MT by others. In human cortex, a motion-sensitive homolog to macaque MT was suspected from neuropsychological work on brain-damaged patients. Zihl and colleagues described a patient who had a lesion in dorsolateral occipital cortex and who had lost the ability to see motion. The motion-blind patient reinforced the concept of Zeki and others that there was a discrete brain region, assumed to include MT, that was obligatory for the perception of motion.

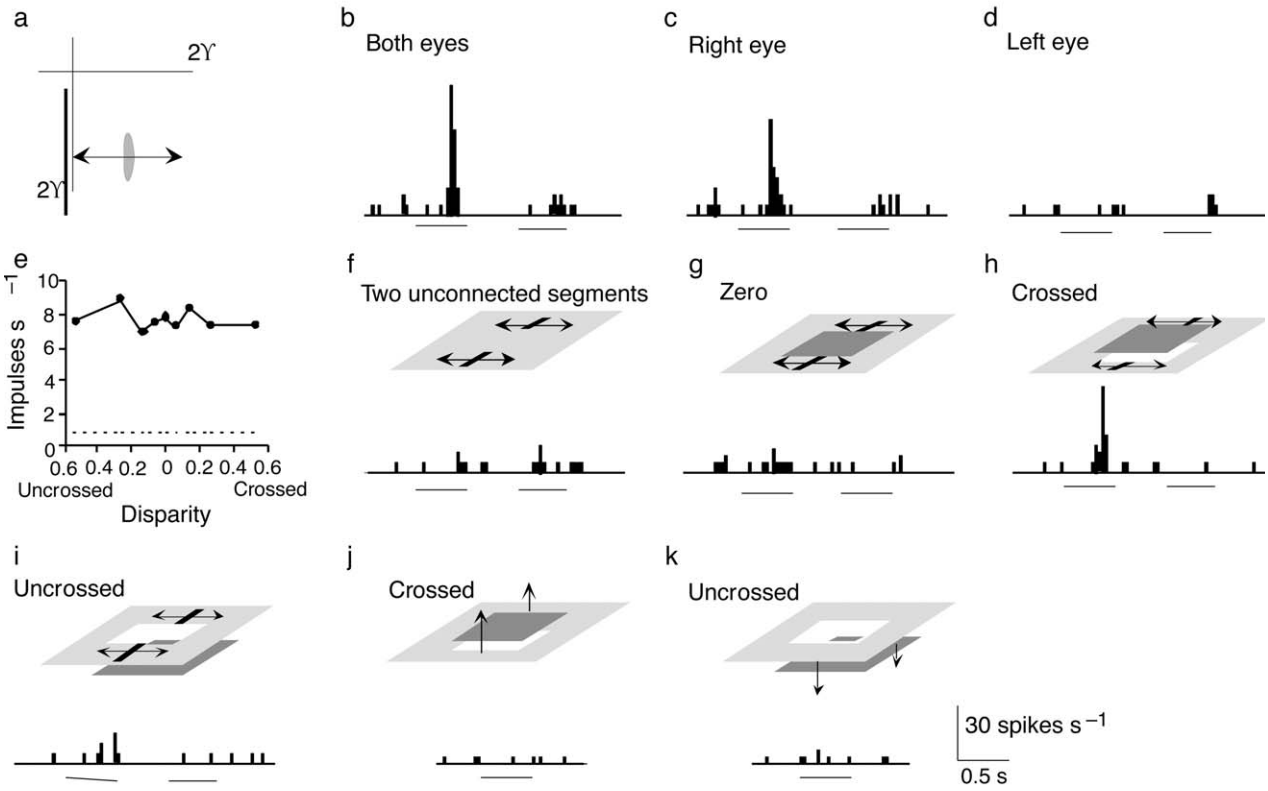

Figure 10 Macaque V1 neurons that respond to amodal completion. The neuron responds to a long contour in its receptive field as in a. It responds to both eyes (b) and to the right eye alone (c) but not to the left eye alone (d). The interesting manipulation is in f–h. In f, the neuron does not respond to two unconnected segments. In g, it does not respond to the same two segments when they are perceived as being in front of a gray region. However, there is a response when the retinal disparity is such that the gray region is in front and occluding the two line segments (h) [reproduced with permission from Sugita (1999). Grouping of image fragments in primary visual cortex. *Nature* **401,** 269–272.]

Functional imaging in normal human subjects, with visual stimulation by moving dots compared to stationary flashing dots, indicated that there was a discrete region in dorsolateral occipital cortex (lateral, dorsal, and anterior to LOC) that had most differential activity. Figure 11 shows the location bilaterally of what is now assigned to be human MT (V5). This is shown in a drawing of a slice of brain, not a flat map. Many other groups have confirmed this localization of MT in human cortex. The location of MT in the flat map representation of fMRI images of occipital cortex is given in Fig. 7 (top), in which MT's 1ocation is mapped and the locations of the retinotopically mapped areas are also indicated.

Classic results on MT in monkey cortex tended to confirm the notion that MT neurons were devoted to extracting velocity (direction and speed) of contours or patterns over the large receptive fields of the MT neurons. A significant number of MT neurons are directionally selective when stimulated with drifting bars or grating patterns. Using plaid patterns similar to those that Hans Wallach introduced to study motion coherency and transparency in human perception, Tony Movshon and colleagues found that some MT neurons were tuned to the coherent motion direction of a plaid pattern, whereas other MT cells were only selective for the motion directions of the component gratings that summed to make the plaid. These two kinds of neurons were given the labels "pattern" and "component" neurons, respectively. The assignment of two separate names might be supposed to carry the implication that there are distinct classes of neurons in MT. However, this was not claimed. In fact, existing data tend to suggest that there are not two distinct types of neurons in MT but rather a continuum of pattern vs component

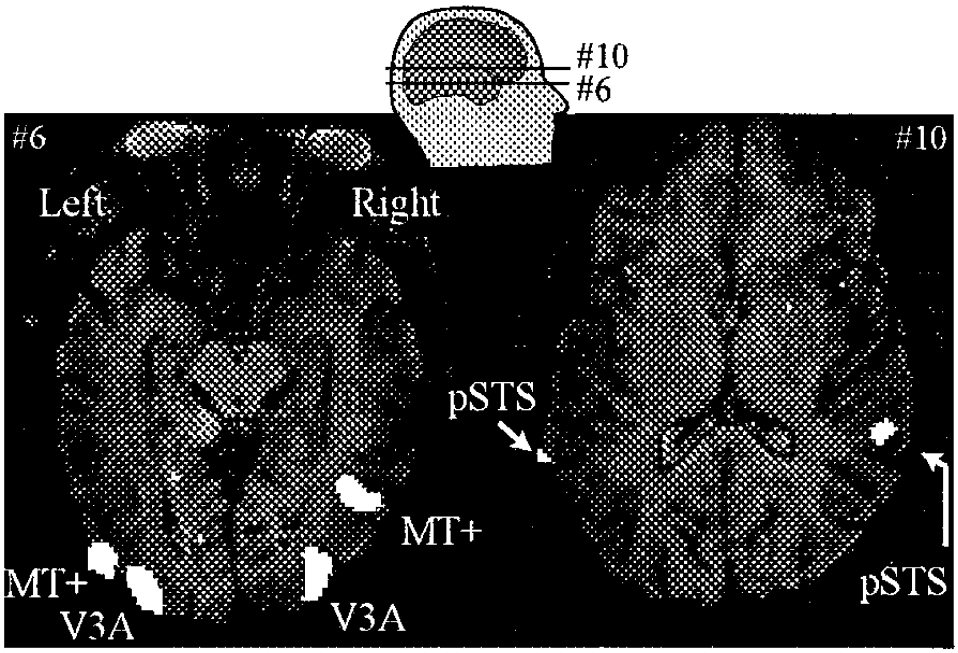

Figure 11 Mapping of human MT with fMRI. Moving vs stationary dot patterns elicit two active regions in the posterior cortex. These are labeled V3A and MT in slice 6 from comparisons with retinotopic maps. A parietal cortex region is also activated by moving vs stationary stimuli and this is shown in slice 10 [reproduced with permission from Ahlfors *et al.* (1999). Spatiotemporal activity of a cortical network for processing visual motion revealed by MEG and fMRI. *J. Neurophysiol.* **82,** 2545–2555.]

selectivity. There is definitely a large group of "mixed" cells that are partially component and partially pattern selective.

Although many macaque MT cells respond to grating patterns and contours, most MT cells respond most vigorously to small dots or populations of dots moved through their receptive fields. Also, it was shown that MT neurons would respond to coherent motion of a proportion of dots embedded within random dot kinematograms, and that the coherency thresholds for individual MT neurons were similar to behavioral thresholds for the monkey. This work in Bill Newsome's laboratory suggested that MT was involved in the perception of coherent motion in a definite direction. The work on cortical microstimulation in macaque MT cortex by Salzman and colleagues in Newsome's laboratory showed that differential activation of subpopulations of macaque MT neurons could bias perceptual judgments of coherency. Indeed, when coherency was low, MT microstimulation could cause the monkey to behave as if it perceived the random dot kinematogram with no coherent dot motions to have significantly suprathreshold coherency. These results were consistent with the interpretation that MT activity determined the perceptual judgment of coherency and direction.

Braddick and colleagues studied human fMRI response to coherency of motion in random dot kinematograms, in analogy to the experiments done by Newsome's group on macaque MT. Their experimental design was broader in that they were comparing the pattern of activation in different cortical areas in response to different kinds of stimuli that were designed to elicit responses to motion coherency and to form coherency. However, for the current discussion, we focus on the motion coherency results. Their stimuli for motion coherency were in essence the same as those used by Salzman *et al.* The comparison stimulus in their fMRI experiments was totally incoherent random motion of a field of dots. They found a widespread pattern of activation caused by motion coherency including MT (V5), the retinotopic area V3, as well as isolated regions of temporal and parietal cortex.

The role of human MT in motion perception has been examined in another kind of experiment: the correlation of brain activation with the motion aftereffect by Roger Tootell and colleagues. Prolonged

viewing of motion in one direction leads to a familiar perceptual aftereffect when the stimulus motion ceases. Stationary objects appear to move in the opposite direction. Tootell *et al.*'s fMRI study of the motion aftereffect used expanding concentric rings as a motion stimulus and stationary concentric rings as a control. They found that at the termination of the motion stimulus, MT activation continued for another 20–30 sec. This prolonged afteractivation paralleled almost exactly the subjective perception of the motion aftereffect (apparent contraction of the concentric rings). Because there was no physical motion during the aftereffect period, but there was subjective experience of motion counter to that seen during the stimulation period, this is a very strong result indicating that MT activation is correlated with the subjective experience of perceived motion. Other studies have confirmed this result, finding motion aftereffect activation in MT.

A number of recent studies indicate that MT cortex is not simply responding to motion direction or speed but, rather, may be playing a role in visual segmentation. For example, at the Salk Institute, Stoner and Albright, working with Ramachandran, initiated a series of studies combining experiments on human perception and on single cells in macaque MT that indicate that MT neurons are affected by form cues as well as by motion. They used plaid patterns and studied human perception of coherency as they changed the brightness at the intersections between the lines of the plaid. When the intersection brightness was not compatible with optical transparency of the perceived overlaying line, the probability of perceiving coherency was high and the probability of perceiving transparency was low. When the intersection brightness was compatible with transparency, the probability of perceiving motion transparency became greater. This perceptual effect was also confirmed in macaque MT neurons, as shown in Fig. 12. The direction selectivity of neurons in MT was changed by the same manipulation of intersection brightness and hence of consistency with physical transparency. Thus, in macaque monkey MT there is evidence that individual neuron activity is determined by segmentation (or combination) of motion signals contingent on cues for transparency.

Another line of evidence that macaque MT neurons are responding to moving surfaces and not simply a

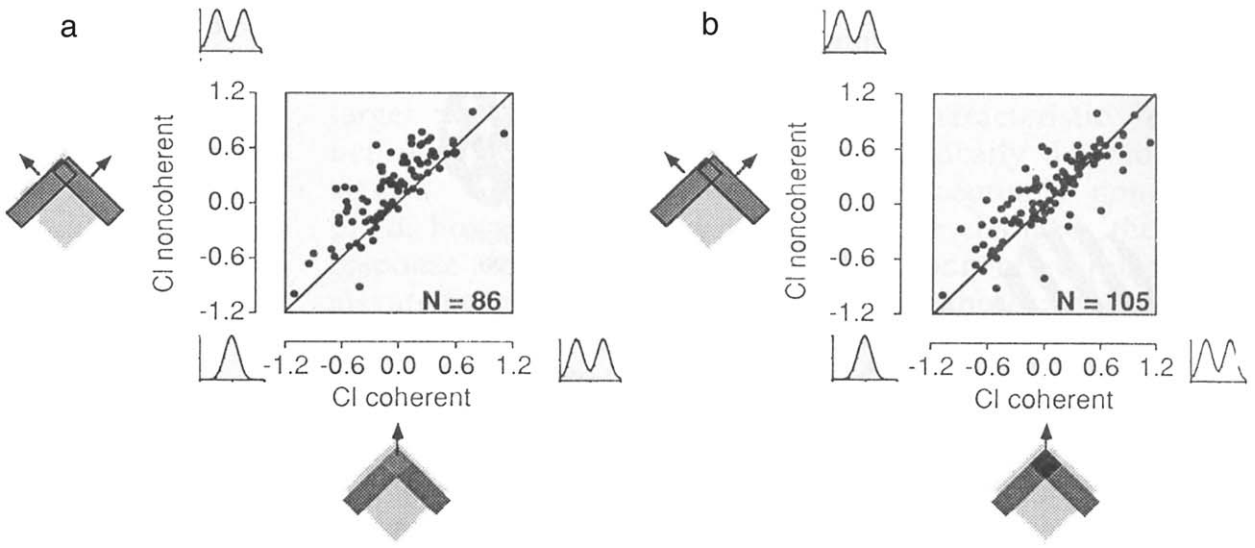

Figure 12 The effect of static form cues on motion coherency in MT neurons in macaque visual cortex. Plaid patterns were moved through MT receptive fields. Each point in each graph represents a single neuron and the scatter plots represent the entire population of MT neurons studied. The graphs plot the calculated component index (CI), which estimates the amount of a neuron's directional tuning curve that is explained by transparent (or "sliding") motion as opposed to coherent plaid motion. The horizontal axis in each graph is the CI measured and calculated for stimuli that should be perceived as coherent because the static brightness of the intersection is not consistent physically with transparency. The vertical axis is for a case in which the intersection brightness is consistent with transparency. The tendency of the points to lie above the line indicates that when physical transparency is possible, motion transparency is perceived more often [reproduced with permission from Stoner and Albright (1992). Neural correlates of perceptual motion coherence. *Nature* **358,** 412–414.]

velocity vector derives from experiments on the phenomenon of the kinetic depth effect (KDE). This is a classical perceptual phenomenon introduced and explored perceptually by Hans Wallach and one of his students in 1953. A visual image formed by the projection of a moving 3D object on a flat screen elicits a strong perception of 3D structure. The perceptual ability to see KDE is the most important means for judging 3D shape for objects that are too distant for a subject to use binocular stereopsis for depth and shape judgments (i.e., for distance >5 m). Such depth from motion is combined with stereo for depth judgments at any distance. David Bradley and colleagues found that many macaque MT neurons were tuned for depth. This finding was confirmed and amplified by the later work of DeAngelis and co-workers, who showed that there was an orderly mapping of depth in MT cortex. For example, some MT neurons would be responsive only when the moving target was in front of the fixation plane. Bradley then showed that such depth-sensitive MT neurons were not only responsive to depth based on stereopsis but also signaled depth from KDE (Fig. 13). The KDE stimuli used by Bradley *et al*. were random dot kinematograms like those used in the 1970s for studying KDE perception by Shimon Ullman and others. The moving dot flow fields are ambiguous stimuli that could be perceived in a number of ways. Bradley *et al*. demonstrated that the neurons responded to KDE when the monkey perceived the KDE as creating a surface at the appropriate depth for the neuron's depth tuning. This is an important result that indicates the perceptual sophistication of MT neurons. However, in this case the homology with human MT may be less close than in other interspecies comparisons. In an experiment on KDE in humans, Paradis and colleagues used fMRI. It revealed that many areas of the brain responded differentially to KDE, but MT was not among those KDE regions. Rather, V3 and regions in parietal and temporal cortex were activated more by KDE than by random dot motion. These authors speculated that in humans, the higher form-related functions of MT were taken over by parietal cortex.

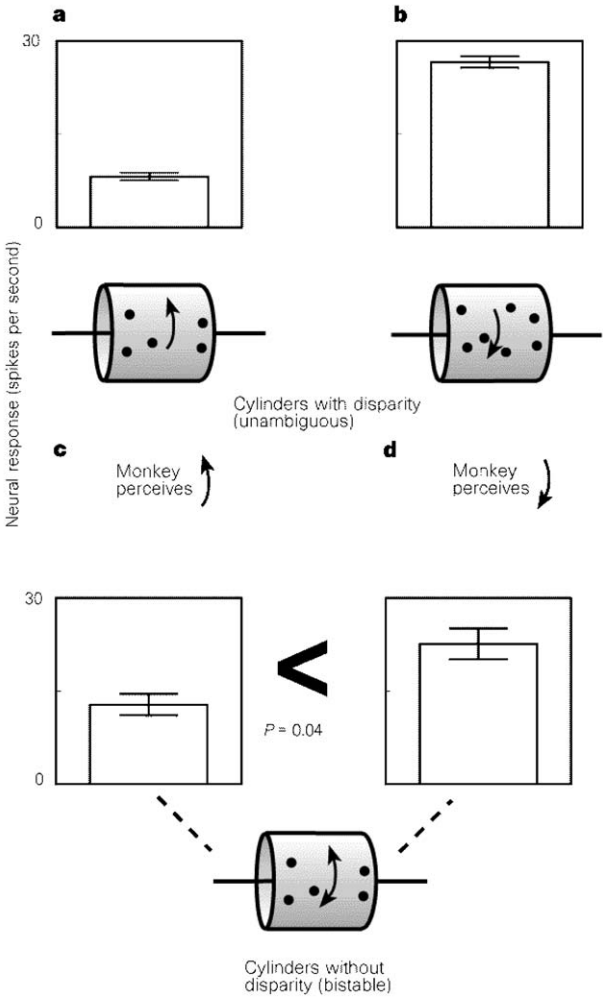

Figure 13 KDE in macaque MT neurons. Monkeys viewed two-dimensional projections of three-dimensional, revolving cylinders. They reported the direction of rotation they perceived by choosing a target moving in the same direction as the perceived front surface. The depth of the cylinders could be determined by stereopsis using disparity or by the motion field (KDE). Data are from an MT neuron. (a, b) Responses to 100%-disparity cylinders (using only trials with correct responses). (c, d) Responses of the same cell to zero-disparity cylinders, when the monkeys reported them as going front-up (c) or front-down (d) [reproduced with permission from Bradley *et al*. (1998). Encoding of three-dimensional structure-from-motion by primate area MT neurons. *Nature*, **392,** 714–717.]

Another important result more directly indicates the linkage between form and motion in human MT. Rainer Goebel and colleagues, studying fMRI activation in humans by different apparent motion stimuli, found that apparent motion of organized Kanizsa squares elicited much more fMRI activation than did apparent motion of shuffled pacmen. This result also corresponds with perception: There is a much stronger percept of apparent motion with moving Kanizsa squares than with the same pacmen pointing outwards. These results suggest that the nature of human MT's response to moving visual surfaces needs to be further investigated. For instance, experiments such as those by Bradley combining motion flow fields with

variations in depth organization should be attempted on human MT and compared with Bradley's results in macaques.

V. COLOR IN VENTRAL OCCIPITAL BRAIN AREAS

The idea that there is a separate localized area in human extrastriate cortex that is specialized for mediating color perception is derived from the phenomenon of cerebral achromatopsia (cortical color blindness). Achromatopsia is usually caused by stroke lesions in ventral occipital–temporal cortex. It is a variable clinical syndrome, with the common feature that patients cannot pass tests indicating they can perceive colors normally. The critical test is the Farnsworth–Munsell 100 hue test, which involves color arrangement. Normal humans perform this test very accurately and achromatopsics can be at chance in this test of arranging hues in an orderly sequence. Failure on the 100 hue test correlates very well with subjective reports that the patients cannot tell what color they are looking at. Because this neurological syndrome is usually accompanied by lesions in a particular region of cortex, there is strong suspicion that this extrastriate cortex subregion is the color-specialist area, a view stated forcefully by Semir Zeki. However, we review and modify this concept of a color module in the following discussion.

Human imaging studies comparing activation by color vs achromatic patterns are quite consistent in identifying a ventral occipital–temporal region as the color area. Originally, this region was dubbed V4 by Lueck and colleagues, who used positron emission tomography (PET) to find the regions of the brain that were preferentially activated by color. This was later confirmed with fMRI by Zeki and colleagues. The naming of the color region as V4 cortex was done in analogy with Zeki's previous studies on macaque cortex, in which he proposed that macaque V4 was specialized for color processing. This proposal of color specialization in macaque V4 has been challenged many times and is still controversial, especially due to the research of Heywood and Cowey, who found that lesions in V4 did not have a major effect on color discriminations in monkeys. Hadjikhani, Tootell, and colleagues mapped the color area in the same manner as Zeki and colleagues, but they also measured retinotopic mapping in the same subjects to find out if the color area Zeki and colleagues discovered was indeed V4 in the retinotopic framework (Fig. 14). They found that it was quite anterior to V4 as measured with retinotopic mapping. There is no disagreement on the location of the color-preferring area, just on its proper name. Hadjikhani and colleagues added an elegancy to their study by showing that the color region they

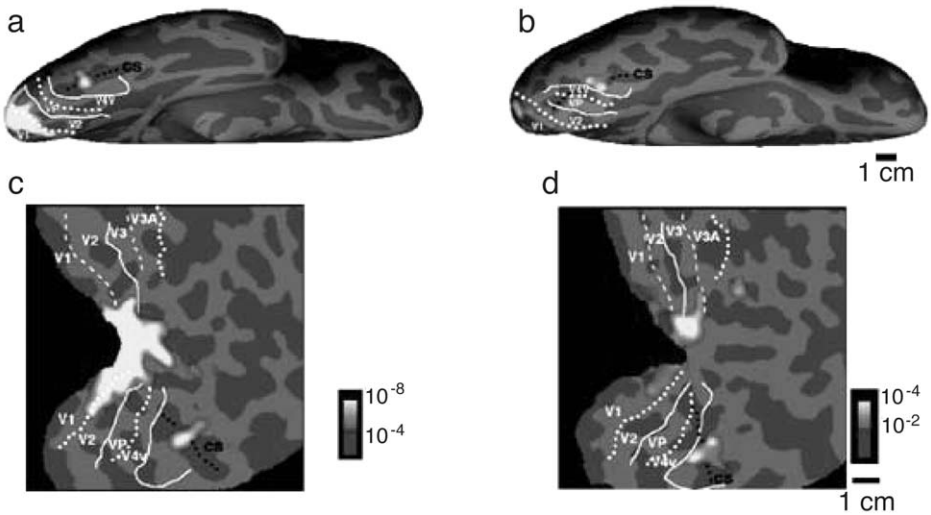

Figure 14 Mapping of human V8 cortex in ventral visual cortex with fMRI. The visual stimuli used for mapping were radial gratings that were either black–white or equiluminant color (red–green). The activation maps are for the difference between these two stimuli. The important point is the placement of the ventral activation outside the region of retinotopically mapped V4 [reproduced with permission from Hadjikhani *et al.* (1998). Retinotopy and color sensitivity in visual cortical area V8. *Nat. Neurosci.* **1,** 235–241.]

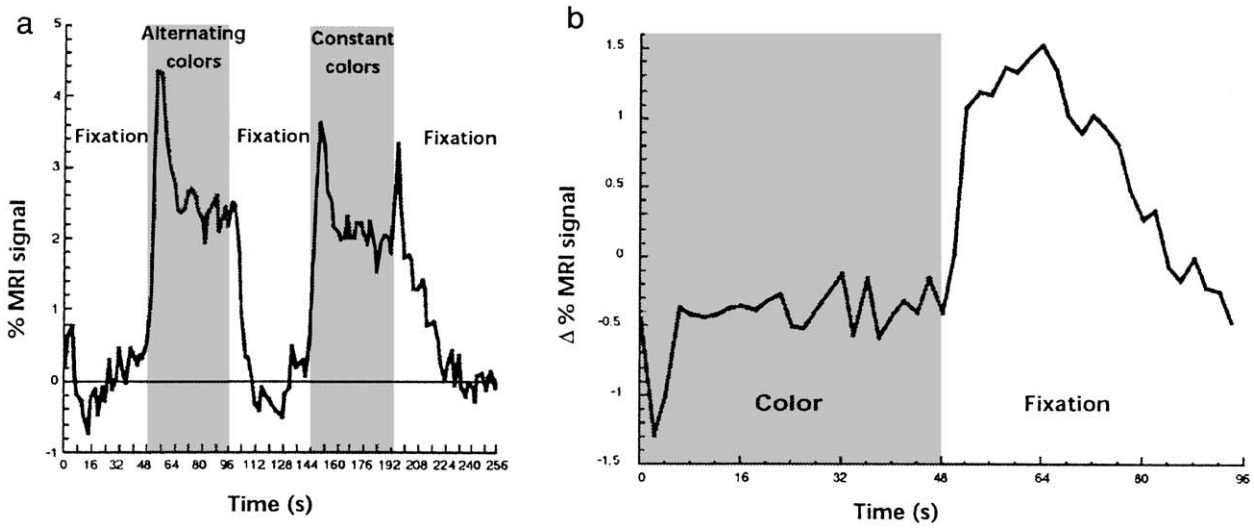

Figure 15 Color afterimages in fMRI of V8 cortex. (a) Activations caused by perceiving stimuli to create color afterimages. The fMRI activation for the constant colors condition outlasts the stimulus by 10–20 sec compared to the response to the alternating colors condition because of the color afterimage. (b) The alternating colors response has been subtracted from the constant colors response to illustrate the time course of the afterimage activation during the fixation period. Only regions of cortex activated by the color mapping stimulus exhibit these long afterresponses to color afterimages [reproduced with permission from Hadjikhani *et al.* (1998). Retinotopy and color sensitivity in visual cortical area V8. *Nat. Neurosci.* **1,** 235–241.]

found, which they named V8, responded persistently after a color stimulus ceased (Fig. 15). This poststimulus activity correlated with the perception of color afterimages. In this way, it resembled the motion aftereffect activity earlier observed in MT by Tootell and colleagues.

There are other methods for testing for color activation besides the differencing method used by Zeki and by Hadjikhani. The differencing method assumes that color perception will be associated with activation that is linked to color but that disappears when achromatic stimulation is used. Implicitly, this method includes the assumption that the neural mechanism for color perception is composed of neurons that only respond to color and do not respond to achromatic stimuli. Engel *et al.* showed that many other areas of visual cortex, including V1, will respond to purely chromatic modulation but will also respond to chromatic modulation. This finding in human fMRI is related to recent single-cell studies in macaque V1 that indicate that there are many neurons in V1 that respond to both color and brightness. Such neurons could play an important role in color perception but would be ignored by the difference image methods. Therefore, the amount of cortex involved in color perception may have been significantly underestimated by these difference methods, a point made by Brian Wandell. Nevertheless, it is important to note that the region of cortex involved in achromatopsia lesions and the region of cortex mapped with PET and fMRI with the differencing methodology are similar.

VI. OBJECT RECOGNITION IN LOC AND VENTRAL OCCIPITAL–TEMPORAL CORTEX

One of the chief functions of visual perception is object recognition. Although it is still too soon to tell the whole story of how the visual system recognizes and categorizes objects, recent research indicates remarkable specialization of specific regions in visual cortex for recognizing objects and even classes of objects. This topic can be subdivided into a discussion of LOC and ventral occipital–temporal cortex.

Lateral and slightly anterior to retinotopic areas V3A and V4V, there are regions of human occipital cortex that are activated preferentially by pictures of objects compared with pictures of random textures. This has been shown repeatedly in fMRI experiments

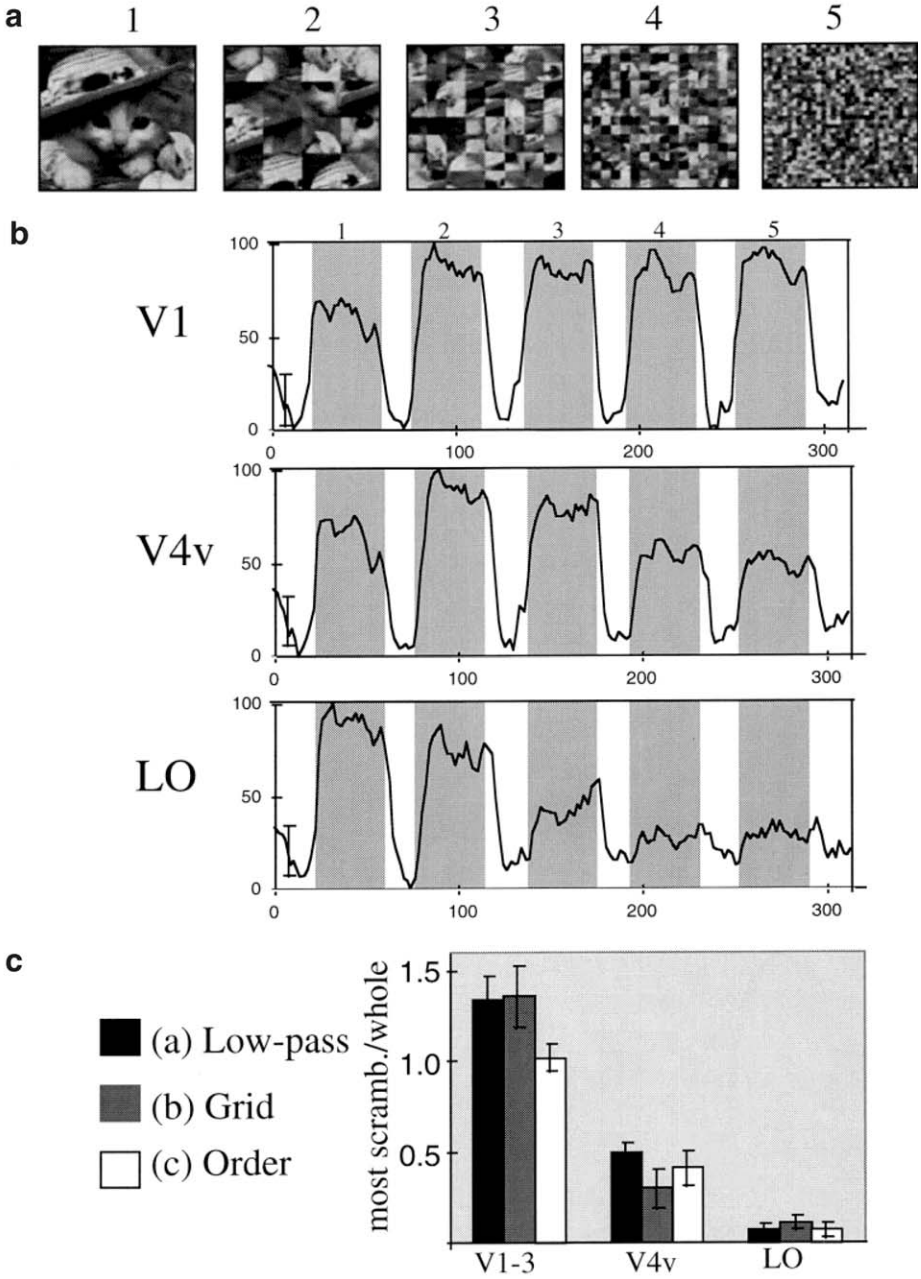

Figure 16 Responses in human fMRI to scrambled pictures of objects in LO and V1 and V4 cortex. Pictures such as those shown in row a were used as stimuli. (b) Time series of responses in LO, V1, and V4v. LO shows the largest effects of scrambling of the object pictures, indicating it is responding to large subregions of each picture and that it cannot tolerate disarrangement of the parts [reproduced with permission from Grill-Spector *et al.* (1998). A sequence of object-processing stages revealed by fMRI in the human occipital lobe. *Hum. Brain Mapping* **6,** 316–328.]

on human subjects, first by Rafi Malach working with Tootell and then by Malach and colleagues. The ventral region most strongly activated is called LOC. LOC activation has many distinguishing characteristics. In experiments with cut and scrambled pictures of objects, LOC activation declined only slightly when the pictures were cut into four pieces and scrambled, but it declined precipitously when the pictures were cut

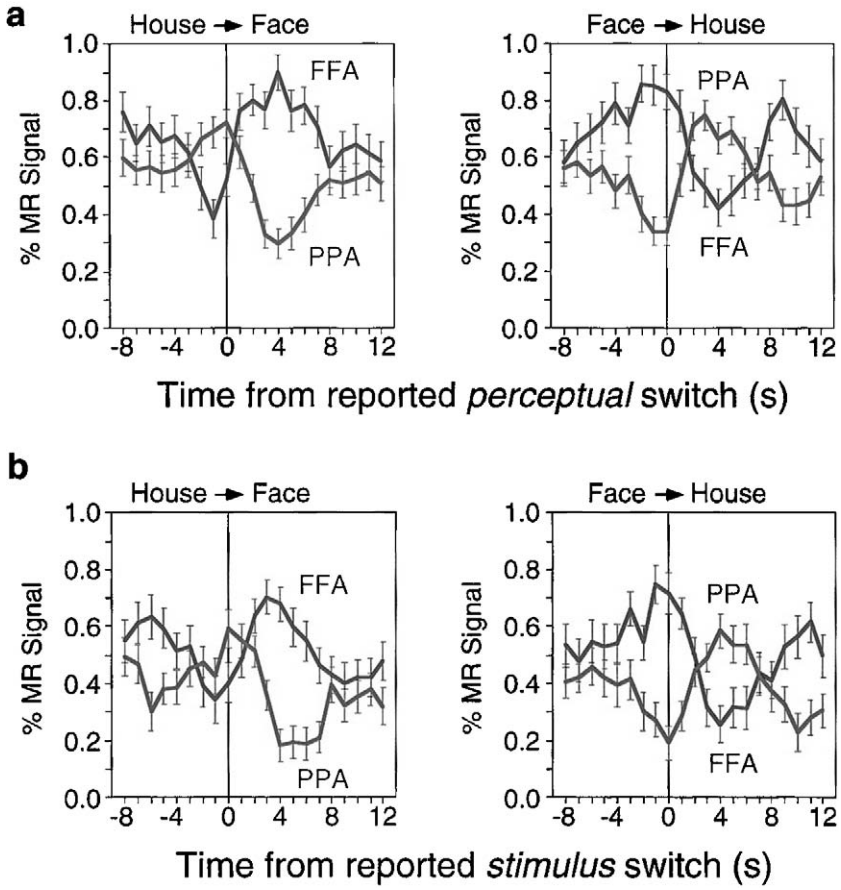

Figure 17 Binocular rivalry between pictures of faces and of houses. The fusiform face area (FFA) and parahippocampal place area (PPA) were monitored with fMRI in human subjects during binocular rivalry between pictures of faces and of houses. There was a clear modulation of the amount of activation during and after the switch from house to face and from face to house, as seen in a. (b) A control by stimulating both eyes with pictures of faces and of houses and measuring the magnitude of fMRI amplitude modulation caused by switching the stimuli and percepts [reproduced with permission from Tong *et al.* (1998). Binocular rivalry and visual awareness in human extrastriate cortex. *Neuron* **21,** 753–759.]

and scrambled into smaller pieces (Fig. 16). LOC activation was relatively invariant to change in location and to changes in the size of pictures of the same object. Therefore, activation of LOC seems to resemble neuronal activation in IT cortex of monkeys. LOC seems to have a bias toward visual information from the center of the visual field. From fMRI studies on retinotopic mapping, Tootell and colleagues concluded that the region in which LOC is located receives interhemispheric inputs, meaning that it represents visual signals coming from both right and left visual fields. LOC is also an area activated by the IC stimuli used by Mendola (Fig. 7). These various experimental results suggest that LOC could be an important area for intermediate-level vision, where segmentation and grouping are made explicit in the activity of neurons and neuronal populations.

Further specialization for the recognition of classes of objects has been found in occipital–temporal areas of human cerebral cortex. These areas are located in the ventral cortex and more anteriorly. A much studied region is the anterior fusiform gyrus, where pictures of faces activate the region preferentially, as first shown by Nancy Kanwisher and colleagues. It was shown that pictures of faces compared to pictures of houses activate this fusiform face area (FFA) differentially. Also, pictures of faces compared to inverted face pictures also produce differential activation in a

comparison paradigm. Nearby but distinct from the FFA is the parahippocampal place area (PPA), a region that prefers pictures of houses to those of faces. This more posterior region is located in the collateral sulcus, also in the ventral occipitotemporal cortex. Malach and colleagues showed that the FFA was biased more toward central vision, whereas the PPA in the collateral sulcus was biased more to the periphery of the visual field. Also, these occipitotemporal regions overlap with the interhemispheric region mapped by Tootell and thus represent both right and left visual hemifields.

The specialization of the face and house regions of the occipitotemporal cortex was shown in an elegant experiment by Frank Tong and colleagues. They used the phenomenon of binocular rivalry combined with fMRI measurements to explore the modulation of activity with change of perceptual state. Subjects viewed face and house pictures that were present monoptically—for example, a picture of a house to the right eye and a picture of a face to the left eye. In these circumstances, perception is bistable: First one sees a face, and then after some time the picture of the face fades and one sees a house, and the two percepts repeatedly alternate in perception. Tong and colleagues asked subjects to press different keys when they saw a face or house, and they averaged the fMRI signal with respect to the key presses. They observed the results in Fig. 17. FFA activation increased when subjects perceived faces in the rivalrous situation, and PPA activation increased when they saw houses. The respective activations were comparable to what was measured when only faces or only houses were shown. This experiment reveals in a very direct manner that activation of these specific cortical areas is highly correlated with the perception of specific categories of objects.

VII. CONCLUSION

Perception requires location and mapping of space, segmentation, sensitivity to motion and color, and recognition of familiar or unfamiliar shapes. We discussed all these aspects of visual perception and the areas of the cerebral cortex that are activated when these are seen. It can be concluded from the experiments we reviewed that the neural basis of visual perception is based on specialized modules in the visual cortex. However, in perception there can be an overriding influence of part of a visual scene on the perception of other parts of the scene, as in the effects of visual cues for segmentation. Therefore, it cannot be definitively concluded that specialized modules are all there is to neural mechanisms of visual perception. A major role may be played by the interaction between different visual areas and between the visual networks in occipital cortex and memory- or decision-related cortical networks elsewhere in the brain. As the Gestalt psychologists used to say about visual images, so also we can say about the visual cortex: The whole is greater than the sum of its parts.

Visual and Auditory Integration

JENNIFER M. GROH and URI WERNER-REISS
Dartmouth College

GLOSSARY

binding The mutual association of all the component features of an individual object or event. Within the visual domain, the features that must be associated include shape, color, and location. When objects are detected by more than one sense, binding refers to the association of all the different sensory cues generated by the same object or event.

frame of reference The particular set of axes used to describe a location in space.

linear function A function $f(x) = mx$, where m is a constant. Linear functions have the property of superimposibility: $f(a + b) = f(a) + f(b)$.

microstimulation A technique for activating a small population of neurons (*in vivo*) by passing electrical pulses into the neural tissue through an electrode.

movement field The range of eye movements in space that are associated with a modulation in the activity of a neuron. A movement field is essentially a receptive field for motor-related activity.

receptive field The range of locations from which a stimulus must originate in order to modulate the activity of a neuron.

saccade A rapid eye movement that brings the fovea to bear on a stimulus of interest. Saccades can be guided by visual, auditory, tactile, or remembered stimuli.

spatial correspondence A systematic relationship falling short of registry between the unimodal receptive field locations in individual multimodal neurons. Correspondence can also occur between the receptive fields of neighboring unimodal neurons that respond to different modalities.

spatial registry Perfect alignment between the locations of the unimodal receptive fields in a multimodal neuron; also, alignment between the receptive fields of neighboring neurons responsive to different modalities.

Our experience of the world as a unitary place requires that our brains meld together the information gleaned from our different sense organs. We can then act on this information, regardless of the source. The multisensory neurons in the brain may contribute to this process. In this article we review the properties of multisensory neurons in areas of the brain that participate in one kind of multisensory behavior: saccadic eye movements.

I. OVERVIEW

Knowledge of the world comes to us through our different senses. Our eyes monitor light patterns, our ears detect air pressure changes, our skin reports the pressure of objects impinging on it, and our noses and mouths measure the chemical content of the sensory scene. Despite the variety of routes that sensory information takes to reach our brains, we tend to experience the world as one place. Furthermore, we are capable of using different types of sensory information in equivalent ways, regardless of which sensory system was initially responsible for detecting the stimulus. For example, object shape can be detected either visually or through our sense of touch. Saccadic eye movements can be directed to the locations of visual, auditory, or tactile stimuli. When discrepancies occur between different sensory cues, one sense can dominate

another. When visual and auditory stimuli are mismatched in space, vision sometimes "captures" the location of the sound, a phenomenon known as the ventriloquism effect.

How is the mental experience of a combined multisensory event constructed from a collection of neurons sensitive to the individual components? Called the binding problem, this class of issues has received considerable attention within a single sensory domain. Vision scientists wonder how our percept of objects is synthesized from the activity of separate populations of neurons encoding individual visual features such as color, contours, and motion. For multisensory binding, the information to be bound together comes from many different sensory systems. Many neurons in the brain respond to more than one sensory modality; such neurons serve as a potential neural substrate for this binding. Multisensory neurons are actually common, having been identified in the parietal, temporal, and frontal lobes as well as in various brain stem areas. In this article, we discuss primarily visual and auditory integration. We take as our model system the areas of the brain that are responsible for guiding saccadic eye movements to visual and auditory stimuli. We review the response properties of neurons in these areas as well as those in selected regions of the brain that provide input to these areas. All the experiments we describe were conducted in either cats or monkeys unless otherwise noted. We seek to answer the following questions:

1. How do the responses of multimodal cells respond to each of the modalities alone? Are the receptive fields in the same frame of reference? Are the visual and auditory receptive fields of individual neurons in spatial register with one another?
2. How do they respond to combinations of stimuli? Is the response to a combined stimulus the linear combination of the responses to the components, for example?

In many instances, the complete answers to these questions are not known. Nevertheless, they will serve as a useful framework for exploring the current state of multisensory research.

II. THE REFERENCE FRAME PROBLEM

How does the brain determine that two pieces of sensory information arise from a common source? Visual and auditory stimuli are more likely to be the result of the same event if they arise from the same location, so determining whether two stimuli of different modalities are coming from the same place is an important task for the brain. However, this task is complicated by the fact that the visual and auditory systems employ different reference frames for their initial encoding of stimulus location. Visual stimuli are initially represented in retinal coordinates. Light is reflected from objects in the world, enters the eye, and activates a particular location on the retina. The site of retinal activation informs the brain concerning the location of the visual stimulus with respect to the direction of gaze. When the eye moves, the site of activation on the retina shifts.

The locations of auditory stimuli are computed based on interaural timing and level differences as well as spectral cues, yielding a head- and ear-centered frame of reference. If the source of a sound is located to the right, the sound will arrive in the right ear first, and it will be louder in the right ear. These interaural timing and level differences can be used to compute the location of the sound with respect to the orientation of the head and ears. Obviously, the position of the eyes would be irrelevant.

In species whose eyes have significant mobility (humans, monkeys, cats, but not barn owls, for example), these different reference frames pose a problem. Moving the eyes without moving the head will affect the location of retinal activation without influencing the auditory cues generated by a given object. On the other hand, moving the head while keeping the eyes pointed in a stable direction in space will alter the interaural acoustic cues without affecting the site of retinal activation. The solution to this problem appears to be a transformation of auditory signals into an eye-centered frame of reference so that comparison with eye-centered visual information can take place more easily.

III. BRAIN AREAS INVOLVED IN SACCADES TO VISUAL AND AUDITORY STIMULI

Saccades are rapid eye movements that direct the fovea to the positions of stimuli of interest. Saccades may be elicited by visual, auditory, or tactile stimuli. Our discussion focuses on some of the motor areas that have been implicated in the control of saccades to these visual and nonvisual stimuli as well as one of the areas that provides auditory input to these areas. The superior colliculus (SC), frontal eye fields (FEF), and

lateral intraparietal areas (LIP) are the major motor or motor-related areas that we discuss. One way that auditory signals reach this pathway is through an auditory cortical area in the anterior ectosylvian sulcus (AES, cat; the location is unknown in primate). Other sensory areas such as the inferior colliculus undoubtedly also contribute, but little is known about the role they play in multisensory processing so they will not be discussed.

A. Superior Colliculus

1. Oculomotor Function

The SC is a laminated structure located on the roof of the midbrain. The superficial layers receive a direct projection from the retina, but the intermediate and deep layers are primarily motor in function. Microstimulation in these layers elicits saccadic eye movements with a very short latency. The direction and amplitude of the evoked movement depend on the location of stimulation in the SC. In primates, the left SC encodes conjugate eye movements toward the right and vice versa. Movement size increases as the stimulating electrode is moved from rostral to caudal positions. Movements with an upward component are represented medially, whereas downward movements are represented laterally. Recording studies reveal that a prominent feature of the discharge characteristics of SC neurons is the vigorous burst of activity that they generate just prior to saccades. This activity is selective for the direction and amplitude of the saccade. The most vigorous activity occurs when the saccade will be directed to the center of the cell's so-called movement field. Movement fields are topographically organized and correspond to the direction and amplitude of the saccade evoked by stimulation at that site. Lesions of the SC, when combined with lesions of the FEF, abolish saccades completely. Taken together, these features place the SC convincingly within the saccade pathway.

2. Sensory Properties

The SC is not just a motor structure, however. Neurons in the intermediate and deep layers of the SC discharge in response to sensory events in three different sensory modalities: vision, hearing, and touch. These responses are sensory in the sense that they occur time locked to the onset of the sensory stimulus and they do not appear to actually trigger an eye movement. In other words, the neural responses occur even if the animal is trained to delay its saccade to the location of the stimulus until some kind of "go" cue is received. Although the responses can be dissociated from saccades in this fashion, the responses are considerably more robust if the animal subsequently makes a saccade to the stimulus than if the animal is asked to ignore the stimulus. Thus, the true character of the discharge is intermediate between purely sensory and purely motor. Indeed, individual neurons can show both sensory-related and motor-related properties. A schematic of an idealized SC neuron's response is shown in Fig. 1. When an animal is performing a delayed-saccade task, neurons in the SC may show a brief burst when the sensory stimulus is first turned on, followed by some level of sustained activity, and culminating in a second burst beginning just prior to the saccade. Actual individual neurons do not necessarily show activity during all three of these epochs.

Many different but overlapping schemes have been used to classify different cell types found in the intermediate and deep SC. Neurons that exhibit a burst of activity at approximately the time of the saccade are usually referred to as saccade-related burst neurons. Neurons that have both visual and motor-related activity are frequently referred to as visuomotor cells. Neurons that have both sustained and motor-related activity have also been called prelude-bursters. Finally, neurons showing any type of activity prior to

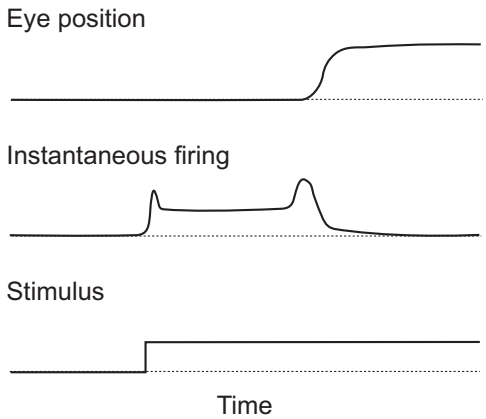

Figure 1 Response profile of an idealized SC or FEF neuron. The top trace illustrates the movement of the eyes, and the bottom trace shows the onset of a stimulus. (Middle) The discharge of the neuron is correlated with both the sensory stimulus and the movement. A burst of activity occurs at target onset and is sustained until another burst occurs at movement onset.

the saccade-related burst have been referred to as "buildup" neurons in many studies. However, this term is not particularly apt because the activity has not been shown to build up—the discharge is typically better characterized as being sustained at a steady level until the saccade-related burst occurs. All of these terms describe overlapping populations of SC neurons.

Early studies of the multisensory properties of these neurons were conducted primarily in anesthetized, paralyzed animals such as cats, rodents, and barn owls. Under these conditions, any motor-related properties of the cells cannot be determined. Instead, cells were classified based on their responses to visual, auditory, or tactile stimuli. Unimodal, bimodal, and trimodal cells have all been identified. Circumstantial evidence suggests that the multimodal cells studied in anesthetized animals might be part of the population of cells that show motor-related activity in awake animals: Multimodal neurons can usually be activated antidromically by microstimulation in the efferent output pathway from the SC. This suggests that they are a source of output from the SC, a role that is likely to involve saccade-related activity.

3. Receptive Field Registry and/or Correspondence

When sensory responses occur, the existence and location of the receptive field(s) become an important issue. Before delving further into this topic, it is important to define our terminology. At issue is the question of the relative locations of visual, auditory, and tactile receptive fields of individual SC neurons. We define the term "spatial registry" to mean that an individual SC neuron responds to stimuli of these different modalities at the same location in space. For example, does the cell respond to the sight, sound, and touch of a mosquito on the back of the hand? If so, then the visual, auditory, and tactile receptive fields may be said to be in register. In contrast, we define "spatial correspondence" to mean that the unimodal receptive fields of multimodal neurons bear a systematic relationship to one another but are not necessarily in truly the same location in space. For example, if most neurons with tactile receptive fields on the hindquarters (outside the field of view) had visual receptive field in the lower eccentric region of the visual scene, the tactile and visual receptive fields would clearly be correlated in a nonrandom way, but because they are not actually in the same position in space they would not be in true register.

In anesthetized cats, visual and auditory receptive fields are usually in spatial register. Alex Meredith and Barry Stein compared the visual and auditory receptive field locations in multimodal neurons and reported that the area of spatial overlap averaged 86% of the smaller receptive field Somatosensory receptive fields show a spatial correspondence with visual or auditory receptive fields: Tactile receptive fields on the face tend to be correlated with central visual receptive fields, whereas tactile receptive fields on the flank or hindquarters tend to cooccur with more peripheral visual receptive fields (Fig. 2). These representations are topographically organized, creating maps of the

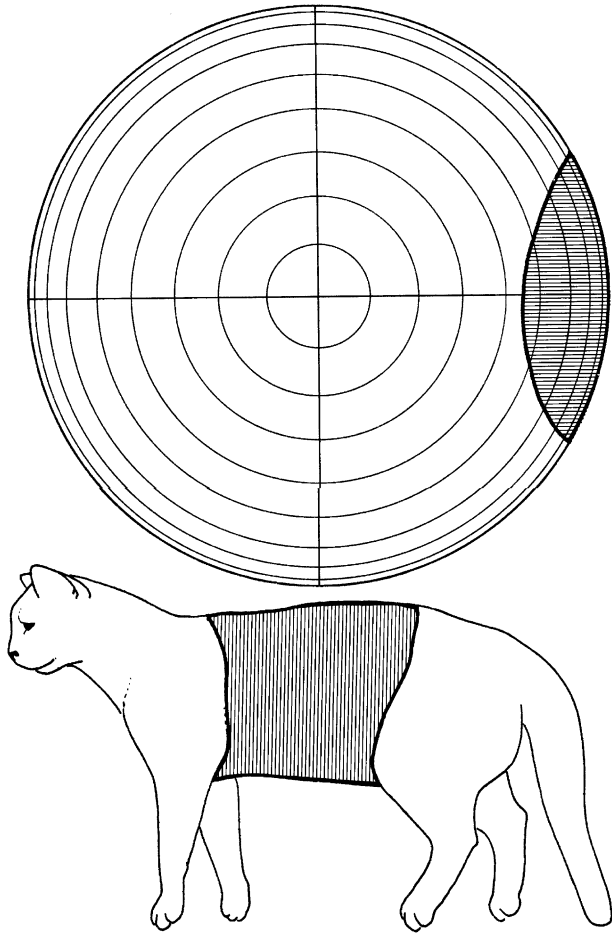

Figure 2 Spatial correspondence between the visual and tactile receptive fields in cat SC. The shaded regions indicate the receptive field locations. The visual (top) and tactile (bottom) receptive fields are closely related to one another but not in register because the body surface containing the tactile receptive field is actually out of the animal's field of view [courtesy of M. A. Meredith and B. E. Stein].

visual, auditory, and tactual scenes. In the rostral part, the auditory and visual receptive fields are centrally located, and the somatosensory receptive fields are on the face or forelimb. Neurons located more caudally have receptive fields located more peripherally in the contralateral space, with tactile receptive fields on the back, hindlegs, or tail. The sensory maps also generally correspond with the motor map for eye movements.

4. Frames of Reference

A priori, one might have expected that registry between receptive fields would be quite poor, due to the fact that the different sensory systems employ different frames of reference. Thus, a visual receptive field anchored to the retina and an auditory receptive field anchored to the position of the head and ears would only match up if the eyes happened to be in the one and only position that would result in alignment. The convergence of visual, auditory, and tactile information onto the SC therefore prompted investigations into the frame of reference of these signals.

Martha Jay and David Sparks were the first to test the influence of eye position on collicular auditory receptive fields. They trained monkeys to make saccades to the locations of auditory stimuli from different initial eye positions. The animals' heads were held fixed so that eye movements were dissociated from head movements. Jay and Sparks found that many of the auditory receptive fields shifted when the eyes moved (Fig. 3), a result that has been confirmed in subsequent studies involving awake cats. Although in principle this should permit perfect registry between visual and auditory receptive fields to be maintained when the eyes move, the alignment of visual and auditory receptive fields was not tested in this experiment. Paradoxically, their findings may actually cast doubt on the possibility of perfect alignment: The receptive fields did not shift as much as they should have to maintain a perfect eye-centered representation of the location of sounds. Instead, the receptive fields shifted an average of only about half the amount of the eye movement, which should disrupt the registry with visual receptive fields. Thus, the alignment of visual and auditory receptive fields in the SC of the awake primate is deserving of further investigation to resolve this apparent conundrum.

An investigation into the frame of reference of tactile signals in the SC was conducted by Jennifer Groh and David Sparks. Monkeys were trained to make saccades from a variety of different initial eye positions to the locations of vibrotactile stimuli delivered to the palms of the hands. The locations of the somatosensory stimuli on the body surface were held constant, as was limb position. Under these conditions, the positions of the eyes influenced the responses of many SC neurons to tactile stimuli. The effect of eye position was suggestive of an eye-centered frame of reference: Cells tended to respond best to the tactile stimulus when the initial position of the eyes brought the location of the tactile stimulus into the visual receptive field or movement field of the neuron under study.

Although the frame of reference of visual and saccade-related activity in the SC is indeed eye

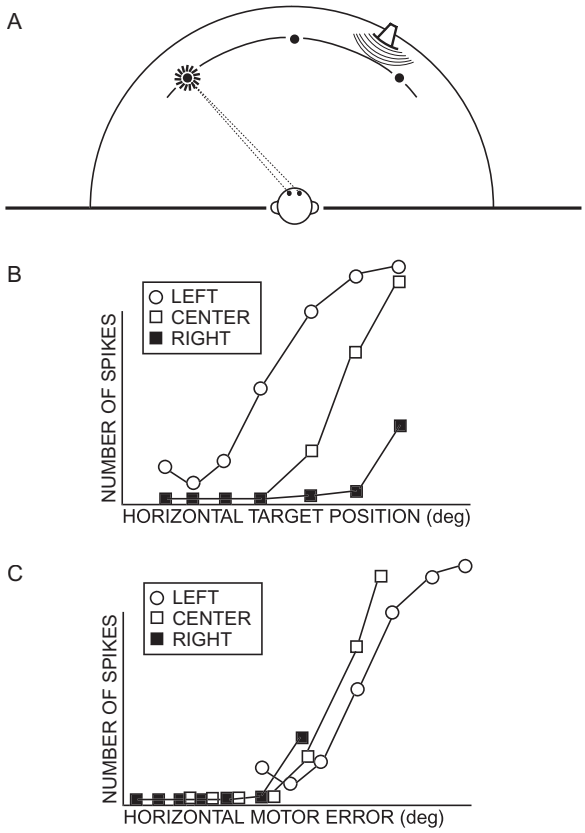

Figure 3 Effect of eye position on auditory responses of a neuron in the SC. (A) Experimental design. Monkeys fixated one of three LEDs while sounds were presented from a range of locations using a speaker mounted on a rotating hoop. Neural responses were better correlated with the location of the sound with respect to the eyes, or motor error (C), than with the location of the sound in space (B) [adapted with permission from Jay, M. F., and Sparks, D. L. (1984). Auditory receptive fields in primate superior colliculus shift with changes in eye position. *Nature* **309,** 345–347].

centered, it is more properly described as a motor error or updating eye-centered frame of reference than a strictly retinal frame of reference. This was demonstrated in 1980 by Larry Mays and David Sparks. They recorded from neurons in the SC that were visually responsive in an ordinary visual saccade task. They then asked monkeys to make saccades to a sequence of two briefly flashed visual stimuli. Both stimuli were illuminated and then extinguished before the first saccade began (Fig. 4). Thus, the direction and amplitude of the saccade to the second target were dissociated from the original retinal locus of that target. Monkeys can perform this task quite well.

If the saccade vector between the first and second targets corresponded to the location of the receptive field, then many cells discharged between the first and second saccades, even though the retinal locus that would normally be associated with that saccade vector had never been activated. Thus, although these cells respond to visual stimuli, in fact they can also represent the remembered locations of visual stimuli in a frame of reference anchored to the eyes—a frame of reference that is updated when the eyes moved. These characteristics led them to be called quasi-visual cells.

5. Multisensory Integration

If a cell responds to both visual and auditory stimuli separately, what happens when the two stimuli are presented together? One might expect individual neurons to treat stimulus energy as equivalent, regardless of the source of the energy. Thus, the response to a joint stimulus might be approximately equal to the sum of the responses to the individual components. In

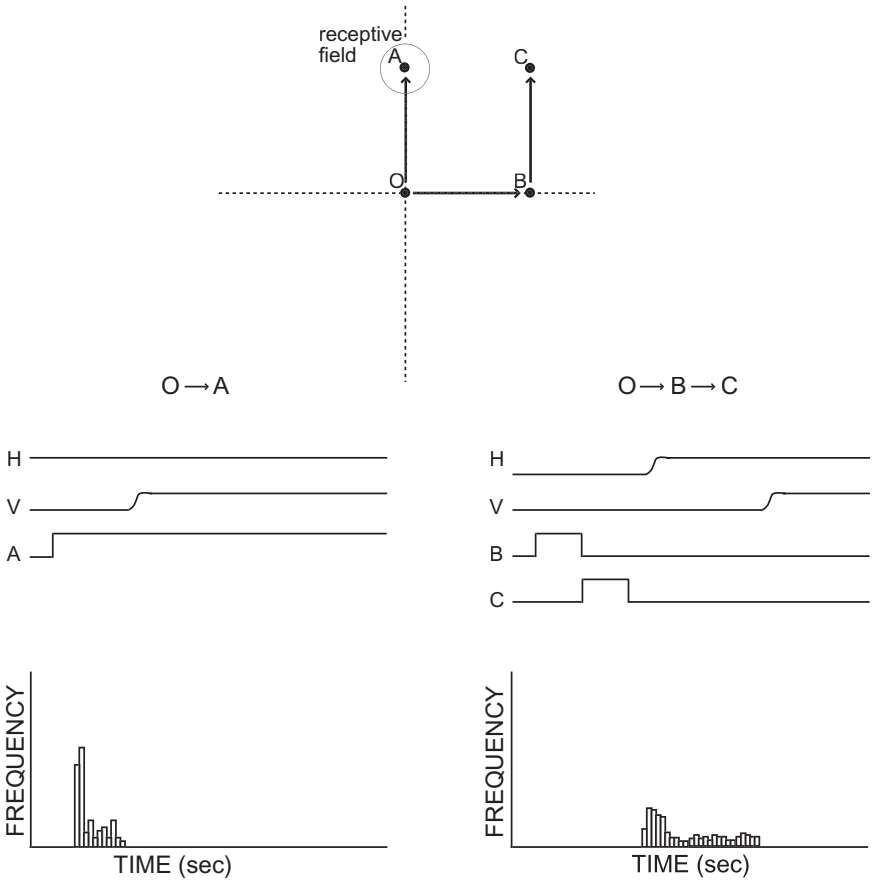

Figure 4 Idealized response of a quasi-visual cell in the SC. (Top) The locations of receptive fields and various visual stimuli. (Bottom left) The response of the cell when the visual stimulus is presented in the receptive field and the monkey makes a saccade directly to it. (Bottom right) The response of the cell when no stimulus is presented in the retinal location corresponding to the receptive field. Rather, a sequence of two stimuli is presented. After the animal makes a saccade to the first, the remembered location of the second lies in the new position of the receptive field and the cell becomes active [adapted with permission from Mays, L. E., and Sparks, D. L. (1980). Dissociation of visual and saccade-related responses in superior colliculus neurons. *J. Neurophysiol.* **43,** 207–232].

other words, SC neurons might behave linearly. Violations of linearity should occur for weak stimuli near the threshold of the neuron, where the combined response should exceed the sum of the two responses, and again for strong stimuli, when responses to combined stimuli might saturate at a level below the sum of the unimodal responses.

An alternative means of characterizing multisensory interactions has been employed by Meredith, Stein, and colleagues. These researchers emphasized the potential benefit for stimulus detection that may be provided by combined sensory stimuli. They therefore compared the joint response to the larger of the two unimodal responses using the following formula:

$$\% \text{ Interaction} = \frac{(\text{joint response} - \text{maximal unimodal response}) \cdot 100}{\text{maximal unimodal response}}$$

Response enhancement is defined as a joint response exceeding the maximal unimodal response, and depression is defined as a joint response that is less than the maximal unimodal response. If the joint response equals the maximal unimodal response, this is defined as "no interaction." Comparing this classification scheme with linearity, any interaction that exceeds 100% must be supralinear: If the joint response is more than twice as large as the largest unimodal response, it must also be larger than the sum of the two unimodal responses. Similarly, any interaction that is less than 0% must be sublinear: If the joint response is less than the maximal unimodal response, it must also be less than the sum of the two unimodal responses (assuming the weaker response is not inhibitory). However, between these two extremes a comparison between the percentage interaction and linearity cannot be made without knowledge of the individual component responses.

When Meredith, Stein, *et al.* characterized the multimodal responses in terms of percentage interaction, they found evidence of all three types of effect: enhancement, depression, and no interaction. The type of interactions depended on three factors: the effectiveness of the component stimuli at driving the cell, the spatial locations of the component stimuli, and the timing between the component stimuli. Response enhancement tended to be largest when the component stimuli evoked only modest responses on their own. Enhancement tended to occur when both stimuli were in the center of their respective receptive fields, whereas depression was more likely to occur when one of the two stimuli was in the suppressive area of its receptive field. The degree of enhancement or depression was largest when the stimuli were presented within the same time frame (with less than 100 msec separating the two). Specifically, stimulus-onset asynchronies small enough that the responses to the individual components would overlap in time tended to produce maximal enhancement. Enhancement decreased with greater stimulus-onset asynchrony, and when asynchrony was increased even further depression often occurred.

Both methods of characterizing multisensory interactions imply certain assumptions. As mentioned previously, comparing the joint responses to the sum of the individual responses suggests a null hypotheses that stimulus energy is stimulus energy, regardless of which sensory system detected the event. Two stimuli have more energy than one, so the response to two should be close to the sums of the individual responses (i.e., linear). In contrast, the percentage interaction (enhancement/depression) analysis emphasizes the relationship between the combined response and the stronger unimodal response. When the two are equal, this is defined as no interaction. However, failure of the joint response to exceed the maximal unimodal response might actually indicate that the stronger unimodal stimulus suppresses any response to the weaker unimodal stimulus. This would hardly be an inconsequential interaction between the sensory signals. Large enhancements (those that exceed linearity) clearly indicate synergistic facilitation between sensory inputs, but anything less than a large enhancement may indicate equally interesting competition between the different types of inputs to individual neurons. Further work is needed using both types of analysis to clarify these issues.

B. Frontal Eye Field

The FEF is a cortical region that is involved in controlling saccadic eye movements. The FEF is similar to the SC in many ways. In awake monkeys, many FEF neurons discharge in conjunction with saccades. Cells have movement fields and discharge most vigorously if the saccade will be directed to the center of the movement field. The idealized FEF neuron has an activity profile with sensory and motor components similar to the idealized SC neuron shown in Fig. 1. Microstimulation in FEF evokes saccades. As mentioned earlier, combined lesions of FEF and SC completely abolish saccades.

Like the SC, the FEF has been implicated in the control of saccades to sounds as well as visual stimuli.

Gary Russo and Charles Bruce investigated the motor-related activity of neurons in the FEF to determine if they were active for saccades to auditory stimuli as well as visual stimuli. Monkeys were trained to make saccades to the locations of both lights and sounds. They found that all the cells in their sample responded prior to saccades to both kinds of targets. Furthermore, the movement fields for both were anchored to the initial position of the eyes. These results, were similar to those of Jay and Sparks for primate SC.

Neurons in FEF also respond to sensory events. Many respond to visual stimuli and a few respond to sounds. Neurons that respond to sounds can be driven by a variety of different types of sound stimuli, and receptive fields tend to lie on the contralateral side. About half of auditory neurons also respond to visual stimuli. Acoustically responsive cells tend to be found primarily at locations in FEF that represent large amplitude movements. Beyond this, little is known. The frame of reference of these sensory responses has not been examined, nor have the interactions between visual and auditory stimuli been characterized. Do bimodal cells have receptive fields that are in register with one another? Do they stay in register when the eyes move? Do the cells show response enhancement/depression to combined stimuli? How do the responses to combined modality stimuli compare with the linear sum of the unimodal responses? Further experiments are needed to answer these questions.

C. Lateral Intraparietal Cortex

Posterior parietal cortex is a region of the brain that has been implicated in spatial attention and eye movements. In humans, lesions of the parietal lobe cause patients to ignore sensory stimuli located in the contralateral half of space, a phenomenon known as neglect. What is the frame of reference of this neglect? One intriguing experiment that addressed this question was conducted by Edoardo Bisiach and Claudio Luzzatti in 1978. They asked patients with parietal lobe lesions to imagine themselves facing the cathedral at the Piazza del Duomo in Milan and report all the landmarks they could recall. From this imaginary vantage point, the patients named primarily landmarks on the side of the piazza ipsilateral to the side of their brain lesion. Then, they were asked to imagine themselves standing on the cathedral steps, facing in the opposite direction. From this opposite perspective, the deficit was reversed. They could now recall landmarks on the opposite side of the piazza, but they failed to name landmarks on the first side—landmarks that they had been able to recall from the first imaginary vantage point.

In monkeys, the lateral intraparietal region of posterior parietal cortex, or area LIP, is believed to play a role in guiding saccades to the locations of visual, auditory, and remembered stimuli. Various groups have debated whether the function of LIP is better characterized as attentional, overseeing the sensory processing of stimuli at a particular location, or "intentional," preparing the motor circuitry to make a saccadic eye movement to a stimulus at that location. Clearly, these two concepts are closely related, perhaps so much so that no experiment could adequately distinguish between them. We therefore remain agnostic on this point and will merely review the relevant literature concerning the representations of visual, auditory, and saccade-related information in LIP.

Neurons in LIP resemble those in both SC and FEF in having both sensory and motor-related activity. For many neurons in LIP, the visual responses are not strictly dependent on the location of the stimulus on the retina. The position of the eye is also important. Richard Andersen, Vernon Mountcastle, and colleagues found that visual stimuli at a given retinal location evoked different responses depending on where the animal's eyes were pointing (Fig. 5). The effects of eye position were dubbed "gain fields" because the level of the visual response was affected by orbital position. Although the term gain normally implies a multiplicative interaction, whether this eye position effect is truly multiplicative has not been studied. Nevertheless, the location of the receptive field stays anchored to the retina when the eyes move, but the responsiveness of the cell varies. Thus, the frame of reference of visual activity is not strictly retinal but reflects the combination of retinal and eye position signals.

Larry Snyder, Peter Brotchie, Richard Andersen, and colleagues further investigated these gain fields to determine whether the position of the eyes with respect to the head, body, or world was the important factor. They varied the positions of the eyes with respect to the head, the position of the head with respect to the body, and the position of the body with respect to the world while keeping the visual stimulus at a fixed position on the retina. These manipulations revealed that the magnitude of the response to a given retinal stimulus depended on the position of the eyes with respect to the body. In LIP, it mattered little whether gaze shifts with respect to the body were accomplished largely by

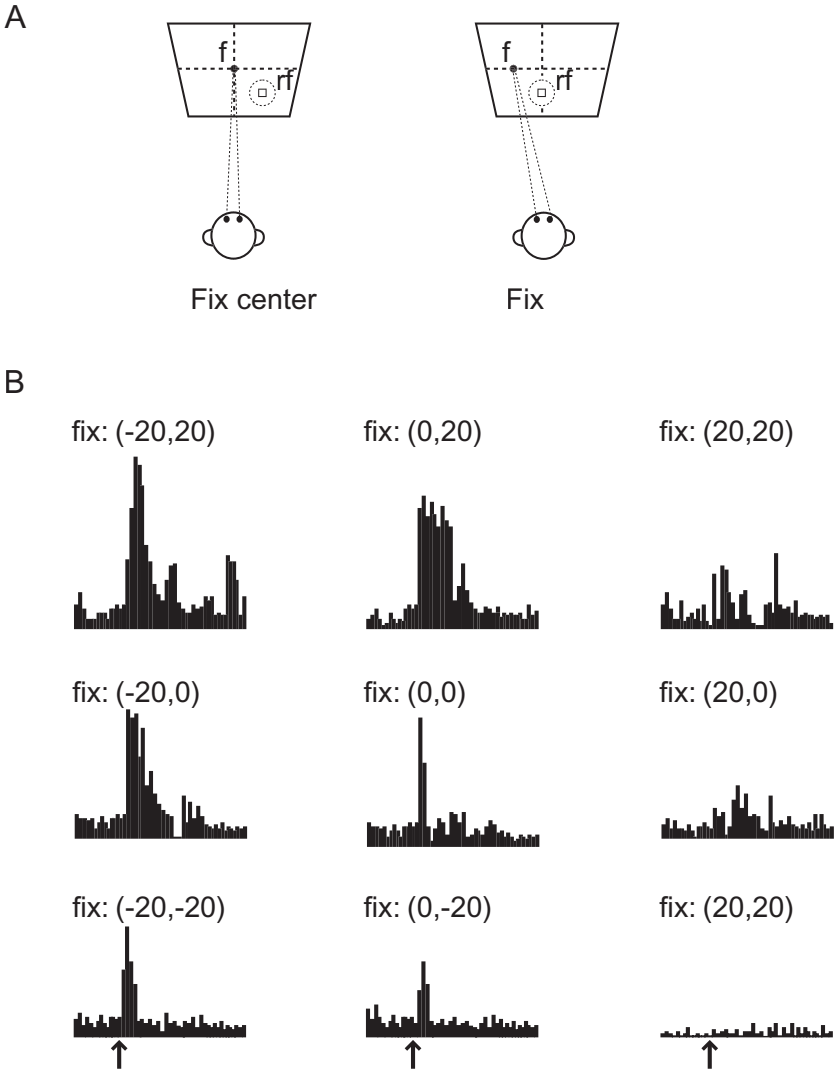

Figure 5 Effects of eye position on visual responses in posterior parietal cortex. (A) Schematic of experimental design. The responses of neurons to visual stimuli at a particular retinal location were examined for a range of orbital positions. (B) Responses varied with eye position, although retinal location was held constant [adapted with permission from Andersen, R. A., Essick, G. K., and Siegel, R. M. (1985). Encoding of spatial location by posterior parietal neurons. *Science* **230,** 456–458].

eye-in-head rotations or head-on-body rotations. (In nearby area 7a, however, more cells were affected by the position of the eyes with respect to the world than by the position of the eyes with respect to the body.)

What about auditory signals in LIP? Pietro Mazzoni, Richard Andersen, and colleagues examined how LIP represents sound location. They presented sounds from two speakers, one located contralaterally and the other in the ipsilateral field. They found that approximately half of neurons in their population responded to sounds at one or both of these locations. Most responded more vigorously from one speaker than from the other. Most neurons also responded to visual stimuli and tended to prefer visual stimuli located near the preferred speaker. However, receptive fields were not mapped in this study, so it is not known how extensive the visual and auditory receptive fields are, nor how closely they correspond with one another.

The frame of reference of auditory signals was examined by Brigitte Stricanne, Richard Andersen, and Pietro Mazzoni. These researchers trained monkeys to make saccades to the locations of five speakers separated 12 degrees apart along the horizontal meridian. Three fixation positions 12 degrees apart

were used. An analysis of variance confirmed that the location of the sound was an important determinant of neural activity. The location of the sound with respect to the head, the location of the sound with respect to the eyes, or both of these factors were predictive of how cells would respond. However, if receptive fields are large relative to the separation between fixation positions, it would be difficult to determine from this analysis whether the activity is better correlated with head vs eye-centered frames of reference because the head- and eye-centered locations are correlated with one another. Nevertheless, this study does suggest that eye position influences the responses of at least a subset of auditory neurons in LIP.

To summarize, LIP contains neurons that respond to auditory stimuli, but many important questions remain unanswered. What is the relationship between visual and auditory receptive fields? Do they overlap? Are they in register? What is the frame of reference? Furthermore, nothing is known about how the cells respond to combined visual and auditory stimuli. Do the cells sum their inputs linearly? Do they show the kind of response enhancement/depression that is found in the SC? These issues await further inquiry.

D. Anterior Ectosylvian Sulcus

In cat, a major source of descending input to the SC derives from the AES. This descending input is of particular interest because this cortical region (whose primate homolog is unknown) contains subdivisions for different sensory modalities. Visual responses are present in area AEV, somatosensory activity occurs in area SIV (the so-called fourth somatosensory cortex, pronounced "S4"), and auditory signals are found in field AES. At the periphery of these unimodal subdivisions are multimodality neurons that do not project directly to the SC. Overall, approximately one-third of the cells are auditory, one-fourth somatosensory, and one-fifth visual. The remaining cells are bimodal or, rarely, trimodal, with visual–auditory cells being most common in this group.

Lee Wilkinson and colleagues investigated the functional role of AES in integrating multisensory information by deactivating it and testing the performance of cats on a task involving multisensory cues. The cats were trained to orient toward a visual target. When the visual target was dim enough to be near threshold for detection, orientation performance could be improved by pairing the visual stimulus with a sound at the same location. Pharmacological deactivation of the AES prevented this facilitation by the paired auditory cue. Orientation to a visual stimulus alone was not affected by the deactivation. Inactivation of primary auditory cortex had no such effect. These results suggest that area AES plays an important role in facilitating orienting movements based on auditory information.

Inactivation of AES has also been shown to affect the responses of SC neurons in an interesting way. When AES is cooled, the responses of SC neurons to unimodal stimuli are unaffected. However, the responses to combined stimuli cease to show the same type of interaction (enhancement or depression) that they showed prior to the inactivation. This result is particularly surprising given that the projection from AES to SC derives from the unimodal cells, not the multimodal cells in that region.

Although they do not project to the SC, the multimodal cells in AES do share many of the properties of multimodal cells in SC. Receptive field locations for the different sensory modalities show a correspondence in space. Visual–somatosensory cells with tactile receptive fields on the forelimbs tend to have visual receptive fields in the lower quadrant of space and so forth. This correspondence is surprising because the unimodal subdivisions of the AES region do not seem to have a topographic organization. As in the SC, multimodal cells show response enhancement when the relevant stimuli are presented simultaneously in their respective receptive fields. How their responses to combined stimuli compare with the linear sum of the responses to the individual components has not been tested.

Our knowledge of area AES is currently quite preliminary. A number of questions remain to be answered. How do these cells respond in the awake, behaving animal? What is the frame of reference of these signals? Are the receptive fields of multimodal cells in true spatial register, and how is the registry influenced by movement of the eyes, ears, head, and body? What is the primate homolog? Experiments in awake monkeys are needed to address these issues.

IV. ALGORITHMS FOR COORDINATE TRANSFORMATIONS

Despite the fact that many of these areas show signs that auditory signals have been translated into an eye-centered reference frame, little is known about how the brain does this. Two models for how this may be accomplished have been proposed by Groh and Sparks.

A. Computation

Transforming signals from one frame of reference into another is mathematically straightforward. If the location of an auditory target with respect to the head ($\boldsymbol{A}_h$) is known, and the position of the eyes with respect to the head ($\boldsymbol{E}_h$) is also known, then subtracting the eye position signal $\boldsymbol{E}_h$ from the head-centered target location signal $\boldsymbol{A}_h$ will yield a signal of the location of the sound with respect to the eyes ($\boldsymbol{A}_e$) (Fig. 6A). The first model, the vector subtraction model (Fig. 6B), implements an algorithm resembling this mathematical calculation using neurons as the computational elements. The second model, the dendrite model (Fig. 6C), uses a different algorithm: a neural analog of a multidimensional lookup table, which is implemented through local circuitry at the dendrites of the units in the eye-centered auditory map.

B. Input and Output Signals

As far as possible, the component signals are provided by units that resemble known populations of neurons. Eye position signals are carried by neurons from a variety of brain areas, such as the brain stem gaze centers, nucleus prepositus hypoglossi, the flocculus of the cerebellum, and posterior parietal cortex. Each of these areas contains neurons whose firing rate is typically linearly related to eye position. This information is most likely derived from a copy of the motor command to move the eyes, although proprioceptive feedback from the extraocular muscle spindles is also possible. No evidence of a place code of eye position, with neurons having response fields for eye position, has been reported. Thus, the eye position units in the model signal the position of the eyes in the orbits in a linear or rate-coded fashion.

For lack of any evidence to the contrary, the representation of the inputs to the model is assumed to be an auditory map of space in a head-centered frame of reference. Units in this map have receptive fields defined with respect to the head. However, convincing evidence for an auditory map of space in a head-centered frame of reference has not been reported—the frame of reference has either not been studied (classical auditory areas such as IC and auditory cortex) or the results have indicated a possible eye-centered frame of reference (SC, FEF, and LIP). Thus, how the inputs to this transformation are actually encoded is an open question.

The output of both of the models is an eye-centered auditory map resembling the primate SC. These units have receptive fields in an eye-centered frame of reference.

C. Neural Architecture

The circuitry of the vector subtraction model is illustrated in Fig. 6B. Neurons in the head-centered auditory map project to a set of intermediate units with a synaptic weighting that is proportional to their receptive field location. Thus, the level of excitation received by these intermediate units will be a linear rate code of the location of the sound with respect to the head. These units also receive an inhibitory synapse from a unit encoding eye position using a linear rate code. This inhibitory connection is the mechanism by which the eye position signal is subtracted from the signal of head-centered target location. The resultant signal encodes the location of the auditory target with respect to the eyes, again as a linear rate code.

The remainder of the circuitry in the model is devoted to converting this rate code into a place code in which neurons have receptive fields in an eye-centered frame of reference, like the map of oculocentric auditory space in the SC. This is accomplished using graded thresholds and inhibitory interneurons.

The simplicity of this mechanism is not without cost: Because of the rate coding at the intermediate stage of processing, the model functions properly for single auditory targets only. In order for an animal to make accurate saccades to the location of one auditory target among distracters, a target selection mechanism must choose the target before the coordinate transformation is executed. If two targets were present, and both were selected as saccade targets, the model as originally proposed would yield the vector sum of two auditory targets as an output. A small modification to this model would allow it to compute the vector average instead of the sum. Vector averaging is a more realistic response to multiple inputs and has been found in a number of other behavioral and physiological experiments. We therefore consider vector averaging of two auditory targets to be more likely than vector summation. Nevertheless, the vector subtraction model is simply not capable of preserving both target locations independently.

The alternative model, the dendrite model (Fig. 6C), can handle multiple targets because there is no rate-coding bottleneck at an intermediate stage of processing. Instead, every unit in the input map projects

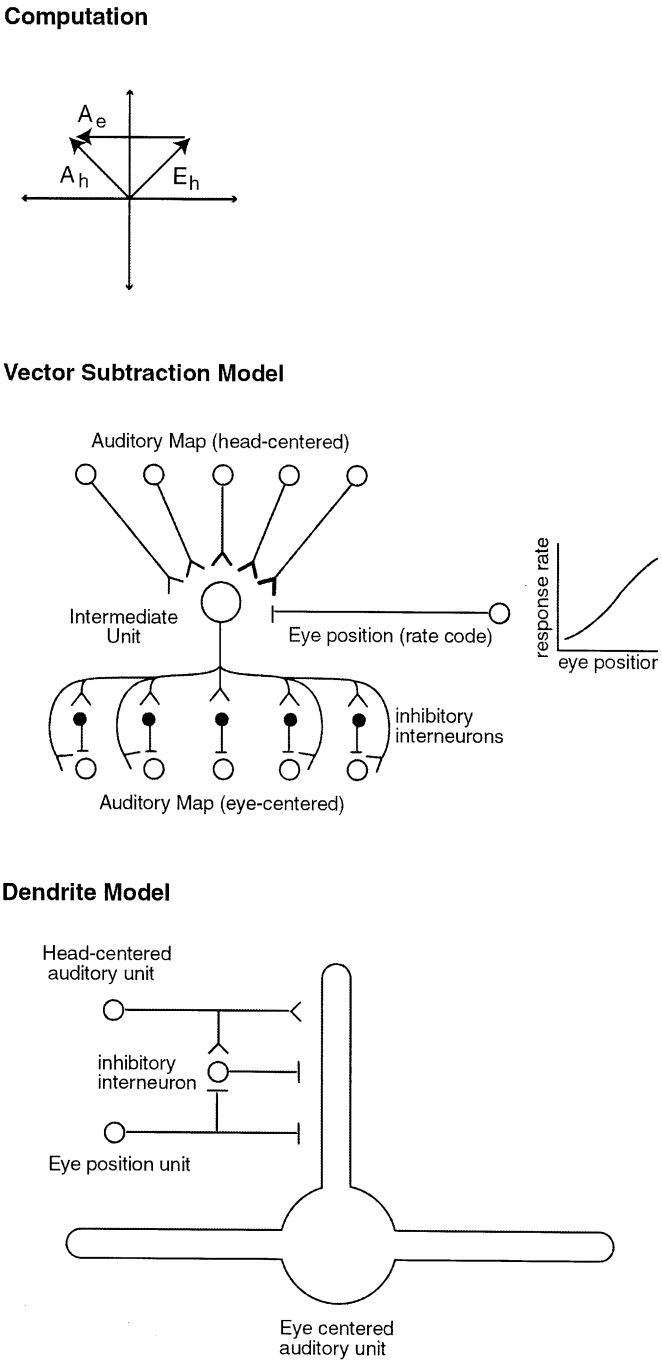

Figure 6 Computation of the eye-centered location of a sound. (A) If the auditory stimulus is located above and to the left of the head ($\boldsymbol{A}_h$), and the eyes are directed upward and rightward in the orbit ($\boldsymbol{E}_h$) as shown here, then the auditory stimulus is located directly to the left of the eyes ($\boldsymbol{A}_e$). (B) The vector subtraction model. The head-centered auditory map projects to the intermediate unit with graded synaptic weights. The eye position signal is subtracted at an inhibitory synapse. The resulting rate code for the target's location with respect to the eyes is converted into a place code for auditory space in an eye-centered frame of reference through graded thresholds and inhibitory interneurons. (C) The dendrite model. Each dendrite receives input from eye position units and one head-centered auditory unit. Thresholds and synaptic weights are balanced so that the cell body receives net excitation if an auditory stimulus is present and the eyes are within a certain range of positions. Each dendrite performs this analysis independently for a particular location in head-centered space. *In toto* the dendrites of an individual neuron create an eye-centered receptive field [for more details, see Groh, J. M., and Sparks, D. L. (1992). Two models for transforming auditory signals from head-centered to eye-centered coordinates. *Biol. Cybernetics* **67,** 291–302].

directly onto separate individual dendrites of every unit in the output map. The eye position units also project directly onto each dendrite. There are also interneurons associated with each dendrite. The local circuitry at each dendrite is set up to activate the unit if (i) there is a sound in the receptive field of the head-centered unit that projects to that dendrite and (ii) the position of the eyes places that sound within the eye-centered receptive field of that unit. Other sounds that are not in the eye-centered receptive field will not activate that particular unit, but they will activate other units in the eye-centered map via the projections to individual dendrites on those units. Because these connections are all independent, the model can accurately transform the locations of an unlimited number of targets.

These are two possible mechanisms whereby auditory signals can be translated from head- to eye-centered coordinates. Other algorithms are undoubtedly also possible. Furthermore, these algorithms are not limited to auditory coordinate transformations nor to translating information from head coordinates into eye coordinates. Translation of visual information from retinal to updated eye-centered coordinates or head-centered coordinates could be accomplished using similar mechanisms.

V. PARALLELS WITH OTHER MULTISENSORY MOTOR SYSTEMS

Thus far, we have concentrated primarily on brain areas implicated in multisensory processing and the control of saccades to sensory stimuli. However, recent work in premotor cortex has revealed that many of the same principles apply for the neural control of skeletal movements guided by sensory stimuli of different modalities. Neurons in premotor cortex can respond to visual or somatosensory stimuli or both. Auditory responses also exist but have been less extensively explored.

Michael Graziano, Charles Gross, and colleagues explored the issues of spatial registry/correspondence and the frames of reference of these signals. They found that bimodal visual/somatosensory neurons show an interesting spatial correspondence, with visual receptive fields tending to occupy a circumscribed three-dimensional volume of space in the immediate vicinity of the region of the body surface that contains the tactile receptive field. Furthermore, the frame of reference appears to be body-part centered. Neurons with tactile receptive fields on the limb and visual receptive fields in nearby space employ a limb-centered frame of reference. The visual receptive fields move in space when the limb moves. If the eyes move but the limb does not, the visual receptive field remains in its original location in space, despite the fact that a different region of the retina would not be activated by stimuli at that location. Thus, the retinal location of a stimulus is irrelevant to these neurons; only the location of the stimulus with respect to the limb is important. Similarly, when the visual receptive fields are located near the face or head, they move when the head moves, even if gaze position in space is constant. In short, like the areas of the oculomotor pathway, the skeletal motor pathway appears to employ frames of reference that are tailored for guiding the movements of individual body parts, regardless of the modality of the stimulus that evokes the movement.

How these visual signals might be translated into a body-part-centered frame of reference is not known. Mechanisms similar to those outlined in the previous section for the translation of auditory signals from head- to eye-centered coordinates could apply in this case as well. For example, the translation of visual signals from eye- to head-centered coordinates is simply the inverse of the auditory transformation and could be accomplished using a retinotopic map as the input. The vector subtraction model would become the vector addition model, with the eye-in-head signal being added to the retinal vector to produce a signal of visual stimulus location with respect to the head. Similar modifications to the dendrite model could also be made. Translation of visual signals from a retinal- to a limb-centered frame of reference is obviously more complicated, but even this computation could be accomplished in an analogous fashion if the brain were to first compute the position of the limb with respect to the eyes. Replacing the eye-in-head signal with an eye-with-respect-to-limb signal in the models might allow the computation to proceed efficiently from that point, without requiring a series of intervening coordinate transformations. Of course, computing such a signal might not be easy, given how many joint angles would be involved.

VI. CONCLUSION

Our brains receive a constant barrage of sensory information from our different sense organs. Making sense of this onslaught requires determining which visual, auditory, somatosensory, olfactory, and

gustatory cues match up with one another and derive from a common event. The multisensory neurons in the brain are likely to play a critical role in this process. Our review of multisensory activity within the saccade pathway reveals evidence for common frames of reference and spatial registry and/or correspondence across sensory modalities. However, we still have much to learn about these cells. Detailed receptive field mapping and more extensive quantitative analysis of the responses to combined modality stimuli in awake animals are needed. Such studies will serve as the foundation on which a bridge between multisensory neural activity and behavior can ultimately be built.

Visual Cortex

MARCELLO G. P. ROSA
Monash University

GLOSSARY

blindsight Refers to the visual abilities of patients with lesions of area V1. Despite having no visual sensation, they are capable of correctly guessing the location and some characteristics of visual stimuli presented in the blind field.

blobs Patches of cortical tissue in area V1, where the neuropil has a high content of the enzyme cytochrome oxidase. There are several thousand blobs in the striate cortex of monkeys and humans, each forming a column of cells 200–300 μm in diameter. Although blobs are most clearly defined in layer 3, they also include corresponding patches of layers 2, 5, and 6.

contextual modulation The changes in the responses of visual cortical cells induced by stimuli presented outside the receptive fields. Typically, the cellular responses are suppressed if a similar visual pattern is presented within the receptive field and in the background.

dorsal stream Group of visual areas located in dorsal occipital and parietal cortices, that are involved with the analysis of motion, spatial relationships, and the visual control of movement.

extrastriate cortex Designation that includes most visual areas in the occipital, parietal, temporal, and frontal lobes. Histologically, they lack many of the laminar subdivisions that characterize striate cortex. Extrastriate areas receive their main thalamic inputs from the pulvinar nucleus.

hypercolumn A group of adjacent cortical columns that includes cells selective to each possible variation of a physical parameter of visual stimulus.

striate cortex A histologically distinct area of the occipital lobe, that receives the bulk of the retinal projections to the cortex via the lateral geniculate nucleus. Also known as area V1.

ventral stream Group of visual areas located in ventral occipital and inferior temporal cortices, which are involved with the analysis of shape, color, and texture of objects.

visuotopic map Imaginary projection of the visual field into a cortical area. Visuotopic maps are created by the spatially ordered connections between the retinae, thalamus, and cortex.

visuotopic reorganization Change in the visuotopic map of a cortical area following a change in the pattern of afferent projections to the cortex; occurs after retinal detachments or retinal lesions.

The visual cortex is responsible for the rich ambit of sensations that form our visual experience. Damage to the visual cortex can be sufficient to cause blindness, even though the eyes are unaffected. Moreover, damage to different areas of the visual cortex can result in the disruption of specific aspects of vision, such as the recognition of shapes, the perception of colors, the sensation of motion, or the determination of the positions of different objects in relation to a person's body. Each of these aspects of vision represents an enormous computational problem, which contemporary artificial systems can only handle to a very limited extent. However, every moment the visual cortex solves these problems in a near effortless manner, and integrates the different solutions into a unified percept of the visual world. Understanding how this is accomplished is a major challenge for contemporary neuroscientists.

The rationale for partitioning the cortex into areas is the belief that each of these subdivisions performs a certain set of neuronal computations, which translate into a unique functional contribution for perception, motor control, or cognition. In reality, a good understanding of the likely role of a visual area in perception usually comes long after its existence is proposed on the basis of nonfunctional criteria, such as histological distinctions or anatomical connections. In addition, there is still much debate regarding the exact number

and limits of visual areas, even in intensively studied animal models like the monkey or the cat. Nonetheless, it is clear that one of the main trends in the evolution of the primate brain has been the growth and diversification of the visual cortical areas. Indeed, humans are highly visual animals in comparison with most other mammals, and it can be argued that our sophisticated visual cortex has been a prerequisite for the evolution of the higher cognitive functions that characterize "humanity" as we know it.

I. CHARACTERIZATION OF VISUAL AREAS

A. Striate and Extrastriate Cortices

The number, shape, and location of visual areas vary enormously among species. However, a useful distinction, which applies to the visual cortex of all mammals, is that between striate and extrastriate areas. The striate cortex (also known as the primary visual area or V1) is the largest area of visual cortex and somewhat different from the other visual areas in terms of its histological structure. In addition, there are multiple extrastriate areas, which in humans and other primates include the remainder of the occipital lobe plus subdivisions of the temporal, parietal and frontal lobes (Fig. 1). The histological and anatomical distinction between extrastriate areas can be very subtle. With few exceptions, these areas are difficult to distinguish from each other without physiological mapping techniques, such as single cell recordings or functional magnetic resonance imaging. Striate cortex is also unique in being the principal cortical target of axonal projections from the lateral geniculate nucleus and thus the first cortical area to receive the information coming from the eyes. The thalamic innervation of extrastriate areas, on the other hand, originates mainly from the nuclei of the pulvinar complex, which receives minor retinal projections.

B. Evolution of Visual Cortex

The contemporary representatives of early branches of the mammalian radiation, such as marsupials, have very few visual areas (Fig. 1). Besides V1, only one other visual area (named the second visual area or V2) has been identified with certainty in these animals. In addition, other regions of cortex that receive anatomical projections from V1 and V2 have been identified as putative visual areas, but their exact characteristics remain unclear. They may represent sites of polysensory convergence rather than purely visual areas. Some marsupial species, such as the Australian quoll (*Dasyurus*) and the South American wooly opossum (*Caluromis*), have enormously expanded visual cortices that occupy more than half of their entire neocortex. However, this is accomplished by the enlargement of V1 and V2 rather than by the addition of new areas. This means that there are relatively few stages of visual processing in the cortex, which probably limits the range of visual sensations and visually guided behaviors in these species. From such a simple organization, expansion and addition of extrastriate areas have occurred in many branches of the mammalian radiation (Fig. 1). Among placental mammals, even species with poor vision such as the rat have additional visual areas beyond V1 and V2. Placental mammals with developed vision, such as cats and primates, may have more than 20 extrastriate areas in addition to V2, although the exact number is not known for any species.

In the course of primate evolution, there has been an enormous expansion of the anterior portions of extrastriate cortex (the *inferior temporal* and *posterior parietal* cortices). Some of the areas in these regions appear to exist only in primates. Although the study of the subdivisions of human visual cortex is still in its infancy, the evidence so far indicates that the visual areas demonstrated in monkeys also exist in humans. In addition, recent studies have suggested the existence of evolutionarily new areas, which are probably specific to higher primates. For example, there is a "kinetic occipital" area that is involved in the integration of motion and shape signals; this area seems to have no counterpart in the monkey. Moreover, in the monkey brain cortical areas devoted to different sensory modalities may be located in close apposition, whereas in the human brain the visual, somatosensory, and auditory cortices have become separated by larger expanses of "association" or polysensory areas, some of which receive afferents from visual cortex.

C. Areas and Modules

In addition to the growth and multiplication of extrastriate cortex, another trend in the evolution of complex visual cortices has been the subdivision of some areas, including V1 and V2, into modules in which neurons differ in their patterns of connections with other brain areas, physiological characteristics, and neurochemical composition. These modules

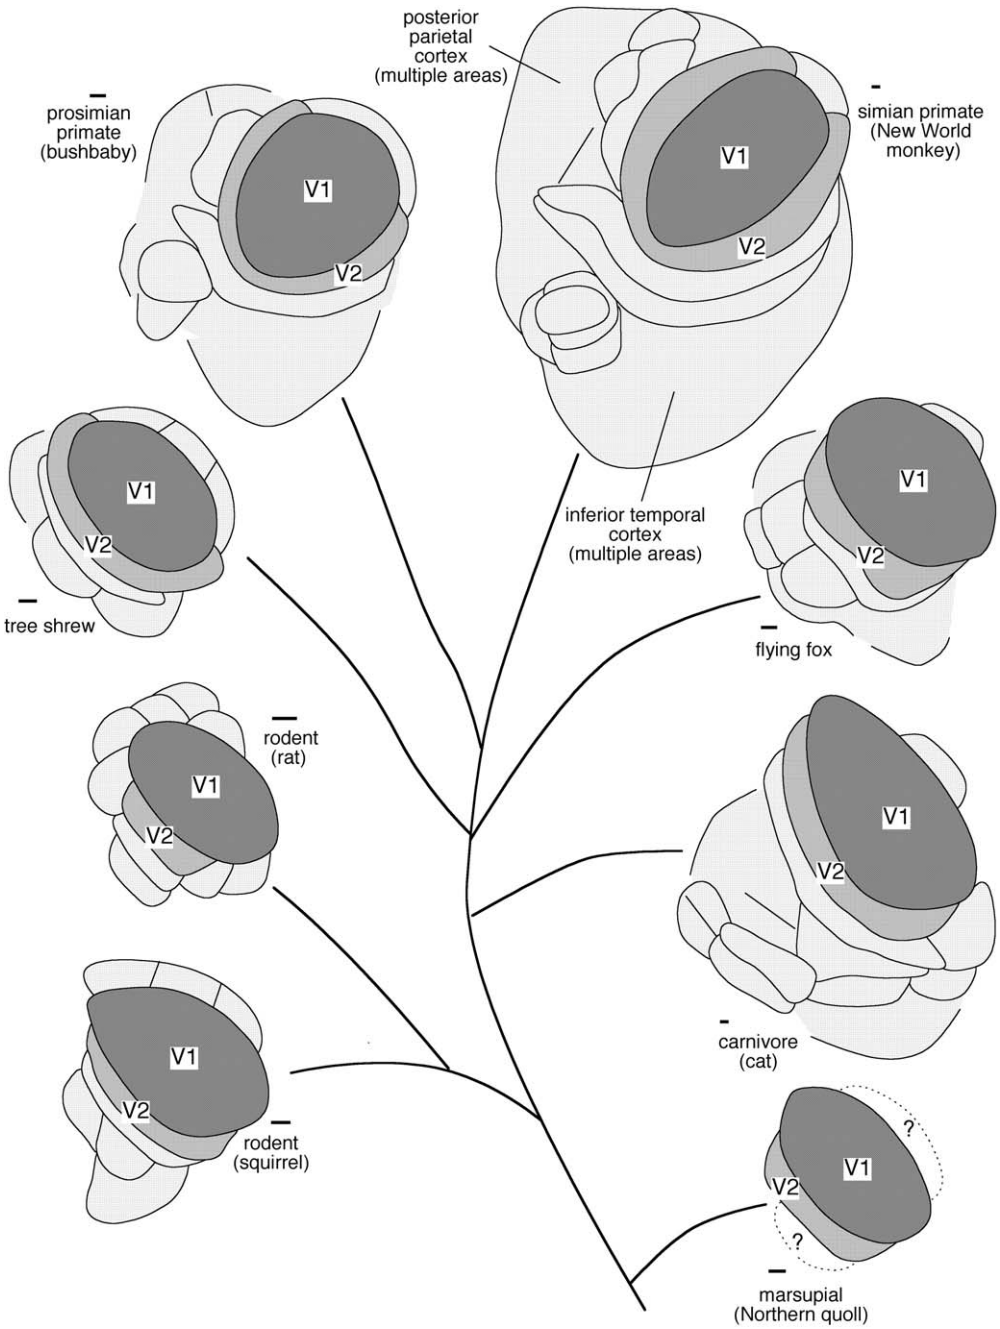

Figure 1 Expansion of extrastriate cortex in mammalian evolution. Each diagram is a schematic view of "unfolded" visual cortex, with striate cortex (V1) shown in dark gray, the second visual area (V2) in medium gray, and other visual areas in light gray. The scale bars, adjacent to the names of the species, correspond to 1 mm.

usually conform to the columnar organization of the cortex, spanning all cortical layers. Although modules are present in mammals from different orders, the most clear-cut examples are found in primates. For example, in V1 of monkeys (Fig. 2) some columns of cells are characterized by a high concentration of neuropil that stains densely for the mitochondrial enzyme cytochrome oxidase. These columns aggregate into modules a few hundred micrometers wide (usually referred to as blobs) that are separated by regions that stain

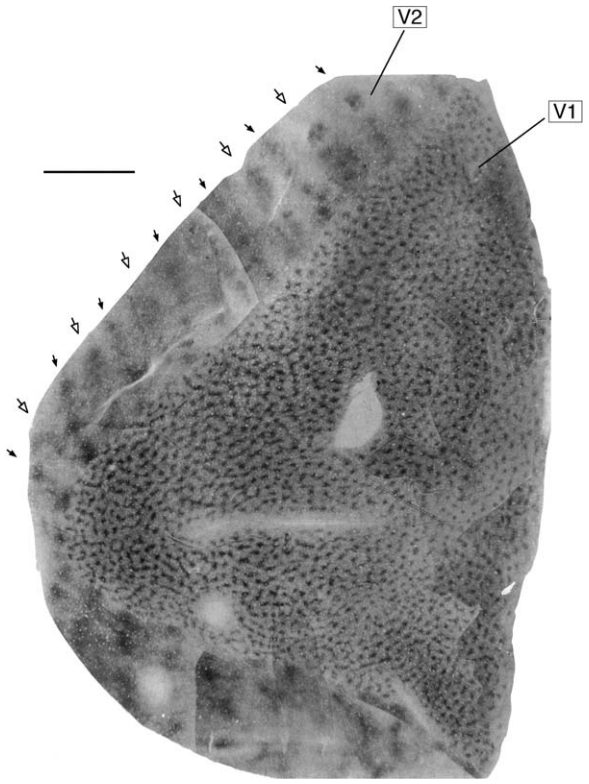

Figure 2 Photographic montage of sections through layer 3 of areas V1 and V2 in a New World monkey (*Cebus apella*). This reconstruction is based on sections tangent to the cortical layers, stained to reveal the mitochondrial enzyme cytochrome oxidase. The V1 blobs and V2 stripes are clearly visible. Thin and thick stripes are indicated by black and white arrows, respectively. Scale bar = 4 mm.

more lightly for cytochrome oxidase (interblobs). Cells in the blobs and interblobs differ even in terms of basic characteristics, such as their dendritic tree morphology and afferent connections from the thalamus. Thus, rather than a homogeneous collection of cell columns, some visual areas are best described as mosaic-like aggregates of two or more types of columns.

It is known that during development, afferents from different sources tend to segregate into adjacent groups of columns, based on the degree of their correlated activity. Thus, one possibility is that modules are formed whenever an evolutionarily new afferent pathway to an already existing visual area emerges. However, why are modules sometimes formed rather than having cells with different characteristics grouped into different areas? One suggestion is that the existence of a modular organization allows more efficient interactions between circuits of neurons that analyze different aspects of the image. For example, a shape can be delineated not only by differences in luminance between an object and the background (e.g., a shadow against a wall) but also by features such as texture, color or the correlated motion of image elements. Shape analysis based on interactions between cells that analyze these different parameters may be facilitated if they are located in modules a few hundred micrometers apart, rather than in separate areas several millimeters apart.

D. What Makes Visual Areas Different from Each Other?

1. Cortical Architecture

The term ''cortical architecture'' refers to the manner in which the different cellular components are distributed and interconnected in the three-dimensional structure of the cortex. In histological sections stained to reveal the neuronal cell bodies, some areas can be seen to differ in characteristics such as the number and thickness of the cortical layers, cell body sizes, and cell densities. These characteristics are referred to as *cytoarchitecture*. In reality, with the exception of the border of V1, cytoarchitecture is not particularly useful in distinguishing visual areas. The study of *myeloarchitecture* (the distribution and density of myelinated axons in the different layers of cortex) has proved more fruitful because several extrastriate areas can be distinguished in this way (Fig. 3). Nonetheless, the myeloarchitectural boundaries are often subtle, and it is normally the case that this type of analysis is used to confirm rather than propose the existence of an area. Finally, particularly in the past 20 years, histochemical and immunocytochemical techniques have revealed that visual areas differ in terms of the distribution of certain chemicals, such as enzymes and neurotransmitters. A good example of this is the detection of modular systems such as the cytochrome oxidase blobs of V1. Combining several architectural techniques in one preparation yields the best precision in determining the boundaries of visual areas because borders that may not be obvious with one stain may be clear with another.

2. Patterns of Connections

In many cases, the first indication that a distinct area exists in a region of cortex is the fact that it receives axonal projections that are different from those of adjacent cortex. For example, only a small region of the superior temporal sulcus of the macaque monkey

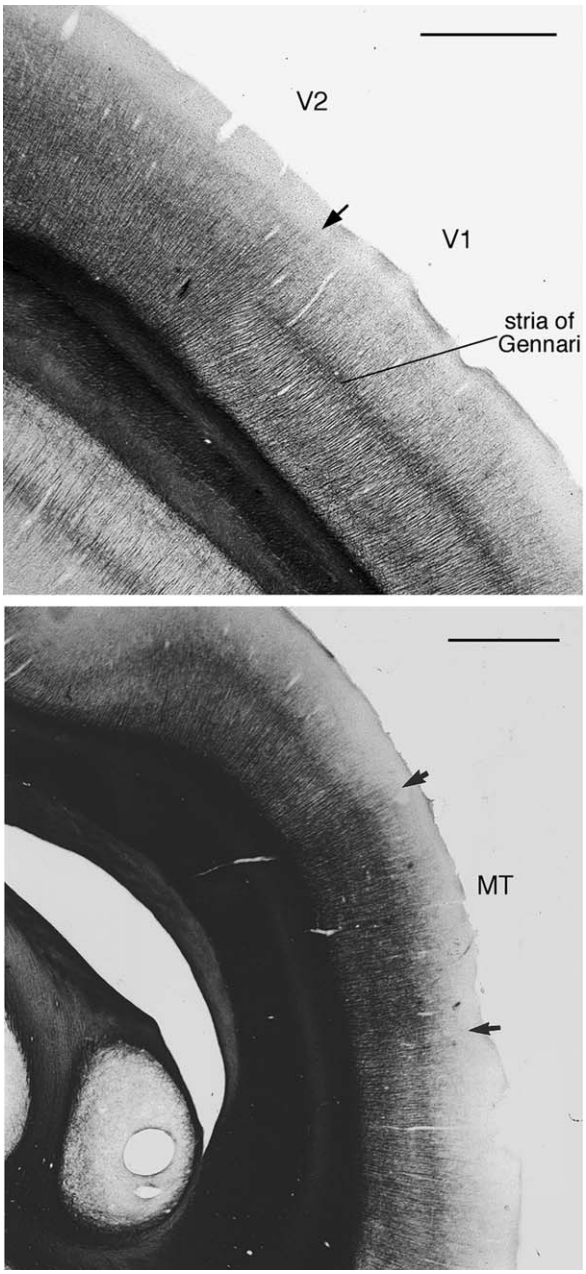

Figure 3 Myelin-stained sections (Schmued's gold chloride stain) illustrating the different myeloarchitectures of visual areas in marmoset monkeys. (Top) Parasagittal section through the V1/V2 border. (Bottom) Coronal section through area MT. The arrows indicate the borders of areas, and the scale bars 1 mm.

receives direct connections from V1. This was one of the first indications of the existence of the middle temporal area (MT), later found to be distinct from adjacent cortex also in terms of architecture and electrophysiological characteristics. Likewise, areas can be identified on the basis of their efferent connections. Thus, in New World monkeys there is a relatively circumscribed region of the inferior temporal cortex (the temporal ventral posterior area) that projects to V1.

3. Receptive Field Characteristics

The *visual receptive field* is the part of the visual field that when stimulated (by the presentation of objects or patterns in front of the eyes) will cause a neuron to respond by changing its firing rate of action potentials (Fig. 4). The receptive fields of neurons in different visual areas are distinct in terms of size, selectivity for stimulus parameters, and other physiological characteristics such as modulation by behavioral context.

Differences in sizes of excitatory receptive fields (i.e., those parts of the visual field in which stimulation causes a cell to *increase* its firing rate) are often a good physiological indicator of the boundary between two areas. In the part of V1 that deals with foveal vision, the receptive field of a single cell may extend only for a fraction of a degree of visual angle (a "window" of visual field about the size of one letter on this page, or even smaller). In the corresponding part of V2, receptive fields are two to five times larger (i.e., enough to include two or three letters), and those in areas anterior to V2 are several times larger again. In general, the average size of receptive fields increases gradually, from the most posterior area (V1) toward anterior areas. Some cells in visual areas of the parietal and temporal lobes may respond to stimuli presented anywhere in the visual field.

The selectivity of a neuron to the characteristics of visual stimuli presented within its receptive field constitutes its *response properties*. This concept is clearly illustrated in the responses of cells in VI (Fig. 4B, C). Some cells are *orientation selective*, i.e., they will only respond if the visual pattern falling within the receptive field contains lines of a given orientation (e.g., vertical). Others will only respond if the visual stimulus is moving in a particular direction (*direction-selective* cells) or if it has a certain wavelength composition (*color-selective* cells). The response properties of cells are thought to be a good indication of the physiological role of an area. For example, nearly all cells in area MT are direction selective, but their responses are nearly the same for stimuli of different colors; this is interpreted as meaning that cells in MT are part of a circuit that analyzes the movement of objects but does not contribute much to the analysis of color.

Finally, the responses of cells in some areas are more strongly modulated by the animal's behavior than are

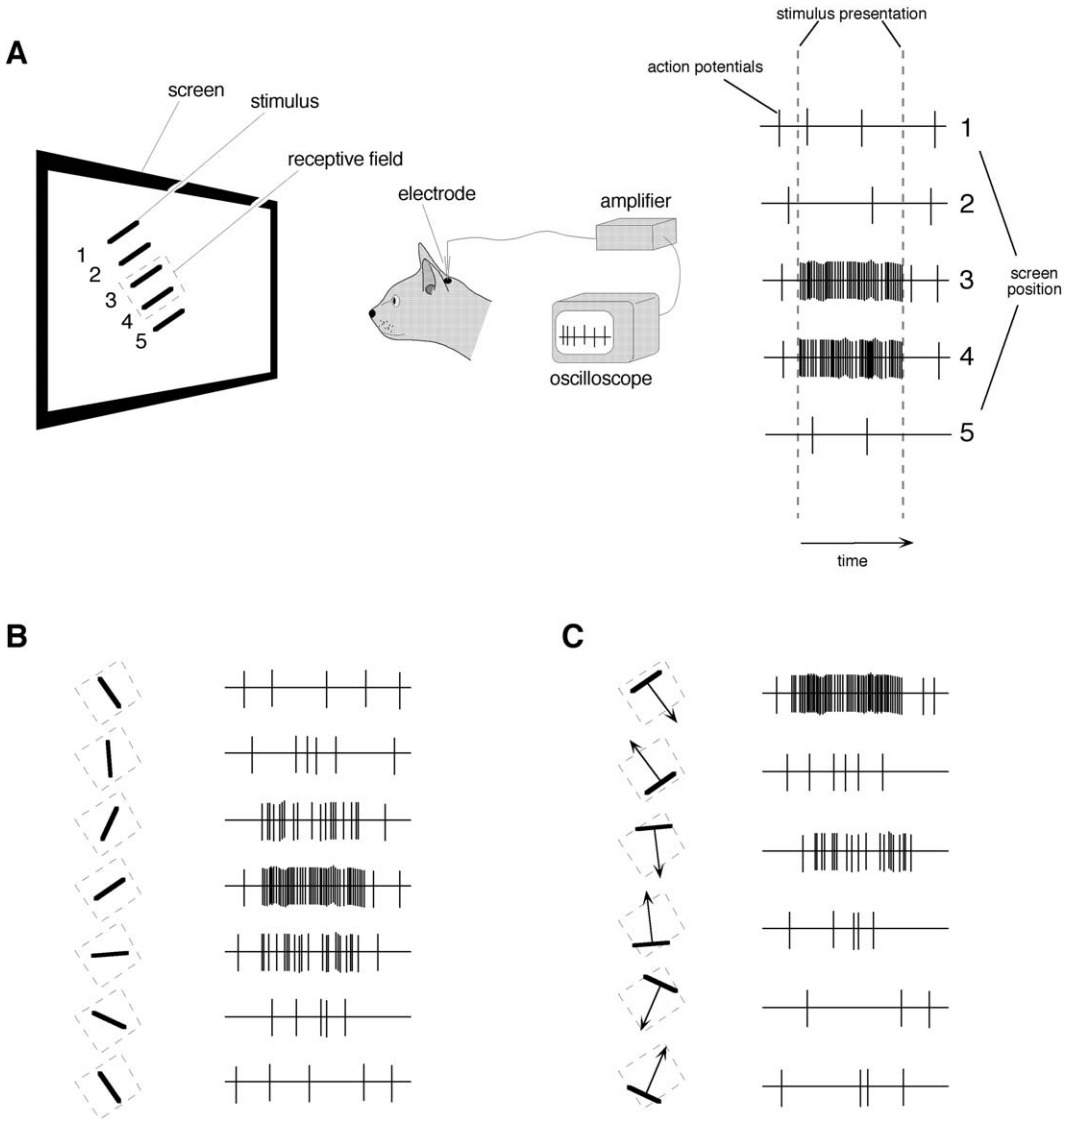

Figure 4 Receptive fields of cortical neurons. (A) Mapping the receptive field extent. The electrical activity of a single cortical cell is monitored while an animal observes a screen. A stimulus (line) is flashed in five different positions (1–5). As indicated on the right, only lines presented in positions 3 and 4 (which are within the receptive field) elicit a change in the cell's firing rate. (B) Orientation selectivity. Lines of different orientations are flashed within the cell's receptive field. The cell's response is greatest to a line of a specific orientation (2–8 o'clock in this case). (C) Direction selectivity. A stimulus moved across the cell's receptive field only elicits a response if it moves downwards, but not upwards.

the responses of cells in other areas. Responses can be elicited from cells in V1 even if the animal is deeply anesthetized, whereas the responses of cells in some extrastriate areas can be suppressed (depending on the type and dosage of anesthetic). In addition, the responses of neurons in some areas can be enhanced or suppressed depending on whether or not the animal is paying attention to that particular part of the visual field, or whether or not it intends to execute an eye movement toward the stimulus. This behavioral modulation is more marked in anterior areas, in comparison with posterior areas such as V1 and V2.

4. Visuotopic Organization

The axonal connections along the visual pathway are organized in such a way that adjacent retinal cells project to adjacent cells in the lateral geniculate nucleus of the thalamus, which in turn project to adjacent cells in V1. As a result of this arrangement, an

ordered map of the visual field (*visuotopic map*) is formed in the cortex. In this map, nearby V1 cells have receptive fields that represent nearby portions of the visual field; moreover, V1 cells on one side of the brain collectively represent the entire contralateral half of the visual field (Fig. 5). The connections between V1 and extrastriate areas, and among extrastriate areas, are also topographically organized; thus, neurons in each extrastriate area form a separate map of the visual field. By counting the number of visuotopic maps in one region of cortex, one can deduce how many areas exist. This has been the basis of many of the proposed subdivisions of primate visual cortex. Recently, non-invasive functional mapping techniques have also been used to map human visual areas based on their visuotopic organization. The visuotopic maps are most precise and therefore more useful as a criterion for subdividing the cortex in V1 and posterior extrastriate areas. Most areas in the inferior temporal and posterior parietal areas have no clear visuotopy.

5. Effects of Lesions

Lesions to different visual areas cause specific deficits in visual perception, and this is one of the best types of evidence to clarify an area's function. It is usually the case that controlled lesion studies are conducted only after there is a good indication of an area's extent. However, this is not always the case. In particular, the study of the effects of lesions in different locations has been instrumental in charting the subdivisions of the inferior temporal cortex, a region without clear visuotopic organization and where architectonic subdivisions are subtle. Long before the existence of multiple extrastriate areas was recognized, clinical evidence revealed that a lesion of a region of the human ventral occipitotemporal cortex causes specific disturbances of color vision (achromatopsia). This syndrome has since been replicated in studies in monkeys, in which the posterior part of the inferior temporal cortex was lesioned.

II. VISUAL AREAS OF PRIMATES

A. Nomenclature

For most of the 20th century, study of the subdivision of visual cortex was based primarily on cyto- and myeloarchitecture. Based on these analyses, it was thought that there were only three visual areas, commonly referred to as areas 17–19 (according to Brodmann's nomenclature). In the 1970s, however, this view was radically changed by the use of intracortical electrophysiological recordings, high-resolution neuroanatomical tract-tracing techniques, and new histological stains, which demonstrated that cytoarchitectural areas 18 and 19 are formed by multiple,

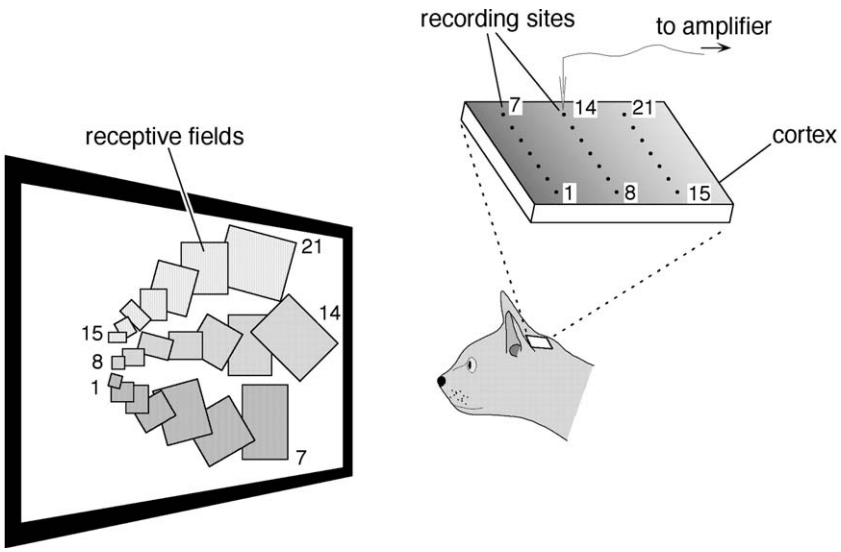

Figure 5 Visuotopic organization of visual cortex. An electrode is moved to different points (1–21) of a cortical area. At each point, the receptive field of a neuron is mapped. The positions of receptive fields in the visual field change systematically as a function of the recording site location.

functionally distinct subdivisions. In addition, the use of single neuron recording techniques demonstrated that visually responsive cells are also common in the inferior part of the temporal lobe (Brodmann's areas 20, 21, and 37), the posterior part of the parietal lobe (area 7), and some parts of the dorsolateral frontal lobe. In each case, these cytoarchitectural subdivisions proved heterogeneous in terms of connections and functions. Thus, although striate cortex is still referred to as area 17 (given that the functional and cytoarchitectural definitions coincide exactly), the numerical nomenclature cannot accurately be used in reference to extrastriate areas.

However, there is no agreement on the best nomenclature of visual areas, a situation that stems from the fact that the borders of these areas are still the subject of debate. Commonly, primate visual areas receive two- or three-letter designations that reflect their location in the brain. For example, area MT was first described in the middle temporal gyrus of the owl monkey, and the lateral intraparietal area (LIP) was first demonstrated in the lateral bank of the intraparietal sulcus of the macaque monkey. This is not an ideal situation, given that the locations of areas in relation to the cortical sulci and gyri vary among species. In other cases, visual areas have received alphanumeric designations that largely reflect the chronology of their discovery (V1 was the first area to be discovered, then V2, V3, V4, etc.). To complicate matters further, some areas have received two or three different designations, and the same name may be used to refer to two different areas. For example, area MT is also known as V5, whereas the name V4 can refer either to a ventrolateral area of the occipital lobe or to the "color center" located in the ventral posterior part of the temporal cortex (to avoid confusion, the latter is best referred to as V8). The emergence of a sensible, unified nomenclature of primate visual areas will probably have to wait until the exact boundaries of extrastriate areas are known and their homologies among species are clarified.

B. The Dorsal and Ventral "Streams"

Figure 6 compares maps of visual areas in a small South American monkey, the marmoset, and man. The likely homologous areas in monkey and man are indicated by similar colors. In monkeys, the boundaries of occipital visual areas have been studied in detail, and most of them can now be identified using a set of reliable criteria. However, the limits of the visual areas of the temporal, parietal, and frontal lobes are still not known with the same level of precision. It should also be kept in mind that relatively few of the human visual areas have had their borders fully determined; thus, most of what we believe about the functions of human visual areas is based on comparative evidence.

As mentioned previously, there are at least a few dozen visual areas in the primate cortex. However, for

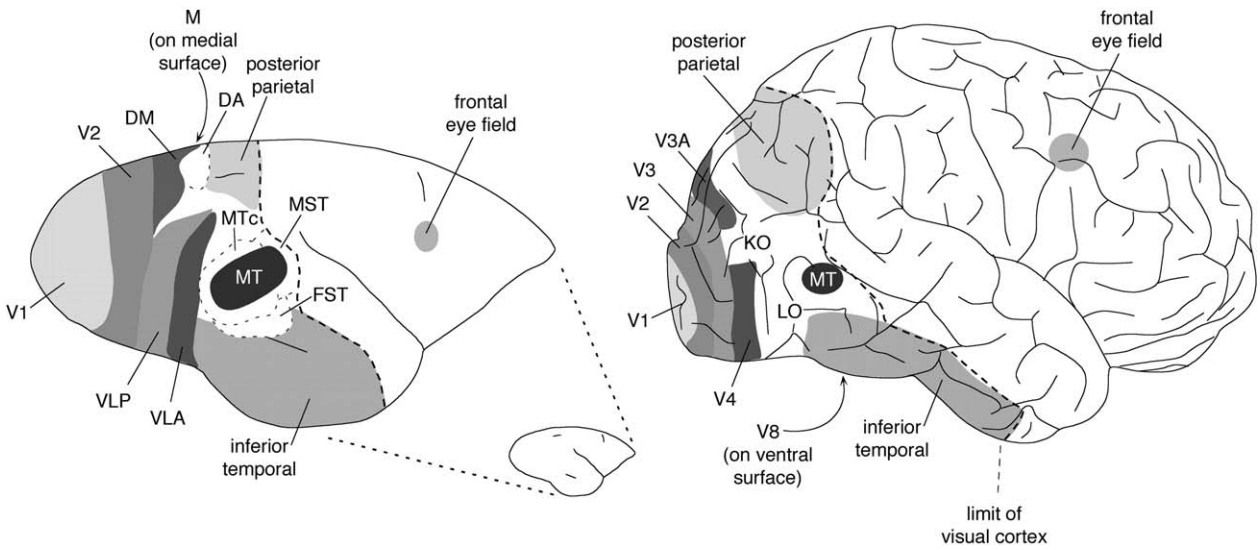

Figure 6 Extent of visual cortex and location of the principal visual areas in a New World monkey (marmoset; left) and man (right). Likely homologous areas are indicated by similar gray shading. The actual size of the marmoset brain in relation to the human brain is indicated in the insert.

didactic purposes, they can be subdivided into functionally related groups. Areas V1 and V2 represent the first cortical stages of visual processing and are characterized by modules that segregate cells that analyze different parameters of vision (contour orientation, luminance, motion, color, texture, etc.). These "*source areas*" project axons to three groups of areas located in the anterior part of the occipital lobe, near the transition with the parietal and temporal lobes: the *lateral*, *dorsomedial*, and *ventrolateral* groups.

Both the lateral group, centered on area MT, and the dorsomedial group, centered on the dorsomedial area (DM), are involved with spatial aspects of vision, including the analysis of motion and the determination of the spatial relationships between objects. These two groups, in turn, project to the *posterior parietal cortex*, in which a unified representation of extrapersonal space, including the location of objects in relation to the observer's body, is created. The ventrolateral group of areas, which in humans includes area V4, performs the early stages of the analyses of shape, color, and texture. These areas project to the inferior temporal cortex, in which these different aspects of object vision are synthesized.

The pathways connecting V1 and V2 to the lateral and dorsomedial groups, and these areas to the posterior parietal cortex, are referred to as the occipitoparietal pathway or "*dorsal stream*" of visual areas; they are involved in telling us *where* things are located. On the other hand, the pathways connecting V1 and V2 to the ventrolateral areas, and these in turn to the inferior temporal cortex, are known as the occipitotemporal pathway or "ventral stream"; they are responsible for establishing *what* things are.

C. Striate Cortex (V1)

Area V1 of primates is located at the most posterior part of the occipital lobe. In humans, it extends from the occipital pole to the rostral tip of the calcarine fissure, near the splenium of the corpus callosum. Flat mounts (histological preparations in which the cortical sulci are physically unfolded and cut parallel to the cortical layers) reveal that V1 forms an elongated oval with fairly sharp boundaries (Figs. 3 and 7). The cytoarchitecture of V1 (Fig. 8) is unlike that of any other cortical area, with each of the six cortical layers being subdivided into sublayers that have distinct afferent and efferent connections. For example, layer 4 is subdivided into two sub-layers (α and β) that are innervated by the magnocellular and parvocellular

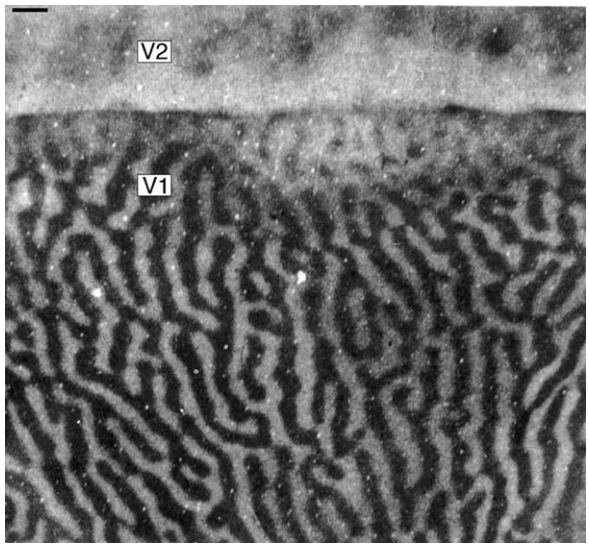

Figure 7 Section tangent to layer 4 of monkey V1, showing ocular dominance stripes revealed by cytochrome oxidase histochemistry. In order to reveal the configuration of stripes, one of the eyes was rendered inactive several weeks prior to the experiment. The light stripes correspond to regions innervated by the inactive eye, and the dark stripes correspond to regions innervated by the active eye. In normal conditions, layer 4 stains uniformly dark for cytochrome oxidase. Scale bar = 800 μm.

subdivisions of the lateral geniculate nucleus, respectively. Indeed, the name "striate cortex" reflects the histological distinctiveness of V1, being derived from the presence of a conspicuous myelinated band (the stria of Gennari; Fig. 3) that lies just above layer 4. The stria of Gennari (which is a subdivision of layer 3, despite being traditionally referred to as layer 4b) allows the easy identification of V1 even in nonstained histological sections. The complex modular and laminar architectures of V1 reflect multiple functional compartments, which process different attributes of vision. For example, the response properties of cells in layer 3 differ depending on whether they are in the blob and interblob compartments. Cells that are strongly selective to stimulus orientation are common in the interblobs, whereas those with selective responses to color contrast tend to reside in the blobs. Moreover, direction-selective cells in V1 concentrate in two layers, the stria of Gennari and layer 6.

Lesions of V1 have devastating effects on visual perception, even when all other visual areas are spared. Partial lesions of V1 cause scotomas, which are blind regions of the visual field whose size and shape reflect the portion of the visuotopic map that was affected by the lesion, whereas larger lesions cause cortical blindness, which is the complete loss of conscious visual

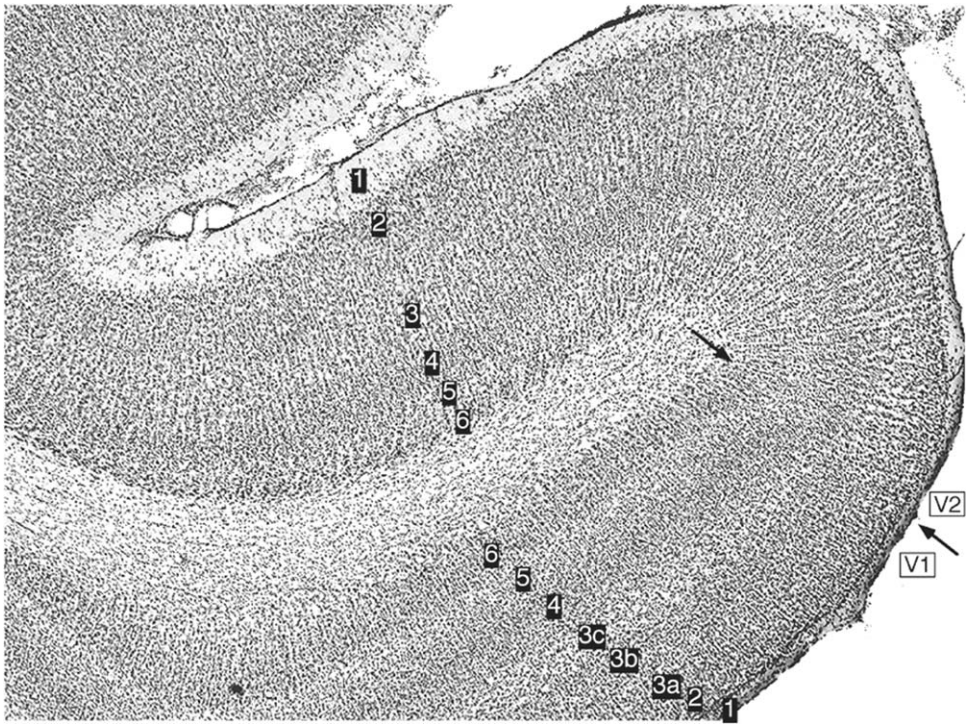

Figure 8 Section through the macaque monkey occipital lobe stained to reveal neuronal cell bodies (cresyl violet stain). The cortical layers are indicated by numbers. The V1/V2 border is indicated by arrows.

perception. This highlights the fact that in primates, V1 receives the bulk of the retinal projections to the cortex via the lateral geniculate nucleus. These projections terminate not only in layer 4 but also in subdivisions of layer 3 (mainly the blob compartments). The corticocortical efferent projections of V1, on the other hand, concentrate in three extrastriate areas: V2, MT, and DM.

D. Second Visual Area (V2)

Area V2 is by far the largest extrastriate area, being on average only slightly smaller than V1. It forms a continuous belt of variable width, which surrounds area V1 except for a small gap near the rostral tip of the calcarine sulcus. The cytoarchitecture of V2 is similar to that of adjacent areas, except V1. However, its limits can be easily determined in flat-mounted preparations stained to reveal the presence of the mitochondrial enzyme cytochrome oxidase. Such preparations reveal a unique architecture of ''stripes,'' alternately rich and poor in cytochrome oxidase content (Fig. 2). Like the blobs and interblobs in V1, these stripes represent modular compartments, containing cells that process different types of visual information. The cytochrome oxidase-poor stripes (or ''interstripes'') concentrate cells whose responses are selective to stimulus orientation and length and thus are likely to be involved in the processing of shape. Cytochrome oxidase-rich stripes, on the other hand, are of two alternate types: thick stripes that contain direction-selective cells and thin stripes that contain cells that respond strongly to color contrast but show little selectivity to either orientation or direction of motion. V2 is the main cortical target of V1 axonal projections. Each type of V2 stripe receives afferents from a different module or layer of V1 (Fig. 9), reflecting its functional specificity; for example, the shape-selective cells in the interstripes of V2 receive projections mainly from the interblobs, whereas the color-selective cells in the cytochrome-rich thin stripes are innervated by the blobs. The efferent connections of V2 are widespread, targeting nearly a dozen other visual areas in the occipital, parietal, temporal, and frontal lobes. Typically, these projections are also specific with respect to the stripe architecture: A given extrastriate area only receives projections that originate in one or two types of stripe.

The effects of V2 lesions have been studied in monkeys, but a clear picture of the exact contribution

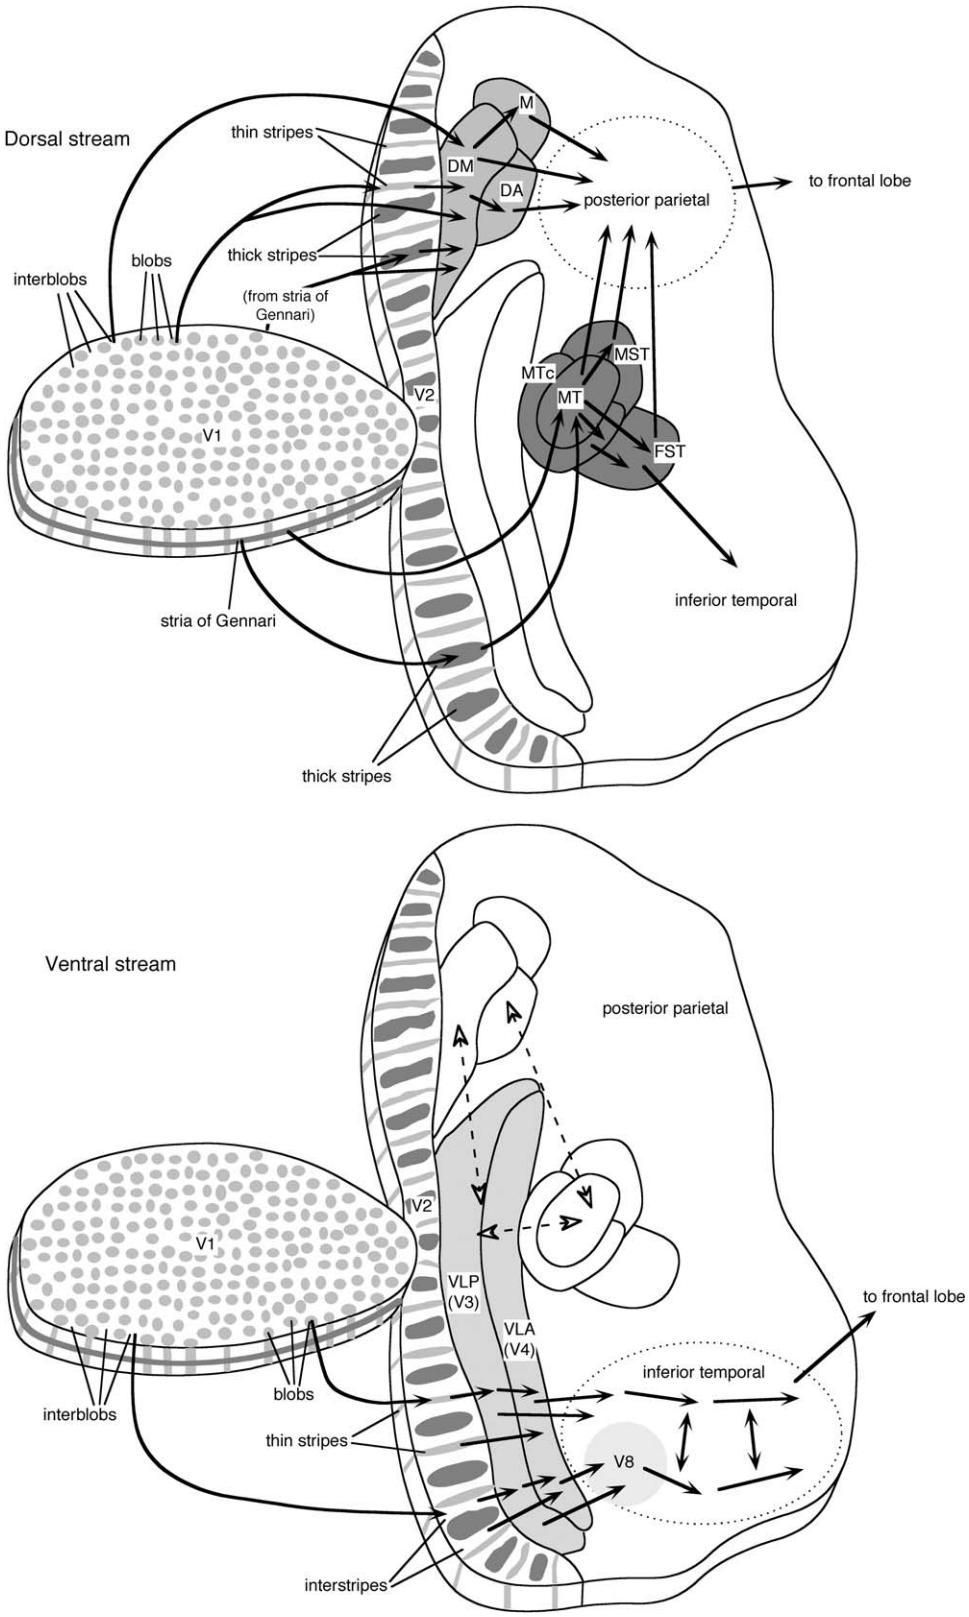

Figure 9 Schematics of the main axonal interconnections between visual areas in the monkey. In these diagrams, V1 has been separated from extrastriate cortex, and the sulci have been "unfolded." (Top) Dorsal stream areas. (Bottom) Ventral stream areas. The white arrows in the bottom diagram indicate interconnections between "streams."

of this area for vision has not yet emerged. Unlike the devastating effects of a V1 lesion, monkeys with V2 lesions are not affected in terms of visual acuity or contrast sensitivity. However, they can be severely impaired in more complex tasks involving spatial discriminations. For example, although these monkeys have no problem detecting the orientation defined by a series of aligned line segments, they perform poorly if the same pattern is presented against a background of line segments of various orientations.

E. Lateral Group

The second main target of V1 projections is MT, an oval-shaped area located near the limit between the occipital and temporal lobes. Area MT is much smaller than either V1 or V2. Unlike most extrastriate areas, it can be easily distinguished from adjacent cortex in histological sections due to an unusually high myelin content (Fig. 3B). Functionally, MT appears to be specialized for the analysis of motion. Nearly 90% of MT neurons are strongly direction selective, and they are far more strongly responsive to moving patterns than to stationary ones. These neurons are organized into two types of modules, which analyze either motion over large parts of the visual field (wide-field motion modules) or the contrast between the direction of motion of one object and that of the background (local-motion modules). Given the response properties of MT cells, it is not surprising that this area's afferent connections from V1 and V2 originate in layer 3 compartments that are themselves involved in motion analysis: the stria of Gennari and the thick cytochrome-rich stripes, respectively (Fig. 9).

The cortex surrounding MT includes a set of small visual areas that are also part of the motion analysis pathway, each being strongly interconnected with MT. The middle temporal crescent (MTc, also known as V4t) is a belt-shaped area that surrounds MT along most of its posterior border, whereas the medial superior temporal area (MST) adjoins MT anteriorly. A third area, FST (first described in the fundus of the superior temporal sulcus of the macaque), is located ventral to MTc (Fig. 9). Although the histological characteristics of MT have allowed the determination of its extent in the human brain, the exact boundaries of MTc, MST, and FST remain unknown. The physiological responses of cells in these areas and their anatomical connections suggest that they are involved in different types of motion analyses. Cells in MST have very large receptive fields, and they respond best to complex moving patterns, such as radial patterns of motion that approach or recede from the fovea. These cells appear suited for the analysis of optic flow, the perceived motion of the visual field that one experiences when moving through the environment. Optic flow is important for determining the direction of an observer's self-motion as well as providing clues about distances (e.g., objects that are closer to the observer move faster than distant ones). In contrast, the neuronal receptive fields in MTc and FST tend to be smaller, and only about half of the cells are strongly direction selective. Whereas the connections of MST focus, to a large extent, on areas of the posterior parietal cortex, those of FST target both parietal and temporal areas. This suggests that FST is involved in the integration of information analyzed by the dorsal and ventral streams of processing.

Due to its small size, lesions of area MT typically also affect its satellite areas to some extent. These lesions cause marked deficits in the perception of motion without affecting the visual acuity for stationary patterns. The deficits can be temporary for simple tests, such as deciding whether an object is moving to the left or to the right. However, more complex discriminations can be permanently affected —for example, in situations of transparent motion (when a group of dots moves coherently in one direction, against a "noisy" background of dots moving in different directions). The specific loss of motion perception caused by bilateral MT lesions (akinetopsia) is extremely rare in humans.

After lesions of V1, some neurons in area MT remain responsive to visual stimuli presented inside the resulting scotoma. These cells are activated by an indirect visual pathway that bypasses V1, involving sequentially the retina, the superior colliculus, the pulvinar, and MT. It is believed that these responsive cells are the physiological basis of *blindsight*, the ability demonstrated by patients and monkeys with V1 lesions to guess correctly the characteristics of visual patterns presented in their blind field, despite their lack of conscious visual perception. Blindsight demonstrates a dissociation between having access to visual information, on the one hand, and being able to consciously experience vision, on the other hand.

F. Dorsomedial Group

The third main cortical target of V1 axonal projections is the DM area, which corresponds to a densely myelinated, wedge-shaped region located anterior to

V2, near the dorsal midline. In humans, the likely homolog of DM has been named V3A (Fig. 6). The exact contribution of DM to visual processing remains unclear. The projections of V1 and V2 to DM originate from multiple modular compartments, suggesting that DM cells can integrate information about different visual parameters. In agreement with this hypothesis, the responses of most DM neurons are strongly dependent not only on the orientation of contours but also on the direction of motion. One possibility is that DM is involved in the separation of objects from background on the basis of motion cues. Another clue to the function of DM neurons is the fact that although the visuotopic maps of most visual areas strongly emphasize the representation of the central part of the visual field, this trend is less marked in DM. This argues against a role in the fine analysis of shape. However, the effects of DM lesions have not been the subject of controlled studies.

In monkeys, the cortex immediately anterior to DM includes other areas that are anatomically and functionally related to DM. These include the dorsoanterior (DA) and medial (M) areas, which are located at the occipitoparietal transition, near the midline. The emphasis on representation of central vision is even less marked in M than in DM; in fact, M remains unique in being the only visual area that represents all parts of the visual field more or less equally. These occipitoparietal areas form an important anatomical link between occipital areas, including DM, and the posterior parietal cortex. This suggests that they represent stages of spatial vision processing and may contribute to visuomotor integration, including the control of eye movements.

G. Posterior Parietal Cortex and Frontal Visual Areas

The designation ''posterior parietal cortex'' encompasses a group of areas located within cytoarchitectural areas 5 and 7, which are important for visuomotor integration and direction of attention to specific parts of extrapersonal space. Most, if not all, areas in this part of visual cortex appear to be specific to primates. One of the best characterized posterior parietal areas is LIP, which is involved in the control of saccadic eye movements and in updating the brain's neural representation of extrapersonal space with respect to eye movements. Other subdivisions of the posterior parietal cortex are involved in the visual coordination of hand movements and the analysis of self-motion. In many cases, this requires combining visual inputs with information processed by the somatosensory and motor systems (e.g., information about the positions of joints and the motor commands sent to the eyes). It is unclear exactly how many areas exist within the posterior parietal cortex. At least six subdivisions have been proposed for the monkey, and more may exist in humans. Lesions involving posterior parietal areas can cause a number of symptoms, including difficulties in initiating or maintaining eye movements, as well as problems with visual orientation toward the side contralateral to the lesion. In some cases, a patient may start to ignore completely the extrapersonal space contralateral to the lesion, a condition referred to as *neglect*.

The posterior parietal cortex is strongly interconnected with the cortex of the frontal lobe, which is involved in complex cognitive functions including motor planning and working memory. Among the frontal areas innervated by the posterior parietal cortex are the frontal eye field and the supplementary eye field, which, as suggested by their names, are closely involved in the control of eye movements including saccades. Cells in both areas respond to the presentation of visual stimuli within their receptive fields but are also active immediately prior to eye movements.

H. Ventrolateral Group

Two relatively large, highly elongated visual areas occupy the regions of cortex located anterior to V2, in the lateral aspect of the occipital lobe and the ventral cortex that overlies the cerebellum. In marmoset monkeys, in which the most complete maps of their extent and organization have been obtained, these are named the ventrolateral posterior and ventrolateral anterior areas, whereas in the most commonly used nomenclature of human areas these have been dubbed visual area 3 (V3) and visual area 4 (V4). An additional area, named LO (lateral occipital area), appears to exist in the human cortex that is functionally related to the ventrolateral group (Fig. 6). Physiological studies in monkeys demonstrate that the ventrolateral areas represent stages in the processing of shape, color, and texture—features that are important for identifying what an object is. For example, the responses of cells in V4 are sensitive to characteristics such as the length/width ratio of a rectangle as well as its size and orientation. Moreover, these cells will respond best if the color of the stimulus is different from that present

in the background. The visuotopic maps of ventrolateral areas are strongly dominated by the representation of the fovea, where visual acuity is maximal. This is in agreement with a role of these areas in the fine analysis of patterns.

Lesions of ventrolateral areas, including V4 and probably parts of V3, have been studied extensively in monkeys. In general, the observed deficits reflect the role of these areas in object recognition. Thus, monkeys with V4 lesions have problems discriminating between objects that are similar in shape but not between very dissimilar objects. They are also profoundly impaired in the recognition of an object presented from different viewpoints, or that has been partially occluded from view by other objects. Finally, V4 lesions cause problems in discriminating the characteristics of an object presented among others, especially if these other objects are more "salient" due to a higher contrast in relation to the background. In humans, lesions involving the ventrolateral areas may be the cause of *object agnosia*, the inability to recognize real objects, and *agnosia for drawings*, the inability to identify a drawn object.

There are relatively few interconnections between V1 and the ventrolateral areas. In contrast, they receive massive projections from V2 that originate from the cytochrome-poor interstripes and the thin cytochrome-rich stripes (Fig. 9). The ventrolateral areas form the bulk of the cortical projections to the inferior temporal areas.

I. Inferior Temporal Cortex

The histological distinctions between inferior temporal areas are subtle, and the best evidence for multiple subdivisions comes from functional studies. We are far from knowing exactly how many areas exist, or even whether the functional subdivisions of the inferior temporal cortex can be adequately described as spatially segregated areas. Nonetheless, evidence indicates that the inferior temporal areas form a posterior-to-anterior gradient of processing, in which increasingly more complex "syntheses" of object features are generated at each stage. Thus, in this simplified model, neurons in the posterior areas of the inferior temporal cortex analyze relatively simple features, such as the number of corners and intersections in a shape or its color composition. These areas project to more anterior areas, which combine these features into increasingly more "explicit" representations of objects. For example, some neurons in anterior inferior temporal cortex are strongly activated upon an animal viewing a picture of a face, but they may respond less strongly to a picture of a face in which the positions of the eyes, nose and mouth have been rearranged (Fig. 10). This suggests that neurons in these areas are not involved in detecting simple physical characteristics but rather the exact combinations of features that characterize an object. It is therefore not surprising that lesions involving the inferior temporal cortex cause deficits not only in object identification but also in the consolidation of visual memory.

Besides the posterior–anterior gradient, there are also distinctions between dorsal and ventral regions of the inferior temporal cortex. Thus, in humans, a ventral area of posterior inferior temporal cortex (V8) appears to be specifically involved in the processing of color. A lesion of this region, which is located in the fusiform gyrus, causes loss or severe distortions of color vision (*achromatopsia*). More anterior lesions of

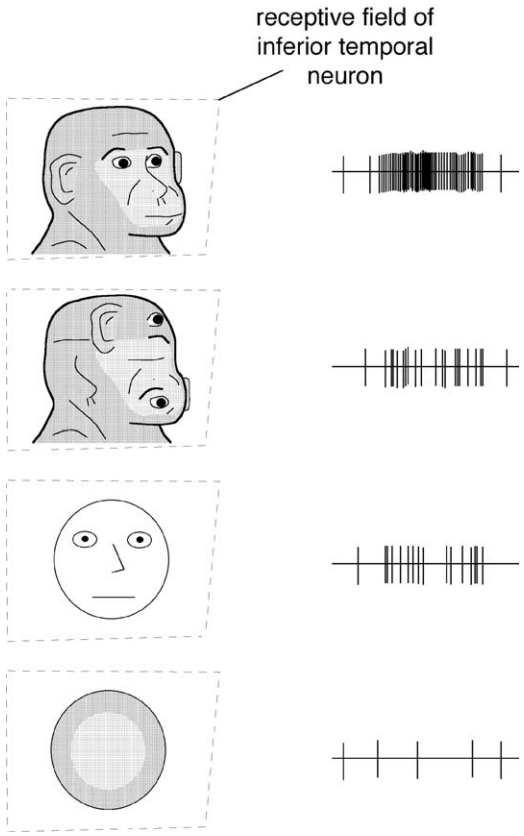

Figure 10 Responses of a face-selective inferior temporal neuron. A photograph of a monkey face presented on the cell's receptive field elicits a strong response (top). Pictures of "scrambled" faces, cartoon faces, or geometric shapes yield weaker responses.

the ventral part of the inferior temporal cortex cause deficits in the discrimination between similar objects that belong to the same category (the most intensively studied of these syndromes is *prosopagnosia*, the inability to distinguish faces). Finally, dorsal areas of the anterior part of the inferior temporal cortex integrate inputs from the ventral and dorsal streams together. In monkeys, neurons in this region, located in the superior temporal sulcus, may respond best to a view of a person walking forward but not backward. This response property requires convergence of shape and motion information onto single cells.

III. FUNCTIONAL ARCHITECTURE OF VISUAL CORTEX

With few exceptions (such as the distinct lamination of V1), the realization that visual areas are often rather distinct in terms of architecture is relatively recent. Indeed, it has been a long-standing view in the fields of cortical anatomy and physiology that the cortical circuits in different areas are essentially similar, and that many of the functional differences between cortical areas are due to the different sources of axonal inputs. Research in the past two decades has demonstrated that this is not an accurate view, and that functional differences are often accompanied by structural differences. This realization is the result of the development of new methods for revealing the chemical architecture of the brain, the detailed morphology of cells, and the way they interconnect within one area.

A. Neurons of the Visual Cortex

Like all neocortical areas, the areas of visual cortex are formed by six layers of cells, numbered sequentially from the surface of the brain to the white matter. Even V1, which has acquired a unique lamination during the course of primate evolution, can be seen as an elaboration of the basic six-layered scheme (Fig. 8). There are two types of excitatory neurons: pyramidal cells and spiny stellate cells. The differences between pyramidal and spiny stellate cells include the shape of the cell body (from which their names derive) and the fact that pyramidal cells have apical dendrites, which project across layers toward the pia mater. Spiny stellate cells tend to concentrate around layer 4, whereas pyramidal cells are more numerous in layers 3, 5, and 6. Whereas spiny stellate cells are usually regarded as local circuit interneurons, there are some exceptions to this rule, including many of the cells that form the pathway from V1 to MT. An elaborate dendritic tree covered in spines (which are membrane specializations for synaptic contact) characterizes both of these cell types. The morphology of pyramidal cells varies systematically between visual areas. For example, the dendritic trees of V1 pyramidal cells tend to be smaller and to have fewer spines per unit length, in comparison with V2 or MT cells. In general, the size of the dendritic tree, the complexity of its branching pattern, and the spine density all tend to increase as one considers cells in successively more anterior visual areas. As a result of these trends, pyramidal neurons in layer 3 of inferior temporal areas, for example, may have 10 times more spines than a V1 cell in the same layer, allowing for the integration of more synaptic inputs.

Smooth stellate are the main cortical inhibitory neurons, which distribute across all cortical layers. They can be further divided into morphological subgroups depending on their axonal branching pattern, the targets of their synapses, and the presence of different calcium-binding proteins. The distribution and connectivity of these inhibitory cell types are distinct in different areas. For example, the inhibitory terminals of parvalbumin-immunoreactive chandelier cells are relatively sparse in V1, more common in V2, and most frequent in inferior temporal cortex.

B. Cortical Layers

Studies of the connections between cells in the same visual area suggest that the six layers of cortex segregate cells that perform distinct sequential stages of visual processing. The basic picture that emerges from these studies (Fig. 11) is as follows:

- Layer 4 is the principal cortical input layer because it receives the majority of the afferent connections that determine an area's function. Thus, the projections from the lateral geniculate nucleus of the thalamus to V1 terminate in layer 4, as do those from V1 to V2. Layer 4 is also known as the *granular layer* in view of the small and closely packed stellate cell bodies contained therein.
- By means of vertical ascending axons, cells in layer 4 project neurons in the *supragranular layers* (layers 2 and 3), either directly or through intervening interneurons. Cells in layers 2 and 3 give origin to *extrinsic connections* (i.e., those that connect an area to

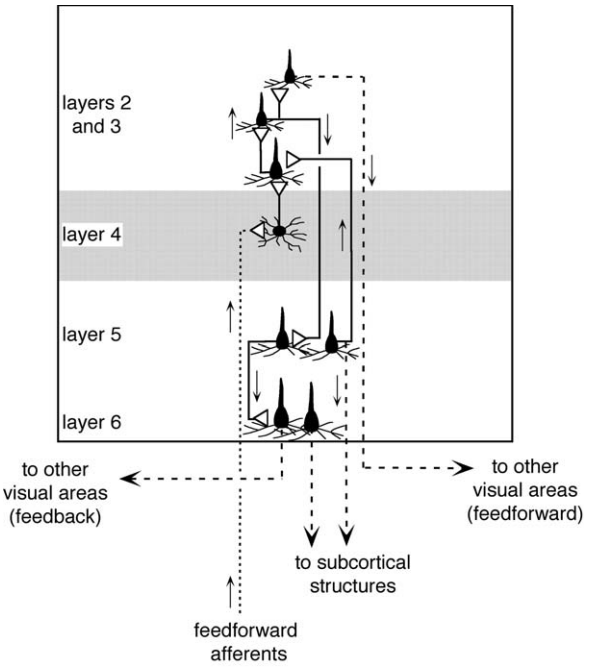

Figure 11 Main laminar excitatory interconnections between cells in a cortical column.

other areas, either in the same or the opposite hemisphere). For example, most V1 cells that project to V2 are located in layer 3.

- Axons of layer 3 cells also project to cells in layer 5, which in turn project to layer 6. Neurons in both layers 5 and 6 (the *infragranular layers*) are the main sources of extrinsic connections to subcortical nuclei (including the lateral geniculate nucleus, pulvinar complex, superior colliculus, pons, and claustrum). In addition, as detailed later, they form "feedback" pathways to other cortical areas (e.g., from MT back to V1).
- In addition to the previously mentioned connections, cells in the different layers interact vertically (i.e., across layers) via other systems of intrinsic axons. For example, cells in layer 5 send axons to layers 2 and 3, and those in layer 6 contact inhibitory cells in layer 4.

C. Columnar Organization

It is clear from the previous discussion that many of the interactions between cells in the same visual area occur via vertical axons, which run across layers. By virtue of this arrangement, the functional organization of visual cortex is dominated by *columns*, groups of tightly interconnected cells that occupy cylindrical compartments of cortex spanning all cortical layers. Functionally, a cortical column is defined by a particular response property, which is shared by all cells that form that column. For example, in many primate species the axons that bring information from the left and right eyes to V1 terminate in interdigitating but largely nonoverlapping territories of layer 4. In these territories (*ocular dominance stripes*; Fig. 7), cells respond exclusively to stimulation of one of the eyes. The inputs from the two eyes then converge onto single cells in the supra- and infragranular layers of V1; nonetheless, binocular cells in these layers continue to respond more strongly to one of the eyes, according to whether they overlie a left- or right-eye layer 4 stripe. Thus, the predominantly vertical interactions between layer 4 and the other layers of V1 result in *ocular dominance columns* spanning all cortical layers. The responses in all cells in a V1 column are also selective for a similar stimulus orientation, characterizing *orientation columns* (Fig. 12).

The columnar organization of different areas reflects the type of analysis performed. For example, area MT is organized into *direction columns* in which all cells respond maximally to stimuli moving in a particular direction, whereas the inferior temporal area is organized into *shape selectivity columns* in which all cells respond maximally to objects sharing certain features, such as curvature, number of intersections, or color.

Normally, the selectivity of cells for a certain stimulus parameter changes gradually between adjacent columns (e.g., the orientation columns in Fig. 12). A group of columns that represent all possible variations of a given stimulus parameter is termed a *hypercolumn*. For example, an ocular dominance hypercolumn in V1 is formed by adjacent left- and right-eye columns, whereas a direction hypercolumn in MT is formed by many columns, which collectively encompass cells sensitive to the full spectrum (360°) of possible directions of motion. Because cells in adjacent columns have receptive fields covering similar regions of the visual field, the hypercolumnar arrangement allows each small region of the visual field to be fully analyzed with respect to the same parameter (i.e., by cells with different sensitivities) within relatively compact "blocks" of cortex. The best studied hypercolumnar systems are approximately 0.5–1.0 mm across (i.e., parallel to the cortical layers), being formed by dozens of individual cell columns. Finally, in some areas many hypercolumns, representing slightly different parts of the visual field, aggregate into modules. The best example of these are in V2, in

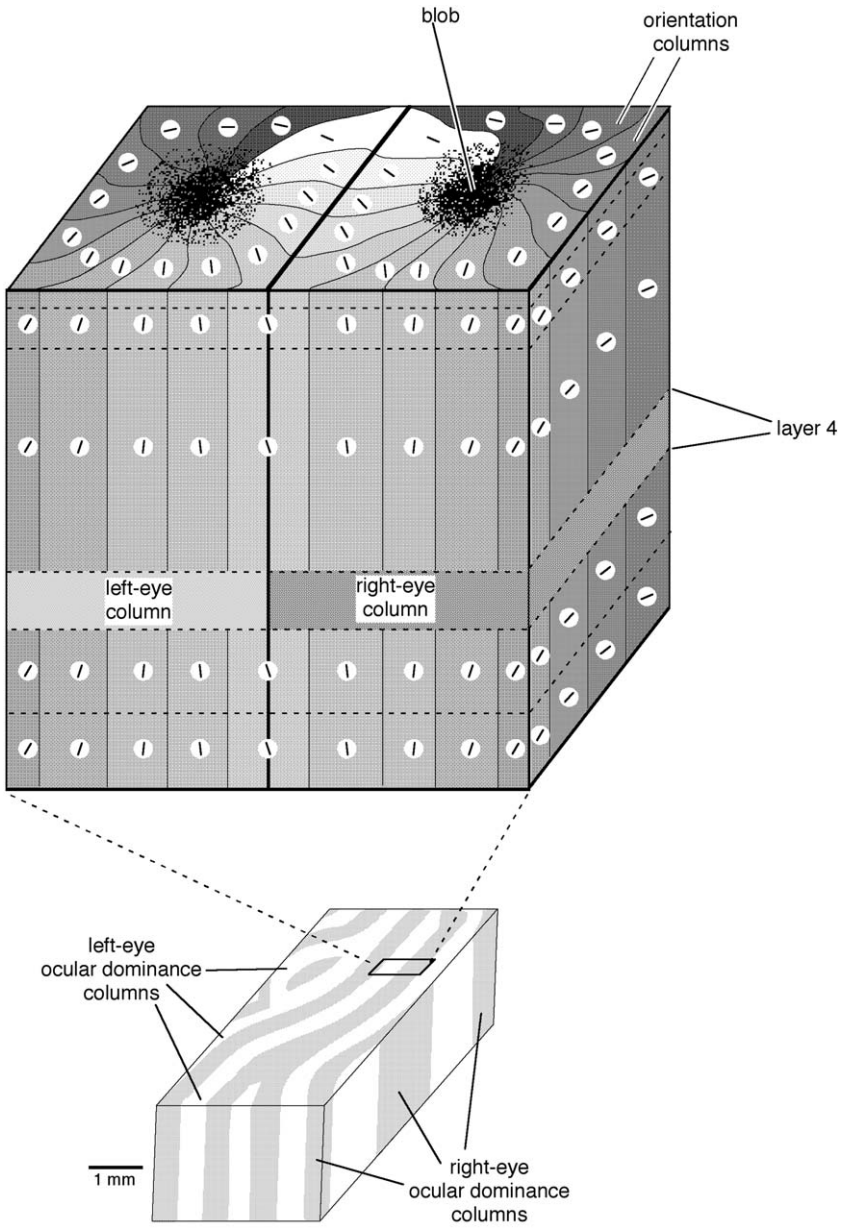

Figure 12 Columnar organization of striate cortex. (Bottom) A small "block" of V1, with ocular dominance columns indicated. A region encompassing two ocular dominance columns is magnified in the top diagram. (Top) Organization of orientation columns. The orientation selectivity of cells in each column is indicated by the line segments. The preferred orientation of neurons changes gradually between adjacent columns. Columns of cells selective to different orientations converge on orientation "pinwheels" centered along the ocular dominance columns. In many cases, cytochrome oxidase blobs (where cells are not strongly selective for orientation) overlie the pinwheels.

which hypercolumns for the same image parameter aggregate to form stripes (Fig. 2).

D. Horizontal Intrinsic Axons

In addition to the vertical axons that connect cells within the same column, visual areas have a system of *horizontal* intrinsic axons that integrate cells in different columns (Fig. 13). Short intrinsic axons connect cells in nearby columns, for example, to mediate inhibitory interactions among cells within the same hypercolumn. Furthermore, there are long horizontal axons whose connections are highly specific: They bypass many columns of cells to form tight clusters of

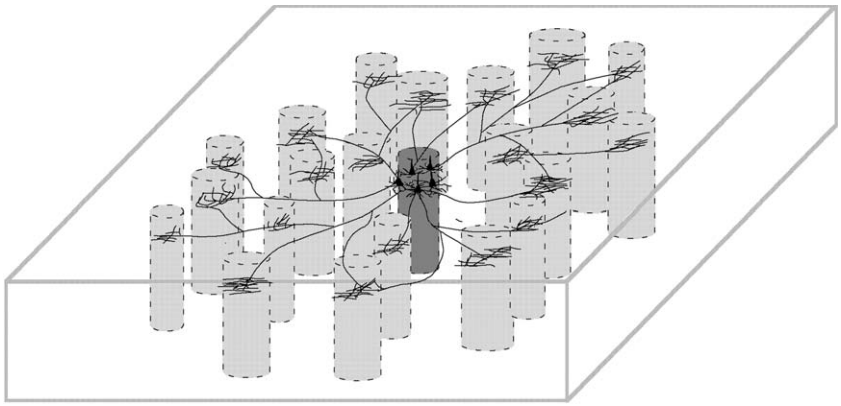

Figure 13 Long-range horizontal connections in layer 3. Cells in one column (dark gray) send horizontal axons to other columns several millimeters away (light gray). Although the horizontal connections are only illustrated for one layer, they in fact extend in register throughout the thickness of the cortex.

terminals in a particular region, sometimes millimiters apart (Fig. 13). The anatomical characteristics of intrinsic axons vary systematically between areas. They are relatively short ranged and have tightly clustered termination patterns in V1. As one moves toward more anterior areas, increasingly longer horizontal axons are observed, and their termination patterns become less tightly clustered. Thus, cells in V1 interact directly only with cells that analyze neighboring parts of the visual field, the interactions of cells in extrastriate areas become progressively more extensive. Horizontal axons are important for a number of physiological processes, most notably contextual modulation, visuotopic reorganization, and sharpening of neuronal tuning to certain stimulus parameters (Fig. 14).

Contextual modulation is the process whereby a neuron's response to a visual pattern is modified by visual stimuli located outside its excitatory receptive field (Fig. 14A). Thus, cells in the local motion modules in area MT will not respond if the background is moving in the same direction as the stimulus presented in the receptive field, whereas cells in V4 may respond less strongly if the object is presented on a background of similar color. These types of comparison, which are mediated by long horizontal axons, require connections between cells with receptive fields located in *different* parts of the visual field but that are selective for the *same* image parameter.

Visuotopic reorganization refers to the changes in the position of neuronal receptive fields that follow changes in the inputs to a visual area. For example, if a region of the retina is inactivated (after a laser lesion or retinal detachment), cells in V1 that had receptive fields in that part of the visual field do not become permanently inactivated (Fig. 14B). Instead, they acquire receptive fields that cover unaffected parts of the visual field surrounding the blind area. This process occurs within a few hours of the lesion and is mediated by long horizontal axons. If the lesion is irreversible, the neuronal responses to stimulation of the new receptive field become gradually stronger over a period of months, a process that appears to be mediated by the growth of new horizontal axons within V1. Visuotopic reorganization has also been observed in area MT after lesions of V1.

The response selectivity of visual cortical cells is sharpened by short-range intrinsic axons. For example, the orientation selectivity of cells in V1 is normally sharp: A cell that is most responsive to vertical contours will only show very weak responses to a similar pattern tilted by 45° and will not respond to a horizontal contour. However, if the strength of inhibitory interactions between adjacent columns is reduced by pharmacological manipulations (Fig. 14C), the same cell starts to show responses to stimuli with those "nonoptimal" orientations. This illustrates the fact that in normal circumstances neighboring columns, which represent different orientations in the same part of the visual field, interact extensively.

E. Feedforward and Feedback Extrinsic Connections

In Section II, the main corticocortical connections between areas were described according to a serial scheme; for example V1 projects to V2, which in turns

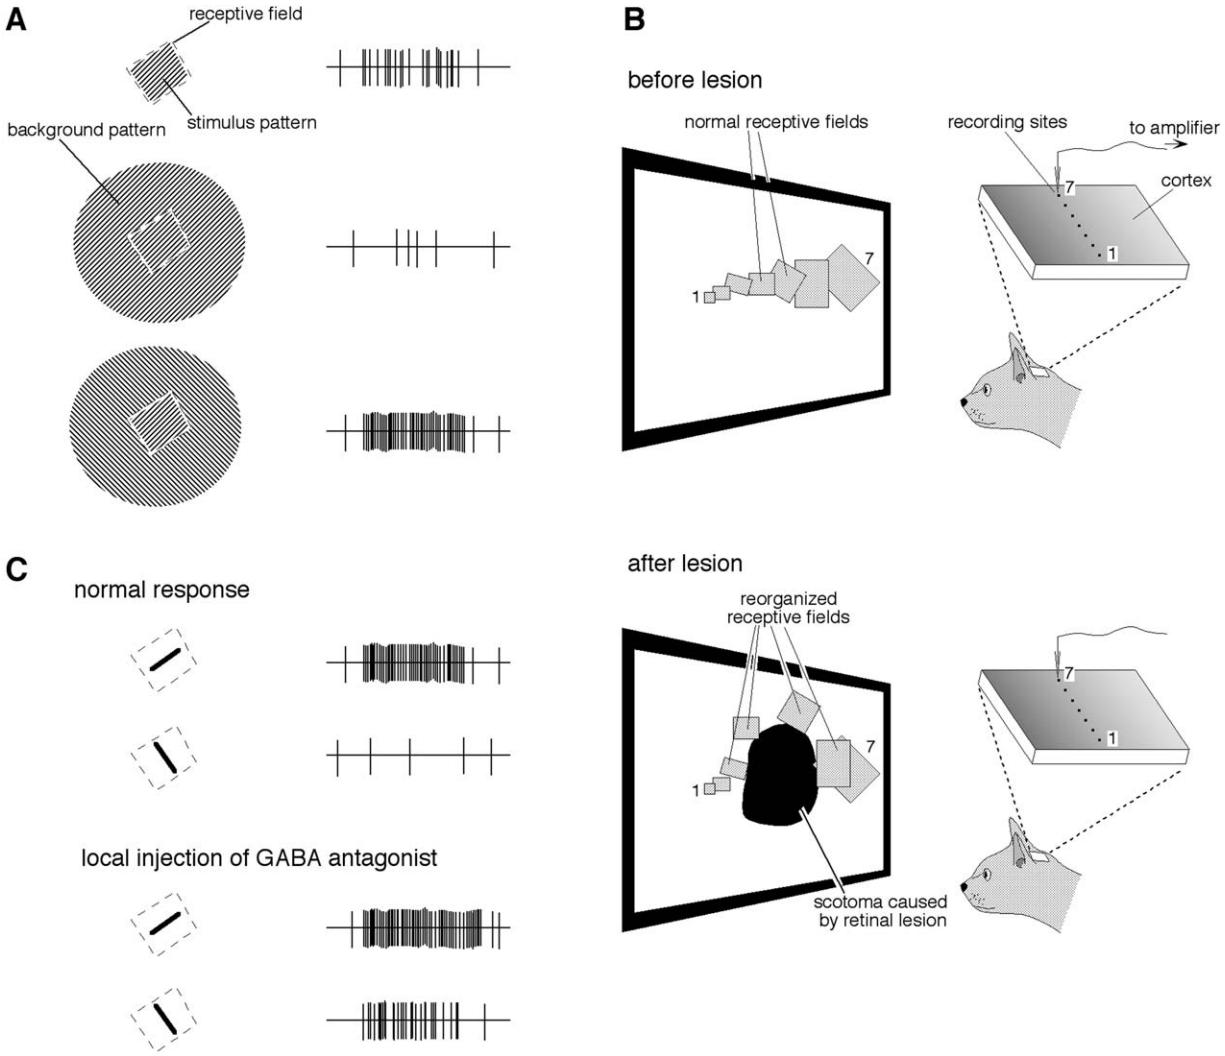

Figure 14 Functions of horizontal connections. (A) Contextual modulation. The neuron's response to a striped pattern presented on the receptive field (top) may be inhibited if the same pattern is presented against a background of similar orientation (middle) or enhanced if the pattern is presented against a background of different orientation (bottom). (B) Visuotopic reorganization. (Top) Normal receptive fields corresponding to a sequence of recording sites in the cortex. (Bottom) After a retinal lesion, the cells that originally represented the affected part of the visual field acquire new receptive fields around the edge of the scotoma. (C) Sharpening of orientation tuning. Upon pharmacological blockage of inhibitory neurotransmission, a neuron starts responding to stimuli of an orientation orthogonal to its preferred orientation.

project to V4, which projects to posterior inferior temporal cortex. This is an oversimplification, because connections between areas are reciprocal: At the same time that V1 projects to V2, some V2 cells project to V1. As a result of this arrangement, connections between different visual areas can be subdivided into two main groups. *Feedforward* connections are those described in Section II. They originate mainly from neurons in layer 3 of one area and contact cells in layer 4 of the target area. In addition, there are *feedback* connections, which originate primarily from infragranular cells and terminate outside layer 4 (Fig. 15). Although cells participating in these two systems appear to be equally numerous, there are good reasons to believe that feedforward connections carry the main flow of information between areas. For example, interruption of the feedforward pathway by means of a lesion of V1 results in a general loss of visual responsiveness in V2 cells, whereas a lesion of V2 only results in subtle changes in the response properties of V1 cells. Moreover, the *response latency* (i.e., the amount of time between the presentation of a visual

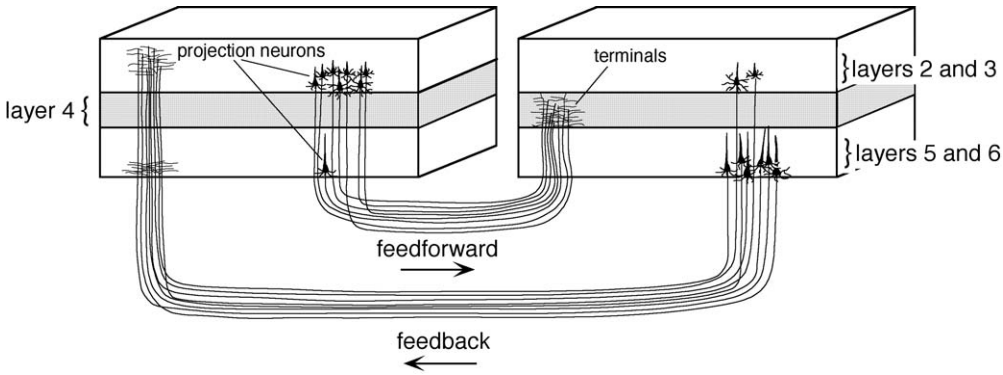

Figure 15 Laminar origin and termination of feedforward and feedback connections between two visual areas.

stimulus and the neuron's response) in different areas reflects, to a large extent, the order suggested by feedforward connections. The patterns of feedforward and feedback connections can be used to rank visual areas according to an *anatomical hierarchy*: V1 occupies the first level of the hierarchy, V2 the second level, etc.

Feedback connections modulate some of the contextual interactions between stimuli presented in the cell's receptive field and the background. Specifically, they enhance these interactions in "low-visibility" situations in which there is little difference between object and background. In addition, it has been suggested that feedback connections are important for visual imagery. According to this view, feedback projections from inferior temporal areas to occipital visual areas (including V1) would be active when one imagines an object while keeping the eyes closed. This would activate the appropriate sets of cells in these areas to form a neural representation of the object that resembles the one elicited by the actual viewing of the same object.

IV. CONCLUSION

The visual cortex can be described at several levels of functional organization. Single cells interconnect according to precise interlaminar patterns to form columns, whereas columns interact not only locally, within the same hypercolumn, but also with distant columns representing other parts of the visual field. Neurons in each cortical area form a separate representation of the visual field, each engineered by natural selection in order to allow the analysis of a different set of features of the visual image. Cells in different areas also interconnect extensively, according to highly precise modular systems that keep cells analyzing different visual parameters more or less segregated in different compartments. However, multiple reentrant pathways, both within and between areas, allow interaction between these different modular systems. In summary, the functioning of visual cortex as a whole is unlikely to resemble that of a linear machine, which generates a representation of the "world outside" on the basis of serial steps of analysis. Instead, the visual cortex could be best described as networks of interconnected cells within progressively larger networks of interconnecting cells. Each of these levels of organization performs certain neuronal operations under the influence of many other neural networks.

The evidence also makes clear that the visual cortex is not a mosaic of specialized areas that are responsible for the analysis of a certain aspect of image. Rather, each visual modality is analyzed by groups of interconnected areas, with the feedforward and feedback interactions between areas being as important as the computations performed within each area. Moreover, each area can contribute to different types of analysis; for example, the information about direction of motion analyzed in MT can be used to detect the movement of an object, a person's self-motion, or the shape of a camouflaged vehicle moving against a background. Thus, the same computation performed in one area contributes to different functions, depending on interactions with other areas. The multilayered, massively parallel organization of visual cortex is probably what allows it to solve difficult computational problems, such as recognizing colors in different conditions of illumination or determining one's heading despite eye and head movements, in real time.

GLOSSARY

achromatopsia Defect in color vision.

alexia Defect in reading.

dyslexia Developmental disability in reading.

Disorders of vision and higher visual functions are common in many patients with neurological disease and are also of considerable scientific and theoretical interest in cognitive neuroscience. The visual system is the most widely researched and best understood higher order sensory system in the brain, owing to decades of research at the levels of cells, physiology, anatomy, systems, and theory. This article is a necessarily selective review of some of the more salient, common, or scientifically interesting disorders of higher order visual functions. Our aim is to review essential neuroanatomy and relate this core knowledge to visual syndromes of clinical and scientific interest. In this context, several case examples of complex visual syndromes and illustrative case material are provided.

I. ANATOMY OF THE VISUAL SYSTEM

Our examination of the visual system begins at the level of gross anatomy. Essential gross anatomic features of the visual system are depicted in Fig. 1. Fibers from the retina form the optic nerve, which is approximately 50 mm in length, and flow posteriorly to the optic chiasm. The chiasm is located just below the third ventricle, close to the hypothalamus, and immediately anterior to the pituitary stalk. At the chiasm, fibers from the nasal side of each retina cross, whereas fibers from the temporal side of each retina remain ipsilateral to the eye from which they came. Posterolateral to the optic chiasm, the optic tract is formed. Fibers in the optic nerve follow from whence they arose in the retina: Superior fibers from the retina course in the superior part of the optic nerve, and inferior fibers from the retina follow an inferior tract in the optic nerve.

The optic tract courses posteriorly through the geniculate bodies, in the posterior ventral thalami. The tracts then form the optic radiations, which connect to primary visual cortex in occipital lobe. Three tracts can be discerned in these optic radiations. First, the superior tract emerges from the lateral geniculate, representing the superior fibers from the retina, and courses posteriorly through deep white matter in the parietal lobe and terminates in the superior aspect of the calcarine fissure. The central tract originates from the central portion of the retina (macula), courses through deep temporal and occipital white matter, and terminates immediately above and below the calcarine fissure. Finally, the lower tract originates in the lower part of the retina, courses through the lateral aspect of the geniculate, follows a wide arc over the temporal horn of the lateral ventricle (Meyer's loop), runs to a point approximately 50 mm posterior to the temporal pole, and terminates in the lower aspect of the calcarine fissure.

With this system, the orientation of objects to brain in the visual system is reversed. That is, objects that are shown to the left visual field only (and thus to the right

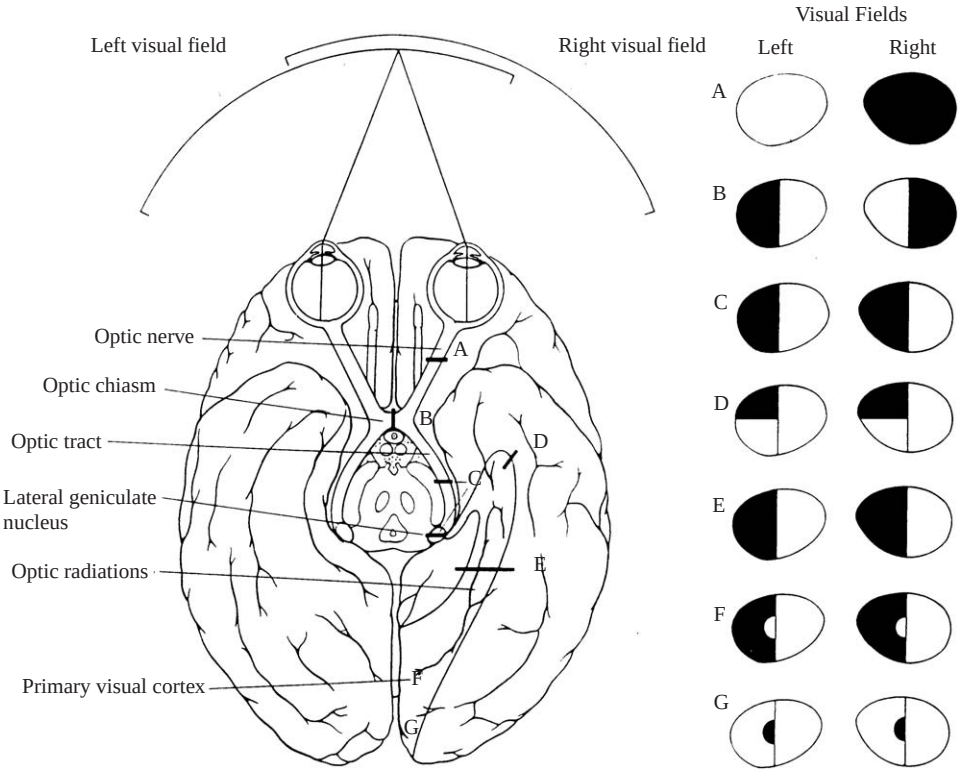

Figure 1 Depiction of the primary components of the visual system and field defects associated with lesions at various levels of the system.

side of the person's retina) are projected only to the right occipital lobe, and objects that appear in the person's right visual field (and thus to fibers in the left side of the retina only) project only to the left occipital lobe. Similarly, objects presented to the upper half of visual space (and thus to the lower half of the retina) are projected only to infracalcarine occipital lobe, whereas objects presented in the lower half of visual space (and thus to the superior aspect of the retinas) project only to supracalcarine occipital lobe.

The site of many lesions of interest in visual function defects can be specified with relative precision. For example, a defect confined to the right eye only would raise suspicion of lesion of the right optic nerve. In the case of *bitemporal hemianopia* (the inability to see on the temporal side of visual space in each eye), a lesion in the midline optic chiasm would be implicated. More commonly, a *homonymous hemianopia* (the inability to see in one-half of visual space in each eye) typically reflects a lesion in the contralateral optic tract, or, with sparing of macular vision, may reflect a contralateral lesion of the entire optic radiation. Finally, a *homonymous quadrantanopia* (the inability to see in one visual quadrant with each eye) reflects a lesion affecting the contralateral optic radiation, with lower (ventral) lesions associated with superior homonymous quadrantanopias and higher (dorsal) lesions associated with inferior homonymous quadrantanopias.

II. DISORDERS OF VISION

A. Pattern Recognition Defects

A broad dichotomy has been observed in the visual system. Specifically, the observation has been made that the visual system can be thought to be composed of two major segments: the superior (dorsal and occipitoparietal) system subserving visual constructive and spatial relationships and the inferior (ventral and occipitotemporal) system subserving object recognition. Lesions in these areas correspond to different identified syndromes, to which we now turn our attention.

1. Visual Agnosia

H. L. Teuber was credited in 1968 with the classic definition of agnosia—that is, a normal percept

stripped of its meaning. In the setting of visual agnosia, such a definition implies normal or near normal sensory perception in the context of impaired recognition of the object being perceived. In fact, given careful neuroophthalmologic and neuropsychological assessment, most patients with visual agnosia can be shown to have some abnormality of perception. With this in mind, it is useful to consider the distinction between "associative" and "apperceptive" agnosia made in 1890 by H. Lissauer. The former corresponds to a "pure" visual agnosia, as reflected in Teuber's definition. The latter, or *apperceptive visual agnosia*, refers to an abnormality of visual recognition in which perceptual features are so prominent as to dominate the clinical picture.

In the course of assessing patients with possible agnosia, it is important to distinguish between defects in naming and defects in recognition. This is a distinction that is commonly either blurred or completely unappreciated in the scientific and clinical literature on agnosia. The key is to understand that an object can be recognized without being named but cannot be named without being recognized. For example, a patient may not be able to produce the name "elephant" but will be able to provide other information that reflects normal recognition (e.g., it has a trunk and tusks, it is found at the zoo/at the circus/in Africa, and there is a story about one named Dumbo). Thus, if a patient is asked to identify an object and fails to produce its name, it is important to probe the patient regarding features of the object to establish that a true recognition defect exists.

2. Prosopagnosia

Prosopagnosia refers to an impairment in familiar face recognition. The term is attributed to Bodamer circa 1947 and derives from the Greek *prosop* (face) and *gnosis* (knowledge). This is a rare condition, but it is of substantial scientific interest.

The patient with prosopagnosia will typically complain of an inability to recognize familiar individuals around them and, in some cases, an inability even to recognize the patient's own face. Individual identities may be recognized by voice, gait, context, or other nonface cues, but the defect may be demonstrated by asking the patient to identify individuals in photographs in which contextual information is deleted. In patients with prosopagnosia caused by acquired brain damage (e.g., by stroke, tumor, or other lesion), there may be some visual field defect, usually a superior quadrantanopia of one or both visual fields. Such patients have otherwise normal neurologic and neuropsychological exams and do not evidence aphasia, amnesia, dementia, or disorders of executive functions. Visual acuity and visual perception may be normal or near normal in associative prosopagnosia, although many cases with clear visual perceptual defects have been described (and probably correspond to an apperceptive type).

In the past 15 years, a series of studies have shed light on a number of the underlying processes involved in prosopagnosia. For example, it has been shown that patients with prosopagnosia demonstrate nonconscious recognition of familiar faces. In one study, patients were shown to have selective electrodermal (skin conductance) responses in relation to familiar but not to unfamiliar faces. These skin conductance responses were elicited to familiar faces despite the fact that the patients were unable to recognize or identify familiar faces. Furthermore, it was demonstrated that patients with prosopagnosia have normal recognition of facial expression, gender, and age based on the perception of faces.

Closer examination of patients with acquired prosopagnosia shows that the recognition defect often extends to objects other than faces. Specifically, patients with prosopagnosia may have difficulty recognizing other objects, provided (i) there are numerous members of the category of the object to be recognized, (ii) there is visual ambiguity (shape similarity) among the objects in the category, and (iii) successful recognition depends on identification at the unique level. Thus, for example, a patient with prosopagnosia may have difficulty recognizing a specific automobile since there is significant visual similarity among exemplars of the category "automobiles," there are numerous members of the category, and the patient is required to identify a specific exemplar of the category.

The lesion associated with acquired prosopagnosia typically involves the occipitotemporal cortex. For the associative type, the lesion is typically bilateral, and the condition is often acquired in stages. That is, particularly with vascular lesions, the patient's history will involve a unilateral occipitotemporal stroke followed some time later by a posterior circulation stroke in a homologous part of the brain in the other hemisphere. For prosopagnosia of the apperceptive type, the lesion may be either bilateral or, in some cases, unilateral. In the case of unilateral lesions associated with apperceptive prosopagnosia, the lesion is typically on the right, is typically large, and includes occipitotemporal cortex, underlying white matter, and may spread

anteriorly and superiorly to include other regions of visual association cortex (Brodmann's areas 18 and 19).

A number of associated clinical conditions can often be observed in prosopagnosic patients. For example, in the associative type of prosopagnosia it is common to see achromatopsia and alexia, whereas in cases of apperceptive prosopagnosia it is common to observe defects in constructional ability and visual attention. These associated conditions are discussed separately later. To merit the term prosopagnosia, however, the central feature of the patient's clinical presentation must be the face recognition defect.

In recent years, a third form of prosopagnosia has been described, termed "developmental prosopagnosia." *Developmental prosopagnosia* refers to a selective face recognition defect that begins in childhood and is not associated with any identifiable structural lesion. A handful of cases have been reported between 1976 and 2001. In general, such cases have shown significant apperceptive features, although one reported case was believed to be an essentially associative prosopagnosia. Similar to cases of acquired prosopagnosia, such patients recognize individuals by gait, voice, or other nonface features. In at least one well-studied case there were features of a broader visual object agnosia. There have been no reported defects in color vision, and neuroophthalmologic exams may be entirely normal. In those cases in which neuroimaging has been completed, no structural brain abnormalities have been identified. Functional imaging has not been done in such cases, but it would be a highly interesting addition to this body of literature. These patients appear to manifest the face recognition disability over many years: Although first identified in childhood, in at least one case the disorder persisted into adulthood. Similar to cases of acquired prosopagnosia, in at least one case nonconscious electrodermal recognition of familiar faces was demonstrated.

3. Defects in Judgment of Emotion and Social Knowledge Based on Face Cues

As noted previously, patients with prosopagnosia, particularly those of the associative type, often have normal judgments of facial emotional expressions. That is, despite their inability to identify the face, judgments related to facial emotional expressions (e.g., happy, sad, angry, and surprised) are similar to those of controls. Recently, the opposite dissociation has been described. In these studies, it was demonstrated that patients with bilateral damage to amygdala were unable to judge emotional facial expressions accurately, despite normal recognition of identity. Similarly, in another study from our laboratory, patients with bilateral amygdala damage were significantly impaired in judging faces that looked "unapproachable" or "untrustworthy." These findings were interpreted to support the proposition that the amygdala was involved in social judgments as well as judgment of emotion based on facial features. The findings indicate the complex, complimentary, and reciprocal relationship between multiple areas of brain—in this case, anatomically quite distinct—in the processing of different aspects of face information (e.g., identity, emotion, and social valence).

4. Visual Object Agnosia

Whereas prosopagnosia is associated with a defect in the identification of individual members of a class, the term *visual object agnosia* is reserved for patients who have difficulty with identification of entities at basic object level. Thus, visual object agnosia refers to a visual recognition defect at the level of nonunique objects rather than at the level of specific members of a category. For example, a patient with visual agnosia may not know that a violin is a violin, that a dog is a dog, or that a car is a car. Patients with visual object agnosia can identify objects by touch, sound, or characteristic movement, thereby ensuring that they know the objects. In fact, in some cases patients are able to accurately draw objects on command but are unable to identify or recognize such objects in the visual modality. This is a rare condition. Memory is normal, and there is no defect in judgment, basic verbal intellectual skills, or language.

Associated conditions often include defects in color recognition and naming and defects in reading. There may be associated visual field defects, although a primary field cut is not always present. Lesions associated with visual object agnosia are typically more extensive than those found in cases of prosopagnosia, including occipitotemporal cortex bilaterally, extending dorsally into visual association cortex, and almost always involving underlying white matter. There is evidence that the left hemisphere plays a more critical role than the right in the development of visual object agnosia.

5. Category-Specific Recognition Defects

In recent years, there has been a considerable amount of research aimed at the issue of differences in

recognition and naming related to different conceptual categories. A common profile, for example, is impaired recognition of living entities, with relative preservation of recognition of nonliving entities. A number of factors may contribute to this observed differentiation, and they are currently being explored. For example, there may be differences in shape, manipulability, or the means by which the entity is learned that operate on subsequent visual recognition of such entities. As an example of this type of research, it was reported in 1997 that defective recognition of persons was associated with lesions in the right temporal polar region, defective recognition of animals was associated with lesions in right mesial occipital/ventral temporal areas and also in the left mesial occipital region, whereas defective recognition of tools was associated with lesions in the left occipital–temporal–parietal junction.

B. Disorders of Reading

Pure alexia refers to the inability to read with preserved ability to write. The term pure alexia refers to an acquired inability rather than a developmental disability in reading (the latter is known as *developmental* dyslexia). This appears to be an apparently bizarre dissociation, one that may evoke the misdiagnosis of a psychiatric disease. These patients are not aphasic, nor is there a defect in memory, orientation, basic intellectual skills, or verbal arithmetic skills. The neurologic exam is normal apart from a typical finding of a right homonymous hemianopia.

In evaluating patients with pure alexia, it is useful to ask them to copy printed material, to write a sentence from dictation, and to write a sentence spontaneously. The latter two tasks are typically completed with relative ease. However, such patients will have difficulty in copying sentences, given their inability to read. However, we have seen patients who are, in fact, able to copy lexical material (written words) accurately, but on questioning these patients it is apparent that they do not appreciate the fact that these are letters or words; rather, they are viewed as a series of geometric shapes. Although such patients are unable to read, if the examiner asks the patient to trace letters with the patient's finger, the patient may be able to discern the meaning of the written word. Furthermore, when visual presentation of the word is enlarged to subsume a large part of the visual field, the patient may be able to read. The mechanism that enables such patients to decode letters and words in a sensorimotor modality is outlined later and may be of particular relevance to rehabilitation efforts.

The lesion associated with pure alexia is in the left occipital lobe and underlying white matter. Such a lesion produces the right homonymous visual field defect that is often found in such cases. The lesion typically abuts the splenium. Thus, visual information is registered only by the right occipital lobe, and such information is blocked from passing to the left hemisphere by virtue of the retrosplenial lesion. This information thus cannot be decoded into lexically meaningful words by association areas in the left parietal cortex, specifically surrounding the left angular gyrus. However, in the instances described previously, when a patient is asked to trace letters with his or her hand, there is no such disconnection between sensorimotor cortex on the left (receiving input from and sending input to the right hand) and the left angular gyrus. Thus, lexically meaningful information can be derived and decoded by connection between sensorimotor cortex on the left (responding to hand movement) and parietal association cortex (decoding motor movements into lexically meaningful units/letters). The key in this case is that the visual system is bypassed. Similarly, in the situation in which words are enlarged to subsume much of the visual field, the motor system of the ocular muscles is invoked; thus, motor movements can be used to decode visual stimuli into lexically meaningful parts.

An interesting but undeveloped area of research in pure alexia has to do with recognition of different levels of lexical material. For example, it has been shown that patients with pure alexia are able to identify words versus nonwords in a lexical decision task. This finding raises questions regarding other aspects of lexical decoding that may be preserved in patients with pure alexia. For example, it is possible that patients with pure alexia will show nonconscious electrodermal evidence of recognition of words. Such patients may also show emotional reactions to words with high emotional valence, as evidenced by psychophysiological measures, in the face of impaired overt recognition. Such questions have not been explored in-depth but are of substantial scientific interest.

1. Case Report: Alexia and Visual Object Agnosia

Case RS is a left-handed, 59-year-old male author and attorney with 20 years of education. He was seen in our laboratory approximately 10 months following the

first of two strokes. Specifically, he experienced sudden visual distortion and rapidly building headache. He noted a subsequent inability to read, although his ability to write, speak, and understand spoken language was normal. The remainder of the neurological exam was normal, and an extensive assessment confirmed a left occipitotemporal stroke. Five months later he experienced sudden onset of left hand, arm, and face numbness which resolved over the subsequent several hours. His ability to read, which had begun to recover, was again lost. At the time of this second event he also experienced difficulty in recognizing other visual objects and had distorted color perception, stating that colors seemed to be "metallic" and "unreal." His impairment in color perception and a mild face recognition defect resolved approximately 3 weeks later. Repeat neuroimaging confirmed a second occipitotemporal stroke, this time in the right hemisphere.

As can be seen in Table I, the patient was intellectually gifted. Basic visual abilities (acuity, contrast sensitivity, and color plates), and visual attention were normal, and visual fields were full. Visual recognition of objects was severely impaired. However, auditory recognition of objects was normal, as was recognition of facial expressions of emotion.

Magnetic resonance imaging (MRI) (Fig. 2) revealed an approximately 3.0×1.5 cm infarct in the left inferior posterior temporal lobe, extending from the surface to the inferior aspect of the lateral ventricle. A second, smaller infarct, measuring approximately 1.0×1.0 cm, involving primarily the cortex, was seen in the right inferior posterior temporal lobe. The first lesion, on the left, accounted for the patient's initial descriptions of dyschromatopsia and pure alexia. The second lesion resulted in visual object agnosia.

A substantial portion of the patient's occupation involved reading; thus, remediation of this ability was the focus of rehabilitation. Two visual dimensions of lexical material were systematically varied in an effort to optimize his speed and accuracy of reading. Specifically, the size of font of letters was systematically tested until both speed and accuracy were optimized, and then it was made smaller in gradual steps until a size was found that was believed to provide the best balance between speed, accuracy, and practicality (very large fonts were impractical for everyday reading). Second, various color contrasts between background and letters were used, again in an effort to maximize speed and accuracy of reading. With these aids, the patient eventually returned to work.

C. Disorders of Color Processing

1. Achromatopsia

Achromatopsia refers to a loss of color vision due to an acquired brain disorder. Patients commonly complain that colors appear to be black and white, washed out, gray, or dirty. Such patients may also demonstrate some color desaturation and dyschromatopsia rather than complete lack of color. Lesions associated with achromatopsia are characteristically found in the infracalcarine medial occipital lobe, typically involving the lingual and fusiform gyri. When the lesion is unilateral, the color defect is in the contralateral visual space. When the lesion is bilateral, the color defect subsumes the entire visual field. There may well be visual field cuts, typically involving superior quadrants.

2. Color Anomia

The term *color anomia* refers to an inability to name colors in the context of normal performances on tests of matching color or of color generation. This disorder is usually associated with pure alexia and right homonymous hemianopia. Such patients are able to match same-color chips and associate colors with objects (e.g., "A banana is… yellow"). However, when shown a specific color, such patients are unable to name it with an appropriate verbal tag. This defect seems to be exacerbated when less contextual information is available. For example, such patients may be able to see a yellow banana and say that the color is yellow but may be unable to name a spot of yellow.

Given the site of the lesion in color anomia and the preponderance of right homonymous hemianopia and pure alexia in such cases, there is some suggestion that this may represent a disconnection syndrome. That is, in the left visual field (ipsilateral to the lesion) color perception is normal, but perception is limited to primary visual cortex in the right hemisphere only. This elementary perceptual information is blocked by a retrosplenial lesion in the mesial left occipital lobe, thereby rendering such information unavailable to the left hemisphere.

3. Color Agnosia

Color agnosia is a rare condition defined as an inability to retrieve color information in the context of normal perception and language. For example, a patient with color agnosia will be unable to remember the colors of

common entities (e.g., "What color is a banana?") and will be unable to provide a list of objects that come in various colors (e.g., "Name things that are red"). Based on a handful of well-studied patients, the neuroanatomical correlates of color agnosia include the occipital–temporal region either unilaterally on the left or bilaterally. To date, this lesion localization provides no clear separation from what might be expected with achromatopsia; however, functional imaging studies suggest that areas associated with color knowledge are probably anterior and lateral to areas associated with color perception. Color agnosia is often associated with visual object agnosia and may be associated with category-related recognition defects, particularly for living entities as opposed to artifactual entities.

4. Case Report: Prosopagnosia, Pure Alexia, and Achromatopsia

A 72-year-old right-handed retired female schoolteacher with 18 years of education suffered a myocardial infarction 5 years prior to her clinical presentation. She had a four-vessel coronary artery bypass graft at the time of her heart attack and suffered a right occipitotemporal cardioembolic stroke with resultant left homonymous visual field defect. Approximately 1 month prior to her presentation in our clinic she suffered a sudden change in color vision, noting that colors in traffic lights were all gray. She also experi-

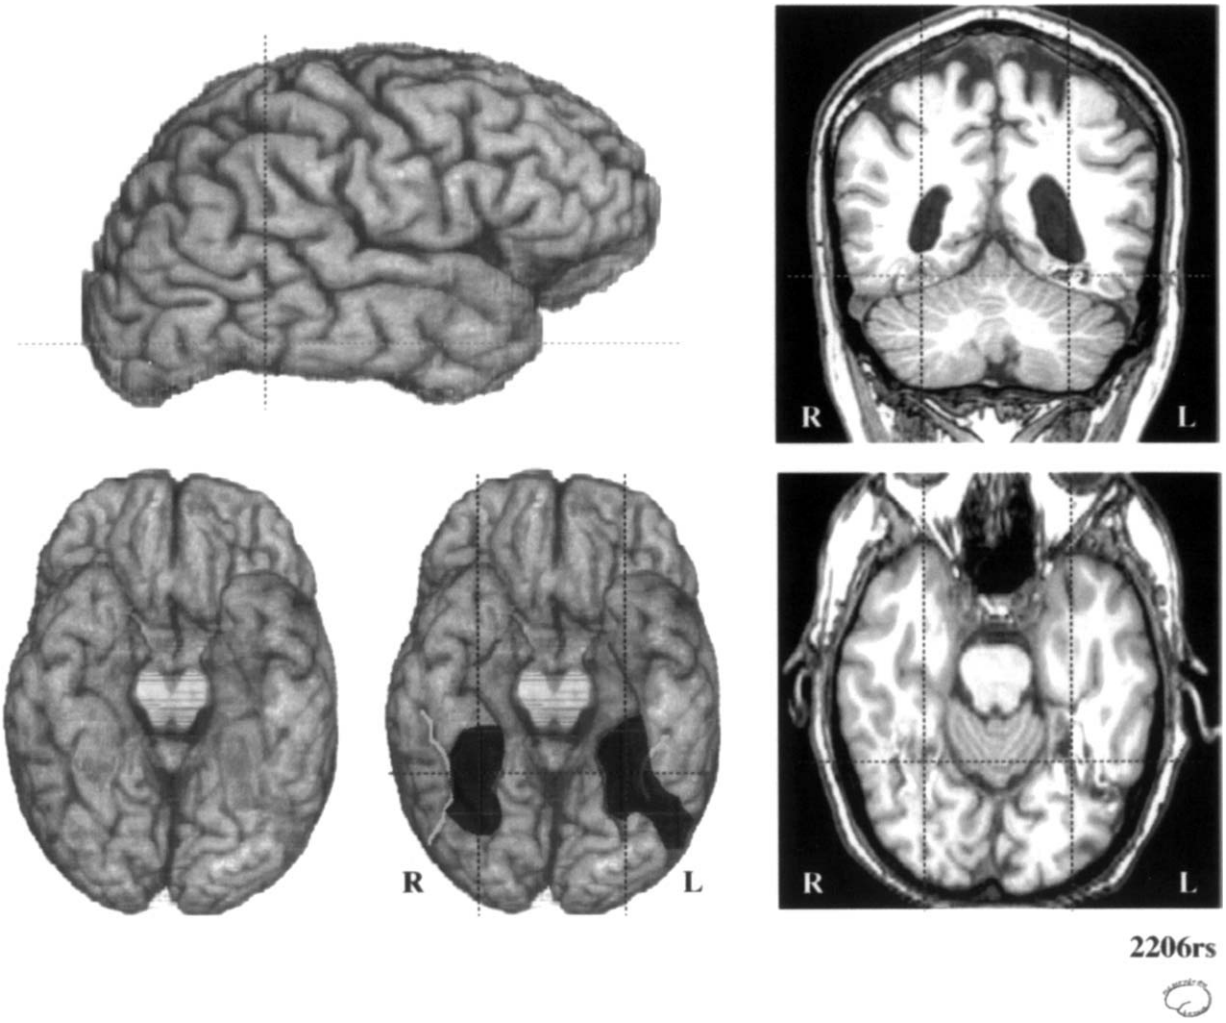

Figure 2 Three-dimensional MRI reconstruction of the brain of a patient with visual object agnosia.

enced vertigo, ataxia, and facial recognition defects. Motor and sensory signs were normal, but she had a wide-based and ataxic gait.

Results of neuropsychological assessment are reflected in Table II. The patient had prosopagnosia (of the associative type), pure alexia, and achromatopsia. Visual acuity was normal with correction, and visual perception of faces was normal (e.g., performance was normal on Benton's Facial Recognition Test). She was able to describe accurately the gender, facial expression, and age of faces in photographs but was unable to indicate the identity of faces. The MRI of the brain is shown in Fig. 3. As can be seen, the patient had bilateral occipitotemporal lesions that accounted for her neuropsychological defects. Basic intellectual skills and language were preserved, as were orientation and attention. Visual spatial judgment was normal.

Her principal concerns were her inability to read (pure alexia) and the face recognition defect. She compensated for her prosopagnosia by identifying individuals by their gait, voice, or, in some cases, a salient visual feature (e.g., baldness). In an effort to identify her favorite family photographs, she wrote the names of the subject of each individual photograph on the back of the picture in large type, and she could read the names by tracing the letters with her finger. Although her reading never returned to baseline levels, she made significant progress by using a magnifying glass and then tracing the letters she wanted to read and thereby invoking the sensorimotor system. In another example of the measures she took to compensate for her pure alexia, she memorized motor patterns associated with emergency telephone numbers (911) and frequently called friends and relatives. She lived

alone successfully and walked several blocks each day to visit her husband in a nursing home nearby. She would count the blocks as she walked so as not to become lost.

D. Disorders of Spatial Analysis

1. Balint's Syndrome

The symptom complex necessary for the diagnosis of Balint's syndrome includes simultanagnosia (also known as visual disorientation), optic ataxia, and ocular apraxia.

Simultanagnosia refers to the inability to synthesize separate features of the visual field into a meaningful whole. This is the core feature of Balint's syndrome. Establishing this aspect of the syndrome necessarily requires the self-report of the patient. Typically, patients will describe features of objects as "coming in and out of view" or "sometimes there and sometimes not." Perception of an object in the visual field will often be limited to small parts of any given object. For example, a patient recently studied in our laboratory was shown a line drawing of a Christmas wreath and reported that the only thing she saw was a bow. In fact, there was a bow attached to the Christmas wreath, but she was unable to perceive the whole and unable to provide a synthesized meaningful description of the disparate parts available to her. Typical misperceptions are based on parts of objects, and the astute clinician can determine the features of objects that are used by the patient to generate responses.

The second essential feature for the diagnosis of Balint's syndrome is optic ataxia. *Optic ataxia* refers to an inability to point to targets under visual guidance. Examination of this sign consists of asking the subject to point to or touch the finger of the examiner in a rapid ballistic movement. Patients with optic ataxia will often miss the target or will slowly approach the target with their hand. Optic ataxia can be observed further when patients are reaching for any object in space (e.g., a pencil or food). It is common for such patients to approximate the target and then "crawl" with their fingers to reach the desired object. It is necessary that such patients have difficulty under *visual* guidance. For example, with eyes closed, a patient with optic ataxia can point as accurately as controls to the source of a sound. Optic ataxia is also known as visual motor ataxia and can be found in some patients in isolation from simultanagnosia and ocular apraxia.

Ocular apraxia can be defined as an inability to shift gaze toward a new visual stimulus. At the bedside, the

patient can be requested to fixate on various objects in the immediate environment, and the examiner should take note of the ease with which this is done. Patients with ocular apraxia will show ocular movements that reflect an inability to shift their gaze to a new object and will approximate their gaze and slowly come to appropriate ocular fixation. The saccadic movements of such patients in focusing on new objects may be completely inaccurate or may be much longer and less accurate than those of normal subjects. This third sign of Balint's syndrome is also known as *psychic gaze paralysis*.

The lesion associated with Balint's syndrome has reliably been reported to be in the occipitoparietal visual association cortex (the upper part of Brodmann's areas 18 and 19). A bilateral lesion is necessary to observe the syndrome fully. This is a watershed zone between middle and posterior cerebral arteries; therefore, the lesion is often associated with the medical phenomenon of sudden hypotension, such as in cardiac arrest. Thus, this is one of the defects associated with the dorsal visual stream. Occassionally, area 17 or area 39 may be involved. A field defect is not necessary, but an inferior field cut may be present in some cases.

2. Case Report: Balint's Syndrome

LA is a right-handed 52-year-old female factory worker with a high school education. Approximately 2 years prior to her clinical presentation she began to notice changes in her vision and had sought consultation for new glasses three times in the 6 months preceding our first examination. Neuroophthalmalogic exam was normal, visual acuity was 20/20 (corrected), and visual fields were full. Her chief complaint was that she was having difficulty at work. Her job involved placing objects in a particular orientation in a box, and she had been having increasing difficulty in completing this task. Prior to this job she had been a grocery store manager but had experienced progressive difficulty with using cash registers, using adding machines, keeping invoice records, and other jobs that demanded execution of serial visually guided tasks. She had been fired after several successful years at this job. She described objects as looking ''shattered'' and ''coming and going'' from her sight.

Neuropsychological assessment (Table III) revealed severe defects in constructional praxis. She was oriented, conversational speech was normal, and verbal memory was normal. The presence of visual disorientation (simultanagnosia) was established by extensive testing. For example, in evaluating her responses to specific naming items it became apparent that she was processing only parts of the larger stimulus. For example, she said, ''ribbon'' when shown a line drawing of a wreath with a ribbon on it. Similarly, she said ''roof'' when shown a pyramid; on follow-up questions she explained that she saw one corner of the pyramid, which she then presumed to be a roof.

The presence of optic ataxia was established both by examination and by clinical observation. As an example of the latter, she had difficulty reaching for pencils on the desk in front of her. Also, on formal testing, she was markedly inaccurate and slow in trying to reach for the examiner's hand under visual guidance. Finally, it is noteworthy that her history of job difficulties suggests the presence of optic ataxia. For example, she had difficulty with ballistic hand movements under visual guidance in many of her job responsibilities.

Ocular apraxia was established by clinical test and observation. She was unable to make effective saccadic movements on command when asked to look at various objects in the room.

Functional and structural neuroimaging were completed. MRI showed bilateral occipitoparietal atrophy, although there was evidence of mild atrophy in other areas. Position emission tomography studies showed bilateral occipitoparietal hypometabolism. The patient was ultimately diagnosed with an atypical progressive dementia, though possibly of the visual variant Alzheimer's type. From a neuropsychological perspective, the principal diagnosis was Balint's syndrome.

3. Visual Neglect

Neglect can be defined as ''the failure to report, respond, or orient to novel or meaningful stimuli presented to the side opposite a brain lesion, when this failure cannot be attributed to either sensory or motor defects.'' In the visual modality, the most common form of neglect is hemispatial neglect. The essential feature of spatial neglect is that the patient ignores objects in the visual hemifield contralateral to the lesion, in the absence of a visual field cut. Such neglect is commonly associated with right hemisphere lesions, resulting in left hemispatial visual neglect. Right hemispatial visual neglect, though rare, can be seen during the acute period in some cases of left hemisphere lesions. The typical lesion is in the occipital–temporal–parietal border zone. The finding of neglect

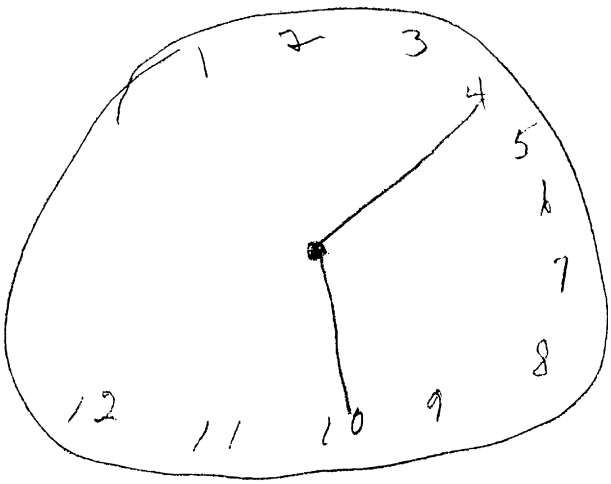

Figure 4 Drawing of a clock showing left hemispatial visual neglect by a 70-year-old right-handed female with a right parietal tumor.

is often not restricted to the visual modality and may be demonstrated in both sensorimotor and auditory systems concurrently with visual neglect.

There are a number of ways to evaluate hemispatial visual neglect in affected patients. One of the more common bedside assessments is to perform a double simultaneous stimulation task, in which the examiner introduces a visual stimulus to the left visual field, to the right visual field, and then to both fields simultaneously. The most clear evidence of neglect from this procedure is that the patient will identify each stimulus individually, but when presented simultaneously the patient will identify only the stimulus presented ipsilateral to the lesion. Furthermore, methods of detecting hemispatial neglect include drawing tasks, line bisection tasks, or line cancelation tasks (Fig. 4). In addition to demonstrating neglect in other modalities (sensorimotor and auditory), associated signs observed in neuropsychological testing of patients with neglect include constructional dyspraxia, anosodiaphoria, and anosognosia.

4. Cortical Blindness and Anton's Syndrome

Bilateral lesions of primary visual cortex result in *cortical blindness*, a condition commonly caused by bilateral infarction of the posterior cerebral arteries. A commonly associated phenomenon with cortical blindness is *Anton's syndrome*, in which the patient with cortical blindness denies all visual difficulties. Anton's syndrome is considered a special form of anosognosia and is frequently seen only in the acute epoch (within 2 or 3 months following the event). Cortical blindness and Anton's syndrome may also result from subcortical lesions to optic radiations. Pupillary responses are preserved, but visual evoked potentials cannot be demonstrated.

5. Topographical Disorientation

The term topographical disorientation refers to an acquired inability to navigate the environment in daily life. This can be conceptualized as a memory defect in the visual realm, but a number of mechanisms of the agnosias can be seen in this disorder. This disorder is highly relevant in patient care and should be considered by clinicians in placement and management of affected patients. Two broad types of topographical disorientation can be discerned. The first may be termed anterograde topographical disorientation, which involves a defect in new learning. Patients with this disorder will complain that they become lost in new places, cannot learn new routes, or cannot retrace their paths in real life. Associated clinical findings may include left hemispatial neglect, left visual field cuts, and constructional dyspraxia. Such patients are not aphasic, nor do they show defects in executive functions or attention. Visual memory may be impaired on formal neuropsychological testing, but verbal memory is typically normal. The site of lesion associated with the disorder is the medial occipitotemporal area, particularly on the right and including the posterior parahippocampal gyrus and lingual gyrus. Anterograde topographical agnosia has been described in cases of right parietal dysfunction and of left mesial occipitotemporal dysfunction, but in these cases the clinical phenomenon appears to be more transient and less severe.

Retrograde topographical disorientation refers to the inability to recognize previously well-known spatial/topographical routes. The patient with retrograde topographical disorientation will be unable to recognize either previously known visual scenes (e.g., rooms in their home and the street on which they lived) or landmarks (e.g., their house and the local grocery). To distinguish this disorder from severe apperceptive defects it is important to note that patients with retrograde topographical disorientation are unable to describe in verbal terms from memory familiar scenes or routes. The lesion most commonly associated with this disorder is in the mesial occipitotemporal cortices of the right hemisphere, thus disconnecting primary visual cortex from higher order association cortices.

6. Defects in Constructional Skills

Constructional ability can be defined as the ability to manipulate materials to form an intended final construction. This ability is known well to most practitioners; examples of tests of constructional ability are the Draw a Clock Test, the block design subtest from the Wechsler Adult Intelligence Test, and the intersecting pentagons from the Mini Mental State Examination. Tests of constructional ability presume that the patient has adequate visual acuity to see the test and that motor skills are adequate to complete the test.

The mechanism whereby a patient manifests defects in constructional abilities may be determined by examination of the process of construction or by examination of the final product. For example, visual neglect may be determined by a drawing task in which the item to be drawn (or copied) is placed far to the side of the page (usually the right side, indicating left hemispatial visual neglect). Hemispatial neglect may also be shown in a case in which one side of the object is distorted or missing. Finally, in the absence of neglect, there may be a lack of appreciation of visual spatial relationships apparent in the production of a drawing by the patient, in which elements of the object to be constructed are present but are distorted in their spatial relationship to one another.

The site of lesion associated with defects in constructional skills is typically the right occipital cortices and adjacent visual association cortex. There may be a greater perceptual component to the defect with more ventral lesions and a greater defect of spatial relationships with more dorsal lesions. In some cases, constructional disabilities can be observed in left-sided lesions in these same sites, but such patients often have a fluent aphasia, a lesser or more transient constructional defect, and the defect is more likely to show a lack of appreciation of spatial relationships and preserved visuoperception.

7. Deficits of Mental Imagery

Visual mental imagery refers to the evocation of visual images in the "mind's eye" in the absence of sensation through the retina. In recent years, research on this topic has resulted in substantial knowledge about the neuroanatomical underpinnings of visual imagery; however, much has yet to be learned.

Early studies demonstrated that patients with various types of deficits in higher order visual functions (e.g., achromatopsia and spatial neglect) tended to show similar deficits in mental imagery. For example, when asked to imagine walking a down a familiar street, a patient with left hemispatial visual neglect would describe only the buildings on the right side of the street. When asked to imagine turning around and walking the other direction up the street, the same patient would describe buildings on the other side of the street that had previously been neglected. Similarly, patients with deficits in color perception due to cerebral lesions have been shown to have deficits in imagining colors of objects. Although not all findings have supported such observations, there appears to be broad general consensus for the idea that visual perceptual deficits in patients can often be demonstrated in some way by similar deficits in visual imagery in these patients.

The neural underpinnings of deficits in visual imagery have been located primarily in visual association cortex (areas 18 and 19) and more anterior association cortices. However, recent data from functional MRI studies suggest that primary visual cortex (area 17) may be more actively involved in mental imagery than had previously been suspected.

III. CONCLUSION

Although disorders of higher visual functions are varied, the visual system as a whole is one of the best understood systems in the brain, due in part to decades of observation of and research on these functions. The visual agnosias, in particular, have been shown to be an area of rich findings in basic brain–behavior relationships. History has demonstrated that such basic findings often serve as the basis of rehabilitation and management of such disorders, an area that is now in its infancy.

Visual System Development and Neural Activity

A. E. WIENCKEN-BARGER and V. A. CASAGRANDE
Vanderbilt University School of Medicine

GLOSSARY

amblyopia The impairment of vision without detectable organic lesion of the eye.

ectopic Positioned abnormally within the body.

neurotrophic factor A molecule, usually a protein, that will facilitate the growth or repair of nerve cells.

ocular dominance column An area in the visual cortex that receives input predominantly from one eye.

transcription factor A protein required for recognition by RNA polymerases of specific stimulatory sequences in eukaryotic genes.

visuotopy The arrangement of cells and the connections between neural structures such that they maintain a topographic representation of the visual field.

Neural structures are specified very early when the future nervous system is still a sheet of cells referred to as the neural plate and before this sheet folds to form the neural tube. These early steps involve evolutionarily conserved inductive signaling pathways that initially establish regional identity. Subsequently, at the time when cells undergo their final cell division, the cells within different regions of the visual system become committed to their specific fates or individual identities. Evidence from studies in a variety of animals suggests that molecular gradients, timing of axon arrival, and correlated spontaneous activity all help to shape early targeting decisions and to establish precise connections. Refinements of the system involve active growth and branching of axons and dendrites, formation of synapses, and elimination of cells, axon collaterals, and some synapses. Further refinements of visual system development depend on activity and competition for limited supplies of neurotrophic factors but do not necessarily require visual experience. However, visual experience, especially during critical periods of active growth, can dramatically modify the final outcome.

I. INTRODUCTION

Mammalian development is an elegant process by which a single cell becomes a complete organism containing multiple organ systems that are highly interconnected. This is never more evident than during neural development. A central issue in the study of neurobiology concerns not only how nerve cells become connected in the first place but also how those connections become organized in such a way that the sensory world is represented. The topographical specificity of different parts of the mammalian visual system is dependent on highly ordered connections. Consider that the mammalian brain contains at least 100 billion neurons and that each of these

neurons can make more than 1000 specific connections with other neurons. Specificity is particularly evident in the visual system, in which a topographic map of visual space is maintained throughout each level of visual processing. For example, in the macaque monkey, a modest estimate of the number of visual areas requires that at least 30 visuotopic maps connect correctly in the developing brain; in humans there may be even more visual areas. Each cell within one of these maps processes information from a specific zone of the visual world, and that cell's neighbor processes information from an adjacent zone and so forth. Neighboring cells connect with neighboring cells in other visual areas. This characteristic is called visuotopy.

One approach that may be useful in elucidating the complex wiring of the mammalian visual system is to assume that axons make connections through a sequence of simpler evolutionarily conserved mechanisms. In mammals, research suggests that the earliest stages in the development of the nervous system are similar across a range of diverse species and involve similar if not identical molecular pathways. The similarities in these early steps of neural development imply the existence of powerful constraints on the regulatory relationships between genes that control early phenotypes (e.g., the characteristics and appearance of different parts of the nervous system). Good examples of these relationships come from genetic studies of eye and head development in flies (*Drosophila*), mice, and humans. In mice and humans the paired box *pax*-6/*aniridia* gene and its homolog in flies, the *eyeless* gene, play major roles in eye and craniofacial development. These genes control transcription factors that regulate a cascade of other genes important for eye and head formation. When loss-of-function mutations are produced in the *eyeless* gene, flies develop with no eyes, very reduced eyes, or defective eyes. Similar phenotypes are seen with genetic mutations in the *pax*-6/*aniridia* gene in mice and humans. Astoundingly, ectopic expression of either the fly *eyeless* gene or the *pax 6* gene results in the development of fully formed insect eyes on parts of the mutant fly's body that do not normally have eyes, such as the leg or wing. These remarkable results not only argue for a common evolutionary origin of eye development, but also reinforce the view that the earliest developmental programs are governed by highly conserved rules.

Although it is not the purpose of this article to focus on these early steps in development, the previous example has relevance. Later steps in neural development, in general, and visual system development, in particular, also involve evolutionarily conserved mechanisms. Since flies, mice, and humans differ in organization, size, and complexity of the brain, it is obvious that there must be developmental differences. Nevertheless, dramatic differences in adult brain organization can involve small changes in basic developmental mechanisms, such as changes in the number of cell divisions that occur before founder populations stop dividing, or changes in the number of cells that are eliminated during the periods of cell death that occur as a part of normal development in all nervous systems. The role of other mechanisms such as neural activity may be more important to the development of connections in large, complex nervous systems, although the basic mechanisms that translate that activity into cell growth or the formation of synaptic connections between nerve cells are also conserved across species.

In this article, we limit our consideration of development to two interconnected and well-studied visual centers in the brain, the lateral geniculate nucleus (LGN) in the thalamus and the primary visual cortex or V1 (Fig. 1). First, we provide an overview of the development of these visual areas in the larger context of brain development and discuss how these structures take on their adult shape. Then, we show how specialized laminar patterns and topographic connections between these structures can develop according to molecular cues. Finally, we explore possible mechanisms for the establishment of specificity, including the role of neural activity in forming and maintaining connections.

II. OVERVIEW OF VISUAL SYSTEM DEVELOPMENT

A. Early Neural Development

The brain begins as a simple plate of progenitor cells that eventually forms a tube that bends and balloons out into three fluid-filled vesicles during the process of development. Even before the neural plate forms a tube, however, communication takes place between cells that determines which progenitor or founder cells will give rise to specific broad regions of the visual system, including regions that contain the retina, the LGN, and the visual cortex (Fig. 2). An enormous array of transcription factors and extracellular molecular signals have been identified that are involved in

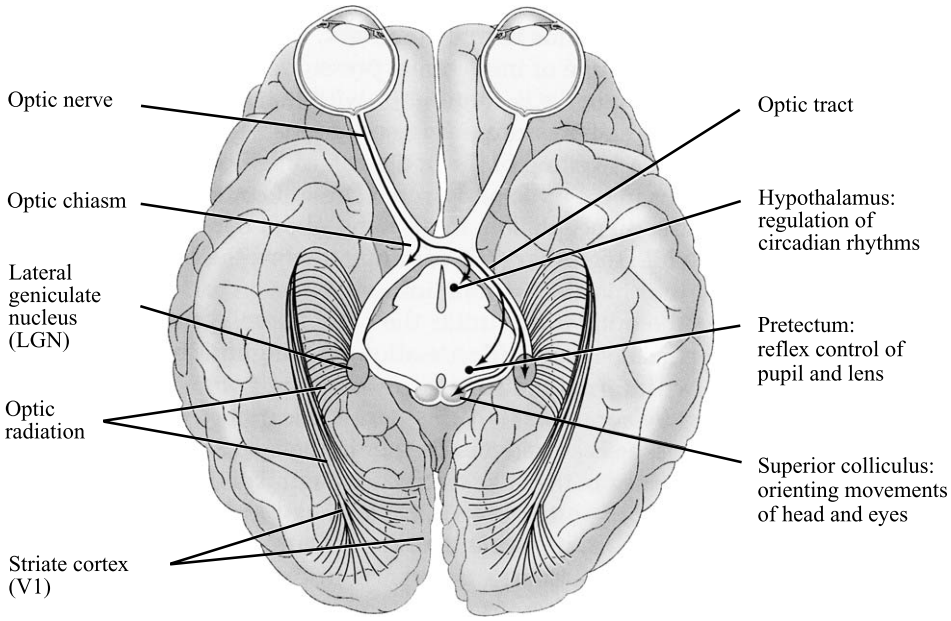

Figure 1 The visual pathways shown as a schematic viewed from the ventral surface of the human brain. The axons from ganglion cells located in the retina leave the eyes as the optic nerve. The ganglion cells located in the temporal retina (shown for the right eye) send axons to the same side (ipsilateral) of the brain (arrow), whereas the axons in the nasal retina cross at the optic chiasm to the other hemisphere or contralateral side of the brain. Once the axons have left the optic chiasm they bundle together as the optic tract. Groups of axons leave the optic tract at various points to make synapses with groups of cells (nuclei) conserved with different visual functions, such as the hypothalamus (circadian rhythms), the lateral geniculate nucleus (LGN); (conscious vision), pretectum (pupillary and lens reflexes), and superior colliculus (orienting head and eyes). The superior colliculus is homologous with the optic tectum of nonmammalian vertebrates. Cells in the LGN send axons to the primary visual cortex or striate cortex, also called V1, located at the back of the brain in the occipital lobe [reproduced with permission from Purves, D., *et al.* (Eds) (1997). *Neuroscience*. Sinauer, Sunderland, MA].

these early stages of regional specification. It has been hypothesized that regional specification of the forebrain, like the hindbrain, involves segmentation, in this case into a series of longitudinal and transverse segments defined by the expression of a number of genes; however, specific molecules that define the exact boundaries of the developing LGN or primary visual cortex have not been identified.

As development progresses, cells divide close to the inner (ventricular) surface of the neural tube. Initially, all cells extend their processes across the full width of the neural tube, but later only a subset of cells, the radial glial cells, span the full width of the developing forebrain. Radial glia are used by other cells as migratory railway guides to move from the ventricular zone to their final destinations, whether in the developing LGN or visual cortex. Each neural progenitor cell, or stem cell, undergoes a certain number of cell divisions in the young animal, until it divides no more in the adult. This final mitotic division is termed the birth date of the neuron. After the final cell division a neuron differentiates or matures. Neurons in different areas of the brain, such as the LGN and visual cortex, exhibit differences, reflecting their variable differentiation programs. Cells within different neural structures mature at different times in the developmental process and at different rates. Additionally, each neural structure may have its own gradient of development, such that some cells in the nucleus mature before others. Finally, as neural structures mature many developing neurons are eliminated through cell death. This natural cell death process not only eliminates cells with incorrect connections but also allows the production of transient cell populations that help to shape the structures and connections of the nervous system by providing temporary scaffolding for migrating neurons and guideposts for developing axons. The development of the mammalian brain is a highly dynamic process involving multiple overlapping gradients of progression. Cells in the brain experience multiple combinatorial genetic and activity-dependent cues at different times in their development that ultimately produce the complex structure of the adult mammalian brain.

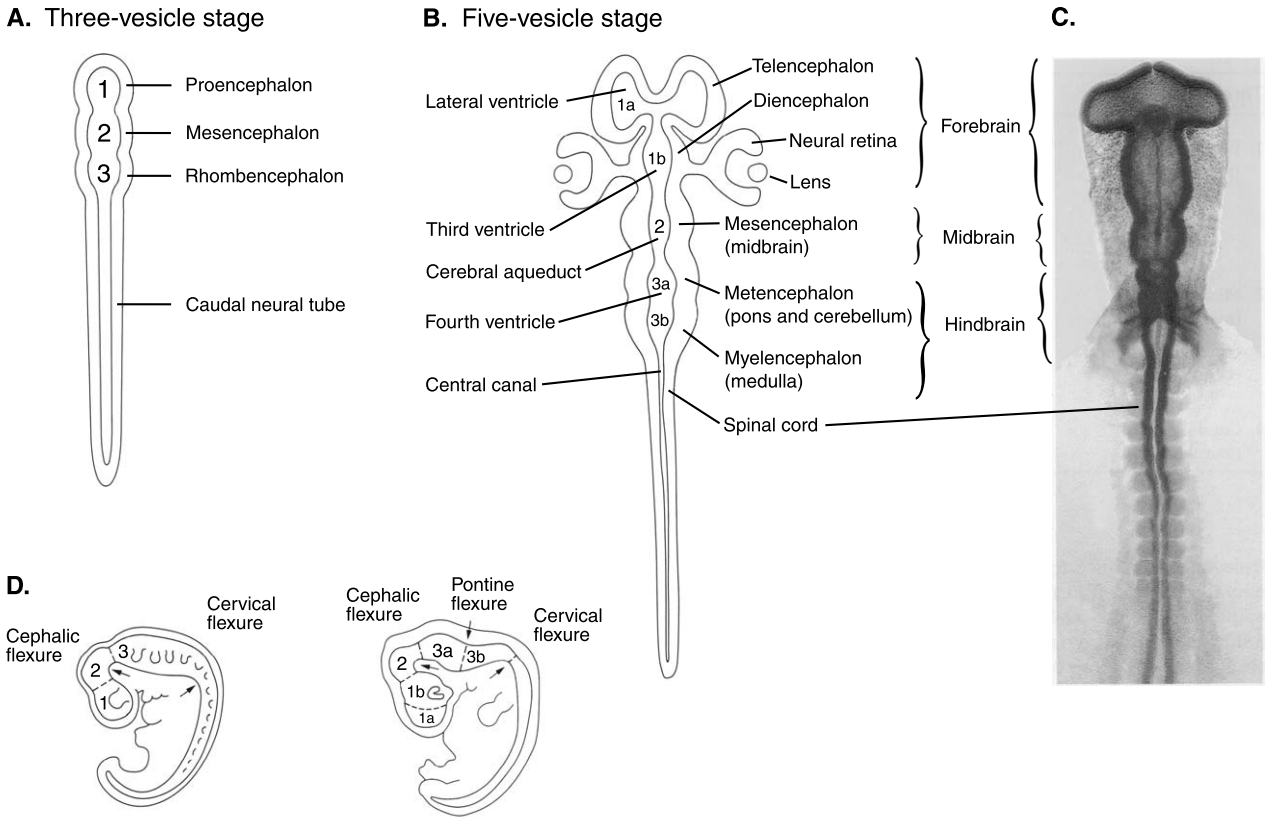

Figure 2 Successive stages of development of the neural tube. The nervous system begins as a plate of tissue (not shown) that rolls up to form a tube. (A) Three-vesicle stage. At early stages of development only three brain vesicles are present. (B) Five-vesicle stage. At later stages, two additional vesicles form, one in the area of the forebrain (1a and 1b) and the other in the hindbrain (3a and 3b). Before the neural tube forms, cells are prespecified such that the retina and lateral geniculate nucleus will form from part of the diencephalon (3b), the visual cortex from the telencephalon (1a), and the superior colliculus from the midbrain (2). (C) Micrograph showing a dorsal view of the neural tube at an early stage of development. The expansion of the future telencephalic vesicle is apparent (micrograph of the chick neural tube provided by G. Schoenwolf). Reproduced McGraw-Hill Companies, with permission of the New York].

B. Development of LGN Structure

The adult LGN of many mammals, including humans, is laminated with compartmentalized input. Each LGN layer receives input from only one eye. Each layer also contains a topographic map of one-half of the visual world. The LGN layers are stacked on top of each other like a set of pancakes (Fig. 3). In primates there is layer specialization such that small, medium, and large cells are segregated into different layers and carry different types of visual messages to primary visual cortex. During development, the future large LGN cells are born and begin migrating from the ventricular surface toward their final destination before the future smaller LGN cells. The differing extracellular environment encountered by LGN cells born at different times during development may change the genetic program of those cells, such that the different classes of cells adopt different morphological and neurochemical identities during differentiation. In fact, in visual cortex there is evidence supporting the view that important decisions about cell fate are made at the time progenitor cells divide in the ventricular zone. It is likely that the same rules apply to cells throughout the developing neural tube. During development, LGN progenitor neurons destined to represent central vision versus peripheral vision divide and mature in a gradient such that cells that will carry information about the central visual world develop earlier than cells that will carry information from the visual periphery. Gradients in the timing of cell birth and maturation of LGN

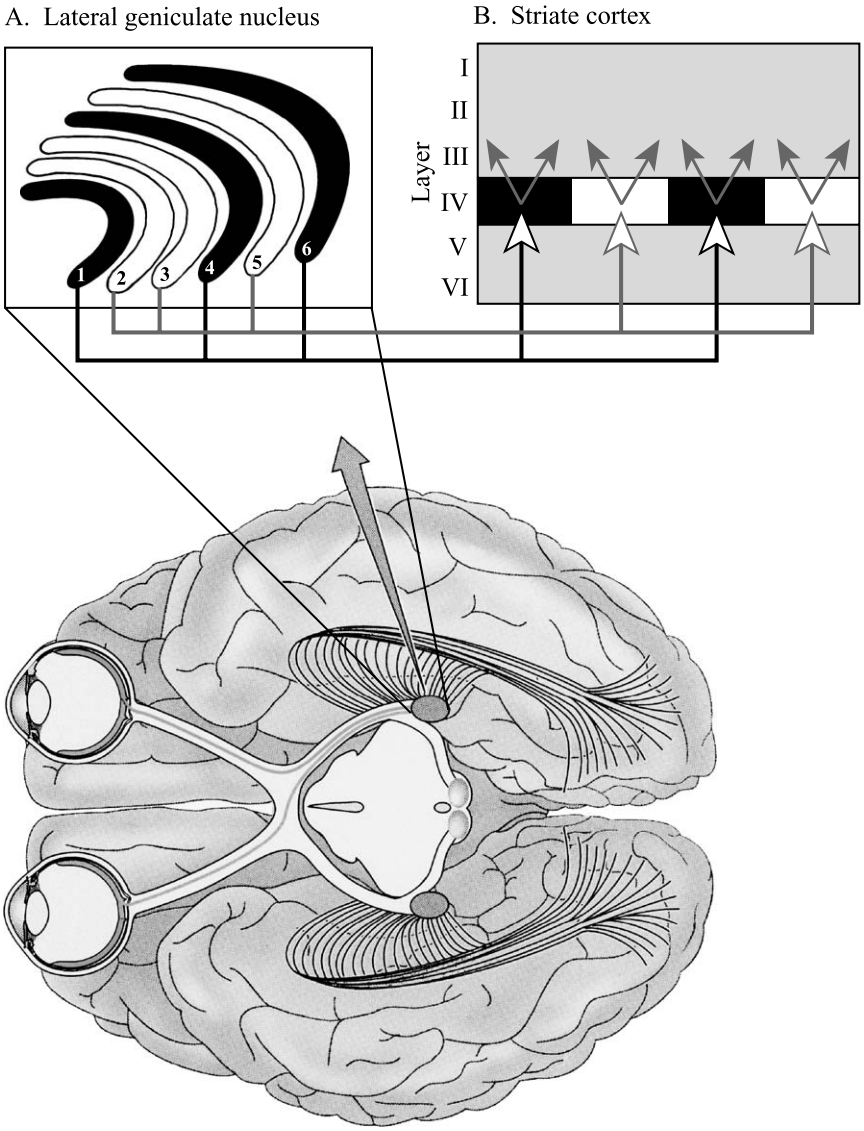

Figure 3 The connections between the lateral geniculate nucleus (LGN) and striate cortex (primary visual cortex). The visual pathway is shown as a schematic viewed from the ventral surface of the human brain. This same view is also shown in Fig. 1. Although the LGN receives inputs from both eyes, these are segregated in separate layers as shown in (A) The first two layers contain large cells (magnocellular layers), and the remaining four layers (parvocellular cells) contain medium-sized cells. Not shown are the small cell (koniocellar) layers that lie between each of the main layers shown. (B) In many species, and most primates, the inputs from the two eyes remain segregated in ocular dominance columns of layer IV, the primary target of LGN axons. Layer IV neurons send their axons to other cortical layers; it is at this stage that information from the two eyes converges onto individual neurons [reproduced with permission from Purves, D., *et al*., (Eds) (1997). *Neuroscience*. Sinauer, Sunderland, MA].

progenitors and within any structures connected to the LGN (such as the eye and the primary visual cortex) may be one of several simple mechanisms that ensure that topographically correspondent regions connect properly.

The retina and the visual cortex, the main inputs to the LGN, both innervate the LGN visuotopically. There is evidence that axons leaving visual cortex and retina grow out very early but may not reach their targets at the same time. In monkeys, retinal ganglion cell axons of different classes grow to the LGN very early and terminate immediately within the appropriate portions of the LGN, demonstrating that some retinal axons are molecularly specified to connect to

specific LGN target regions. However, retinal ganglion cell axons of the same class, arriving from the two eyes initially invade overlapping regions of the LGN. The segregation of these axons into eye-specific layers seems to depend on correlated waves of spontaneous activity in the retina since blocking such activity blocks the normal segregation of retinal axons, at least in carnivores. Cortical axons, like retinal axons, approach the LGN very early in development but, unlike retinal axons, do not invade the nucleus immediately. A special early-born class of cortical cells, the cortical subplate cells, may be the first to send axons to the thalamus. These cells may pioneer the later-born layer VI cell axons that will form permanent connections with the LGN; however, the pioneer axons must still find their way to the LGN. Evidence suggests that the earliest axons use a variety of membrane-bound cues to locate correct targets. When cortical axons do invade the LGN, they immediately grow into visuotopically correct areas of the nucleus and do not appear to require a sorting period, although some smaller refinements may take place as these axons mature.

C. Development of Visual Cortical Structure

Multiple cortical areas, defined by morphology, physiology, and connections with other cortical and subcortical nuclei, make up the neocortex, like a patchwork quilt. One patch of the quilt is the primary visual cortex, located in posterior or occipital cortex. The adult visual cortex contains a precise topographic map and, like all of mammalian cortex, is laminated. The neocortex has six layers. Axons arriving from the LGN synapse primarily in layer IV of visual cortex. In primates, axons from LGN cells of different functional classes (e.g., large versus small LGN cells) synapse in different divisions of cortical layer IV or in distinct compartments located above layer IV. Additionally, LGN cells representing the left and right eye send axons to separate columns of cortex such that cells in a particular column of cortex respond to a stimulus to one eye or the other preferentially (Fig. 3). Cells in layer IV make connections with layers above and below layer IV, and this is where the fusion of information from the two eyes occurs. Cortical cells in layer VI send axons back to the LGN. Also, each ocular dominance column is divided into smaller columns in which cells respond to one orientation of a bar of light. Orientation columns are arranged mainly in pinwheels, such that all orientations are roughly represented within each ocular dominance domain and visuotopy is maintained across columns (Fig. 4). The aforementioned scenario is more simplistic than the biological situation but serves to emphasize some of the complexities of organization that must be achieved during development for the visual cortex to function properly.

As does the developing LGN, the developing cortex begins as a simple epithelium—a thin columnar sheet of cells. As development advances and cells divide, this sheet of cells becomes thicker. The radial glial cells maintain contact with both the ventricular and the pial sides of this sheet, whereas cortical neuroblasts begin dividing at the ventricular zone. Soon, three precortical subdivisions can be recognized. The ventricular zone is the most ventral, where excitatory cortical cells are born from a resident stem cell pool. Interestingly, inhibitory cortical cells, like olfactory bulb cells, may originate from a noncortical stem cell population located in the ganglionic eminence (e.g., the developing basal ganglia). Above the ventricular zone is the intermediate zone, a highway for axons, where corticofugal and corticopetal axons are located. Above the intermediate zone is the preplate, a layer of early born cells that have migrated along radial glial fibers to lie

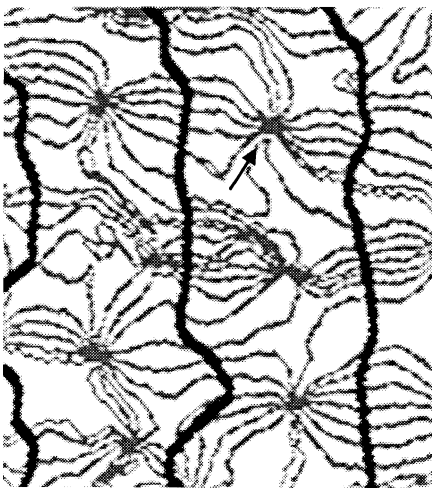

Figure 4 Orientation columns in the visual cortex of the monkey. Comparison of optical image maps of orientation preference and ocular dominance in monkey visual cortex. The thick black lines represent the borders between ocular dominance columns. The thin gray lines represent isoorientation contours, which converge at orientation pinwheel centers (arrow). Each left and right eye ocular dominance column represents a common region of visual space. An adjacent set of columns represents an adjacent region of visual space and so forth across the visual cortex [adapted with permission from Obermeyer, K., and Blasdel, G. G. (1993). Geometry of orientation and ocular dominance columns in monkey striate cortex. *J. Neurosci.* **13,** 114–129].

adjacent to the pial surface. As cell division proceeds, the preplate is split by migrating cells to form the marginal zone (the future layer I of cortex) dorsally and the subplate ventrally. Cells that will form the remaining adult cortical layers will migrate to lie between the marginal zone and subplate. Most of the cells within the preplate and subplate subsequently die. Unlike the LGN, in which cells that are born first lie closest to the pial surface of the neural tube, cortical layers II–VI are formed in an inside–out gradient such that cells born early become the lower layers, whereas cells born later migrate through these layers to form the upper layers (Fig. 5). The transitory layers formed from the original preplate are very important for the proper formation of the other layers of cortex. If the marginal zone is disrupted or not formed, then the cortical layers will not develop in the proper order. For instance, in the reeler mouse, a mutant mouse lacking the gene *reelin* (normally expressed by cells in the marginal zone), the cortical layers develop upside-down or in an outside–in gradient. If the subplate is experimentally removed, the cortical layers develop normally, but axons from the developing LGN are unable to find their proper cortical target.

How the many functionally distinct areas of the neocortex (e.g., the patches of the quilt) differentiate within the forebrain is less well understood. Evidence indicates that parcelation of the forebrain into subdivisions such as the visual cortex involves the expression of a cascade of regulatory genes that first subdivide broad regions of the forebrain and subsequently interact to regulate functionally specific areas. As mentioned previously, in the hindbrain, sequential bands have been identified that differentially express certain genes. These segmental regions are termed rhombomeres and are thought to represent early specification of nuclei in different segments of the brain stem. Some candidates for mediating interactions across brain stem boundaries are members of the Ephrin (Eph) receptor tyrosine kinase family. It is noteworthy that mutant mice lacking connections between the thalamus and cortex still show differential regional expression of genes across the neocortex as well as the normal development of cortical layers independent of this extrinsic input. Nevertheless, there is considerable evidence that extrinsic inputs from the thalamus, particularly those that bring sensory information about the outside world such as visual signals from the retina, can radically alter the pattern of development of cortical areas.

III. AXON PATHFINDING: WIRING THE LGN AND VISUAL CORTEX

A. Molecular Cues

A persistent mystery in developmental neuroscience is how axons travel great distances to find their way to highly specific targets. Correct target selection and the refinements involved in the formation of visuotopic connections between the retina, LGN, and cortex involve both genetic and epigenetic cues. Examples of

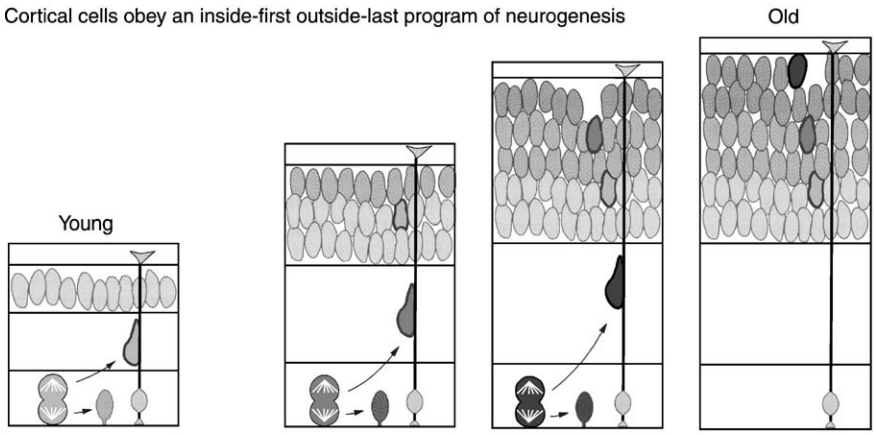

Figure 5 Generation and migration of neurons in the mammalian cerebral cortex. Cortical neurons are generated in an inside-first, outside-last order. Neurons born within the ventricular zone at the early stage migrate to the deepest layers of the cortical plate. Neurons generated at later stages migrate past the earlier generated neurons to form the more superficial layers of the cortex [adapted with permission from McConnel, S. K. (1992). The determinants of neuronal identity in the mammalian cerebral cortex. In *Determinants of Neuronal Identity* (M. Shantiland, and E. Macegno, Eds.), pp. 391–432. Academic Press, New York].

genetic mechanisms include the presence of membrane-bound and secreted molecules, which are permissive, instructive, or obstructive cues for axons with the proper receptors. Axons can grow on various substrates in the brain, including the extracellular matrix, other neural cell membranes, and glial cell membranes (such as the radial glia on which LGN and cortical cells migrate). Developing axons have a specialized structure, a growth cone, at their tip to help them navigate through the extracellular milieu (Fig. 6). This highly motile structure contains receptors capable of transmuting signals about the local environment. The growth cone guides the axon along pathways toward the target region defined by a combination of positive or negative cues.

Once an axon reaches its target, it often will send out a simple T-shaped branch as shown for the LGN axon growing into visual cortex in Fig. 7. Within the visual system, axons often reach their target region while the target cells are still migrating into position or just after migration is complete. Growth cones on the tip of axon branches can detect gradients of membrane-bound molecules to guide axons to their general addresses within a target structure. Axons respond differentially to these molecular gradients within the target based on their initial specification that likely occurred at the time of final cell division and prior to axon outgrowth.

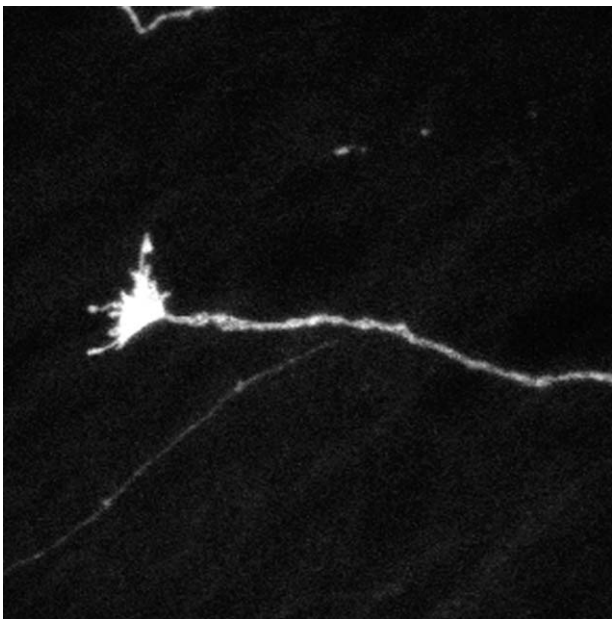

Figure 6 An example of a thalamocortical axon with a growth cone in neonatal mouse brain. The growth cone is a complex, dynamic structure at the tip of the growing axon that samples the local environment, guiding the axon to its target.

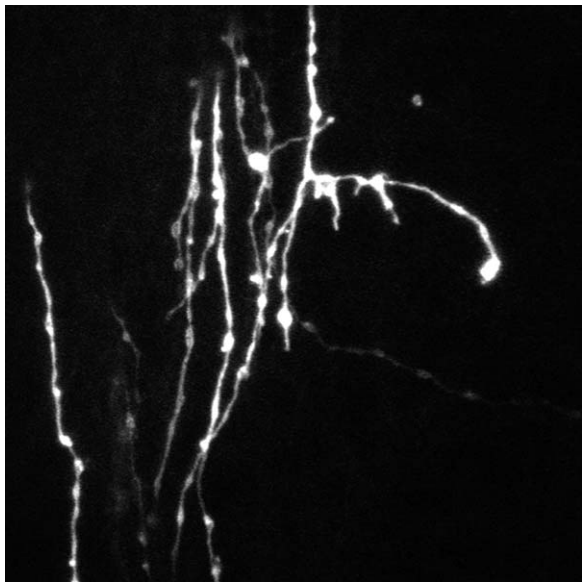

Figure 7 Thalamocortical axons initially exhibit collateral T-shaped side branches when they begin to innervate the cortical plate as shown here from the neocortex of a mouse on the day of birth.

Retinal ganglion cell axons from different retinal locales will therefore respond differently to cues at the target based on their unique growth cone receptors. As mentioned previously, a good example of this process involves the specificity with which different retinal ganglion cell classes target regions of the LGN. Although many molecules have been identified that may guide retinal ganglion cell axons to the right targets, evidence has converged on two membrane-bound ligands of the receptor tyrosine kinases, ephrin A2 and ephrin A5. Both of these ligands are expressed in gradients in the optic tectum, another brain area innervated by retinal ganglion cells. Eph kinases are distributed in gradients in the retina. These two molecular gradients may regulate retinotectal and retinogeniculate topography because ephrins bind to Eph kinases and activation of Eph kinases inhibits axon outgrowth. In particular, the levels of ephrin A2 and A5 are higher in the posterior tectum than in the anterior tectum, and this could inhibit growth of temporal retinal axons, which are rich in the appropriate Eph kinases (Fig. 8). Moreover, retinal axons in mice with mutations in ephrin A2 and A5 exhibit a loss of visuotopy and innervate areas of the optic tectum that they normally would avoid. Interestingly, members of this same family of ephrin molecules are implicated as cues for establishing the proper laminar connections in visual cortex. Therefore, members of the ephrin family may be involved in early regional

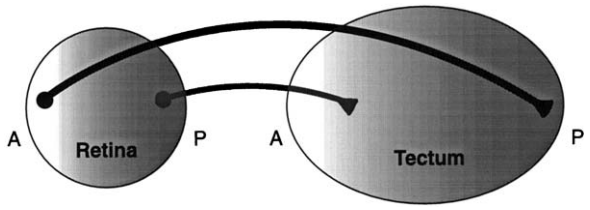

Figure 8 Eph kinases are distributed in gradients in the retina, and ephrins are distributed in gradients in the optic tectum. These two molecular gradients may regulate retinotectal visuotopy because ephrins bind to eph kinases and activation of eph kinases inhibits axon outgrowth.

differentiation in the brain, as well as the establishment of axonal connections later. This example illustrates how a single family of similar molecules can direct several very different developmental programs, sometimes simultaneously, in different neural regions and with overlapping expression patterns, and it underscores the high level of conservation of mechanisms in neural development.

B. The Role of Activity

As neurons mature, they begin to display electrical activity. Neural activity has been shown to play an important role in the correct targeting of axonal connections as well as the formation and maintenance of synapses. The role of neural activity in shaping connections is not restricted to the postnatal period when animals begin to use their senses to explore their environment. Neurons are active well before birth, especially in animals such as primates that are born at a relatively mature developmental stage. Experiments in cats and ferrets have demonstrated that prior to visually driven activity (at a time when the eyelids are still closed), correlated waves of spontaneous activity already exist in the retina and brain. Neurons at this stage are coupled by developmentally transient gap junctions (at least in the retina and the visual cortex, but probably also within other areas of the visual system). The waves of spontaneous activity appear to be important to the segregation of left and right eye inputs within the developing LGN layers and to the segregation of eye-specific inputs into ocular dominance columns in cortex. As mentioned earlier, blocking this activity in prenatal cats and postnatal ferrets disrupts the binocular segregation process. In the examples cited previously, activity likely affects the construction of new axonal branches and synapses and not the retraction of inappropriate connections since the manipulations are initiated when retinal and geniculocortical axons still have a simple stick-like morphology.

During the period of activity-dependent modification of connections, many manipulations are made to the visual system in an effort to define the mechanisms that relate activity to the growth of neural processes and to synaptogenesis. The most famous of these experiments were done in the 1960s by David Hubel and Torsten Wiesel, who showed that preventing one eye of a kitten from seeing during early life resulted in a number of dramatic changes in the connections and function of the visual system. In their experiments, they sutured the lid of one eye closed, but it is now known that the same effects are obtained as long as useful pattern vision is prevented; the amount of light reaching the retina is not as important. In these experiments, they found that kittens could no longer see well out of the deprived eye (i.e., they developed amblyopia) if the deprivation continued past 3 months of age. These investigators also found that geniculocortical axons from the deprived eye occupied less territory in layer IV of visual cortex (the deprived ocular dominance column was smaller) and cells in the cortex now responded mainly to the normal eye. If the kittens were allowed to develop normally for the first 3 months of age, monocular lid suture would no longer affect ocular dominance columns, suggesting that there is a window of time or critical period during which visual experience can have an impact on ocular dominance column formation. If the eye was sutured and shortly afterwards opened again during the critical period, then normal ocular dominance formation would occur. The effects of monocular deprivation are not the consequences of disuse, as Hubel and Wiesel clearly demonstrated, since depriving both eyes of useful pattern vision has much milder effects on the visual system (Fig. 9).

These experiments, along with numerous experiments that followed, suggest that developing geniculocortical axons that receive input from the left and right eyes can compete with one another for territory in cortex. The working hypothesis is that appropriate levels of activity and the temporal correlation of that activity in potential pre- and postsynaptic partners provide axons access to appropriate levels of growth factors (i.e., neurotrophins). These neurotrophins, in turn, activate the cellular machinery that allows axons to grow and develop synapses (Fig. 10). Axon growth is clearly constrained by many other factors in the target tissue discussed earlier, including factors that directly repel or attract axons or substrates that

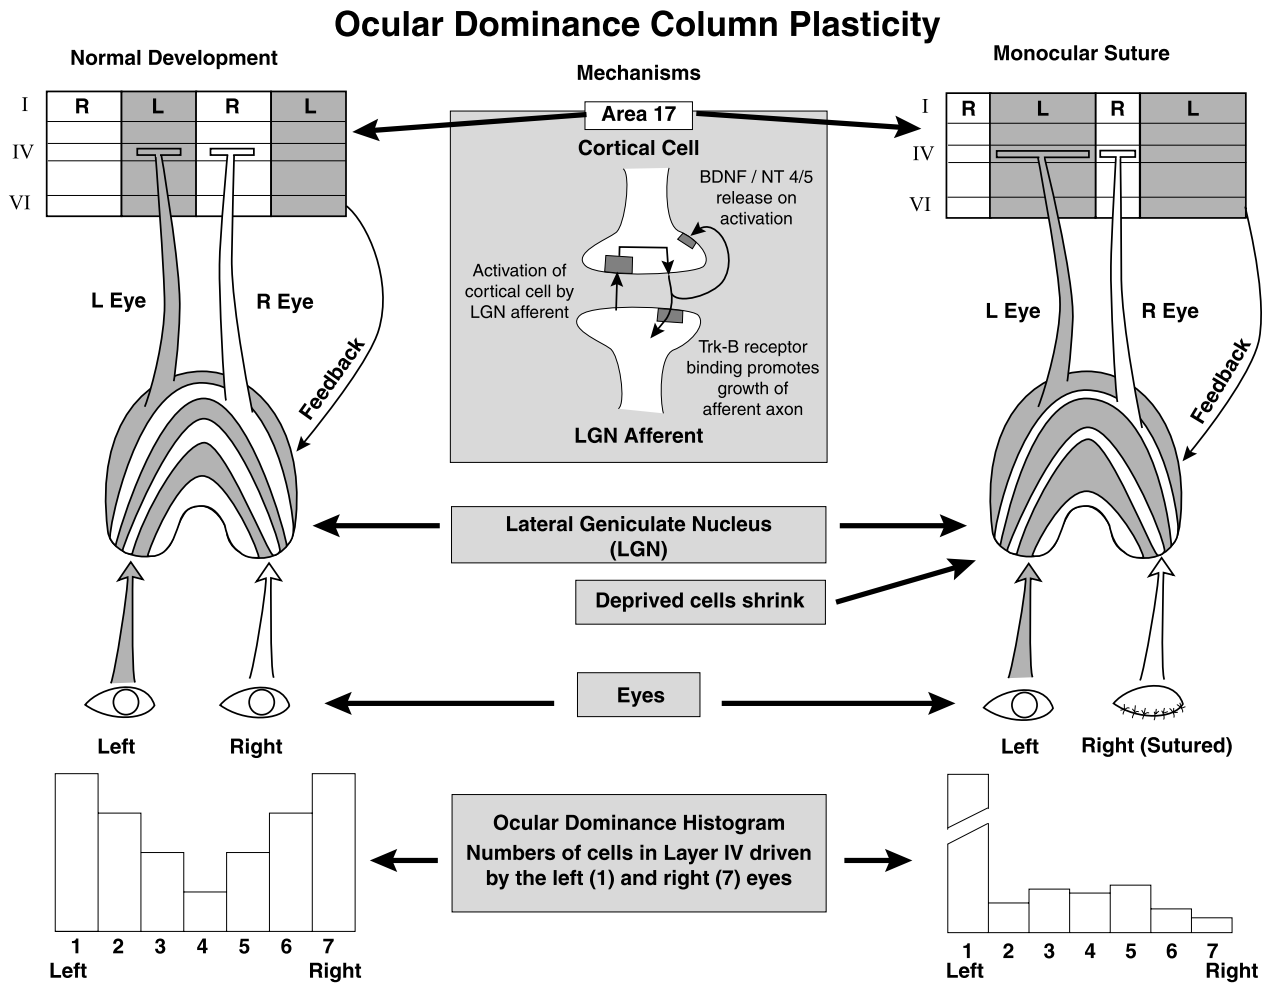

Figure 9 Changes within the LGN and visual cortex (area 17) seen following monocular lid suture in a macaque monkey. Axons from the left and right eyes segregate into six layers within the LGN early in development. LGN axons segregate into ocular dominance columns within layer IV of area 17. Axon segregation within the LGN and cortex takes place before birth, without visual experience. However, correlated spontaneous activity initially within each eye and subsequently via connections between segregated eye inputs in the LGN and cortex including corticogeniculate feedback may help axons segregate into ocular dominance territories. At birth, LGN axons are very immature. Neonatal lid closure eliminates useful patterned activity within the sutured eye. As a result, deprived LGN axons grow less and their LGN cell bodies shrink, and nondeprived LGN axons expand more than normal. Since deprived LGN cell bodies within the monocular segments of the LGN do not show these changes, it is likely that LGN axons innervated by the left (L) and right (R) eyes compete within cortex for limited quantities of neurotrophic factors. Evidence suggests that the neurotrophins, brain-derived neurotrophic factor (BDNF) or neurotrophin (NT) 4/5, are involved, as shown in the center. These neurotrophins bind to tyrosine kinase receptor B (Trk-B), which can be located both pre- and postsynaptically. In this model activation of the cortical cell by axons would cause release of BDNF or NT4/5, which would act to promote growth and survival of the LGN axon. Neurotrophin release could also influence the dendritic growth of cells from which it was released via autocrine mechanisms [adapted with permission from Barker, R. A., and Barasi, S., (with Neal, M. J.) (1999). *Neuroscience at a Glance* Blackwell Science, Oxford].

support growth. In addition, it is evident that pattern vision per se is not essential for setting up ocular dominance columns in the first place since monkeys are born with well-developed ocular dominance columns. Nevertheless, basic cellular mechanisms that normally help axons driven by the left and right eyes to segregate into layers in the LGN and into columns in the cortex are likely the same as those that allow for plastic changes following manipulations of visually driven activity.

How does activity help some developing axons to grow processes or form or strengthen some synapses at the expense of others? A working model for this process was originally derived from the learning model

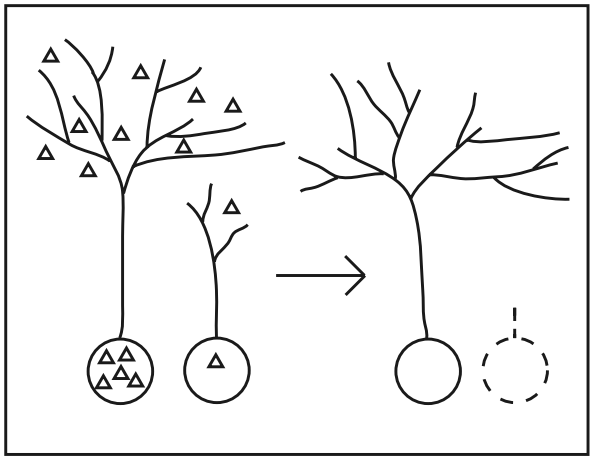

Figure 10 Selective access to growth factors can influence the survival of neurons. Neurons (circles) compete for a limited supply of growth factors (triangles). Neurons that do not get enough of the growth factor may die or have smaller axonal trees.

of Donald Hebb (1949). Hebb proposed that pathways that are active together form or strengthen connections at the expense of those that are inactive or not co-active (Fig. 11). In Hebb's model each instance of coactivation in an assembly of connected cells strengthens these connections. The favored synapses eventually become so strong that memories form. Hebb's idea for the strengthening of synapses in learning and memory provides a good model to explain how activity can influence the development of initial connections.

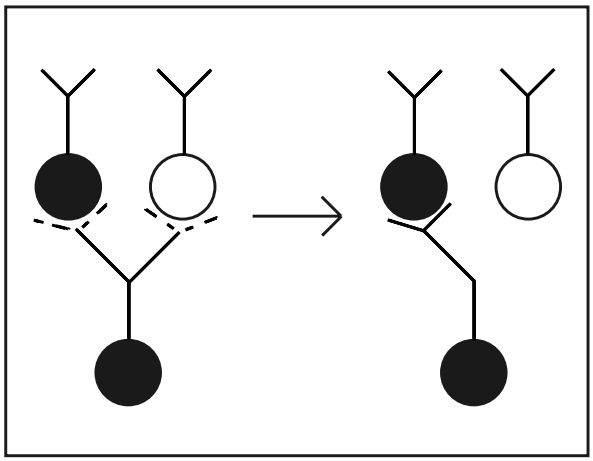

Figure 11 A simple schematic depicting Hebbian mechanisms of axonal plasticity. The two black cells on the left have synchronous action potentials. The white cell does not fire coincidently with the black cells. Initially, the lower black cell sends a synapse to both upper cells (dashed lines). After a certain amount of time, the synapse between the black cells is strengthened, whereas the synapse between the black and white cells is weakened or eliminated.

Hebb's hypothesis can be used to explain the development of ocular dominance columns if sets of correlated inputs tend to exclude uncorrelated inputs and are additionally constrained by molecular gradients related to retinotopy. Support for this idea was best demonstrated in cases in which an extra eye was transplanted to the head of a developing frog (Fig. 12). In frogs, each eye normally sends a crossed projection to each optic tectum. When a third eye is introduced, two eyes divide one tectal territory by developing ocular dominance bands in the dually innervated tectum as would be predicted by the model.

At the cellular level in mammals, the working model that has been proposed to explain how correlated activity can influence the formation and strengthening of synapses and the growth of neural processes involves a special class of receptors for the transmitter glutamate, the *N*-methyl-D-aspartate (NMDA) class of glutamate receptors. The NMDA receptors bind the transmitter glutamate, but such binding has no effect unless another condition is satisfied. At the "resting" membrane potential, the NMDA receptor's channel is blocked by magnesium. Strong depolarization of the postsynaptic membrane removes the magnesium block by electrostatic repulsion. If glutamate now binds to the NMDA receptor while the cell is depolarized, calcium is able to enter the cell via the NMDA channel. Calcium ions that enter through the NMDA channel activate kinases in the cell. Through either kinase activation or some other calcium-dependent series of steps, the postsynaptic cell is modified and potentially more sensitive to transmitter release. Additionally, a retrograde molecular signal or neurotropin (e.g., neurotrophin 4/5 or brain-derived neurotrophic factor) may be released from the postsynaptic cell that can influence presynaptic axon growth or the level of transmitter released by that axon (Fig. 13). Strong evidence in support of the special role for NMDA receptors also comes from work in the three-eyed frog, where infusion of the NMDA antagonist 2-amino-5-phosphonovaleric acid into the optic tectum blocks retinal axon segregation into ocular dominance bands. Subsequently, there have been many other studies that have supported aspects of this model, which has been useful not only in explaining how connections are refined during development but also how plastic changes can occur following different forms of visual experience. Among these studies, those showing that neurotrophin release can be influenced directly by activity and that different classes of neurotrophins and neurotrophin receptors can differentially affect the growth of axons and dendrites depending on the cell

type are especially relevant because they link activity with other basic cellular mechanisms involved in cell survival and selective outgrowth and targeting of neural processes. In addition to neurotrophic factors and activity-dependent mechanisms, a variety of other factors can impact the development of visual system connections, including, but not limited to, levels of various hormones, a variety of neurotransmitters, and neuromodulators.

For the examples given previously, it is important to keep in mind that although ocular dominance columns do not require visual experience to form in the first place (at least in primates), there are other aspects of vision that do require appropriate visual experience and are not present before birth even in primates. Stereoscopic depth perception, for example, appears to require adequate coordinated activity from both eyes since it does not exist at birth and becomes disrupted if input from the two eyes is not appropriately correlated. Such a situation can arise in humans or other animals that are born and grow up wall-eyed or cross-eyed. In the latter case, stereoscopic depth perception is lost and binocular connections do not form. Only if the eyes are surgically aligned early in a child's life will he or she develop normal stereoscopic vision. Nevertheless, the same activity-driven mechanisms described previously likely operate to allow appropriate binocular connections to form in visual cortex that, in turn, help us to appreciate our three-dimensional world.

IV. CONCLUSIONS

During neural development, cells proliferate and influence each others' fates through an elaborate interplay of extrinsic and intrinsic signals. Cells become committed to specific fates, such as laminar location in visual cortex, early in development before they begin to migrate. Molecular axon pathways are established through a variety of secreted factors and membrane-bound molecules. Correct axon targeting involves gradients of chemoattractant and chemorepellent molecules. Major waves of cell death take place at this stage that help to sculpt connections. Unlike spontaneous neural activity, activity driven by visual experience is not required for basic aspects of axon targeting, map formation, and segregation of axons into ocular territories within the LGN or visual cortex in precocial species such as primates. In all species,

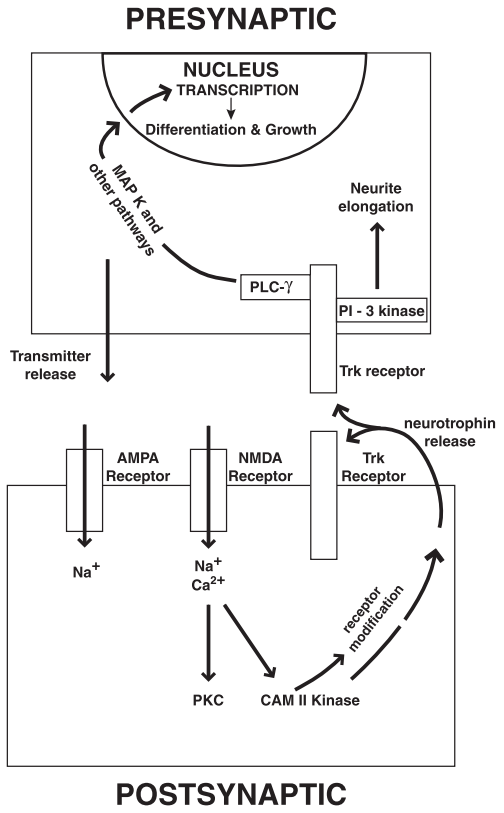

Figure 13 The NMDA receptor channel can open only during depolarization of the postsynaptic neuron from its normal resting level. Depolarization expels Mg^{2+} (not shown) from the NMDA channel, allowing current to flow into the postsynaptic cell. Since the NMDA channel is permeable to Ca^{2+}, there is a significant Ca^{2+} entry into the cell that can trigger other events involving Ca^{2+}. Through either kinase activation (protein kinase C) or a separate Ca^{2+}-dependent mechanism (calmodulin kinase II) or other pathways, neurotrophins can be released from the postsynaptic cell that can act in a paracrine fashion to influence growth of the presynaptic cell/processes or in an autocrine fashion to influence its own growth via pathways shown in the diagram for the presynaptic terminal/cell. Binding to neurotrophin Trk receptors permits Trk molecules to phosphorylate tyrosine residues. Phosphorylation of specific tyrosine residues creates binding sites for PI-3 and phospholipase C (PLC)-γ and recruitment of these proteins into a complex, thus initiating a signaling cascade that can lead to neurite elongation or, via the MAP kinase pathway, to transcription and ultimately differentiation and growth [from Casagrande, V. A., and Wiencken, A. E. (2000). Developmental plasticity in the mammalian visual system. In *The Mutable Brain. Dynamic and Plastic Features*. (J. H. Kaas, Ed.), Copyright © 2000 by Overseas Publishers Association Adapted with permission from Gordon and Breach Publishers].

however, visual system wiring can be profoundly affected by abnormal visual experience, especially during the phase of rapid axonal and dendritic growth.

An elaborate interplay between genetic and epigenetic factors defines specific connections in the highly complex system that is the mammalian nervous system. Molecular cues are important for guiding axons to their general target region and neural activity refines these connections. Even if genetic factors initially define axonal boundaries, it is not necessarily the case that these boundaries are static. The boundaries are partially plastic into adulthood and can be changed even in adults as the result of insult or injury. Neural activity can affect the growth of neural processes and synapses or strengthen existing synapses through Hebbian activity-dependent mechanisms and/or the limited availability of neurotrophins. These same Hebbian mechanisms allow for more limited plasticity in the wiring of the adult brain. Major changes in wiring only occur when processes are growing, but less dramatic changes are possible in the adult and likely involve the same cellular machinery that is used to establish and refine connections normally. The mature visual system at all levels can respond via expression of immediate early genes and regulation of a variety of transmitter and neuropeptide-related molecules to conditions of visual deprivation and damage. Despite the striking similarities that are found between developmental and adult neural plasticity, there are fundamental differences in the developing and adult brain. Younger organisms characteristically seek a variety of forms of visual stimulation and repeat visuomotor activities in ways more sedentary adult animals do not. Adult animals that are forced to use their visual systems via training show greater compensation for early damage than adult animals that are not. Understanding the neural mechanisms that drive early visual self-stimulation and how these factors interact with the activity-dependent mechanisms discussed to allow for compensation after visual system damage is one of the challenges for future investigations.

Wernicke's Area

ELEANOR M. SAFFRAN
Temple University School of Medicine

GLOSSARY

neologism Production of a nonword when a word is intended.

phonemic paraphasia A speech error in which some of the sounds of a word are replaced by other sounds.

jargon aphasia A speech pattern in which most of the nongrammatical elements are neologisms.

paragrammatism A pattern denoting the occurrence of grammatical errors in the speech of a fluent aphasic patient.

priming A task in which the presence of one word facilitates processing of another related word.

Wernicke's area, located in the left temporal lobe, was identified by Carl Wernicke in 1874 as the locus of damage of an aphasic syndrome characterized by impairment in language comprehension and production. These patients are impaired in understanding words and sentences, and their speech is riddled with errors, principally affecting the phonological content of words. This article examines the nature of the deficits in detail, along with related disorders such as word deafness. Evidence pertaining to the localization of Wernicke's area is summarized, as is recent functional imaging data that aim at identifying brain regions concerned with the comprehension and production of language.

I. HISTORICAL BACKGROUND

Wernicke's area is named for the physician who first identified the functions associated with this region of the brain. Carl Wernicke, a 26-year-old physician-in-training in the early 1870s, saw several patients with very impaired language comprehension. Their production was disrupted as well. Although they spoke fluently, their speech made little sense; they had difficulty finding words and produced many nonwords (neologisms) along with semantically related word substitutions. When one of the patients died, Wernicke was able to examine her brain. He found evidence of a cerebral infarct (a stroke) involving the middle third of the posterior superior temporal gyrus of the left hemisphere, extending into the middle temporal gyrus below (Fig. 1). (Note, however, that this was not a pure case because the patient also suffered from dementia.) Since the affected area lay close to primary auditory cortex, which receives auditory input from the thalamus, Wernicke reasoned that this region must be part of the auditory association cortex, where auditory input would undergo further analysis. He concluded that this area of the brain must serve as a second "center" for language in the left hemisphere, in addition to the articulatory center in the frontal lobe identified a decade earlier by Paul Broca.

Wernicke's interpretation of his findings was guided by the reflex physiology that dominated neurological thinking at that time. A central assumption was that motor acts were triggered by sensory input. Wernicke took the temporal lobe area to be the repository of "auditory word images," which were the product of language learning. Because it seemed obvious that children must learn the sounds of the words of their

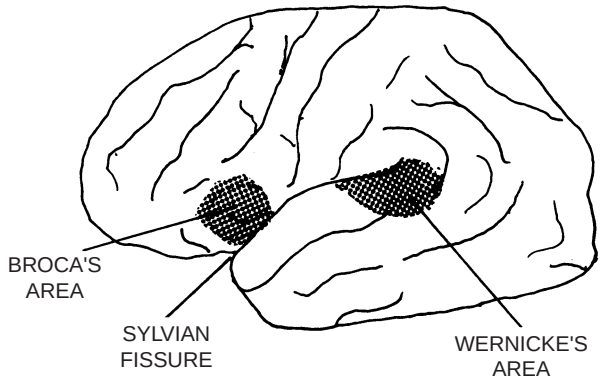

Figure 1 Location of Wernicke's and Broca's areas.

native language before they acquire the ability to produce them, he suggested that these images were not only essential for comprehension but also guided word production. Hence, the sensory and motor centers for language must be connected. Wernicke predicted that disruption of the connections between the two would give rise to a syndrome in which production was impaired but comprehension preserved because the superior temporal area would not be disrupted.

In the mid-1880s, Wernicke's theorizing was extended by Ludwig Lichtheim, who added a "concept center" to Wernicke's model. He termed it a center, although he viewed this information as diffusely represented in the brain. The concept center would serve as the end point for the comprehension of language as well as the starting point for the generation of spoken utterances. Lichtheim developed the model depicted in Fig. 2. The concept center is labeled B in his diagram; Wernicke's area is labeled A and Broca's area M. The only regions that Lichtheim localized in the brain were A and M because he accepted Broca's and Wernicke's placements for these centers.

Lichtheim's model generated predictions for additional syndromes that had not yet been identified. These included the transcortical aphasias—sensory and motor—in which the concept center was isolated either from Wernicke's area (transcortical sensory aphasia; disruption at area 6 in Fig. 2) or Broca's area (transcortical motor aphasia; disruption at 4). In both cases, repetition of the speech of others would be relatively preserved because the connection between Broca's and Wernicke's areas remained intact; however, comprehension and production would be disrupted in transcortical sensory aphasia, and production would be disrupted in the case of transcortical motor aphasia. In contrast, repetition of the speech of others would be impaired by a lesion at 3, which interrupted the connection between A and M (conduction aphasia); as Wernicke predicted, the patient would generate error-ridden speech. Lichtheim also postulated a disorder in which speech perception would be disrupted by removing the sources of auditory input to Wernicke's area (lesion at 7; pure word deafness) and a disorder of production that resulted from disrupting the connections between Broca's area and lower brain centers that control the articulatory musculature (lesion at 5; aphemia). All these disorders were subsequently identified. This approach to the explanation of neurologically based cognitive disorders came to be known as connectionism. This term should not be confused with its current usage, which applies to computer-implemented models that simulate cognitive functions. In these models, connections support the flow of activation from one cognitive subsystem to another.

Although the connectionist approach seemed to be productive, it soon became the target of criticism. One of the early critics was Sigmund Freud, who argued in his 1891 book on aphasia that the approach was overly simplistic. Freud maintained that connectionism could not account for the complexities of language function; nor, he contended, could it explain the language disorders that resulted from damage to the brain. He illustrated this point by attempting to use the connectionist model to generate the symptom patterns of aphasia cases that had been reported in the literature. Today, most would agree that a major limitation of the early work is that it focused on single words. The

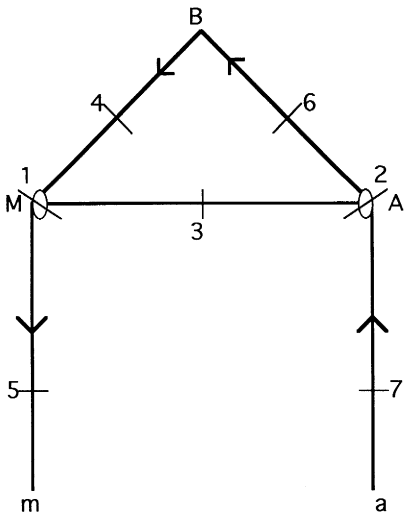

Figure 2 Lichtheim's connectionist model. Numbers indicate sites of lesions. See text for explanation.

connectionist model did not deal with sentence production and comprehension and the syntactic issues raised by these more complex language behaviors.

For much of the first half of the 20th century, researchers rejected the connectionist model and adopted a more diffuse and wholistic view of the representation of language in the brain. In the 1960s, the connectionist approach was revived, largely due to the work of neurologist Norman Geschwind, who offered accounts of a range of cognitive disorders in terms of the interruption of pathways between centers in the brain. Geschwind's theorizing was largely based on case studies of patients with highly selective impairments. At approximately the same time, Hildred Schuell (a speech pathologist) and colleagues at the University of Minnesota promoted a more diffuse view of language organization, arguing that the language area of the brain operated as a whole. Their conclusions were based on factor analyses of data obtained from an unselected series of aphasic individuals, which may have included patients with extensive brain lesions. Similar differences persist in the study of aphasia today: Some researchers advocate intensive single-case studies of patients with specific disorders, whereas others base their conclusions on studies of groups of patients defined by one of the classical aphasia syndromes.

II. FUNCTIONAL DEFICITS ASSOCIATED WITH DAMAGE TO WERNICKE'S AREA

A. General Characteristics

On the widely used Boston Diagnostic Examination for Aphasia (BDAE), constructed by Harold Goodglass and Edith Kaplan in the 1970s, Wernicke's aphasia is defined by impaired comprehension, difficulty with repetition, word-finding deficits, and fluent but paraphasic speech (i.e., the frequent production of speech errors). The BDAE profile that defines the syndrome is illustrated in Fig. 3. Additional information on the performance of a Wernicke's aphasic, NC, studied in our laboratory, is provided in Table I. These data reflect a more psycholinguistic approach to the analysis of aphasic impairments than that of the BDAE. It is important to note two characteristics of this patient: First, his ability to discriminate phonemes is not impaired, at least when they are presented in close proximity; second, his performance with written input is better than his performance with auditory input. It appears, however, that he loses phonological information rapidly. This is demonstrated not only by his difficulty in discriminating two syllables when they are separated by a 5-sec delay but also by his tendency to generate semantic errors in repeating single words (e.g., "windmill" → "lighthouse, something to do with light"). It should be noted, however, that some Wernicke's aphasics perform more poorly than NC on tests of phoneme discrimination, and that some are more impaired with printed words. Other characteristics of these patients include rapidity of spoken output, a pattern referred to as "logorrhea" or "press of speech." Another significant finding is that most of them do not seem to be aware of their speech errors, at least in the initial phase of their illness.

B. The Comprehension Problem

The Russian neuropsychologist Alexander Luria attributed the comprehension deficit in Wernicke's aphasia to a phoneme discrimination problem. He found such impairments in 95% of World War II missile wound casualties with lesions in the superior temporal gyrus. Subsequent investigations did not support this finding. In general, there appears to be little correlation between phoneme discrimination deficits and auditory comprehension impairments in aphasics. One possible explanation of Luria's results is that they reflect the nature of the population he tested. Missile wounds are likely to penetrate into the white matter that delivers input to the superior temporal lobe. As discussed later, depriving the left temporal lobe of auditory input does indeed result in severe phoneme discrimination deficits.

Sheila Blumstein and colleagues found that Wernicke's aphasics were less impaired on phoneme discrimination tasks than other language-impaired patients, and that their performance was dependent on the lexical status of the stimuli. The Wernicke patients demonstrated better discrimination between words than nonwords, a pattern similar to that of other aphasic groups that were tested. Another significant finding from these investigators was that Wernicke's patients were more likely to err by selecting semantically than phonologically related foils on a word–picture matching task, although they did show a greater effect of phonological similarity than Broca's aphasics. Blumstein and colleagues also found that some aphasic patients who did well on phoneme discrimination performed poorly on tasks that required them to identify the syllable they heard

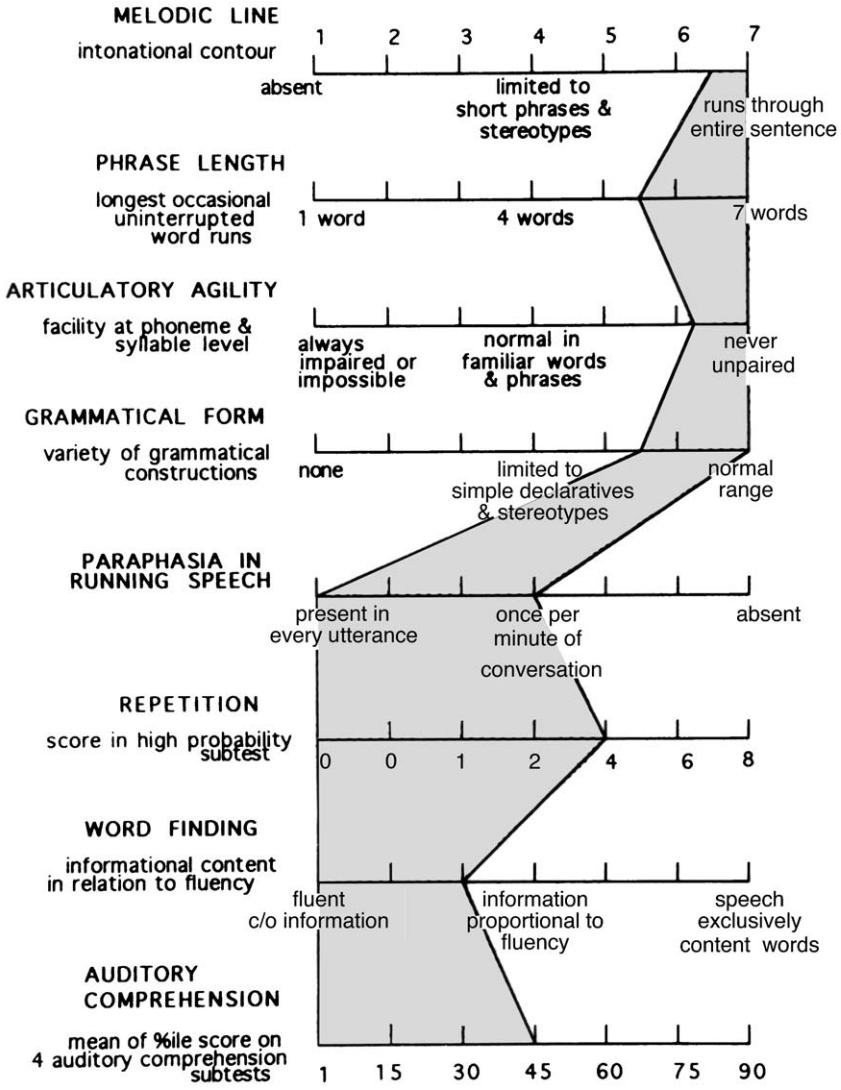

Figure 3 Range of Wernicke's aphasic scores on the Boston Diagnostic Examination for Aphasia (redrawn with permission from Goodglass and Kaplan, 1983).

(e.g., by pointing to the matching syllable in a written array). Many, but not all, researchers assume that phoneme identification is a critical step in language processing. As Blumstein has also noted, speech perception deficits may underlie language comprehension deficits, but these deficits are revealed only in the context of larger streams of speech. Therefore, focusing on the perception of segments in isolated words or syllables may not be a sufficiently sensitive index. This conclusion is supported by the data from NC (Table I), which indicate that phonemes may be perceived accurately but that this information is rapidly lost.

Other findings suggest some imprecision in the responses of Wernicke's aphasics to auditory speech input. For example, Blumstein and colleagues found that Wernicke patients responded to stimuli that were phonologically similar to semantically related words (e.g., "wat" or "gat", where the target was "dog"), whereas Broca's aphasics did not. These words were presented in a priming task, in which the nonword preceded a lexical decision response ("Is the stimulus a word or not?") to the word target. In the Wernicke patients, the phonologically similar nonword speeded the response to the word target in the lexical decision

Table I
Data from Wernicke Patient NC

Peabody Picture Vocabulary Test (matching spoken word to one of four pictures)	< First percentile for normal subjects	
Word-to-picture matching (four choices)		
Within-category choices ($n = 15$)	69%	
Across-category choices ($n = 28$)	100%

Reversible choices (1 of 2; $n = 60$)	68%	

task. In another study, Blumstein and colleagues investigated lexical effects on phoneme classification in aphasics. These studies were based on findings in normal subjects indicating that the location of the boundary between similar phonemes (e.g., /d/ and /t/) depends on the context in which the phoneme is embedded. In normal subjects, the boundary shifted toward /d/ responses when the /d/ stimulus was a word (''dash-tash'') and in the direction of /t/ when the /t/ stimulus was a word (''dask-task''). These investigators found that Broca's aphasics showed the lexical effect—in fact, one that was exaggerated relative to control subjects—whereas the Wernicke patients did not. This finding suggests that the Wernicke's aphasics were less sensitive to the phonological differences among the stimuli: That ''dask'' was as effective as ''task'' in contacting the lexical representation of task. A tendency toward less discriminating responses may reflect some degradation of the lexical network.

One finding that might seem surprising, given the relatively poor performance of Wernicke patients on word comprehension tasks, is that they demonstrate semantic priming effects. Priming refers to the effect of presenting a word that facilitates processing of a second word (e.g., presenting ''horse'' and then the semantically related word ''sheep''). These effects are usually assessed in lexical decision tasks (deciding whether a stimulus is a word or not), in which presentation of a related word speeds the decision to the target word. Sheila Blumstein, William Milberg, and colleagues have shown that Wernicke patients demonstrate semantic priming effects in lexical decision tasks. These effects have been demonstrated with written as well as spoken words. Data cited previously indicate that Wernicke patients frequently make semantic errors in tests of word comprehension. For example, note the relevant data for NC in Table I: He performed well in a word–picture matching task when the foils came from different semantic categories (the

across category condition) but not when they came from the same semantic category (the within-category condition). The priming data suggest that information with respect to semantic category is likely to be retained, although the specific features that differentiate one category member from another may not be accessible from word stimuli.

Wernicke's aphasics are impaired on sentence processing tasks as well. This is evident in the data from NC presented in Table I. Data from 10 Wernicke's aphasics tested in our laboratory on the Philadelphia Comprehension Battery are summarized in Fig. 4. Note that their average scores consistently lie below the aphasic mean (based on data from 64 aphasics). In particular, they perform quite poorly on the grammaticality judgment subtest, in which they are asked to determine whether a spoken sentence adheres to the rules of English syntax, and on the sentence comprehension subtest with lexical distractors, in which one of the pictures depicts an entity or relationship that is not present in the sentence. In contrast, Broca's aphasics ($n = 9$) perform well on these tasks (92 and 97% correct, respectively), although they also break down on the reversible subtest of sentence comprehension (76% correct). The sentence comprehension task included a number of different syntactic structures, from simple actives (e.g., "The girl washed the boy") to passives (e.g., "The boy was washed by the girl") and object relatives (e.g., "The boy that the girl washed was tall"). Although the Broca's aphasics showed a clear effect of syntactic complexity (e.g., worse performance on passives and object relatives compared with active voice sentences), statistical analyses revealed no effect of structural complexity in the Wernicke's aphasics. In Serbo-Croatian, a language that relies heavily on affixes to mark grammatical distinctions, Katarina Lukatela and colleagues found that Wernicke's aphasics also performed more poorly than Broca's aphasics on a grammaticality judgment task. Additional data come from a sentence comprehension study conducted with German-speaking aphasics. Jacqueline Stark and Rudolf Wytek found that Wernicke patients were more likely than Broca's aphasics to choose distractors that incorporated an agent (doer of the action) that was not mentioned in the sentence or one that depicted an action involving the wrong verb. The Wernicke patients made almost three times as many lexical as syntactic errors; in contrast, the Broca patients made almost twice as many syntactic as lexical errors. Note a similar finding in our own study, in which Broca patients rejected picture choices that contained an entity or relationship that was not present in the sentence (the Lexical Sentence Comprehension subtest), whereas the Wernicke patients frequently selected such alternatives instead of the correct target.

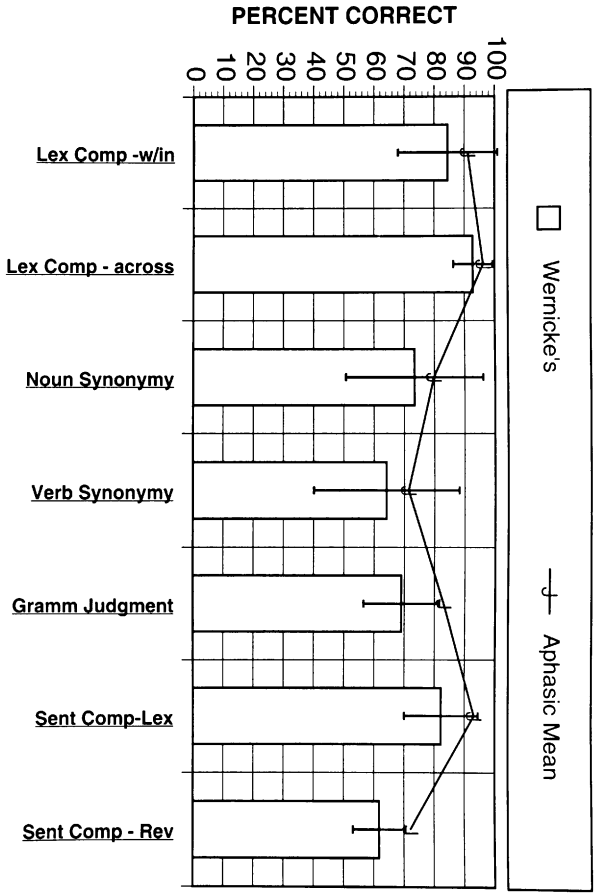

Figure 4 Data for Wernicke's aphasics ($n = 10$) from the Philadelphia Comprehension Battery. Bars indicate standard deviations. The aphasic mean represents average scores for 64 aphasics. Subtests are as follows: lexical comprehension-within—word-to-picture matching with four choices, with the three foils from the same semantic category; lexical comprehension-across—word-to-picture matching with four choices, with the three foils from different semantic categories and with phonologically related foils in some cases; noun synonymy—choose the least related of three nouns, presented in spoken and written form; verb synonymy—choose the least related of three verbs, presented in spoken and written form; grammaticality judgment—sentences representing a range of syntactic forms, half of which violate English syntax; sentence comprehension–lexical—match a sentence to one of two pictures, with the foil containing an item that is not in the sentence; sentence comprehension–reversible—match a sentence (range of syntactic structures) to one of two pictures, with the foil reversing the roles of the two participants.

Although the Wernicke's aphasics resemble Broca's aphasics in demonstrating effects of semantic reversi-

bility, it is difficult to argue that the two sets of phenomena reflect the same underlying impairment. In the case of the Wernicke patients, some of the difficulty with semantic reversibility may reflect confusion with respect to word meaning. Furthermore, it appears from the grammaticality judgment data that the Wernicke's aphasics may not be computing the syntactic structure of the sentence, which the Broca's appear capable of doing, although they are clearly deficient in utilizing the structural information to derive an interpretation for the sentence.

There is an additional comparison worth noting. Semantic dementia is a disorder in which patients have difficulty retrieving words and are impaired in word comprehension as well. This degenerative condition reflects damage to structures outside the classical perisylvian language area—the region on both sides of the Sylvian fissure (Fig. 1) which separates the temporal from the frontal and parietal lobes. Semantic dementia patients show loss of tissue in the inferior, anterior portion of the left (or both) temporal lobe(s). In contrast to Wernicke's aphasics, these individuals perform relatively well on sentence comprehension tasks. To the extent tested, the semantic dementia patients also perform successfully on grammaticality judgment tests, whereas the Wernicke patients do not. It is necessary to conclude, then, that the Wernicke patients are impaired in other aspects of sentence processing in addition to their semantic deficits in word comprehension. However, the nature of these limitations is not clear: Do they involve lexical access, syntactic computation, short-term memory limitations, or perhaps all these mechanisms? Because lexical access is necessary to retrieve syntactic information for words, it is likely that this process is impaired in Wernicke's patients. Also, in view of the Broca patients' greater sensitivity to grammatical violations compared to Wernicke's aphasics, it might be conjectured that the recovery of syntactic structure is supported by left temporal (and perhaps parietal) structures that are damaged in Wernicke's aphasia. Left parietal areas have been implicated in short-term verbal memory, particularly with respect to the retention of phonological information.

C. Word Deafness

There is another impairment that appears to reflect the loss of auditory input to phonological processing areas in the left temporal lobe. This disorder, predicted in Lichtheim's model, is termed pure word deafness. Patients demonstrating this impairment have great difficulty understanding and repeating spoken input, although they speak, read, and write relatively normally. The disorder is rare; it is thought to result from small lesions affecting the pathways that supply auditory input to the left temporal lobe (from the medial geniculate in the thalamus) as well as callosal input from homologous areas of the temporal lobe in the right hemisphere. This account is supported by evidence from a word deaf patient whose lesion involved white matter underlying the left temporal and parietal lobes, leaving Wernicke's area intact. As a consequence of its rarity, all the data in the literature are reported in the form of case studies. In some cases, the lesion is restricted to the left hemisphere; in others, the lesions are bilateral. For example, one patient originally diagnosed as a Wernicke's aphasic following a left temporal lesion became word deaf following a subsequent lesion to the right temporal lobe.

As might be expected from differences in the lesion sites, the behavioral findings are not altogether consistent across patients. Although vowel perception may remain relatively intact, word deaf patients perform very poorly on phoneme discrimination tasks that involve consonants. This difference reflects the nature of the two types of speech sounds: Vowels are longer in duration and have a consistent auditory pattern, whereas consonants involve rapid changes in pitch as well as small differences in the timing of elements of the pattern. There is evidence that the left temporal lobe is specialized to detect these transient changes and timing differences. With respect to consonant perception, some patients have proved more sensitive to place distinctions (the locus of production of the sound, whether it involves the lips or particular placements of the tongue), whereas others appear more sensitive to differences in voicing (whether vocal fold vibration begins with the onset of the sound, as in /b, d, g/ or is slightly delayed, as in /p, t, k/). These individuals are generally able to distinguish speech from other forms of auditory input, but some of them report that the speaker appears to be conversing in a foreign language. In a few cases, dichotic listening tests, which involve presenting two different inputs simultaneously to the two ears, have shown that patients respond better to stimuli delivered to the left ear, which projects more extensively to the right temporal lobe than the left. This finding suggests that these patients are utilizing right temporal lobe areas to process speech input. These data are consistent with the view that the left temporal lobe is specially equipped to deal with the perception of speech.

D. Production in Wernicke's Aphasia

With respect to production, Wernicke patients speak fluently, although it may be difficult to understand what they are trying to say. The sample in Table II illustrates this pattern. Errors include semantic substitutions as well as the production of nonwords (neologisms). The nonwords are sometimes divided into two classes: phonemic paraphasias, which bear some phonological similarity (often defined as 50% or more overlap) to the target word, and nonwords that bear little or no similarity to the target, sometimes referred to as abstruse neologisms. In severe cases, the majority of substantive words (nongrammatical words) are neologisms, a production pattern termed jargon aphasia. It should be noted that these nonwords are nevertheless consistent with the phonotactic constraints of the speaker's language—that is, their phoneme sequences do not violate the language's combinatory rules.

In addition, running speech usually contains grammatical violations, a pattern known as paragrammatism. This production pattern is distinguished from agrammatism, which is found in nonfluent Broca's aphasics with frontal lobe damage, where sentence structure may be absent or vastly simplified. In many cases, the paragrammatic errors involve omissions of grammatical elements or substitutions of one for another. There are also instances in which the errors appear to reflect combinations of two syntactic structures (e.g., "I feel fine"/"I'm feeling fine" → "I'm feel fine"; Table II). Wernicke's aphasics generally appear insensitive to the errors they are producing, suggesting that they are not monitoring their output or not doing so successfully. This pattern contrasts with that of conduction aphasics, who also produce phonological errors but generally attempt (often without success) to correct them. In a study of word production in Wernicke's aphasics carried out in 1982 by Sarah Williams and Gerald Canter, it was found that the patients performed better on picture description tasks, in which the word was generated in the context of a sentence, compared with a task that simply required them to name single items in pictures. This finding suggests that the sentence context facilitates production of the word in these patients, possibly as a result of activation from the syntactic frame for the sentence that stipulates selection of a word from a particular syntactic category (e.g., noun, verb, and adjective). It is interesting that the opposite effect—better performance on picture naming than on picture description—was obtained in Broca's aphasics, who generally have difficulty with sentence production. Another recent report, by Helen Bird and Sue Franklin, examined the relationship between word and sentence production in a Wernicke's aphasic. As word retrieval improved, so did the complexity of the patient's utterances. This finding does not prove that there is a causal relationship between the two language functions, although it does seem reasonable that an increase in the ability to retrieve words would facilitate the construction of more complex sentences.

Clearly, one aspect of the problem with word production in Wernicke's aphasia reflects difficulty in accessing their phonological forms; this difficulty could account for errors that bear a phonological relationship to the target word. However, it is likely that semantic input to the lexicon has also been degraded. It has sometimes been suggested that errors that bear no phonological resemblance to the target word (so-called abstruse neologisms) reflect a combination of the two types of errors: First a semantic error

Table II
Speech Sample from a Wernicke's Aphasic (FL)

Examiner: OK, so tell me what the problem's about.

FL: From the doctors, wh'where, from, from what **eh'spect**?

Examiner: Tell me what you think your problem is.

FL: Ah, where do I start the **tesseinemen** from? They tell me that my brain, physically, my brain is perfect, the attitudes and everything is fine, but the silence now, that I have to **reeh-learn** through **edgit** again, physically nothing wrong with it. It's perfect the doctors tell me. They have attitude. Physically I have **loozing** absolute nothing on my head, but now I have to go through these new attitudes to **looalize** how, some, how can I say to ? Some what that I can **reeh-learn** again so I can **estep** my knowledges, so th'you **kyou** again, what how can I say that …

Examiner: That's OK, I got you, it's clear … so how are you feeling?

FL: I'm feel fine. My wife, I love wife. I'm uh sorry that, I still feel bad, that **he** has been **she** upset by this thing, from 'till three weeks ago nothing was goin,' you know. **Sutting** happened to her, so I feel for her. She was caught, has a, she's been caught in a **herrible** situation by **meem**, that, that, uh there's just no way, you know, I'm just beginning from the doctors that I've learned now, they had my **doctors** open for eight day, **kuntinueh** days.

is generated, and this is followed by failure to access the correct phonological form of the semantically related word. Another proposal, from Brian Butterworth, is that abstruse neologisms are generated by a neologism-generating device that is employed when access to the phonological form of a word is blocked. Butterworth found that the production of neologisms that bore little relationship to the presumed target word followed longer hesitations in running speech compared with other kinds of errors (such as phonemic paraphasias), suggesting that they were generated by a different mechanism. Yet another possibility is that the errors result from the utilization of phonemes that have high levels of activation. Evidence from studies of normal subjects indicates that words that are semantically related to the target are activated along with the target item; if activation of the target word or its phonological form is relatively weak, this would allow phonemes from other words to intrude into the response. Currently, the source (or sources) of these errors, which include phonemic paraphasias as well as errors that are more remote from the target word, has yet to be determined.

Many words represent combinations of morphemes—either inflectional, as in "walk" + "ed", or derivational, as in "distribute" + "tion." Butterworth noted that inflectional affixes were used appropriately by the jargon aphasic he studied. A study of an Italian jargon aphasic, carried out by Marta Panzeri and colleagues, noted the generation of neologisms formed by adding legal derivational affixes to nonword roots. Although these were clearly nonwords, the word category reflecting the affix (noun, verb, adjective, or adverb) was appropriate to the syntactic context in which the erroneous item appeared. For example, the affix "—mente" in Italian turns an adjective into an adverb; the neologism "atamente" occurred in the appropriate context for an adverbial modifier. Thus, it appears that although the patients cannot retrieve the correct root morphemes, they are nevertheless capable of generating nonwords with affixes that are appropriate to the syntactic context.

There is evidence that semantic information is disrupted by lesions affecting the anterior, inferior portions of the left temporal lobe, the area damaged in semantic dementia and in herpes simplex encephalitis, which also results in semantic impairment. The lesion sites in Wernicke's aphasia are likely to sever connections between this region and word forms presumptively stored in the superior temporal gyrus, which may also be lost if this region is damaged as well. Note that in contrast to semantic dementia patients, who have difficulty with semantic tasks that involve pictures, Wernicke's aphasics may perform well on such tests, indicating that conceptual information per se has not been affected. For example, patient NC scored at a normal level (98% correct) on the pictorial version of the Pyramids and Palm Trees test, in which a target picture must be matched to one of two alternatives (e.g., a pyramid to a palm or fir tree). In contrast, he was only 69% correct in the within-category word to picture matching task, in which a spoken word must be related to one of four pictures (e.g., "strawberry" to pictures of a strawberry, watermelon, pear, and pineapple).

In some cases the difficulty with word retrieval may decrease over time, accompanied by some improvement in word comprehension. Hence the frequent change in diagnostic category from Wernicke's aphasia to conduction or anomic aphasia. For example, the profile of patient NC (Table I) changed to that of a conduction aphasic over a period of 18 months. Also, in a number of published cases of Wernicke's aphasia, the production of written words was found to be much better preserved than oral naming. One exceptional case, a Wernicke's aphasic studied in our laboratory, had a lesion involving most of the left temporal lobe. Although his responses on an oral picture-naming test consisted mostly of neologisms, his spontaneous speech, sampled 4 years after the lesion occurred, was free of such errors. To compensate for his deficit, this patient substituted orally spelled words (not always spelled entirely correctly, but recognizable), which were inserted at the proper locations in his utterances. This patient, as in other cases in which written word production is superior to oral production, made semantic errors in writing words to dictation. As has also been reported for other such patients, his sentence writing was agrammatic. We have suggested that this performance pattern may reflect right hemisphere support for written word generation in these patients.

With respect to the production of connected speech, some researchers have noted the persistence or overuse of certain phonemes in Wernicke's aphasics. For example, Butterworth found that the samples from a jargon aphasic contained many examples of infrequent phonemes, such as /z/. One published analysis, by Myrna Schwartz and colleagues, examined the production of the patient FL (whose speech sample is provided in Table II) for the occurrence of anticipation and perseveration errors. Anticipatory errors reflect the production of phonemes in advance of their correct position in the utterance; perseveratory errors reflect

the recurrence of phonemes after they have been produced. Schwartz and colleagues' analysis of published normal speech corpora revealed that anticipatory errors prevailed. However, a bias toward perseverations was noted in the early responses of normal subjects who were learning to produce tongue-twisters (e.g., "flea-free fruit flies"), although there was a shift in the direction of anticipatory errors toward the end of the learning trials. FL's analysis demonstrated a preponderance of perseveratory errors (e.g., "me" → "meem"; Table II). This tendency may reflect the utilization of phonemes that remain activated after they are produced; these phonemes may have higher activation levels than phonemes that are appropriate to the planned utterance, which may be weakly activated in the impaired lexicons of such individuals. In contrast, anticipatory errors might be considered "good" errors in that they reflect the retrieval of upcoming units in the phrase.

Although the speech of Wernicke's aphasics is subject to paragrammatic errors, their production is more syntactically complex than that of Broca's aphasics, whose speech is often characterized as agrammatic. This observation suggests that the retrieval of syntactic form for the purpose of generating sentences may not depend on Wernicke's area. The finding that Wernicke's aphasics are better at retrieving words in sentence contexts than in single picture naming tasks provides additional support for this possibility.

One major question concerns the relationship between the comprehension and production impairments in Wernicke's aphasia, which remains unclear. Do the two deficits reflect reliance on a common set of word forms, or are there different phonological representations of words for comprehension and production? Those who are concerned with the architecture of the language system view this as a central question, which has yet to be resolved.

E. Repetition

As is evident from the profile in Fig. 3, repetition is impaired in Wernicke's aphasia. This is to be expected, given the problems in the perception and production of words, along with what appears to be the rapid loss of phonological information. Examples from NC's single word repetition performance include the following: "drum" → "rum," "train" → "tree," "dragon" → "wagon," "camel" → "captain." Not surprisingly, NC's sentence repetition was seriously impaired, as is evident from the following examples: "Each night the guard checks all the locks" → "Security checks all the doors every night," "While walking under an elm, the man was hit on the head" → "A man was walking down the street and fell down."

One additional pattern deserves mention. In some cases of Wernicke's aphasia, the patients produce semantic errors in single word repetition tasks (e.g., "tobacco" → "cigarettes"). This pattern is termed deep dysphasia, an analogy to the reading disorder termed deep dyslexia, which is characterized by the production of semantic errors in reading single words aloud. The semantically related response indicates that the input signal was processed to a deep, or semantic, level. Other features of this disorder include great difficulty repeating nonwords and better performance on concrete rather than abstract words. One possible account of this pattern is that it reflects abnormally rapid loss of phonological information. The patients hear the word, process it semantically, and regenerate the word from the semantic representation without reference to the phonological form of the input signal. The difference between abstract and concrete words could reflect the richer and less contextually dependent representations attributed to the latter. Deep dysphasics typically perform very poorly on verbal short-term memory tasks, which require them to retain and report strings of digits or words. Patient NC, who demonstrated very rapid loss of phonological input (Table I), was a deep dysphasic. In a functional imaging study of a deep dysphasic patient, Dominique Cardebat and colleagues found high levels of activation in the right temporal lobe, which suggests that this area may support the processing of auditory verbal input in such patients. If this is the case, the generation of semantic errors in word repetition could reflect the nature of right hemisphere semantic relationships, which have been characterized as "coarsely coded" relative to those of the left hemisphere. Furthermore, the phonological capacities of the right hemisphere are thought to be limited.

F. Computational Models

During the past 15 years, a number of investigators have turned to computational models—language processing models implemented as computer simulations—in an attempt to further understand the nature of the deficits in aphasia. One approach has been to utilize, or develop, a model that accounts for normal language behavior and then to "lesion" the model in

order to generate impaired performance. For example, Gary Dell and collaborators took a model that captured features of normal performance in a picture-naming task and created lesions to simulate the error patterns (quantitative distributions of correct responses as well as several error types) generated on the same task for each of 21 aphasics. The model stipulates a set of semantic features for words, which connect to word entries in a lexicon; the word entries then connect to their component phonemes. In this model, the connections are bidirectional; that is, activation flows downward from semantics to the word level to phonemes and back up from phonemes to the word representations and then to the semantic level. The word with the highest activation is selected for production. One way to inflict damage on the model is to reduce the strength of the connections in the network, which decreases the flow of activation between levels. Dell and colleagues showed that reducing the strength of the connections in the model resulted in the production of nonword errors. Intuitively, this is obvious because this lesion essentially disconnects phonemes from the semantic features that are initially activated. Another way to damage the model is to increase the rate of decay of activation in the model. Extreme changes in decay rate will also generate nonword errors, although at intermediate levels of connection weight and decay lesions, the error patterns differ, with the decay rate lesions yielding larger numbers of word substitutions that are semantically or phonologically related to the target word. Overall, the simulations of the performance of the 21 aphasics were quite successful in generating the pattern of each patient's responses. The sample in this study included 5 Wernicke's aphasics. In one case, the lesion was modeled by a reduction in connection strength and in two others by an increase in decay rate; the others were simulated by changes in both parameters. One possible account of the errors generated by Wernicke's aphasics entails reduction in the connection strength among levels of representation in the internal lexicon and/or increases in the rate of decay of activation. However, although the simulations captured the rates of production of various kinds of errors, the model is only capable of generating monosyllabic words. For this reason, there was no attempt to simulate the features of the errors in phonological form—the phonological paraphasias and neologisms that are so common in Wernicke's aphasia. In many cases, these involve the intrusion of phonemes that are not present in the utterance, a rarity in normal speech errors. Attempts to simulate these error patterns await the development of models that generate multisyllabic words, which can then be "lesioned" to generate phonological errors.

III. ANATOMICAL ASYMMETRY AND EVOLUTION OF WERNICKE'S AREA

For many years, neuroanatomists were struck by the similar appearance of the two cerebral hemispheres in the human brain, despite clear evidence of differences in their function. However, measurements performed by Norman Geschwind and Walter Levitsky in the late 1960s uncovered significant differences between them. In particular, the human planum temporale, the area at the junction of the temporal and parietal lobes, was larger in the left than in the right hemisphere in 65% of the brains they examined. This asymmetry is associated with a longer Sylvian fissure on the left side of the brain (Fig. 1). The planum temporale is the location of much of Wernicke's area. Although originally interpreted as the consequence of left hemisphere specialization for language, the same asymmetry has recently been described in chimpanzees. It is possible that the enlargement of this area in other primates led to its eventual support for language function.

In a recent functional magnetic resonance imaging (fMRI) study carried out by Amanda Bischoff-Grethe and colleagues, it was found that the activation of Wernicke's area, as well as its right hemisphere homolog, was negatively correlated with the temporal predictability of a color sequence pattern. The subjects in this study were instructed to perform a different task and were not consciously aware of the predictability of the pattern. The authors suggest that the predictability of sequential information is useful in processing both the phonological and the syntactic aspects of language, and that this capability could conceivably have given rise to the utilization of Wernicke's area for language function.

IV. LOCALIZING WERNICKE'S AREA

Wernicke located his second center for language in the superior temporal gyrus, with some extension into the middle temporal gyrus below. Bogen and Bogen, in a 1976 article titled "Where Is Wernicke's Area?," noted that this localization was not consistently supported by subsequent investigators. Some placed it largely in the parietal lobe, encompassing the angular and supramarginal gyri with some extension to the superior and

middle temporal gyri; some excluded parietal cortex altogether; others extended it into the middle temporal gyrus, whereas some did not. The Russian neuropsychologist Luria, who studied military casualties in World War II, located the center of the area in the superior temporal gyrus, where 95% of the cases exhibited a phonemic perception deficit; of those with lesions in the parietal area posterior to it, 53% had such an impairment. Luria took a probabilistic view of the extent of Wernicke's area, which is probably the correct approach given that brains differ across individuals and that lesions are rarely the same from one case to another. Moreover, language is the product of learning, and there may well be variability across individuals with respect to the brain region(s) that supports this knowledge.

We are in a stronger position today because we can draw not only on computed tomography (CT) and MRI scans to localize the lesions of neurological patients but also on functional imaging studies that track brain activation (indirectly via blood flow to active brain areas) as normal individuals perform language tasks. In the case of patient studies, two factors are critical. The first is temporal. CT scans will not reveal evidence of ischemic infarctions (those that reflect blockage of an artery) soon after the event because cell death and clearing of the infarcted area are required to differentiate the affected area from normal brain. However, if one waits too long, the behavior pattern may change; in many cases, those initially diagnosed as Wernicke's aphasics transmute into conduction or anomic aphasics over time, reflecting an improvement in comprehension and, in some cases, production as well. The neurological basis for the amelioration of symptoms is not always clear, although in some cases there is evidence for right temporal lobe involvement, as indicated by a decline in performance following a right hemisphere lesion or an increase in right hemisphere activation over time in functional imaging studies. Second, it is necessary to adopt clear and replicable parameters for the diagnosis of Wernicke's aphasia. This can be accomplished by using one of the aphasia batteries that specify criteria for such a diagnosis, such as the Boston Diagnostic Examination for Aphasia or the Western Aphasia Battery.

All of the studies that have gathered CT, MRI, or the earlier generation of radionucleotide scans from Wernicke patients have noted variability in the lesions. This is to be expected because the disorder generally results from vascular injuries that vary in the extent of the damage to the circulatory system and, hence, the brain region that is affected. Andrew Kertesz, who superimposed radionucleotide scans from 13 Wernicke's aphasics, found the area of maximum overlap of the lesions in the superior temporal gyrus of the left hemisphere, with some extension into the parietal lobe, both dorsally and posteriorly. Nina Dronkers and colleagues analyzed the lesions in 6 chronic cases of Wernicke's aphasia identified by the Western Aphasia Battery. They found that the region of maximum overlap lay in the middle rather than the superior temporal gyrus; the underlying white matter was affected as well. A sixth patient's lesion was restricted to subcortical white matter, possibly isolating Wernicke's area from input sources. A recent study that examined MRI scans in 10 Wernicke's aphasics noted damage to the posterior portion of the temporal gyri in 7, damage to the anterior portion of the temporal gyri in 6, and damage to the inferior parietal area in 4; lesions in the underlying white matter were present in 8 of the patients. Currently there is disagreement with respect to the localization of Wernicke's area. What is critically needed is a lesion overlap study that includes a larger set of patients, along with the stipulation of quantitative criteria for defining the syndrome.

Regarding functional imaging [positron emission tomography (PET) or MRI] studies, which record blood flow to active areas in the brain, there is evidence that auditory stimuli activate superior temporal cortex bilaterally. The region activated by words as well as nonwords generally includes Brodmann's areas 22, 41, and 42 in both cerebral hemispheres, identified on the basis of histological differences early in the 20th century. All these regions are located in the superior temporal gyrus. When activation patterns for nonwords are subtracted from those for words, much of the left superior temporal activation disappears. However, there is evidence that auditory word stimuli activate areas located more ventrally and posteriorly in the left superior temporal lobe, along with the middle temporal gyrus.

A study conducted with French subjects demonstrated that the left superior temporal lobe was activated by spoken stimuli in an unfamiliar language (Tamil), a finding that implicates this area in prelexical processing of speech input. In a recent magnetoencephalographic (MEG) study conducted in Finland, it was found that the left temporal lobe showed a greater response to a Finnish vowel sound compared to a vowel sound taken from another language (Estonian). No human language draws on all the sounds that the articulatory musculature can produce, and there is evidence from work by Peter Jusczyk and colleagues

that infants become familiar with the sounds of their native language in the first year of life. The Finnish finding suggests that this process is supported by the left temporal lobe.

It should be noted that some phonological processing tasks activate other structures along with those in the temporal lobes. For example, Robert Zatorre and colleagues have shown that tasks that require decomposition of the phonological structure of words, such as determining that both cat and pet contain the /t/ sound, activate frontal lobe areas either within or adjacent to Broca's area, along with areas in the superior temporal gyrus. It may be that subvocal articulatory mechanisms participate in such tasks. Parietal regions that have been implicated in phonological short-term memory processes are activated as well.

Additional evidence that implicates left temporal lobe structures in speech perception and comprehension comes from the use of electrical current to disrupt the operations carried out by the stimulated brain area. Dana Boatman and colleagues examined these effects in three patients with indwelling electrode arrays implanted prior to surgery for intractable epilepsy. These arrays are often used to localize language areas prior to surgery so that these regions can be avoided when tissue is removed. Three types of tasks were administered, with and without electrical stimulation: phoneme discrimination (e.g., pa-ta or pa-pa), phoneme identification (matching a CV syllable to an array of four written choices), and comprehension (matching a spoken word to one of four pictures; Token Test, a measure of comprehension in which the subject manipulates a set of tokens in response to spoken instructions). Stimulation sites in the left superior temporal gyrus elicited several different patterns: comprehension impaired but discrimination and identification spared; comprehension and identification impaired but discrimination spared; and discrimination, identification, and comprehension all impaired. In all three patients, the sites where stimulation disrupted all three functions were located more anteriorly than the sites where comprehension alone was impaired. The behavioral data are in accord with evidence from patients, in that phoneme identification has been found to be impaired independently of discrimination; however, patients impaired on discrimination tasks are also impaired on phoneme identification. As noted previously, there is other evidence that comprehension can be impaired independently of phoneme discrimination and identification because phoneme discrimination scores do not correlate well with comprehension measures in aphasics.

Sentence comprehension has also been examined using functional imaging techniques. Several studies have shown greater activation of Broca's area as a function of increased syntactic complexity. In other studies, activity in both Wernicke's and Broca's areas increased with the structural demands of the sentences. A recent fMRI study of sentence processing showed that both areas were activated, along with a region in the anterior temporal lobe that was active in an earlier PET study involving sentence materials. Finally, Japanese investigators, using a new imaging technique that tracks blood oxygenation through probes attached to the skull (optical topography), found that left superior temporal cortex was activated as subjects listened to a story.

With respect to production, Peter Indefrey and Willem Levelt recently reviewed the literature, which includes functional imaging studies as well as experiments that employ electrophysiological recording and stimulation. Word repetition activates the middle and posterior superior temporal gyrus on the left as well as the middle temporal gyrus. As might be expected, repetition of nonwords involves less activation of the middle and posterior superior temporal gyrus because no other information is associated with these stimuli. Other tasks, such as picture naming, activate a wider range of structures in addition to those implicated in repetition; these include the anterior superior, middle, and inferior temporal gyri as well as the rest of the middle and superior temporal gyri. Additional structures in the frontal lobes and cerebellum are involved in the motor programming of speech.

V. CONCLUSION

The syndrome described by Wernicke more than 125 years ago is still observed today. These individuals demonstrate impaired comprehension at the word and sentence level as well as disordered production. The impact of this disorder on communication can be devastating, although the patient (at least initially) may not be aware of the extent of his or her deficit. The implementation of recent technological advances, such as functional imaging and brain stimulation studies, demonstrates that the superior temporal lobe is involved in the perception of spoken language and also in its generation. Thus, it appears that Wernicke was correct in attributing auditory language processing and aspects of word retrieval to the left temporal lobe. What remains to be delineated is the precise localization of the mechanisms that support these

processes. Answers to these questions are likely to come from functional imaging studies, particularly as their capability for fine-grained resolution of brain structures increases over time. Another important question concerns the relationship between word comprehension and production, which has yet to be defined: Is there a single set of word forms that serve both functions, or are receptive and productive aspects of language served by different sets of word representations? The answer to this question will require additional behavioral investigations in normal individuals as well as further studies of the relationships between comprehension and production in aphasics.

Working Memory

SERGIO DELLA SALA and ROBERT H. LOGIE
University of Aberdeen, Scotland

GLOSSARY

central executive The theoretical component of working memory involved in the control and regulation of the working memory system. It provides a range of executive functions, such as coordinating activity of the other components, focusing, switching and maintaining attention, activating representations from long-term memory, and manipulating information in cognitive tasks.

dual task An experimental paradigm in which volunteer human participants undertake the concurrent performance of two distinct tasks, such as recalling a sequence of digits while tracking a moving target or, in everyday life, walking while talking.

phonological loop The theoretical component of working memory intended to account for the human ability to retain verbal sequences in a range of cognitive tasks through the use of phonological codes and mental, phonologically based rehearsal.

visuo-spatial sketch pad The theoretical component of working memory intended to account for the human ability to retain over periods of a few seconds visual and geometric properties of objects or scenes from the immediate environment or drawn from past experience. A subcomponent is thought to account for retention of movement sequences.

working memory A theoretical model, derived from empirical research, comprising multiple specialized components of cognition that is intended to account for the human capacity to comprehend and mentally represent the immediate environment; to retain information about immediate past experience; to support the acquisition of new knowledge; to solve problems, and to formulate, relate, and act on current goals.

Working memory (WM) can be thought of as the desktop of the brain, a set of cognitive functions that allows humans to keep track of what they are thinking, what they are doing, or where they are moment to moment. It holds information long enough to make a decision, to acquire vocabulary, to mentally image the layout of one's home, to support creative thinking, or to remember what to do next.

I. WHAT IS WORKING MEMORY FOR?

The notion of WM has figured prominently in theories and explanations for human on-line cognition as well as offering a basis for understanding how humans accomplish a wide range of everyday tasks. Moreover, it constitutes a mental tool that aids survival; if an organism is to interact successfully with its environment, then clearly there must be some means to record, on a temporary basis, its own most recent actions and to have some means to plan actions for the immediate future. This faculty gives a significant advantage over organisms entirely driven by automatic responses to external stimuli that signal basic needs. Examples of how this mental tool is used in everyday interaction with the environment highlight its utility. Humans use WM every time they have to solve a problem such as which career path to follow or to perform a mental calculation, to recall where an object has just been laid down, or to repeat a strange foreign word that has just been heard.

From these examples, it is clear that the concept is much broader than the more traditional idea of short-term memory. Indeed, the concept of WM arose from the need to provide a theoretical account of a wide range of everyday tasks that require both temporary memory and on-line cognition. Until the early 1970s, the focus of research on this topic was on retention of random sequences of words, letters, or digits, with the everyday example of recalling telephone numbers while dialing. However, a mental faculty would not have evolved to deal with these relatively artificial tasks; therefore, WM is intended to encapsulate on-line cognition and temporary verbal and visuospatial memory in both laboratory tasks and everyday life.

II. THEORIES OF WORKING MEMORY

Most researchers on memory agree that WM is a useful concept that can account for a substantial body of experimental evidence with relatively few assumptions: It is a system with limited capacity, which loses information over periods of seconds, whose contents are subject to displacement by new input, and which interacts and is supported by other parts of the cognitive system such as stored knowledge or the products of perception. Most theories of WM would incorporate these features, however, it remains a developing concept whose detailed characteristics are the subject of an ongoing debate. One class of theories views WM as the sum total of what is currently activated from our long-term memory, and another class views WM as separate from long-term memory. However, even among these kinds of theories there is discussion about whether the cognitive functions are supported by a single flexible system that provides both temporary storage and on-line processing or whether they comprise multiple components, each specialized for a particular function. The first class of theories can account for a wide range of data from experimental psychology with healthy adults. However, they run into difficulty when we consider dissociations that are apparent from studies of neuropsychological patients. Such patients suffer from impairments of cognitive functions, but the impairments are often selective with, for example, very poor performance on immediate memory tasks coupled with normal performance on long-term retention. The converse dissociation also occurs, namely normal immediate memory contrasting with very poor retrieval from long-term memory or difficulties in long-term learning. Theories that assume temporary activation of long-term memory predict that if long-term memory access is impaired then temporary activation should also result in poor performance. Therefore, theories that can account for the neuropsychological dissociations as well as the data patterns from healthy adults would appear to be more useful.

One theory of WM that has been particularly successful during the past three decades was developed largely in Britain and inspired by the seminal work of Alan Baddeley and Graham Hitch. The theory offers an attractive level of simplicity coupled with success in accounting for many laboratory and everyday demands on moment to moment cognition. It has also helped the interpretation of a range of cognitive deficits following brain injury or brain disease.

III. EVIDENCE FOR A TWO-STORE MODEL OF WORKING MEMORY

The prevailing view in North America during the first half of the 20th century was of human memory as primarily the result of observable learning of associations, and theories of learning dominated. During the same period in Europe, memory as a cognitive concept was more salient, for example, in the work of Bartlett, Broadbent, and Zangwill. By the mid-1950s, this became the more generally accepted view, and a cognitive view of memory gave rise to major new avenues of research. Very quickly it became clear that memory might best be thought of as comprising more than one element, with one focusing on temporary or short-term retention and the other on long-term retention. This revived a dichotomy suggested in the 17th century by John Locke, who suggested that the "faculty of retention" comprised "contemplation" or "keeping an idea in mind" and "memory" or the "storehouse of these ideas." This distinction appeared again in the late 19th century when William James referred to primary memory, which he contrasted with retention. During the 1960s, the contrast between primary memory and what then became secondary memory was demonstrated experimentally. For example, when healthy adult volunteers are asked to retain sequences of words for immediate recall in any order, omissions tend to occur among words from the middle part of the list and much better recall is observed with items near the beginning or near the end of each list. This gives rise to a U-shaped recall pattern known as the serial position curve (Fig. 1). If, instead, the volunteers are asked to recall the items following a delay, performance on the last few items is no better

than it is for items in the middle of the list. However, initial items in the list retain their advantage despite the delay. The pattern for delayed recall is also shown in Fig. 1. The contrasting patterns shown in Fig. 1 have been thought to support the idea that two memory systems are reflected in different parts of the curve: The early list items are thought to be rehearsed and transferred into a longer term memory system, and this part of the curve is typically referred to as the "Primacy effect." As the list progresses, rehearsal becomes more difficult and therefore few items are transferred to a long-term store. The final items are thought to be held in a temporary memory system whose contents are lost unless recall is immediate. The advantage for the final items with immediate recall is known as the recency effect.

Further support for the dichotomy comes from amnesic patients—that is, people who, following brain damage, suffer from severe memory impairment that is characterized by an inability to learn new material. When such patients are tested for immediate free recall of word lists, their serial position curve lacks the advantage for the initial items in the list but retains a normal recency effect. Typical patterns for healthy adults and for amnesic patients are shown in Fig. 2.

The importance of rehearsal is emphasized in a different experimental paradigm whereby participants are given short sequences of letters for immediate recall or for recall after delays from 3 to 18 sec. These delays were either unfilled, and the participants were free to rehearse, or they were filled with verbal tasks such as counting backwards. Counting backwards was thought to prevent verbal rehearsal of the letters, and the number of letters recalled after each period allowed a plot of forgetting over time. After filled delays of

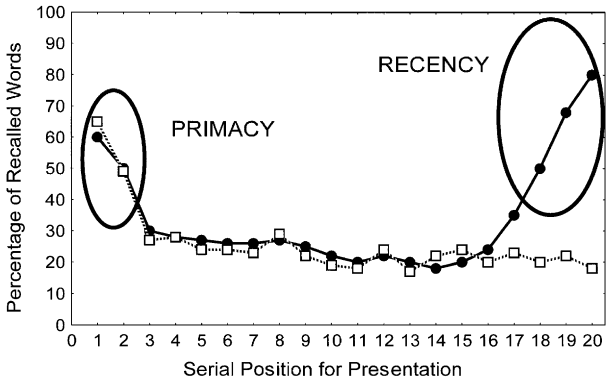

Figure 1 Idealized serial position curve for immediate (●) and delayed (□) free recall of lists of words in healthy participants.

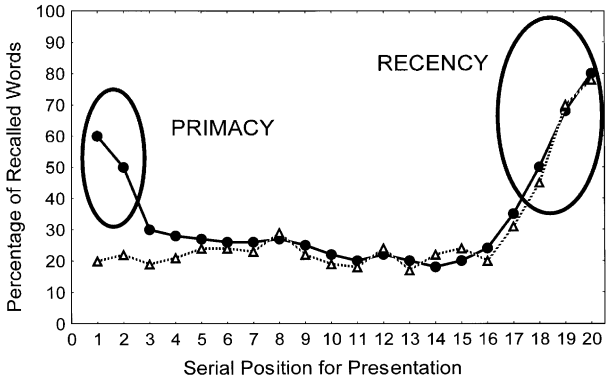

Figure 2 Idealized serial position curve for immediate free recall of lists of words in healthy participants (●) and amnesics (△).

18 sec, recall was extremely poor, indicating that the letters had been lost from the memory system in a relatively short period. This suggested that the passage of information from perceptual input to long-term storage was not automatic, and that information will be lost unless rehearsed.

A third paradigm demonstrated that different memory codes are used in immediate and delayed recall. Here, volunteers were given lists of words that were similar in meaning (e.g., "wide," "broad," "tall," "fat," "huge," "big," "great") or were similar in sound (e.g., "man," "mad," "mat," "map," "cap," "can," "cat") for immediate recall or for recall after a delay. Recall of both lists was compared with memory for lists of words that were neither semantically nor acoustically similar (e.g., "car," "lock," "spoon," "book," "chair," "pen," "dog"). With immediate recall, acoustically similar words were recalled more poorly than were words from the other lists, a phenomenon known as the acoustic similarity or the phonological similarity effect. With delayed recall, the semantically similar words led to poorest recall. Because acoustic similarity affected short-term but not long-term retention, whereas semantic similarity showed the converse, this led to the conclusion that acoustic codes were a signature of a temporary memory system and semantic codes were characteristic of the use of a longer term memory system.

IV. DEVELOPMENT OF THE WORKING MEMORY CONCEPT

The concept of primary and secondary memory provided a useful framework to account for the

accumulating body of experimental data in support of a dichotomous view of the memory system. However, it was limited by the fact that virtually all the research relied on experiments with presentation and recall of words, letters, or digits. It is clear that we can also retain information about the appearance of objects and scenes as well as their names and descriptions. Therefore, in the late 1960s, primary memory began to be seen as a system that could support temporary retention of different kinds of material as well as offering a means to process and manipulate that material. The dominant or ''modal'' concept then became that of a short-term or WM processing and storage system. This modal model retained the notion that information was transferred from the senses via WM to secondary or long-term memory. It also incorporated the assumption that the system has a maximum capacity that can be employed by storage, by processing, or by elements of both.

The idea that information from vision or hearing could reach long-term memory only through WM ran into difficulties when faced with contrasting memory disorders observed in patients with neurological damage. For example, one famous case is that of patient H.M., who, following surgery for the relief of epilepsy, suffered bilateral damage to the temporal lobes and the hippocampus. He showed a very severe deficit in learning anything new and had considerable difficulty in recalling details of events in his life. However, he had normal intelligence and had normal ability to repeat sequences of words that relied on temporary memory. His neuropsychological profile is in stark contrast with that of other patients, such as P.V., who, following a stroke in the Sylvian region of the left hemisphere, presented with a very severe deficit in retaining sequences of words or digits for immediate recall but had no difficulty in retrieving details of autobiographical events and proved well able to learn new material. Several other patients with contrasting patterns similar to those of H.M. and P.V. have been described in the neuropsychological literature. The pattern for patients such as P.V. in particular suggests that access to long-term memory does not depend on normal function in short-term verbal retention, either for new learning or for recall of past events. This undermines one of the key assumptions of the modal model.

A second assumption of the modal model was that of WM as a single, flexible, limited-capacity system. This theme remains in one contemporary strand of WM research that has focused on measures of individual differences in cognitive capacity. In a typical task, healthy adult volunteers are presented with a series of sentences. The requirement is to recall the last word of each sentence after all the sentences have been presented. The number of sentences is gradually increased until the participants can no longer accurately recall all of the final words, and the maximum number of words that can be recalled is taken as a measure of the individual processing and storage capacity. In various forms, the measure has been shown to correlate well with other measures of cognitive ability, such as reading comprehension or mental arithmetic performance. These correlations are then used to argue that WM is a mental capacity for processing and storage that can be applied to a wide range of both laboratory and everyday cognitive tasks. In this sense, the sentence ''span'' (or WM capacity) measure has been quite useful and provides the basis for a standardized test of cognitive ability. Set against its pragmatic value, the underlying theoretical assumptions are that there is a single flexible cognitive system supporting performance. One possible alternative view is that the task taps several aspects of cognition, and that this same range of cognitive functions are employed for other complex cognitive tasks such as reading comprehension. A further limitation is that the test provides only a measure of memory in the context of processing (retention of the final words while reading). In recent tests of the previously mentioned assumptions, a separate measure was taken of processing capacity by asking volunteers to verify each of the sentences for their semantic content without a memory requirement. Memory ability was measured independently by asking volunteers to recall lists of individual words. Participants were then asked to combine verification with recall of all the final words, with the task demands set at the maximum that had been determined for each task component separately. If WM were a single flexible, limited capacity system, we might expect performance to be very poor when these two demanding task elements were combined. Results showed that despite the high processing demand and high memory demand, performance on both elements of the task remained very similar to that obtained when the subjects performed the tasks independently.

These results point to the notion that temporary memory might be served by a different aspect of the cognitive system from that used to support on-line processing. This argument in turn suggests that WM might be best thought of as the orchestrated operation of multiple cognitive instruments, each with a specific role for temporary memory or for processing.

V. COGNITIVE ARCHITECTURE OF A MULTIPLE-COMPONENT WORKING MEMORY

The most influential model of multicomponent WM was proposed in 1974 by British scientists Alan Baddeley and Graham Hitch. The model included some elements of the modal model by incorporating processing and memory; however, these were viewed as distinct. Three components were originally proposed to provide respectively temporary verbal storage, temporary visuospatial storage, and a coordinating or "executive" function. A schematic diagram is shown in Fig. 3. The verbal storage component was originally named the articulatory loop, although subsequently it has been referred to as the phonological loop. The visuospatial component has been known as the visuospatial scratch pad, whereas the coordinating mechanism is generally referred to as the central executive.

The phonological loop comprises a passive phonological store and an articulatory rehearsal process. Auditorily presented verbal information gains direct access to the passive store, which retains information in a phonological form. Information in the store is subject both to decay over time and to interference from new verbal material. Loss of information from the store can be prevented by means of subvocal rehearsal, and with continuing rehearsal the contents of the store could in principle be retained indefinitely. The operation of the store is impaired when it is subject to irrelevant speech. This disruptive effect is even greater when the irrelevant speech is phonologically similar to the material already in the passive store. For example, if the store contains a sequence of digits, its content would be disrupted by listening to digit-sounding words such as "ton," "woo," "tee," "soar," and "thrive."

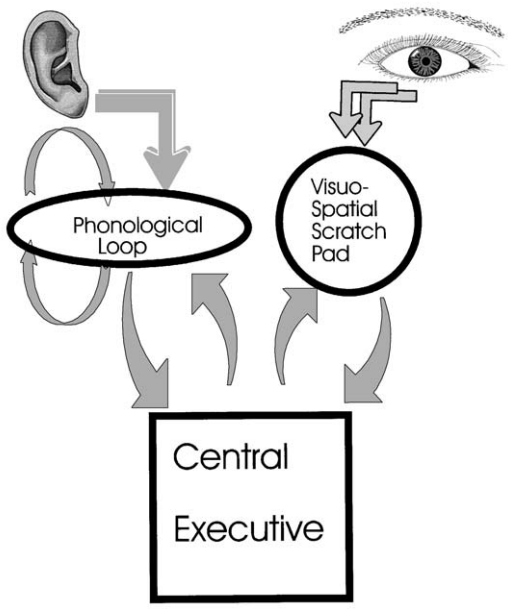

Figure 3 Schematic diagram of an early version of the multiple-component model of working memory.

The store also operates less efficiently when required to retain materials that are phonologically similar to one another compared with when the materials are phonologically distinct. These phonological confusions support the claim that the store is phonologically based. According to the model, subvocal rehearsal is also responsible for translating visually presented verbal material into a phonological code for temporary retention in the phonological store. The evidence for this derives from studies showing that the phonological similarity effect is removed for visually presented words and letters when subjects are required to suppress subvocal rehearsal by repeating aloud an irrelevant word such as "the-the-the." In other words, when subjects are unable to rehearse the visually presented items, they are not translated into a phonological code for retention in the store and may be retained using visual or semantic codes. Finally, the operation of the loop is limited by the length of time taken to pronounce the words for recall. That is, words such as "cricket," "wicket," "bishop," and "parrot" take less time to say than do words such as "Friday," "typhoon," "vendor," "practice." Likewise, words with five syllables, such as "refrigerator," "university," "hippopotamus," and "aluminium" take longer to say than do words of one syllable, such as "salt," "pen," "cat," and "chair." Based on these findings it has been argued that the capacity of the loop was limited by how much speech a subject could produce in approximately of sec. This word-length effect was thought to indicate the rate of decay of information from the phonological store.

The visuospatial scratch pad was thought to serve an analogous function for visual and spatial material and to serve a role in visual imagery tasks. The central executive component of the Baddeley and Hitch model provides the coordinating function for dual-task performance as detailed previously. It also appears to play a role in reasoning and problem solving and to be involved in the allocation of attention.

Although the link between WM and long-term memory has not been specified in detail, there is the general assumption that information can enter one or

more components of WM either from sensory input or from long-term memory. In its original conceptualization, WM was assumed to play an important role in transferring information to long-term memory from sensory input and in particular to be closely involved in learning novel information. For example, as noted previously, auditory input of verbal material is thought to have obligatory access to the phonological store, whereas visual material is thought to have obligatory access to the visuospatial scratch pad. The model accounts for normal long-term learning in patients with verbal short-term memory deficits by arguing that only the phonological loop system is impaired, allowing the central executive and the visuospatial scratch pad to effect learning. This preserves the idea that WM functions as a gateway between perception and long-term memory by means of additional assumptions that are supported by experimental evidence about the nature of the various WM components rather than about the demonstration of their existence. In the next section we address the issue as to whether WM acts as a gateway or more as a mental work space. The following section will then return to the precise characteristics of the WM components and the evidence from which those characteristics have been derived.

VI. WORKING MEMORY AS A WORK SPACE, NOT A GATEWAY

Short-term memory or WM is often thought to function as a form of temporary holding device following perception and to be closely involved in transfer of information from perception to long-term memory. This was a feature of the modal model and also an implicit assumption in the original version of WM as multiple components. It is also an assertion in many contemporary introductory textbooks that discuss the psychology of memory. However, during the past few years it has been increasingly clear that this view is unable to account for new empirical evidence and patterns of impairment and sparing in brain-damaged patients. For example, in normal reading, it is possible for healthy adults to generate the sound characteristics or the phonology of words without having to speak the words aloud. It is possible to have an auditory mental experience of the word from the print on the page. The sounds of the words can be mentally rehearsed and recalled orally or in writing. There is ample evidence that immediate memory for visually presented words relies heavily on the use of mentally rehearsing the phonological properties of those words. This could not be possible if the words being read did not access phonological knowledge in long-term memory before they were rehearsed in WM. The point is also clearly illustrated in studies of patients with acquired anarthria, a syndrome that is characterized by an inability to produce overt speech following damage to the brain stem. However, such patients can clearly access stored knowledge about the phonological properties of words presented visually. As with healthy adults, if the words are being read, the information about their sound has to be extracted from long-term stored knowledge.

Problems with the gateway assumption are not restricted to verbal immediate memory tasks; they also appear with visuospatial WM tasks, particularly in the neuropsychological disorder known as neglect. These patients ignore half of their visual field, of objects and of their body space, most commonly on the left. Thus, when asked to copy a picture they will tend to draw only its right-hand side. When they are asked to describe the scene in front of them they will omit objects on their left. However, although such patients appear to ignore information on their left side, they are nonetheless affected by that information. In one classic experiment, neglect patients were shown pictures of two houses. In one of the pictures, the left half of the house was shown on fire. The patients denied that there was any difference between this picture and a picture of an identical house that was not on fire. That is, they ignored the left half of the picture. However, when asked which house they would prefer to live in, they chose the one that was not on fire.

One well-argued interpretation for these data is that although the sensory information did not appear to be available in WM, it was nevertheless activating semantic knowledge about fires and their unpleasant consequences. Therefore, as with normal subjects, it appears that information can gain direct access to information in long-term memory without going through WM first. Moreover, the results of that access to long-term semantic knowledge, in neglect patients at least, may feed into decisions without the individuals being aware of why they are making a particular decision. One possibility is that the activated information about unpleasant consequences becomes available to WM, even though the visual information from sensory input does not.

Neglect not only impair perception but also can affect mental representations. For example, when some left-sided neglect patients are asked to describe

a familiar scene from memory, such as a town square, they tend to leave out details of the square that would be on their imagined right in the mental image but to report several details on their imagined left. This difficulty does not result from simple forgetting of these details, because if they are asked to imagine standing at the opposite end of the square they can readily report details, now on their imagined right, that they had previously omitted. They also leave out details from what is now their imagined left but which had previously been reported.

Neglect is not a unitary deficit and it appears in several forms. Many patients appear to have difficulties with perception and some of these patients are also reported to have representational problems. However, there are a small number of cases that appear to have a pure form of representational neglect. Such patients have no difficulty describing the immediate scene. However, they omit details from the one side of scenes that are mentally imaged from memory. Moreover, representational neglect occurs even when perception of a scene has been normal. In one study, neglect patients were shown an array of objects and could describe the objects and their locations perfectly. However, if the objects were removed and the patients had to describe the objects and positions from memory they failed to report items that had been shown on the left but were just as good as healthy volunteers in recalling items that had been shown on the right. WM as a gateway between perception and long-term memory cannot account for this pattern of observations since perception was perfectly normal and the objects were correctly identified, showing normal access to information in long-term memory about the objects. However, the information was clearly not available in WM. The pattern is more readily explained if WM is thought of as a work space whose contents are derived from activated knowledge in long-term memory.

The patient data yield insight into functioning of visuospatial WM in the normal brain. Perceiving and interacting with the environment demands the generation of mental representations of that environment. Such representations would incorporate the location of various objects in relation to one another and the location of objects in relation to the observer. Thus, when retrieving information about objects or scenes held in long-term memory, the mental representation contains information about the scenes, such as when they were previously experienced and the names of objects depicted. In this sense, the contents of WM necessarily comprise some of the products of perception and subsequent mental processing, including the semantic properties. WM can then be considered as a multicomponent work space that stores and manipulates information that has been activated from the long-term store rather than as a primary route into long-term memory from the environment. Therefore, WM is better viewed as a system accessed by information stored in long-term memory and by sensory input only *after* that input has been processed by long-term memory.

The model as a work space has the advantage that it specifies something of the way in which visually presented words can be made available to the phonological loop; a feature that was underspecified in the original WM model. For example, if the word ''book'' is heard, the phonological representation of book and the articulatory codes can be used to store a phonological trace in the phonological loop, to rehearse the word, and to articulate it. On hearing the word, the visual and spatial properties of the word book become available to the visuospatial scratch pad, allowing generation of a temporary representation of the visual form of the word that could then be written. Semantic information about books, such as what they are used for, could also be activated. This information would then be available to the central executive, allowing generation of an image of what a book looks like. The central executive could also draw on information stored in the phonological loop and in the visuospatial system to carry out further processing on the properties of the visual or phonological form of the word to allow spelling, segmentation, rotation of an image of the word, and so on.

This conception of WM fits neatly with the notion that people are strategic in how they use their cognitive functions. For example, in recalling a list of words, this can be accomplished by rehearsing the sounds of the words, thinking about their meaning, organizing them into groups, or imagining the objects or concepts to which they refer. As a result, phenomena such as the word length effect only appear if the participants rely on mentally rehearsing the words prior to recall. There is evidence that some participants in experiments spontaneously use other strategies that might rely on visual or semantic codes, and for them the word length effect does not appear. The same argument holds for other well-established phenomena such as the phonological similarity effect. Such strategic use of different aspects of WM would not arise if the material did not activate knowledge stored in long-term memory prior to it being held in WM for the period until recall is required.

VII. FRACTIONATING THE MODEL

The different components of the WM model have been further fractionated and we now describe some of the evidence and rationale for this development. A diagram of the revised version of the model is depicted in Fig. 4.

A. Verbal Storage and Rehearsal

The three-component model provided a useful framework in that it could account for a wide range of laboratory findings with relatively few assumptions. However, it has proved to be rather simplistic when employed to account for details of experimental findings from healthy adults and from patients or as the basis for deriving formal computational models that could simulate human data patterns. For example, the phonological similarity effect and the word-length effect cannot wholly be explained by a single system, and the phonological loop evolved into a two-component system comprising a phonological store, which was subject to decay and that was responsible for the phonological similarity effect, and articulatory rehearsal, which was used to help account for the word-length effect. One source of evidence for this dissociation comes from using a manipulation known as articulatory suppression. This involves asking the volunteer to repeat a word over and over such as "go go go go" while attempting to retain a sequence of words, letters, or digits. The technique is thought to prevent the operation of subvocal articulatory rehearsal, and it typically results in very poor immediate recall performance. In addition, it tends to remove the effect of word length when the words are heard. However, phonological similarity is unaffected by auditory presentation of the items for recall. The model neatly accounts for this contrast by suggesting that because articulatory suppression prevents subvocal rehearsal, this prevents the use of the system that is responsible for the word-length effect. However, this form of suppression has much less impact on phonological similarity because this effect arises from the use of a different part of the system, namely the phonological store.

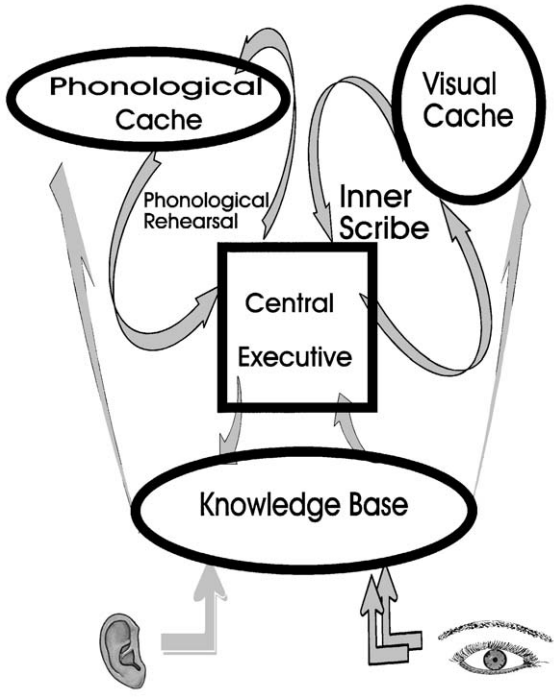

Figure 4 Schematic diagram of a recent version of the multiple-component model of working memory.

A similar argument can be used to account for a pattern of data obtained from anarthric patients whose deficits result from cortical lesions. Such patients show normal phonological similarity effects with auditory presentation but fail to show a word-length effect that they hear. The model explains this by suggesting that the subvocal rehearsal system is damaged, whereas the phonological store is intact. The converse pattern has been observed in patients with severe short-term verbal memory impairments. These patients fail to show phonological similarity effects but do show effects of word length when they are instructed to rehearse the items. They appear to have damage to the phonological store but retain the ability to use articulatory rehearsal. These contrasting patterns point to a dissociation that supports the notion of the two components of the phonological loop.

A final source of evidence is from studies using brain imaging techniques, such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). These techniques identify the areas of the brain that are active during the performance of particular tasks. No task will involve only a single area of the brain because aspects of brain function operate in concert. However, current evidence indicates that the storage and rehearsal aspects of the phonological loop could be mapped onto relatively clearly segregated neuroanatomical networks, both making use of functions associated with activation of the left hemisphere. In particular, while storage and rehearsal result in activation of areas of the frontal lobes, rehearsal appears to also involve activation of Broca's area, normally linked to the production of speech, whereas phonological storage involves activation of the supramarginal gyrus. These areas correspond on the whole

with those areas found to be damaged in patients with vocal rehearsal problems or deficits in temporary phonological storage, respectively.

B. Visual and Spatial Storage and Processing

Recent evidence regarding storage and processing of visuospatial material also appears to require further fractionation of the original model. From our own and other laboratories, it is clear that retention of sequences of movements appears to rely on different cognitive functions from those employed in temporary retention of static patterns and visual appearance. One task commonly used to access memory for movement sequences involves an array of randomly arranged wooden blocks on a board. The experimenter taps a sequence of blocks, after which the participant is required to reproduce the sequence. The length of the sequences gradually increases from trial to trial until the participant can no longer recall the sequence accurately. This then allows a measure of individual differences in capacity for immediate recall of movement sequences.

Tests for immediate recall of visual patterns typically involve presenting checker board arrays of black-and-white squares arranged randomly. Participants are then given a blank array of squares and are required to indicate which squares were previously shown in black. As before, the number of squares in the array increases from trial to trial until participants reliably fail to recall all the relevant squares, thereby giving a capacity or span measure for the task.

The previously mentioned tasks have been contrasted in children, in adults, and in adults following brain damage. When the same individuals perform both tasks, the correlations between the span scores are low both for children and for healthy adults. In children, performance on the visual pattern task develops much more rapidly with age than does the movement sequence or block tapping task, indicating that the cognitive functions on which each task relies follow different developmental trajectories. The distinct nature of the two tasks is further emphasized by the observation of double dissociations among brain-damaged patients (strokes or dementia); specifically, some patients show deficits on one task but do well on the other, whereas other patients show the converse. This indicates that the cognitive functions required for each task do not completely overlap.

Further evidence for the separation of visual and spatial cognition comes from dual-task interference studies in healthy adults. In particular, performance on the block tapping task is selectively disrupted if, during retention interval, the participant is required to tap his or her hand on the table top in a different regular pattern (e.g., tapping four buttons arranged in a square). The visual matrix pattern task is not disrupted by concurrent tapping in a square. In contrast, the visual task is selectively disrupted by presentation during a retention interval of irrelevant pictures or patterns, whereas the block-tapping memory task is not. The separation between visual and spatial components is strengthened by evidence from neuroimaging studies showing neuroanatomical segregation in the brain areas involved in either task. Indeed, evidence of independence between visual and spatial neuroanatomical substrates has been reported from studies of nonhuman primates.

The component thought to be responsible for temporary retention of visual information has been referred to as the "visual cache," whereas the component linked with retention of movements has been referred to as the "inner scribe."

C. Executive Functions

The original view of the central executive was of a conceptual Pandora's box, charged with a wide range of complex cognitive functions including reasoning, problem solving, decision making, allocating attention, and coordinating the functioning of the storage and processing systems described previously. One danger with this approach is that it appears to require the notion of a conceptual "fat controller" or homunculus responsible for implementing these executive functions, and we are left with the question as to what is inside the head of the fat controller. One way out of this apparent impasse is to consider how a cognitive system might deliver each of the executive functions, one possibility being that the executive can be fractionated into several specialized components and another being that the executive is a flexible processor that can implement a range of acquired skills and expertise. Before discussing these options, we first consider evidence that there is a need for the concept of WM to include an executive system.

One putative-specific function for the executive is that of coordinating the operation of the phonological loop and the visuospatial system. A number of studies have shown that normal healthy adults can hold verbal sequences such as digits while performing visuospatial tasks, such as following a moving target around a screen or holding visual matrix patterns. This dual-task condition results in little or no decrease in the

performance of either task, even when both tasks are very demanding or when the participants are drawn from the healthy elderly. These data further support the notion that visuospatial WM and verbal WM are served by separate cognitive functions that can operate in parallel. However, the pattern was different in groups of patients suffering from the early stages of Alzheimer's disease. The patients were first tested on each of the tasks individually and the demands of each task were set at the capacity limits for each patient, as done for the healthy subjects in the experiments described previously. In this way, performance on each task was equated between the healthy subjects and the patients. However, when the patients were asked to perform the two tasks together, performance on both was severely disrupted, quite unlike the case for their healthy counterparts. In other studies, patients with early Alzheimer's disease also show difficulty in dealing with information from more than one source, such as in a conversation among several people, although they can adequately cope when conversing with a single individual. These patterns of data have been interpreted to suggest that the patients have a deficit in a coordination function that allows normal healthy subjects to cope with more than one task or source of information almost seamlessly, providing different components of their cognition system are required for each of the tasks involved.

The dual-task impairment found with Alzheimer's patients does not arise simply from the general difficulty of performing two tasks rather than one against the background of a damaged brain. When the individual tasks are gradually increased in difficulty, the relationship between task demand and performance is very similar to that found for healthy elderly volunteers. Therefore, it appears to be a specific deficit in performing two different tasks simultaneously.

Complementary evidence comes from brain imaging studies of healthy adults performing single tasks that recruit either the visuospatial or the verbal component of WM and then require the two tasks to be performed simultaneously. When a single task was increased in difficulty, more of the same brain areas were activated. However, when the two tasks were performed together, both brain networks were involved; in addition, there was activity in the dorsolateral regions of the prefrontal cortex. Consistent with the experimental data, Alzheimer's patients show a significant neurochemical deficit in this same cortical area, and dual-task coordination deficits have also been shown in some stroke patients who have suffered focal damage to the frontal lobes.

The evidence from dual-task performance indicates that there may indeed be a coordination function as suggested for the concept of a central executive. Among the other functions attributed to executive operation, the maintenance and switching of attention appears to also be specifically impaired in early Alzheimer's disease, independently of temporary visuospatial or verbal memory. This again points to the need for a theoretical concept to account for allocation of attention, although any possible links between a coordination function and the control of attention have yet to be explored in detail.

It would be possible to take a similar empirical approach to executive functions such as reasoning, problem solving, decision making or planning, and activation of representations in long-term memory. There is a growing literature on studies of patients with frontal lobe damage, indicating impairments in some of these areas of cognition. However, the link between the range of executive functions and the operation of the frontal lobes is far from clear. For example, the intercorrelations between tests of these functions are far from dramatic, and few of the tests have been subject to adequate task analysis. Such analysis would be essential to establish that each test measures the intended cognitive function. Therefore, it is important to separate conceptually the cognitive frame of reference from its neuroanatomical substrate.

We can avoid some of the problems associated with the homunculus by considering the executive as a flexible mechanism that can serve as the medium for implementing learned strategies, acquiring skills, and accessing stored knowledge relevant to the task at hand. In this view, the executive functions as the central processor of a computer that can run different kinds of software. Without pressing this analogy too much, we then can use the executive to implement the process of language comprehension during reading or listening to conversations, the acquired procedures for mental arithmetic when undertaking calculation, the strategies for mental imagery when holding or manipulating mental representations of objects or scenes, strategies for planning, or the heuristics for switching of attention between tasks. This idea of the executive is compatible with several of the alternative views of WM. However, the notion is very much of an executive that is a distinct feature of the cognitive architecture and not simply the sum total of what is currently activated from long-term memory or the long-term knowledge base. The concept of a flexible executive in this sense would also incorporate the use of the specialist temporary memory systems, such as the

phonological loop or the visuospatial resources, to hold material recently processed or to retain partial solutions while the executive acts on other aspects of a problem.

VIII. APPLICATIONS OF THE WORKING MEMORY CONCEPT

The idea of a multiple component has proved useful in understanding some of the cognitive deficits suffered by individuals with brain damage as well as in accounting for important aspects of healthy cognition, such as temporary memory, acquisition of vocabulary, mental arithmetic, the use of imagery in creative thinking, or remembering to do things. We previously discussed some of the insights into cognitive deficits that have arisen from the use of the model and how studies of patients with such deficits also give possible insight into the organization of normal cognition. The concept of the phonological loop also appears to offer an account of how young children acquire vocabulary. One feature of the loop is that it offers a means to retain a recently heard word—to mentally rehearse the word and then generate the word as articulate speech. A number of studies have examined the ability of young children to repeat aloud new or nonsense words that they have just heard. Their ability to do so correlates well with their general competence in language and predicts their language competence several years later. Patients with severe verbal short-term memory deficits also appear to have difficulty acquiring new foreign vocabulary. These findings led to the suggestion that the phonological loop is a cognitive function that has evolved to support the acquisition of language, and that an emergent property of such as system is a temporary verbal memory system that can be used in a wide variety of tasks.

Among the acquired skills that appear to depend on the phonological loop are counting and mental arithmetic. Keeping track of a running total by counting relies on subvocal rehearsal of the counting sequence, and keeping track of partial solutions in mental arithmetic again appears to rely on subvocalization or the subtotals involved, unless the solution is already well learned. For example, for most people the answer to $6 + 5 + ?$ would be available without the need for mental calculation because it would be recalled as an arithmetic fact. However, the answer to $13 + 18 + 25 + 17 = ?$ would require a series of operations with temporary memory for the subtotals (held in the phonological loop) as each part of the sum is completed. Evidence for these conclusions arises from studies in which volunteers perform counting or mental arithmetic while suppressing articulation through repeating an irrelevant word. Accuracy in counting and in arithmetic is disrupted by this procedure but is not disrupted by performing other irrelevant tasks, such as tapping the table in a regular pattern, or even when presented with irrelevant speech sounds. The phonological loop seems to support accuracy in counting and arithmetic, but when asked simply to make estimates of the final totals while suppressing articulation, the errors tend to be quite close to the correct response. This indicates that generating an estimate may rely on some other aspect of cognition. Additional insight into how this is achieved comes from an additional manipulation in which volunteers are required to generate random sequences of letters while simultaneoulsy adding numbers. People find it almost impossible even to generate estimates under these conditions. This result indicates that generating random letter sequences not only uses up the phonological loop but also requires the operation of the central executive to inhibit the production of well-learned sequences of letters such as "a-b-c-d-e…" and to keep track of which letters of letter sequences they have already generated. This points to the use of the executive for estimating totals in arithmetic. It also supports the idea that the executive might be a flexible system that can implement different cognitive operations according to tasks demands but cannot implement two different operations, such as random generation and arithmetic estimation, at the same time.

Among the other characteristics of WM, mental manipulation and the development of new knowledge are the focus of a developing research area that is sometimes described as mental discovery. The tasks that are employed in this research are ideally suited to illustrate the utility of WM as a bailiwick of specialized functions rather than a general-purpose memory and processing device.

This is best illustrated by attempting a simple mental discovery task. For example, by imagining the capital letter "D" and the capital letter "J," it is possible without the use of any external aids, such as pencil and paper, to mentally construct a recognizable object by rotating the D leftward 90° and putting it on top of the J. The result would be an umbrella (Fig. 5). Similarly, it is possible to construct the shape of an ice cream cone by combining the shapes "V" and "O," and more complex figures can be constructed from combinations of larger numbers of shapes. It is not immediately clear that the outcome of these combinations would be known or predicted from the letters or shapes, and therefore this constitutes a form of mental discovery

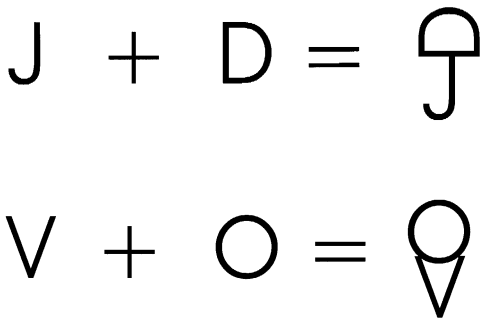

Figure 5 Examples of mental discovery tasks using mental imagery.

using visuospatial WM. One account of the task is that the partial combinations of shapes are held in a temporary visual store, such as the visual cache mentioned previously; the names of the shapes may be rehearsed within the phonological loop; and the manipulation, transformation, and combination would be achieved by the strategies and heuristics of mental imagery run by the central executive.

The visuospatial resources of the WM can support a wide range of other everyday cognitive tasks, such as remembering where we are on the page while reading, maintaining and updating a representation of objects in our immediate environment, mental scanning to plan a route around a familiar town, or imagining the configuration of furniture in an empty room.

Remembering to carry out tasks that we had planned or intended is generally referred to as prospective memory, and it also appears to rely to some extent on WM. To remember to send a letter on the way to work, to switch off the oven when the meal is ready, or to pack the slides and overheads when leaving for a conference requires that we have formed an intention and that we act on that intention at the appropriate time. For some activities, the time of day triggers the intention; for others, it may be a physical cue such as the mailbox. Other activities, such as remembering to call someone later in the day, are triggered by internal cues and may require that the intention is held in WM or written down in order to ensure that it is carried out. Recent evidence from our laboratory suggests that if WM is occupied by a demanding arithmetic task, then prospective memory failures are more frequent.

IX. CONCLUSION

Working memory is an evolving concept that may be subject to change in light of new evidence or questions as to its detailed characteristics. Nevertheless, it allows the interpretation of a great deal of evidence and phenomena from both laboratory tasks and everyday experience.

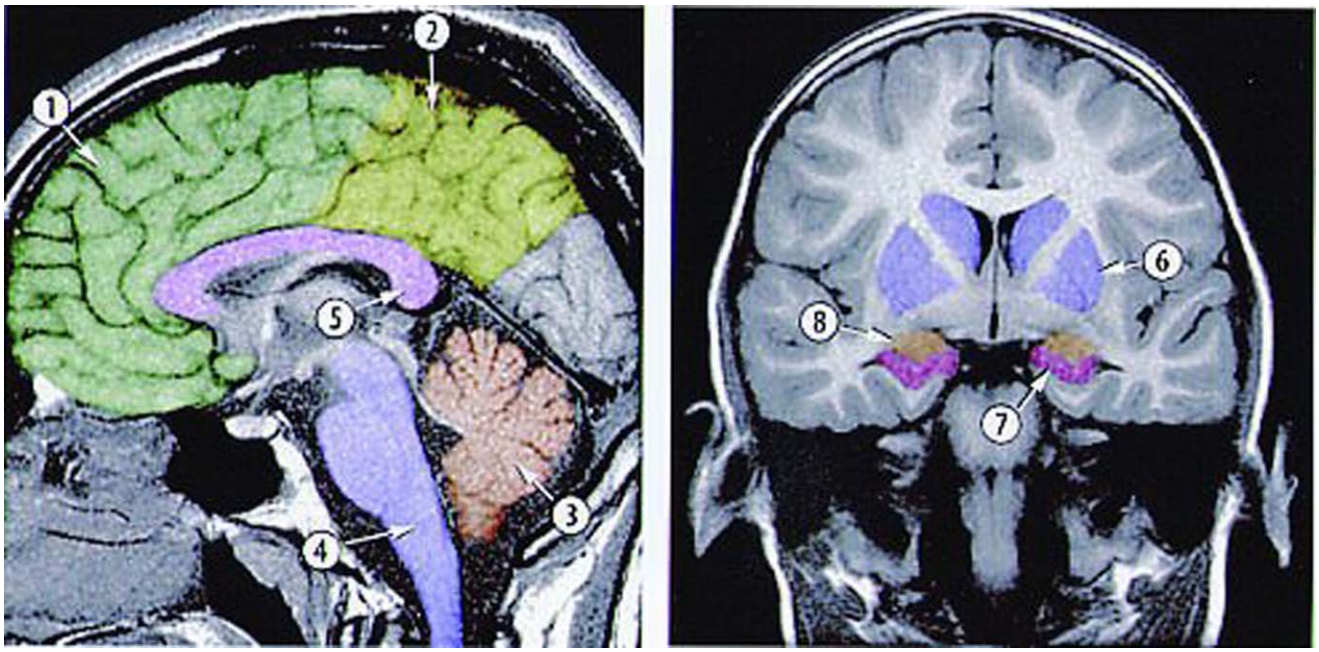
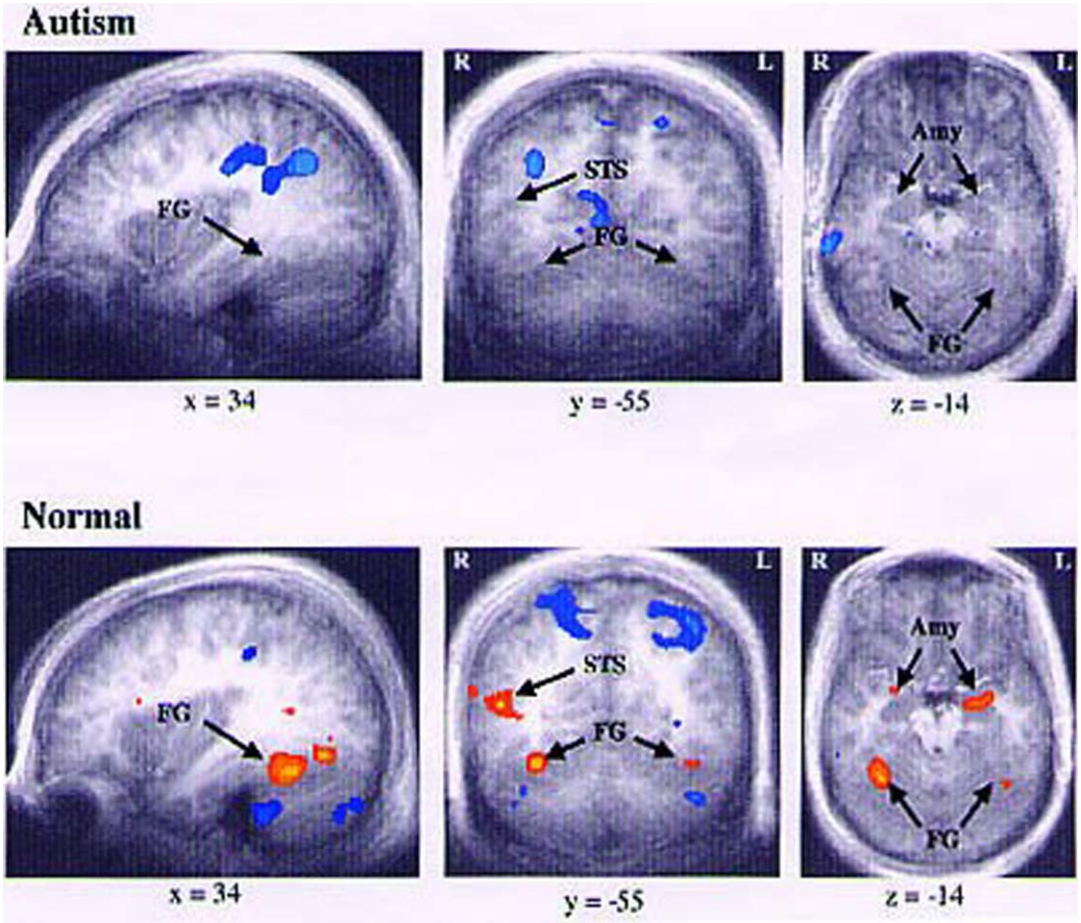
Plate 1



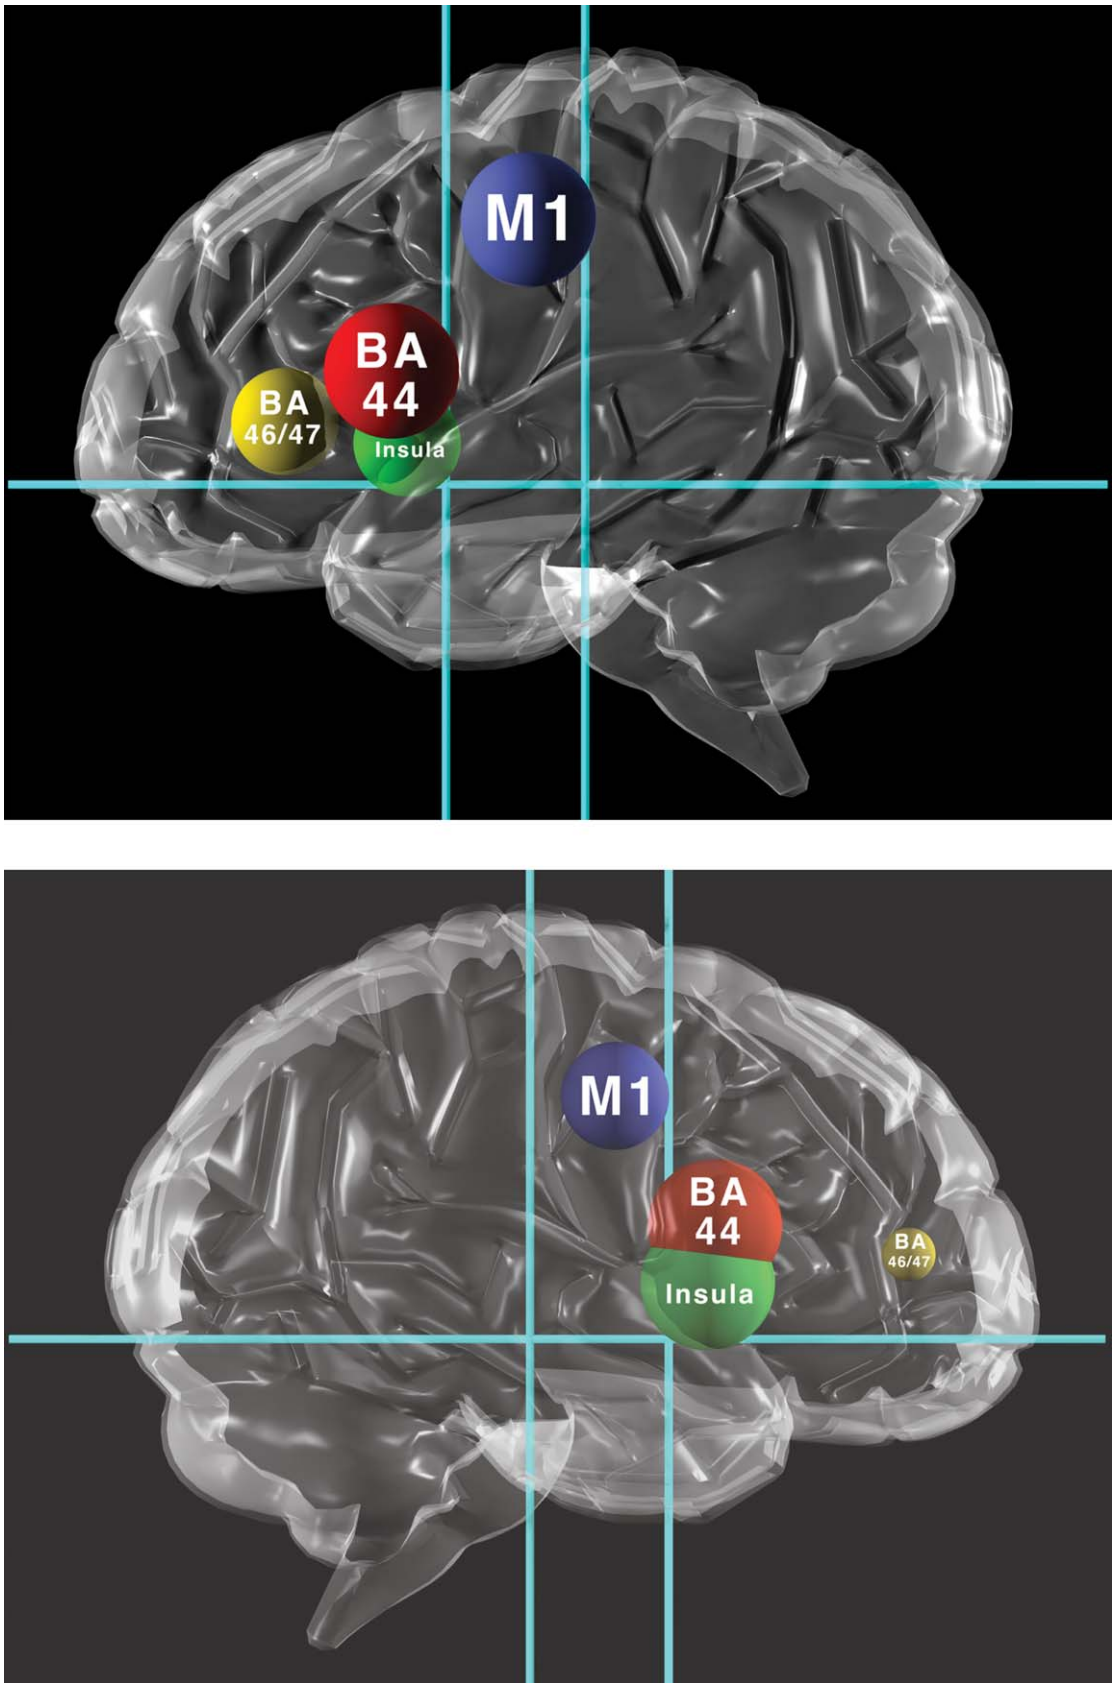
Depiction of cortical and subcortical structures reported as abnormal in autism via autopsy or MRI data from laboratories throughout the United States and Europe. 1, frontal lobes; 2, parietal lobes; 3, cerebellum; 4, brain stem; 5, corpus callosum; 6, basal ganglia; 7, amygdala; 8, hippocampus. See article AUTISM.

Plate 2



Within group t-maps for both autism and normal groups showing significant regions of activation (statistically significant positive activation noted by yellows and orange, deactivation noted by blues). Note fusiform, superior temporal sulcus and amygdala activation in normals, in comparison to a lack of positive activation in the autism group. Decreased functional activity in the autism group is likely due to the inconsistent patterns of activation noted across individual autism subjects, which would fail to beseen when results are averaged (from Pierce et al., 2001). See article AUTISM.

Plate 3

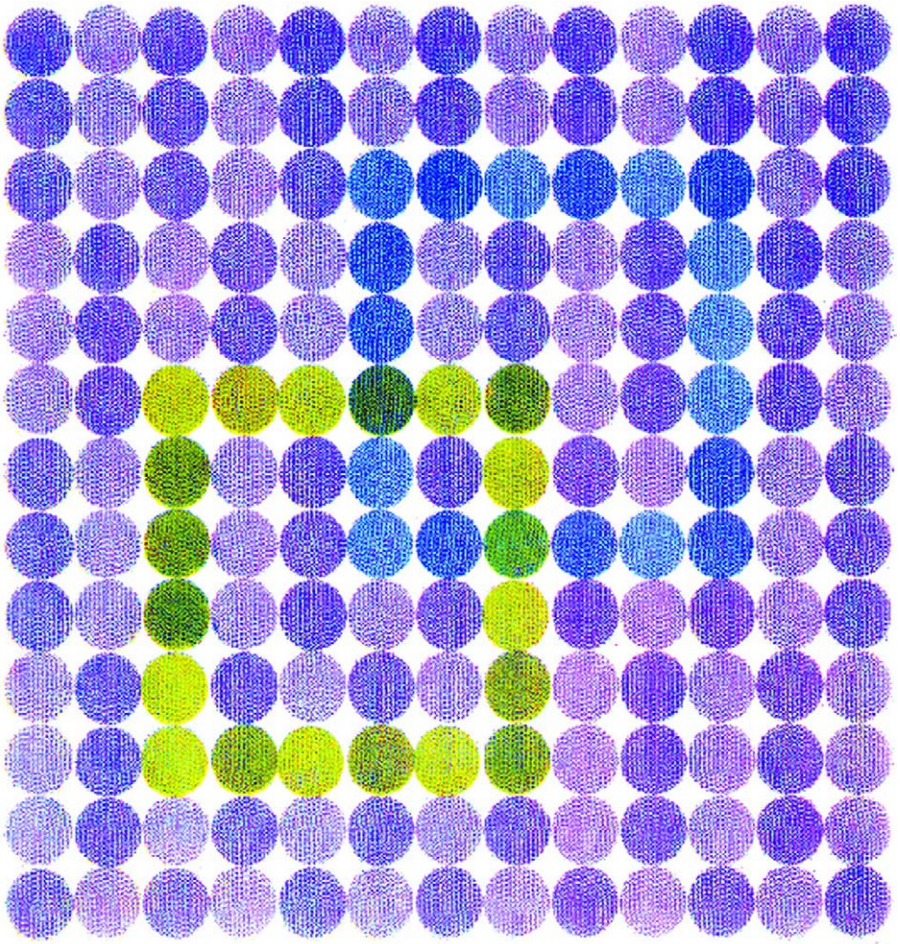


Three-dimensional representations of the three subdivisions of Broca's area and the motor area for the mouth are shown from the left (top) and right (bottom). Broca's area proper (BA 44/6) is shown in red. Sub-Broca's area (anterior insula) is shown in green. Pre-Broca's area (BA 46/47) is shown in yellow. The motor area for the mouth, shown in blue, is laterlized to the left hemisphere and shows activation on that side comparable to that of Broca's area proper. See article BROCA'S AREA.

Plate 4

Segment of a painting by Jan van Eyck (1434). Left, the luminace information has been removed, rendering an image based soley on the chromatic contrasts. Right, the chromatic contrast has been removed, rendering an achormatic black-and-white image of the same scene. Center, the fusion of the two different forms of contrast produces color vision.

Plate 5

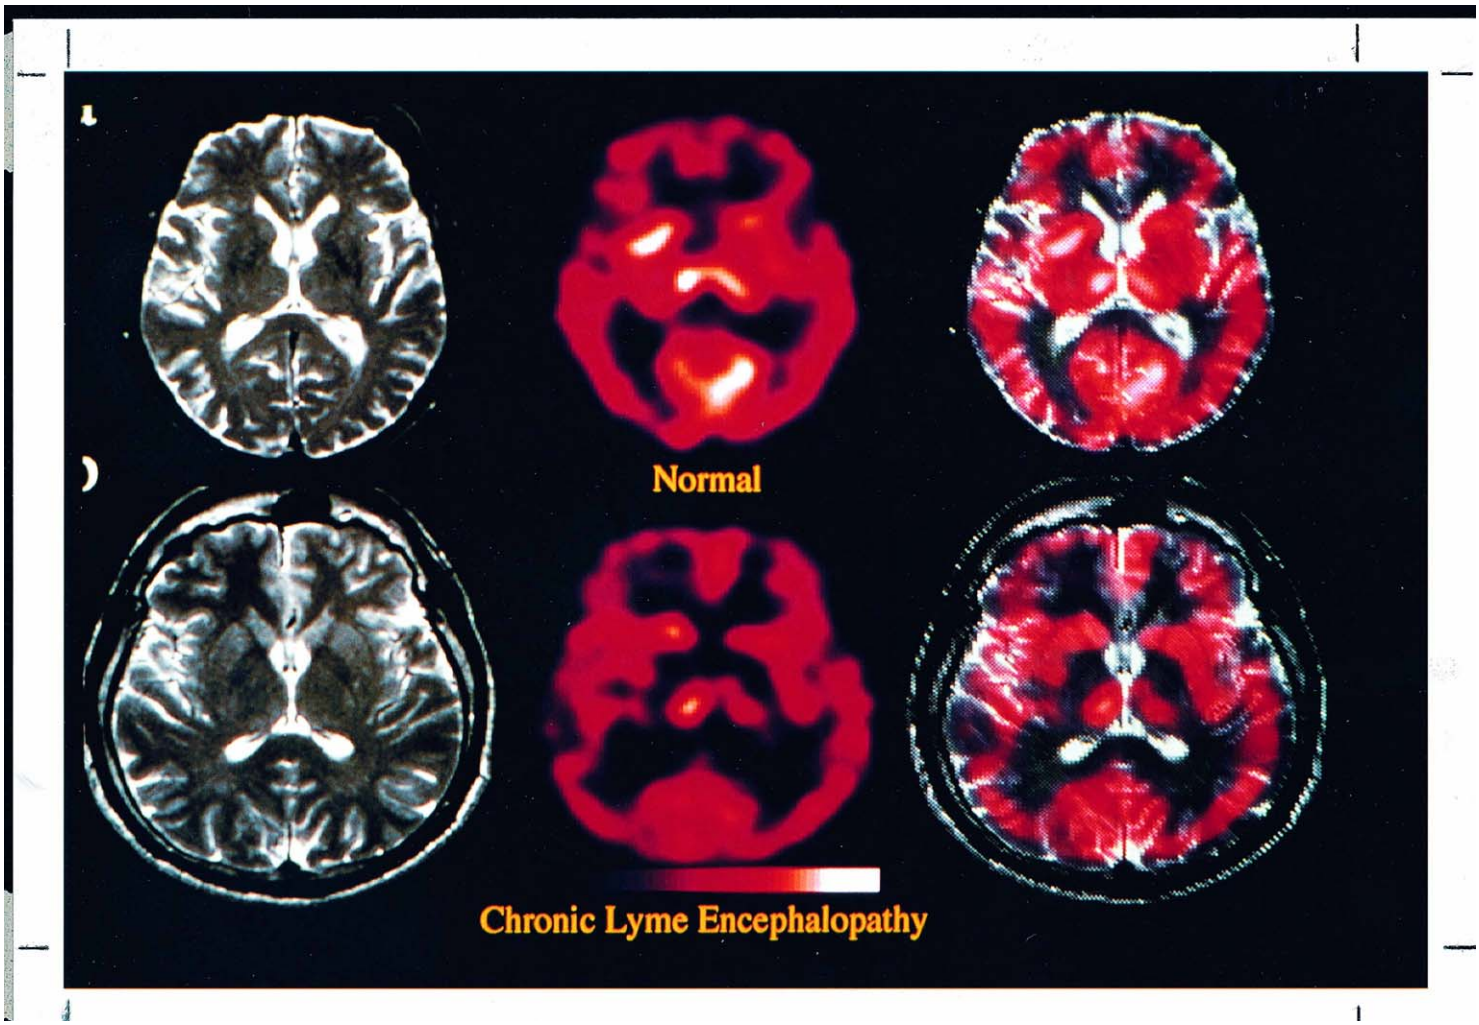


A pseudoisochromatic plate that detects protanopes, deuteranopes, and tritanopes, who fail to see the blue square at the upper right side. See article COLOR PROCESSING.

Plate 6

Some of the human brain areas important for emotion. (Left) medial view of left hemisphere showing orbitofrontal cortex (red) and, deep within the temporal lobe, amygdala (red), as well as hypothalamus and periaqueductal gray (both orange). Right, lateral view of the right hemisphere showing orbitofrontal cortex (red) and, buried in temporal cortex, amygdala (red), and also somatosensory cortex (blue) and, buried under overlying cortex, insula (blue). The amygdala and orbitofrontal cortex receive perceptual information and project to effector structures (principally, the hypothalamus and peraqueductal gray), which effect automatic changes in body state, including blood pressure, heart rate, and so on. See article EMOTION.

Plate 7



Representative MRI scan (left), SPECT image (center), and superimposed MRI/SPECT image (right) in a normal subject and in a patient with objective evidence of lyme encephalopathy. Blue corresponds to lower perfusion, red to higher perfusion. See article LYME ENCEPHALOPATHY.
