Action Potential

JOHN A. WHITE
Boston University

GLOSSARY

activation The time-dependent growth of a membrane conductance in response to membrane depolarization.

all-or-nothing A term that refers to the property that action potentials, if they occur, have a stereotyped shape that is largely independent of the size and form of the suprathreshold stimulus.

current clamp An experimental protocol in which transmembrane current is controlled, usually at a series of constant values, and resulting transmembrane potentials are measured.

deactivation The time-dependent reversal of activation in response to membrane hyperpolarization; leads to a decrease in membrane conductance.

deinactivation The time-dependent reversal of inactivation, triggered by hyperpolarization; leads to an increase in membrane conductance.

depolarization Making membrane potential less negative.

hyperpolarization Making membrane potential more negative.

inactivation The time-dependent decline of a conductance (e.g., the Na^+ conductance), which follows after its activation; triggered by depolarization.

membrane potential The voltage difference across the neural membrane, determined by the balance of ionic fluxes across the plasma membrane.

refractory period The period immediately after an action potential, in which it is difficult or impossible to induce a second action potential.

space clamp The condition in which membrane potential is the same throughout the spatial extent of the cell.

threshold The value of membrane current or membrane potential necessary to induce an action potential.

voltage clamp An experimental protocol in which membrane potential is controlled, usually in a stepwise fashion, and resulting transmembrane currents are measured.

voltage-gated ion channels Transmembrane proteins that open in response to changes in membrane potential, allowing a particular ionic species to cross the membrane.

The action potential is the all-or-nothing electrical impulse used to communicate information between neurons and from neurons to muscle fibers. The energy used to generate action potentials is in the form of electrochemical gradients of ions (in particular, sodium and potassium) that are established by ion pumps. The rising phase of action potentials is caused by the autocatalytic activation of many Na^+-selective ion channels in response to sufficiently large increases in membrane potential. The falling phase of the action potential is caused by two factors that develop more slowly but dominate the electrical response after a few milliseconds: the inactivation of sodium channels and the activation of potassium channels, both of which occur in response to depolarization. Understanding the diverse mechanisms underlying electrical excitability in neurons remains a rich field of experimental and theoretical study, with wide-ranging implications for human health.

I. BASIC PROPERTIES OF THE ACTION POTENTIAL

The basic properties of the action potential can be studied using a microelectrode constructed from a glass capillary tube with a fine tip and containing artificial intracellular solution. This microelectrode,

inserted into the cell body or axon of a neuron (Fig. 1a, inset), measures the value of membrane potential relative to the extracellular space. At rest, typical values of membrane potential range from −40 to −90 mV. Passing positive electrical current into the cell depolarizes it (i.e., makes membrane potential less negative). In response to small depolarizing stimuli, the neuron's response is small as well (Fig. 1a, bottom). In response to larger stimuli, above a threshold value, the response is fundamentally different; the membrane potential quickly rises to a value well above 0 mV and then falls over the course of 1–5 msec to its resting value (Fig. 1a, middle). Often, the falling phase of the action potential undershoots resting potential temporarily. The action potential is said to be all-or-nothing because it occurs only for sufficiently large depolarizing stimuli, and because its form is largely independent of the stimulus for suprathreshold stimuli. In some neurons, a single action potential can be induced by the offset of a hyperpolarizing stimulus

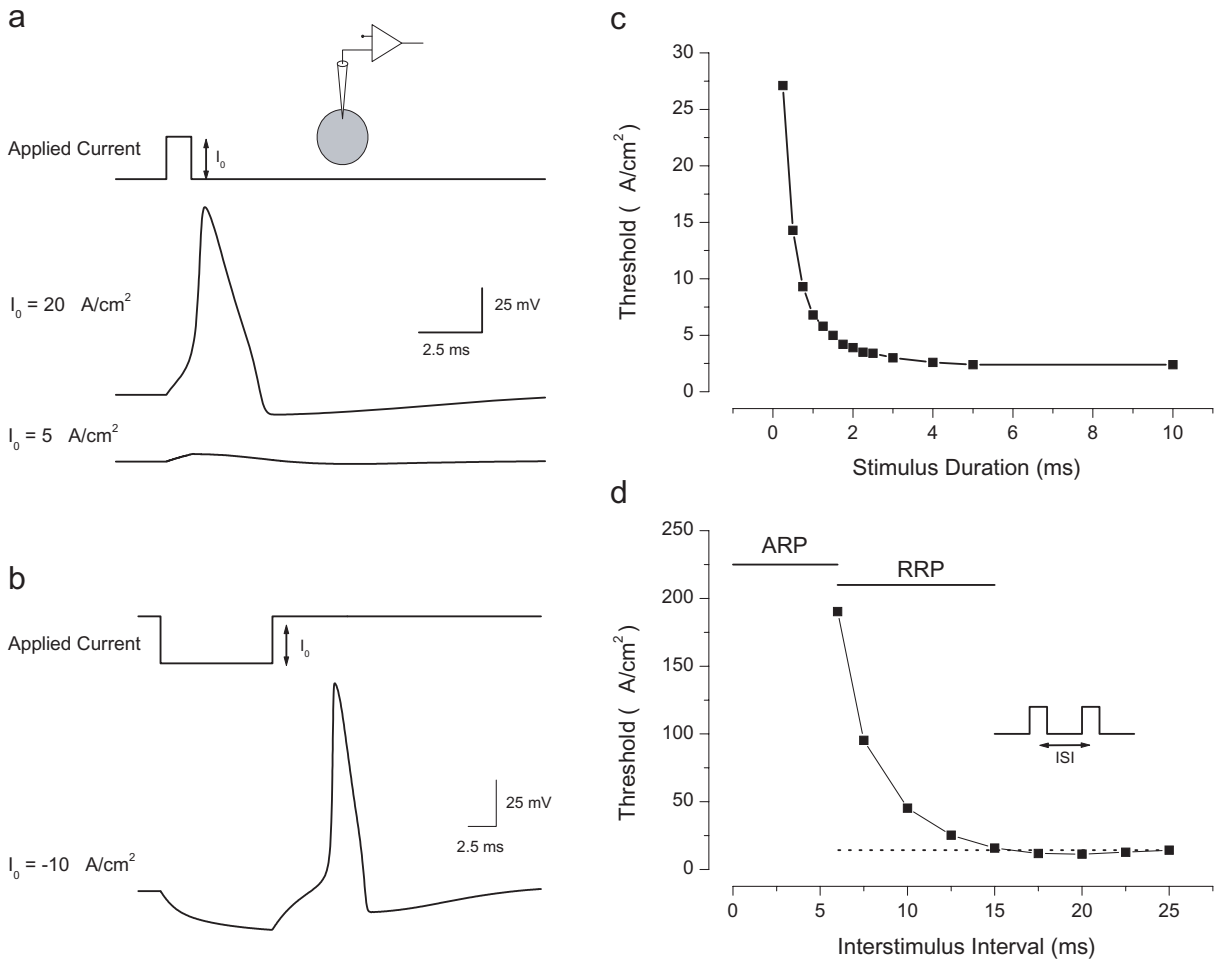

Figure 1 Basic properties of the action potential. (a) Traces show responses of a simulated space-clamped squid axon ($T = 6.3°C$) to intracellularly injected current pulses of duration 0.5 msec (top trace). The simulated recording configuration is shown in the inset. Sufficiently large inputs evoke all-or-nothing action potentials (middle trace). The response is minimal to subthreshold stimuli (bottom trace). The inset shows the basic recording configuration. (b) A simulation demonstrating anode-break excitation in response to the offset of a hyperpolarizing current pulse (duration = 10 msec). (c) Current threshold (the minimal amplitude of a current step necessary to evoke an action potential) plotted vs stimulus duration. (d) Simulation results demonstrating refractoriness. Two current pulses (duration = 0.5 msec each) were delivered to the model, with interstimulus interval (ISI) varied systematically. The first pulse had magnitude twice the threshold for evoking an action potential. The *y*-axis shows the magnitude of the second pulse necessary to evoke a spike. For ISI < 15 msec, threshold is above its normal value (dashed line). During the relative refractory period (RRP), threshold is elevated; during the absolute refractory period (ARP), it is not possible to evoke a second action potential.

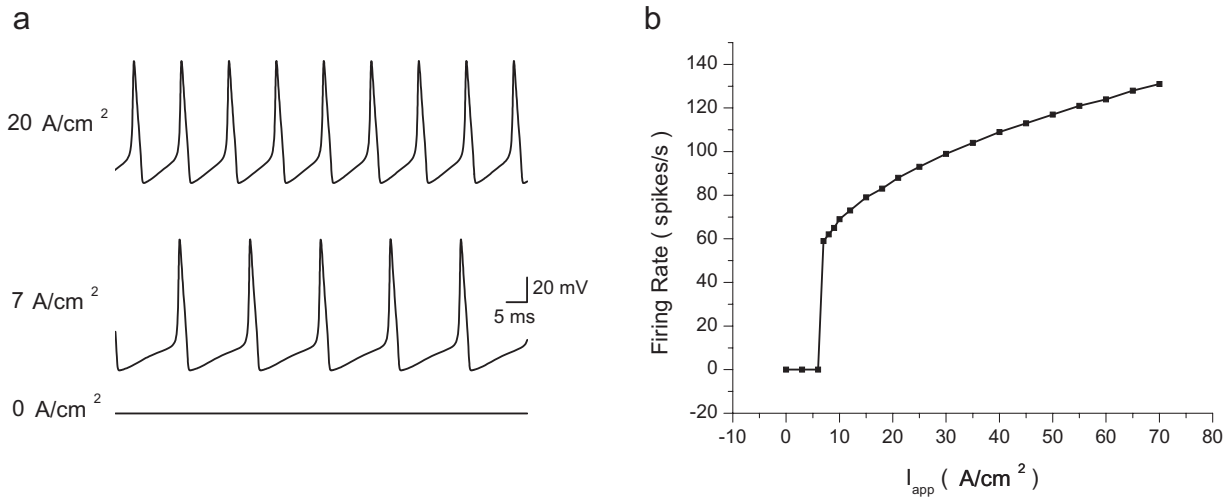

Figure 2 Spike rate depends on the magnitude of applied current. (a) Simulated traces of space-clamped squid giant axon ($T = 6.3°C$) to constant applied current. (b) Firing rate increases with increasing applied current. Note that the minimal firing rate is well above zero spikes/sec.

(Fig. 1b). This phenomenon is called anodal break excitation or rebound spiking.

The value of threshold depends on the duration of the stimulus (Fig. 1c); brief stimuli are required to be larger to evoke an action potential. Threshold also depends on more subtle features of the stimulus, such as its speed of onset. For a short time after an action potential has occurred, it is impossible to evoke a second one (Fig. 1d). This period is referred to as the absolute refractory period (ARP). After the ARP comes the relative refractory period (RRP), in which an action potential can be evoked, but only by a larger stimulus than was required to evoke the first action potential. Stimulation by an ongoing suprathreshold stimulus leads to repetitive firing at a rate that is constant once any transients have settled out (Fig. 2a). The rate of repetitive firing increases with increasing depolarization (Fig. 2b), eventually approaching the limit imposed by the ARP.

Once initiated, the action potential propagates down the axon at an approximately constant velocity. The leading edge of the action potential depolarizes adjacent unexcited portions of the axon, eventually bringing them to threshold. In the wake of the action potential, the membrane is refractory, preventing reexcitation of previously active portions of the cell. In unmyelinated axons, the action potential travels smoothly, with constant shape and at constant velocity. In myelinated axons, conduction is saltatory: The action potential ''jumps'' nearly instantaneously from one node of Ranvier to the next, greatly increasing the speed of propagation.

II. CLASSICAL DESCRIPTIONS OF THE ACTION POTENTIAL

A. Electrochemical Potentials and Voltage-Dependent Membrane Conductances

Changes in electrical potential in excitable cells are driven by movement of ions through ion-specific membrane conductances. For a perfectly specific conductance G, the current across the membrane $I = G \times (V_m - V_n)$, where V_m is the electrical potential across the membrane and V_n is the equilibrium potential for the ion, given by the Nernst equation:

$$V_n = \frac{RT}{z_n F} \ln \left(\frac{[X_n]^{\mathrm{o}}}{[X_n]^{\mathrm{i}}} \right)$$

where $R = 8.314$ J/(mol K) is the gas constant, T is absolute temperature, z_n is the valence of ion n, $F = 9.648 \times 10^4$ C/mol and is Faraday's constant, $[X_n]^{\mathrm{o}}$ is the outer concentration of ion n, and $[X_n]^{\mathrm{i}}$ is the inner concentration of ion n. Intuitively, the equilibrium potential is the value of membrane potential at which ionic fluxes due to concentration gradients and voltage gradients cancel one another, leading to zero net flux of the ion. Note that ionic

current, as defined, is positive for outward flux of a positive ion. For neurons, $[Na^+]^o > [Na^+]^i$; consequently, V_{Na} typically ranges from 40 to 50 mV and $I_{Na} < 0$. In contrast, $[K^+]^i > [K^+]^o$; V_K ranges from -70 to -100 mV and $I_K > 0$. The fact that resting membrane potential is far from V_{Na} and close but typically not equal to V_K implies that these ions are out of equilibrium, and thus that there is a constant trickle of each, even at rest. This flux is opposed by energy-expending ionic pumps, most notably the Na^+/K^+ ATPase, which serve to maintain Na^+ and K^+ concentration gradients and, consequently, equilibrium potentials.

Among the first quantitative clues regarding the mechanisms underlying the action potential came from ionic substitution experiments demonstrating that Na^+ and K^+ are the primary ions responsible for the phenomenon. Other early experiments demonstrated that membrane conductance, but not membrane capacitance, changes during the course of the action potential. Together, these results suggested the hypothesis that fluxes of Na^+ and K^+, driven by changes in ion-specific conductances, are responsible for the action potential. It is important to note that changes in membrane potential are not induced by changes in intracellular concentrations of Na^+ and K^+: Ionic fluxes during individual action potentials are small enough that concentrations remain essentially unperturbed. Instead, ionic fluxes alter V_m by changing the distribution of charge very near the membrane.

B. The Hodgkin–Huxley Model of the Space-Clamped Action Potential

Researchers in the middle of the 20th century hypothesized that the Na^+ and K^+ conductances underlying the action potential are "gated" (i.e., turned on and off) by changes in membrane potential. To test this hypothesis, they devised methods to measure ionic fluxes while controlling membrane potential V_m at a fixed value throughout the length of the axon. The process of controlling V_m, called voltage clamping, simplifies the behavior of the hypothesized voltage-dependent "gates." The process of making V_m the same throughout the axon, called space clamping, prevents complex spatial spread of excitation. Under these conditions, Na^+ and K^+ fluxes can be isolated either by manipulation of ionic concentrations (and thus equilibrium potentials) or by using specific blockers of particular conductances. (Tetrodotoxin is the classic blocker of Na^+ conductances; tetraethyl ammonium blocks many K^+ conductances.) Isolated Na^+ and K^+ fluxes from simulations are shown in Fig. 3 for many values of membrane potential. As hypothesized, these fluxes are voltage dependent. Na^+ and

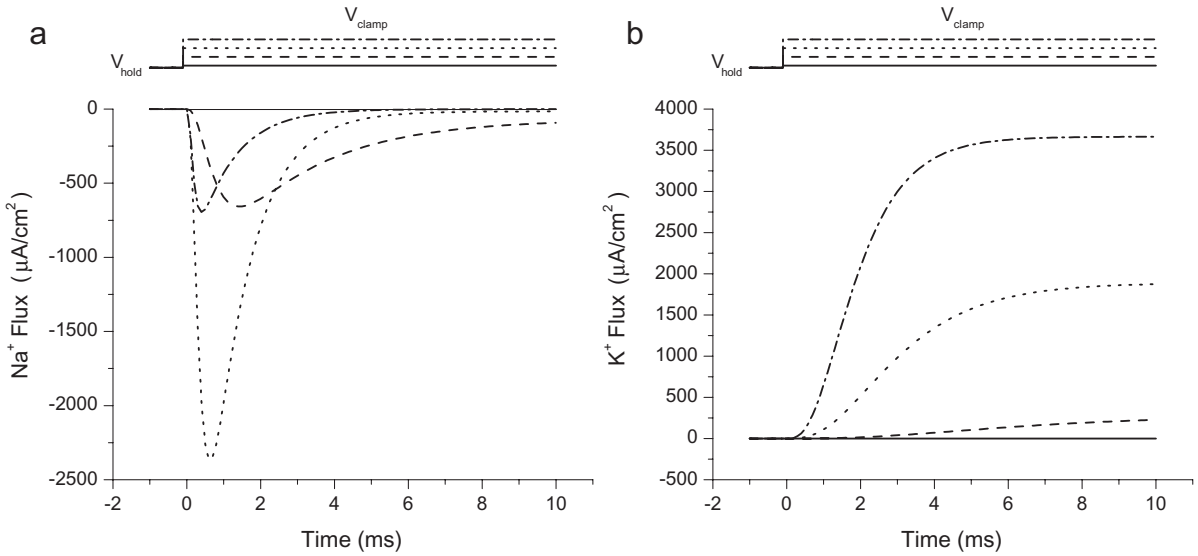

Figure 3 Simulated responses to voltage-clamp stimuli. Simulated Na^+ (a) and K^+ (b) in response to voltage-clamp steps from a holding potential of -90 mV to clamp potentials of -80 (solid lines), -40 (dashed lines), 0 (dotted llines), and 40 mV (dashed and dotted lines). The Na^+ flux is inward (negative) and is characterized by rapid activation and slower inactivation. The K^+ flux is outward (positive) and activates significantly more slowly than the Na^+ flux.

K^+ fluxes differ in several important aspects. First, they are opposite in sign for most values of membrane potential: The Na^+ flux depolarizes the neuron, whereas the K^+ flux hyperpolarizes the cell. Second, the Na^+ flux turns on ("activates") much more quickly than the K^+ flux. Third, the Na^+ flux turns off ("inactivates") after a brief period of depolarization. In contrast, the K^+ conductance remains activated in response to a prolonged depolarizing stimulus.

A watershed event in the history of neuroscience was the development by Hodgkin and Huxley of a relatively simple mathematical model, derived from voltage-clamp studies of the giant axon of the squid, that accounts for the generation and propagation of the action potential. The Hodgkin–Huxley model describes the membrane as an electrical circuit (Fig. 4a) that includes descriptions of membrane capacitance C_m; voltage-gated, Na^+- and K^+-selective conductances (G_{Na} and G_K, respectively), each in series with a battery representing the appropriate equilibrium potential; and a constant "leak" conductance that passes more than one ion. Mathematically, the Hodgkin–Huxley model includes four differential equations, which describe how the derivatives of membrane potential and three "gating variables" (variables that range between 0 and 1 and determine the values of voltage-gated conductances) behave. Two time- and voltage-dependent gating variables determine the size of the Na^+ conductance: The m gate captures the rapid activation of the Na^+ conductance after a step depolarization, whereas the h gate describes the slower inactivation process by which the

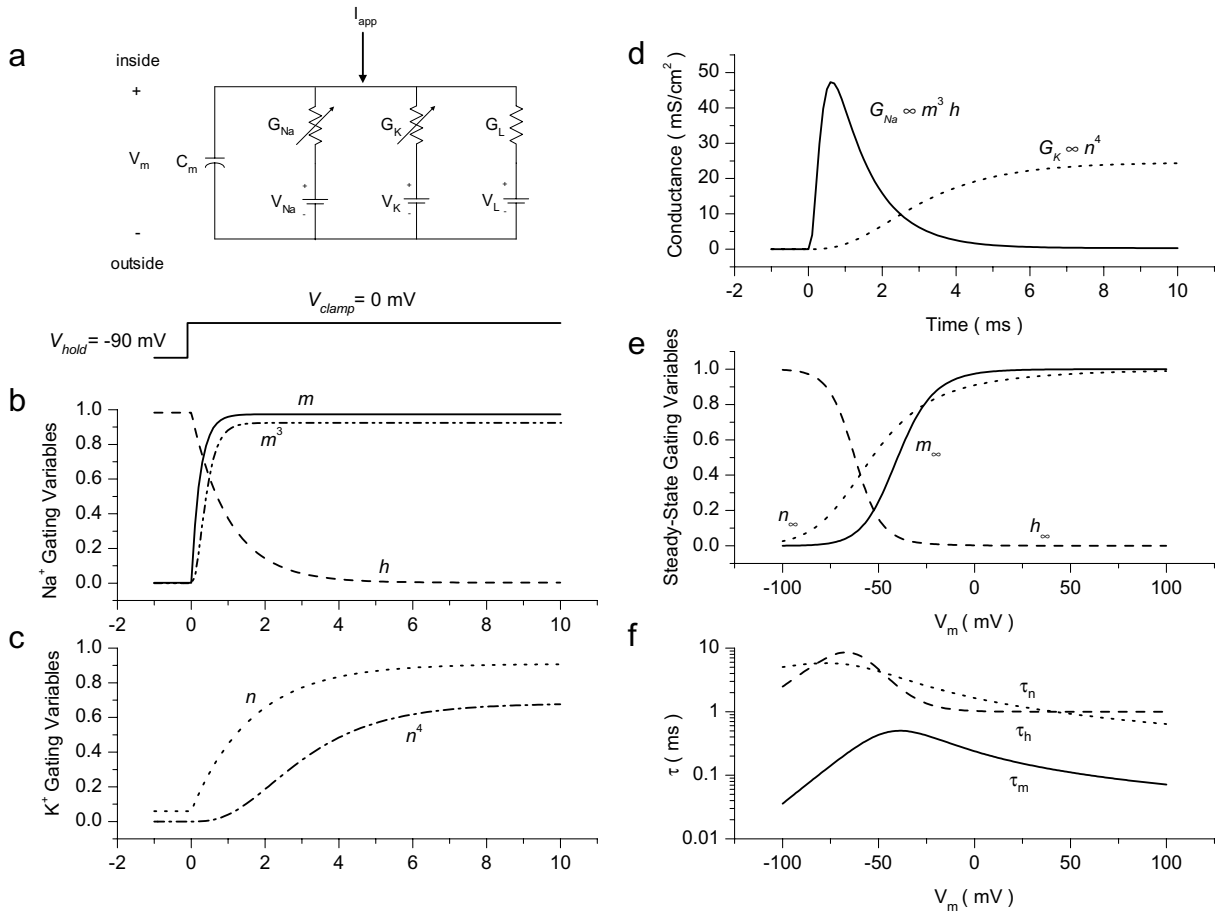

Figure 4 The Hodgkin–Huxley model of voltage-gated Na^+ and K^+ conductances. (a) Electrical circuit representation of the Hodgkin–Huxley model of squid giant axon under space-clamped conditions. (b–d) Responses of the Hodgkin–Huxley gating variables to a voltage-clamp step from $V_{hold} = -90\,mV$ to $V_{clamp} = 0\,mV$. The m and h gates determine the value of $G_{Na} \propto m^3h$. The n gate determines the value of $G_K \propto n^4$. (e) Steady-state values of m, h, and n for the entire physiologically relevant range of membrane potential V_m. (f)Time constants describing how quickly the gating variables m, h, and n reach their steady-state values, plotted vs V_m. Note the log scale on the y-axis.

Table I
Definitions and Units of Mathematical Symbols

C_m	Membrane capacitance per unit area ($\mu F/cm^2$)
$\bar{G}_{Na}, \bar{G}_K$	Maximal values of voltage-gated Na^+ and K^+ conductances per unit area (mS/cm^2)
G_{Na}, G_K	Voltage-gated Na^+ and K^+ conductances per unit area (mS/cm^2)
G_L	Leak conductance per unit area (mS/cm^2)
m, h, n	Voltage-dependent gating variables that determine magnitudes of voltage-gated conductances (dimensionless)
$m_\infty, h_\infty, n_\infty$	Voltage-dependent steady-state values of gating variables (dimensionless)
τ_m, τ_h, τ_n	Voltage-dependent time constants associated with gating variables (msec)
$\frac{dm}{dt}, \frac{dh}{dt}, \frac{dn}{dt}$	Time derivatives of gating variables (1/msec)
V_{Na}, V_K	Equilibrium potentials for Na^+ and K^+ (mV)
V_L	Reversal potential for the multi-ion leak conductance (mV)
I_{app}	Applied current flux ($\mu A/cm^2$)
V_m	Membrane potential (mV)
$\frac{dV_m}{dt}, \dot{V}_m(t)$	Time derivative of membrane potential (mV/msec)

Na^+ conductance turns off in response to prolonged depolarization. One gating variable, the n gate, describes voltage-dependent activation of the K^+ conductance G_K. An additional conductance (the leak conductance G_L) is voltage independent and small. In mathematical terms, the Hodgkin–Huxley equation is written as follows, with symbols defined in Table I:

$$C_m \frac{dV_m}{dt} = -[G_{Na}(V_m - V_{Na})$$

$$+G_K(V_m - V_K) + G_L(V_m - V_L)] + I_{app}$$

$$G_{Na} = \bar{G}_{Na} m^3 h \qquad G_K = \bar{G}_K n^4$$

$$\frac{dm}{dt} = \frac{m_\infty(V_m) - m}{\tau_m(V_m)} \qquad \frac{dh}{dt} = \frac{h_\infty(V_m) - h}{\tau_h(V_m)}$$

$$\frac{dn}{dt} = \frac{n_\infty(V_m) - n}{\tau_n(V_m)}$$

In response to a step change from an initial value of membrane potential (often referred to as the holding potential, V_{hold}) to the clamp potential, V_{clamp}, each of the Hodgkin–Huxley gating variables (m, h, and n) changes from an initial value to a steady-state value with an exponential time course (Figs. 4b and 4c). The steady-state values (m_∞, h_∞, and n_∞) and exponential time constants (τ_m, τ_h, and τ_n) are determined solely by the current value of V_m, which equals V_{clamp} for voltage-clamp experiments (Figs. 4e and 4f). The initial values of the gating variables are determined by the holding potential. G_{Na} is proportional to $m^3 \times h$; G_K is proportional to n^4 (Figs. 4b–4d). The powers to which the gating variables m and n are raised were used by Hodgkin and Huxley to induce small delays in activation of the conductance in order to better match experimental data.

C. The Hodgkin–Huxley Model Accounts for the Basic Properties of the Action Potential

Although the Hodgkin–Huxley model is incorrect in some details (see Section III.A), it can account for many of the basic properties of the neuronal action potential. For example, two properties of the m gate account for the phenomenon of the all-or-nothing action potential with a distinct threshold in response to a particular type of stimulus:

1. Because the m gate activates (opens) with depolarization, and its activation leads to further depolarization, this gate is prone to autocatalytic "positive feedback" that can magnify a small depolarization into a full-blown action potential. The current threshold for firing an action potential is the amount of current required to engage this cycle of positive feedback (see Section III.D for a discussion of the threshold value of membrane potential). In contrast with the m gate, the h and n gates react to oppose depolarization (h because it becomes smaller with depolarization, and n because its activation increases the size of an outward K^+ current).
2. The m gate is much faster than the h and n gates (Fig. 4e). The speed of the m gate means that the rapid rising phase of the action potential can occur before the stabilizing influences of the h and n gates can engage to bring V_m back to near resting potential. The speed of inactivation of h (i.e., its decrease with depolarization) and activation of n determine the width of the action potential.

Traces of each of the gating variables during the course of a depolarization-induced action potential are shown in Fig. 5a. Like spike threshold and spike duration, the phenomena of absolute and relative refractory periods can be accounted for by tracking gating variables. The ARP is associated with elevated values of n and, most important, greatly reduced

values of *h* after a spike (Fig. 5a). These factors make it impossible for a second spike to be elicited soon after the first. The RRP lasts as long as it takes for the *h* and *n* gates to return to their baseline values (about 15 msec in squid giant axon).

At resting potential, the voltage-gated Na^+ conductance is partially inactivated in that the *h* gate is partly closed and the *n* gate is partly open (Figs. 4 and 5). Hyperpolarizing the neuron below resting potential increases the value of *h*, in a process called deinactivation, and decreases the value of *n*, in a process called deactivation. Deinactivation of the Na^+ conductance and deactivation of the K^+ conductance can leave the neuron more excitable after hyperpolarization, and thus can account for anodal break excitation (Fig. 5b), also known as rebound spiking. Neurons typically fire only one rebound spike because after that spike the Na^+ and K^+ conductances return to their baseline states and the cell returnes to its resting level of excitability.

The first major success of the Hodgkin–Huxley model was that this relatively simple model, derived from voltage-clamp experiments, accounted successfully for many aspects of the action potential in the current-clamped and space-clamped axon. Even more impressive, and strikingly demonstrative of the level of understanding this model represents, was its ability to accurately account for the shape and velocity of the propagating action potential. The quantitative arguments involved are complex and will not be discussed here, but Fig. 6 shows qualitatively how action potentials propagate in unmyelinated axons.

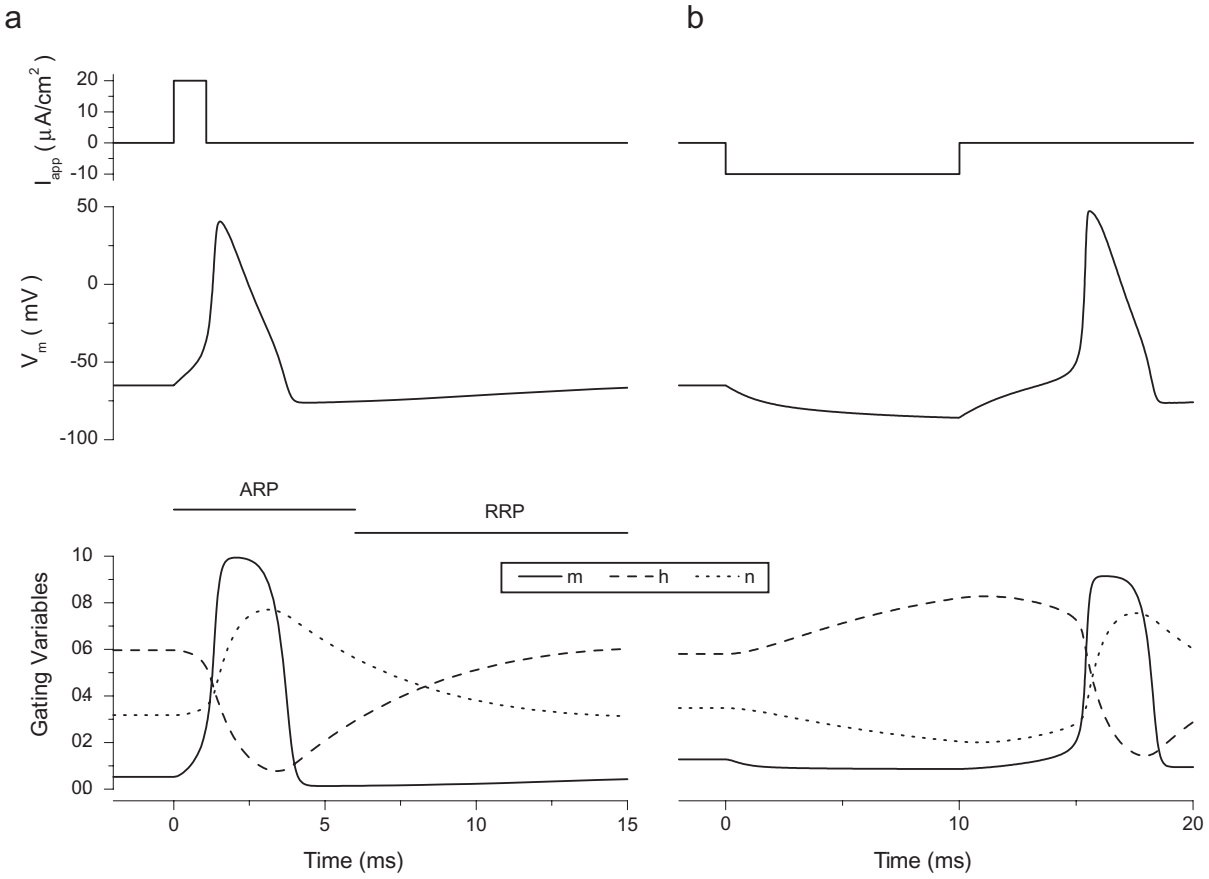

Figure 5 The Hodgkin–Huxley model accounts for axonal excitability. (a) From top to bottom, applied current I_{app}, membrane potential V_m, and each of the gating variables are plotted vs time. Curves were derived from the Hodgkin–Huxley model at 6°C. The rapid activation of the *m* gate underlies the action potential in response to this brief current pulse. The slower inactivation of the *h* gate and activation of the *n* gate repolarize the membrane a few milliseconds later. The duration of the absolute and relative refractory periods (ARP and RRP, respectively) is controlled by the duration of *h* gate inactivation and *n* gate activation. (b) After a hyperpolarizing input, the Hodgkin–Huxley model (6°C, with enhanced density of the Na^+ conductance) can produce a rebound spike (also known as anode break excitation). Data are plotted in the same order as in (a). Deactivation of the *n* gate and deinactivation of the *h* gate underlie this phenomenon.

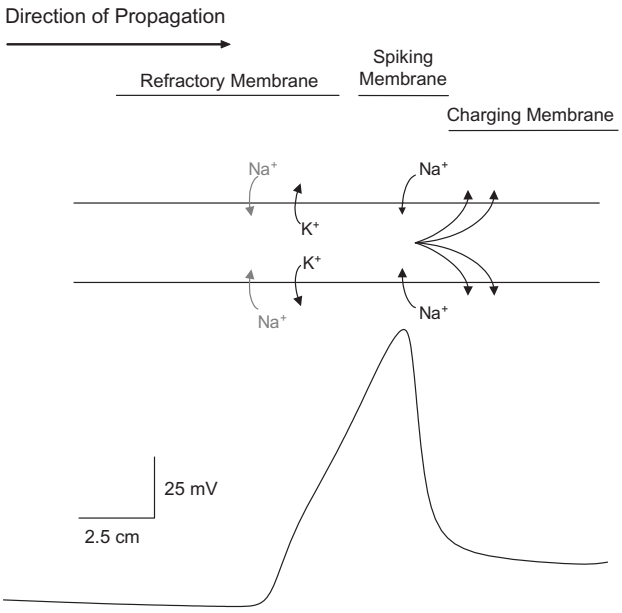

Figure 6 Propagation of the action potential in an unmyelinated axon. (Top) Schematic of the unmyelinated axon showing the sequence of events as an action potential propagates from left to right. The point of maximal Na^+ flux characterizes the locus where V_m is greatest. Positive charge from this point spreads to the right, gradually depolarizing the membrane on the leading edge of the action potential until threshold is reached. At the trailing edge of the action potential, to the left, the membrane is refractory. (Bottom) "Snapshot" of V_m plotted vs axial distance for the propagating action potential, with an assumed conduction velocity of 20 m/sec. Note that the form of the action potential is reversed when plotted vs distance rather than time.

Membrane potential reaches its peak value near the position of maximal Na^+ flux. Adjacent, unexcited membrane (Fig. 6, right) is depolarized by positive current from the site of Na^+ flux. Eventually, this depolarization is large enough that the membrane at the leading edge is excited as well. The membrane in the wake of the action potential is refractory (i.e., dominated by small G_{Na} and large G_K, and thus unable to spike) and thus unlikely to be reexcited. Elaborations of this model can account for saltatory conduction in myelinated axons.

III. CURRENT TOPICS RELATED TO THE ACTION POTENTIAL

A. Voltage-Gated Ion Channels Underlie Voltage-Dependent Membrane Conductances

In the past two decades, improvements in recording methodologies, pioneered by the group of Sakmann and Neher, as well as an explosion of knowledge in the field of molecular biology have demonstrated directly that membrane protein assemblies called ion channels underlie voltage-gated conductances in neurons and other excitable cells. The main (α) subunit of voltage-gated Na^+ channels (Fig. 7a) is a membrane protein approximately 2000 amino acids in length and has a molecular weight $>200{,}000$. This protein includes four domains, each of which consists of six putative transmembrane segments. A smaller β subunit is not necessary to form the channel but is crucial for regulating aspects of channel function such as the speed of inactivation. The main subunit of the K^+ channel has a very similar structure, except that the each protein codes for only one domain. Thus, four α subunits are necessary to form a K^+ channel.

Recordings from single channels (Fig. 7b) typically reveal two conductance states: "open" and "closed." Switching between open and closed states appears random, but the probability that the channel is in the open state varies with membrane potential. These probabilities correspond approximately to the values of gating variables in the Hodgkin–Huxley formulation. Sums of repeated recordings from an individual ion channel show behavior that is very similar to the macroscopic behavior of the channel population (Fig. 7b). Sophisticated analyses of single-channel recordings yield probabilistic models that can account for both microscopic and macroscopic behavior. These

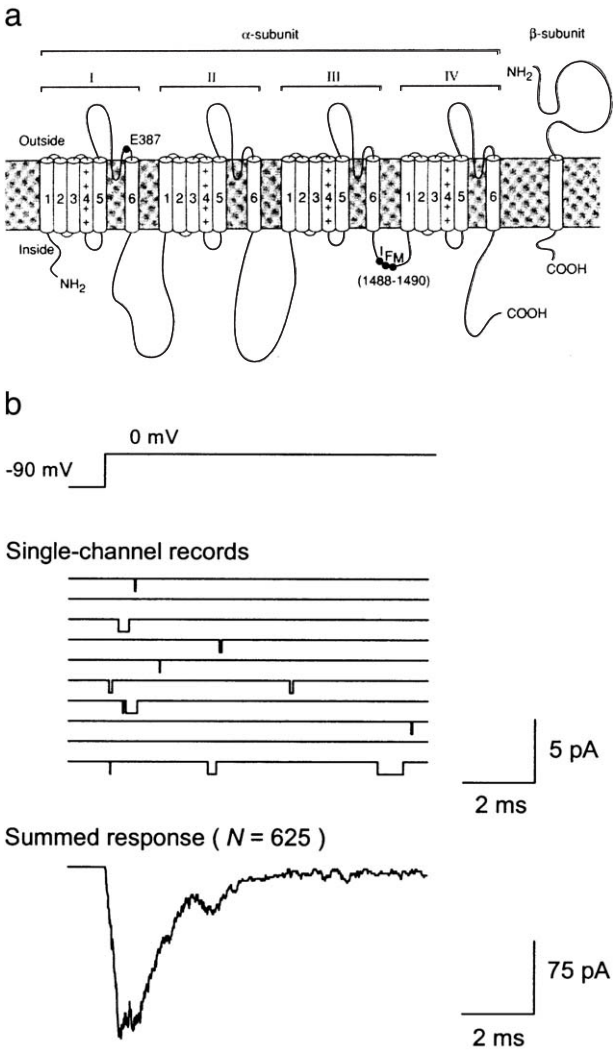

Figure 7 Na^+ channels underlie the voltage-gated Na^+ conductance. (a) Putative structure of the α and β subunits of the rat brain Na^+ channel (IIA). Roman numerals indicate the domains of the α subunit, each of which includes six putative transmembrane segments. Indicated residues are implicated in binding the channel blocker tetrodotoxin (E387) and in forming the inactivation gate (IFM 1488–1490) (adapted from Ashcroft (2000)). (b) The 10 middle traces show simulated single-channel recordings from a Na^+ channel under voltage clamp. The top trace shows the voltage-clamp command. The bottom trace shows the sum of 625 single-channel records.

models are similar in structure to Hodgkin–Huxley-type models but different in some details. For example, careful analysis of recordings from single Na^+ channels shows that their inactivation state is not controlled by an activation-independent process like the h gate but, rather, that Na^+ channels must activate before they can inactivate.

Experiments with channels that have been subjected to site-directed mutations have revealed close connections between particular loci on the protein and specific aspects of channel behavior. Among the properties that have been tied to specific loci on the α subunit are those of pore formation, ionic selectivity, voltage dependence, inactivation, and blockage by specific toxins (Fig. 7a).

B. Diversity of Mechanisms Contributing to Neuronal Excitability

In the approximately 50 years since the development of the Hodgkin–Huxley model, researchers have discovered many ion channel-based mechanisms for generating and controlling electrical activity in neurons. Often, these mechanisms rely on Na^+, Ca^{2+}, and K^+ channels. Sodium channels are relatively consistent in

their properties from case to case but do show some variety. In particular, some Na^+ channels do not exhibit fast inactivation; it is not clear whether these noninactivating Na^+ channels are a separate population from the typical, fast-inactivating Na^+ channels or a subset of the fast-inactivating Na^+ channels that have slipped into a different "mode" of gating. Calcium and potassium channels show more diversity than Na^+ channels. In particular, different classes of Ca^{2+} and K^+ channels show widely diverse properties with regard to the presence and speed of inactivation, pharmacological properties, and voltage ranges of activation. Some K^+ channels are sensitive to both membrane potential and the local intracellular concentration of Ca^{2+}, giving rise to interesting interactions between these two systems.

C. Modulation of Voltage-Gated Ion Channels

The properties of voltage-gated ion channels are not static. Many neuromodulators have been shown to alter ion channel function and the properties of action potentials by phosphorylating or dephosphorylating one or more sites on the channel protein. A host of neuronal firing properties, including spike width, average firing rate, and refractory period, are subject to metabolic control.

Ion channel expression profiles and neuromodulatory states can have profound consequences for neuronal function. A striking example of this point derives from thalamic relay neurons (Fig. 8). Depending on the level of depolarization or neuromodulatory state, these cells have two distinct firing modes. When relay neurons are hyperpolarized, they exhibit rhythmic bursting (Fig. 8a). The long interburst interval is determined by interaction of the low-threshold Ca^{2+} current and slowly activating, inwardly rectifying cation current. Superimposed on each slow Ca^{2+} spike are many fast action potentials, mediated by Na^+ and K^+ channels. When relay neurons are depolarized, either by electrical current or any of a number of neuromodulators, the low-threshold Ca^{2+} channels and inwardly rectifying cation channels are unimportant and the neurons fire in a tonic pattern much more reminiscent of the Hodgkin–Huxley model (Fig. 8b).

D. Mathematical Analyses of Neuronal Excitability

Although much about neuronal excitability can be learned by simply tracking changes in gating variables of the Hodgkin–Huxley-style model, computational neuroscientists and applied mathematicians have used mathematically based techniques to gain more general (and thus deeper) insights. Mathematical approaches

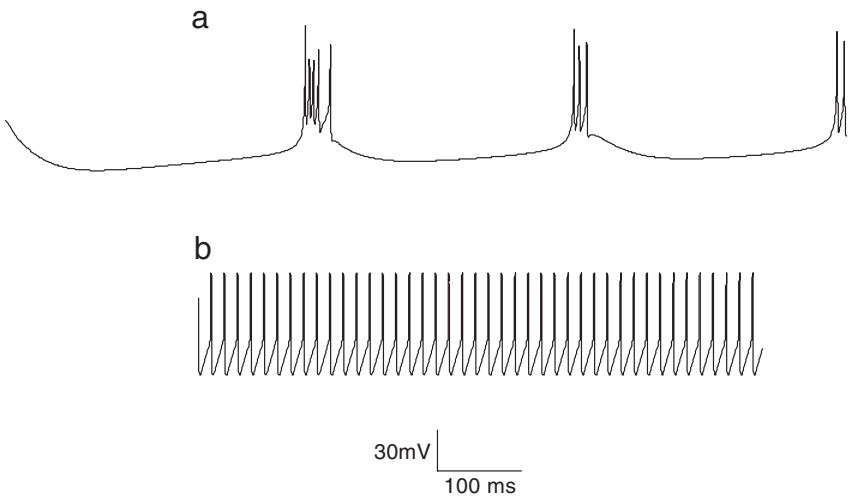

Figure 8 Thalamic relay neurons show two distinct firing modes. Shown are simulated responses of a thalamic relay neuron [Figure generated using the computational model from D. A. McCormick and J. R. Huguenard (1992). A model of the electrophysiological properties of thalamocortical relay neurons. *J. Neurophysiol.* **68,** 1384–1400]. (a) Under hyperpolarized conditions, relay neurons fire in an oscillatory manner. Slow oscillations are generated by interactions of the transient Ca^{2+} current I_t and the slow, hyperpolarization-activated cation current I_h. Fast action potentials, mediated by Na^+ and K^+, occur at the peaks of the Ca^{2+} spikes. (b) Depolarization by any of a number of means (e.g., current injection or neuromodulation) puts the neuron in a "tonic firing" mode. In this mode, I_t is inactivated and I_h is deactivated. Consequently, the cell's behavior is dominated by the Na^+ and K^+ currents exclusively.

based on the techniques of nonlinear dynamics have been successful in identifying the particular features that determine a host of important features of neuronal excitability, including threshold, the relationship between sustained firing rates and applied current, and particular patterns of bursting.

Figure 9 shows how nonlinear dynamics can be applied to understand neuronal threshold. Figures 9a and 9b show results from simulations of the Hodgkin–Huxley equations with zero applied current but two different initial conditions in membrane potential. As Figs. 9a and 9b demonstrate, excitable cells can be exquisitely sensitive to initial conditions. Examining the time derivative of membrane potential $\dot{V}_m(t)$ shortly after the perturbation in initial conditions gives insight into this phenomenon. Figure 9c shows results from hundreds of simulations conducted over a large range of initial values V_0. $\dot{V}_m(t)$, evaluated at $t = 0.5$ msec, is plotted vs V_0 (solid line; the value $t = 0.5$ msec was chosen because this is long enough for the m gate to react significantly to the perturbation away from resting potential but short enough that the h or n gates remain relatively near their resting values). Also plotted are the contributions to $\dot{V}_m(0.5)$ from Na^+ conductance (dashed line) as well as K^+ and leak conductances (dotted line). These contributions can be obtained easily from the Hodgkin–Huxley equation describing $\dot{V}_m(t)$. The effect of the Na^+ conductance is to elevate $\dot{V}_m(t)$; the effect of the K^+ conductance is to reduce $\dot{V}_m(t)$.

Figure 9d shows a magnified view of $\dot{V}_m(0.5)$ in the region near spike threshold. The plot shows two zero-crossings, at $V_0 = -65$ and -59 mV. These zero crossings, often called fixed points, are especially important because where $\dot{V}_m(t) = 0$, membrane potential V_m is by definition not changing, meaning that $\dot{V}_m$ has the potential to remain fixed at that point indefinitely (for a system with constant parameters). The slope of the curve at each zero crossing tells us much about the stability of that fixed point in response to small fluctuations (e.g., due to noise). For example, consider the special case of no perturbation. In this case, V_0 equals resting potential (-65 mV), which we expect to be a fixed point. For V_m slightly less than -65 mV, $\dot{V}_m(0.5) > 0$, implying that V_m will return to its resting value. For V_m slightly higher than -65 mV, $\dot{V}_m(0.5) < 0$, implying again that V_m will return to

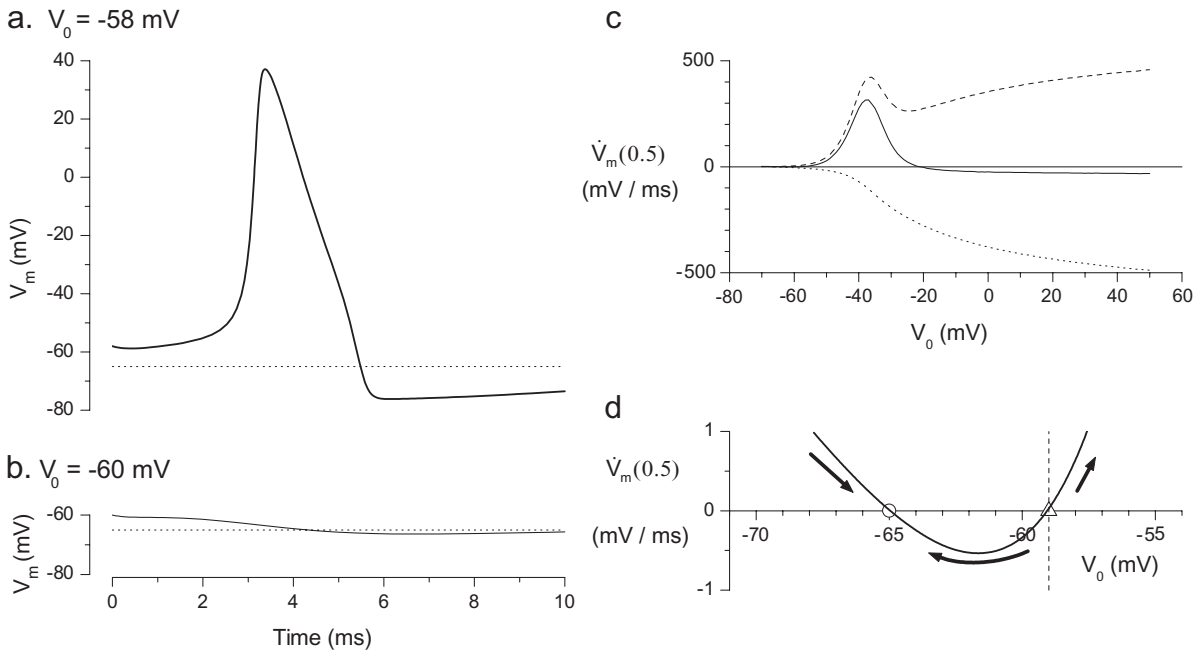

Figure 9 Threshold of the Hodgkin–Huxley model can be explained by examining the stability of "fixed points." (a, b) Spiking behavior in the Hodgkin–Huxley model is very sensitive to V_0, the initial value of voltage. Resting potential (-65 mV) is depicted by the dotted lines. (c) $\dot{V}(0.5)$, the time derivative of membrane potential at $t = 0.5$ msec, plotted vs V_0. Also plotted are the contributions of G_{Na} (dashed line), as well as G_K and G_L (dotted line), to $\dot{V}(0.5)$.The contribution of G_L is minimal because this conductance is very small. (d) A magnified plot of $\dot{V}(0.5)$ vs V_0. Two fixed points [points where $\dot{V}(0.5) = 0$] are shown. As indicated by the arrows, the sign of $\dot{V}(0.5)$ makes the solution flow toward the open circle at (-65, 0), indicating stability; the solution flows away from the open triangle at (-59, 0), indicating instability. For $V_0 > -59$ mV, an action potential will be generated.

–65 mV. The value $V_m = -65$ mV is said to be a stable fixed point because after small perturbations above or below that value, V_m will return to it.

Next, consider the fixed point at $V_0 = -59$ mV. In this case, $\dot{V}_m(0.5) < 0$ for $V_m < V_0$, and $\dot{V}_m(0.5) > 0$ for $V_m > V_0$. This result implies that this fixed point is unstable: After small perturbations above or below V_0, V_m will move away from the fixed point. The implication of this fact is that the point $V_0 = -59$ mV serves as a threshold. For $V_0 < -59$ mV, the model returns to resting potential (Fig. 9a); for $V_0 > -59$ mV, V_m rapidly increases as the action potential begins [Fig. 9b; in these cases, $\dot{V}_m(t)$ continues to evolve, eventually bringing the cell to rest]. For these simulations, the fixed point at $V_0 = -59$ mV corresponds exactly with the threshold for generation of an action potential (vertical dashed line in Fig. 9d).

E. Backpropagation of the Action Potential

In the traditional view, information flow in the mammalian neuron is in one direction only: The dendrite receives input from the presynaptic population, the soma integrates this information, the decision regarding whether or not to fire an action potential is made at or near the axon hillock, and the action potential is propagated to other neurons by the axon. This view has been amended in recent years as scientists have developed techniques for recording simultaneously from multiple locations within the neuron (e.g., the soma and a primary dendrite). In pyramidal neurons of layer V of neocortex, for example, suprathreshold synaptic input to the apical dendrites leads to initiation of an action potential near the soma. This action potential can then travel back from the soma toward the distal end of the apical dendrite. The reliability of backpropagation depends on recent patterns of input and spike generation. Given the crucial role of dendritic depolarization for synaptic plasticity, backpropagating action potentials may be important for experience-dependent alterations of neuronal circuitry in learning and memory.

F. Diseases Related to Mutations in Ion Channels

Given the central role that electrical excitability plays in nervous system function, it is not surprising that mutations of voltage-gated ion channels alter neuronal function. Although work in this area is just beginning, a host of maladies have been associated with nonlethal mutations of neuronal voltage-gated channels, including the following:

- Generalized epilepsy with febrile seizures, so-named because patients have fever-induced seizures that develop later in life into seizures without a clear trigger, is associated in some cases with a rare mutation of the β_1 subunit of the Na^+ channel. This mutation may promote epilepsy by slowing the inactivation process in neuronal Na^+ channels, leaving the brain hyperexcitable.
- Benign familial neonatal epilepsy is associated with mutations that lead to reduced expression of slow, voltage-gated K^+ channels of the KCNQ family, thereby leaving some neurons hyperexcitable.
- Some forms of episodic ataxia, a condition of triggered events of imbalance and uncoordinated movements, has been associated with many missense mutations of the $K_v1.1$ channel, which gives rise to an inactivating K^+ conductance. Ataxia-associated mutations of $K_v1.1$ have been shown to lead to pathologically rapid deactivation, enhanced inactivation, and increases in the threshold of activation. These disparate changes all have the effect of broadening the neuronal action potential, but it is not known how the broadened spike may lead to ataxia.

Adolescent Brain Maturation

JAY N. GIEDD, ELIZABETH A. MOLLOY, and JONATHAN BLUMENTHAL
National Institute of Mental Health

GLOSSARY

arborization From the Latin word for tree, the process of brain cells growing extra "branches, twigs, and roots."

corpus callosum A collection of myelinated neuronal axons connecting similar areas of the left and right cerebral hemispheres.

magnetic resonance imaging A technique that combines a powerful magnet, radio waves, and computer technology to acquire images of the human brain without the use of harmful radiation.

pruning The process by which axonal or dendritic branches are cut back or eliminated.

use-it-or-lose-it principle The hypothesis that brain cells and connections that are used will survive and flourish, whereas those that are not used will wither and perish.

Any parent of a teen can attest that the brain of a 13-year-old is very different from the brain of a 9-year-old. However, actually defining these differences in a scientific way has been elusive, because nature has gone through a great deal of trouble to protect the brain. It is wrapped in a tough, leathery membrane surrounded by a protective moat of fluid and completely encased in bone. This has shielded the brain from falls or attacks from predators but it has also shielded the brain from scientists. However, recent advances in imaging technology now allow us to examine the living, growing human brain as never before. Magnetic resonance imaging (MRI) provides exquisitely accurate pictures of brain anatomy. It does so without the use of ionizing radiation, permitting not only the scanning of healthy children and adolescents but also repeat scans of the same individuals throughout their development. In this article, we discuss the anatomical changes that occur in the adolescent brain as detected by MRI.

I. BRAIN DEVELOPMENT

Human brain development, like central nervous system development in all vertebrates, takes place by an overproduction and then selective elimination of cells. Most of the dynamic activity of brain development takes place *in utero*. However, as indicated in Fig. 1, competitive elimination, myelination, and dendritic and axonal arborization continue throughout childhood and adolescence.

Brain cells are of two general types—neurons and glial cells. Although neuronal number peaks during gestation, neuronal size changes with age as axonal thickness, dendritic number, and the number of synaptic connections undergo cyclic changes throughout development. Environmental factors influence which synaptic connections and neurons thrive and remain viable. For instance, children with cataracts who do not receive treatment prior to age 1 suffer irreversible cortical blindness.

The other main class of central nervous system cells is the glial cells, which unlike neurons continue to

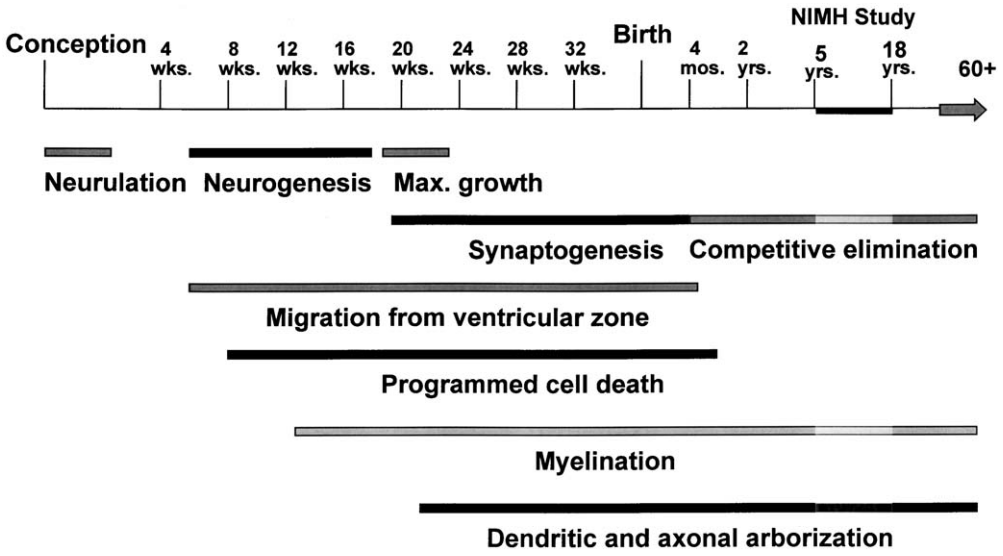

Figure 1 Time course of critical events in the determination of human brain morphometry (reproduced with permission from J. N. Giedd, 1997, Normal development. *Neuroimaging* **6,** 265–282).

actively proliferate and die postnatally. Glial cells outnumber neurons by ratios ranging from 1.7 to 10. Myelination by a subclass of glial cells, oligodendrocytes, is an important determinant of increases in structure size during childhood and adolescence. Ultimate structure size is determined by this dynamic interplay between glial cells and decreasing numbers but increasing size of neurons. Synaptic pruning is an important aspect in the functional development of the brain but may have little impact on overall structure size. Estimates from research on the primary visual cortex of the macaque monkey indicate that a total loss of all boutons would result in only a 1–2% decrease in volume. However, synaptic pruning may have an effect on the thickness of the parent axon or dendritic branches. Another parameter to consider in structure size is packing density, which is influenced by degree of vascularity, extracellular volume, and hydration.

Genetics, hormones, growth factors, nutrients in the developing nervous system, diet, infections, toxins, trauma, stress, and degree of enriched environment all play a role in determining structure size, and the complexity of these factors and their interactions should be considered in any interpretation of the significance of gross structural volume.

II. TOTAL CEREBRAL VOLUME

The brain consists of two cerebral hemispheres, the ventricles, the cerebellum, and the brain stem. The total size of the cerebral hemispheres changes little from childhood to adolescence, reaching 95% of its adult size by the age of 5 years. This is perhaps surprising to anyone who has watched an adult's hat falling down over the eyes of a child. The seeming discrepancy is due to the fact that head circumference does indeed increase from ages 4 to 18 (approximately 2.0 in. in boys and 1.9 in. in girls), but the increase is accounted for by an increase in skull thickness and less so by an increase in ventricular volume. Many factors, including intelligence, handedness, psychiatric illness, body size, and gender, have been related to total brain size in teens as well as adults.

A. Intelligence

Recent studies have found small but statistically significant relationships between brain size and intelligence. Although in the most robust of these findings IQ accounts for only 17% of the variance, this parameter should be considered in any group comparison. Education and socioeconomic status have been reported to influence brain size as well, although interdependence with factors such as nutrition, prenatal care, and IQ is not clear.

B. Psychiatric History

Abnormalities of brain structure have been observed in many pediatric neuropsychiatric illnesses, including

autism, attention deficit/hyperactivity disorder (ADHD), childhood-onset schizophrenia, dyslexia, eating disorders, fetal alcohol syndrome, obsessive–compulsive disorder, Sydenham's chorea, and Tourette's syndrome. It is evident that a normative sample must be carefully screened to rule out these conditions. Likewise, affective disorders and substance abuse have been associated with structural anomalies in adults and should be considered as potential confounds in pediatric samples as well.

C. Handedness

Beginning with Geschwind, several investigators have noted a relationship between handedness and structural symmetry measures of the brain. Handedness should not be viewed as strictly left or right but as a continuum, and it should be quantified as such. Patient and control groups must be matched for handedness since symmetry differences are often key features in discriminating groups such as ADHD, dyslexia, or Tourette's disorder.

D. Body Size

The relationship between brain size and body size in humans is surprisingly weak. In contrast to the relative stability of brain weight after childhood, body weight varies widely among individuals and can vary substantially within individuals from time to time. Height is also a poor indicator of brain size, as can be implied by contrasting the notable increases in height from ages 4 to 18 years with the lack of corresponding increase in brain size. This general trend for the young to have disproportionately large head-to-height ratios compared to adults is widely observed throughout the mammalian species.

E. Gender

As indicated by autopsy and imaging studies, the male brain is approximately 10% larger than the female brain across all ages. Of course, gross structural size may not be sensitive to sexually dimorphic differences in connectivity between different neurons, known differences in receptor density, or more subtle differences in the size or connectivity of various nuclei. Given the multiple parameters determining brain size, a larger size should not be interpreted as imparting functional advantage or disadvantage.

A plot of total cerebral volume versus age for 146 healthy boys and girls is presented in Fig. 2. As can be seen, brain sizes are highly variable. This large variability of brain sizes means that a larger number of subjects, or following the same subjects over time, is necessary to discern how brain anatomy changes during adolescence. The relative stability of total brain size throughout childhood and adolescence belies the dynamic activity of the various subcomponents of the brain. In the following sections, the effects of age and gender on these different parts of the brain are examined.

III. GRAY MATTER

Brain tissue can be broadly categorized as gray matter, white matter, or cerebrovascular fluid. These different tissue types are discriminated by MRI and define the anatomical boundaries of most brain structures. Gray matter generally consists of cell bodies and white matter of myelinated axon fibers. The gray matter changes during adolescence are presented for different regions of the cerebral cortex as well as for the subcortical basal ganglia, amygdala, and hippocampus.

A. Cortical Subdivisions

The brain is often divided into four lobes with functionally distinct properties: the frontal, temporal, parietal, and occipital lobes.

1. Frontal Gray Matter

The functions of the frontal lobe include planning, organizing, strategizing, as well as initiating, shifting, and sustaining attention. It is sometimes referred to as the "executive" of the brain. As seen in Fig. 2, frontal gray matter increases throughout childhood, peaks at 11 years in girls and 12 years in boys, and then declines throughout adolescence. The peaks correspond to the onset of puberty, although a direct relationship between hormonal changes of puberty and this process has yet to be established. The thickening of cortical gray matter is thought not to reflect an increase in the number of neurons but to be caused by an increase in the number and thickness of branches and connections on the dendrites and axons of existing neurons, a process called arborization. Following this peak of arborization is a pruning process whereby the number of branches and connections are selectively cut back.

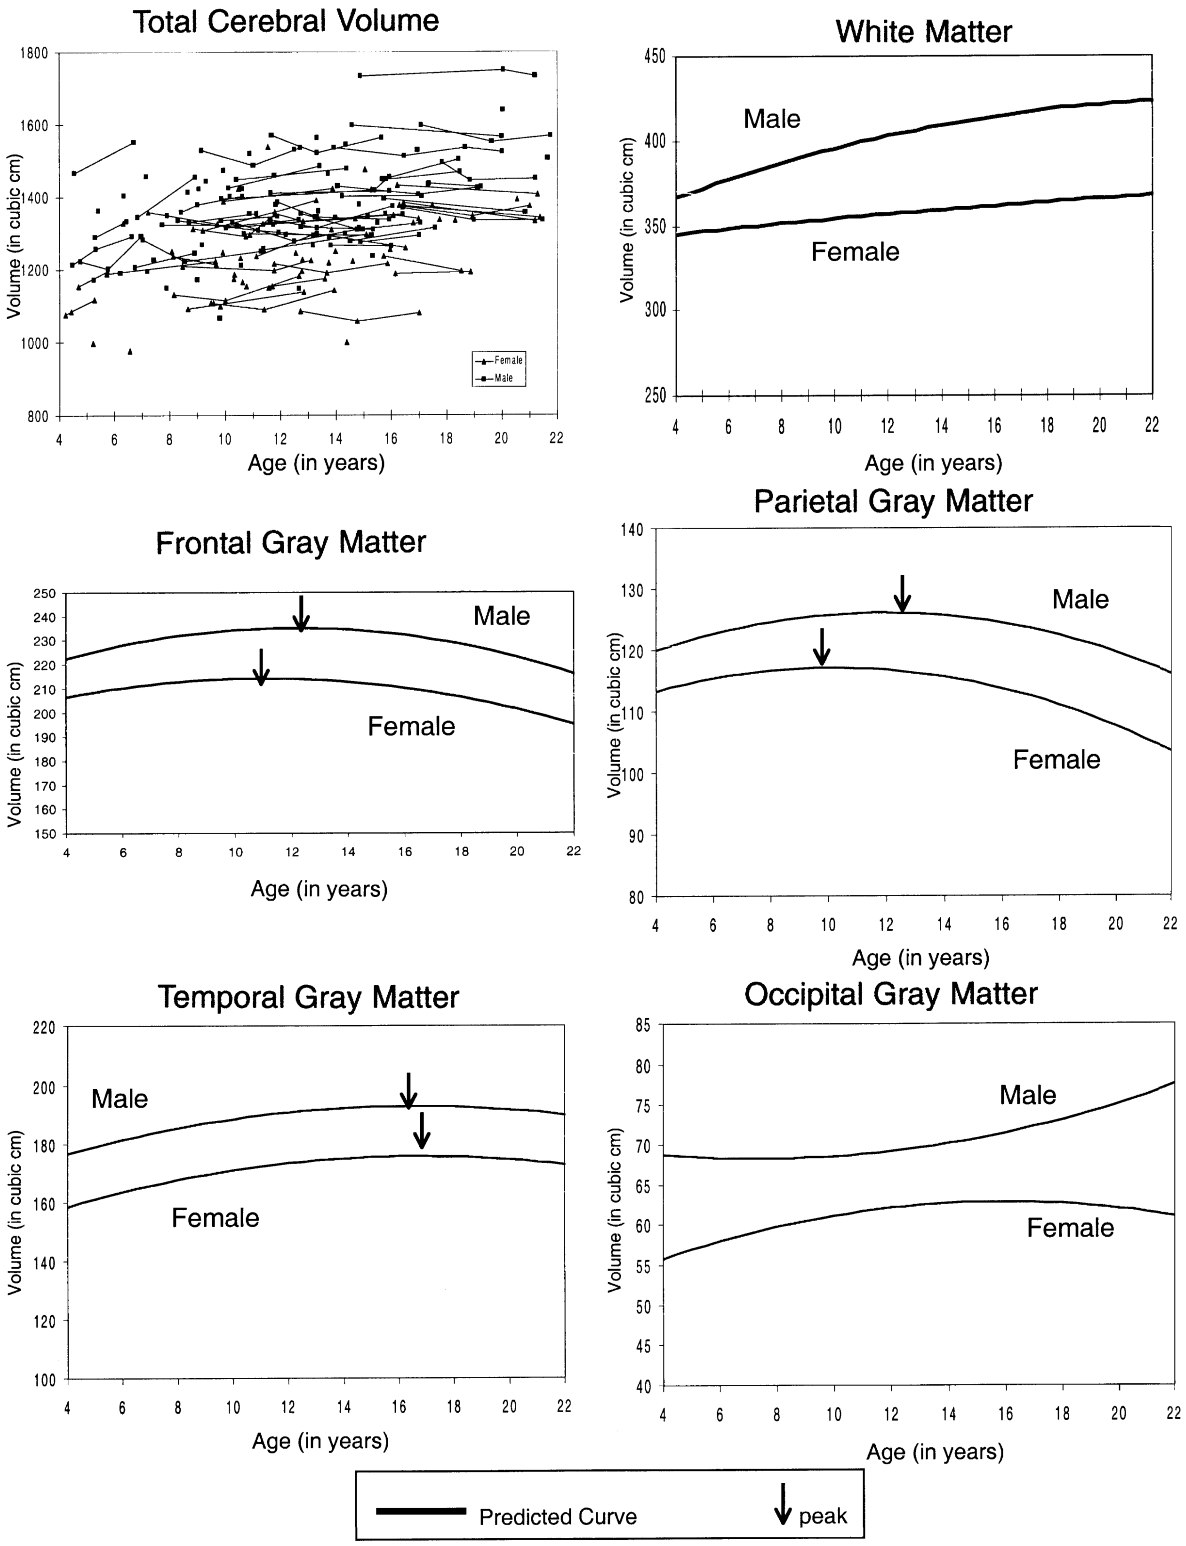

Figure 2 Predicted size with 95% confidence intervals for cortical gray matter in frontal, parietal, temporal, and occipital lobes for 243 scans from 89 males and 56 females, ages 4–22 years. The arrows indicate peaks of the curves (reproduced with permission from J. N. Giedd, *et al.*, 1999, Brain development during childhood adolescence. *Nat. Neurosci.* **2,** 861–863).

2. Parietal Gray Matter

The parietal lobes are primarily responsible for receiving and processing sensory input such as touch, pressure, heat, cold, and pain. The parietal lobes are also involved in the perception of body awareness and the construction of a spatial coordinate system (mental map) to represent the world around us. Individuals with damage to the right parietal lobe often show striking abnormalities in body image and spatial relations, such as failing to attend to part of the body or space (contralateral neglect). Patients with damage to the left parietal lobe often experience difficulty with writing (agraphia), an inability to recognize familiar objects (agnosia), and language disorders (aphasia). Bilateral damage can lead to problems with visual attention and motor abilities. As with the frontal gray matter, parietal gray matter increases during childhood and decreases during adolescence, peaking at 10.2 years in girls and 11.8 years in boys (Fig. 2).

3. Temporal Gray Matter

The temporal lobes subserve functions of language, emotion, and memory. As opposed to the frontal and parietal gray matter, the temporal gray matter does not peak until age 16.7 years in girls and 16.5 years in boys (Fig. 2). Electroencephalographic studies of adolescents and young adults also indicate ongoing maturation of the temporal lobes throughout the second decade of life.

4. Occipital Gray Matter

The occipital lobes are involved in visual information processing and object recognition. The gray matter in the occipital lobes continues to increase during childhood and adolescence (Fig. 2).

B. Subcortical Divisions

1. Basal Ganglia

The basal ganglia are composed of the caudate nucleus, putamen, globus pallidus, subthalamic nucleus, and substantia nigra. These structures are well-known to influence movement and muscle tone as indicated by their dysfunction in Parkinson's and Huntington's disease, but they are also integral components of circuits mediating higher cognitive functions, attention, and affective states. Of the basal ganglia components, only the caudate, putamen, and globus pallidus are large enough to be readily quantifiable by MRI. Like frontal and parietal cortical gray matter, the basal ganglia generally decrease in volume during the teen years.

2. Amygdala/Hippocampus

The amygdala and the hippocampus are adjacent gray matter structures in the medial temporal lobe. The amygdala is an almond-shaped structure that plays a key role in the brain's integration of emotional meaning with perception and experience. It coordinates the actions of the autonomic and endocrine systems and prompts release of adrenaline and other excitatory hormones into the bloodstream. The amygdala is involved in producing and responding to nonverbal signs of anger, avoidance, defensiveness, and fear. The amygdala has been implicated in emotional dysregulation, aggressive behavior, and psychiatric illnesses such as depression. It has also been shown to play an important role in the formation of emotional memory and in temporal lobe epilepsy.

The hippocampus is a horseshoe-shaped region that is involved in short-term memory storage and retrieval. Human capacity for these functions undergoes marked changes from ages 4 to 18 years. However, the relationships between changes in these abilities and changes in brain morphology are not well understood. New memories are kept in the hippocampus before being transferred to the cerebral cortex for permanent storage. This may explain why people with brain damage to their hippocampal region retain previous memories of faces and places, which are stored in the cortex, but have difficulty forming new short-term memories. The hippocampus is also implicated in the learning and remembering of space (spatial orientation). Animal studies show that damage to the hippocampus results in the inability to navigate through familiar areas. In humans, hippocampal damage results in a failure to remember spatial layouts or landmarks. Following stroke damage to the parahippocampus, patients lose the ability to learn new routes or to travel familiar routes.

During adolescence the size of the amygdala increases sharply for males and less sharply for females. In contrast to the amygdala, the hippocampus increases more robustly in adolescent females. These sex-specific maturational patterns are consistent with nonhuman primate studies that have found a predominance of androgen receptors in the amygdala and a predominance of estrogenic receptors in the hippocampus.

Other lines of evidence also support the influence of estrogen on the hippocampus. Female rats that have had their ovaries removed have a lower density of dendritic spines and decreased fiber outgrowth in the hippocampus, which can be alleviated with hormone replacement. In humans, smaller hippocampi have been reported in women with gonadal hypoplasia, and a recent MRI study of 20 young adults found relatively larger hippocampal volumes in females.

In addition to receptors for gonadal steroids, the hippocampus and amygdala are rich in receptors for adrenal steroids, thyroid hormone, and nerve growth factor. In addition to direct effects on hippocampal development, estrogen may influence development by blocking neurodegenerative effects of glucocorticoids.

The intricacy of various neurochemical systems and the diversity of afferent and efferent connections to the many distinct nuclei of most brain structures make straightforward relationships between volumes of a single structure and performance on a particular cognitive task uncommon. One of the rare exceptions to this rule is the relationship between hippocampal size and memory function. Birds that store food need better memory than their non-food-storing counterparts and correspondingly have larger hippocampi. Likewise, male polygamous prairie voles travel far and wide in search of mates and have significantly larger hippocampi and perform better on laboratory measures of spatial ability than their female counterparts. In the monogamous vole species, which do not show male-female differences in spatial ability, no sexual dimorphism of hippocampal size is seen. Correlations between memory for stories and left hippocampal volume in humans have also been noted.

Anomalies of temporal lobe and medial temporal lobe structures have been reported for a variety of psychiatric disorders, including affective disorders, autism, and, most consistently, schizophrenia, which is increasingly understood as a neurodevelopmental disorder. These disorders have marked sex differences in age of onset, symptomatology, and risk factors. The sex-specific maturational differences may have relevance to the expression of these disorders.

IV. WHITE MATTER

Unlike the nonlinear regionally specific changes in gray matter during adolescence, white matter volume increases linearly with age in all lobes. The net increase across ages 4–22 is approximately 12% (Fig. 2). In addition to volumetric changes in white matter, the density of white matter increases particularly in language-relevant left frontotemporal pathways.

V. CORPUS CALLOSUM

The linear increases in lobar white matter parallel increases for the major white matter tract in the brain, the corpus callosum. The corpus callosum is a bundle of approximately 200 million nerve fibers connecting the left and right hemispheres of the brain. Most of the fibers are myelinated and most connect homologous areas of the cortex. The corpus callosum integrates the activities of the left and right cerebral hemispheres. It combines information from bilateral sensory fields, facilitates memory storage and retrieval, allocates attention and arousal, and enhances language and auditory functions. Efficiency of interhemispheric integration has been linked to creativity and intelligence and becomes more crucial as task difficulty increases. Capacities for these functions improve during childhood and adolescence, making morphologic changes in the corpus callosum during these ages intriguing.

The myelinated fibers of the corpus callosum make it particularly easy to see on midsagittal MR images, which along with its clinical interest have made it a common target of investigations. The corpus callosum is arranged in an approximately topographic manner, with anterior segments containing fibers from the anterior cortical regions, middle segments containing fibers from the middle cortical regions, and so on. Progression of corpus callosum development continues throughout adolescence, and corpus callosum anomalies have been reported in several childhood disorders. Sexual dimorphism of the corpus callosum remains a controversial topic, with some reports indicating sex differences and many others no differences.

VI. VENTRICLES

The ventricles are the cerebrovascular fluid-filled cavities of the brain. Lateral ventricular volume increases about 30% between the ages of 4 and 20, with the greatest increase occurring before adolescence. There is not a significant gender difference in the shapes of the developmental curves.

VII. CEREBELLUM

Although the cerebellum has historically been viewed as a brain region primarily involved in the coordination of movement, an increasing number of neuropsychological, neurophysiological, and neuroimaging studies show that the cerebellum plays a role in higher cognitive function, language, and emotional control. The development of the cerebellum in childhood and adolescence demonstrates two unique characteristics compared to other structures quantified by MRI. First, it is the most sexually dimorphic, being robustly larger in males (Fig. 3). Second, cerebellar size is the least heritable. That is, its size is similar in monozygotic versus dizygotic twins. Also, it is relatively late maturing. These features imply that the cerebellum is particularly sensitive to environmental influences during critical stages of development.

VIII. CONCLUSIONS

Adolescence is a tumultuous time in the development of the brain. Although scientists are now able to observe and quantify anatomic changes, much work remains to be done in interpreting the changes and understanding the forces that shape and guide them. One hypothesis for what influences the adolescence gray matter pruning is the "use-it-or-lose-it" principle. According to this principle, those cells and connections that are used will survive and flourish, whereas those cells and connections that are not used will wither and die. If this theory is correct, then the activities of the teen would have a powerful influence on the ultimate "hardwiring" of the adult brain.

The sexual dimorphism of the developing brain is of particular interest in child psychiatry, in which nearly all of the disorders have different ages of onset, symptomatology, and prevalences between boys and girls. The extent to which the sex differences in healthy brain development interact with other genetic and environmental effects to account for some of these clinical differences between boys and girls is an active focus of study.

Future directions of adolescent brain imaging are likely to include studies of identical and nonidentical twins, longitudinal studies, and the use of new tools such as functional MRI and diffusion tensor imaging.

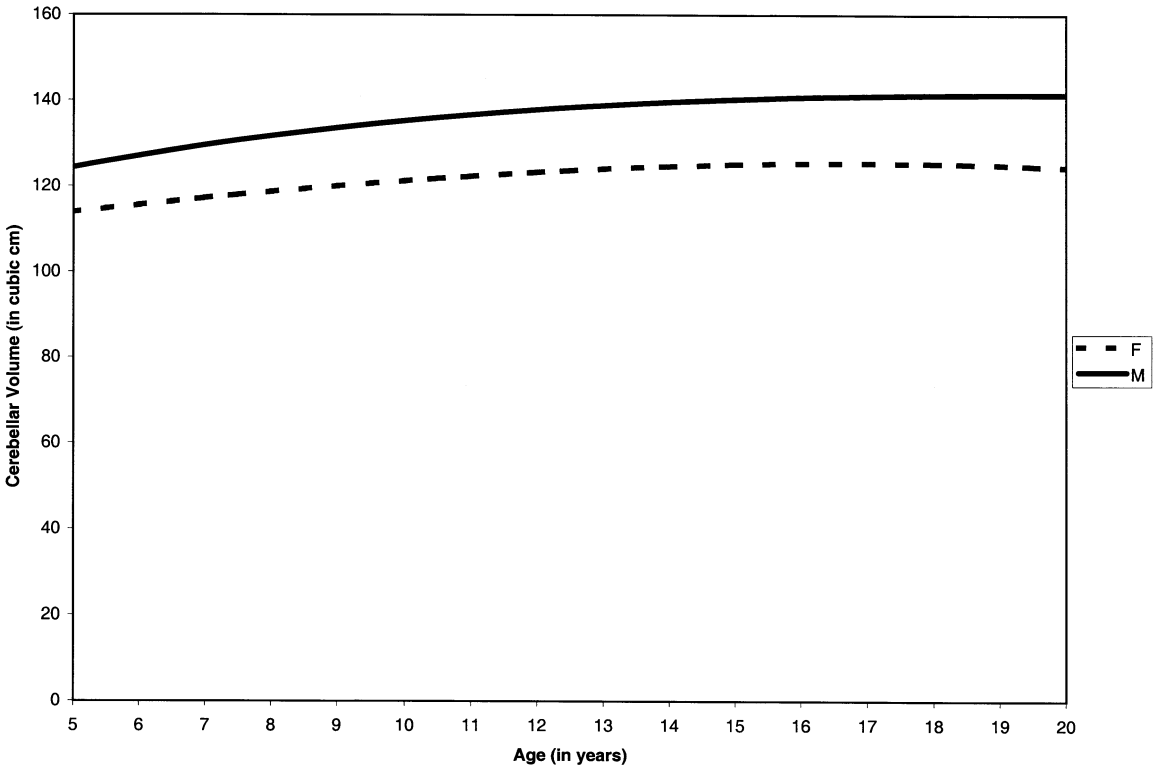

Figure 3 Cerebellar growth curves based on 145 individuals (243 scans).

Understanding the nature and influences of brain changes during childhood and adolescence may help parents, teachers, society, and teens take steps to optimize the development of the brain.

Aggression

JEFFREY L. SAVER
University of California, Los Angeles

GLOSSARY

amygdala Almond-shaped neuronal structure located in the inferomesial temporal lobe, anterior to the hippocampus, a component of the limbic system.

hypothalamus Neuronal structure constituting the inferiormost component of the diencephalon, connected with the pituitary gland via the infundibular stalk, and intimately concerned with visceral, autonomic, and endocrine function.

impulsivity Prone to act rashly; unable to resist urges.

prefrontal cortex Cortical sectors in the frontal lobe anterior to the motor strip.

sham rage A state in which an animal deprived of all cortical, or bilateral amygdaloid, input reacts to stimuli with behavioral displays of extreme anger.

violence The forceful infliction of physical injury on another individual or object.

Aggression is physical or verbal behavior that is threatening, destructive, or intended to harm. Aggression is a fundamental component of social behavior, essential to drive fulfillment and survival. Aggressive behavior in humans may be broadly divided into at least two phenomenological forms, an irritable–impulsive–affective subtype and a controlled-instrumental predatory-instrumental subtype. Each subtype is likely controlled by distinct, albeit overlapping, neuroanatomic and neurochemical substrates.

I. NATURE AND NURTURE IN AGGRESSIVE BEHAVIOR

Attempts to understand the brain basis of human aggression have often been thwarted by the outmoded dichotomies of nature versus nurture. Cultural and social influences are of critical importance in the genesis of human aggressive behavior. Violence may be motivated by the highest political and religious ideals and promoted and reinforced by cultural and governmental authorities. However, every violent behavior, whether springing from the most elevated or the basest of impulses, requires a neurobiological substrate to orchestrate the complex array of perceptual, motor, and autonomic components of acts that constitute aggressive conduct.

Recent developmental studies demonstrate that nature and nurture are closely intertwined in the genesis of aggressive behaviors. Early life experiences strongly shape an adult's regulation of aggressive

conduct. Large-scale cohort studies demonstrate that key environmental variables promoting the development of repeatedly violent individuals include rearing in disordered households, physical abuse in childhood, sexual abuse in childhood, and social deprivation. However, these environmental influences interact with an individual's biological vulnerabilities. Twin and adoption studies suggest that genetic factors control half the variation in propensity to oppositional temperament (angry, vindictive, and resistant to control), lack of empathy (callousness), and impulsivity, and each of these traits increases the risk of chronically violent behavior. Longitudinal cohort studies may be summarized as demonstrating that most violent children do not become violent adults, but that most violent adults were violent children. These observations indicate that although biological vulnerabilities are critical to the genesis of adult aggressive behavior, social interventions early in life can often avert the development of chronically violent behavior in adulthood. Recent studies tie nature and nurture together even more directly, demonstrating in nonhuman primates and in humans that early life social deprivation and adverse events can alter brain seroternergic systems, reshaping the neural systems for regulation of hostile behaviors.

Patients with acquired brain lesions represent a distinctive, and informative, population. When focal injuries disrupt the neural networks that regulate aggression, hostile behaviors may appear that have no relevant developmental or environmental precipitant or only minimal social provocation. More often, damage to neuronal systems controlling assertive behavior leads not to random acts of overt aggression but to alterations in temperament and inappropriate choices of targets and settings for aggressive behavior. Studies correlating loci of focal injury and patterns of altered aggressivity afford unique insights into the neural architecture responsible for implementing and inhibiting hostile behavior.

II. AN INTEGRATIVE NEUROSCIENCE APPROACH TO AGGRESSION

An overly simplified concept of "organicity" has been an additional obstacle to past attempts to understand the brain substrates of human aggression. Explicitly or implicitly, some investigators have suggested that neurologic insults produce a unitary "organic aggression syndrome," posessing stable, invariant behavioral features independent of lesion location or lesion type. In most formulations, this stereotypic organic aggression syndrome is postulated to lower a general threshold for aggression or to result in episodic dyscontrol. This view is imprecise, obscuring fundamental evolutionary, neurochemical, neurophysiologic, and behavioral distinctions among discrete aggression-related neural circuits in the brain stem, diencephalon, limbic system, and neocortex. This article instead advances an integrative neuroscience perspective, drawing on converging sources of evidence from evolutionary studies, ethology, neurophysiology, pharmacology, and clinical neuroscience to delineate a multiregional, hierarchical model of the neural regulation of aggression.

III. EPIDEMIOLOGY

Aggression is common among neurologically normal individuals and in diverse populations of brain-injured individuals. Homicide is the second most common cause of death among young adults and the 12th leading cause of death at any age in the United States. One population-based survey suggested that 3% of individuals commit violent acts annually, with a lifetime prevalence of 24%. However, other studies suggest that 94% of parents in the United States physically punish their toddlers, 11–17% of husbands physically hit their wives, and 11% of wives physically hit their husbands. Up to 40% of individuals admitted to psychiatric wards of general hospitals are violent immediately before admission, and up to 37% assault staff or patients during their hospitalization. Relatives of individuals with traumatic brain injury identify temper and irritability as major behavioral difficulties in 70% of patients. Imprisoned criminals evidence schizophrenia, major depression, and manic-depressive disorder at twice the rate of the general population.

IV. EVOLUTIONARY PERSPECTIVES

Aggression serves vital, evolutionarily adaptive functions. Along with the fundamental drives of fear, hunger, sexual desire, and social affiliation, adaptive aggression is present throughout the order Mammalia, triggered by environmentally appropriate and highly specific stimuli. Agonistic behavior to obtain food,

defend a territory, win a mate, or protect offspring is essential for the survival of the individual and for propagation of its genetic material.

Recent formulations of evolutionary theory suggest that competitive selection fosters the development of closely regulated and intertwined aggressive and affiliative behaviors. Unregulated, wanton aggression would rapidly reduce support among an organism's conspecifics and impair reproductive success. Conversely, uniformly submissive and avoidant behavior would prevent an organism from gaining access to critcial resources. Selection pressures on social behavior consequently tend to favor evolutionarily stable strategies with which an organism may variably express either aggressive or affiliative behaviors, depending on the state of several variables at the moment of a particular encounter with conspecifics, including its past interactions with that individual, position in dominance hierarchies, age, strength, and the general availability of environmental resources. In social primates the need for precise neural regulation of aggression is particularly advanced compared with that of species that lead a more solitary existence.

One domain in which the influence of natural selection may be clearly discerned is in the principles of outward display of aggressive and submissive signaling among conspecifics that recur in invertebrates, dogs, cats, primates, and humans. Emotional displays are highly stereotyped and opposing emotions are frequently conveyed by antagonistic postures, promoting accurate communication of an organism's emotional state. Darwin was the first to suggest that human facial expressions originated from postures associated with adaptive actions among mammalian forebears. He proposed that the sneer, an expression of anger, evolved from the baring of the canine teeth prior to a biting attack. Over time, fighting postures expressed in the body and facial musculature come to signal the threat, rather than solely the enactment, of attack. Inhibition of the neuronal assembly triggering an aggressive posture and activation of neurons enabling opposing postures conveys the opposite emotion of friendliness or submissiveness. The substantial role of subcortical neuromodulators, such as norepinephrine, acetylcholine, and serotonin, in modifying aggressive propensities in humans likely developed from their phyologenetically ancient function in promoting relevant peripheral skeletal and autonomic processes relevant to conspecific displays. From these origins a complex affective communication system developed, hardwired at its lowest neuronal level of implementation, regulated by higher centers that moderate the timing and intensity of display.

The complexity of neural regulation of aggression in mammals is driven in part by the existence of several distinct subtypes of aggressive behavior. For each subtype, aggressive acts are triggered, targeted, promptly terminated, and specifically inhibited by distinct classes of environmental stimuli. Ethologists have advanced several typologies of aggressive behavior, with each class demonstrating a specific outward display and set of determining stimuli. Moyer's widely recognized classification scheme divides hostile behavior into predatory, territorial, intermale, maternal, defensive, fear-induced, irritable, and instrumental subtypes (Table I). In various animal models, neuronal recording and lesion studies have identified important loci participating in neural networks controlling these discrete assertive behaviors (Table II). Evidence for broadly similar clustering of aggressive behaviors into an impulsive–reactive–hostile affective subtype and a controlled–proactive–instrumental–predatory subtype has been reported among violent children, psychiatric patients, and perpetrators of murder.

Table I
Behavioral Classification of Aggression

Type	Eliciting stimulus	Form
Predatory	Natural prey	Efficient, little affective display
Territorial	Boundary crossing	—
Intermale	Conspecific male	Ritualized responses
Fear induced	Threat	Autonomic reactions, defensive behaviors
Maternal	Distress calls, threat to offspring	Initial attempts to avoid conflict
Irritable	Frustration, deprivation, pain	Hyperactivity, affective display
Instrumental	—	—

Table II
Neuroanatomic Correlates of Aggressive Behavior Subtypes in Experimental Animals[a]

Triggers	Suppressors
Predatory offensive aggression	
Anterior hypothalamus	Prefrontal cortex
Lateral hypothalamus	Ventromedial hypothalamus
Lateral preoptic nuclei	Basolateral amygdala
Ventral midbrain tegmentum	Mammillary bodies
Ventral midbrain	
Ventromedial periaqueductal gray matter	
Intermale (competitive) aggression	
Laterobasal septal nuclei	Dorsolateral frontal lobe
Centromedial amygdala	Olfactory bulbs
Ventrolateral posterior thalamus	Dorsomedial septal nuclei
Stria terminalis	Head of caudate
Fear-induced aggression	
Centromedia amygdala	Ventromedial hypothalamus
Fimbria fornix	Septal nuclei
Stria terminalis	Basolateral amygdala
Ventrobasal thalamus	Ventral hippocampus
Maternal–protective aggression	
Hypothalamus	Septal nuclei
Ventral hippocampus	Basolateral amygdala
Anterior hypothalamus	Frontal lobes
Ventromedial hypothalamus	Prefrontal cortex
Dorsomedial hypothalamus	Medial prepiriform cortex
Posterior hypothalamus	Ventromedial hypothalamus
Anterior cingulate gyrus	Head of caudate
Thalamic center median	Dorsomedian nucleus of thalamus
Ventrobasal thalamus	Stria terminalis
Ventral hippocampus	Dorsal hippocampus
Ventral midbrain tegmentum	Posterior cingulate gyrus
Ventromedial periaqueductal gray matter	Periamygdaloid cortex
Cerebellar fastigium	
Sex-related aggression	
Medial hypothalamus	Septal nuclei
Fimbria fornix (male)	Fimbria fornix (female)
Ventral hippocampus	Cingulate gyrus
	Dorsolateral amygdala

Whereas in simple organisms neurohormonal mediation of aggressive–submissive postures may suffice for regulating hostile behavior, in social mammals and especially primates, the need for flexible and precise control of aggressive and other emotional behaviors has propelled the evolution of hierarchic levels of intermediate and higher neural circuitry. In general, nervous system evolution, like somatic evolution, proceeds not by replacing existing structures but by modification and addition of subtler levels of control over older structures—evolution by tinkering. The human brain has developed through a progressive elaboration of neural elements surrounding the brain stem core found in less complex organisms. In the regulation of emotion, more recently evolved limbic, paralimbic, and neocortical components of the nervous system have established anatomic and physiologic controls over brain stem and primary cortical structures that implement autonomic, endocrine, and motoric somatic states.

Discrete structures controlling drives exist at each level of the neuraxis, mediating between sensory and motor systems. Relatively simple protoreptilian nervous system regulatory mechanisms persist in the human brain at the level of the brain stem and hypothalamus. Limbic structures provide a second critical level of control in the mammalian brain, each projecting directly to the hypothalamus. The frontal neocortex constitutes a third level, greatly expanded in higher primates, that modulates both limbic and hypothalamic output. These levels are functionally distinctive, with characteristic inputs (afferent circuitry), outputs (efferent circuitry), and functional organization, providing varying representations of the internal milieu and external environment (Fig. 1).

Neurons controlling such basic drives as feeding and reproduction are closely associated at each anatomical site. Circuitry regulating aggression, often an instrumental response in the service of these drives, is localized in adjacent regions. Because of this anatomical juxtaposition, dysregulation of aggression caused by brain injury is frequently accompanied by simultaneous abnormalities in feeding and sexual behavior.

V. BRAIN STEM REGULATION OF AGGRESSION

Pontine and mesencephalic nuclei coordinate full-fledged aggressive behaviors in rodents but only fragments of aggressive behavior in primates. Inputs

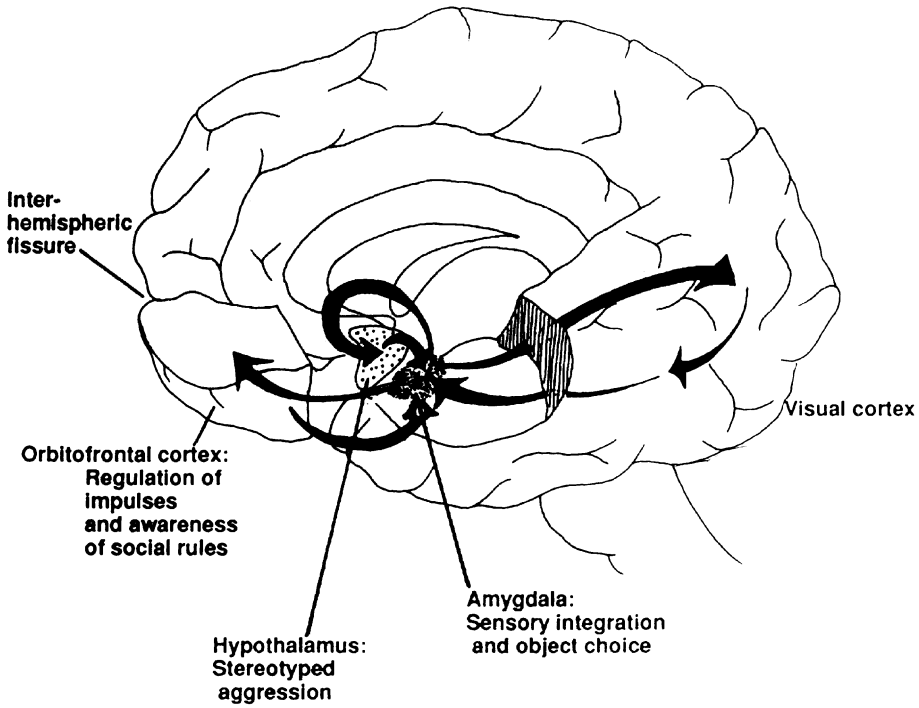

Figure 1 Critical sites in the hierarchical, multiregional neural system regulating aggression. Portions of the left temporal and orbitofrontal regions are cut away in this midsagittal view of the human brain to optimize visualization. [Reproduced with permission from Saver *et al.*, 1996, Neuropsychiatry of aggression. In: *Neuropsychiatry: A Comprehensive Textbook* (Fogel, B. S., Schiffer, R. B., Rao, S. M., Eds.) p. 532. Williams & Wilkins, Baltimore].

to the system include spinoreticular proprioceptive and nociceptive sensory circuits. Outputs incorporate pontine (facial) and descending motor centers, leading to stereotypic movements. Electrical stimulation of upper brain stem nuclei in subhuman primates produces different fragments of aggressive facial expressions and vocalizations, dissociated from offensive or defensive behavior. Other brain stem circuits contribute to somatomotor patterns for gestures and approach and avoidance behaviors. Medullary sympathetic and parasympathetic nuclei exert direct autonomic effects on cardiovascular, respiratory, and gastrointestinal peripheral organ systems. In humans, however, full-fledged aggression-related behavior patterns are not produced at the brain stem level. Response coordination and decision making are carried out at higher processing stations. As a result, brain stem lesions, although sometimes disturbing fragments of aggressive behavioral output, generally do not produce major syndromes of altered aggressivity.

However, an important clinical aggression syndrome does arise from disruption of brain stem regulation of sleep–wake states—the rapid eye movement (REM) sleep behavior disorder. In normal individuals, neurons in the vicinity of the locus ceruleus actively inhibit spinal motorneurons during REM sleep, preventing the expression of motor programs being actively generated in the motor cortex. In the cat, bilateral pontine tegmental lesions compromise REM sleep muscle atonia, permitting the enactment of oneiric behaviors, including frequent biting and other attack conduct. In humans, focal or degenerative lesions in the pontine tegmentum similarly produce the REM sleep behavior disorder, in which affected individuals physically perform their dream movements. Although normal dreaming subjects report an extremely diverse array of movements and activities fictively performed in dreams, violent actions comprise the overwhelming preponderance of behaviors actually enacted by individuals with REM sleep behavior disorder. Most commonly, middle-aged men experience a violent dream in which they are attacked by animals or unfamiliar people. In response, the dreamer engages in vigorous, coordinated motor acts that are often violent in nature. Individuals may

jump off the bed, smash furnishings, or attack their bed partner, with frequent resulting injury to both patient and spouse. It is likely that aggressive responses generated in the forebrain during REM dreaming produce more powerful descending motor outputs than feeding, sexual, or other drive-related activities and disproportionately override the partial residual muscle atonia in these patients.

VI. HYPOTHALAMIC REGULATION OF AGGRESSION

The human hypothalamus receives inputs conveying information regarding the internal state of the organism through chemoceptors, osmoceptors, and viscerosensory cranial nerves. In contrast to these rich sources of interoceptive data, the hypothalamus does not directly receive sensory input regarding the external world from primary or association sensory cortices. Important outputs of the hypothalamus are to the pituitary gland through releasing factors and directly transported peptides, to the autonomic nervous system, for which it serves as "head ganglion," and to midbrain and spinal motor centers that coordinate stereotypic movements.

In controlling biological drives, the hypothalamus employs a functional decision-making strategy of hardwired antagonism of excitatory and inhibitory nuclei. Algebraic, neurophysiologic comparison of biochemically coded inputs leads to either graded and homeostatic or threshold, stereotypic all-or-none responses. These characteristics are illustrated by the reciprocally active lateral and medial hypothalamic centers controlling hunger and satiety. In rodents, stimulation of the lateral hypothalmic area initiates feeding, and ablation may lead to starvation; stimulation of the ventromedial hypothalamus terminates eating, and lesions produce obesity. These hardwired systems generate predictable responses independent of the animal's experience.

Numerous studies in animals suggest that the priniciple of threshold elicitation of stereotypic response similarly characterizes hypothalamic control of aggression. In cats, when neural structures rostral to the hypothalamus are destroyed, the decorticate animals periodically produce rage displays with little or no provocation, exhibiting hissing, piloerection, pupil dilation, and extension of claws. Direct electrical stimulation of the posterior lateral hypothalamus reliably elicits this "sham rage" in animals that have undergone cortical ablation. In the intact feline and rodent brain, stimulation of the posterior lateral hypothalamus shortens the latency for species-specific predatory attack. Instillation of acetycholine or cholinomimitic drugs in the lateral hypothalamus similarly facilitates attack behavior, promoting biting attacks of a cat on a rodent, or a rat on a mouse or frog, even by previously docile animals. Injection of cholinergic antagonists will eliminate biting attacks, even among usually aggressive felines and rodents. Conversely, ventromedial hypothalamic stimulation inhibits rather than facilitates aggressive behaviors and may promote assumption of a defensive posture. Bilateral ablation of the ventromedial nucleus increases the overall level of aggression in operated cats, including unprovoked attacks by previously friendly animals on their caretakers.

Clinical observations in humans suggest a broadly similar role for the hypothalamus in human aggression. Neoplasms that destroy the ventromedial hypothalamic area bilaterally are associated with attacks on caregivers reminiscent of animal aggression following ventromedial lesions. In the classic report of Reeves and Plum, a 20-year-old woman developed bulimia and obesity, amenorrhea, diabetes insipidus, and profound behavioral change. Over a 2-year period, she displayed outbursts of aggression characterized by indiscriminately scratching, hitting, or biting examiners who approached. She denied experiencing angry or vindictive internal feelings toward these individuals and expressed surprise and regret regarding her attacks. The outbursts tended to occur more frequently when she had not eaten for several hours, suggesting the emergence of predatory-like aggression. Postmortem examination revealed a hamartoma destroying the ventromedial hypothalamus. In another case report, a patient with bilateral hypothalamic lesions exhibited aggressive outbursts that appeared to be influenced by seasonal light levels, erupting more often in dark, winter months. These and other clinical cases suggest that in the human brain the hypothalamus plays an important role in the setting of a threshold for aggressive responses.

VII. AMYGDALA AND TEMPOROLIMBIC CORTEX REGULATION OF AGGRESSION

In contrast to the hypothalamus, the amygdaloid complex is reciprocally connected with multiple

cortical sensory systems capable of conveying highly processed information regarding the external world. Rich connections are established with a variety of both unimodal and polymodal sensory regions, such as the perirhinal cortex and the superior temporal sulcus, allowing convergence of information from visual, auditory, tactile, and gustatory cortices. The basolateral amygdala receives extensive projections from unimodal visual cortices in the inferotemporal cortex (such as area TE in primates) that are specialized for recognizing objects such as faces in central vision. Extensive intrinsic connections within the amygdala promote further coordination of sensory information.

Important outputs from the amygdala in primates are to the hypothalamus, through the stria terminalis and ventral amygdalofugal pathway; to brain stem centers controlling heart rate and respiration through the central nucleus projection pathway; and to the extrapyramidal motor system, especially the ventral striatum, also through the stria terminalis and ventral amygdalofugal pathway.

The amygdala appears to provide a critical link between sensory input processed in the cortical mantle to produce a model of external reality and hypothalamic and somatomotor centers evoking pain, fear, and other basic drive–related emotions. Many observations in animals and humans suggest that a fundamental function performed by the amygdaloid complex and related temporolimbic structures is linking perceived objects with appropriate emotional valences. The result is a qualitative steering of behavior rather than quantitative regulation of threshold. On the basis of prior experience, sensory–emotional associations direct consummatory behavior to appropriate targets in the external world.

The importance of the amygdaloid complex in the recall of the affective signficance of stimuli is demonstrated by the drive–object dysregulation of the Kluver–Bucy syndrome observed in animals when the amygdala (and often overlying temporal neocortex) are removed bilaterally. Monkeys with such lesions engage in a continuous olfactory and oral exploration of their environment in which each object evokes the same response of tasting and sniffing as though the monkeys had never encountered it. The animals fail to distinguish food from inedible objects and eat metal bolts and feces as readily as normal dietary items. Animals have difficulty distinguishing appropriate from inappropriate sexual partners; similarly, lesioned cats will attempt copulation with chickens or other animals. These results suggest that lesioned animals cannot identify particular objects as being appropriate or inappropriate to satisfy hypothalamic drives.

The effects of bilateral amygdalectomy on aggressive behavior are consistent with such a hypothesis. Amygdala removal results in taming and placidity in most animals. Objects that previously evoked signs of fear or provoked attack appear to lose their past associations. Monkeys no longer behave aggressively toward experimenters, becoming docile and easy to handle. Unilateral amygdalectomy with lesions of all commissural pathways produces taming when stimuli are presented to the operated hemisphere but appropriate hostile responses when the stimuli are displayed to the unoperated hemisphere. However, amygdalectomy in submissive monkeys has led to a maintained or increased level of aggression, consonant with the view that the fundamental effect of amygdalectomy on aggression is not a change in aggressive threshold but a modification of previously acquired patterns of linking stimuli with aggressive responses. Fundamentally appetitive drives, such as feeding and reproduction, are released onto inappropriate targets. An instrumental drive such as aggression is no longer elicited or suppressed according to past, learned responses of the animal.

In humans, extensive bilateral temporolimbic damage produces behavior that is similar to that of lesioned monkeys, frequently accompanied by amnesia, aphasia, and visual agnosia (Fig. 2). Patients may engage in indiscriminate oral and tactile exploration of their environment (hyperorality and hypermetamorphosis) and change their sexual preferences. Affected individuals exhibit a flattened affect and report diminished subjective emotional responses to stimuli. Aggressive behaviors become uncommon, and apathy with lack of either strongly positive or negative responses becomes the rule. In one series of 12 patients with acquired Kluver–Bucy syndrome, placidity was noted in all. Functional imaging and lesion studies in humans suggest that the amygdala plays a critical role in processing of perceived threat stimuli. Fearful responses to threatening faces and objects are diminished in individuals with lesions largely confined to the amygdala bilaterally. A group performing bilateral amygdalotomies in aggressive patients reported that among 481 cases, approximately 70% showed a reduction in either restlessness or destructiveness, and one-half of these remained placid even when purposefully provoked.

The first reported case of the Kluver–Bucy syndrome in humans illustrates the characteristic clinical picture. A 19-year-old man sequentially underwent left

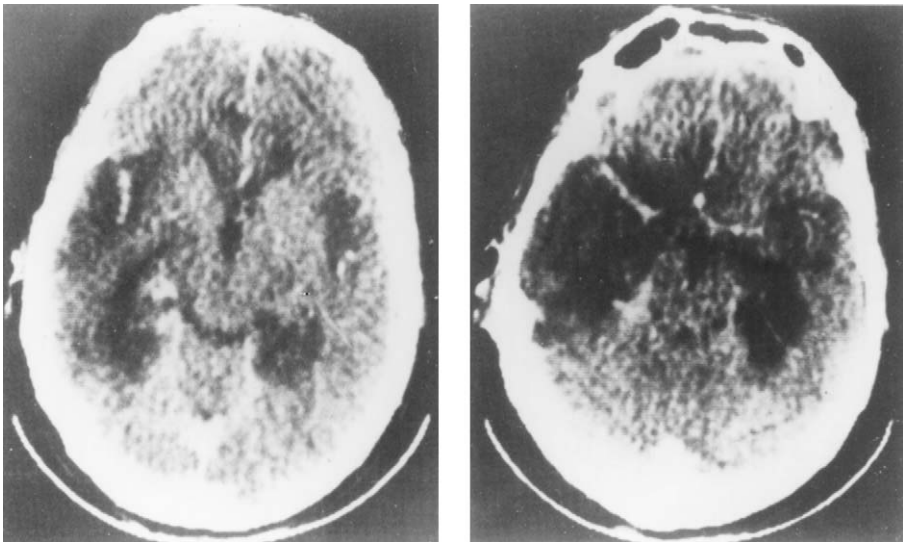

Figure 2 Bilateral temporolimbic lesions from herpes simplex encephalitis producing Kluver–Bucy syndrome including hypoaggression (passivation). This 42-year-old man was apathetic, indifferent, and impassive. In addition, he constantly manipulated and frequently mouthed objects, made sexual propositions to staff, especially men (prior to his illness he had been heterosexual), and exhibited severe anterograde amnesia and visual agnosia. CT axial images demonstrate large right temporal and smaller left mesial temporal hypodense lesions (reproduced with permission from S. Bakchine, F. Chain, and F. Lhermitte, 1986, *Rev. Neurol.* **142,** 126–132. © Masson Editeur).

and then right temporal lobectomies for treatment of a refractory seizure disorder accompanied by frequent outbursts of violent behavior. Following the second operation, he demonstrated dramatic behavioral changes, including compulsive manual manipulation of objects in the environment, insatiable appetite, sexual exhibitionism with frequent masturbation, severe retrograde and anterograde amnesia, and prosopagnosia. The reporting physicians were particularly surprised by a new placidity and the resolution of his previously aggressive behavior:

> *He no longer manifested the slightest rage reactions toward the nurses and doctors, upon whom, before the second operation, he used to rush as soon as they came into sight. The patient, on the contrary, now assumed an extremely childish and meek behavior with everyone and was absolutely resistant to any attempt to arouse aggressiveness and violent reactions in him.*

Related, modality-specific alterations in aggressive responding appear when bilateral lesions spare the amygdaloid complex but selectively interrupt pathways linking unimodal cortical sensory processing areas with the temporolimbic region. Stimuli presented solely within the sensory modality disconnected from the amygdala then fail to evoke learned associations, but stimuli that may be processed through other sensory channels elicit normal responses. One reported case of modality-specific limbic disconnection concerned a 39-year-old college graduate who suffered severe brain injury in a motorcycle accident. Computed tomography (CT) scans demonstrated bilateral cerebral hemorrhages in the inferior occipitotemporal region, interrupting visual input to polar and mesial temporolimbic structures. In addition to right hemiparesis, left hemidystonia, and prosopagnosia, he exhibited visual hypoemotionality—a diminished ability to react affectively to visual stimuli. A former assistant city planner, he was no longer moved by aesthetic differences between buildings. He ceased hiking because he now found natural scenery dull. He complained of total loss of emotional reaction to seeing attractive women in everyday encounters and to erotic visual stimuli. However, he maintained a strong interest in music, to which he listened almost constantly. He could be sexually aroused by verbal–auditory stimuli and derived pleasure from touching and being touched. This modality-specific limbic disconnection extended to fear and aggressive responses. In laboratory testing, when exposed to a series of slides, he rated as neutral and unemotional threatening images such as a gun and a snake, which normal controls scored as negative and highly arousing.

An intriguing contrast to the behavioral alterations that result from removal of the temporal lobes is provided by a far more common clinical condition, temporal lobe epilepsy, in which abnormal neuronal excitability develops within temporolimbic cell populations. Within the temporal lobe, the amygdaloid complex is particularly sensitive to the phenomenon of kindling, in which repeated stimulation of neurons leads to a progressive lowering of the threshold for discharge. Because many processing pathways converge on the amygdala, activity of epileptic foci throughout and beyond the temporal lobe can affect amygdalar excitability. The resulting enhancement of amygdaloid activity may, in a general sense, be the converse of the decreased activity underlying Kluver–Bucy syndrome.

In normal animals, individual amygdaloid neurons respond selectively to biologically significant food and social stimuli. Kindling may lead to long–term changes in limbic physiology that alter and enhance aggressive and other emotional responses to both drive–related and neutral stimuli. Rather than losing previously acquired associations between sensory stimuli and drives, some temporal lobe epilepsy patients appear to forge new, fortuitous associations. Rather than a lack of emotional response to stimuli, they exhibit deepened and generalized affective associations.

Interictal behavioral changes consistent with this model have been observed in a subset of patients with temporal lobe epilepsy. These individuals exhibit a cluster of interictal behaviors that have been labeled the Geschwind–Gastaut syndrome, encompassing deepened emotions, a sensitivity to moral issues, often with religious and philosophical preoccupations, and hypergraphia—a tendency to write about these subjects at great length. As a consequence of strongly felt emotions, these individuals may become highly sensitive to slights or violations of principle and experience intense anger. These patients' strong moral and philosophical beliefs often preclude violent acts. However, if they do act aggressively, their behavior typically is performed in clear consciousness and often followed by sincere regret.

In an illustrative case, a 40-year-old man developed complex partial seizures in his 20s, characterized by fear followed by flushing, tachycardia, and loss of consciousness. He had suffered febrile seizures in childhood. Electroencephalography (EEG) showed bilateral temporal discharges, and pneumoencephalography demonstrated a dilated temporal horn of the left lateral ventricle. His interictal behavior was remarkable for extreme seriousness with virtually no sense of humor and a sensitivity to infractions of minor military procedures. When fellow servicemen lightheartedly violated minor rules, he would attempt to reason with them. However, he became incensed by their failure to appreciate his concerns, and brawls often ensued. The patient was enraged when sentenced to a military stockade for 1 week, especially because his elaborate ethical justification for his actions was not taken seriously. To indicate his anger, he destroyed plumbing fixtures in his cell and subsequently threatened to kill the magistrate whom he believed had treated him unfairly.

Following release and neuropsychiatric treatment, his temper became better controlled as he developed strong religious and philosophical convictions that prohibited violence. Nonetheless, several years after overt violent behavior had ceased, he told an examiner, "I have more of a problem with anger than anybody I have ever met in my life." He described a constant internal tension between feelings of being treated unjustly and a sincere desire not to harm another individual. Other aspects of his behavior consistent with the interictal behavior syndrome included evangelical religiosity, extensive and detailed writing, and inappropriately prolonged encounters with fellow patients and caretakers (enhanced social cohesion/viscosity).

VIII. PREFRONTAL CORTICAL REGULATION OF AGGRESSION

The dorsolateral prefrontal cortex receives extensive afferents from multiple posterior neocortical association areas, including dense connections with the inferior parietal lobule, a region responsible for surveying extrapersonal space for relevant stimuli. The orbitofrontal cortex is reciprocally connected to the rest of the neocortex principally via the dorsolateral convexity of the frontal lobe. Projections from the hypothalamus through the dorsal medial nucleus of the thalamus and from the rostral temporal lobe through the uncinate fasciculus inform the frontal lobes of both internal (hypothalamus) and external (neocortical association to temporal lobe) stimuli of affective significance.

The prefrontal cortex has direct outputs to the pyramidal motor system, the neostriatum, temporal neocortex, and the hypothalamus. Schematically, prefrontal cortices appear to integrate a current account of the outside world, the state of the internal

milieu, and the recognition of drive-relevant objects with knowledge of learned social rules and previous experiences relating to reward and punishment. The prefrontal cortex may play a particularly important role in both working memory and social modeling, maintaining an abstract representation of the world that allows anticipation of the effects of one's actions on other individuals and the likely consequences of such actions. The prefrontal cortices construct a behavioral plan that is consistent with experience and especially the rules of socialization in order to optimize the satisfaction of biological drives.

The simplest summary of these complex functions in humans is judgment, which should not be simply equated with purely rational cost–benefit calculations that may be quite time-consuming and biologically uneconomical. Rather, it has been proposed that, in selecting among alternative response options, prefrontal cortices are guided by internal, somatic state markers—physiological cues that allow rapid choice of previously rewarded, effective options. Damage to the dorsal convexity in humans results in a diminution of long-term planning and a state of apathy or indifference. On formal neuropsychological testing, shifting of response set and the ability to apply strategy to problem solving are impaired. In contrast, damage to the orbital undersurface of the frontal lobe has classically been described as resulting in superficial, reflexive emotional responses to stimuli in the immediate environment. Patients are impulsive, acting without foresight or consideration of the remote consequences of their actions. Orbital frontal lesions thus lead to episodes of transient irritability. Often, a patient strikes out quickly after a trivial provocation, with little consideration of social prohibitions limiting aggressive behavior or untoward future consequences. The targets of aggression are categorically appropriate, but patients are unable to apply abstract rules that would override the immediate environmental provocation.

Numerous case reports illustrate the tendency of patients with orbitomedial frontal injuries to act impulsively, without regard to long-term consequences or sustained courses of action. Most well-known is the paradigmatic case of Phineas Gage, a railroad worker who suffered an injury primarily to the left orbitomedial frontal lobe when an explosion projected a tamping rod through his skull. Subsequently, in the words of his physician, "he was no longer Gage." Previously a temperate, hardworking individual, he became "disrespectful," "irreverent," and "profane." He rejected all attempts to restrain him from satisfying desires of the moment but rapidly abandoned plans he made to achieve these desires.

In addition to detailed single case studies, case series of murderers have demonstrated a high incidence of frontal structural abnormalities on CT and magnetic resonance imaging (MRI), frontal hypofunction on position emission tomography (PET), and abnormal neuropsychologic performance on frontal systems tasks. Frontal ventromedial lesion location independently predicted aggression and violence among 271 America veterans who suffered penetrating head injuries in the Vietnam war.

Convergent evidence for a critical role of the orbitofrontal cortex in evoking internal somatic markers to regulating aggression is supported by studies of neurologically normal individuals with antisocial personality disorder and high psychopathy scale scores, who demonstrate diminished autonomic reactions to negative stimuli, decreased orbitofrontal activity in some functional imaging studies, and reduced prefrontal gray matter volumes on volumetric MRI studies.

IX. COMBINED LESIONS OF TEMPORAL AND FRONTAL LOBES

Some pathological processes tend to damage simultaneously multiple levels of neural circuitry critical to the regulation of aggression. The orbitofrontal surface and rostral temporal poles are particularly susceptible in closed head injuries, and conjoint lesions in the same patient are not uncommon. Temporolimbic epilepsy is a frequent sequel of both closed and open head injury.

Aggressive behavioral syndromes may result that have features associated with dysfunction of several brain regions. For example, as a result of brain trauma, a patient may, develop a temporolimbic epileptic focus as well as a contusion of the orbital frontal cortex. Such a patient can display the deepened emotions and anger associated with the interictal behavior syndrome as well as a failure to inhibit or modulate hostile responses typical of a frontal lesion. In one reported case, a young man suffered severe brain injury in a motor vehicle accident. Imaging studies demonstrated enlargement of the frontal and temporal horns of both lateral ventricles and EEG abnormalities were recorded over the right frontotemporal area. The patient displayed intermittent apathy suggestive of frontal lobe damage but also developed personality changes characteristic of the interictal behavior syndrome of

temporal lobe epilepsy. He had outbursts of extremely violent behavior and eventually attempted to murder his parents and former girlfriend. When questioned regarding his aggression, the patient failed to appreciate that his behavior might be distressing to others. PET studies provide further evidence for frontal and temporolimbic dysfunction in psychiatric patients and in violent criminals. In one study of eight repeatedly violent psychiatric patients, low metabolic rates were noted in prefrontal and medial temporal cortices. Similarly, in a study of 41 murderers, reduced glucose metabolism was noted in the prefrontal cortex, superior parietal gyrus, left angular gyrus, and corpus callosum, and reduced left hemisphere activity compared with right hemisphere activity was noted in the amygdala, thalamus, and medial temporal lobe. These differences were particularly pronounced among individuals classified as having performed affective, impulsive violence compared with planned, predatory violence.

Figure 3 Association of left hemisphere lesions with aggression. Template mapping of CT scan lesions in 18 consecutive stroke patients with violent aggressive outbursts demonstrates a preponderance of left hemisphere lesions, especially left frontal (reproduced with permission from S. Paradiso, R. G. Robinson, and S. Arndt, 1996, *J. Nerv. Mental Dis.* **184,** 750).

X. HEMISPHERIC ASYMMETRIES IN THE REGULATION OF AGGRESSION

Several lines of neuropsychological research suggest differences in left and right hemisphere specialization for the processing of emotion, including anger and aggression. The left hemisphere plays a greater role in decoding linguistically conveyed emotional information, and the right hemisphere is more important in processing nonverbal emotional cues, such as prosody and facial expression of emotion. Moreover, the right hemisphere may be more highly specialized for mediating emotional responses in general and negative emotional responses such as fear and anger in particular. These conclusions are supported by studies of functional asymmetry for verbal versus nonverbal expression of affect, verbal versus nonverbal decoding of affects expressed by others, and asymmetric facial expression of affect in patients with unilateral stroke, other asymmetric neurological injuries, and transient hemisphere inactivation during Wada testing and also in normal experimental subjects.

Studies in focal lesion patients suggest an important role of hemispheric specialization in the genesis of hostile behaviors. A case control study in focal stroke patients identified lesion location in the anterior, left hemisphere as a predictor of aggressive behavior, independent of the presence of depression (Fig. 3). Among 50 patients with temporal lobe epilepsy, those exhibiting intermittent explosive disorder were more likely to have left amygdala and left periamygdala lesions due to encephalitis or other structural insults.

Neuropsychological and psychophysiologic studies in unselected populations of violent criminal offenders also show frequent evidence of left hemispheric dysfunction. When neuropsychological deficits are observed in studies of violent groups, they tend to involve not only frontal-executive functions but also verbal comprehension, expressive speech, and other left hemisphere language functions. These findings are consonant with those of many studies in conduct-disordered and delinquent juveniles. In addition to lower average overall IQ, these individuals frequently have a disproportionately lowered verbal IQ (language, left hemisphere) compared to performance IQ (visuospatial, right hemisphere). Psychophysiologic studies employing computerized EEG spectral analysis indicate that persistently violent behavior among psychiatric inpatients is linked to increased 8-band

slow-wave activity in left frontotemporal derivations. Divided visual field, dichotic listening, skin conductance asymmetry, and lateral preference studies additionally suggest subtle abnormalities of left hemispheric function in sociopathic individuals without overt neurological lesions. In one small series of subjects examined by PET, decreased blood flow and metabolism were observed in the left temporal lobe of all four institutionalized, sexually violent offenders studied, and left frontal hypometabolism was observed in two of the four. In a SPECT study, left anterior temporal and bilateral dorsofrontal hypoperfusion were among the abnormalities distinguishing dementia patients with aggression from those without.

Based on the results of these and other laterality studies in violent individuals, different theorists have proposed that either left hemispheric or right hemispheric networks play a predominant functional role in the regulation of aggression, and that subtle developmental hemispheric abnormalities underlie repeatedly aggressive behavior in a proportion of "functional" psychopaths. A broader view is that each hemisphere performs complementary processing related to hostile behavior, and functional abnormalities of either hemisphere may produce disturbed aggressive responding through distinctive mechanisms. Left hemisphere dysfunction, implicated in a preponderance of studies, may lead to overt expression of negative affects mediated by the right hemisphere, diminished linguistic regulation over behavior, and adverse social encounters due to impaired verbal communication. Right hemisphere dysfunction may lead to improper intrahemispheric decoding and encoding of prosody, facial expressions, and other nonverbal emotional responses, overreliance on semantic processing, impaired self-awareness of physiological arousal, and a distinctive pattern of altered aggressivity.

Right hemisphere parietofrontal lesions may impair an individual's ability to interpret and produce emotional gestures, prosody, and affect and to monitor internal somatic states. This may produce an acquired "sociopathy," even in the absence of bifrontal lesions. Although the most frequently noted pattern of altered behavior after right parietal cortical lesions is one of inappropriate cheerfulness and denial of illness, irritability and aggressive outbursts may also ensue. A well-known case is that of former Supreme Court Justice William Douglas, who exhibited disturbed social judgment following a right hemisphere stroke. Although he retained sufficient linguistic and abstract reasoning ability to return to the bench, inappropriate social behaviors soon forced his retirement.

XI. NEUROCHEMISTRY OF AGGRESSION

During the past two decades, there has been an explosion of knowledge regarding neurotransmitter–receptor systems that modulate aggressive behavior in animals and humans. However, many studies have focused exclusively on the effects of a specific neurotransmitter or receptor subtype on one or more aspects of violent or aggressive behavior. Integration of such fine-scale neurochemical data with the large-scale neurocognitive network data acquired in neuroanatomical and neurophysiological studies has been limited. Most experimental and clinical reports on the "neurochemistry of aggression" likely describe the effects of neuromodulators at peripheral, brain stem, hypothalamic, and diffusely projecting hemispheric sites, which can reduce or raise the individual's overall predisposition to aggression. Still lacking are studies that evaluate the multisynaptic integration of parallel-processed streams of complex sensory and limbic information that link amygdala, orbitofrontal, and other higher cortical centers. It is quite likely that these networks are subserved by diverse messenger systems and not exclusively controlled by a single neurotransmitter. We also have insufficient understanding of the complex interactive effects that neurotransmitters and neurohormones exert on one another or the specific receptor subtypes mediating a particular response. However, because neurochemical studies provide the basis for pharmacological interventions in aggressive patients, data from such studies are clinically invaluable.

The hypothalamus, amygdala, and frontal lobe are richly innervated by monoaminergic neurotransmitters, acetylcholine, and neuropeptides. Neurotransmitter systems strongly linked to mediation of aggressive behaviors in animal and human studies include serotonin, acetylcholine, norepinephrine, dopamine, γ–aminobutyric acid (GABA), and testosterone and other androgens as well as nitric oxide, opioids, and glutamate. Serotonergic systems appear to be particularly important and have been the subject of intense experimental and clinical investigation.

A. Serotonin

Diverse animal and human studies suggest that serotonin is a critical modulator of aggressive behavior. Experimental work in animal models of aggressive conduct supports a critical role of serotoninergic

systems in hostile behavior. Eltoprazine, a 5-HT_1 agonist, reduces attack behavior in several species. In the rat brain, eltoprazine binding is greatest in the dorsal subiculum, substantia nigra, ventral pallidum, and globus pallidus. Other 5-HT_{1A} agonists, including buspirone and gepirone, reduce isolation-induced aggression in mice without causing sedation or incoordination. It has been proposed that serotonin increases the ability of an organism to arrange for and tolerate delay. Decreased serotonin leads to an increase of behaviors that are usually suppressed. Studies of isolation-induced aggression, shock-induced fighting, and muricidal and filicidal behavior have demonstrated an inverse relationship between serotonin activity and aggression in rats and mice. Recent studies have begun to delineate more complex species-specific and receptor-specific effects of serotonin on aggression. One recent rat study found that agonists at 5-HT_{1A}, 5-HT_{1B}, and 5-HT_2 receptors all reduced offensive aggression, but only 5-HT_2 agonists reduced defensive aggression.

Findings of studies of naturally behaving animal populations are consonant with the findings from experimentally induced aggression paradigms. Domesticated silver foxes, who easily tolerated human contact, had a higher level of midbrain and hypothalamic serotonin than wild silver foxes bred in captivity. The domesticated foxes also had a reduced density of 5-HT_{1A} receptor binding in the hypothalamus. Rhesus monkeys with the highest blood levels of serotonin were socially dominant, whereas animals with decreased whole blood serotonin tended to be ostracized. Aggressive behavior was also associated with high levels of cortisol, suggesting greater stress. Adolescent male rhesus macaque monkeys show an inverse correlation between cerebrospinal fluid (CSF) levels of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) and risk taking and aggression in the wild.

Serotonin interacts with other neurotransmitter and neurohumoral systems in modulating impulsivity and aggression. For example, one group of investigators examined the effects of testosterone and serotonin administration on dominance and aggression in rats. Male rats given testosterone became dominant. Quipazine, a serotonin agonist, blocked aggression in both naturally dominant and testosterone–induced dominant rats. Nonspecific serotonin antagonists blocked aggression only in testosterone–induced dominant males. This study demonstrates pharmacoselectivity among different forms of aggression, a property that may be desirable for the development of pharmacologic treatments.

Data from human clinical studies are consistent with data from the experimental and observational animal literature, suggesting a critical role for serotonergic systems in human aggression. One major domain of investigation has focused on serotonergic markers in patients who have attempted or committed violent suicide. Caution must be exercised when interpreting these studies. The psychologic and biologic substrates of aggression against the self, manifest in suicide, are likely to differ from the underpinnings of aggression directed against others. Nonetheless, there are important behavioral affiliations between self-directed and outwardly directed violence and the two actions often cosegregate. Lifetime externally directed aggression is more frequent in suicide attempters than in others. Accordingly, findings in suicide patients offer important insight into general neurobiologic substrates of violent behavior.

Many postmortem studies have found decreased levels of serotonin and of presynaptic serotonin binding sites, such as the serotonin transporter site, in subcortical and neocortical brain regions in patients completing violent suicide. Recent studies suggest these abnormalities are more prominent in the orbital prefrontal cortex than in the dorsolateral prefrontal cortex. Similarly, postsynaptic serotonin receptors, such as 5-HT_{1A} and 5-HT_{2A} receptors, are generally elevated in the frontal cortex of violent suicides, especially in orbitofrontal sectors. These findings are consistent with a regulatory increase in postsynaptic serotonin receptors in response to decreased presynaptic serotonergic activity.

Cerebrospinal fluid levels of 5-HIAA are decreased in patients attempting suicide and in violent criminal offenders. A stronger correlation has been noted between CSF 5-HIAA and suicidal behavior than suicidal ideation alone, suggesting that low CSF 5-HIAA levels are a marker not simply of depression and suicidal risk but also of a tendency to aggressive and impulsive behavior. Several studies in criminal and interpersonally violent psychiatric populations support this view. Lowered CSF 5-HIAA levels were found in samples of impulsive arsonists and impulsive murderers. In a group of soldiers with behavior problems, CSF 5-HIAA was negatively correlated with aggressive behavior, and CSF 5-HIAA was reduced in a group of borderline patients with aggressive and suicidal behavior.

Neuroendocrine challenge studies have been utilized to probe serotonergic function in aggression. Serotonin administration in normals causes a release of prolactin. Suicidal depressed patients and patients

with personality disorders who exhibit impulsive and aggressive behavior have a blunted prolactin response to fenfluramine, a releaser of presynaptic serotonin stores, and to *m*-chlorophenylpiperazine, a 5-HT_2 agonist. This work suggests that suicidal and impulsive/aggressive patients have serotonergic hypoactivity. On the other hand, patients with depression and suicidality demonstrated an increased release of cortisol to 5-hydroxytryptamine, suggesting hypersensitivity of other postsynaptic serotonin receptors in this group. Other workers have not found a significant correlation between neuroendocrine challenge abnormalities and suicidality.

Additional support for the influence of central serotonergic activity on aggressive propensities comes from studies of normal volunteers administered selective serotonin reuptake inhibitors. The resulting increase in central serotonergic activity correlated with decreases in hostility and in negative affect generally and an increase in affiliative behaviors.

At least 14 different receptors for serotonin exist in the human brain. Recent investigations of the relationship between serotonin and aggression have begun to more precisely dissect serotonergic systems by employing molecular probes of specific serotonergic receptor subtypes. Buspirone, a 5-HT_{1A} agonist, produced a normal prolactin release when given intravenously to healthy male volunteers. This effect was blocked by the nonselective 5-HT receptor antagonist metergoline and by pindolol, a β-adrenergic and 5-HT_1 antagonist, in a dose-related fashion. Prolactin response to buspirone was inversely correlated with levels of "irritability" in patients with personality disorders, suggesting that decreased sensitivity of the 5-HT_{1A} receptor may be responsible for components of impulsive–aggressive behavior in patients with personality disorders.

Recently, genetic studies have provided further evidence of an important role of serotonin in aggression regulation. A polymorphism in the gene for tryptophan hydroxylase, the rate-limiting enzyme in the biosynthesis of serotonin, has been associated with suicidal behavior in impulsive alcoholic criminals and in individuals with major depression. Amino acid substitutions in the 5-HT_7 receptor gene have been reported among alcoholics with violent behavior.

B. Acetylcholine

Some of the earliest work on the neurochemistry of aggression focused on acetylcholine. Electrical stimulation of the lateral hypothalamus in rats leads to predatory attack on mice in animals that previously tolerated mice in their cage without attacking them. The attack terminates as soon as the electrical stimulation is discontinued. Applying carbachol, a cholinergic agonist, to the lateral hypothalamus provokes the sterotypic aggressive response, which can be blocked by atropine and facilitated by acetylcholinesterases. This cholinergic-induced predatory response is target specific—directed only at the animal's usual prey—and without affective display. Electrical stimulation of the lateral or dorsal amygdala facilitates predatory attack through its connections to the lateral hypothalamus. Applying carbachol to the amygdala also induces a predatory response. Aggressive behavior following human exposure to cholinesterase inhibitors has been observed in several clinical case reports. Despite well-documented early animal experimentation, cholinergic mediation of aggression and its clinical implications have been understudied in recent years. For example, the muscarinic receptor subtypes mediating hypothalamic aggression and cholinergic regulation of aggression in the frontal cortex have not been characterized in detail.

C. Norepinephrine and Dopamine

Catecholamine systems are associated with aggressive behavior in several animal models and clinical populations. Peripherally administered norepinephrine (NE) enhances shock induced fighting in rats. α_2 receptor agonists increase rat aggressive behavior, whereas clonidine decreases rodent aggressive behavior acutely. β-Adrenergic blocking decreases aggressive behavior in laboratory animals. Several human studies have found a correlation between increased CSF or frontal cortex NE or its metabolite 3-methoxy-4-hydroxyphenylglycol and aggressive behavior. It has been proposed that central noradrenergic tracts originating in the locus coeruleus innervate a behavioral inhibitory system that projects widely to the hippocampus, septal region, and frontal lobes. Modulatory disturbances in central norepinephrine would then lead to impulsivity and episodic violence. Long-term β-adrenergic blockade with agents such as propranolol is a well-established, effective therapy to reduce aggressive responding in diverse neuropsychiatric patient groups with violent behaviors.

L-Dopa can induce aggressive behavior in rodents and humans. Apomorphine, a potent dopamine agonist, can induce fighting in rats. Dopamine antagonists

tend to reduce aggression but usually at doses that also slow motor and cognitive performance. A few studies have shown reduced levels of a dopamine metabolite, homovanillic acid, in suicidal patients.

Recent genetic studies support an important role of catecholamine systems in human aggression. The genetic loci for MAO and catechol-*O*-methyltransferase (COMT), two enzymes critical in the catabolism of catecholamines, are located on the X chromosome. In a large human kindred, impulsive violent behavior and mental retardation among several males co-segregated with a point mutation in the MAO type A gene that produced enzyme deficiency and presumably increased central catecholaminergic activity. Male knockout mice lacking the MAO-A gene also show aggressive behavior. COMT gene alleles include a common polymorphism that produces three- or four-fold variation in enzyme activity. The allele coding for the less active form of the enzyme (and resulting increased central catecholaminergic activity) has been associated with violent behavior in two studies of schizophrenic and schizoaffective patients and in male knockout mice.

D. γ-Aminobutyric Acid

Several lines of evidence suggest that GABA inhibits aggression in animals and humans. GABA injected into the olfactory bulbs in rats inhibits mouse killing, whereas GABA antagonists can induce muricidal behavior. Benzodiazepines and other agents that facilitate GABA can decrease isolation-induced fighting in mice and attenuate aggression caused by limbic lesions. In humans, despite their tranquilizing and antiaggressive effect in the vast majority of patients, benzodiazepines can rarely lead to a transient increase in aggressive behavior (''paradoxical rage'').

E. Testosterone and Other Androgens

Testosterone is an important mediator of aggressive responding in diverse mammalian species. In rats, dominant males have higher levels of testosterone than submissive males. Cortisol increases in both groups, but cortisol is higher in the submissive group, suggesting a greater level of stress. In vervet monkeys, increases in serum and salivary testosterone levels correlated with the number of aggressive encounters. Moyer suggested that androgens increased intermale and irritable, but not predatory, sexual, fear-induced, and maternal forms of aggression. An interaction between androgens and other neuromodulators such as the monoamine neurotransmitters appears to govern aggressive responding. Testosterone-induced dominance in rats is reduced after treatment with 5-HT1A, -1B, and -2A/2C receptor agonists.

The association of androgens with aggression suggested by the simple observation that males enact aggressive behaviors more frequently than females in most mammalian species, including humans, is supported by observations of convergent hormonal–behavioral relationships in female spotted hyenas. The spotted hyena is one of the most aggressive animals in the wild. Spotted hyenas also have a very organized and highly nurturant clan society. Male and female hyenas are approximatley equal in size, and female genitalia are masculinized. The colonies are dominated by the females in a tightly ranked hierarchy. Females are more aggressive than males, and adult males are usually not able to feed from a kill while the dominant females are eating. The females' large body habitus, androgenous genitalia, and aggressive behavior are related to the high circulating levels of androstenedione. The role of androgens in mediating aggression thus transcends sexual lines in this species.

In humans, numerous studies support an important link between circulating androgens and aggressive behavior. Elevated testosterone levels in adolescent boys correlate with low frustration tolerance and impatience. Boys with increased testosterone are more likely to respond aggressively when provoked. Increased levels of free testosterone have been measured in the saliva of incarcerated violent criminals. Victorious collegiate wrestlers show a greater increase in their serum testosterone than do their defeated counterparts. Violent behaviors have been reported in individuals taking anabolic steroids for body-building programs. Male alcoholics who abused other people had higher levels of testosterone and lower levels of cortisol than those who did not. In a treatment study, inhibiting gonadal function with a GnRH antagonist reduced outward-directed aggression. A meta-analysis of reported studies demonstrated a strong positive correlation between testosterone levels and observer-rated aggressiveness.

It is important to note some common weaknesses in the data currently available on the neurochemistry of aggression. Most studies on neurotransmitter and neurohormonal effects on aggression have been conducted on male animals and men. Endocrine and neurochemical factors influencing aggression in

females have not been fully evaluated. Caution must be exercised when generalizing findings across species, particularly when comparing responses between humans, other primates, and other mammalian orders. Many aggression-related neurotransmitters are conserved across species, but there are likely important variations in receptor subsystems. Precision in defining and measuring aggression, impulsivity, and irritability in many animal models and humans is difficult to achieve. Also, many studies fail to recognize and fully clarify state–trait distinctions. Neuroendocrine challenge studies are subject to wide variability, depending on agent dosage, route of administration, and outcome measure.

Nonetheless, progress in basic investigations of the neurochemical and neuroendocrine mediators of aggression sets the stage for advances in the pharmacotherapeutics of violent disorders. Moreover, once a better understanding of the individual neurochemical and neuroendocrine factors contributing to aggression is attained, interactions among the multiple systems operating convergently and divergently at hierarchial sites in the neuraxis that regulate hostile behavior may be more fully explored.

XII. MAJOR CLINICAL SYNDROMES OF AGGRESSION

A. General Considerations

The recognition that specific neurological lesions may lead to violent behavior in human beings, and that abnormalities at different levels of the neuraxis result in distinctive types of aggressive behavior, provides a guiding schema for the evaluation and treatment of inappropriately aggressive (and inappropriately hypoaggressive) individuals (Tables III–V). In addition to emphasizing the need for careful neuropsychiatric evaluation of every violent patient, the hierarchical model for the regulation of aggression suggests important parameters that may help to characterize any aggressive act. Integrating information regarding the clinical manifestations of aggressive behavior, additional aspects of the history (particularly related to other drive-related behaviors), the neurological and psychiatric examinations, and structural and functional laboratory studies allows classification of individual patients among major syndromes of impulse dysregulation and aggression.

1. Hypothalamic/Brain Stem Syndromes

In patients with brain stem-mediated sleep–related disorders of violence, aggressive actions are generally nocturnal, associated with incomplete maintenance of REM or non-REM sleep states. The REM sleep behavior disorder predominantly occurs in middle-aged men. Violence most commonly occurs during a vivid and frightening dream, is often directed at a bed partner mistaken for a dream figure, and is unplanned, without the use of weapons. Affected patients are difficult to arouse from their dreaming state. Afterwards, they generally recall the dream material that provoked aggression but report believing they were attacking animal or human oneiric figures rather than their furniture or spouse. They exhibit remorse about their actions and, before a diagnosis is made, may self-treat their disorder by tying themselves in restraining devices at night.

Table III
Distinguishing Features of Focal Lesion Syndromes of Aggression in Humans

Syndrome	Provocation	Eliciting stimulus	Outbursts	Complex plans	Amnesia for acts	Remorse
Hypothalamic	Basic drive (e.g. hunger); unprovoked	Individuals who happen to be present	Yes	No	No	Yes
Ictal	None	Any near individual or inanimate object	Yes	No	Yes	Yes
Postictal	Attempts to restrain/protect patient	Caretakers	Yes	No	Yes	Yes
Interictal	Perception of moral injustice; threat, including misinterpretation of trivial stimulus	Individuals	Occasional	Yes	No	Yes, may be intense
Orbitofrontal	Minor provocation	Individuals	Yes	No	No	No

The REM sleep disorder must be distinguished from other parasomnias that may be injurious to patient and spouse, such as somnambulism, sleep drunkenness, and sleep terrors, which arise out of non-REM sleep. Nocturnal seizures must also be excluded. The evaluation in suspected cases includes a thorough history of sleep complaints from patient and bed partner, neurological and psychiatric examination, overnight polysomnographic study, and MRI. REM sleep behavior disorder has been associated with a variety of neurological conditions, including Parkinsonism, dementia, stroke, multiple sclerosis, and alcohol withdrawal. However, more than 50% of cases are idiopathic. Pontine tegmental lesions, which might be expected from animal studies, are rare, possibly because pontine injury frequently produces devastating motor and arousal deficits that preclude expression of the disorder. Approximately 90% of patients exhibit sustained improvement when treated with clonazopam.

Table IV
Selected Causes of Syndromes of Hyperaggressivity and Hypoaggressivity (Passivity)

Site/syndrome	Common etiologies
Hyperaggressivity	
Hypothalamic	Hamartoma
	Craniopharyngioma, astrocytoma
Temporal lobe epilepsy	Mesial temporal sclerosis
	Vascular malformation
	Glioma
	Traumatic brain injury
Orbitofrontal systems	Traumatic brain injury
	Anterior communicating artery aneurysm
	Orbital meningioma
	Huntington's disease
	Frontotemporal dementias
	Herpes simplex encephalitis
Combined frontotemporal	Traumatic brain injury
	Frontotemporal dementias
	Herpes simplex encephalitis
Multifocal or poorly localized	Attention deficit disorder
	Toxic–metabolic encephalopathies
	Vitamin B12 deficiency
	Alcohol, cocaine
	Multiple sclerosis
	Vascular dementia
Delusional cognition	Paranoid schizophrenia
	Late-life paraphrenia
	Endogenous depression
	Mania
	Alzheimer's disease
	Vascular dementia
Hypoaggressivity	
Bilateral amygalotemporal	Herpes simplex encephalitis
	Frontotemporal dementias
	Posterior cerebral artery infarctions
	Traumatic brain injury
	Urbach–Wiethe disease
	Temporal lobectomies
Dorsolateral frontal systems	Subdural hematomas
	Glioma
	Progressive supranuclear palsy
	Anterior cerebral artery infarctions

In patients with hypothalamic lesions, outbursts of violent behavior in the awake period may be precipitated by internal or visceroceptive states, such as hunger, fatigue, light deprivation, or hormonal stimulation. Alternatively, patients may exhibit a heightened general level of aggressivity. Frequently, attacks are on individuals who happen to be near the patient, without the formation of complex plans. Patients often have diminished insight into the reasons for their actions, although they recall and may demonstrate remorse for their behaviors. Subjects with hypothalamic lesions may demonstrate altered patterns of sleeping or eating, polydipsia, and polyuria or deficient regulation of sex hormones, thyroid, or adrenocortical function. Heteronymous visual field impairments may be evident if lesions extend to involve the optic nerves, chiasm, or tracts. The workup of patients with suspected hypothalamic lesions should include MRI or other structural imaging of the region of the third ventricle, endocrine studies, and formal visual fields. The differential diagnosis includes benign and malignant tumors such as craniopharyngiomas and astrocytomas, which present with subacute alterations in behavior. Another etiology is hypothalamic hamartoma, which usually presents with a distinctive clinical profile of childhood onset of gelastic epilepsy (ictal laughter), sometimes accompanied by precocious puberty, along with interictal bouts of uncontrolled rage (Fig. 4).

2. Temporolimbic Epilepsy Syndromes

Few topics in behavioral neuroscience are more controversial than the relationship of aggression to

Table V
Strategies for Treating Aggressive Behavior

Setting of aggression	Initial therapeutic approaches
Impulsive aggressive acts in setting of congenital or acquired intellectual impairment or hypothalamic injury	Control of appetite, sleep, diurnal cues
	β-Adrenergic blocker
	Selective serotonin reuptake inhibitors
	Cholinergic (muscarinic) antagonists (?)
	Valproic acid
	Avoid barbituates, benzodiazepines, sedatives
Aggression related to deepened affect or ideation in the interctal syndrome of temporolimbic epilepsy (moralistic conviction)	Antiepileptic medications
	Selective serotonin reuptake inhibitors
	Reality-oriented psychotherapy
	Avoid lithium carbonate (may worsen seizures)
Disinhibited aggression in response to transient environmental stimuli, $\pm$ frontal systems dysexecutive signs	Explicit, concrete social structure
	Selective serotonin reuptake inhibitors
	β-Adrenergic blocker
	Avoid barbituates, benzodiazepines, sedatives
Aggressions precipitated by delusions, hallucinations	Atypical antipsychotics
	Neuroleptics
Irritability related to manic or hypomanic states	Mood stabilizers
Acute agitation	Neuroleptics
	Benzodiazepines

epilepsy. Failure to adequately distinguish between aggressive actions in the ictal, postictal, and interictal periods has contributed greatly to the confusion regarding the relationship between temporolimbic epileptic foci and violent behavior.

Ictal aggression does occur, but with extreme rarity. An international consensus panel found that only 7 of 5400 patients studied on video EEG monitoring exhibited aggressive behavior during recorded seizures. Hostile behaviors ranged from physical violence directed toward inanimate objects to mild verbal or physical aggression directed toward a person. When aggressive acts during complex seizures occur, they may appear without provocation or in response to an environmental stimulus and are characterized by spontaneous, undirected aggression toward nearby objects or individuals. The patient is amnestic for actions and often expresses remorse.

A much more common form of aggressive behavior in epilepsy is resistive violence during the postictal period. Following a complex partial seizure or, more frequently, a generalized convulsion, patients may be disoriented and confused. During this epoch, well-intended attempts at physical restraint can provoke aggression, which almost always ceases when restraint is withdrawn. The attacks generally involve striking out without the use of a weapon or sometimes with objects that happen to be close at hand. Patients have no memory for their actions upon clearing of consciousness and will express dismay if they have injured others.

Aggression in the subacute period following the end of a seizure activity can also occur. Often, the aggression appears in the context of postictal psychosis and mania, especially in patients with paranoid delusions and threatening hallucinations. However, recently a syndrome of subacute postictal aggression was described in four patients, occurring hours to days after a seizure, without postictal psychosis or mania. Subacute postictal aggression appears to be a rare phenomenon. The attack behaviors are intentionally directed after minor provocations, and patients retain full recall of the episodes.

Overt aggression related to the interictal behavior syndrome of temporolimbic epilepsy is unusual because the heightened moral and religious values that

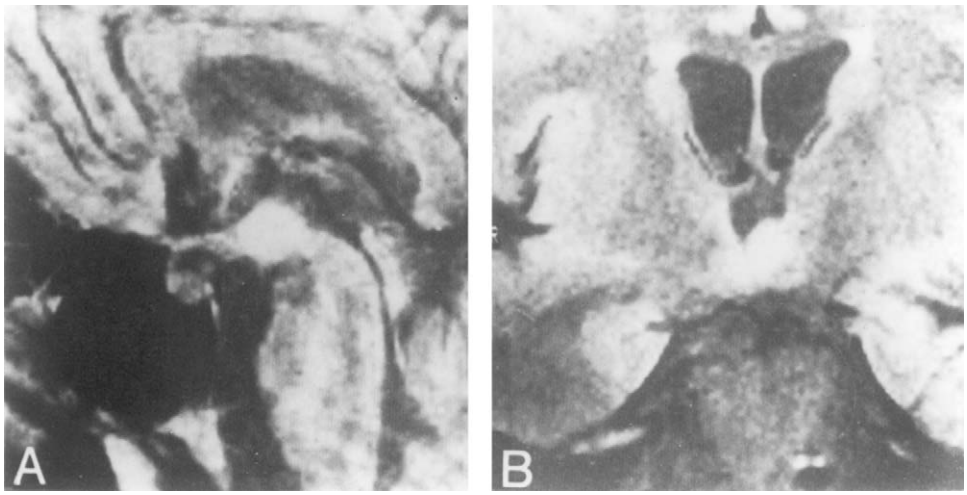

Figure 4 Aggression due to hypothalamic lesion. A 19-year-old man presented with several years of aggressive behavior, poor social adjustment, and seizures of multiple types, including ictal laughter. Coronal proton density-weighted MRI scan demonstrates a hypothalamic hamartoma, evident as a 1-cm-high signal intensity mass in the substance of the hypothalamus (reproduced with permission from S. F. Berkovic, F. Andermann, and D. Melanson, *et al*., 1988, *Ann. Neurol*. **435**).

are features of the syndrome preclude violent actions. However, in rare circumstances, intense emotional reactions to perceived injustice or threat can lead subjects to formulate and carry out complex plans of violent response. Attacks may be directed against a specific individual and could involve the use of a weapon. Not all hostile actions by these patients involve long-term planning—rarely, the intensity of feelings evoked in a particular situation might lead to an immediate response. Patients fully recall their actions and often exhibit extreme remorse. Some individuals continue to believe their acts had ample moral justification.

In individuals with epilepsy, sedative antiepileptic medications such as barbiturates may contribute to hostile behaviors by impairing impulse control. Irritability, a common complaint among patients with poorly controlled partial and primary generalized seizures, may result from environmental factors, medications, or in relation to the underlying cerebral pathology or epileptogenic process.

The laboratory evaluation for epilepsy in violent individuals includes routine scalp EEG and more sensitive sleep recordings and the use of nasopharyogeal or spheroidal leads. In select cases, ambulatory EEG, long-term inpatient video EEG monitoring with scalp and sphenoidal electrodes, or invasive subdural grids or depth electrodes may be necessary to establish the seizure focus.

CT and especially MRI are utilized to exclude slowly growing gliomas and other mass lesions. Volumetric MRI or careful visual analysis of the hippocampus and amygdala (seen best on T_1-weighted coronal cuts) may aid in the diagnosis of mesial temporal sclerosis by demonstrating unilateral or bilateral atrophy. Metabolic imaging with PET or SPECT may show increased blood flow and hypermetabolism in mesial temporal structures during ictal discharges and decreased blood flow and hypometabolism interictally. PET is the more sensitive technique interictally; SPECT is more practical for capturing ictal events. Common etiologies of temporolimbic epilepsy include mesial temporal sclerosis, hamartomas, dysplasia, low-grade astrocytomas, oligodendrogliomas, vascular malformations, and traumatic brain injury.

3. Orbitofrontal Systems Syndromes

Patients with lesions in orbitofrontal cortices or associated subcortical structures such as the caudate nucleus may engage in directed acts of aggression. However, they are often incapable of planning or executing a complex response that requires an extended sequence of actions. Failure to consider long-term and especially social consequences of violent outbursts is a salient feature. Frequently, the patient engages in impulsive, unreflective responses to identifiable but trivial environmental provocations. In some patients, extended but inefficient rational analysis of social situations without guidance from somatic–emotional systems is observed. Patients remember their actions but often lack remorse, and they fail to link aggressive

actions with punishment or other long-term adverse outcomes, contributing to repeated offenses.

The neurological exam may reveal anosmia due to damage to the olfactory nerves or tracts on the undersurface of the frontal lobes and release phenomena such as the grasp reflex. If the lesion is confined strictly to orbitofrontal cortices, subjects may show few deficits on conventional IQ tests or even on neuropsychological tests explicitly designed to probe frontal-executive function. When lesions trespass upon dorsolateral frontal territories, deficits in go-no-go testing, verbal and nonverbal fluency, and set shifting may be evident. CT and especially MRI studies are helpful in screening for structural lesions. Common etiologies indude traumatic brain injury, anterior communicating artery aneurysm rupture, anterior cerebral artery infarction, orbital meningioma, the frontotemporal dementias (Fig. 5), and Huntington's disease.

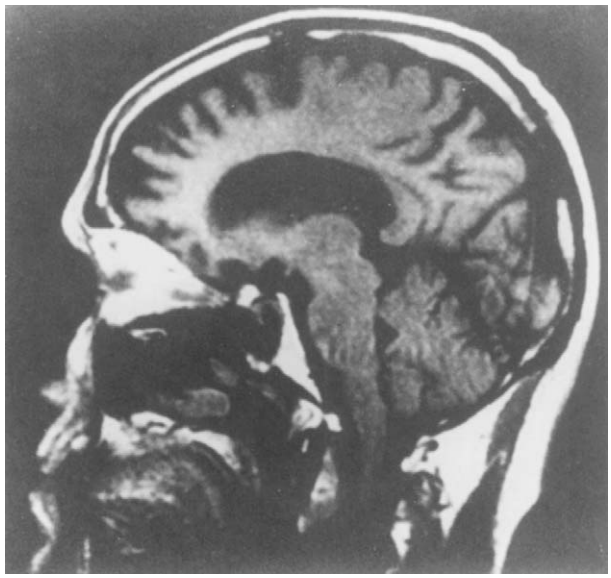

Figure 5 Aggression with bifrontal lesions. Over 3 years, a 56-year-old man developed frequent violent outbursts and persistent foul language, as well as ritualistic behaviors, disinhibition, and jocularity. MRI demonstrates focal frontal lobar atrophy, consistent with Pick's disease. [Reproduced with permission from Saver *et al.*, 1996, Neuropsychiatry of aggression. In *Neuropsychiatry: A Comprehensive Textbook*. (Fogel, B. S., Schiffer, R. B., Rao, S. M., eds.) p. 540. Williams & Wilkins, Baltimore].

4. Syndromes of Diffuse or Multifocal Brain Injury

Several medical conditions that produce aggression have effects on the brain that are diffuse or multifocal. A large body of investigative literature has demonstrated an increased frequency of "minimal brain dysfunction" and poorly localized neurological "soft signs" in violent patients. In one study, minor and irregularly distributed perceptual, motor, sensory, reflex, and cognitive defects were noted in 119 of 286 patients with a history of recurrent attacks of uncontrollable rage. Minor neurologic findings are common in violent individuals in juvenile reform school and on death row. Attention deficit disorder was significantly correlated with criminal and violent offenses in a prospective study. Not surprisingly, developmental or acute medical conditions producing scattered minor neurological impairments place an individual at higher risk of expressing aggressive impulses. Diffuse or multifocal brain insults are likely to affect one or several circuits within the multiregional, hierarchical aggression regulatory system. In addition, a history of being abused or reared in an unstable household is likely to interact synergistically with multifocal brain injuries. An individual who has learned a model of acting on impulse and possesses a limited repertoire of other response options is all the more likely to demonstrate diminished flexibility and inhibition of aggression after diffuse, especially frontal, injuries.

The clinical manifestations of aggression in these patients are heterogeneous. History of school difficulty, learning disability, hyperactivity, or head trauma associated with brief loss of consciousness or amnesia are often elicited. School records are helpful because patients may deny or minimize past academic or disciplinary problems. A clouded sensorium or subtle sensorimotor or visual impairments may be found on neurological examination. Etiologies of diffuse brain dysfunction with episodic violence include, in addition to attention deficit disorder, toxic–metabolic encephalopathies (such as hyper- and hypoglycemia, B_{12} deficiency, and thiamine deficiency), multiple schlerosis, and subcortical vascular dementia.

5. Delusional Syndromes

Delusional individuals are prone to violent behavior. In these patients, aggression-related neural systems may, like the intellect, be placed in service of the psychosis. In a variety of neuropsychiatric disorders, including schizophrenia, endogenous depression, mania, Alzheimer's disease (AD), and other dementias, the presence of thought disorder and hallucinations,

especially of the persecutory type, increases the risk of violent outbursts. In a series of 181 subjects with probable AD, physical aggression was observed in 30% of patients; delusions and misidentifications frequently preceded violent outbursts. Dementia patients with paranoia and aggressive behavior have an increased rate of early institutionalization. Delusions are more likely to lead to aggression if frontal systems are also impaired.

The clinical approach to these patients is focused on the diagnosis and treatment of the underlying psychotic disorder. Etiologies of delusional disorders include paranoid schizophrenia, affective illness, late-life paraphrenia, AD, multiinfarct dementia, and subcortical dementias.

XIII. TREATMENT

Consideration of multiregional neural processing may guide selection of appropriate environmental and biological interventions to control aggression.

Regular satisfaction of feeding drives and sleep–awake cycles may minimize hostile outbursts in patients with hypothalamic aggression. Much of our current pharmacological armamentarium for the treatment of violence is focused on neuromodulators with cell bodies in the brain stem and hypothalamus that project widely to hemispheric structures, relying on a pharmacologically induced bias against all types of aggressive responses. For example, brain stem nuclei are the likely sites of action for drugs that block β–adrenergic receptors, activate 5-HT receptors, and enhance GABA activity. By raising the threshold for aggressive responding, such agents may have an ameliorative effect on aggression resulting from lesions at all levels of the neuraxis. Agents modulating muscarinic cholinergic receptors in the lateral hypothalamus are worthy of more systematic investigation for antiaggressive effects based on observations that cholinomimetics directly instilled in the lateral hypothalamus elicit aggression. In one patient with lesions thought to disconnect hypothalamic circuitry from higher control, oral administration of a centrally active cholinergic antagonist dramatically suppressed aggressive, biting behavior. Intervention at the temporolimbic level of control introduces additional considerations. Patients in whom a focal seizure disorder is diagnosed should be treated with agents effective for complex partial seizures, especially those such as carbamazepine, valproate, and gabapentin which have mood-stabilizing effects. Neuroleptics, which lower the seizure threshold, should be employed with caution. Avoiding restraint and providing gentle reassurance and reorientation in the postseizure period reduces postictal resistive violence. Patients whose clinical seizures remain refractory to antiepileptic therapy and who have well-defined unilateral foci are candidates for surgical resection. Temporal lobectomies or amygdala hippocampectomies produce excellent seizure control in the preponderance of such patients and may have a beneficial effect on aggression in patients whose epilepsy is associated with violent behaviors. Reduced aggression has been reported in more than 35% of violent epilepsy patients after temporal lobectomy.

The principles of pharmacological therapy for interictal aggression differ from those directed at reducing aggression levels in the hypothalamus. At the amygdalar level, the problem of timing is critical. To form appropriate sensory–emotional associations, the normal amygdala must be active in a brief time window to bind a specific stimulus or event with the hypothalamic signal of hunger or anger. Prolonged responses evoked by temporolimbic epileptic foci lead to an inappropriate broadening of the range of associated stimuli. Antiepileptic agents such as carbamazepine or valproic acid, which reduce prolonged, rapid discharges of neurons, may favor more selective, adaptive associations.

Recent studies have suggested that excitatory amino acid receptors, such as the class activated by *N*-methyl-D-aspartate (NMDA), may be critically involved in the associative process of long-term potentiation within the hippocampus and amygdala. Agents that modulate this response, such as selective NMDA–receptor blockers or nitric oxide synthetase inhibitors, merit investigation for antiaggressive and serenic properties in temporolimbic epileptic patients.

Processing within the orbitofrontal cortices represents an advanced stage of synaptic interaction occurring at the convergence of multiple streams of prior sensory evaluations. It is unlikely that a single neurotransmitter could be modulated to duplicate or restore prefrontal functions. Conversely, drugs that nonselectively inhibit neuronal function through inhibition of chloride channels or other mechanisms, such as ethanol, benzodiazopines, and barbiturates, exert a disproportionate effect on prefrontal functioning, which is particularly dependent on polysynaptic inputs. A paradox in the current psychopharmacology of aggression may be illuminated by considering the prefrontal effects of agents that simultaneously act at

other levels of the neuraxis. For example, benzodiazepines have antiaggressive properties in many species and tranquilizing effects in humans, likely mediated by their potentiating effects at GABAergic inhibitory receptors. However, these compounds are known to precipitate paradoxical rage, the release of previously inhibited hostile responses. A possible explanation is that benzodiazepines impair prefrontal processing through nonselective neuronal inhibition in a manner similar to ethanol intoxication. In some patients, the resulting loss of social insight and judgment more than offsets the general tranquilizing effects of these agents.

Serotonergic agents may also exert substantial effects on prefrontal function. Serotonergic efferents from prefrontal cortices appear to serve an important role in the inhibition of impulsive responses. Lowered levels of 5-hydroxyindoleacetic acid and blunted responses to fenfluramine in impulsive aggressive individuals are consonant with this formulation, suggesting that serotonergic agents, especially those acting at 5-HT_1 receptors, may be beneficial to patients with orbitofrontal dysfunction. α_2 adrenergic agonists, such as clonidine and guafacine, have been shown to ameliorate frontal focused attention deficits and may thus be helpful to individuals with orbitofrontal derangements.

Supportive psychotherapy is helpful to many patients with temporolimbic and orbitofrontal aggression syndromes. Insight-oriented therapy is unlikely to benefit the patient with prefrontal injury who may verbally comprehend a behavioral problem and propose solutions but cannot reliably call on this knowledge to control behavior. Some patients with interictal behavior changes associated with temporal lobe epilepsy are amenable to insight psychotherapy, but many accept neither criticism nor advice. However, by alerting patients to their intensified emotional responses, and capitalizing on their heightened moral and religious sensitivities, a therapist may reduce their likelihood of aggressive actions.

XIV. CONCLUSIONS

Many aggressive behaviors are neither maladaptive nor the result of neurological disease. Even when violent behavior and neurological lesions coexist, they may not be causally related. A violent lifestyle may lead to head trauma and neurological abnormalities that are the consequence, rather than the cause, of aggression. While fully accepting these qualifications, behavioral neuroscience is enriched by recognizing both that a diverse array of neurological lesions may contribute to violent behavior in human beings and that abnormalities at different levels of the neuraxis produce distinctive subtypes of aggression. Basic and clinical studies that consolidate and extend our understanding of the multiregional, hierarchical neural networks regulating aggression are urgently needed to refine diagnostic and therapeutic approaches to violent individuals.

Aging Brain

LORI L. BEASON-HELD and BARRY HORWITZ
National Institute of Aging

GLOSSARY

Alzheimer's disease A progressive neurodegenerative disease causing dementia that is common in the elderly, whose symptoms include memory dysfunction, deficient cognitive function, and an inability to deal with the activities of daily living. Neuropathologically, it is characterized by the presence of senile plaques, neurofibrillary tangles, and neuronal loss in the hippocampal area, association areas of the cerebral cortex, and a number of subcortical nuclei, including the nucleus basalis of Meynert.

nucleus basalis of Meynert A group of neurons in the basal forebrain that project to the cerebral cortex, constituting the cholinergic input to the cerebral cortex.

typical and successful aging Typical aging refers to individuals who are cognitively intact, even though they may have some nondementing illness that could affect brain structure and/or function (e.g., hypertension); successful aging refers to individuals who are free of any illness that could affect brain structure or function.

white matter hyperintensities Abnormal signals in the white matter observed with magnetic resonance imaging. Two kinds are denoted: periventricular white matter hyperintensities and deep white matter hyperintensities.

This article reviews some of the changes that occur in the human brain with advancing age. After some introductory comments, we give a brief overview of the age-related alterations in cognition and sensorimotor performance, discuss senescent changes in brain structure at the macroscopic and cellular levels, and examine age-associated changes in brain function as assessed by functional neuroimaging.

I. INVESTIGATING THE AGING BRAIN

The changes in the brain associated with aging are seemingly both evident and elusive. Obviously, aging continually takes place from conception to death, but in this article, we address only that aspect of aging associated with senescence. What is evident is that there is apparently a clear decline in numerous brain-mediated sensory, motor, and cognitive processes with advancing age, although what exactly declines is not fully understood. Likewise, the gross morphology of aged brains looks different than that of young brains; generally, they have larger sulcal widths and correspondingly smaller gyri. Neurons also should be affected by age; after all, these cells are postmitotic, and once they die most will not be replaced. However, documenting neurobiological alterations due to aging in humans (and nonhuman primates) has been remarkably difficult and the results controversial.

Four fundamental problems make the investigation of the senescent human brain complex. First, how should one study aging? Comparing a group of young versus a group of old subjects (i.e., a cross-sectional design) has numerous disadvantages, including that one is not studying the aging of any single subject, and the results can be compromised by secular effects. For example, the young subjects of today grew up in a world of better health care than did the old subjects. They may be physically larger, may have engaged in

different kinds of physical activity, and may have different diets. On the other hand, elderly subjects have the advantage that they have survived to be old subjects. Also, comparable levels of formal education in each group may not mean the same thing. The other option is to study a single group of subjects as they grow old (i.e., a longitudinal design). This is quite difficult for many reasons: Some age-related changes can begin as early as the fifth or sixth decade, if not earlier, but following subjects over several decades is clearly expensive and logistically complex. Moreover, a longitudinal design often forces one to continue using a technique that can become outmoded [e.g., employing X-ray computed tomography (CT) to examine the structure of the brain when magnetic resonance imaging (MRI) scans give much better information]. Also, as subjects age, they may develop a brain-related disorder; therefore, the question arises as to how much of their previously acquired data should be used. Although longitudinal designs probably are the better choice, the majority of aging studies employ a cross-sectional design.

The second fundamental problem in studying the aged brain has to do with brain disease. Presumably, we are interested in those changes due to the aging process. However, the incidence of many neurological and psychiatric disorders increases with advancing age. Some neurodegenerative diseases, especially Alzheimer's disease, are extremely difficult to differentiate in their early stages from normal aging. Often, the diagnosis for some of these diseases can only be made postmortem by searching for specific neuropathological markers in autopsied tissue; thus, if a healthy aged subject shows a behavioral change, is it because there is subclinical disease present or does the change actually represent something that is age related? What makes this especially troubling for the scientific investigator is that the pathology of some disorders such as Alzheimer's disease may start to occur one or two decades prior to the onset of clinical symptoms. Until reliable *in vivo* markers for these diseases are available, the problem of knowing what constitutes an aging change from an alteration due to disease will continue to affect this field of research. A similar problem occurs for MRI white matter signal abnormalities, which are also present in many disorders, such as hypertension, vascular disease, and diabetes. Moreover, what exactly is meant by the term "healthy aging"? For example, it is still an unanswered question as to whether everyone will become demented if they live long enough; that is, some of the pathological features and some of the cognitive symptoms of Alzheimer's disease (or a related dementia) are found in old nondemented people, but to a lesser degree.

One relatively recent set of findings illustrates this problem particularly well. Several studies have shown that the female sex hormone estrogen may affect neurons so that higher hormonal levels improve learning and memory. Moreover, some research suggests that estrogen may protect against Alzheimer's disease. Therefore, when women go through menopause, they could show a decline in cognitive function due to reduced estrogen levels, and thus, there will be a sex-based aging difference. For those women at risk for Alzheimer's disease, there may be a further insult on neuronal function. Estrogen replacement therapy, more common now than in previous years, may ameliorate these effects. Whether or not these specific findings hold up as research continues, this illustration shows the complex interactions involving aging changes, sex, cognitive alterations, and disease risk factors that can confound experimental studies of aging and that can affect our ability to define what healthy aging even means.

These considerations have led investigators to try to distinguish between typical (or usual or normal) and successful aging. Cognitively intact individuals in the first category may have nondementing illnesses that increase in prevalence with advancing age. For example, they may have vascular risk factors such as hypertension that are associated with impaired cognition in the old. The second category, successful aging, refers to individuals who are free of these illnesses. Because various research groups differ as to whether they study typical or successful aging, their results often are at odds with one another.

The third fundamental problem for the investigator of brain senescence has to do with neuroplasticity, a term we use in its most general sense. Changes due to neuroplasticity can include such regionally local processes as axonal and dendritic sprouting as well as long-range processes best expressed in terms of altered patterns of task- and behavior-related neural activity in functional systems distributed across the brain. The brain's inherent plasticity allows it to compensate to a degree for the degradative processes associated with aging. This means that behavioral performance may appear unchanged even in the presence of structural and functional neurobiological age-related alterations. It means that it can be difficult to correlate any specific neurobiologic change with a corresponding cognitive deficit. It also means that some of the changes seen with aging may represent the effects of plasticity and thus are related to aging only indirectly. Finally,

neuroplasticity can make it difficult to distinguish subjects who have disease-related pathology from the healthy aged. On the other hand, neuroplasticity also means that the brain has some capacity to adjust to both aging and disease in such a way that many individuals can maintain a normal and productive mental life even into advanced old age.

The fourth problem, which can be particularly acute for those who work at the cellular and subcellular levels of analysis, is that the brain is incredibly heterogeneous in terms of structure and function. Different parts of the brain may show differential aging effects, as might different neuronal populations even within the same brain region. Because the brain operates by means of distributed networks, it can be difficult to relate the age-associated anatomical changes seen in one brain area to functional changes in behavior.

These points are worth keeping in mind as we review what has been learned about the neurobiological alterations with advancing age. These issues provide a framework for appreciating the difficulty investigators have found in arriving at a detailed consensus about what features of the brain decline during old age.

Before we begin our review, however, several other items need to be pointed out. First, a central finding in almost all studies is the increased variability in whatever one is measuring in the old compared to the young; this often means that values for the quantity of interest of many old subjects are well within the range of values found in the young subjects. Second, the age-related differences we discuss are quite small compared to the differences found between normal subjects and those with brain disease. Finally, unless stated otherwise, when we talk about the old or elderly, we are usually referring to subjects between the ages of 65 and 90 years. The "oldest old" individuals appear to constitute a special group, perhaps due to genetic factors.

II. COGNITIVE CHANGES WITH AGE

There is a rich literature detailing the age-related changes in cognitive and sensorimotor function. Cognitive ability is generally tested using a battery of neuropsychological measures that includes tests of intelligence, executive function, language, visuospatial ability, attention, and memory. From such batteries it has been concluded that healthy aging is associated with a decline in several domains of cognitive function, some of which can begin as early as the sixth decade of life.

In evaluating these tests, it is important to distinguish aspects of performance that engage peripheral processes from central processes. For example, as we age, the lens of the eye changes so that we become farsighted. Obviously, to assess visual processing, an investigator must take account of this peripheral age-related effect. The declines in cognitive performance with age discussed next are thought to be mediated primarily by the central nervous system and not by peripheral neural processes.

A. General Intellect

Whereas general knowledge is preserved with aging, studies show a differential decline on some intelligence measures, leading aging researchers to propose that there are two distinct types of intelligence. Crystallized intelligence refers to knowledge accumulated over the life span and includes vocabulary, general information knowledge, comprehension, and arithmetic. Performance on tests of crystallized intelligence is generally preserved with aging. The ability to evaluate and respond to novel events is referred to as fluid intelligence. Tests of fluid intelligence evaluate deductive reasoning, problem solving, memory spans, and figural rotation. These measures decline with age. Because many of these tests must be completed in a given time period, poorer performance in the elderly on tests of this nature may be related to slower information processing speed and slower motor response times, which also show age-related decrements.

B. Executive Function

Executive function includes processes associated with high-level cognitive abilities. Tests of executive function involve mental flexibility, abstraction, and planning; many are thought to be related to frontal lobe function since patients with frontal lobe lesions perform badly on such tests. Mental flexibility can be assessed with tasks requiring sorting and set shifting, such as a card sorting task in which the rules governing the sorting process change at intervals during the task. Performance on tests of this nature is impaired with age. These impairments are worse if the tasks involve a memory component. Abstraction can be assessed using tests involving concept formation, reasoning,

and categorization. Tests which involve the ability to detect similarities between stimuli and the rules governing the sequencing of a string of letters or numbers are used to measure abstraction capabilities. Although these abilities decline with age, some impairments appear to be education dependent. For example, on tasks of concept formation, the higher the education of the subject, the slower the decline in performance ability with age.

C. Motor Processes

Slowing of motor processes has long been associated with aging. For example, performance on tests of walking speed and finger tapping rates declines with age. Elderly subjects are also slower than young subjects when moving a hand toward a target, sorting a stack of cards, and writing. Many studies that require a motor response, such as pushing a button, also show increased reaction times in the elderly, with or without a decrease in response accuracy. It is of interest that tests that require a verbal response do not show significant changes with age, suggesting that speed may be an important factor on those tasks requiring hand or finger movements, and especially on tasks that must be completed in a given time period. Some skills acquired early in the life span which require motor abilities, such as typing and playing musical instruments, are preserved with age.

Areas of the brain that have been shown to be important in the control of movement include motor and premotor cortex in the frontal lobe, the basal ganglia, and the cerebellum.

D. Language

Most components of language are preserved with age and those that change do so late in the life span. Four aspects of linguistic ability that have been measured are phonological, lexical, syntactic, and semantic knowledge. Phonologic knowledge, or the ability to use different sounds and understand the rules of their combination, is preserved with age. However, because there is a decline in hearing sensitivity with age, the elderly often report difficulties in understanding speech. Nonetheless, under normal conditions, when hearing sensitivity is controlled for, the young and old seem to understand speech equally well. Lexical knowledge, or understanding the actual name of an object or action, is preserved with age. The elderly can also discriminate as well as young subjects between words and nonsense words. The ability to meaningfully combine words into sentences is referred to as syntactic knowledge. This ability is also preserved with age unless a memory component is involved. Semantic knowledge, which is one type of long-term memory, refers to word meaning. Naming and verbal fluency assess semantic ability and decline with age, although impairments usually do not become significant until age 70.

For right-handed individuals, the regions of the brain considered essential for language include several areas bordering the Sylvian fissure in the left cerebral hemisphere (e.g., Wernicke's area in the posterior superior temporal gyrus for comprehension and Broca's area in the inferior frontal lobe for production).

E. Visuospatial Processes

Visuospatial tasks assess the ability to recognize and reproduce geometric drawings, perform construction tasks, and carry out object recognition tasks that require the subject to identify specific object features. Although elderly subjects can perform some types of visuospatial tasks with the same accuracy as young subjects, albeit more slowly, many visuospatial abilities do decline with age. Elderly individuals are impaired on tasks of construction with blocks, object assembly, maze learning, and performance of puzzles with a spatial component. Impaired ability to draw and to judge the accuracy of drawings also occurs with age. A decline in the ability to detect a target position in the visual field and to detect the direction of motion is additionally observed with aging. Some of these tasks require the integrity of regions in the occipital and parietal lobes, especially in the right hemisphere.

F. Attention

Attention can be defined in a number of ways, but for this discussion, perhaps the best definition is the ability to concentrate or focus mental powers on the task at hand. Studies have examined different types of attentional capacities. One type, sustained attention, involves the ability to focus on a simple task without losing track. No decrease in the ability to perform tasks involving simple vigilance or sustained attention is seen with aging. However, if the task is more complex and requires the subject to remember previous stimuli,

for example, an impairment can be observed. Another type of attention, selective attention, requires the subject to ignore extraneous information and to focus only on the relevant stimuli. Early studies suggested that older subjects were impaired on this type of task because they were less efficient at ignoring irrelevant stimuli. Recent studies involving the ability to search an array of stimuli for specific targets indicate that there is no change with age, although there does seem to be an impairment in controlling the focus of attention during visual search. Another type of test used to assess concentration ability involves divided attention in which subjects must perform at least two tasks simultaneously. This testing paradigm requires not only that the subject focus attention but also that the subject switch his or her attention from one task to the other. On tests involving divided attention, older subjects appear to be impaired on all tasks except those involving simple perception. Examples of more complex tasks used to study divided attention include remembering strings of letters and numbers simultaneously and responding when a specific number of dots appear in the field of view while performing a driving simulation. Some researchers attribute impairments on measures such as these to task difficulty and slower response times in the elderly.

G. Memory

Memory problems are the most common complaint of the elderly. Difficulties with memory can begin as early as the 50s. In general, the ability to access remote information and the capacity to attend to new information are not affected by age, although there does seem to be an age-related increase in difficulties with word finding and naming, as mentioned previously. Instead, aging deficits are seen in the ability to learn and retain new information. It is clear that there are several types of memory as well as several processes involved in the ability to remember. Sensory or immediate memory, which involves the ability to remember items instantly, is preserved with aging. Short-term (or working) memory involves memory for items held over seconds or minutes. This is a limited capacity store where the material must be actively rehearsed to be maintained in memory. Tests of short-term memory include remembering lists of words or letters. This ability is relatively preserved with aging, although there are some suggestions of a reduced short-term storage capacity in the elderly. The modern conception of working memory also entails a component that permits the information in the short-term store to be manipulated. Evidence suggests that this component becomes impaired with advancing age. The dorsolateral frontal cortex is thought to play a central role in working memory.

Items stored in long-term memory may be accessed over hours, days, or years. Tests of recall or recognition of stimuli are often used to assess long-term memory. Both types of tests are impaired in old subjects, with recall appearing to be worse than recognition. Three processes are involved in long-term memory: encoding, storage, and retrieval of information. Long-term storage abilities appear intact in the elderly because the results of studies examining rates of forgetting are similar for old and young subjects. It is theorized, instead, that older subjects have difficulties with encoding and retrieval. Studies of encoding suggest that the elderly are less efficient at using proper strategies when committing information to memory. Because tests of recall are impaired with age, it is also thought that the retrieval process is disrupted in elderly subjects.

There is also a distinction between the types of material to be remembered. Episodic memory includes memory for events, whereas semantic memory involves memory for facts, ideas, and concepts. Episodic memory is impaired in aging. Early studies found that semantic memory was relatively preserved with age, but recent studies suggest that there is also a slight decline in the ability to remember semantic information. Another distinction involving types of material includes implicit and explicit memory. Implicit memory refers to memory for information known to the subject. This can be tested using word fragment completion and degraded picture tasks. These types of tasks are performed relatively well by elderly subjects. Explicit memory involves conscious recollection of new information. This type of memory is impaired with age.

Based on lesion studies in nonhuman primates and rodents, and on research with amnestic patients, structures in the medial temporal lobe, particularly the hippocampus and entorhinal cortex, are thought to play a central role in encoding information into long-term memory.

H. Summary: Cognitive Changes with Age

Aging results in declines in a variety of cognitive domains, but some abilities appear to be relatively preserved. General intellectual knowledge and

crystallized intelligence measures such as vocabulary and comprehension remain largely intact with age, as do attention processes that allow one to remain vigilant or to selectively attend to situations. Language abilities related to phonologic, lexical, and syntactic knowledge are also relatively stable, as are motor skills that are learned early in the life span and repeatedly used. Although the most common complaint among the elderly involves memory problems, some aspects of memory are also preserved with age, including processes involved in immediate and implicit memory, and some aspects of short-term memory.

Processing speed needed for most types of cognitive operations slows with age, and there are declines in the ability to reason and solve problems—areas of fluid intelligence. Older subjects also have difficulty dividing their attention between two tasks when these tasks are performed concurrently. Executive function domains such as mental flexibility, abstraction, and concept formation are impaired, as are visuospatial skills required for drawing, construction, and maze learning. Declines are also observed in language skills involving semantic knowledge needed for naming and verbal fluency. Motor skills that require speed are impaired. Also, as early as age 50, studies show that there are age-related declines in the ability to learn and retain new information for long-term access. These memory impairments are thought to be related to deficits in encoding and retrieving information to be remembered.

III. ANATOMICAL CHANGES WITH AGE

There are two ways to assess changes in brain structure in the senescent brain: *in vitro* studies of postmortem tissue and *in vivo* studies of the living brain using techniques such as X-ray CT or MRI. Until about 1990, most *in vivo* studies used X-ray CT, whereas most current investigations generally employ MRI because of its better spatial resolution and contrast. Studies of structural changes at the cellular and subcellular level require the use of either light or electron microscopy and generally are performed on postmortem tissue that has been chemically fixed.

A. Gross Anatomical Changes

1. Postmortem Tissue Studies

Brain weight is known to decrease with age. Changes begin in the third and fourth decades and show a progressive decline throughout the life span. At age 20, the average weight of the male brain is approximately 1400 g, and by the age of 65 brain weight is approximately 1300 g. Brain weight for females follows a similar trend, although the total weight is 100–150 g less than that of males. Most changes occur after age 55, with a total loss of up to 15% of the peak brain weight by age 90.

Shrinkage of brain tissue or atrophy also occurs with age. Atrophy is clearly seen along the surface of the cerebral hemispheres where the gyri or cortical ridges become progressively more narrow and the spaces between the gyri, referred to as sulci, widen. Mild to moderate cerebral atrophy occurs in a heterogeneous fashion, with frontal, parasagittal, and temporal regions affected more than other areas of the cortex. The cerebral ventricles also dilate with age, typically becoming apparent in the 60s. Severe atrophy is generally associated with disease processes. Changes in brain volume are also associated with aging and begin after age 50, with a 2 or 3% progressive decrease per decade. Until age 50, a decrease in volume is predominantly observed in the gray matter of the cerebral cortex. After age 50, decreases in white matter are greater. Autopsy data suggest that the volume of white matter is decreased in old (75–85 years) compared to young subjects by approximately 11%.

2. *In Vivo* Structural Changes

Both cross-sectional and longitudinal aging studies of changes in brain structure have been performed on healthy subjects using either X-ray CT or MRI. Our focus is mainly on the results of the MRI studies because of the better spatial resolution and contrast obtainable with this method. One can manipulate the scanning parameters of a MRI device in several ways, each of which emphasizes signals corresponding to somewhat different features of brain tissue. In this overview, we discuss senescent changes in volumetric measures of gray matter, white matter, cerebrospinal fluid (CSF) space, and a few fairly well-defined brain regions, such as the hippocampus and the basal ganglia. The absence of clearly and easily identifiable landmarks makes it difficult to measure the volumes of specific regions of the neocortex in a rigorous way. We also review some of the findings about age-related alterations in white matter hyperintensities.

a. Some Fundamentals Concerning Structural Brain Imaging Before discussing the specific structural brain imaging findings, it is worthwhile to provide some information about how these types of data are

acquired. Both CT and MRI generate images of the brain in the form of slices parallel to one another. With MRI, these slices can be parallel to any plane that one chooses. The slices have a certain thickness and may or may not be contiguous. Recent imaging studies have tended to use quite thin slices (about 1 mm thick).

There are essentially two distinct methods that have been used to evaluate brain volumetrics on CT or MRI images. The first involves determining the volumes of specific brain regions by manually tracing their areas on individual slices. The second method uses some type of computer algorithm to segment automatically each image into specific tissue types (e.g., gray matter, white matter, and CSF). Each method has limitations. The trace method is more subjective, although it enables the tracer to make use of his or her knowledge of neuroanatomy. The most precise results are obtained with thin slices, but the analysis can be quite time-consuming. The segmentation method has the advantage of objectivity, but it can be especially susceptible to the partial volume problem: Even a single pixel (the smallest element in an image) may contain a mixture of brain tissues, and thus it becomes difficult to categorize every element in the image as belonging to one kind of tissue versus a second. In an image in which the blackest pixels correspond to one tissue type and the whitest to a second, gray pixels may correspond either to a third tissue type or may represent the partial volume averaging of the first two types. As investigations of this sort have continued, improvements in both the trace and segmentation methods have been devised, but the types of problems indicated previously persist.

One last technical point needs to be mentioned. Because the size of an individual's brain and its components is related to the size of the subject (and thus, for example, men have on average larger brains than women), almost all studies of brain volumetrics use normalized volumes; for instance, a commonly used volumetric measure is the percentage of the intracranial volume of the subject.

b. Age-Related Volumetric Changes There seems to be essentially uniform agreement that the total amount of brain tissue decreases with advancing age. Also, all investigations have reported an increase in the volume of CSF in the brain of elderly compared to young subjects. When these changes begin and whether the loss of brain tissue corresponds primarily to gray matter, white matter, or both have been contentious issues. Several investigations have indicated that gray matter shows a gradually accelerating decline with age, but after approximately age 50 the white matter of the brain shows a more pronounced age-related decrease and seems to be the main contributor to the age-related loss of brain volume. Also reasonably clear is that these changes are different for men and women. Whereas the increase with age in ventricular CSF is the same for the two sexes, men show a greater increase in peripheral CSF (i.e., subarachnoid CSF) than do women. Peripheral CSF is considered to be a marker of cortical atrophy.

The frontal lobes have been shown to decline in volume with advancing age, with some research groups reporting that the loss of tissue is greater in men than in women. The parietal lobes have also been shown to be reduced in aging, but to a greater extent in women compared to men. Some groups have found no age-related change in the volume of the temporal lobes, whereas others have; the different findings could be attributable to whether or not the subjects under study represented successful (no change in temporal lobe volume) versus typical aging. Some studies have also examined the size of the corpus callosum (the large bundle of nerve fibers connecting the left and right cerebral hemispheres) as a function of age. Several of these have found that the anterior portion of the corpus callosum shows age-related atrophy, which is consistent with the age-related reduction in frontal lobe volume.

Most brain structures that are measurable by manual tracing with MRI have been found to show age-related decreases in volume. These include basal ganglia structures, such as the caudate and lenticular nuclei, and the anterior portion of the thalamus. Many studies have examined the hippocampus and other components of the medial temporal lobe. Most, although not all, investigations have reported a decrease in the size of the hippocampus with advancing age. In one longitudinal study of individuals ranging in age from 70 to 89 years, it was found that the hippocampus decreased in volume by approximately 1.5% per year.

In summary, although there is still much debate in the scientific literature, it seems that most brain structures show a measurable decrease in size with advancing age. However, compared to neurodegenerative diseases such as Alzheimer's disease, these age-related decreases are small. For example, the study that reported the 1.5% annual rate of hippocampal atrophy also found that this rate was approximately 4% in patients with Alzheimer's disease. Moreover, these changes generally do not begin until the sixth decade. The most notable feature of these data is the

increase in variance with advancing age. That is, there are elderly individuals with values within the young normal range, even though some older subjects show significant atrophy. This aspect of aging is not restricted to brain volumetrics, however; as mentioned previously, it essentially typifies most quantitative studies of aging. Finally, it should be noted that the relationship of these measures of increased atrophy to cognitive decline is unclear. Very few investigations have examined the correlation between cognitive decline and brain volumetrics, especially in a longitudinal design.

c. White Matter Hyperintensities With the advent of MRI, abnormal signals were observed in the white matter in a number of neurological diseases known to affect the white matter (e.g., multiple sclerosis and Binswanger's disease), in various dementias, as well as in the elderly. Because these MRI signals are often best observed using scanning parameters that result in their appearing as bright lucencies against a black (low-signal) white matter, they have been termed white matter hyperintensities (WMHs). Two kinds have been distinguished: (i) Periventricular white matter hyperintensities (PWMHs) appear either as frontal or occipital caps of the cerebral ventricles or as a thin lining surrounding the ventricles, and (ii) deep white matter hyperintensitites (DWMHs) are seen as subcortical punctate foci, although larger confluences of foci form with increased severity and often merge with the PWMHs. The neuropathological substrate for these signals can vary depending on the disease. In aging, the PWMH most likely results from the breakdown of the ventricular ependyma, which leads to an increase in the water content of the nearby myelin, demyelination, and reactive gliosis. DWMHs likely correspond to gliosis, demyelination, and atrophy and shrinkage of axons and myelin around blood vessels. Because DWMHs are found in patients with cerebrovascular disease, vascular dementia, and hypertension, their appearance in the elderly may have an ischemic origin.

The general finding of MRI studies is that WMHs are rare in healthy individuals less than 50 years of age, but their presence increases with advancing age. WMHs are present in a majority of elderly subjects but are generally mild in those individuals who have no cerebrovascular disease; the PWMHs appear as a capping or pencil-thin lining of the lateral ventricles, whereas DWMHs are seen only as diffuse, focal, punctate foci. One meta-analysis of 156 studies showed that the prevalence of WMHs increased from 25% at age 30 to 75% at age 80. This study also found that age and hypertension were the major predictors of the presence of WMHs.

The relation between severity of WMHs and deficient cognition is less clear. As indicated previously, aging leads to measurable deficits in certain cognitive functions. Individuals at all ages with essential hypertension have also been shown to have impaired cognition in several domains compared to normotensive control subjects, even if the hypertension has been well controlled by drugs. Elderly hypertensive subjects have a greater amount of brain atrophy than do normotensive age-matched controls. Also, as stated previously, the extent of WMHs is greater in hypertensives than in controls. However, even in healthy subjects free of cerebrovascular risk factors, it has been reported that increased volume of WMHs is associated with increased ventricular volume and deficient cognitive function, especially on neuropsychological tests sensitive to frontal lobe dysfunction. Interestingly, there seems to be a correlation between elevated systolic blood pressure, even in the normal age-related range, and WMH burden.

B. Microscopic Changes in Neuronal Structure and Neurotransmitter System Integrity

1. Cellular Changes

There are a number of cellular changes that occur in the gray matter of the brain with aging. Although these changes are more dramatic in disease states, there are also degenerative processes associated with healthy aging. One of the most fundamental and currently unresolved issues is whether or not there is a loss of neurons in the cerebral cortex of the aged brain. Early studies suggested that cell loss did occur with age, but recent studies have shown a decrease in the number of large cells and an increase in the number of small cells, suggesting that shrinkage of the cell body, as opposed to a decrease in number, is associated with senescence.

Some areas of the brain do show a decrease in neuronal number, including the hippocampus, thalamus, putamen, cerebellum, and subcortical nuclei such as the substantia nigra, locus coeruleus, nucleus basalis of Meynert (NBM), and inferior olive. The hippocampal region is of interest because of its purported role in encoding new memories; the earliest neuropathological changes in Alzheimer's disease occur in parts of this structure and in surrounding tissue. Parts of the basal ganglia (putamen, globus pallidus, and portions of the

thalamus), along with the cerebellum and substantia nigra, are key components of the neural system involved with regulating movement. Neuronal death of the dopaminergic cells in the substantia nigra causes Parkinson's disease; several symptoms of this degenerative disease increase their frequency in the aged. Some studies have reported neuronal loss in the NBM, the source of the cholinergic projection to the cerebral cortex. This nucleus shows a significant loss of neurons in Alzheimer's disease.

There are also degenerative changes that occur within the nerve cell body, including accumulation of lipid products, vacuoles, inclusions, and abnormal protein within the cytoplasm. Pigment accumulation or lipofuscin occurs at different rates within different areas of the brain. The large neurons of the precentral gyrus are particularly predisposed to lipofuscin deposits, which are composed of lipids, proteins, and carbohydrates. Neuromelanin, which results from peroxidation of the lipofuscin granules, also occurs in the neurons of the substantia nigra and locus coeruleus. Granulovascular degeneration, which results in the accumulation of cytoplasmic vacuoles, is common in aging. Lewy bodies, commonly found in Parkinson's disease, occur in a small number of healthy aged subjects, whereas colloid inclusions or fine granular material in the cisterns of rough endoplasmic reticulum are often found in the senescent brain. Marinesco bodies, composed of fine granules and filaments in a lattice-type network, also commonly occur with advancing age. Neurofibrillary tangles (abnormal fibrous protein accumulation in the cytoplasm), which are one of the key pathological markers of Alzheimer's disease, occur within parts of the hippocampus and amygdala, several subcortical nuclei, and some regions of the cerebral cortex (primarily in the entorhinal cortex in the temporal lobe) but with a density far less than that found in patients diagnosed with Alzheimer's disease.

A few studies have found senescent changes in the dendritic system of neurons, although this kind of analysis is sensitive to the type of fixation used to preserve the brain. These changes include a decrease in dendritic number, which usually begins with dendrites farthest away from the cell body. A decrease in the number of synaptic terminals is also seen. A proliferation of existing dendrites can be observed and is thought to be a compensatory mechanism for those that are lost. These changes can be seen after age 60. Neuroaxonal dystrophy, or enlargement of the distal ends of axons, occurs predominantly in some nuclei in the medulla and increases in frequency with age.

Neuropathologic changes that occur in the neuropil, or the area surrounding cells, include the development of neuropil threads, senile plaques, and Hirano bodies. Neuropil threads consist of the abnormal protein seen in neurofibrillary tangles, but these proteins are located in the neuronal process surrounding amyloid plaque cores and are rare in aging. Senile plaques are composed of amyloid protein, degenerating neuronal processes, and reactive glial cells. There are different types of plaques and these are classified by the organization of amyloid and the presence or absence of degenerating cell processes. In normal aging, senile plaques may exhibit dystrophic neurites, but these neurites usually lack the paired helical filaments seen in Alzheimer's disease. These plaques are commonly found in the frontal and temporal cortex and in the hippocampus. Hirano bodies are spindle or rod shaped structures found in the neuropil surrounding neurons and are commonly seen in senescent brains.

2. Neurotransmitter Changes

There are numerous substances in the brain which play a critical role in neural transmission. The class of neurotransmitters that we discuss are called neuromodulators; their effect on neurotransmission has a longer time course than classical transmitters such as glutamate and GABA, and they seem to affect the responsiveness of target neurons to other inputs. These substances, which originate from midbrain and brain stem nuclei, include acetylcholine, dopamine, serotonin, and noradrenaline. They play a central role in many of the neurological and psychiatric illnesses that are common in the elderly, including Alzheimer's disease (acetylcholine), Parkinson's disease (dopamine), and depression (serotonin).

a. Cholinergic System The NBM in the basal forebrain provides most of the cholinergic innervation of the cerebral cortex. One study found that cells within the NBM increase in size until age 60 and then begin to atrophy, particularly in posterior regions of the nucleus. Acetylcholine (ACh) is the primary neurotransmitter produced by cells within the NBM. There is little change in acetylcholinesterase content, an enzyme responsible for the breakdown of ACh, in elderly subjects. There are also minimal changes in high-affinity choline uptake, which is the rate-limiting step in ACh production. However, age-related changes in ACh receptors are observed. There are two principal cholinergic receptor types: muscarinic and nicotinic. A 10–30% reduction in muscarinic receptor density is

seen in the cerebral cortex and striatum. The cortex and hippocampus exhibit a decrease in nicotinic receptors, whereas the thalamus shows a decrease in nicotinic and an increase in muscarinic receptor density.

b. Dopaminergic System Dopamine innervation of the cortex, limbic system, and basal ganglia originates from the ventral tegmentum and the substantia nigra. There are substantial changes to neurons of the substantia nigra with age. After age 65, there is a progressive decline in cell number within this region. The remaining cells exhibit decreased nucleolar volume and mild accumulation of neurofibrillary tangles, Lewy bodies, and neuromelanin. Studies that have examined the effects of aging on dopamine have shown that the density of presynaptic D_1 receptors decreases, whereas the density of postsynaptic D_1 receptors increases in the striatum with age. The striatum also shows a decrease in pre- and postsynaptic D_2 receptor density.

c. Noradrenergic System Noradrenaline is produced by locus coeruleus neurons found in the brain stem. There is a progressive loss of noradrenergic neurons from the brain stem beginning from age 30–40. Noradrenergic neurites can be found in senile plaque formations in aging. A decrease in tyrosine hydroxylase, which is needed for the production of dopamine and noradrenaline, is also observed in elderly subjects. The cerebral cortex contains both α- and β-adrenergic receptors. Adrenergic α_2 receptors significantly decrease with age. Loss of β-adrenergic receptors occurs in a more heterogeneous fashion based on cortical region. Receptors in the frontal lobe show no decrease in number, whereas those in the precentral, temporal, occipitotemporal, and cingulate cortical regions exhibit a linear decline with age.

d. Serotonergic System The raphe nuclei in the midbrain supply the serotonergic innervation of the brain. The primary metabolite resulting from the breakdown of serotonin, 5-hydroxyindoleacetic acid, does not decline with age. However, there is a decrease in imiprimine binding with aging; the imiprimine binding site is a presynaptic marker for the reuptake of serotonin. Two types of serotonergic receptors (S_1 and S_2) have been found to decline with age. S_1 receptors demonstrate up to 70% reduction in number; S_2 receptors density is decreased by 20–50% in elderly subjects. Functional imaging studies using markers for the S_2 receptor have found decreases in receptor density in occipital, parietal, temporal, and frontal lobes of the brain. Of these regions, the most significant decreases in density are observed in frontal and temporal cortices.

C. Summary: Anatomical Changes with Age

There is a general decrease in brain weight with advancing age, and macroscopic atrophy in the form of increased sulcal and ventricular size becomes clearly evident. The volumes of a number of brain structures are reduced in old versus young brains. The most prominent of these include the hippocampal formation, the frontal lobes, and a number of subcortical structures in the basal ganglia and the nuclei that are the source of the neuromodulatory transmitters (e.g., NBM and the substantia nigra). White matter changes, which are associated with vascular problems such as hypertension, are also more common in the elderly.

At the cellular level, the aging brain exhibits many neuropathologic changes, but these changes are diffuse and relatively modest in relation to those associated with neurodegenerative diseases. Decreased overall size and volume of gray and white matter occur relatively early in the life span. Degenerative processes that affect the gray matter of the brain appear to begin later and include diffuse accumulation of abnormal products within and around neurons and changes in the ultrastructure of neuronal processes. Neuromodulatory neurotransmitter systems show declines in concentration and/or receptor densities in aging brains, but these declines are generally mild to moderate in degree.

IV. FUNCTIONAL NEUROIMAGING STUDIES OF AGING

A. Fundamentals of Functional Neuroimaging

Although other articles in this volume treat functional neuroimaging in detail, it is important to mention a few methodological issues here as they pertain to aging. The two basic types of functional neuroimaging methods are those that measure the electric or magnetic fields generated by neural activity [electroencephalography (EEG) and magnetoencephalography (MEG)] and those that measure the hemodynamic or metabolic consequences of neural activity [positron emission tomography (PET), single photon emission

computed tomography (SPECT), and functional MRI (fMRI)]. These two types differ in many ways, but they differ primarily in terms of spatial and temporal resolution and in the extent of the brain about which information is provided: PET (and SPECT; most research studies on brain aging have used PET; we will not specifically distinguish between SPECT findings and those obtained using PET) and fMRI can localize activity for most of the brain to a resolution of a few millimeters but with temporal resolution on the order of several seconds at best. EEG and MEG have a temporal resolution in the millisecond range but with poor localizability for activity of many brain regions simultaneously. PET can be used to ascertain markers for a number of neurophysiological and neurochemical processes, including glucose metabolism (most commonly using ^{18}F-fluoro-deoxyglucose as the radioligand), cerebral blood flow (often using [^{15}O]water as the radiotracer), and neuroreceptor concentration, whereas most fMRI studies provide information about the amount of blood oxygenation (oxygenated and deoxygenated blood have different magnetic susceptibilities). Blood oxygenation, cerebral blood flow, and glucose metabolism are mostly used as indirect indicators of regional neural activity.

In the next section, we review a number of studies of brain cognitive function in aging that have used either PET or fMRI. Two kinds of PET studies are discussed: (i) resting state studies, in which a subject lies in the scanner "at rest," having no specific task requirement except to remain awake, and (ii) activation studies, in which a subject in the scanner is asked to perform a set of specific tasks while the neural activity in his or her brain is measured. Although resting studies are easier to perform, two advantages of activation studies are that specific cognitive systems can be probed, and subject performance during the scanning session can be obtained and correlated with the functional neuroimaging data.

Two different data analysis strategies are used to analyze PET and fMRI data so that inferences can be made about the brain processes involved in cognition. The first is called the subtraction paradigm, which is concerned with the functional specialization of different brain areas. In functional neuroimaging studies using PET/fMRI, this paradigm is implemented in its simplest form by comparing the functional signals between two scans, each representing a different experimental condition. The locations of the major differences in signal between the two presumably delineate the brain regions differentially involved in the two conditions. For example, if the two conditions differed by the presence of an additional cognitive operation in one compared to the other, then the brain areas "activated" would, it is assumed, be associated with that cognitive operation. For aging studies, one would be interested in those brain regions that show a task-by-age interaction. In resting brain studies, signals obtained from young and old subjects are compared directly.

The second data analysis method is called the covariance paradigm. This approach aims at determining how different brain regions interact with one another during the performance of specific cognitive tasks. It does this by examining the interregional covariances in brain activity (often called the interregional functional connectivity). Functional neuroimaging methods obtain data simultaneously from multiple brain regions and therefore are ideal for use with the covariance paradigm. These two paradigms for analyzing functional neuroimaging data complement one another; both are necessary to get a clear picture of how the brain works.

The possibly confounding issue of partial volume artifacts needs to be mentioned before discussing the functional changes observed in aged brains. PET and fMRI provide images of function, not structure. As such, these functional images must be interpreted in the context of an underlying anatomical substrate. When comparing young and old subjects, the anatomical region that is the source of the functional neuroimaging signal may be reduced in size due to atrophy in old compared to young subjects. The question then arises as to whether a reduced functional signal indicates a functional deficit or simply reflects atrophy. Although attempts to correct PET and fMRI images for atrophy have been made in a few studies, it is not commonly performed due to inherent technical difficulties. Thus, most results presented in the next few sections have not addressed this issue.

B. Resting Studies

Resting studies of cerebral function generally have been performed using PET and have measured either regional cerebral glucose metabolism or regional cerebral blood flow (rCBF). Global or overall resting metabolism shows a decline of approximately 12–20% over the adult age range of 20–80 years. One study found a 12% reduction in resting metabolism after age 60. Regional assessment of metabolism shows a differential decline in glucose utilization with age.

The frontal, temporal, and parietal lobes all exhibit decreased resting metabolism, with the frontal lobes, particularly the dorsolateral cortex, showing the largest decline with age. In the temporal cortex, both lateral and medial temporal areas have been found to have resting metabolism that declines with advancing age. The largest age-related difference within the temporal lobe is in anterior temporal cortex.

Measurements of resting cerebral blood flow show a linear decline in global gray matter values beginning after age 55. An overall decline in the range of 18–28% of global flow is observed in the elderly compared to young subjects. Regional analysis reveals that association areas are affected more than primary cortical areas with age. Decreased blood flow is observed in the frontal, temporal, parietal, and occipital lobes of the brain as well as in the cingulate cortex. In the frontal cortex, a linear decrease in blood flow of 30% from ages 22 to 82 has been reported. In the temporal lobe, superior temporal cortical regions appear to be affected most.

Whether the modest declines observed in resting cerebral metabolism and blood flow represent a true functional decrease or occur because of atrophy-related partial volume effects is not known. Also, almost all the measurements discussed previously have the feature mentioned in other sections of this article—their variance increases with advancing age.

Interregional correlations of resting glucose metabolic rates have also been evaluated in young and old subjects to assess changes in brain interactions during aging. Older subjects have significantly fewer large correlations between frontal and parietal regions than do young subjects, suggesting an age-related decrease in integrated function between anterior and posterior cortex.

A number of PET studies have examined differences in neurotransmitter function between young and old subjects, with most focusing on the integrity of the dopaminergic system. Several groups have found an age-related decline in D_2 receptor (postsynaptic) availability in the striatum of approximately 8% per decade. A similar percentage decline in the amount of dopamine transporter (a presynaptic marker) has been reported. Loss of striatal presynaptic dopamine function, evaluated by measuring the uptake of a positron-labeled version of L-dopa, likewise has been found during aging. The age-related loss of these makers has been shown to correlate with motor function and also with performance on some tests sensitive to frontal lobe function. These studies thus point to a decline in nigrostriatal function with age.

C. Cognitive Activation Studies

Studies using brain activation paradigms can be divided into two domains: those examining the effects of sensory stimulation or motor function and those investigating higher level cognitive functions. Interestingly, few activation studies have been performed that examine motor performance in aging. With regard to the sensory domain, it has been shown that vibratory stimulation of either hand in healthy subjects results in increased rCBF in the contralateral primary sensorimotor and supplementary motor areas of the brain. No correlation is observed with age, suggesting that this form of response does not change in the elderly. Conversely, fMRI has been used to demonstrate that there are age-related changes in basic visual function. Using goggles that generate alternating checkerboard stimuli to examine photic stimulation in the elderly, researchers found that the primary visual cortex in aged subjects demonstrated a significantly lower response level than that seen in young subjects. Another study using PET to assess visual function in the cerebral cortex also found age-related differences. When subjects were shown visual textures made up of black-and-white check patterns, the brains of older subjects demonstrated decreased activation of visual extrastriate and temporal regions and increased activation of frontal lobe areas relative to young subjects. Together, these findings suggest that there are cortical changes in the way visual material is processed with age.

Studies have also been performed that examined differences in visual perception. When subjects were asked to identify the two identical human faces out of a choice of three faces in a display, the occipitotemporal object visual pathway of the brain was activated. Older subjects, however, exhibited slightly different regional activation of the visual cortices than did younger subjects. Similar findings were observed when subjects were required to perform a task involving location or identification of similar spatial configurations. Here, activation of the occipitoparietal spatial visual pathway was observed, with old subjects again demonstrating a different regional activation of the visual cortices, along with exhibiting additional activation of frontal lobe regions not seen in the young subjects. These results suggest that recruitment of cortical regions different from those observed in young subjects occurs with age during visual perception. Reaction time data showed that older subjects were slower in responding than young subjects on both types of tasks, although accuracy was well above chance.

An analysis of interregional functional connectivity performed on these data adds some insight into the nature of cortical recruitment. For the face-matching task, it was found in young subjects that the functional connection between ventral frontal cortex and posterior visual cortex was fairly weak. In the healthy aged, however, there was a strong functional linkage between these two brain areas, perhaps indicating greater use of the frontal cortex for strategic processing or monitoring of behavior in the old compared to the young subjects. These results suggest that changes in functional connectivity in the aged brain, a form of neuroplasticity, may be one way by which behavioral performance can be maintained.

In terms of other cognitive functions, studies have been performed that evaluate attention, executive function, and memory for both verbal and visual material. Using a visual search paradigm to assess attention, age-related differences have been demonstrated with PET in both brain activation and behavioral performance. When subjects were asked to selectively attend to a central target position in a grid of letters, no age differences were observed. However, differences were seen when subjects were required to divide their attention between different portions of the grid in search of a specific target. Although both young and old subjects exhibited activation of occipitotemporal, occipitoparietal, and frontal regions, the young group demonstrated more activation of posterior brain regions (occipitotemporal), whereas the old group showed more anterior (frontal) activation patterns. The old subjects were also slower and less accurate in choosing the correct target during the divided-attention task.

The ability to sort objects into specific categories is a measure of executive function. Brain activation patterns obtained using PET that result from the ability to sort cards based on number, color, or shape showed involvement of frontal, parietal, and occipital regions in both young and old subjects. Although similar regions were activated in both age groups, the magnitude of the increased rCBF was reduced in the old group, suggesting that there is a decrease in cortical efficiency associated with aging. The elderly again performed more slowly and made more errors than the young subjects on this task.

Several functional imaging studies have examined processes related to the ability to remember specific stimuli, such as faces or words. With regard to memory for faces, it has been shown that young subjects activate frontal cortex in the left hemisphere as well as temporal lobe regions, including the hippocampus, while encoding a series of faces. Old subjects, however, show no significant activation of these regions during this condition. When retrieving or recognizing the faces, young subjects demonstrate involvement of frontal cortex in the right hemisphere as well as parietal regions, whereas old subjects only activate frontal regions. These findings led to the conclusion that memory dysfunction seen in the elderly results from impaired encoding of material to be remembered. Another study investigated brain function during a working memory task involving face stimuli. Here, the subjects were required to remember specific faces over varying delay intervals. During this task both young and old subjects exhibited activation of the frontal cortex, which increased in magnitude in the left hemisphere with increasing delay, and of extrastriate visual cortex, which showed decreasing activation with increasing delay. However, in old subjects there was less activation overall, and they had increased activation of occipitoparietal cortex and different frontal regions than those seen in the young. Although there were subtle differences in response time and accuracy in task performance, it was suggested that the differences in activation may represent different strategies employed by the elderly in maintaining a short-term memory for faces.

Verbal material has also been used to examine memory function in the elderly. Several studies have been performed using retrieval paradigms of words from cues given in the form of three-letter word stems. It was found that explicit retrieval of words results in frontal activation in young and old subjects, but the regions differ between the two groups. One study also found medial temporal activation only in the old, whereas another found it in both groups when the task became more difficult. These findings suggest that there are functional differences in retrieving verbal information with age, especially in the frontal lobes of the brain. Decreased accuracy in the old group also supports the conclusion that retrieval processes are impaired in the elderly.

Other studies have investigated encoding and retrieval of single words or word pairs. Although the results of these studies vary to a certain degree, there are similarities among the brain activation patterns. During encoding of words or the letters that make up words, young subjects demonstrated activation of the frontal cortex in the left hemisphere in addition to occipital and temporal regions. Age-related differences in activation were observed in frontal regions of both cerebral hemispheres. During retrieval, young subjects showed involvement of the right frontal

cortex. Occipitotemporal activation was also observed in this condition. Old subjects demonstrated bilateral activation of the frontal cortex and both increased and decreased activation of occipitotemporal regions relative to the young groups. A study examining the functional connectivity of the brain during these tasks revealed that young subjects used the frontal cortices of the right and left hemispheres differentially during encoding and retrieval, whereas the old tended to use networks in both cerebral hemispheres for both encoding and retrieval. Together, these results again suggest that there is a functional reorganization of brain regions mediating memory processes with age.

D. Summary: Functional Neuroimaging Studies

Studies of resting brain function indicate that there are small reductions in both glucose metabolism and cerebral blood flow with age and an age-related reduction of nigrostriatal dopamine function. The declines in global measurements occur within the average range of 10–20% after age 60. Regional metabolism and blood flow also decrease with age. Changes have been observed most commonly in frontal, temporal, and parietal lobes of the brain. Of these regions, the frontal lobes appear to exhibit the greatest decline when assessed with either glucose or blood flow techniques.

Brain function during activation also demonstrates age-related changes. Studies of visual function show activation differences in occipital, temporal, and frontal regions. Generally, these differences are seen as decreases in activation of visual areas within the occipital and temporal lobes and increases in activation of areas in the frontal cortex. Although individual studies of memory function yield slightly different results, the similarities suggest that there is a reorganization of brain activation patterns in the elderly during memory tasks. This reorganization can been seen during tasks involving both encoding and retrieval of visual and verbal information. Some differences are observed in occipital and parietal lobes of the brain, but the most prominent age-associated differences are seen in frontal lobe activation, especially involving prefrontal cortical regions. These frontal lobe differences include increased activation as well as involvement of regions unlike that observed in young subjects. Often, in tasks in which frontal activation is predominant in one hemisphere in young subjects, the activation becomes bilateral in the elderly. Together, the activation data suggest that decreases in cortical function and subsequent recruitment of novel regions during task performance may represent some form of functional compensation in the aging brain, although perhaps not sufficient to maintain performance at the same levels of accuracy and speed as in young subjects.

V. CONCLUSIONS

Several conclusions can be drawn from our review of selective changes in neural structural and function with aging. First, as we have stressed, compared to the types of brain-related changes observed in neurological and psychiatric disorders, the alterations seen in the brain with advancing age are modest. Almost all the measures of cognition, brain structure, and brain function that we examined showed essentially the same behavior: If change was found, it became worse after approximately 60–70 years of age. However, the variability in the old increased significantly, and often there were old subjects whose values on these measures were well within the range of those of young subjects.

Although much controversy exists in the research literature, some findings seem fairly consistent. The two areas of cognition that show clear declines with advancing age are some types of memory and measures of mental flexibility (i.e., fluid intelligence). Speed of cognitive and sensorimotor processing also seems to decline with age. Areas of the brain that demonstrate structural alterations include medial temporal lobe regions such as the hippocampus, the frontal lobes, regions within the basal ganglia, and a number of subcortical nuclei, such as the nucleus basalis of Meynert and the locus coeruleus, which are the sources of neuromodulatory neurotransmitters in the cortex. These transmitters play a key role in numerous cognitive processes, including memory and attention. There also seems to be an increase in the presence of white matter abnormalities with advancing age, although how this relates to alterations in cognitive performance is unclear.

Although we did not discuss in detail brain abnormalities associated with age-related neurodegenerative disorders, the distinction between aging changes and disease-associated alterations was difficult for us to maintain. Long ago, it was thought that senescence was part of a continuum with dementia and perhaps also with movement disorder of the Parkinsonian type. About two decades ago, the view changed to the notion that healthy brain aging could be distinguished from brain diseases, particularly those that lead to dementia. That is, there are changes that

occur in the brain that are part of the aging process, but these are distinct from the changes due to specific brain disorders such as Parkinson's disease, cerebrovascular disease, and especially Alzheimer's disease. In our view, this distinction has become blurred. There are interactions between genetic risk factors for various brain disorders and environmental factors, such as diet, exercise, and education, that can modulate the neural changes associated with aging and brain disease. The estrogen example we presented earlier illustrates this point. Successful aging seems to be based on a sufficiently robust neuroplasticity that can keep dysfunction due to the aging and subclinical disease-related processes in check.

Agnosia

JONATHAN J. MAROTTA and MARLENE BEHRMANN
Carnegie Mellon University

GLOSSARY

alexia An acquired condition, usually as a result of brain damage (such as follows strokes in adults), marked by an impairment in reading, in which reasonable vision, intelligence, and most language functions other than reading remain intact.

apperceptive agnosia A form of visual agnosia in which a person cannot reliably name, match, or discriminate visually presented objects, despite adequate elementary visual function (visual fields, acuity, and color vision).

associative agnosia A form of visual agnosia in which a person cannot use the derived perceptual representation to access stored knowledge of the object's functions and associations but is able to copy and match the drawing even though unable to identify it.

Balint's syndrome Agnosic syndrome that results from large bilateral parietal lesions and is composed of three deficits: (i) paralysis of eye fixation with inability to look voluntarily into the peripheral visual field, (ii) optic ataxia, and (iii) disturbance of visual attention such that there is neglect of the peripheral field.

dorsal simultanagnosia An inability to detect more than one object at a time, with difficulty shifting attention from one object to another.

dorsal stream The stream of cortical visual projections from primary visual cortex to posterior parietal cortex, concerned primarily with the visual control of action and representation of spatial information.

inferotemporal cortex Inferior surface of the temporal lobe that is particularly important for object recognition.

Klüver–Bucy syndrome A group of impairments, including visual agnosia, resulting from bilateral damage to the temporal lobes.

optic aphasia A condition in which a person cannot name a visually presented object, despite being able to indicate the identity of the object through gesture and to sort the visual stimuli into categories.

prosopagnosia A form of visual agnosia in which a person cannot recognize faces, despite adequate elementary visual function (visual fields, acuity, and color vision).

ventral simultanagnosia A reduction in the ability to rapidly recognize multiple visual stimuli, such that recognition proceeds in a part-by-part fashion.

ventral stream The stream of cortical visual projections from primary visual cortex to the inferotemporal cortex, concerned primarily with representing the identity of stimuli by such characteristics as shape and color.

Visual agnosia is a disorder of recognition confined to the visual realm, in which a person cannot arrive at the meaning of some or all categories of previously known visual stimuli despite normal or near-normal visual perception and intact alertness, intelligence, and language. This article takes a multidisciplinary approach in discussing this impairment and considers clinical and neurological studies in humans as well as neurophysiological data in nonhuman primates.

I. CASE STUDIES

JW is a relatively young man, in his early forties, who, despite many preserved cognitive abilities, fails to recognize many common objects. In August 1992, JW suffered a severe cardiac event while exercising and was subsequently anoxic. A computed tomography (CT) scan revealed multiple hypodensities in both occipital lobes with minor hypodensities in his right parietal lobe. Although JW has normal visual acuity as well as intact color and motion perception, Behrmann and colleagues have shown that he recognizes approximately 20% of black-and-white line drawings and a slightly higher percentage of color pictures. He is almost totally unable to recognize photographs of famous people. He is poor at copying simple line drawings presented to him (Fig. 1), at matching rectangles and squares of various dimensions, at simple shape detection (e.g., deciding that an "X" is present among a background of visual noise), and even at detecting symmetry in a visual image. Despite these impairments, he is able to recognize objects well from tactile/haptic input and from definitions that are read to him. These findings suggest that his long-term knowledge of objects is preserved. This is further confirmed by his ability to generate visual images in his "mind's eye" and to describe those in detail. Needless to say, this impairment significantly limits his ability to interact with objects and his world. Whereas JW was the owner of a hardware computer company (and had a master's degree in computer science), currently he works as a volunteer and provides instruction on computer use to people who are blind.

CK, like JW, is impaired at recognizing objects and has been studied extensively by Behrmann, Moscovitch, and Winocur. CK sustained brain damage in a motor vehicle accident in 1988; he was struck on the head by the side mirror of a truck while he was jogging. Except for a hint of bilateral thinning in the occipitotemporal region, no obvious circumscribed lesion is revealed on magnetic resonance imaging (MRI) or CT scan. This may not be surprising given that his lesion was sustained via a closed head injury which often results in shearing of axons or more microscopic neuronal damage. Despite his deficits, CK functions well in his life; he has a responsible managerial job and makes use of sophisticated technology that allows him to translate written text into auditory output.

When asked to identify line drawings, CK misrecognized a candle as a salt shaker, a tennis racquet as a fencer's mask, and a dart as a feather duster, presumably because of the feathers on the end (Fig. 2). As

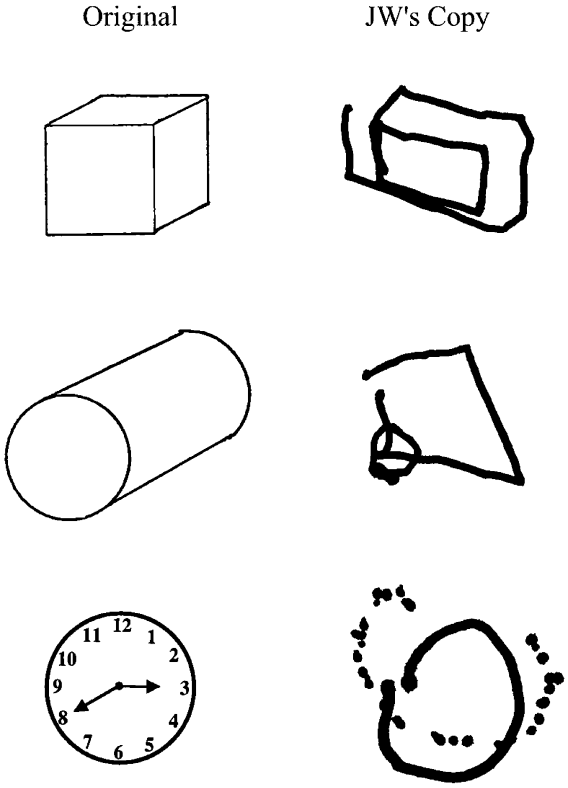

Figure 1 Patient JW's copies of simple line drawings.

illustrated by these examples, CK, like JW, is clearly not blind. However, despite his intact visual acuity, he fails to recognize even familiar and common visually presented objects. This deficit holds irrespective of whether the objects are drawn in black-and-white on a piece of paper or whether they are shown in slides or even as real three-dimensional objects, although the addition of information such as color and surface texture does assist recognition to some extent.

CK, like JW, can also use tactile/haptic information to recognize objects; he was perfectly able to recognize a padlock and a paper clip by touch alone. CK can also provide detailed definitions for an object whose name is presented to him verbally; for example, he defined a pipe as "a long cylindrical hollow object to convey liquid or gas" and a card of matches as "a cardboard container containing long sticks or matches which are struck against cordite." These definitions clearly demonstrate that his deficit is not attributable to a failure to name objects nor a loss of semantic knowledge.

CK is unable to read and, although he writes flawlessly, he cannot read his own writing presented to him at a later point in time. CK's hobbies have also

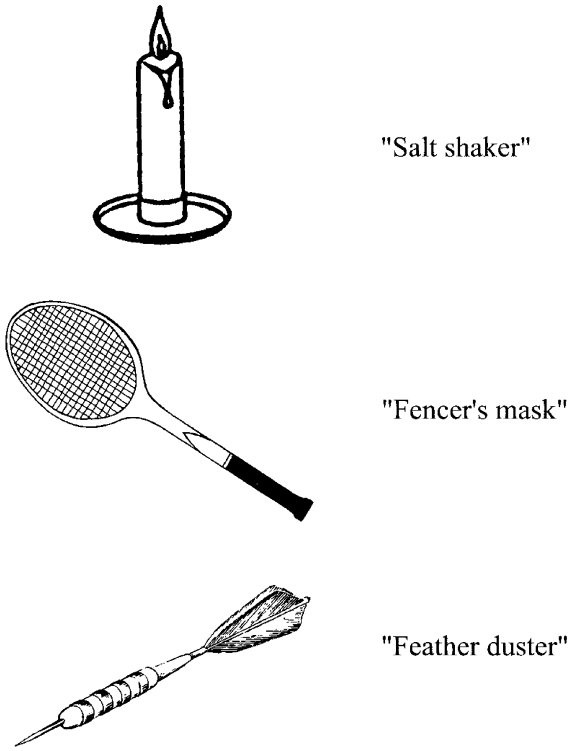

Figure 2 Line drawings misnamed by patient CK.

been affected; he is no longer able to design complex configurations of his large plastic soldier collection or visually differentiate airplanes, a domain in which he had rather extensive knowledge premorbidly.

II. BACKGROUND

Despite the behavioral differences between JW and CK, they have a dramatic deficit: They are unable to recognize even common, familiar objects—a disorder termed "agnosia" by Sigmund Freud (coined from the Greek "without knowledge"). Visual agnosia is a disorder of recognition, in which a person cannot arrive at the meaning of some or all categories of previously known visual stimuli, despite normal or near-normal visual perception and intact alertness, intelligence, and language. Despite the visual recognition problems associated with agnosia, there is normal recognition of objects through modalities other than vision (touch, auditory, and verbal definitions or description of their function), which suggests that the deficit is not simply a difficulty in retrieving names or in accessing the necessary semantic information. Visual recognition has been more extensively studied than recognition in other modalities, although similar deficits have been observed in patients with auditory (auditory agnosia) or tactile (tactile agnosia) deficits.

The traditional view of agnosia as a specific disorder of recognition has undergone considerable challenge in the past, with critics contending that all visual agnosias can be explained by a subtle alteration in perceptual functions likely accompanied by a generalized intellectual deterioration. Despite this early skepticism, there is now widespread acceptance of this disorder as a legitimate entity and detailed case studies have been concerned with characterizing both the underlying mechanisms that give rise to this disorder and the overt behaviors.

Lissauer was the first to classify visual object agnosia into two broad categories: apperceptive "mindblindness" and associative mindblindness. These impairments were evaluated by requiring patients to (i) describe the formal features of a pattern, (ii) reproduce it by drawing, and (iii) recognize it among similar alternatives. Using Lissauer's classifications, a person with apperceptive agnosia is assumed to be impaired at constructing a perceptual representation from vision and subsequently is unable to copy, match, or identify a drawing. In contrast, a person with associative agnosia is one who cannot use the derived perceptual representation to access stored knowledge of the object's functions and associations but is able to copy and match the drawing even though he or she is unable to identify it.

Recent neuropsychological accounts by Humphreys and Riddoch as well as by Warrington and colleagues and computational accounts such as that of Marr and colleagues have sought to extend Lissauer's dichotomy for two reasons. The first reason is the growing understanding that visual object recognition comprises many distinct steps not captured by the simple dichotomy. For example, it has been suggested that apperceptive processes include encoding the primitive dimensions of shape and segmentation of figure from ground. Associative processes may also be subdivided to include access to stored visual knowledge of objects, followed by access to stored associative and functional (semantic) knowledge from the description derived from the image. The second reason for further differentiation of the underlying processes, and the lesion types, derives more fine-grained neuropsychological analysis. One such example is of patients who show impaired access to knowledge of associative and functional properties of the object but have well-preserved understanding of the object's shape, as

reflected in a high-complexity object decision task (differentiating real objects from novel objects that are composed of parts of real objects). Other patients perform relatively poorly at object decision but are still able to carry out many high-level perceptual tasks, such as matching objects across different viewpoints and sorting pictures into basic categories. These developments have forced a further refinement of our understanding of visual processing and the types of breakdown that are possible. Despite the simplicity of Lissauer's dichotomy and its clear inadequacy, it provides a coarse framework that has proved useful in describing agnosia, as illustrated in the book *Visual Agnosia* by Farah. Following Farah, we adopt this dichotomy as a starting point and describe these two forms of agnosia, we also provide a detailed discussion of the patients described previously and the implications of such disorders for our further understanding of visual object recognition. Before we continue our exploration of these types of agnosia, however, we first identify the underlying neuromechanisms responsible for this visual perceptual processing.

III. NEUROANATOMY

Milner and Goodale proposed that the two prominent cortical visual pathways that have been identified in the primate brain (after Mishkin, Ungerleider, and Macko) are each involved in two very different processes. The underlying mechanisms in the ventral stream, which projects from primary visual cortex to the inferotemporal cortex (via many routes involving areas V2, the ventral portion of V3, V4, and TEO) are thought to be involved in visual perception, whereas the dorsal stream, which projects from primary visual cortex (and the superior colliculus via the pulvinar) to the posterior parietal cortex is thought to be involved in the visual control of action (Fig. 3). Both streams are thought to process information about object features and their spatial locations, but each stream uses this visual information in different ways. The transformations carried out by the dorsal stream deal with moment-to-moment information about the location and orientation of objects and thereby mediate the visual control of skilled actions, such as manual prehension, directed at those objects. In contrast, visual information is transformed in the ventral stream to deliver the enduring characteristics of objects and their relations, permitting the formation of long-term perceptual representations of the world. Such representations play an essential role in the recognition and identification of objects and enable us to classify objects and events, attach meaning and significance to them, and establish their causal relations. Such operations are essential for accumulating a knowledge base about the world.

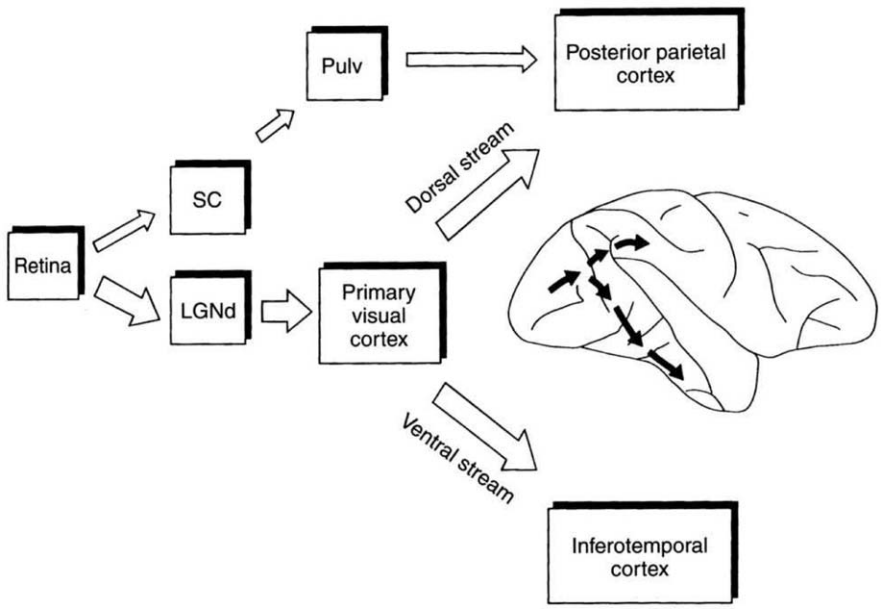

Figure 3 Diagram of the major routes leading from the retina into the dorsal and ventral streams. LGNd, lateral geniculate nucleus, pars dorsalis; Pulv, pulvinar; SC, superior colliculus. Reprinted from *Current Biology* **4**(7), Goodale, M. A., Meenan, J. P., Bulthoff, H. H., Nicolle, D. A., Murphy, K. J., and Racicot, C. L., Separate neural pathways for the visual analysis of object shape in perception and prehension, pp. 604–610, copyright 1994, with permission from Elsevier Science.

Many of the cells in inferotemporal cortex, the terminus of the ventral stream, respond best to complex visual stimuli, such as hands and faces; in particular, the more anterior parts of the inferotemporal cortex are remarkably selective in their responses to object attributes. The receptive field of virtually every cell in the inferotemporal (IT) cortex, a complex of areas lying ventrally below the superior temporal sulcus, including various subdivisions of area TE along with area TEO, includes the foveal region, where fine discriminations are made. These cells also have large receptive fields that allow for generalization across the entire visual field and for coding the intrinsic features of an object independent of its location. The critical features that activate cells in the anterior IT cortex are moderately complex and can be thought of as partial features common to images of several different natural objects. There are also neurons in the IT cortex that demonstrate properties consistent with object constancy in that they remain selectively responsive to a visual stimulus despite changes in stimulus viewpoint, retinal image size, or even color. Thus, the ventral stream is uniquely set up to process visual information into perceptual representations to which meaning and significance can be attached and stored. Damage to the ventral stream is believed to cause the disturbances of object recognition that are characteristic of visual agnosia.

Evidence for this derives from nonhuman primate work, in which large bilateral resections of the temporal lobe result in a form of visual agnosia, Klüver–Bucy syndrome. Lesions of the IT cortex impaired the monkey's ability to identify objects when the discriminations required use of color, pattern, or shape. These monkeys had difficulty using vision to learn associations with objects and could no longer recognize objects or distinguish between objects on the basis of their visual dimensions. They were unable to distinguish food from nonfood objects using vision alone and were unable to learn new visual discriminations between patterns for food reward. Although they incessantly examined all objects in sight, these animals recognized very little and often picked up the same item repeatedly. Klüver–Bucy syndrome can also be achieved with just the removal of IT but, like human visual agnosia, the IT monkey's recognition deficits cannot be explained by "low-level" sensory impairments since large bilateral lesions of IT have been found to have no residual effect on visual acuity.

Recent functional neuroimaging studies of regional blood flow in normal human subjects have revealed many different visual areas beyond primary visual cortex that appear to correspond to those in the ventral stream of the monkey brain that are specialized for the processing of color, texture, and form differences of objects. These studies have shown that face-matching tasks involve the occipitotemporal regions, detection of shape activates regions along the superior temporal sulcus, and the ventral region of the temporal lobe, and the perception of color is associated with activation of the lingual gyrus (V4).

IV. APPERCEPTIVE AGNOSIA

Individuals with apperceptive agnosia, such as patient JW, have profound difficulty recognizing and naming line drawings; their ability to recognize, copy, or match simple shapes as well as more complex objects is severely impaired. However, their elementary visual functions, such as acuity, brightness discrimination, and color vision, are relatively preserved, along with reasonable sensory and semantic memory functioning in the visual domain. These patients have normal visual fields and can maintain fixation on a visual target. The fundamental deficit involves an inability to process features, such that they are not fully available for developing a percept of the overall structure of an object.

One of the classical cases of apperceptive agnosia, described by Benson and Greenberg, was thought to be blind for several months following carbon monoxide-induced anoxia until he was seen successfully negotiating his wheelchair down a passage. Testing revealed that his fields were full to a 3-mm stimulus, that he could reach accurately for fine threads placed on a piece of paper and detect small changes in size, luminance, and wavelength, and that he was aware of small movements. Despite these fundamental abilities, he was unable to recognize objects, letters, or numbers and was unable to discriminate between any visual stimuli that differed only in shape.

Even though recognition of real objects is also impaired in these individuals, it is often better than recognition of line drawings; identifications of objects are typically inferences, made by piecing together color, size, texture, and reflectance clues. These individuals can often make accurate guesses about the nature of objects from such cues, such as the shininess of the glass and metal on a salt shaker or the color of an apple. A striking feature of this disorder is that many patients spontaneously use quite laborious and time-consuming tracing strategies of the hand or

head to aid in the recognition of visual objects. These strategies, although helpful, may not always produce an accurate result because one needs a reasonably good visual image in the first place for the purposes of tracing.

Apperceptive agnosia corresponds to the breakdown at the stage at which the sensory features of the stimulus are processed and its structural description is achieved—a relatively early stage of the visual recognition networks in the human equivalent of the ventral stream. The deficit appears to be at the level of shape or form discrimination. Some apperceptive agnosic patients are more impaired at perceiving curved than straight lines. JW, for example, is poor at deciding whether two line features are the same or different unless their orientations are very different. He also does not show "popout" of a target that differs from the background distractors if the difference is one of curvature or orientation (unless the differences are very great). Some patients may also fail to achieve perceptual constancy, interpreting a circle as an ellipse.

Interestingly, at least one apperceptive agnosic patient, DF, reported in the literature by Milner and Goodale appears to have implicit knowledge of object attributes that is not available for explicit report. As a result of carbon monoxide-induced anoxia, DF sustained damage to her occipital lobes bilaterally that extends into ventral occipital and dorsal occipitoparietal regions, while largely sparing primary visual cortex. Even though DF's "low-level" visual abilities are reasonably intact, she can no longer recognize common objects on the basis of their form or even the simplest of geometric shapes. Nevertheless, despite her profound inability to perceive the size, shape, and orientation of visual objects, DF can direct accurate and well-formed grasping movements, indistinguishable from those shown by normal subjects, toward the very same objects she cannot identify or discriminate. It has been argued that this intact visuomotor function is mediated by relatively intact parietofrontal cortical mechanisms (accessed via the dorsal stream) in DF, which continue to operate efficiently despite severely damaged occipitotemporal (ventral stream) structures. At this point, it is worth noting that DF also appears to have implicit knowledge of visual attributes even though she appears not to have this information available to her when tested directly. The critical evidence comes from studies that show that DF is influenced by the McCullough effect. This is a color aftereffect that is contingent on the orientation of grating patterns. When shown white-and-black line gratings in horizontal or vertical orientations, DF is poor at reporting orientation explicitly. However, after she was adapted to a green-and-black vertical grating alternating with a red-and-black horizontal grating, she reported seeing color on white-and-black gratings with the horizontal subcomponent appearing greenish and the vertical component appearing pinkish. As in control subjects, the effect was strongly dependent on the congruence of the angles in the testing and adaptation phase. In a follow-up, DF revealed a preserved McCullough effect with oblique gratings, indicating more fine orientation discrimination ability than simply vertical and horizontal.

The neurological damage in apperceptive agnosia tends to be diffuse and widespread and can involve damage to the posterior regions of the cerebral hemispheres, involving occipital, parietal, or posterior temporal regions bilaterally. This damage is often the result of cerebral anoxia, where a lack of oxygen to the brain produces neuronal death in "watershed" regions or regions lying in the border areas between territories of different arterial systems. Carbon monoxide-induced anoxia not only produces multifocal disseminated lesions but also affects the interlaminar connections between neurons. Mercury poisoning, which is also known to give rise to apperceptive agnosia, affects the white matter, thereby compromising connections between neurons rather than the neurons themselves.

V. SIMULTANAGNOSIA

A person with simultanagnosia can perceive the basic shape of an object but is unable to perceive more than one object, or part of an object, at a time. Thus, these patients appear to have limited ability to process visual information in parallel, although they are relatively good at identifying single objects. Farah distinguished between two forms of simultanagnosia according to whether the patients had lesions affecting the dorsal or ventral visual stream. Each is discussed in turn here.

Although a person with dorsal simultanagnosia is able to recognize most objects, he or she generally cannot process more than one at a time, even when the objects occupy the same region of space. These individuals often have counting deficits and their descriptions of complex scenes are slow and fragmentary. The underlying impairment in dorsal simultanagnosia appears to be a disorder of visual attention so severe that these individuals cannot explicitly report perceiving the unattended objects. Dorsal simultanagnosia is often observed in the context of Baliant's

syndrome, is accompanied by oculomotor deficits and optic ataxia, and results from a bilateral parietooccipital lesion.

Individuals with apperceptive agnosia and those with dorsal simultanagnosia share many characteristics. In some cases, they may act effectively blind, being unable to negotiate visual environments of any complexity, and their perception appears to be piecemeal and confined to a local part or region of the visual field. The piecemeal nature of their perception, however, differs in significant ways. In apperceptive agnosia, only very local contour is perceived, whereas in dorsal simultanagnosia whole shapes are perceived, but only one at a time. Individuals with apperceptive agnosia use color, size, and texture to guess at objects but cannot use shape information. In contrast, individuals with dorsal simultanagnosia have intact shape perception. In contrast to apperceptive agnosia, the deficit in dorsal simultanagnosia appears to be attention related rather than shape related.

A person with ventral simultanagnosia usually has a lesion to the left inferior temporooccipital region. Although such a patient is generally able to recognize a single object, he or she does poorly with multiple objects and with single complex objects, irrespective of their size. Although they cannot recognize multiple objects, they differ from individuals with dorsal simultanagnosia in that they can perceive multiple objects. These individuals can count scattered dots and, if given sufficient time, can also recognize multiple objects. They respond slowly and often describe explicitly individual elements of the picture without appreciating the whole scene. This is also true in reading, and these patients are classified as letter-by-letter readers because they only recognize one letter of a word at a time, and hence show a linear relationship between reading speed and the number of letters in a word.

A recent reconceptualization of simultanagnosia by Humphreys and colleagues suggests that the two different forms are well characterized in terms of impairments in constructing different forms of spatial representations. Although those with ventral lesions are limited in the number of parts of an object they can represent, those with dorsal lesions are limited in the number of separate objects they can represent.

VI. HIGHER ORDER APPERCEPTIVE DEFICITS

Many patients have been identified who, although still classified as having apperceptive agnosia, appear to have some residual visual processing ability and can copy and match objects to some degree. These patients have object recognition difficulty under challenging conditions and do somewhat better in more optimal conditions. For example, they are impaired at recognizing objects under poor lighting conditions when shadows are cast, creating misleading contours. An additional manipulation that proves difficult for these patients is recognition of foreshortened or degraded objects. They are also poor at recognizing objects from unusual viewpoints or unconventional angles relative to more standard viewpoints. The classification of these patients is unclear because there is ongoing debate regarding the mechanisms that give rise to such deficits and whether, indeed, these deficits arise from a common source. Warrington and colleagues argued that the failure to identify objects from unusual but not conventional views is consistent with a deficit that occurs once sensory information has been processed and is attributable to a problem in categorizing two instances of the same stimulus as identical. Some patients appear to be impaired at deriving viewpoint-independent representations, despite the fact that they are able to construct a viewpoint-dependent representation. This distinction between viewpoint-dependent and -independent representation parallels the distinction made by Marr in his well-known theory of vision.

VII. ASSOCIATIVE AGNOSIA

Unlike apperceptive agnosia, a person with associative agnosia can make recognizable copies of a stimulus that he or she may not recognize subsequently and can also successfully perform matching tasks. Teuber elegantly referred to this deficit as "perception stripped of meaning." As in the case of apperceptive agnosia, recognition is influenced by the quality of the stimulus and performance on three-dimensional objects is better than on photographs, and performance on photographs is better than on line drawings. The recognition deficit appears to result from defective activation of information pertinent to a given stimulus. There is a failure of the structured perception to activate the network of stored knowledge about the functional, contextual, and categorical properties of objects that permit their identification. In effect, this is a deficit in memory that affects not only past knowledge about the object but also the acquisition of new knowledge. Unlike individuals with apperceptive agnosia, who guess at object identity based on color and

texture cues, people with associative agnosia can make use of shape information. When these individuals make mistakes in object identification, it is often by naming an object that is similar in shape to the stimulus. For example, FZ, a patient of Levine, misidentified a drawing of a baseball bat several times. Interestingly, his answer differed on each occasion, referring to it as a paddle, a knife, or a thermometer.

Although these patients can copy drawings well, the drawings are not necessarily normal; the end product might be a fairly good rendition of the target but the drawing process is slow and slavish and they can lose their place if they take their pen off the paper since they do not grasp component shapes. As can be seen in Fig. 4, a copy of a geometric configuration by patient CK, an individual with associative agnosia, was reasonably good, although the process by which he copied indicates a failure to bind the contours into meaningful wholes.

One of the important claims of associative agnosia is that perception is intact and it is meaning that is inaccessible. Much effort has been directed at evaluating this claim and the general finding is that even patients with associative agnosia have some form of visual impairment. For example, LH, a well-known and thoroughly documented agnosic patient studied by Levine and Calvanio, was moderately impaired on several tests of perception. He was considerably slower than normal subjects in making rapid comparisons between shapes or in searching for a prespecified target figure. His performance was also poor on tasks that required him to identify letters that were fragmented or degraded by visual noise, relative to control subjects. Based on the findings from LH and other associative agnosic patients, it is clear that their perception is not normal. Although it may be considerably better than that of apperceptive agnosic patients, it is still impaired to some extent.

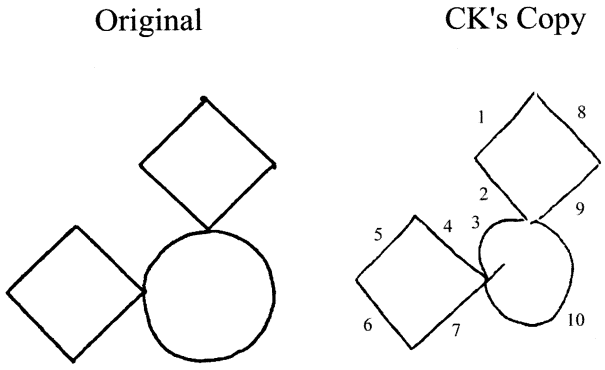

Figure 4 Patient CK's copy of a geometric configuration. The numbers assigned to his copy indicate the order in which the lines were drawn and show that he copies in a very literal fashion, failing to integrate lines 1, 2, 8, and 9 into a single shape.

The brain damage in associative agnosia is more localized than in apperceptive agnosia. Some cases appear to involve only unilateral damage to the occipital lobe and bordering posterior temporal or parietal lobe. The lesions are often more circumscribed, sometimes involving the left inferior longitudinal fasciculus, which connects fusiform gyrus to temporal structures, or the bilateral posterior hemispheric areas in posterior cranial artery territory.

VIII. INTEGRATIVE AGNOSIA

Lissauer's dichotomy makes provision for two main stages of processing, apperception and association. Object recognition, however, involves more than matching stimuli coded in terms of primitive features such as line orientation to stored knowledge. Instead, the spatial relations between the lines and features need to be coded, the object needs to be segregated from its ground, and parts of an object need to be related and integrated. These processes are typically thought of as serving intermediate-level vision. There have been several recent detailed reports of patients with deficits due to poor perceptual integration of form information ("integrative agnosia"). Patient HJA, studied by Riddoch and Humphreys, appears to oversegment identify objects piecemeal. For example, when presented with a paintbrush, HJA responded that "it appears to have two things close together or else you would have told me." CK's descriptions of errors reveal a similar pattern; he is able to perceive and report some part of the image but not the whole. Indeed, CK appears to oversegment the image, as illustrated in his copying performance. Whether or not integrative agnosia might previously have been considered an apperceptive or associative form of agnosia is difficult to determine. On the one hand, these patients appear not to be able to exploit Gestalt grouping principles, in which case the problem is closer to that of apperceptive agnosia. On the other hand, these patients perform well on standardized testing of perceptual processes, suggesting that they are more akin to associative agnosic patients. For example, these patients can discriminate between Efron shapes (squares and rectangles that have the same surface area but vary in aspect ratio) and can make orientation and

size matching judgments at a normal level. Given the uncertainty of the classification, a separate category is obviously warranted.

The hallmark of integrative agnosia is an impairment in integrating elements, which are well detected, into a perceptual whole. For example, these patients do more poorly at recognizing overlapping objects than when the same objects presented nonoverlapping, presumably because of the difficulty in segregating and assigning boundaries in the former case. Counterintuitively, these patients perform better when the stimuli are silhouettes rather than line drawings. This finding suggests that the lines that usually enhance perception and add information to the display disrupted the patients' ability to recognize objects. This is likely a consequence of their inability to group elements into a whole and this process is less taxing in the case of silhouettes. These patients also do more poorly when the exposure duration of stimuli is limited. Finally, the performance of the patients improves under limited exposure duration. This is not surprising because it has been suggested that the segmental visual processing is done in a serial fashion and limiting the exposure of the items likely affects this adversely.

Because these patients are impaired at grouping, they appear to be oversensitive to segmentation cues and to parse stimuli inappropriately into parts. In fact, grouping and segmentation are likely two sides of the same coin, with the grouping impairment leading to piecemeal and fragmented image processing. The integrative agnosia deficit appears to affect a stage of visual coding intermediate between basic shape coding and visual access to memory representations, concerned with parallel perceptual grouping and the integration of parts into wholes. It is revealed most strikingly under conditions when segmentation or grouping are stressed.

IX. OPTIC APHASIA

Like agnosic patients, patients with optic aphasia have a modality-specific (visual) recognition deficit and can recognize objects from both auditory and tactile presentation. The critical distinction between agnosia and optic aphasia, however, is that optic aphasic patients can recognize objects. This is evidenced by their nonverbal identifications (e.g., through gesture) and their ability to sort a visual stimulus with other stimuli of the same category. Additionally, these patients are also not particularly sensitive to the visual quality of the stimulus and performance is approximately equivalent for object, photographs, and line drawings, unlike the case for associative agnosic patients. Another important distinction concerns the error types. The errors made by patients with optic aphasia are usually semantic in nature and hardly ever visual, whereas in associative agnosia the errors are primarily visual. One of the best studied patients by Lhermitte and Beauvois, Jules F., when shown a picture of a boot correctly gestured pulling on a boot but called it a hat. Optic aphasia patients also appear to make many perseverative errors, reproducing the error response from previous trials and sometimes producing "conduites d'approache" or progressive approximation to the target.

X. CATEGORY-SPECIFIC VISUAL AGNOSIA

For some patients with associative agnosia, recognition is not equally impaired for all categories of objects. Category-specific visual agnosia (CSVA) is a deficit in which the boundary between impaired and intact recognition can be approximately defined along the semantic criterion of biological vs nonbiological objects. In other words, these patients can show severely impaired visual recognition of objects from biological categories while recognition of most other categories is largely spared. For example, a patient may be able to recognize all manners of tools or artifacts but show marked difficulties in recognizing even the most common fruits or vegetables. CSVA is believed to be a semantic disorder, in which patients have problems associating the view of an object, in a specific category, with stored knowledge of its identity. The mechanisms underlying visual perception do not appear to have access to the semantic knowledge of certain categories of objects.

It has also been proposed that this dissociation may be the result of the recognition of living things depending on some specialized neural mechanisms that are not needed for the recognition of nonliving things. Evidence for this derives from the findings that CSVA for biological objects usually follows inferior-temporal damage. Moreover, recent studies have found that defective recognition of persons was associated with damage to right temporal regions, defective recognition of animals was associated with damage to the right mesial occipital/ventral temporal region and left mesial occipital region, and defective

recognition of tools was associated with damage in the occipital–temporal–parietal junction of the left hemisphere. As we discuss later, these studies have helped to reveal the extent to which there is modular organization in the visual system.

XI. RELATIONSHIP BETWEEN VISUAL OBJECT AGNOSIA AND WORD AND FACE RECOGNITION

One of the interesting recent developments in our investigations of object agnosia concerns different forms of category specificity, but here the category refers to different forms of visual stimulus recognition, such as face and word recognition. The critical issue is whether agnosia can be restricted to object recognition or whether it is reflects a broader form of visual impairment. In an extensive review of the literature, Farah suggested that the latter is more correct and that because visual recognition procedures for objects, words, and faces are not neurally separated, not all pure forms of visual deficit are possible. This argument was based on the fact that some but not all patterns of dissociation have been observed between these three classes of stimuli. In particular, Farah argues that there have been no convincing reports of patients with visual object agnosia without alexia or prosopagnosia or with prosopagnosia and alexia without visual object agnosia. The failure to find these two patterns of deficit has been taken to suggest that, instead of there being independent and separate mechanisms subserving objects, words, and faces, there may be a continuum of recognition processes. At one end of this continuum is a more holistic or gestalt form of processing that is optimized for processing nondecomposable perceptual wholes, such as faces, and at the other end is a process that is optimized for processing multiple perceptual parts, such as letters of words. Object recognition may be mediated by either process depending on the nature of the stimulus and its perceptual characteristics. By this account, patients may be selectively impaired as a consequence of damage to one of these two processes. Thus, in its pure form, damage to the more holistic process will result in prosopagnosia in isolation, whereas damage to the more part-based processes will result in alexia in isolation.

An obvious claim of this account is that it should not be possible to observe a patient for whom the recognition of objects is impaired, in isolation, given that object recognition is subserved by one of the two other processes. Despite this interesting hypothesis, there have been several recent case studies that challenge it. Thus, for example, there have been several detailed studies of patients who have a selective deficit in object recognition with retained face and word recognition. The presence of such a pattern undermines the two-process account of visual recognition and is more consistent with a view in which there is neural differentiation between all types of visual stimuli. Whether this differentiation refers to the fact that different mechanisms are involved in encoding the three stimulus types or in accessing their stored knowledge remains unclear. The proposal that the three types of visual stimuli are differentiated to some extent is generally (although not perfectly) consistent with recent functional neuroimaging data that shows that different brain areas are activated for the different stimulus types. Thus, for example, word recognition is associated with an increase in cortical activation in the left medial extrastriate region, whereas face recognition is associated with increased activation in the right fusiform gyrus. Object recognition is a little more problematic. Although enhanced activity is observed in a host of regions in the left hemisphere and some in the right hemisphere, some of these activations appear to overlap those associated with face recognition and the extent to which there is some sharing of mechanisms for faces and objects remains controversial.

XII. AGNOSIA AND ACTION

Previously we discussed patient DF, who developed a severe form of apperceptive agnosia following carbon monoxide-induced anoxia. Although DF's visual system is unable to use shape information to make perceptual judgments and discriminations about an object, she is able to use the same information to accurately guide her prehensile movements to those same targets. For example, even though DF is unable to discriminate solid blocks of differing dimensions, she accurately scales her grasp when picking up the blocks, opening her hand wider for larger blocks than she does for smaller ones, just as people with normal vision do. DF also rotates her hand and wrist appropriately when reaching out to objects in different orientations, despite being unable to describe or distinguish the size, orientation, and shape of the different objects. It appears that although the perceptual mechanisms in DF's damaged ventral stream can no longer deliver any perceptual information about the

size, orientation, and shape of objects she is viewing, the visuomotor mechanisms in her intact dorsal stream that control the programming and execution of visually guided movements remain sensitive to these same object features.

Although the discussion of the dorsal and ventral streams in this article has emphasized their separate roles, there are many connections between the two streams and thus the opportunity for "cross-talk." Recent investigations have shed light on the role that the communication between these two streams plays in object recognition. In some cases of associative agnosia, it has been reported that the ability to identify actions and to recall gestures appropriate to objects could play a significant role in preserving recognition of certain objects. Sirigu suggested that sensorimotor experiences may have a critical role in processing information about certain objects. It has been reported that the object categories that individuals with associative agnosia have difficulty reporting are those that they could not recall their action. The objects that they do not recognize would thus appear to be those that they do not associate with their sensorimotor experiences. The objects that they do recognize may be those whose action plays a critical part. This could help explain the "living" versus "nonliving" dissociation seen in CSVA. Action is certainly an important element for knowing tools, kitchen utensils, and clothes. In contrast, most animals do not evoke any gestures, and the only action linked with most fruits and vegetables is a simple gripping. It also appears that the recognition of action is well preserved in these individuals. The impairments in recognizing static objects perceived visually in associative agnosia sharply contrast with the relatively better ability to recognize objects from gestures illustrating their use and to recognize actions shown in line drawings.

It appears that the dorsal stream not only provides action-relevant information about the structural characteristics and orientation of objects but also is involved in the recognition of actions and in the recognition of objects when sensorimotor experience is evoked. This suggests that the dorsal pathway is involved in conscious visual perception and in the interpretation of goal-oriented action, even when shown in a static way. It is possible that when ventral stream damage in agnosia prevents direct access to representations of an object for perception, sensorimotor information from the dorsal stream may provide a limited mechanism for recognition. In other words, semantic information about objects may be accessed by the dorsal stream and passed onto the ventral stream for recognition. The preservation of how to manipulate an object may play a crucial part in assisting object recognition in patients with associative agnosia.

XIII. WHAT AGNOSIA TELLS US ABOUT NORMAL VISION

A major obstacle to understanding object recognition is that we perform it so rapidly and efficiently that the outcome belies the underlying complexity. One approach to discovering the processes that mediate object recognition is to study the performance of individuals who have an impairment. This breakdown approach has proven extremely illuminating and has provided important insights into the mechanisms involved in normal object recognition. The breakdown approach as reflected in the study of neuropsychological patients with agnosia is related to other approaches that also examine the system in its nonoptimal state. These approaches include the study of visual illusions in which the perception of normal subjects is distorted through some stimulus manipulation and the study of perception when cues are reduced, such as in monocular versus binocular vision.

Neuropsychological studies of agnosia have not only identified a major distinction between "early" and "late" stages of object recognition, as well as differentiated more discrete impairments within each of these stages, but also uncovered deficits associated with "intermediate"-level vision. Additionally, investigations with patients have allowed us to address issues such as category specificity both within the domain of objects and across visual domains, relating faces and words to objects. Finally, how perception might be related to action has been a focus of neuropsychological research and important observations have been gleaned from the detailed and thorough study of these patients with agnosia.

Studies of patients with agnosia have also shed light on the extent to which there is modular organization in the visual system. Although we have been concerned only with deficits of object recognition following brain damage, there are also patients with selective deficits of depth, motion, and color processing. One interpretation of these selective deficits is that there are independent regions of the brain that are specialized for certain functions. An even more extreme view, but one that has been tempered recently, is that these independent regions are exclusively dedicated for particular visual functions. At a higher

level, whether there are truly independent areas for recognition of different categories of visual objects (living/nonliving) or for different types of stimuli (faces, words, or objects) remains a matter of ongoing investigation.

Perhaps most important is that these studies of patients with visual object agnosia have constrained our theories of object recognition and, in turn, these theories have guided our investigation of these interesting and illuminating deficits.

GLOSSARY

afferent control systems Neural systems involved in monitoring visual and kinesthetic feedback during the execution of handwriting movements.

agraphia Acquired disorders of spelling and writing caused by neurological damage.

allographic conversion The process by which abstract graphemic representations are converted into the appropriate physical letter shapes.

allographs Different physical forms of a letter (i.e., upper- vs lowercase or print vs script).

grapheme Letter or cluster of letters that corresponds to a single phoneme in the language.

graphemic buffer Working memory system that temporarily stores abstract orthographic representations while they are being converted into codes appropriate for various output modalities (i.e., writing, oral spelling, typing, or spelling with anagram letters).

graphemic output lexicon The memory store of learned spellings. Representations in the graphemic output lexicon contain information about the orthographic structure of familiar words.

graphic innervatory patterns Motor commands to specific muscle effector systems involved in the production of handwriting. Graphic innervatory patterns determine the correct sequence of muscle activations and set the appropriate kinematic parameters for the writing task, including absolute stroke size, duration, and force.

graphic motor programs Abstract spatiotemporal codes for writing movements. Graphic motor programs contain information about the sequence, position, direction, and relative size of the strokes necessary to create different letters.

phoneme–grapheme conversion The mental process by which individual units of sound are translated into the corresponding letters.

The term agraphia refers to disorders of spelling and writing caused by neurological damage. In this article, we review the neuropsychological characteristics and anatomical correlates of the various agraphia syndromes encountered in clinical practice. Patterns of abnormal performance are interpreted within the framework of a cognitive information processing model of normal spelling and writing. Converging evidence from patients with focal brain lesions and functional neuroimaging studies (position emission tomography and functional magnetic resonance imaging) in normal subjects is used to identify the neural systems involved in writing.

I. INTRODUCTION

Writing is a system of communication in which conventional graphic signs are used to represent various elements of spoken language (i.e., words, syllables, or phonemes). In its fully developed form, writing is probably no more than 6000 years old—a relatively recent achievement in human evolution. The neuropsychological study of writing has an even shorter history that begins with the work of nineteenth-century European neurologists. These early investigators noted that although spoken and written expression were both frequently impaired following damage to the language-dominant hemisphere, disorders of writing, or agraphia, occasionally occurred

in isolation. This important clinical observation led to the proposal that speech and writing may have distinct neuroanatomic substrates. The potential independence of writing from speech was cogently argued by William Ogle in a landmark paper published in 1867 which also included the first classification system of agraphia. Specifically, Ogle described a type of linguistic agraphia in which patients produced well-formed letters but spelling was inaccurate or one word was substituted for another. He also noted that in other patients, agraphia was characterized by defective motor execution resulting in poorly formed letters that were frequently unrecognizable. Although Ogle's views about the relationship between speech and writing drew criticism from many of his contemporaries, the proposed clinical distinction between linguistic and motor forms of agraphia was generally accepted.

Ogle's pioneering observations were soon followed by attempts to localize the brain areas involved in writing and to clarify their anatomical and functional interactions with the cortical speech centers identified by Broca and Wernicke (Fig. 1). These efforts, spearheaded by the so-called "diagram makers," culminated in neuroanatomical models that postulated two distinct cortical centers for writing. Following Dejerine's suggestion, orthographic information relevant to the correct spelling of words was believed to be stored in the dominant angular gyrus in the form of "optic word images." In contrast, the "motor graphic images" responsible for controlling the execution of writing movements were localized to a premotor cortical area at the foot of the second frontal convolution, sometimes referred to as Exner's writing center. The act of writing presumably required the coordinated activity of the putative parietal and frontal cortical centers.

In addition to these anatomical considerations, the diagram makers also engaged in lively debates about the nature of the linguistic codes or representations used in writing. A central and often controversial topic concerned the role of phonology. The fact that writing is acquired relatively late in linguistic development, after oral language functions are firmly established, suggested to many that written expression was parasitic upon speech and that it involved obligatory phonological mediation. Consistent with this view, simple introspection reveals that writing is normally

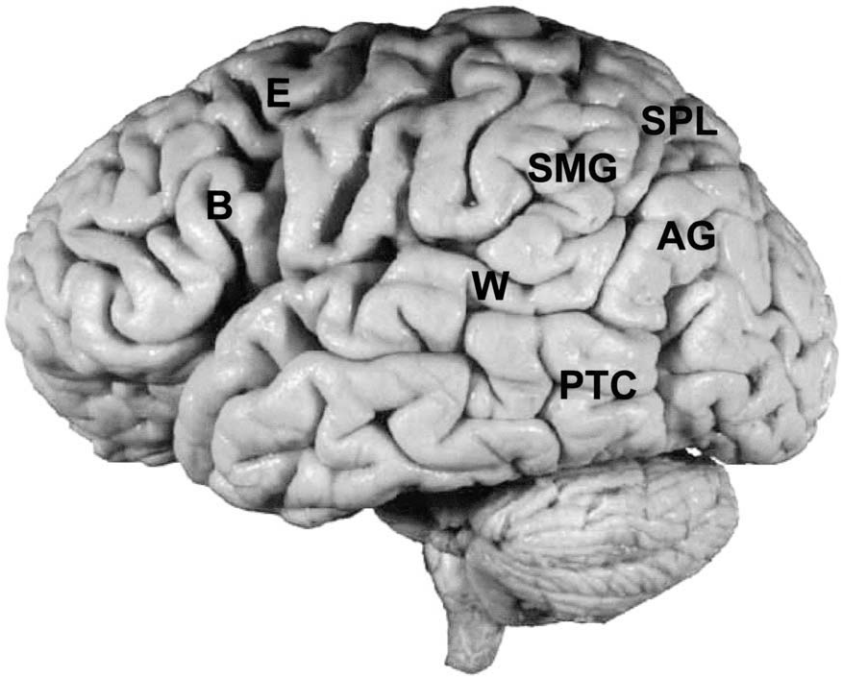

Figure 1 Cortical areas involved in speech and writing. B, Broca's area; W, Wernicke's area; E, Exner's writing center; AG, angular gyrus; PTC, posterior temporal cortex; SMG, supramarginal gyrus; SPL, superior parietal lobule [reproduced with permission from Nolte, J. (1998). *The Human Brain: An Introduction to Its Functional Anatomy*. Mosby, St. Louis, Missouri].

accompanied by "inner speech." Phonological theories of writing took two distinct forms. Some investigators explicitly denied the existence of word-specific orthographic representations and proposed that writing entailed segmenting spoken words into their constituent sounds, followed by the conversion of each sound into the appropriate letter (i.e., phoneme–grapheme conversion). As we shall see, this hypothesis is falsified by patients who lose the ability to perform phoneme–grapheme conversion but who can nonetheless spell familiar words accurately. Another version of the phonological theory of writing allowed for the possibility of stored orthographic representations for familiar words but maintained that these representations could only be activated indirectly via the spoken form of the word. The problem with this proposal is the clinical observation that in some aphasic patients written expression is superior to or is qualitatively different from speech production. These findings demonstrate that access to orthography is possible even when the corresponding phonological representation of the word is unavailable and further suggest that lexical representations for written and spoken words are neuroanatomically distinct. Note, however, that although the neuropsychological evidence is clearly at odds with the view that writing involves obligatory phonological mediation, it need not imply that phonology plays no role in writing under normal circumstances.

Although the fundamental questions raised by nineteenth-century investigators about the neural substrates and linguistic mechanisms of writing are still relevant today, contemporary work on agraphia has also been strongly influenced by cognitive models of language processing. The cognitive method of analysis relies on an information processing approach and seeks to understand complex language skills by decomposing them into several potentially independent processing components with distinct functional roles. In order to interpret the performance of neurological patients within this type of a theoretical framework, it is necessary to make the additional assumption that the proposed processing modules are also neuroanatomically distinct and can therefore be selectively impaired by brain damage. Following this line of reasoning, we begin our discussion of agraphia by presenting a cognitive model of normal spelling and writing. Next, we describe the clinical characteristics and neuroanatomical correlates of various agraphia syndromes and attempt an explanation of abnormal writing performance in terms of damage to different functional components of the model.

II. COGNITIVE MODEL OF WRITING

According to the model presented in Fig. 2, writing requires the coordinated activity of "central" and "peripheral" processing modules. Central processing components are linguistic in nature and are involved in generating spellings for familiar or unfamiliar words, whereas the peripheral components are responsible for converting orthographic information into motor commands for writing movements.

A. Central Components

The central components of the model correspond to three potentially independent linguistic spelling routes. Two of these, the lexical–semantic route and the lexical–nonsemantic route, are used for spelling familiar words. In contrast, plausible spellings for unfamiliar words or pronounceable nonwords (e.g., sprunt) are assembled by the nonlexical route. An additional central component that receives and temporarily stores the abstract orthographic representations computed by the three spelling routes is referred to as the graphemic buffer.

1. Lexical–Semantic Route

Spelling by the lexical–semantic route relies on interactions between the semantic system and the graphemic output lexicon (Fig. 2). The semantic system represents conceptual knowledge of word meanings independent of word forms. The graphemic output lexicon contains information about the orthographic structure of familiar words and thus functions as the memory store of learned spellings. As depicted in Fig. 2, semantic input to orthography may be direct (pathway A) or indirect via the phonological representation of the word that is also used in speech production (pathways B and C). It has been proposed that representations in the graphemic output lexicon are normally activated by combined input from both the direct and the indirect routes. Such dual coding may safeguard against errors that might occur if one or the other route was used exclusively. For instance, relying on the indirect route via the phonological output lexicon may result in homophone confusions (e.g., "stair"–"stare") since these words have the exact same sound pattern even though they are spelled differently. On the other hand, spelling by the direct route might be susceptible to semantic errors (e.g.,

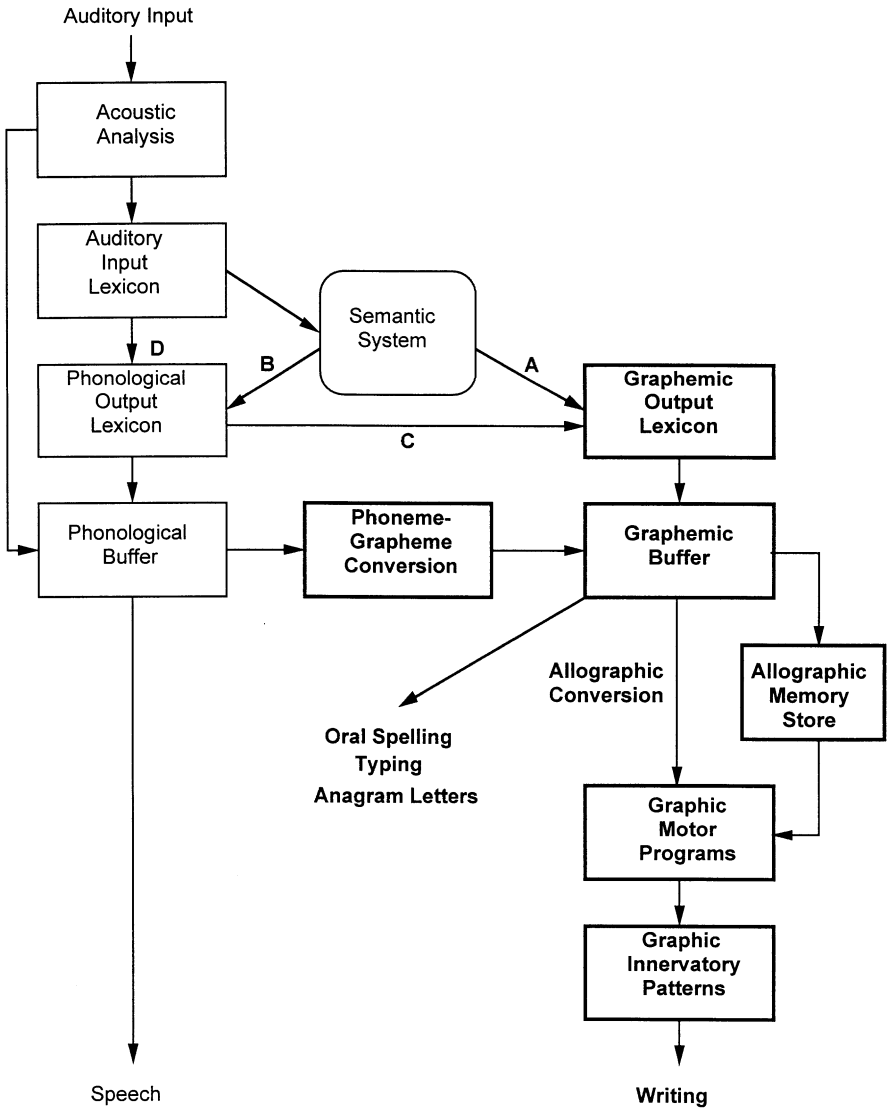

Figure 2 Cognitive information processing model of spelling and writing.

"day"–"week") unless the response was constrained by simultaneous phonological input to orthography via the indirect route. Postulating dual access to the graphemic output lexicon may also provide an explanation for the clinical observation that some aphasic patients with damage to the phonological output lexicon can write words they are no longer able to say (by relying on the direct route to the graphemic output lexicon via pathway A).

As can be seen in Fig. 2, the lexical–semantic route provides the only mechanism for incorporating meaning into writing. Therefore, this spelling route plays a critical role in conceptually mediated writing tasks such as written composition and written naming. It is likely that writing familiar words to dictation is normally performed via the lexical–semantic route as well, although the lexical–nonsemantic route can also potentially be used for this purpose.

2. Lexical–Nonsemantic Route

Spelling to dictation by the lexical–nonsemantic route relies on connections between the spoken and written forms of the same word that bypass the semantic system. One possibility is that the dictated word first activates its representation in the auditory input lexicon, followed by the retrieval of the corresponding entry from the phonological output lexicon, which in

turn activates the appropriate orthographic word form in the graphemic output lexicon (Fig. 2, pathways D and C). An alternative mechanism might involve direct connections between corresponding representations in the auditory input and the graphemic output lexicons. As it will become apparent later, the evidence for lexical–nonsemantic spelling comes mostly from patients with agraphia, and it is not entirely clear what function this spelling route might serve under normal circumstances.

3. Nonlexical Route

Normal individuals can produce plausible spellings for unfamiliar words or nonwords without significant difficulty. Since these novel items are not represented in the graphemic output lexicon, spelling cannot simply rely on the activation of stored orthographic patterns. According to our model, the spelling of unfamiliar words and nonwords is accomplished via the nonlexical spelling route. Unlike the lexical spelling routes that rely on a whole-word retrieval process, spelling by the nonlexical route involves a subword-level algorithmic procedure based on phoneme–grapheme conversion rules (Fig. 2). In this process, the novel auditory stimulus is first broken down into its component sounds, following which each constituent phoneme is converted into the corresponding grapheme. It is possible, however, that the nonlexical route can also perform phonological-to-orthographic translations based on units larger than individual phonemes and graphemes (e.g., syllables). Finally, it has been suggested that spelling nonwords may not be entirely nonlexical and may instead be based on lexical analogy with familiar words.

Phoneme–grapheme conversion plays an important role in learning to spell, but this rule-based nonlexical procedure is resorted to much less frequently once the normal adult spelling vocabulary is established. However, the nonlexical route can serve as a backup strategy when word-specific orthographic information is temporarily unavailable or is incomplete. This might happen when normal individuals attempt to spell words they do not use very often (i.e., low-frequency words). It should be noted that in orthographically opaque languages such as English, in which sound-to-spelling relationships are notoriously inconsistent, the nonlexical procedure can only succeed with unambiguous or regular words that have highly predictable phoneme–grapheme correspondences (e.g., ''mint''). Ambiguous words, in which the same phonology can be realized by more than one combination of letters (e.g., ''drain'' and ''drane''), and irregular words that contain exceptional phoneme–grapheme mappings (e.g., ''choir'') cannot be spelled correctly by the nonlexical route since the straightforward application of phoneme–grapheme conversion rules for such words will result in phonologically plausible errors (e.g., ''yot'' for ''yacht''). The spelling of ambiguous and irregular words, therefore, depends critically on access to precise word-specific orthographic knowledge.

4. Graphemic Buffer

Central spelling routes compute abstract orthographic representations that can be externalized in writing, oral spelling, typing, or as an arrangement of anagram letters. The graphemic buffer is a working memory system that temporarily stores these abstract orthographic representations while they are being converted into codes appropriate for the various output modalities (e.g., letter shapes for written spelling or letter names for oral spelling). As shown in Fig. 2, this processing module receives the output of all three spelling routes and therefore occupies a strategic position between the central and peripheral components of the writing process. The maintenance of information within the graphemic buffer is influenced by stimulus length (i.e., the number of graphemes that make up the spelling of a word or nonword) since longer items require more storage capacity than shorter ones. Dysfunction of the buffer is associated with the loss of information relevant to the identity and serial ordering of stored graphemes, leading to letter substitutions, additions, deletions, and transpositions.

B. Peripheral Components

The peripheral processing components of writing are responsible for converting abstract orthographic information into movements of the pen. This complex sequence, which begins with letter shape selection and ends with neuromuscular execution, is carried out by a set of hierarchically organized processing modules, the operational characteristics of which are discussed in this section. Peripheral conversion mechanisms that subserve other output modalities (i.e., oral spelling, typing, and spelling with anagram letters) will not be discussed here, except to note that these systems most likely diverge from writing at the level of the graphemic buffer (Fig. 2).

1. Allographic Conversion

The first step in producing writing is the allographic conversion process, which involves the selection of the appropriate letter shapes for the string of graphemes held in the graphemic buffer. In handwriting, letters can be realized in different case (upper vs lower) or style (print vs script). The various physical forms each letter of the alphabet can take are referred to as allographs (e.g., B, b, *b*, *b*). The choice of allographs is influenced by convention (e.g., capitalizing letters in sentence-initial position), contextual factors (e.g., filling out a form vs writing a note or a letter), and individual style.

The exact nature of the representations involved in allographic conversion remains poorly understood. Some investigators have proposed that allographs are stored in long-term memory as abstract visuospatial descriptions of letter shape (the allographic memory store in Fig. 2). Others have suggested that allographs correspond to letter-specific graphic motor programs in which shape information is specified in terms of the sequence of strokes necessary to produce the desired letter. Although it is currently not possible to adjudicate between these competing proposals, the latter interpretation certainly has the appeal of parsimony. In particular, it is not entirely clear why one would need to retrieve abstract visuospatial information about letter shapes once the characteristic stroke patterns of different letters are firmly established in procedural memory and writing becomes an automatic motor task.

2. Graphic Motor Programs

Handwriting is a highly specialized motor activity that takes years to master. Similar to other complex motor skills, the neural control of writing movements is organized in a hierarchical fashion, with the general outline of the movement represented at the highest level and lower levels regulating increasingly specific details of neuromuscular execution. At the highest level, writing movements are controlled by graphic motor programs. It is assumed that these programs are stored in long-term memory rather than being assembled *de novo* every time a particular letter is written. Graphic motor programs contain information about abstract spatiotemporal movement attributes, including the sequence, position, direction, and relative size of the strokes necessary to produce different letters. However, graphic motor programs do not specify concrete kinematic parameters such as absolute stroke size, duration, and force. Although graphic motor programs are letter specific, they are effector independent in the sense that they do not determine which particular muscle groups are to be recruited for movement execution. An interesting aspect of writing is that it can be performed by using different muscle–joint combinations of the same limb (e.g., writing with a pen is accomplished with the distal muscles of the hand and wrist, whereas writing on a blackboard mostly involves the proximal muscles of the shoulder and elbow) or by using different limbs altogether (e.g., dominant vs nondominant hand or foot). The finding that writing produced by different effector systems displays striking similarities with respect to overall letter shape suggests a high degree of motor equivalence, consistent with the notion of effector-independent graphic motor programs.

3. Graphic Innervatory Patterns

The final stage in handwriting involves the translation of the information encoded in graphic motor programs into graphic innervatory patterns containing sequences of motor commands to specific effector systems. It is at this lower stage in the motor hierarchy that the appropriate combinations of agonist and antagonist muscles are selected and concrete movement parameters specifying absolute stroke size, duration, and force are inserted into the program. Since the biophysical context of the actual writing task may vary from one occasion to another (e.g., different writing instruments or surfaces), the motor system must have the flexibility to compute the appropriate kinematic parameters "on-line." Therefore, parameter estimation is viewed as a more variable and dynamic process than the retrieval of stored graphic motor programs specifying relatively invariant movement attributes. Once the kinematic parameters for the given writing context have been selected, the motor system executes the strokes required to produce the desired letters as a rapid sequence of ballistic movements (between 100 and 200 msec/stroke).

4. Afferent Control Systems

Central motor programs for skilled movements can be executed in an "open-loop" fashion (i.e., relatively independent of sensory feedback). Consistent with this general principle of motor physiology, it is possible to write letters in the absence of vision or when the writing hand is deafferented as a result of severe peripheral or central sensory loss. It is also clear, however, that

normal handwriting requires afferent input for maximum speed and accuracy. This fact can be readily demonstrated by depriving normal individuals of visual feedback (either by having them write with their eyes closed or by using delayed visual feedback). Characteristic production errors under these conditions include the tendency to duplicate or omit letters or strokes, especially when writing sequences of similar items (e.g., words with double letters or letters containing repeated stroke cycles such as "m" or "w"). These errors can also be observed when subjects are asked to write while performing another task simultaneously (e.g., counting aloud or tapping with the other hand). In the dual-task situation, visual and kinesthetic feedback are available, but sensory information is not being used efficiently because attention is diverted from it by the secondary task. It has been proposed that the accurate monitoring of afferent feedback plays an important role in updating graphic motor programs as to which letters or strokes have already been executed. This "place keeping" function becomes especially critical when similar or identical stroke patterns have to be produced or when the complex sequence of muscle activations required for handwriting needs to be sustained over longer periods of time. Sensory feedback is also required to maintain the correct spacing between letters and words and to keep the line of writing properly oriented on the page.

III. NEUROPSYCHOLOGICAL DISORDERS OF WRITING

Having identified the major functional components of the normal writing process, we now turn our attention to clinical disorders of writing in patients with neurological damage. If we are correct in assuming that the various processing components of our cognitive model are subserved by dedicated neural systems, then damage to specific brain regions should be associated with distinct types of agraphia. Selective damage to a single processing component should result in a "pure" agraphia syndrome with a characteristic and predictable combination of impaired and preserved writing abilities. Specifically, the particular functions assigned to the damaged module should be disrupted, whereas those mediated by other modules should be relatively spared. Although pure cases fulfilling these criteria are encountered occasionally, in clinical practice writing disorders often display features consistent with simultaneous damage to several processing modules, resulting in mixed or multicomponent agraphia syndromes.

From a neuropsychological perspective, agraphia syndromes can be subdivided into central and peripheral types. In essence, this classification system is similar to the distinction between linguistic versus motor forms of agraphia introduced by previous investigators. Central agraphias reflect damage to the proposed linguistic spelling routes or the graphemic buffer. These syndromes are characterized by qualitatively similar spelling deficits across all possible modalities of output (i.e., writing, oral spelling, typing, and spelling with anagram letters). In contrast, in the peripheral agraphias the damage involves processing components located distal to the graphemic buffer (Fig. 2), and the impairment primarily affects the selection and production of letters in handwriting.

A. Central Agraphias

Central agraphia syndromes include lexical or surface agraphia, phonological agraphia, deep agraphia, semantic agraphia, and graphemic buffer agraphia. The characteristic linguistic features and neuroanatomical correlates of these syndromes are discussed in this section.

1. Lexical Agraphia: The Selective Impairment of Word-Specific Orthographic Knowledge

Lexical agraphia is characterized by an impairment of vocabulary-based spelling. Patients have difficulty spelling familiar words, especially words that contain ambiguous or irregular phoneme–grapheme mappings. In contrast, spelling of regular words is relatively preserved, as is the ability to spell unfamiliar words or nonwords. Errors in spelling ambiguous or irregular words are usually phonologically plausible (e.g., "oshen" for "ocean"). In addition to the strong effect of orthographic regularity, spelling is influenced by word frequency, with an advantage of high-frequency words over low-frequency ones. However, spelling performance is typically unaffected by other lexical–semantic variables such as imageability (i.e., high imageability or concrete words such as "apple" vs low imageability or abstract words such as "pride") and grammatical word class (i.e., content words including nouns, verbs, and adjectives vs functors such as prepositions, pronouns, articles, and auxiliaries).

The central linguistic features of lexical agraphia can be accounted for by postulating an impairment at the level of the graphemic output lexicon (Fig. 2). The loss

or unavailability of stored word-specific orthographic information forces patients to generate spellings by relying on the preserved nonlexical route. As indicated earlier, this route is primarily used to compute plausible spellings for unfamiliar words and nonwords, but it can also handle regular words that strictly obey phoneme–grapheme conversion rules. However, attempts to spell ambiguous or irregular words by the nonlexical route result in phonologically plausible errors.

In most reported cases of lexical agraphia the responsible lesion involved the left temporo–parieto–occipital junction. The lesion sites overlap in the region of the angular gyrus (Brodmann area 39) and posterior middle and inferior temporal gyrus (Brodmann area 37), typically sparing the perisylvian language cortex that includes Wernicke's area (Brodmann area 22), the supramarginal gyrus (Brodmann area 40), and Broca's area (Brodmann area 44). Lexical agraphia has also been described in patients with Alzheimer's disease (AD) and semantic dementia. Similar to patients with focal brain lesions, lexical agraphia in these neurodegenerative disorders may reflect the frequent involvement of left hemisphere temporal and parietal cortical association areas by the disease process and the relative sparing of the perisylvian language zone. Consistent with this hypothesis, one study found that lexical agraphia in AD correlated with reduced metabolic activity in the left angular gyrus, as measured by positron emission tomography (PET). In summary, the neuroanatomical findings in patients with lexical agraphia suggest that information relevant to the spelling of familiar words is stored in the left angular gyrus and/or ventrally adjacent posterior temporal cortex, making this extrasylvian cortical area a likely neural substrate of the graphemic output lexicon. The critical role of posterior temporal cortex in orthographic processing is also supported by PET and functional magnetic resonance imaging studies in normal subjects which demonstrated activation of left Brodmann area 37 during various writing tasks.

2. Phonological Agraphia: Dysfunction of the Nonlexical Spelling Route

In phonological agraphia, spelling of unfamiliar words and nonwords is significantly impaired, whereas the spelling of familiar words is relatively spared. The contrast between phonological agraphia and lexical agraphia constitutes an important double dissociation and provides strong support for the proposed distinction between the linguistic procedures involved in spelling unfamiliar vs familiar words. The existence of phonological agraphia also effectively disproves the claim that spelling familiar words must normally rely on phoneme–grapheme conversion.

Phonological agraphia reflects the selective disruption of the nonlexical spelling route. The spelling impairment may be attributable to at least two qualitatively different types of processing deficits. Some patients seem to have lost their knowledge of phoneme–grapheme correspondence rules, as suggested by their inability to write even single letters correctly when given their characteristic sounds. Others can translate single phonemes into the appropriate graphemes, and in these cases the nonlexical spelling deficit may reflect an inability to segment novel auditory stimuli into their constituent sounds. However, it is important to keep in mind that defective phoneme–grapheme transcoding may also be caused by imperception of the stimuli (i.e., phoneme discrimination deficit) or reduced phonological short-term memory.

In pure cases of phonological agraphia, spelling of familiar words (including ambiguous and irregular words) can be performed at a fairly high level, consistent with preserved access to representations in the graphemic output lexicon via the lexical–semantic route. The fact that spelling in phonological agraphia relies on a lexical–semantic strategy is also suggested by the observation that some patients cannot write words to dictation unless they have access to their meaning. Furthermore, spelling performance may be influenced by lexical–semantic variables such as imageability, grammatical word class, and frequency. Specifically, some patients spell high-imageability words better than low-imageability words, and content words may have an advantage over functors. In addition, high-frequency words may be spelled more accurately than low-frequency words. Orthographic regularity, however, does not have a significant effect on spelling. Spelling errors in phonological agraphia are usually phonologically implausible, although they may have visual similarity to the target. Morphological errors (e.g., ''works''–''working'') and functor substitutions (e.g., ''over''–''here'') are also observed occasionally.

The most common neuroanatomical correlate of phonological agraphia is damage to the perisylvian language zone, including Wernicke's area, the supramarginal gyrus, and, in some cases, Broca's area. In contrast, the extrasylvian temporoparietal cortical areas implicated in lexical agraphia are typically spared. It has been suggested that the critical neural

substrate of phonological agraphia is damage to the supramarginal gyrus. Therefore, this cortical area may play an important role in subword-level phonological-to-orthographic transcoding. In general, the neuroanatomical observations in patients with phonological agraphia are consistent with the results of functional neuroimaging studies in normal subjects that demonstrated prominent activation of perisylvian cortical areas during language tasks requiring phonological processing. However, the precise role of the different perisylvian cortical regions in lexical vs nonlexical phonology, subvocal rehearsal, and phonological short-term memory remains to be elucidated.

3. Deep Agraphia: Semantic Errors in Writing

The hallmark of deep agraphia is the presence of frequent semantic errors in writing. Semantic errors have no orthographic or phonological similarity to the target; the only relationship is based on word meaning (e.g., "apple"–"banana"). Apart from these pathognomonic errors, deep agraphia has several linguistic characteristics in common with phonological agraphia. These include the severe difficulty in spelling unfamiliar words and nonwords; the effect of imageability, grammatical word class, and frequency in spelling familiar words; and the presence of morphological errors, functor substitutions, and visually similar misspellings. The substantial overlap in terms of both linguistic features and anatomical lesion location suggests that a strict taxonomic separation between phonological and deep agraphia may be artificial.

Semantic errors in writing indicate dysfunction of the lexical–semantic spelling route and may reflect several different processing impairments. Possible mechanisms include damage to the semantic system or faulty transmission of information between the semantic system and the graphemic output lexicon (Fig. 2). In writing to dictation, semantic errors may also result from damaged connections between the auditory input lexicon and the semantic system. However, dysfunction of the lexical–semantic route alone is not sufficient to explain semantic errors in writing to dictation since the correct spelling of the target word could potentially be generated by spelling routes that normally bypass the semantic system and are therefore not susceptible to errors based on word meaning. Specifically, potential semantic errors could be blocked by phonological-to-orthographic transcoding via either the lexical–nonsemantic or the nonlexical spelling routes. For instance, although the damaged lexical–semantic route may activate the entry "banana" in the graphemic output lexicon in response to the dictated word "apple," the overt semantic error could be avoided if the phonological code /æpəl/ was simultaneously released from the phonological output lexicon and provided a second source of input to orthography via the lexical–nonsemantic spelling route (Fig. 2, pathways D and C) or if the correct spelling was computed by phoneme–grapheme conversion via the nonlexical route. Therefore, the appropriate conditions for semantic errors arise when the output of the dysfunctional lexical–semantic spelling route remains completely unconstrained by orthographic information generated by the lexical–nonsemantic and nonlexical routes. In conclusion, an adequate linguistic explanation of deep agraphia requires that we postulate multiple processing impairments affecting all three central spelling routes.

Deep agraphia is typically associated with large left hemisphere lesions that produce extensive damage to the perisylvian language zone. The near-complete destruction of left hemisphere language areas documented in some cases of deep agraphia raises important questions about the neural systems that mediate the residual writing abilities of these patients. One possibility is that writing is generated by spared left hemisphere cortical/subcortical structures. Alternatively, deep agraphia may arise when writing is produced by the right hemisphere. According to the latter hypothesis, the syndrome reflects the intrinsic functional limitations of the intact right hemisphere language system. Several features of right hemisphere language are consistent with this view. For instance, neuropsychological studies of auditory and written word comprehension in split-brain patients suggest that the semantic system of the right hemisphere may not be as precisely organized as its left hemisphere counterpart, making it susceptible to semantic errors. In addition, the right hemisphere has reduced phonological competence and may completely lack the ability to perform nonlexical or subword-level phonological operations. Finally, the right hemisphere lexicon is thought to be biased toward high-imageability words and may have only limited representation of low-imageability words, functors, and bound morphemes (i.e., prefixes and suffixes). Therefore, right hemisphere writing remains a viable explanation of deep agraphia in patients with massive left hemisphere lesions. The isolated right hemisphere's capacity to generate elementary written expression has also been documented in split-brain patients and in patients with left hemispherectomy.

4. Semantic Agraphia: Writing without Meaning

As previously discussed, knowledge of word meanings is incorporated into writing via the lexical–semantic spelling route (Fig. 2). Semantic influence on writing is essential for written composition and for written naming. Damage to the semantic system or a disconnection of the semantic system from the graphemic output lexicon may interfere with the ability to use meaning to guide the selection of the appropriate orthographic word forms, resulting in a writing disorder known as semantic agraphia. In semantic agraphia, spontaneous writing and written naming may be significantly compromised, but writing to dictation is relatively preserved since this task can be accomplished without semantic mediation by relying on the lexical–nonsemantic or nonlexical spelling routes (Fig. 2). Using spelling routes that bypass the semantic system, patients with semantic agraphia can write familiar words to dictation even when their meaning is not understood (either because of damage to the semantic system or because of a disconnection of the semantic system from the auditory input lexicon). Accurate spelling of ambiguous and irregular words without comprehension of their meaning in semantic agraphia provides the best available evidence for the existence of a lexical–nonsemantic spelling route (i.e., direct transcoding between phonological and orthographic lexical representations via pathways D and C in Fig. 2), since these words could not be spelled correctly by relying on a nonlexical strategy.

Although writing to dictation in semantic agraphia may be reasonably accurate, homophones create major difficulties for these patients. Since homophones have identical sound patterns (e.g., ''blue''–''blew''), the selection of the correct orthographic form depends on the semantic context in which the word is used (e.g., ''she has *blue* eyes'' vs ''the wind *blew* hard''). In semantic agraphia, meaning has limited influence on spelling. Therefore, patients are unable to use semantic context to disambiguate dictated homophones and they frequently produce the semantically inappropriate orthographic word form.

Semantic agraphia has been associated with both frontal and temporoparietal left hemisphere lesion sites that typically spare the perisylvian language zone. The widespread anatomical distribution of lesions in semantic agraphia is consistent with functional neuroimaging studies in normal subjects that documented activation of multiple frontal and temporoparietal extrasylvian cortical association areas during language tasks requiring semantic processing. Homophone confusions, consistent with impaired semantic influence on spelling, have also been observed in patients with lexical agraphia, demonstrating the close anatomical proximity of semantic and orthographic processing modules within the left extrasylvian temporoparietal cortex. Semantic agraphia in patients with AD or semantic dementia may also reflect the pathological involvement of these posterior left hemisphere regions by the cortical degenerative process.

5. Graphemic Buffer Agraphia: The Interaction of Spelling, Memory, and Attention

As can be seen in Fig. 2, the output of all three central spelling routes converges on the graphemic buffer. Therefore, damage to this working memory system results in similar errors across all writing tasks (i.e., written composition, written naming, and writing to dictation). Furthermore, dysfunction of the buffer is expected to have a detrimental effect on the processing of all stored graphemic representations, regardless of lexical status (i.e., words vs nonwords), lexical–semantic features (i.e., frequency, imageability, and grammatical word class), or orthographic regularity. In contrast, spelling accuracy is strongly influenced by word length since each additional grapheme introduces a potential error by increasing the demand on limited storage capacity. Because the graphemic buffer is a central processing component that supports all possible modalities of output, qualitatively similar errors are observed in writing, oral spelling, typing, and spelling with anagram letters.

Dysfunction of the buffer interferes with the short-term retention of information concerning the identity and serial ordering of stored graphemes. Spelling errors take the form of letter substitutions, deletions, additions, and transpositions, and their frequency increases as a function of word length. The distribution of errors may also be influenced by letter position. In some cases, more errors were produced on letters at the end of the word, consistent with the hypothesized serial left-to-right readout process from the buffer (i.e., items retrieved last are more vulnerable to degradation because they have to be retained in memory longer). Errors on terminal letters may decrease in frequency if patients are asked to spell backward, suggesting that it is the order of retrieval rather than the spatial position of the letter within the word that is the critical factor. In other patients, spelling errors primarily involved letters in the middle of the word. The usual explanation offered for this phenomenon is that letters in internal

positions are more susceptible to interference by neighboring items than are letters located at either end.

In addition to memory storage capacity, the retrieval of information from the graphemic buffer is also influenced by attentional factors. For instance, it has been demonstrated that some patients with neglect produce more spelling errors on the side of the word opposite their lesion, regardless of stimulus length or modality of output (i.e., oral vs written spelling) and independent of whether they spell in conventional left-to-right order or in reverse. These observations are consistent with a unilateral defect in the distribution of attention over an internal graphemic representation in which the order of graphemes is spatially coded within a word-centered coordinate system (i.e., a spatial coordinate frame whose center corresponds to the midpoint of the word).

Lesion sites in patients with agraphia due to dysfunction of the graphemic buffer have been variable. Damage to the left posterior parietal cortex is a common finding, although some patients have evidence of frontal lobe involvement. This provisional localization of the graphemic buffer is consistent with the prominent role of frontoparietal cortical networks in verbal working memory and spatial attention, as revealed by recent functional neuroimaging studies in normal subjects.

B. Peripheral Agraphias

Clinically, the peripheral agraphias are characterized by defective selection or production of letters in handwriting. In pure cases, the central or linguistic components of writing are intact, and the preservation of orthographic knowledge can be demonstrated via spared output modalities that include oral spelling, typing, and spelling with anagram letters. The major subtypes of peripheral agraphia include allographic disorders, apraxic agraphia, nonapraxic disorders of motor execution, and afferent dysgraphia.

1. Allographic Disorders: Impairments of Letter Shape Assignment

In allographic writing disorders the main difficulty involves the activation or selection of letter shapes appropriate for the abstract graphemic representations held in the graphemic buffer. As noted earlier, it is not clear whether the underlying deficit reflects a failure to access visuospatial letter shape information from an independent allographic memory store or whether it is caused by a functional impairment of the procedures necessary for activating the correct letter-specific graphic motor programs (Fig. 2).

The breakdown of the allographic conversion process can take different clinical forms. In some cases it may result in partial or complete inability to write the intended letters, apparently because of a failure to remember how to create the appropriate physical letter shapes. The letter production deficit may be specific to certain allographic forms. For instance, patients have been described who could write uppercase letters significantly better than lowercase letters, whereas others showed the opposite dissociation. These findings imply independent neural representations for upper- versus lowercase letters that can be selectively disrupted by brain damage. Allographs for different lowercase writing styles may also be organized separately, as suggested by the reported dissociation between printing lowercase letters versus writing the same letters in a cursive style.

Other patients with allographic disorders have no difficulty in producing individual letters but they seem to have trouble specifying the contextually appropriate allographic repertoire, resulting in an uncontrollable mixing of upper- and lowercase letters in handwriting. In still other patients, case and style specification procedures are intact, but written spelling is characterized by numerous well-formed letter substitution errors. Substitution errors typically involve the production of letter shapes physically similar to the intended target, and the occurrence of these errors may be influenced by letter frequency (i.e., more errors on letters used less frequently in the English language). Whether the documented physical similarity effects in letter substitution errors are based on shared visuospatial features or whether they reflect the fact that graphic motor programs containing similar stroke sequences are more likely to be confused has not been established conclusively.

In the majority of reported cases, allographic writing disorders were associated with left temporo-parieto-occipital damage. Therefore, this posterior cortical region may play an important role in activating and selecting the appropriate letter shapes for written output.

2. Apraxic Agraphia: Defective Motor Programming of Writing Movements

Apraxic agraphia is characterized by poor motor execution of the stroke patterns necessary to produce letters. In order to classify the writing disorder as

"apraxic," it is important to demonstrate that the letter production deficit is not caused by more elementary sensorimotor (i.e., weakness or deafferentation), basal ganglia (i.e., tremor or rigidity), or cerebellar (i.e., dysmetria or ataxia) dysfunction affecting the writing limb.

Although patients with apraxic agraphia may be able to grasp the pen correctly, the spatiotemporal attributes of handwriting are severely disturbed and the facile strokes normally used to produce the required spatial trajectory are replaced by slow, effortful, and imprecise movements. In severe cases, all attempts at writing may result in an illegible scrawl. When the writing disorder is less severe, it may be possible to distinguish between various writing styles and between upper- and lowercase forms, although individual letters may be difficult to recognize. Typical errors of letter morphology include spatial distortions, stroke omissions, and the insertion of anomalous strokes resulting in nonletters (Fig. 3A). When letters are more legible, it may be possible to demonstrate that written spelling is actually preserved. The writing difficulty may be specific to letter formation since in some cases numbers could be produced correctly. Patients with apraxic agraphia can sometimes copy letters better than they can write them spontaneously or to dictation. However, copying is slow and fragmented, and it is usually accomplished in a "stroke-by-stroke" fashion relying heavily on visual feedback. These production features are characteristic of unskilled graphomotor performance and are reminiscent of the way children first learn to write.

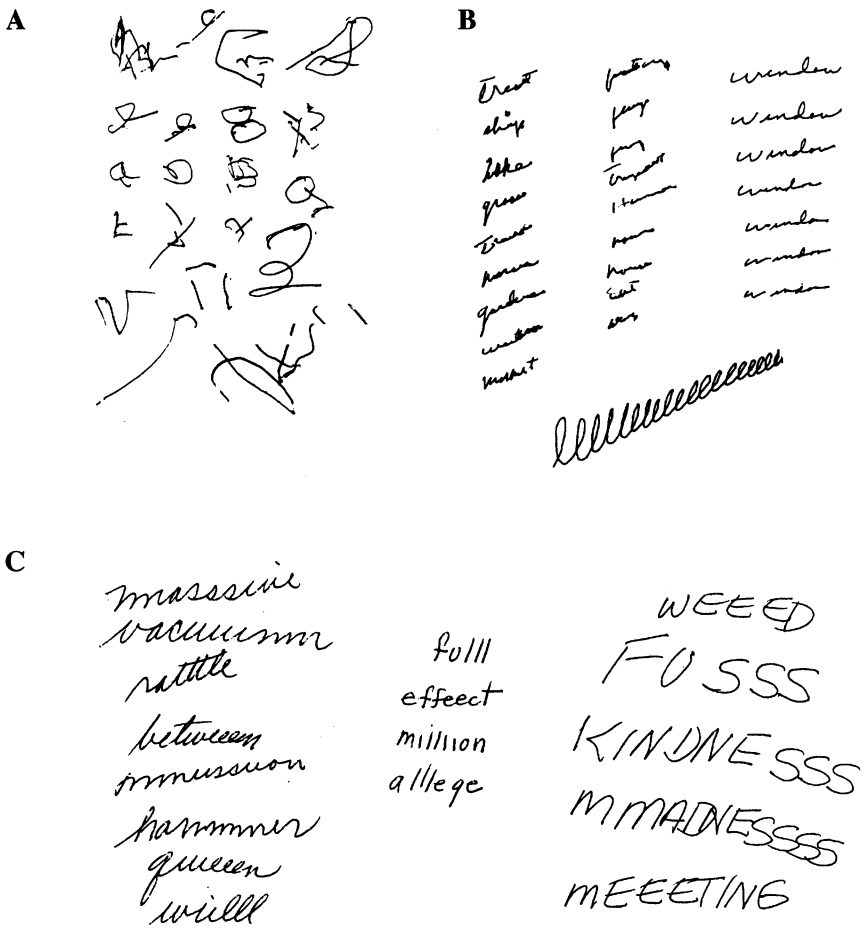

Figure 3 (A) Errors of letter morphology in the writing produced by a patient with apraxic agraphia following left parietal lobe damage. (B) Micrographia in Parkinson's disease. Note overall reduction of letter size. Progressive reduction of writing amplitude is seen with repeated attempts to write the same word or letter. (C) Afferent dysgraphia in a patient with right parietal lobe damage. Duplications occur mostly in words with double letters and when writing letters that contain repeated stroke cycles.

Within the framework of our model, apraxic agraphia can be explained by postulating damage to processing components involved in the programming of handwriting movements. Possible neuropsychological mechanisms include the destruction or disconnection of graphic motor programs or damage to systems involved in translating the information contained in graphic motor programs into graphic innervatory patterns (Fig. 2). Apraxic agraphia is dissociable from limb apraxia, suggesting that motor programs for writing are distinct from programs for other types of purposeful skilled movements.

Apraxic agraphia has specific clinicoanatomical correlations. In right-handers, the responsible lesions typically involve the left posterior–superior parietal region. In particular, damage to cortical areas surrounding the intraparietal sulcus (i.e., superior parietal lobule and the superior portions of the angular and supramarginal gyri) is a common finding. In other cases, the lesions involve dorsolateral frontal cortex, including the premotor area at the foot of the second frontal convolution known as Exner's writing center. Finally, apraxic agraphia has been described following damage to the supplementary motor area (SMA). Taken together, these neuroanatomical observations suggest that the motor programming of handwriting is controlled by a distributed neural system that includes parietal and frontal cortical components with distinct functional roles. Specifically, posterior–superior parietal cortex may contain abstract spatiotemporal codes for writing movements (i.e., graphic motor programs), whereas the frontal components of the network (dorsolateral premotor cortex and SMA) may be responsible for generating the appropriate motor commands to specific muscle effector systems. Parietal lesions may cause apraxic agraphia by damaging or destroying graphic motor programs, whereas frontal premotor lesions may interfere with the process of translating these programs into graphic innervatory patterns specifying the proper sequence of muscle activations necessary for producing the appropriate stroke patterns. White matter lesions located deep to these cortical areas may cause apraxic agraphia by disconnecting the parietal and frontal components of the network.

The existence of a distributed frontoparietal cortical system responsible for controlling handwriting movements receives additional support from functional neuroimaging studies in normal subjects (Fig. 4). These studies have consistently demonstrated activation in posterior–superior parietal cortex, dorsolateral premotor cortex, and the SMA during the performance of various writing tasks. Similar brain regions are activated during imagined writing movements, suggesting that mentally executed and real graphomotor gestures are subserved by partially overlapping neural systems. Frontoparietal cortical networks are also implicated in other types of skilled hand movements typically performed under visual guidance, including reaching, grasping, and object manipulation. These observations suggest that distinct frontoparietal cortical systems may form the neural substrate of specific object-oriented motor behaviors.

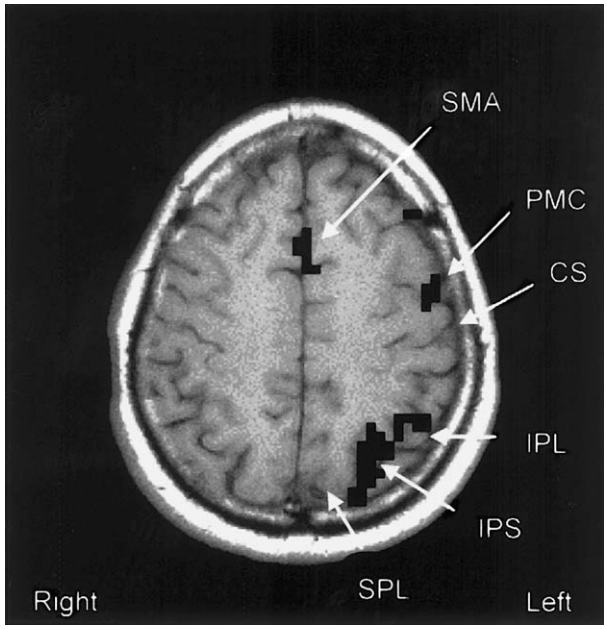

Figure 4 Functional MRI scan in a normal right-handed subject demonstrating the cortical network involved in the production of handwriting movements. Regions of activation correlate with writing to dictation minus a control task of drawing circles. SMA, supplementary motor area; PMC, premotor cortex (including Exner's area); IPL, inferior parietal lobule (angular and supramarginal gyri); IPS, intra parietal sulcus; SPL, superior parietal lobule; CS, central sulcus.

In most right-handed persons the left hemisphere is dominant for writing. Consequently, writing with the left hand in these individuals must involve transfer of linguistic and motor information from the left to the right hemisphere across the corpus callosum. Consistent with this hypothesis, damage to the corpus callosum in right-handers produces unilateral agraphia of the left hand. Neuroanatomical observations in patients with callosal agraphia suggest that information critical for programming the skilled movements of writing is transferred through the body of the corpus callosum, whereas linguistic information is transferred

more posteriorly through the fibers of the splenium. Furthermore, the fact that unilateral apraxic agraphia and ideomotor apraxia are occasionally dissociable following callosal damage implies that motor programs for writing and programs for other types of skilled limb movements are transferred through anatomically distinct callosal pathways.

3. Impaired Selection and Control of Movement Parameters: Nonapraxic Disorders of Writing Force, Speed, and Amplitude

In addition to determining the correct sequence of muscle activations, the neural systems responsible for generating graphic innervatory patterns must also select the appropriate kinematic parameters for the writing task. The breakdown of these operations may result in the insertion of incorrect movement parameters into otherwise intact graphic motor programs, leading to defective control of writing force, speed, and amplitude.

A typical example of this type of motor production deficit is the micrographia of patients with Parkinson's disease. As its name implies, micrographia is characterized by a striking reduction in handwriting size (Fig. 3B). Letters may get progressively smaller during the writing process. Even though letter size is diminished, writing remains legible in milder cases and there are no stroke-level errors of the type seen in apraxic agraphia. These findings indicate that the control of writing movements at the level of graphic motor programs is preserved. Although patients with micrographia can activate the correct muscles in the appropriate sequence, they cannot generate the forces necessary to maintain proper letter size. Writing speed is also significantly reduced. These production features are consistent with the general reduction of movement amplitude and speed in Parkinson's disease.

Micrographia in Parkinson's disease reflects basal ganglia dysfunction caused by the loss of striatal dopamine. Dopaminergic projections to the striatum originate in the substantia nigra of the midbrain. It has been demonstrated that focal lesions of the substantia nigra or the striatum can produce micrographia of the contralateral hand. Basal ganglia structures exert their influence on motor behavior through reciprocal connections to cortical motor areas, including dorsolateral premotor cortex and SMA. Operating as a functional unit, the cortical and subcortical components of the basal ganglia–thalamocortical motor loop play an important role in the control of movement force, speed, and amplitude. Consistent with this hypothesis, micrographia has been observed not only in patients with basal ganglia lesions but also following damage to the SMA.

Poor penmanship is also typical of the writing produced by patients with cerebellar dysfunction. Cerebellar lesions interfere with the smooth and automatic execution of the rapid alternating movement sequences that characterize normal handwriting. Writing movements are slow, effortful, and disjointed. Precise control over movement direction, force, speed, and amplitude is no longer possible. As a result, the writing trajectory becomes irregular and may be subject to unpredictable perturbations that the patient is unable to correct. Letters with curved shapes tend to be decomposed into straight lines, reflecting abrupt transitions in movement direction.

Similar to the basal ganglia, the cerebellum is connected to frontal premotor areas via re-entrant neuronal circuitry. Clinical observations in patients with cerebellar lesions suggest that the corticocerebellar motor loops are involved in the selection and control of kinematic parameters for skilled movements. The cerebellum also plays an important role in monitoring motor performance by comparing premotor commands for the intended movement with sensory feedback about the actual movement taking place. This comparator function is critical for error detection and for adjusting the evolving movement to changing contextual requirements.

In summary, basal ganglia–thalamocortical and cerebellocortical motor networks are possible neural substrates of the system responsible for generating the graphic innervatory patterns that guide the execution of handwriting movements. This conclusion is supported by functional neuroimaging studies that demonstrated activation of premotor cortex, basal ganglia, and cerebellum during the performance of various writing tasks.

4. Afferent Dysgraphia: The Role of Sensory Feedback in Handwriting

Patients with afferent dysgraphia have difficulty using sensory feedback to monitor and control the execution of handwriting movements. The writing errors produced by these patients are similar to those observed in normal subjects under experimental conditions that interfere with the efficient use of visual or kinesthetic feedback. Typical findings include duplications and omissions that are especially common when writing sequences of similar letters or strokes (e.g., "shampoo" written as "shampo" or "shampooo," or the addition

of extra loops in writing letters containing repeated stroke cycles) (Fig. 3C). Writing errors are usually not detected by the patients and therefore remain uncorrected. Cursive handwriting tends to be more severely affected than writing in uppercase print. In addition to letter/stroke duplications and omissions, patients may have difficulty keeping the correct spacing between letters and words and may not be able to write in a straight, horizontal line.

Afferent dysgraphia is typically seen following right parietal lobe damage, although features of the syndrome can occasionally be observed in patients with left parietal lesions. These findings suggest that the parietal lobes in general, and the right parietal lobe in particular, play an important role in monitoring visual and kinesthetic feedback for the proper control of writing movements. Writing produced by patients with right parietal damage also frequently shows evidence of left-sided spatial neglect. However, neglect-related errors (e.g., the tendency to write on the right side of the page or the failure to cross t's and dot i's at the beginning of the word) and feedback-related errors (e.g., letter/stroke repetitions and omissions) are dissociable. Furthermore, the type of neglect that affects the peripheral aspects of writing is distinct from the type of neglect that affects the internal graphemic representations of words and leads to unilateral spelling errors during the readout process from the graphemic buffer. These observations suggest that attention interacts with the writing process at several different levels. Thus, we must distinguish between attentional resources directed toward spatially coded internal graphemic representations computed by central spelling routes and attentional resources directed toward stimuli located in external visual space, including the letters and words produced on the page during writing.

In addition to being mediated by neural systems distinct from those involved in spatial attention, afferent control of stroke and letter production may also be separate from control over the more general (i.e., nonlateralized) visuospatial aspects of writing, such as maintaining the proper horizontal orientation and keeping the correct spacing between letters and words. According to this hypothesis, the core deficit in afferent dysgraphia is the inability to use sensory feedback to keep track of the number of letters and strokes produced in handwriting, whereas the other features of the syndrome may reflect simultaneous damage to functionally independent visuoperceptual and spatial attention modules located in close anatomical proximity within parietal cortex.

Letter/stroke duplications have also been observed in the writing produced by patients with right frontal lobe lesions, and it has been proposed that these errors may represent a form of motor perseveration. In addition, features of afferent dysgraphia have been documented following cerebellar damage. This finding is consistent with the view that the cerebellum is normally involved in the monitoring of sensory feedback during the execution of handwriting movements.

IV. CONCLUSIONS

Writing is a complex cognitive activity that requires the interaction of linguistic, motor, spatial, and perceptual systems for normal performance. For these reasons, and perhaps also because it is the least frequently used language modality, writing remains a fragile skill that is highly vulnerable to disruption by brain damage.

In this article, we provided evidence that the various agraphia syndromes observed in neurological patients are interpretable within the framework of a cognitive model of normal spelling and writing. It is anticipated that the functional architecture of the model will undergo further modifications and refinements not only as a result of neuropsychological case studies but also on the basis of relevant observations in normal subjects and insights gained from computational models of spelling and writing.

Most of our knowledge concerning the neural substrates of writing comes from clinicoanatomical observations in patients with focal brain damage. Currently, there are only a few neuroimaging studies of writing in normal subjects, but it is clear that this methodology holds tremendous promise for functional localization. By combining patient lesion data with neuroimaging studies in normal individuals, it will be possible to map the cognitive operations involved in writing onto specific brain regions with much greater precision than either technique alone would permit. We are confident that future research in the related fields of cognitive neuropsychology, neurolingustics, and functional neuroimaging will lead to exciting new insights into the neural mechanisms underlying this unique cognitive skill, the development of which had the revolutionary impact of allowing human beings to communicate their ideas across space and time.

Alcohol Damage to the Brain

JOHN W. OLNEY
Washington University, St. Louis, School of Medicine

GLOSSARY

alcoholic hallucinosis Auditory hallucinations and accompanying delusions, often of a paranoid type, occurring in a patient who is not withdrawing from ethanol but rather is engaged in ongoing drinking.

blackout A phenomenon in which an individual who is intoxicated with ethanol behaves as if he or she is in command of his or her faculties and is aware of the acts he or she is performing but upon sobering up has no recollection of having performed these acts.

delerium tremens A toxic psychosis featuring vivid and often frightening visual hallucinations and tremulousness that typically develops in chronic alcoholics 24–96 hr after cessation of ethanol intake.

fetal alcohol effects A syndrome observed in children who were exposed to ethanol *in utero* consisting of some but not all of the components of the fetal alcohol syndrome. A term currently recommended for partial syndromes primarily featuring central nervous system disturbances is alcohol-related neurodevelopmental disorder.

fetal alcohol syndrome A syndrome observed in children who were exposed to ethanol *in utero* consisting of growth deficiency, a pattern of dysmorphic facial features, and neurobehavioral disturbances.

Korsakoff syndrome A syndrome, first described by Korsakoff in 1887, characterized by peripheral neuropathy, confusion, disorientation, memory loss, and a tendency to confabulate.

Wernicke's encephalopathy A syndrome, first described by Wernicke in 1881, in which neurodegenerative changes occur in the thalamus, hypothalamus, periaqueductal region, and floor of the fourth ventricle. The clinical symptoms consist of ocular abnormalities, ataxia, and alterations in the state of consciousness varying from mild confusion to coma.

In modern society, we live with an alcohol conundrum: Alcohol (ethanol) is, and has been for much of recorded time, the euphoriant of choice for human adults who perceive ethanol as user-friendly. However, it has damaged the brains of more human fetuses than any other agent in the human environment, and today it continues to damage the brains of human fetuses. In addition, either directly or indirectly, it has caused neurodegenerative changes in the brains of countless human adults, causing them to have cognitive disturbances ranging from mild memory loss to profound dementia. Medical science has been slow in deciphering the mechanisms underlying ethanol's deleterious effects on the brain, but recent findings, particularly pertaining to fetal alcohol syndrome, are beginning to shed new light on how ethanol damages the human brain.

I. CLINICAL SYNDROMES ASSOCIATED WITH ETHANOL CONSUMPTION

A. Acute Ethanol Intoxication

Ethanol is a simple molecule that freely enters the brain and interacts with many cellular or subcellular systems. Ethanol's well-known ability to cause acute intoxication qualifies it as a central nervous system (CNS) intoxicant, a word that implies a toxic action on the CNS. However, toxic actions can be transient, reversible, and relatively harmless or long-lasting,

irreversible, and very harmful. On the basis of all available evidence, it appears that acute exposure of human adult to ethanol, even in large doses, produces an intoxication syndrome that is transient, reversible, and not damaging to the brain.

The mechanism(s) by which ethanol transiently renders an individual intoxicated is not fully understood. However, accumulating evidence suggests that ethanol interacts with, and alters the status of, several transmitter systems in the brain, and this provides the most promising clues to its intoxicating effects. There is evidence that ethanol, by either a direct or indirect action, alters the status of the acetylcholine, dopamine, serotonin, glutamate, and GABA transmitter systems. Of these systems, the two that are most likely to play a primary role in ethanol's intoxicating effects are the glutamate and GABA systems, which are responsible for most of the excitatory (glutamate) and inhibitory (GABA) transmitter activity in the brain. The basis for this interpretation is that ethanol's intoxicating effects are akin to the effects that general anesthetics have on the brain, and it is becoming increasingly well recognized that all agents currently used as general anesthetics act by one of two mechanisms. Either they block excitatory neurotransmission through NMDA glutamate receptors or they promote inhibitory neurotransmission through $GABA_A$ receptors.

In recent years, researchers have shown repeatedly that ethanol blocks the excitatory functions mediated by NMDA glutamate receptors and promotes the inhibitory functions mediated by $GABA_A$ receptors. Both of these actions (reduced excitation and increased inhibition) translate into a suppressant effect on neural circuits in the brain. Although ethanol has an immediate activating effect on human behavior, its overall net effect is one of CNS depression. For example, at excessive doses it produces a comatose state similar to that induced by general anesthetic agents. The immediate activating effects may be due to the NMDA blocking action of ethanol in that other NMDA blocking drugs are known to have a disinhibition effect on certain neural circuits. These are neural circuits that are ordinarily held under restraint by a mechanism whereby glutamate, acting at NMDA receptors on GABAergic inhibitory neurons, tonically activates these neurons causing them to maintain a high level of inhibitory tone in the circuit. When ethanol blocks the NMDA receptors, glutamate ceases activating the inhibitory neurons and these neurons cease inhibiting the circuit. In the absence of inhibition the circuit becomes hyperactive, which would explain ethanol's activating effect on human behavior. It should be noted that in these particular circuits glutamate is performing an unusual function: It is serving as a regulator of inhibitory tone and the net effect of glutamate stimulation of NMDA receptors in these circuits is inhibitory. The net effect of glutamate stimulation of NMDA receptors in many other neural circuits is excitatory so that ethanol blockade of NMDA receptors in these other circuits would have a depressant effect on behavior. Similarly, ethanol's promotion of GABAergic inhibitory transmission would have a depressant effect. Thus, the simultaneous action of ethanol at both $GABA_A$ and NMDA glutamate receptors in neural circuits that are sometimes wired in a paradoxical manner can explain why it has an immediate activating effect on human behavior that is transient and soon gives way to a more prolonged depressant effect.

B. Blackouts

It has been observed that individuals who imbibe large quantities of ethanol may appear to be in conscious control of their behavior and may behave as if they have an intact memory, but on the following day after they have sobered up they have a blank memory for important events that they participated in during the inebriation episode. This phenomenon is referred to as a "blackout." It is most likely due to the important role that NMDA glutamate receptors play in memory. It has been shown that various drugs that block NMDA glutamate receptors interfere with the acquisition of memory. While under the influence of an NMDA receptor blocking drug, laboratory animals lose their ability to acquire new information and commit it to memory. However, they are still able to recall and act on information previously learned and committed to memory. Moreover, in the future when they are not under the influence of the drug they are able to acquire new information and commit it to memory. It has also been shown that NMDA receptor blocking drugs interfere with the phenomenon known as long-term potentiation (LTP), which is a synaptic mechanism that is thought to mediate memory functions. LTP has been studied extensively in the hippocampus, a brain region that is prominently involved in memory functions. It is well established that when NMDA glutamate receptors at synapses in the hippocampus are stimulated at a high frequency they become conditioned so that subsequent application of glutamate to the receptor elicits a much more robust (potentiated) response than if the receptor had not received the

high-frequency stimulation. This conditioned status is referred to as LTP. Drugs that block NMDA receptors, including ethanol, interfere with the induction of LTP at hippocampal synapses. Thus, there is evidence at both a synaptic level and a behavioral level that ethanol, by its NMDA receptor blocking action, can interfere with memory functions in a way that would explain blackouts associated with heavy ethanol consumption. It is not known with certainty whether chronic heavy drinking with repetitive blackouts can result in permanent damage to memory mechanisms at a synaptic or molecular level or whether it entails only reversible effects on neural pathways that mediate memory function.

C. Alcoholic Hallucinosis

Alcoholic hallucinosis refers to a condition in which a chronic heavy user of ethanol displays persistent auditory hallucinations and related delusional beliefs but remains oriented, with intact memory, and does not manifest other psychotic behaviors. This is a relatively rare complication of chronic alcohol use, and the underlying mechanisms are poorly understood. However, it is not unlikely that the NMDA antagonist properties of ethanol play a role because drugs that block NMDA receptors are notorious for inducing psychotomimetic symptoms. As discussed later, drugs that have NMDA antagonist properties have the potential to cause psychotic symptoms, including auditory hallucinations and delusions, and also have the potential to cause physical injury and even death of cerebrocortical neurons. Phencyclidine (PCP; angel dust) is a well-known example of a drug that has powerful psychotomimetic actions that are solely attributable to its blocking action at a recognition site within the NMDA receptor ion channel. Another well-known NMDA antagonist that has psychotomimetic activity is ketamine, a drug that is used in human medicine as a general anesthetic. Because of its psychotomimetic properties, ketamine has recently become a popular drug of abuse (street name, special K). The psychotic reactions associated with ketamine anesthesia have been referred to as "emergence" reactions and it was learned many years ago that these reactions could be substantially ameliorated by treatment with drugs that activate $GABA_A$ receptors, sometimes called GABAmimetic agents. Recently, it has been found that PCP, ketamine, and many other drugs that have NMDA antagonist properties cause pathomorphological changes in cerebrocortical neurons of the adult rat brain, and it has been clearly demonstrated that these changes can be completely prevented if a GABAmimetic drug is administered together with the NMDA antagonist. In light of this information, the fact that ethanol has strong GABAmimetic activity as well as NMDA antagonist activity should cause it to behave as if it did not have psychotomimetic and neurotoxic properties because ethanol's potential to cause these adverse effects due to its blocking action at NMDA receptors would be cancelled out by its counterbalancing action at $GABA_A$ receptors. It is interesting to note that in the ketamine anesthesia situation the psychotic reactions were often not completely prevented because it was the practice to administer the GABAmimetic drug toward the end of the anesthesia period or in the recovery room after the brain changes conducive to psychotic behaviors had already occurred. The door was being closed after the horse was already out of the barn. In contrast, in animal experiments, the GABAmimetic drug has been administered in advance or at the same time as the NMDA antagonist, and this results in complete prevention of the neurotoxic effects of the NMDA antagonist. Thus, since ethanol has the GABAmimetic property built-in, its user is always protected against the expression of its psychotomimetic or neurotoxic potential.

The psychosis produced by NMDA antagonist drugs closely resembles a schizophrenic psychosis and this has given rise to a currently popular hypothesis that hypofunction of the NMDA glutamate receptor system may contribute to the pathophysiology of schizophrenia. Previously, the emphasis in schizophrenia research was on the dopamine system, the hypothesis being that hyperactivity of this system may be responsible for schizophrenic symptomatology. These two hypotheses are not mutually exclusive. There is evidence that dopamine is an inhibitory regulator of the release of glutamate at NMDA glutamate receptors. Thus, if the dopamine system were hyperactive, this would result in hyperinhibition of glutamate release at NMDA receptors which would produce an NMDA receptor hypofunctional state that could explain the symptoms of schizophrenia. Ethanol hallucinosis occurs in people who are not withdrawing from alcohol but rather are chronically ingesting alcohol on a steady basis. Under this condition, the NMDA transmitter system is being blocked and hence is hypofunctional, and the dopamine system is believed to be in a hyperactive state. Thus, it is reasonable to propose that dopamine hyperactivity, NMDA receptor hypoactivity, or both may be responsible for the

symptoms of alcoholic hallucinosis. Because alcoholic hallucinosis is a relatively rare condition, it seems likely that it occurs only in individuals who harbor a genetic predisposition to manifest psychotic symptoms, perhaps due to dysfunction of one or more of the transmitter systems with which ethanol interacts. The genetic predisposition may not be strong enough by itself to trigger psychotic symptoms, but ethanol's interaction with the genetically defective transmitter system(s) may be enough to tip the balance and cause the genetic predisposition to be expressed as a clinical illness. However, in the absence of a genetic predisposition, the GABAmimetic properties of ethanol may be strong enough to prevent propsychotic mechanisms from breaking through.

D. Tolerance, Dependence, and Addiction

Mechanisms underlying tolerance, physical dependence, and addiction are exceedingly complex and are not very well understood. These topics will be addressed only briefly because they are only indirectly related to the topic of alcohol damage to the brain. This is not to say that they are unimportant in relation to the brain damage problem. On the contrary, they are exceedingly important. If ethanol did not have properties that cause an individual to become psychologically and physically dependent on it, no one would drink it chronically in large enough amounts to cause brain damage either directly or indirectly. If ethanol did not have these properties, large segments of society would not habitually imbibe ethanol, and if large segments of society were not imbibing ethanol, many fewer fetuses would be exposed during critical periods when the developing brain is particularly vulnerable to damage from ethanol. It is likely that ethanol induces long-term (but not necessarily permanent) changes in transmitter systems, and such changes may be largely responsible for physical and psychological dependence and addiction. However, it has not been demonstrated that such changes represent a permanent alteration in the brain that could be considered irreversible damage.

E. Withdrawal Phenomena

1. Delirium Tremens

The withdrawal syndrome experienced by an individual who is physically dependent on ethanol is called delirium tremens because its most prominent manifestations are tremors of the extremities and a delirious mental state. The picture is one of a toxic psychosis consisting of agitation, distractability, sleeplessness, visual hallucinations, disorientation, and confusion. Although, the mechanisms are not completely understood, the symptoms reflect CNS hyperactivation, and it is very likely that an imbalance between excitatory and inhibitory transmitter systems in various brain regions is responsible. Transmitter systems that have been primarily implicated are the NMDA glutamate excitatory system, the $GABA_A$ inhibitory system, and the dopamine inhibitory system. There is good agreement among investigators that chronic heavy alcohol intake causes an upregulation of the NMDA glutamate excitatory system, a condition that develops presumably as a compensatory effort of the NMDA receptor system to overcome the persistent blockade of NMDA receptors by ethanol. The upregulation consists of an increased amount of NMDA receptor protein, an increased expression of mRNA for synthesis of NMDA receptor subunits, and an enhanced capacity of this receptor system to mediate excitatory activity. In addition, chronic ethanol intake is associated with increased extracellular concentrations of glutamate presumably reflecting increased release of glutamate at both NMDA and other glutamate receptors. In the withdrawal state, the absence of ethanol leaves the upregulated and overly responsive NMDA receptor system unblocked and free to respond in an exaggerated way to glutamate that is present in excessive concentrations in the synaptic cleft. Chronic exposure to ethanol also produces changes in the $GABA_A$ transmitter system but there is less agreement among investigators regarding the nature of these changes, one problem being that the changes are apparently different in different brain regions. The consensus appears to be that the $GABA_A$ system becomes downregulated and less capable of performing its inhibitory functions. In the withdrawal state, the dopamine system shows a marked decrease in functional activity, which apparently is fostered by hyperactivity of the NMDA glutamate system. It seems likely that the tremors associated with alcohol withdrawal are a reflection of the combined disturbances in the dopamine and NMDA receptor systems, and the psychotic manifestations, including vivid visual hallucinations, may also relate to disturbances in one or both of these systems.

2. Convulsions

Patients who are undergoing withdrawal from chronic heavy alcohol use are prone to epileptiform seizures. The seizure activity may be quite severe and can be

injurious to the brain or even life threatening. Years ago, the tendency of chronic alcoholics to have seizures was recognized but it was assumed that it was the excessive, continuous exposure to ethanol that triggered the seizures. Thus, the condition was referred to as rum fits. Today, it is recognized that chronic heavy ethanol intake *per se* does not typically trigger seizure activity; rather, it causes changes in the brain that set the stage for seizures to occur whenever there is an abrupt decrease in ethanol intake. In ordinary circumstances, brain circuits are not subject to epileptiform activity because a stable balance is maintained between glutamatergic excitatory activity and GABAergic inhibitory activity. However, any substantial decrease in inhibitory activity or increase in excitatory activity alters the balance in favor of excitation and increases the chances that seizures (runaway excitatory activity) can occur. As described previously, chronic heavy ethanol intake causes chronic blockade of NMDA glutamate receptors and a compensatory upregulation of the NMDA glutamate transmitter system. At the same time, it causes chronic overactivation of the $GABA_A$ receptor system, which produces a compensatory downregulation of the GABAergic system. Upregulation of glutamatergic excitation coupled with downregulation of GABAergic inhibition sets the stage for seizure activity, but seizures do not occur as long as steady ethanol intake continues because ethanol prevents runaway excitation by blocking NMDA excitatory receptors and activating $GABA_A$ inhibitory receptors. In the interval from 12 to 48 hr after chronic alcohol intake has been abruptly discontinued, brain circuits are in a seizure-prone hyperirritable state in which stimuli that would ordinarily be innocuous can trigger seizure activity that may be difficult to control with a standard anticonvulsant drug such as dilantin. If seizure activity in limbic circuits is not promptly brought under control it feeds on itself in a reverberating manner and can cause neurons that have NMDA receptors on their surface to undergo excitotoxic degeneration, which entails a cascade of events initiated by excessive influx of sodium and calcium through NMDA receptor ion channels. Some anticonvulsant drugs, such as barbiturates and benzodiazepines, are more effective than others in the clinical management of rum fits which is consistent with the postulated role of $GABA_A$ receptor down regulation as a causative mechanism, in that these drugs act at $GABA_A$ receptors to restore GABAergic inhibition to more normal levels.

In addition to seizures associated with ethanol withdrawal, there are individuals who have an epileptic diathesis, which implies that a state of excitatory/inhibitory imbalance already exists. In this case, even isolated episodes of acute alcohol intake may upset the balance further and trigger seizure activity.

F. Wernicke's Encephalopathy

Neuropathologists have recognized for many years that chronic heavy ethanol intake can result in a syndrome first described by Wernicke in 1881, in which neurodegenerative changes occur in the thalamus, periaqueductal region, and floor of the fourth ventricle. Individuals with Wernicke's encephalopathy typically manifest a triad of clinical symptoms consisting of ocular abnormalities, ataxia, and a disturbance in consciousness varying from mild confusion to a profound comatose state. Whether a direct action of ethanol in the brain contributes to this neuropathological syndrome is unclear. A very similar syndrome is known to occur in individuals who have severe nutritional deficiencies, especially thiamine deficiency, and the Wernicke pattern and type of brain damage can be induced in experimental animals by rendering them severely thiamine deficient. Chronic alcoholics are typically deficient in thiamine because they tend to substitute ethanol for other more nutritional sources of calories, and because ethanol intereferes with the gastrointestinal absorption of thiamine. Also strongly implicating thiamine deficiency in Wernicke's encephalopathy is evidence that treatment of patients manifesting early signs of a Wernicke syndrome with massive doses of intramuscular thiamine prevents the Wernicke pattern of brain damage and markedly diminishes its symptomatic manifestations. In fact, there has been a striking reduction in the incidence of Wernicke's encephalopathy since clinicians have adopted the practice of treating chronic alcoholics with large doses of thiamine as a prophylactic measure. Thus, it is generally believed that nutritional deficiency is primarily responsible for Wernicke's encephalopathy, and that ethanol contributes only indirectly by promoting thiamine and other nutritional deficiencies.

G. Korsakoff Syndrome

In 1887, Korsakoff described a clinical syndrome associated with chronic ethanol intake featuring amnesia, confabulation, disorientation in time and place, and peripheral neuropathy. The tendency of chronic alcoholics to suffer from nutritional deficiency

and to display a mixed clinical picture, including symptoms of both the Wernicke and Korsakoff type, has led some investigators to categorize the two syndromes together under the heading Wernicke–Korsakoff syndrome and to ascribe the overall syndrome to a multivitamin-deficiency state. Reinforcing this tendency is the observation that both syndromes tend to occur initially in an acute alcohol withdrawal context as part of a delirum tremens episode. However, the Korsakoff syndrome reportedly can occur in individuals who have no history of delirium tremens and who lack the typical symptoms of Wernicke's encephalopathy. Moreover, the pattern of brain damage in the Korsakoff syndrome, although sometimes overlapping with the Wernicke pattern, tends to involve other brain regions, including the cerebral cortex, not typically affected in the Wernicke syndrome. Therefore, it must be assumed that the Wernicke and Korsakoff syndromes are two separate conditions, but the role of ethanol vs vitamin deficiencies or other contributing causes in producing the Korsakoff syndrome remains to be clarified.

H. Alcoholic Deterioration

Progressive ataxia, degeneration of cerebellar Purkinje neurons, cerebral atrophy, and mild to severe dementia have been described by many authors as findings typically associated with chronic heavy alcohol use. In one study, loss of Purkinje neurons from the cerebellar vermis correlated with long-term daily ingestion of moderate doses of ethanol, but in other studies a definite correlation could not be established between either cerebrocortical or cerebellar atrophy and the long-term pattern or amount of ethanol intake. Dementia syndromes of mild to moderate degree have been described in chronic alcoholics, with stabilization or improvement occurring if ethanol ingestion is discontinued. Thus, there is suggestive evidence that ethanol can have deleterious effects on the adult brain which may be separate and distinct from the Wernicke and Korsakoff syndromes, but it remains to be determined whether or how ethanol directly contributes to these brain damage syndromes.

I. Fetal Alcohol Syndrome

For many centuries, perhaps several millennia, ethanol has served as the euphoriant of choice by human adults throughout the world. Undoubtedly, over that period of time countless human fetuses have been exposed *in utero* to ethanol, but it was less than 30 years ago that P. Lemoine and colleagues in France and K.L. Jones and D.W. Smith in the United States reported the first evidence that ethanol can have deleterious effects on the human fetus. For several years after these authors described the fetal alcohol syndrome there was a tendency to disbelieve that ethanol could cause such dramatic changes in the human fetus. Their description of the syndrome focused on craniofacial malformations and severe neurobehavioral disturbances, including frank mental retardation, as the primary clinical manifestations. In subsequent research it was determined that all fetuses affected by ethanol do not show all features of the syndrome. For example, some may show either craniofacial malformations or CNS effects, but not both. Moreover, sometimes the CNS effects were limited to relatively mild degrees of learning impairment and/or hyperactivity/attention deficit disorder. By convention, the term fetal alcohol syndrome (FAS) has been used to refer to the full syndrome featuring both dysmorphogenic and neurobehavioral aspects, and an alternate term, fetal alcohol effects (FAE), has sometimes been used to refer to partial or less severe syndromes that tend to feature primarily neurobehavioral aspects. A Committee of the Institute of Medicine, National Academy of Sciences proposed in 1996 that partial syndromes affecting primarily the CNS be termed alcohol-related neurodevelopmental disorder (ARND). Regardless of terminology, it is generally recognized that the CNS effects are the most debilitating component of the syndrome. It is not known what percentage of births currently or in the past qualify for a diagnosis of ARND, but there is little doubt that ethanol has contributed to more cases of developmental neuropsychiatric impairment than any other substance in the human environment and perhaps more than all other substances combined.

FAS research initially focused on efforts to identify the critical period when the developing fetus is vulnerable to the toxic effects of ethanol. Initially, there was a tendency to assume that there was only one window of vulnerability during which all aspects of the syndrome were caused. However, when it was realized that some fetuses may have predominantly craniofacial malformations and others subtle neurobehavioral disturbances, it became evident that ethanol may act by more than one mechanism and each mechanism may have its own critical period of vulnerability. Because the progenitor cells that form the skull and

bony skeleton differentiate much earlier than those that give rise to neurons in the brain, it was logical to assume that the vulnerability time window for producing the craniofacial malformations must be early, within the first trimester, whereas the vulnerable period for causing neurobehavioral disturbances would have to be later, perhaps in the second or third trimester, when neuronal progenitor cells are differentiating, migrating, and undergoing maturation. While mechanisms giving rise in the first trimester to the craniofacial malformations remain largely unknown, insights described below have been gained into third trimester mechanisms responsible for the deleterious effects of ethanol on the developing brain.

II. MECHANISTIC CONSIDERATIONS

A. Mechanisms Operative in the Adult Brain

It is generally agreed that chronic heavy use of ethanol by human adults results in a substantially higher incidence of neurodegenerative disorders than is encountered in a comparable population of individuals who are not chronic heavy users of ethanol. However, in a high percentage of cases, nutritional deficiency, uncontrolled seizure activity, head trauma, or factors other than direct impingement of ethanol on CNS neurons can account for the damage to the brain. The question that remains unanswered is whether ethanol, by a more direct toxic action on neurons, can trigger neurodegeneration in the adult brain. To address this question it may be useful to examine the known mechanisms by which ethanol interacts with neurons and consider whether ethanol, acting through any of these mechanisms, might have an injurious effect on neurons.

Of the known mechanism by which ethanol interacts with CNS neurons, there is only one mechanism that is known to have neurotoxic potential—the NMDA receptor blocking action of ethanol. In several studies, ethanol has been shown to have NMDA antagonist properties when applied to neurons in concentrations comparable to those attained in the ethanol-intoxicated human brain. It is well established that systemic administration of drugs that block NMDA glutamate receptors causes acute pathomorphological changes in cerebrocortical neurons of the adult rat brain. Low doses of NMDA antagonist drugs produce reversible pathomorphological changes in restricted cerebrocortical brain regions, whereas higher doses induce irreversible neuronal degeneration, not only in these restricted regions but also in many other corticolimbic brain regions and in the cerebellum. Most experiments demonstrating the neurotoxic properties of NMDA antagonist drugs have involved acute administration. However, it has also been shown that continuous infusion of low to moderate doses of an NMDA antagonist drug to adult rats over a 4-day period results in widespread irreversible degeneration of corticolimbic neurons. Therefore, because of its NMDA antagonist properties, ethanol would be expected, following either acute high-dose intake or chronic lower-dose intake, to be damaging to the brain, and the logical question to be addressed is how adult humans have been able to use ethanol in high doses either acutely or chronically without routinely incurring damage to the brain.

It might be argued that the neurotoxic action of NMDA antagonist drugs is a species-specific effect to which rats are vulnerable but humans are not. However, it is well-known that human adults are vulnerable to another type of toxic effect caused by NMDA antagonist drugs, namely, a psychotoxic effect. Phencyclidine is an NMDA antagonist that was introduced into human medicine as a general anesthetic in the 1950s and was soon withdrawn because of the severe psychotic reactions it produced. Subsequently, it has become notorious as a psychotomimetic drug of abuse. Ketamine, an NMDA antagonist that is less potent than PCP, has been used in human medicine as an anesthetic for several decades and is well-known to produce psychotomimetic reactions that are termed emergence reactions. In recent years, many newly developed NMDA antagonist drugs have undergone clinical trials for certain neurotherapeutic indications, and all such trials have been prematurely stopped because of the psychotomimetic side effects of these drugs. Given this clear-cut evidence that NMDA antagonist drugs cause psychotic reactions in adult humans, how is it possible for adult humans to use ethanol in high doses either acutely or chronically without its NMDA antagonist action triggering psychotic symptoms?

The most likely answer is that ethanol has a built-in mechanism that serves as an antidote to counteract and cancel out the neurotoxic and psychotoxic effects that would otherwise occur due to its NMDA antagonist properties. In support of this interpretation, ethanol has been shown to have GABAmimetic activity and it is well established that GABAmimetic drugs prevent either the neurotoxic action of NMDA antagonist drugs in adult rats or the psychotomimetic actions of these drugs in adult humans. Therefore, a

logical explanation for the observation that in human experience ethanol triggers neither acute psychotoxic nor neurotoxic reactions is that in the same circuits through which the NMDA antagonist action of ethanol would be expected to trigger psychoneurotoxic effects it exerts an action at $GABA_A$ receptors that nullifies these effects. In other circuits, ethanol may exert both NMDA antagonist and GABAmimetic actions, which combine in an additive manner to produce relaxation and a sense of euphoria. This would explain why ethanol has been perceived by human adults for many centuries as a user-friendly and relatively innocuous nectar from the gods.

From this information, an interesting question arises: Is the postulated GABA protective mechanism a totally fail-safe mechanism? A working hypothesis currently being entertained is that the GABAmimetic action of ethanol may effectively counterbalance and nullify its toxic potential in acute situations and in the context of intermittent or long-term moderate use, but under conditions of heavy chronic intake the GABA protective mechanism may gradually weaken (e.g., through receptor downregulation) and lose its ability to prevent the NMDA antagonist psychotomimetic or neurotoxic actions from being expressed. This might explain why alcoholic hallucinosis occurs in some chronic alcoholics and why a pattern of corticolimbic and cerebellar neurodegeneration occurs in others. It is noteworthy that the Wernicke pattern of neurodegeneration that can be attributed to thiamine deficiency is a pattern involving the thalamus, hypothalamus, midbrain, and brain stem, whereas another pattern of damage frequently seen in alcoholics which is not explained by thiamine deficiency involves corticolimbic and cerebellar neurons. Consistent with this hypothesis are recent reports that a single high dose of ethanol does not induce brain damage, but a steady infusion of ethanol at a dose that maintains a state of constant inebriation for 4 days results in degeneration of corticolimbic neurons in certain regions of the adult rat brain in which the NMDA antagonist mechanism would be expected to be operative.

Although this proposal is speculative, it is built on a foundation of evidence pertaining to the known properties of ethanol and is the most promising hypothesis that has been generated to date to explain how ethanol can appear to be relatively harmless for human adults but be associated with deterioration of neurological or cognitive function in more cases than can be easily explained by obvious mechanisms such as nutritional deficiency, head trauma, or uncontrolled seizure activity.

B. Mechanisms Operative in the Developing Brain

Many efforts during the past two decades to develop a suitable animal model for studying FAS met with only limited success. Microencephaly (reduced brain mass) is a characteristic finding in FAE/FAS victims, and it was demonstrated that exposure of immature rodents to ethanol in late gestation or during the first two postnatal weeks caused a reduction in brain mass. However, numerous additional animal studies failed to provide an explanation for the reduced brain mass. A modest loss of neurons from the cerebellum was described, but this cannot explain an overall reduction in brain mass, nor can it explain the types of neurobehavioral disturbances observed in FAE/FAS victims. The fact that treatment during the neonatal period (the first 2 weeks after birth) caused cerebellar neuronal loss and a reduced brain mass helped to narrow the period of peak vulnerability to the early neonatal period, which in the rodent is a time of rapid brain growth, sometimes called the brain growth spurt period. These findings have potential relevance to the human FAS because in humans the comparable developmental period when the brain growth spurt occurs is in the third trimester of gestation.

In the year 2000, three decades after FAS was first described, Ikonomidou and colleagues demonstrated that administration of ethanol to infant rodents during the brain growth spurt period triggers widespread apoptotic degeneration of neurons in many regions of the developing brain. The degeneration pattern they observed (Fig. 1) was so extensive that it could readily explain the reduced brain mass and also the myriad neurobehavioral disturbances associated with FAE/FAS. Numerous prior studies had failed to detect this dramatic pattern of neurodegeneration because optimal methods were not applied at the optimal time for detecting this type of damage, the acute period when the degenerating neuronal profiles are conspicuously evident. Examining the brains of ethanol-treated animals after a long delay interval is not optimal because at late intervals there is nothing to detect except a scattered pattern of missing neurons. If the pattern of neuronal dropout is diffusely distributed over many brain regions, tens of millions of neurons can be deleted without gross or conspicuous alteration in any given brain region. In addition, when neuronal dropout occurs during development by an apoptotic mechanism, it does not elicit a scarring response which the neuropathologists often rely on for detecting a site of brain injury long after the injury has occurred.

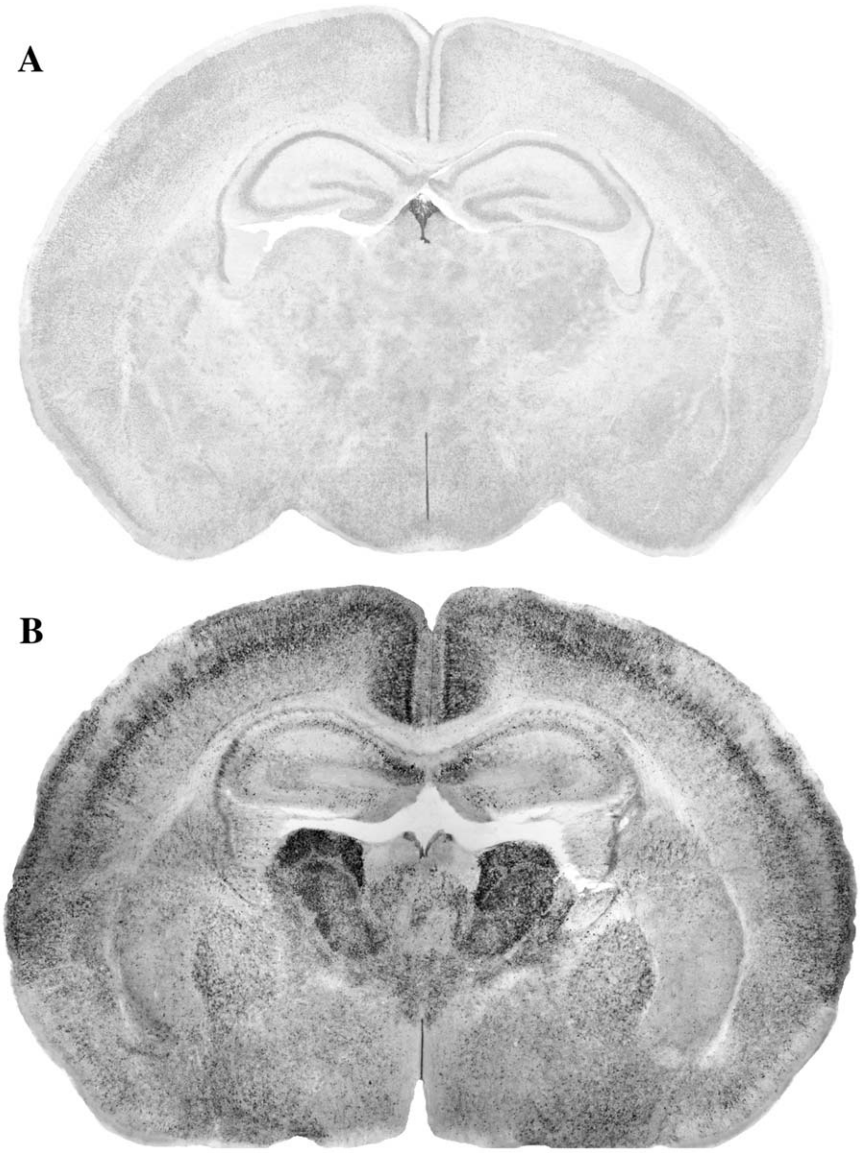

Figure 1 Ethanol-induced apoptotic neurodegeneration in the C57BL/6 mouse brain. (A) Photomicrograph of a silver-stained brain section from an 8-day-old mouse 24 hr after saline treatment. In this normal control brain, as in any normal brain during development, a few neurons in scattered distribution are undergoing degeneration. However, because the concentration of degenerating neurons in any given region is so low, the degenerating profiles are barely visible at this low magnification. (B) Photomicrograph of a silver-stained brain section from an 8-day-old mouse 24 hr after ethanol administration. Degenerating neurons (small black dots) are so abundant that they make various brain regions containing a high density of vulnerable neurons stand out in relief. Regions that are heavily affected at this brain level include the caudate nucleus, globus pallidus, hippocampus, hypothalamus, cingulate and parietal cortices, and various anterior thalamic nuclei. [From Olney, J. W., *et al.* (2000). Ethanol-induced apoptotic neurodegeneration in the developing brain. *Apoptosis* **5,** 515–521.]

In a recent neuroimaging study of the brains of living FAE/FAS subjects, there was evidence for a generalized reduction in brain mass, especially in the thalamus and basal ganglia, but no sign of a gross or conspicuous defect in any given brain region. It was concluded that the deleterious effects of ethanol on the developing brain must occur by a mechanism that reduces brain mass at a cellular or molecular level in an evenly distributed manner. The findings of Ikonomidou *et al.* in infant rodents treated with ethanol fit this description very well. The pattern of neuronal deletion was very diffuse but with the most dense degeneration

occurring in specific structures such as the thalamus and basal ganglia.

Ikonomidou *et al*. demonstrated that the cell death process induced by ethanol is an apoptotic process in which the developing neurons commit suicide. They concluded that ethanol drives neurons to commit suicide by a dual mechanism—blockade of NMDA receptors and excessive activation of $GABA_A$ receptors. They determined that the time window of vulnerability to this brain damage mechanism coincides with the brain growth spurt period. The brain growth spurt period is a period when synaptogenesis is occurring at a rapid rate, and neurons are expanding their dendritic arbors extensively to provide additional surface area for receiving newly formed synaptic connections. During this period neurons depend on a balanced level of excitatory and inhibitory input through NMDA glutamate and $GABA_A$ receptors, respectively. Either blockade of NMDA receptors or hyperactivation of $GABA_A$ receptors abnormally suppresses neuronal activity. By mechanisms that remain to be deciphered, suppressed activity during synaptogenesis translates into a message for the neuron to commit suicide. The role of the NMDA and $GABA_A$ receptor systems in this neurodegenerative syndrome was established by treating infant rodents with various agents that block NMDA receptors or agents that promote $GABA_A$ neurotransmission and showing that all such agents trigger massive apoptotic neurodegeneration during synaptogenesis. Treating infant rodents with agents that interact as either agonists or antagonists of other transmitter receptor systems did not elicit a neurodegenerative response.

An important feature of these new findings is that only a transient exposure to ethanol—a single episode of ethanol intoxication—was required to trigger extensive apoptotic neurodegeneration. In terms of blood ethanol concentrations, it required elevations in the range of 180 mg/dl, lasting for approximately 2–4 hr, to produce a robust neurodegenerative response. If blood ethanol concentrations remained at this elevated level for longer than 4 hr, the severity of degeneration escalated rapidly. Extrapolating to the human situation, it seems unlikely that maternal ingestion of a single glass of wine with dinner during the third trimester would cause neurons to degenerate in the fetal brain, but if on a single occasion several alcoholic beverages are imbibed within a period of a few hours, this might approach or exceed the threshold for causing neurons in the fetal brain to commit suicide. A major problem in assessing risk is that there is no way to know precisely how to extrapolate from rodents to humans, but prudence dictates that the extrapolation be made conservatively because of unknown variables that might cause the human fetus to be substantially more sensitive than the rodent fetus to this brain damage mechanism.

Another important point is that within the brain growth spurt period different neuronal populations were found to have different temporal patterns for responding to the apoptosis-inducing effects of ethanol. Thus, depending on the timing of exposure, different combinations of neuronal groups were deleted, which signifies that this is a neurodevelopmental mechanism that can contribute to a wide spectrum of neuropsychiatric disturbances. Consistent with this observation are recent findings by Famy and colleagues pertaining to FAE/FAS subjects who were studied in adulthood. In addition to a history of childhood hyperactivity/attention deficit disorder and varying degrees of learning impairment, a high percentage of these individuals were found to have adult-onset neuropsychiatric disturbances, including a 44% incidence of major depressive disorder and 40% incidence of psychosis. This is an important study that used a longitudinal research design to assess for the first time the full range of neuropsychiatric disturbances that human fetal exposure to ethanol can cause. Because ethanol effects on the fetus were not even suspected until 27 years ago, a prospective longitudinal study could not be completed until a cohort of individuals bearing the FAE/FAS diagnosis had grown to adulthood and begun manifesting adult-onset disturbances.

It is interesting to consider how mechanisms by which ethanol damages the immature brain compare with mechanisms by which ethanol might be damaging to the adult brain. The first important consideration is that ethanol has NMDA antagonist properties and it is known that NMDA antagonist drugs typically cause a specific type of neurodegenerative reaction in the adult brain to which the immature brain is not sensitive. The adult neurodegenerative reaction occurs by an excitotoxic mechanism and is detectable in the neuronal cytoplasm as a vacuolization reaction within 2–4 hr after drug treatment, and it has been shown that immature animals are totally insensitive to this neurotoxic mechanism. However, if immature animals during the synaptogenesis period are treated with an NMDA antagonist drug, it causes a different type of neurodegenerative response—a response that is apoptotic rather than excitotoxic and causes neurodegeneration that becomes detectable at 16–24 hr and

distributes in a pattern different from the adult pattern of degeneration. Thus, it is clear that drugs with NMDA antagonist properties have two different mechanisms by which they are damaging to the brain; one mechanism is operative only during a certain period in development, whereas the other is operative only in adulthood.

Given that ethanol has NMDA antagonist properties, it would be expected to cause one type of degeneration in the immature brain and another type of degeneration in the adult brain. However, empirical findings in animal studies indicate that ethanol produces a robust neurodegenerative reaction in the immature brain but does not, even at very high doses given acutely, produce the expected neurodegenerative reaction in the adult brain. To understand this paradox, it is necessary to analyze another major property of ethanol—its GABAmimetic property. During the period of synaptogenesis, GABAmimetic drugs are very toxic to the developing brain. They trigger massive apoptotic neurodegeneration in many regions of the developing brain. However, GABAmimetic drugs are not toxic to the adult brain. Instead, they are neuroprotective. They do not produce any neurotoxic effects when administered by themselves; when administered together with an NMDA antagonist drug, they protect against the mechanism by which NMDA antagonists damage the adult brain. Since ethanol has both NMDA antagonist and GABAmimetic properties, the logical conclusion, based on all available evidence, is that the NMDA antagonist and GABAmimetic properties of ethanol act in concert to produce a ''double-whammy'' type of damage in the developing brain, whereas in the adult brain these two properties are subtractive—one property is neurotoxic and the other is neuroprotective—with the end result being that the neurotoxic potential is there but is not expressed, except perhaps under conditions of heavy chronic ethanol abuse.

III. SUMMARY AND CONCLUSIONS

Ethanol is a simple molecule that freely enters the brain and interacts with many cellular or subcellular systems. Recent research suggests that its acute intoxicating effects and its ability to induce more permanent deleterious effects in the brain may be due to its interaction with ion channels through which many of the brain's normal functions are mediated. Of particular importance are ion channels associated with neurotransmitter function, especially channels that mediate the excitatory actions of glutamate and those that mediate the inhibitory actions of GABA. Recent evidence indicates that ethanol, by a dual mechanism (blockade of NMDA glutamate receptor ion channels and excessive activation of $GABA_A$ channels), can trigger widespread apoptotic neurodegeneration in many regions of the developing brain. This is a mechanism that can explain the reduced brain mass and lifelong neurobehavioral disturbances associated with the human fetal alcohol syndrome.

Mechanisms operative in the adult brain are different from those operative in the developing brain Wernicke's encepalopathy, a well-recognized ethanol-related adult syndrome involving neurodegenerative changes in the thalamus, midbrain, and brain stem, is believed to be due to thiamine deficiency that typically accompanies heavy chronic ethanol intake. Several lines of evidence suggest that ethanol can cause neurodegenerative changes in other regions of the adult brain by other mechanisms, but the nature of the other mechanisms remains largely a matter of speculation. Promising for its explanatory potential is a hypothesis involving the same transmitter systems (NMDA and GABA) that have been implicated in FAS. It is known that drugs that block NMDA receptors trigger a disinhibition syndrome in the adult brain that can injure or kill neurons by an excitotoxic mechanism (as opposed to the apoptotic mechanism operative during development). It is also known that drugs that activate $GABA_A$ receptors reverse this disinhibition syndrome and prevent it from injuring neurons in the adult brain. Thus, in the adult brain ethanol has neurotoxic potential because of its NMDA blocking property, but it is prevented from expressing neurotoxicity by its $GABA_A$ activating property. Recent evidence supports this concept and suggests that the protective mechanism is more than adequate to prevent expression of ethanol's neurotoxic potential in circumstances of acute heavy intake or intermittent chronic intake, but the protective mechanism may weaken and be overcome under conditions of heavy, steady chronic intake.

This proposed concept is appealing because it can readily explain the historical reality that ethanol has been used by human adults throughout the world for many centuries without apparent harm to most users, but with a subpopulation of chronic heavy abusers developing alcoholic hallucinosis and/or an irreversible neurodegenerative dementia syndrome. The other notable aspect of this historical reality is that because adult society has tended to perceive ethanol as user-friendly, countless human fetuses have been exposed

in utero by mothers who were unaware that ethanol can act in the fetal brain by a dual neurotoxic mechanism (and no counteractive protective mechanism) to drive millions of neurons to commit suicide—neurons that would otherwise have developed normally and made a positive contribution to the brain's intellectual potential. Deletion of these neurons from the developing brain results in a variety of neurobehavioral disturbances, ranging from hyperactivity/attention deficit and learning disorders in childhood to major depressive and psychotic disturbances in adulthood.

Alertness

VERITY J. BROWN and ERIC M. BOWMAN
University of St. Andrews

GLOSSARY

ascending reticular activating system The collection of forebrain projections, arising in the brain stem reticular formation, that were traditionally regarded as a single arousal system.

attention A variety of cognitive processes that enable selectivity of information processing.

readiness A state of premotor activation in preparation for action.

reticular formation Tissue in the central brain stem, from the spinal cord to the diencephalon, having a net-like appearance in histological section due to the arrangement of fiber bundles.

vigilance A form of attention involving a state of expectation or preparedness for the receipt and processing of specific information.

Alertness refers to a state of enhanced readiness to receive and process information and to respond. When a subject is alert, stimuli are processed more efficiently (indicated by improved response accuracy) and responses are initiated more rapidly (indicated by shorter response latencies). Alertness carries connotations of arousal, vigilance, and readiness, although it may be distinguished from all of these.

I. FUNCTIONAL CONSIDERATIONS

A. Arousal and Alertness

Alertness differs from arousal in that alertness refers specifically to a cognitive state, whereas arousal is a more general term that includes peripheral physiological states as well as forebrain activation and cognitive state. Arousal and alertness are related in that a state of cognitive alertness often accompanies a state of high physiological arousal. Nevertheless, physiological arousal is associated with activity of the sympathetic nervous system, which is manifest in various measures (including increased heart rate and pupil dilation) that do not necessarily correlate with subjective mental alertness. The converse is also the case: Alertness indicated by forebrain cortical activation, as when directed to the processing of task relevant stimuli, is not necessarily associated with an increase in arousal. Thus, a state of high alertness is an attentive state, whereas a state of high physiological arousal may or may not be associated with a particular attentive state. Factors that increase alertness may also increase arousal and vice versa, but the two processes are psychologically, physiologically, and neuroanatomically distinct.

In 1909, Yerkes and Dodson proposed that an inverted U-shaped function described the relationship between arousal and performance. The Yerkes–Dodson

law states that (i) increasing arousal is associated with improved task performance to a certain (task-specific) optimum and thereafter further increases in arousal impair performance and (ii) the optimum level of arousal for a given task is inversely related to task difficulty. Although this idea has been hugely influential and seems to apply to many situations, there are problems with it, not the least being the assumption of a unitary process of arousal. However, by regarding arousal and alertness as distinct processes, the Yerkes–Dodson inverted-U function can be seen to be a product of both of these processes. Optimal performance of any task is likely to be achieved in a state of high alertness rather than high arousal *per se*. The rising portion of the Yerkes–Dodson function can be accounted for to the extent to which arousal and alertness correlate; increasing arousal improves alertness, which improves performance. However, a state of high physiological arousal can result in physiological reactions that interfere with cognitive processes, which could account for the falling portion of the Yerkes–Dodson function.

The second part of the Yerkes–Dodson law states that the optimum level of arousal decreases with increasing task difficulty. Tasks that are cognitively more challenging would almost certainly be improved by higher levels of alertness. One way to achieve higher alertness is by increasing arousal. Nevertheless, arousal also increases the probability of physiological effects that might be distracting, such as a racing heart rate, sweating, and an increase in respiratory rate. There might also be distracting cognitive factors, such as anxiety if arousal is induced by aversive stimuli. It is possible that tasks that are more cognitively demanding might also be more susceptible to disruption by such factors. In these circumstances, arousal and alertness conflict: Arousal can increase cognitive alertness but, as a side effect, cognitive performance suffers from sympathetic nervous system activation. Thus, the relationship between task difficulty and arousal might depend on the extent to which the side effects of arousal compromise cognitive function.

B. Vigilance and Alertness

Just as alertness can be distinguished from arousal, it can also be distinguished from vigilance. Vigilance has also been described as the focused readiness to detect and respond to a given stimulus. When a warning is given prior to a stimulus, the response to the stimulus is improved—the warning is said to "alert" the subject to a forthcoming event. This "alerting" effect of cues actually refers to an increase in the state of vigilance. Vigilance, therefore, refers to directed alertness—one can be vigilant for a specific event, whereas alertness is a state of more generalized readiness.

Vigilance also carries connotations of effort, in contrast with alertness, which does not carry such connotations. Thomas Jefferson did not say the price of freedom is eternal alertness but rather, eternal vigilance. With vigilance, one is alert to particular possibilities, threats or dangers, and signs or signals. Eternal vigilance is possible to imagine, whereas eternal alertness is impossible. However, eternal vigilance is not easy because vigilance requires effort. The cost of vigilance is clearly seen in the laboratory as the "vigilance decrement"—a decline in performance over time. In a classic vigilance task, the target stimuli to which the subject must respond are temporally unpredictable. They may also be spatially unpredictable or of low intensity. When a subject performs such a task, over time the detection rate of targets decreases and the reaction time to targets increases. This is the vigilance decrement and it is greatest under conditions in which the targets are most difficult to detect and the requirement for vigilance is greatest. Not only is adequate performance of a target detection task difficult to maintain over time but also the effort involved is tiring.

Motor readiness is also called phasic alertness. This refers to the short duration (typically measured within a second rather than over minutes or even hours) performance enhancement, which is related to temporal expectation of targets. Reaction times to targets are faster as the temporal probability of the target increases. Phasic alertness is related to vigilance and may indeed reflect operation of similar processes.

C. The Orienting Response

Orienting refers to the movement of the head and eyes to foveate a target of interest. Bringing the most sensitive region of the retina to a target of interest improves the visual processing of that target. Covert orienting refers to attentional orienting (the movement of the mind's eye), which may occur in the absence of an overt orienting response. When a subject is alert, orienting responses are more rapid. Orienting is so fundamental to information processing that it might be regarded as a manifestation of alertness, with no

possibility of making an operational distinction between the state of alertness and the orienting response. Alternatively, the orienting response might be improved by increased alertness in the same way that vigilance performance is improved by increased alertness, although neither one is synonymous with alertness. This is perhaps most obvious when one considers disorders of consciousness in which there may be evidence of visual tracking and smooth pursuit eye movements in a subject who is otherwise unresponsive. The patient is unconscious but is regarded as alert solely because of the presence of such orienting responses.

Thus, alertness is defined here as a general state of cognitive readiness, reflected in cortical arousal. It is distinct from physiological arousal and from the demanding and costly processes of vigilance and phasic motor readiness. The processes are related in that high arousal may be accompanied by increases in alertness and increased overall alertness will benefit specific cognitive functions, including vigilance performance.

II. SUBJECTIVE ALERTNESS

The most common method of measuring alertness is to ask subjects how they feel, often employing a checklist of adjectives or paired adjectives (e.g., sleepy–awake, anxious–relaxed, and lethargic–energetic). The problem with this approach is that subjective measures do not always correspond to performance measures, such as measures of reaction time or problem-solving tasks. This may be because the relationship between alertness and performance is not necessarily linear (see Section I.A). Alternatively, it may be because the performance measures commonly used do not measure alertness directly but another function, such as vigilance. Finally, it could be because responses to such adjective checklists are contaminated by arousal level and therefore they are not good indicators of alertness. Whatever the difficulty, it is clear that resorting to adjective checklists is less than satisfactory.

III. CORTICAL ELECTROENCEPHALOGRAM

An alternative method to assess alertness is to measure neural activity using an electroencephalogram (EEG). The EEG is the summed electrical activity (postsynaptic potentials) of many thousands of neurons. It is recorded noninvasively using scalp electrodes. Because the site of recording is on the scalp, much of the recorded signal emanates from cortical neurons. When neurons fire in synchrony, the EEG has a pattern of high amplitude and low frequency. Desynchrony, when the neurons fire independently, is reflected as low amplitude and high frequency in the EEG. The amplitude and frequency of the neural activity correlate with sleeping and waking states. Four different patterns of neural activity may be identified: alpha, beta, theta, and delta activity. Theta waves are high-amplitude, low-frequency (4–7 cycles per second) waves that characterize the period of drowsiness before the delta waves (fewer than 3 cycles per second) of deep, so-called "slow-wave" sleep are seen. When subjects are awake, two patterns of neural activity are recorded in the EEG—alpha waves and beta waves. In quiet resting, particularly when the eyes are closed, alpha waves are recorded with a frequency of about 10 cycles per second. The higher amplitude, lower frequency pattern that defines alpha waves reflects neural synchrony. When subjects are alert, low-amplitude, high-frequency beta waves (15–30 cycles per second) dominate the EEG: This is the state of desynchrony. Desynchrony in the EEG can be elicited by stimulating the subject with a loud noise or by engaging the subject in a mental activity such as problem solving. These different patterns of neural activity recorded in the EEG represent a continuum of neural states rather than absolute qualitative differences. Thus, in the EEG trace, it is possible to identify periods of alpha activity or synchrony and beta activity or desynchrony, but it is not necessarily possible to determine when one type of activity gives way to another. The presence and proportion of beta activity in the EEG are correlated with a subjective sense and behavioral evidence of alertness in the subject.

The EEG also has features that may be related to vigilance and motor readiness; therefore, this technique might be a useful method to distinguish alertness from vigilance and motor readiness. The noise in the EEG signal is such that it is not easy to identify changes in the raw electrical signal evoked by stimuli. However, if the signals are averaged over many occurrences of an event, it is possible to extract an event-related potential from the background noise. In vigilance tasks, sustained negativity in the EEG reliably follows a warning signal that precedes a stimulus event. This particular scalp potential, with increasing negativity in the period preceding the expected target, is referred to as the N1. It is also called the expectancy wave or contingent negative variation (CNV) because it is elicited by

neither the warning signal nor the stimulus event alone but by the expectancy of the target following the warning signal due to the contingency between them. It is not possible to conclude with certainty that the CNV does indeed reflect a single psychological process (by implication, the warning-target contingency) rather than the totality of multiple processes, which might include orientation to the warning signal and expectancy of the target stimulus. Nevertheless, the CNV appears to be a correlate of vigilance and the issue of whether the CNV reflects a single process informs the debate about whether vigilance is a single process. Another negativity in the EEG, the N2, is recorded over secondary motor cortex, preceding the onset of movement. This is called the readiness (or Bereitschafts) potential. This negative potential reflects movement preparation or motor readiness. The ''vigilance decrement'' is reflected in the overall amplitude of the CNV and the motor readiness potentials; therefore, there is support for the contention that these negative brain potentials reflect the operation of effortful attentional vigilance.

IV. MODULATION OF ALERTNESS

Knowing the determinants of alertness has implications for the ability to control levels of alertness, which in turn has economic implications. We live in a 24-hr-day society, in which many industries and services operate in shifts. Shift workers want to feel alert and are expected to maintain optimal performance even when working during the night. Nevertheless, mistakes of all kinds are more likely during the early morning hours, particularly when body temperature is at its minimum, indicating the low point in the circadian cycle. Therefore, there is considerable interest in methods to improve alertness, with implications for health and safety.

Alertness shows diurnal variation. There are individual differences in cycles of alertness, but generally after a normal night of sleep people are most alert during the morning and experience a ''low point'' in alertness in the mid-afternoon, which rises again in the early evening. It is most difficult to maintain alertness if one is awake during the early morning hours, between 2 and 6 AM. Alertness is also modulated by time since sleep; that is, with an increasing sleep deficit, there is decreasing alertness.

Alertness is altered by ingested substances. Apart from drugs, food can modulate alertness. Some food items have psychoactive effects. For example, certain foods, such as warm milk, turkey, or bananas, facilitate sleep. Turkey and bananas have a known direct physiological effect: They are good dietary sources of tryptophan, which is a precursor chemical for serotonin. Milk also contains tryptophan, but the quantities are lower: The value of milk, particularly, warm milk, could well have more to do with stimulus-induced expectations (the warm milk might be a conditioned stimulus, associated with a bedtime routine). Nevertheless, although a banana at bedtime might improve sleep quality (which might perhaps impact alertness the following day), it is not obvious that a banana at breakfast would make a person less alert. Indeed, there is evidence that it might improve alertness. Dietary supplements of tryptophan are reported to be useful to reduce the symptoms of depression, including psychomotor retardation. Glucose is an important substance for neural functioning. Because there are no stores of glucose in the brain, availability in the blood is critical. Hunger, or, more specifically, low blood glucose, is associated with feelings of mental and physical fatigue. Conversely, reaction times are faster (both during a baseline period and after a glucose drink) if the blood glucose values are high or increasing. Epinephrine does not cross the blood–brain barrier, but when administered peripherally it improves alertness and enhances performance on cognitive tests. One of its actions is to cause the release of stores of glucose from the liver and thus increase blood glucose levels. Interestingly, with increasing age, glucose regulation appears to become less efficient and this might account for some of the decrement in mental acuity that accompanies aging.

Alertness varies according to the demands of current activity, with internal cognitive factors (such as feedback following performance errors) or a change in the task demands (such as an increase in the density of traffic on the road for a motorist) modulating levels. An increase in activity or mild exercise are known to improve alertness. A modern office is often warm, the chairs are comfortable, and computers generate a constant soporific hum—the ideal conditions for sleep. Alertness can be improved by reducing the temperature and making the inhabitants slightly uncomfortable. The occurrence of an unpredictable event or a change in posture and activity are arousing, improve cardiovascular function, and also improve alertness.

Alertness is improved by napping. A prophylactic nap, before a long period without sleep, is beneficial. Cat-napping is also beneficial, particularly a nap lasting up to 20 min, which is sufficient to be refreshing

but not disorienting on awakening. If a sleeper is awakened from rapid eye movement sleep, a period of which would be inevitable in a longer nap, he or she will be less alert and more disoriented than if he or she had less overall sleep.

Night-shift workers benefit from bright lighting in their working environment. The beneficial effect of this is likely to be due to the influence of the circadian clock, which is reset by environmental light.

V. ANATOMICAL BASIS OF ALERTNESS

The anatomical basis of alertness is likely to be common to mammals; therefore, in addition to the information derived from clinical studies of patients with brain damage, the anatomy of arousal systems can be investigated in laboratory animals. In the following sections, brain regions commonly agreed to be involved in cortical arousal and attention are discussed with regard to how these functions relate to alertness.

A. The Mesencephalic Reticular Formation

Work in the 1930s and 1940s established the importance of the brain stem reticular formation and its ascending projections in the sleep–wake cycle and arousal. In experiments in the cat, Frédéric Bremer had shown that knife cuts at different levels of the neuraxis had different effects on the patterns of sleep and wakefulness. A knife cut made between the inferior and superior colliculi (which Bremer called the "cerveau isolé" preparation) resulted in a persistent sleep-like state from which the animal did not recover. The pupils were constricted and the EEG showed only synchronized activity. If a posterior cut was made severing the spinal cord from the brain (which Bremer called the "encephalé isolé" preparation), the cat, although paralyzed, showed sleep–wake cycles with normal EEG signs of alternating synchrony and desynchrony.

In the 1940s, the research of Guiseppe Moruzzi and Horace Magoun firmly established the functional significance of these ascending projections using electrophysiological techniques: recording of single neurons and electrical stimulation. In their classic 1949 paper, they reported that stimulation of the reticular core of cats (particularly of the rostral mesencephalon) results in cortical EEG desynchrony and a change in behavior to alert wakefulness.

The reticular formation-to-forebrain projections, severed by Bremer's knife cuts and stimulated by Moruzzi and Magoun, became known collectively as the ascending reticular activating system, reflecting their supposed importance in arousal and activation. The ascending reticular projections are to thalamic nuclei, the hypothalamus, and basal forebrain. Integrity of the ascending reticular activating system is essential for an animal to be alert and awake. If these pathways are severed, the animal is in a state of coma; if stimulated, the animal shows EEG desynchronization and behavioral activation.

The reticular formation continues to be regarded as an important structure in alerting processes. However, it is now accepted that the reticular formation is not merely a single "wakefulness center," the loss of which results in sleep and the stimulation of which results in arousal. Rather, the reticular formation is composed of multiple areas, with distinct functional and neurochemical contributions, that collectively are able to gate sensory information as well as modulate cortical excitability and motor output. In particular, it was ascertained that a midpontine transection (between Bremer's cerveau isolé and encephalé isolé preparations) resulted in a large *reduction* in sleep. Bremer interpreted the effects of the midcollicular section as due to a loss of forebrain activation and arousal because sensory information was no longer passed to the cortex. The midpontine section also severed sensory input to the forebrain but resulted in a cat that showed very little sleep. This suggested that the coma resulting from Bremer's midcollicular section was due to damage to an arousal mechanism, but that there were also complementary sleep-producing mechanisms, which were isolated by the more posterior knife cut. Following the midpontine section, there are cycles of synchrony and desynchrony in the EEG. During the periods of desynchrony, pupil dilation and visual tracking (with pursuit eye movements, vergence, and accommodation) are seen in response to visual stimuli, suggesting normal arousal mechanisms.

Just as the concepts of arousal, activation, alertness, and attention have been distinguished and dissociated, so to have the functions of the reticular formation. In particular, the variety of neurochemical systems arising in the mesencephalon necessitates that the traditional view of the reticular formation be replaced by consideration of the function of a multiplicity of brain stem neurochemical systems.

B. Thalamus

The thalamus, located in the diencephalon, is functionally interposed in the sensory and motor pathways from the brain stem to the basal ganglia and cortex. The thalamus is subdivided according to functional criterion, with the principal component being sensory and motor relay nuclei and the intralaminar nuclei.

1. Thalamic Relay Nuclei

Each of the relay nuclei may be distinguished and defined by their cortical connectivity. For example, the medial and lateral geniculate nuclei are auditory and visual, respectively. The anterior group is connected to cingulate cortex and has "limbic" functions, the medial group is connected to prefrontal cortex, presumably mediating cognitive, or so-called executive, functions, whereas the lateral group (which includes the pulvinar) is associated with visual and somatosensory association cortices and premotor cortex and mediates higher order sensorimotor integrative functions. The relay nuclei are not connected to each other but, rather, might be regarded as independent channels of information.

The oscillation of thalamic cells is the origin of the synchronous activity measured in the cortical EEG. Release of acetylcholine in the thalamus, which precedes EEG desynchrony and wakefulness, returns the thalamic cells to the mode in which information can be relayed to cortex. Release of acetylcholine in the thalamic relay nuclei depolarizes the relay cells, increasing their excitability. There is a simultaneous hyperpolarization of the local inhibitory interneurons: Because this releases the relay cells from local circuit inhibition, the likelihood of the relay cell firing is further increased. Thus, acetylcholine release in thalamic relay nuclei influences the speed, likelihood, and veracity of information transmission to cortex.

2. Intralaminar Nuclei

The intralaminar nuclei comprise cell groups located in the paramedian thalamus, within the white matter called the internal medullary lamina. The mesencephalic reticular formation provides noradrenergic and cholinergic input to the intralaminar nuclei. There are also inputs to the intralaminar nuclei from cortex, globus pallidus, cerebellum, and spinal cord. Output is to the dorsal (caudate nucleus and putamen) and ventral (nucleus accumbens) striatum of the basal ganglia and to widespread areas of cortex. The anterior intralaminar nuclei project to prefrontal cortex, parietal cortex, and primary sensory areas. The posterior nuclei project to the parietal cortex and premotor (including the frontal eye fields) cortex. These intralaminar–cortical projections are likely to provide the route by which thalamus directly influences cortical arousal. Whereas the cortical projections of the relay nuclei transmit specific sensory and motor information to the relevant areas of cortex, the cortical projections of the intralaminar nuclei do not follow the boundaries of cortical areas. Electrical stimulation of the intralaminar nuclei results in eye movements. When neurons in the intralaminar nuclei are driven by input from the mesencephalic reticular formation, EEG desynchrony results. Thus, the intralaminar nuclei can mediate the effects of mesencephalic influence on the activity of frontal cortical–basal ganglia–thalamic circuits carrying complex sensory and motor information as well as directly influencing cortical tone.

3. The Thalamic Reticular Nucleus

Reflecting the organization of the relay nuclei, the thalamus is often referred to as the "gateway" to cortex. Surrounding the thalamus on its anterior, ventral, and lateral surfaces is the thalamic reticular nucleus, which is a sheet of GABAergic cells. Corticothalamic and thalamocortical fibers pass through the thalamic reticular nucleus and fibers passing in both directions have axon collaterals that synapse in the reticular nucleus. Within the thalamic reticular nucleus, signals are segregated by sensory modality, maintaining the topography accorded by their thalamic and cortical origins. The cells of the thalamic reticular nucleus do not project to cortex but rather to the thalamus (including to nuclei other than those from which they received signals) and to other sectors of the thalamic reticular nucleus. These connections imply that the reticular formation is privy to information passing between thalamus and cortex and can moderate that flow of information. Activity in the thalamic reticular nucleus may gate the flow of information from thalamus to cortex by sharpening receptive fields and response times of thalamic neurons and by modulating cortical arousal.

The thalamic reticular nucleus also receives cholinergic input from the reticular formation, specifically from the cholinergic cells of the laterodorsal and pedunculopontine tegmental nuclei, as well as from the

basal forebrain nucleus basalis of Meynert. The reticular nucleus also plays a role in the origin of EEG desynchrony by hyperpolarizing the thalamic relay cells, increasing the probability of burst firing and oscillatory activity. Because of the topography of cortical connections, the thalamic reticular nucleus is able to control the functional state (synchronous oscillatory activity as opposed to desynchronous activity compatible with information transmission) of individual specific channels to cortex.

In a series of studies in the 1970s, Skinner and Yingling examined the role of the system comprising the reticular formation, the thalamic reticular nucleus, and the corticothalamic circuits. Yingling and Skinner proposed that the circuits linking cortex and thalamus control the implementation of intention. The input from the mesencephalic reticular formation to the thalamic reticular nucleus is able to interrupt this pathway by controlling the inhibition by thalamic reticular nucleus of specific thalamic relay nuclei. Position emission tomography and functional magnetic resonance imaging and functional magnetic resonance imaging scans in human subjects have confirmed the role of thalamus and the mesencephalic reticular formation when subjects are mentally engaged and performing a task compared to resting scans.

VI. NEUROCHEMICAL BASIS OF ALERTNESS

A. Norephinephrine

The principal noradrenergic cell groups are found in the locus coeruleus, the lateral tegmentum, and the dorsal medulla. The most important of these for the processes discussed here, being implicated in processes of arousal and attention, are the neurons of the locus coeruleus. These neurons project widely to the forebrain, including thalamus and hypothalamus, cerebellum, basal forebrain, hippocampus, and throughout the neocortex. They also have descending projections to the sensory nuclei of the brain stem and to the spinal cord. Inputs to the locus coeruleus contrast with these widely distributed outputs because they are restricted to two nuclei of the rostral medulla—the nucleus paragigantocellularis and the nucleus hypoglossi prepositus. The locus coeruleus does not receive direct sensory input, or indeed any direct input from the forebrain, but rather excitatory sensory input is relayed through these medullary nuclei.

The activity of the locus coeruleus varies with the sleep-wake cycle. The neurons are most active during alert waking and least active during rapid eye movement sleep, even though the cortical EEG shows desynchrony under both of these conditions. Pharmacological stimulation of the locus coeruleus in anesthetized cats results in desynchrony in the EEG.

Neurons of the locus coeruleus respond to sensory input, particularly salient–novel or noxious–environmental stimuli. On the other hand, these neurons are quiet when the subject is awake and behaviorally alert but merely engaged in activities such as grooming or eating. This suggests that the neurons are responding to external stimuli but not to internal stimuli. However, although the neurons respond to salient, unexpected events, the response of the locus coeruleus is not dependent simply on the sensory properties of stimuli but also on their relevance. For example, in vigilance tasks the neurons are responsive to targets but not to nontargets. Furthermore, these neurons show a vigilance decrement, with a decrease in their responsivity over time in the task that corresponds to the behavioral decline in performance. This evidence suggests that locus coeruleus norepinephrine may play a role in vigilance.

B. Acetylcholine

Acetylcholine is metabolized from choline and acetyl coenzyme A by choline acetyltransferase. Choline is available in food such as egg yolks, or by breakdown of phosphatidylcholine, more commonly known as lecithin, which is used as an emulsifier in foods such as chocolate. Choline is the rate-limiting step in the production of acetylcholine, such that insufficiency of choline in the diet can lead to deficits in acetylcholine, whereas dietary supplements can increase the production of acetylcholine. Acetylcholine is broken down in the synaptic cleft by acetylcholinesterase; thus, acetylcholinesterase inhibitors, such as physostigmine or tetrahydroaminoaridine, have the effect of increasing the availability of acetylcholine in the synapse. There are two types of cholinergic receptors—nicotinic (found in striated muscle and in the central nervous system) and muscarinic (found in smooth muscles and in the central nervous system).

The two brain stem cholinergic groups (at the junction of the pons and mesencephalon) are the pedunculopontine tegmental nucleus, giving rise to the dorsal tegmental pathway, which innervates the

thalamus, and the laterodorsal tegmental nucleus, giving rise to the ventral tegmental cholinergic pathway, which innervates the thalamus and hypothalamus. Brain stem cholinergic neurons are active when the EEG shows desynchrony (i.e., during alert waking and during rapid eye movement sleep). Furthermore, an increase in activity of these neurons precedes the onset on desynchrony, suggesting a causal relationship.

In the forebrain, the septal cholinergic cell groups give rise to projections to the hippocampus, whereas the basal forebrain nucleus basalis of Meynert projects to the cortex and the thalamic reticular nucleus. These basal forebrain cholinergic projections are intimately related to the brain stem cholinergic system and represent a functional extension of it. The forebrain cholinergic cells receive input from the ascending reticular cholinergic cells. Like brain stem cholinergic cells, the activity of basal forebrain cholinergic neurons correlates with EEG desynchrony and shows the same circadian fluctuations related to the sleep–wake cycle. Cortical cholinergic innervation from the basal forebrain has been implicated in states of attention, particularly sustained and selective attention. In the case of well-practiced performance, with predicable and expected stimuli, cortical cholinergic input from the basal forebrain maintains vigilance performance. As such, this system is involved in attention and does not determine levels of alertness, although the basal forebrain is likely to be the substrate in which attentional performance is modified by changes in alertness.

It is not possible to be certain where systemic drugs exert their effects. In the case of cholinergic drugs, it could be at the level of the relay nuclei of the thalamus, the thalamic reticular nucleus, or cortex, all of which are believed to be important in alertness and attentional processes but in different ways. Cholinomimetics (e.g., nicotine) are alerting and improve cognitive performance of normal humans and patients with Alzheimer's disease. Conversely, anticholinergics (e.g., scopolamine) impair the cognitive function of normals and have sedative effects. The cognitive deficits of scopolamine most likely reflect specifically the role of acetylcholine cognitive functions rather than being due to the sedative effects *per se*: Amphetamines increase arousal and alertness but exacerbate the cognitive deficits following scopolamine. The effects of cholinomimetics in normal humans and patients with Alzheimer's disease (who have measurable loss of cortical acetylcholine) are more likely due to facilitation of attention and the efficient allocation of limited cognitive resources rather than enhancement of memory.

C. Dopamine

Dopamine-containing cells of the mesencephalon are located in the substantia nigra (A9 cell group), the ventral tegmental area (A10 cell group), and the retrorubral nucleus (A8 cell group). The cell projections are used to define two systems: The mesostriatal (from the substantia nigra and ventral tegmental area to the dorsal striatum, as well as other nuclei of the basal ganglia) and the mesolimbic and mesocortical (from the ventral tegmental area to the ventral striatum and frontal cortex).

Given the specificity of these projections, it is reasonable to assume that the functions of these pathways should be easily defined. The mesostriatal pathway is known to degenerate in Parkinson's disease, which results in imbalances of activity in circuits of the basal ganglia of the forebrain and the attendant motor impairments of the disease. The function of dopamine in this pathway can be described as motor activation: Akinetic patients with Parkinson's disease (with degeneration of the mesostriatal dopamine pathway) have been reported to declare that they desire to move but are unable to initiate the action. Conversely, the drug amphetamine, one of the actions of which is to stimulate the release of dopamine in this pathway, is dubbed "speed" for its motor activation effects. The mesolimbic–mesocortical pathway can also be stimulated by drugs, and the ability of a drug to stimulate dopamine in *this* system is predictive of a drug's potential for abuse in humans and self-administration in animals.

The spontaneous activity of dopaminergic neurons does not correlate with the sleep–wake cycle. Dopaminergic neurons respond to environmental stimuli but not in the same manner that would be expected of a sensory system. In particular, the neurons are likely to respond initially to the presentation of a primary reinforcer such as food when the reinforcer is unexpected. Over repeated presentations, when the primary reinforcer is no longer unexpected, the neuronal response is seen to diminish, while preceding predictive stimuli come to elicit the neuronal response. Thus, it is thought that the mesostriatal and the mesolimbic–mesocortical dopamine systems play a role in motivation and behavioral activation in the pursuit of a goal.

D. Serotonin

The raphe nuclei, running rostro-caudally along the midline of the pons and medulla, contain the majority of the serotonergic neurons of the brain. The posterior groups send descending projections to the cerebellum and to sensory and motor neurons and also modulate neuronal excitability. The ascending forebrain projections arise from the anterior groups. The dorsal raphe projects to frontal cortex and striatum and the median raphe projects to the hippocampus and the septum.

Neurons of the raphe nuclei fire tonically during active alert wakefulness when there is EEG desynchrony, but they fire at very low rates during sleep and are silent during rapid eye movement sleep when the EEG is also desynchronized. However, lesions of the raphe nuclei result in reduction of forebrain serotonin and a correlated reduction in time spent sleeping. Furthermore, drugs that acutely reduce forebrain serotonin also lead to a reduction in sleep. With chronic inhibition of serotonin synthesis (maintaining levels of serotonin below 10% of normal), there is nevertheless a partial recovery of sleep. This evidence suggests that serotonin is necessary for the expression of normal sleep–wake cycles, although serotonin does not appear to be necessary for initiation of sleep.

A role for serotonin in cognitive processes is suggested by the specificity of the neuronal responses during alert wakefulness. There is evidence that serotonin might be involved in processes of behavioral inhibition, particularly the ability to withhold punished responses. Such deficits would be manifest as impulsivity.

E. Combined Effects

The serotonergic, noradrenergic, and cholinergic transmitter systems show changes in their activity as a function of the sleep–wake cycle. These transmitter systems are implicated in setting levels of cortical excitability, which presumably forms the basis for variations in alertness. Nevertheless, it is still the case that very little is understood about how these systems interact to modulate or mediate alertness and varieties of attention in the waking state. The role of glutamatergic neurons of the mesencephalon, which project to the thalamus and have similar patterns of activation as those of the brain stem cholinergic projections across the sleep–wake cycle, also remains relatively uninvestigated.

VII. DRUGS THAT CHANGE ALERTNESS

A. Stimulants

Psychomotor stimulants, which include amphetamine and related compounds, caffeine, and nicotine, increase alertness, whereas sedatives decrease alertness. The term ''psychomotor stimulant'' is of interest because it draws attention to the cognitive effects of the drugs and emphasizes that they do not merely stimulate the motor system, although motor stimulation is a feature of many of these drugs.

The methylxanthine derivatives (caffeine, theophylline, and theobromine found in coffee, tea, and chocolate, respectively) are the most popular and commonly used stimulants. They increase the release of dopamine, serotonin, and norepinephrine. Fatigue is reduced and there is an increase in alertness and improvement in vigilance performance. However, caffeine consumption can impair complex motor tasks. At doses exceeding approximately 250 mg (the quantity in three fresh-brewed cups), tremor, nervousness, and anxiety can result. Contrary to popular belief, caffeine does not counteract the effects of alcohol: Caffeine (or another stimulant) will arouse a drunk but will not make him or her sober.

Amphetamines are stimulant drugs that cause euphoria, hyperactivity, increased confidence and subjective alertness, and reductions in fatigue and appetite (hence their use for weight control). Response latency is decreased in a variety of tasks, with increases in errors generally being due to anticipations (i.e., not waiting to process a target signal). Amphetamines also cause sympathetic arousal (increasing heart rate and blood pressure). The principal pharmacological effect of amphetamines is to increase the release and decrease the reuptake of the neurotransmitters dopamine and norepinephrine throughout the brain.

The stimulants adrafinil and modafinil are agonists at the noradrenergic postsynaptic (α_1) receptors. At doses that have alerting effects, these drugs are reported to have few side effects. Specifically, unlike other stimulant drugs that inhibit sleep, reports suggest that these drugs do not impair the ability to fall asleep and do not alter sleep patterns. Furthermore, they are less likely than amphetamines to result in rebound hypersomnolence, and the motor effects (tremors and hyperactivity) are much less pronounced. In addition, although modafinil increases dopamine turnover in the striatum, the motor stimulatory effects of modafinil are not antagonized by drugs that block dopamine receptors, suggesting that the mechanism of

the stimulant properties of modafinil is entirely independent of the motor stimulatory effects of amphetamines. Reboxetine, an antidepressant noradrenegic reuptake inhibitor, is also a stimulant.

Nicotine is an agonist at cholinergic nicotinic receptors, but by binding at presynaptic cholinergic receptors it has the indirect effect of causing the release of dopamine. Nicotine improves performance on a variety of tests of attention and cognitive function.

B. Sedatives

The narcotic analgesics (or narcotics) belong to the class of opioid drugs. Opiates (e.g., opium, morphine, and codeine) are derived from the opium poppy, whereas the synthetic derivatives (e.g., heroin) and purely synthetic drugs (e.g., Demerol and methadone) are called opioids. Heroin crosses the blood–brain barrier faster than morphine, giving a larger and faster "high," but it is converted to morphine once in the brain. These drugs are sedative analgesics, because they have pain-relieving properties as well as being central nervous system depressants. All of the drugs also have abuse potential because they result in euphoria. The sedative effects of opioids result from opiate receptors in the mesencephalic reticular formation, whereas the reinforcing effects are due to stimulation of the mesolimbic dopamine system. The psychoactive effects of opium have been known for centuries. After the opiate receptor was identified, the search began for the endogenous chemical that bound to this receptor. The endorphines (the name is derived from "endogenous morphine") were identified. Endorphines are released with stress and exercise; they appear to function as natural painkillers. It is the release of endorphines that is responsible for "runner's high," the feeling of euphoria and sedation that follows strenuous exercise.

Central nervous system depressants are similar to opiates but without the analgesic effect. They include barbiturates (e.g., pentobarbital, secobarbital, amobarbital, and phenobarbital), sedative hypnotics [e.g., scopolamine and methaqualone (quaaludes)], and anxiolytics (e.g., diazepam). Barbiturates are used as sleeping pills and there is cross tolerance and cross dependence with alcohol, which has similar depressant effects on cognitive function. Alcohol is a central nervous system depressant, which has effects on membrane excitability.

VIII. DISORDERS OF ALERTNESS

Fatigue is a deficit in alertness, which is a normal response following physical or mental exertion and instructs the body to rest and repair. Fatigue is a symptom of many illnesses, which reflects in part the importance of rest in recuperation from illness. However, there are occasions, such as after resting, when fatigue is inappropriate and, when alertness is required, debilitating. If such unexplained fatigue is persistent and is accompanied by other symptoms (such as sleeping problems, depression, concentration or memory problems, headache, sore throat, swelling of the lymph nodes, and muscle or joint pain) it is likely to be diagnosed as chronic fatigue syndrome.

Alertness is generally considered a good thing, but it is worth considering whether there are conditions in which a patient might complain of hyperalertness. Insomnia is the most obvious candidate; however, this is better thought of as a condition of inability to sleep rather than inability to be "not alert." Typically, the insomniac will complain that he or she is drowsy and fatigued and, in fact, suffers from a lack of alertness when awake because of an inability to sleep. The best example of hyperalertness is perhaps mania.

A. Mania

Mania describes a state of high, perhaps frenzied, psychic and physical energy in which the patient shows hyperactivity, impulsivity, and disproportionate emotional reactions (often mirth, but also irritability). Mania, which may be regarded as the converse of depression, is rarely seen alone without the patient also experiencing depressive periods, alternating with the periods of mania. The cycle of mania and depression in bipolar disorder is many months, with more than four cycles in a year described as "rapid cycling."

The neurochemical basis of bipolar disorder is not known, although serotonin and norepinephrine are implicated, as they are in unipolar depression. Clues to the nature of the neurochemical dysfunction, and therefore clues to the nature of normal neurochemical function, are often found in the effective treatment regimes. The most effective treatment for bipolar disorder is chronic administration of the drug lithium carbonate. Lithium has a rapid and beneficial effect on calming mania and once the mania is treated, it seems that the depression does not follow. The neurochemical effects of lithium are on the noradrenergic and

serotonergic systems. The biological action of lithium is complex, with effects seen on membrane excitability, neurotransmitter receptor density, and modulation of second messenger systems. The functional consequences of such actions are that reuptake of norepinephrine and serotonin is enhanced and the release of serotonin is enhanced. One of the current hypotheses regarding bipolar disorder is that there is a synergy between these neurotransmitters in the determination of mood, such that low norepinephrine "sets the scene" for affective disorder while the levels of serotonin determine the form the illness will take. It is unlikely that the explanation will be as simple as the relative overall levels of serotonin and norepinephrine, but understanding the complex action of lithium might provide important insight into the normal functional harmony of these brain transmitter systems.

B. Depression

The converse of mania is depression, and psychomotor retardation is one of the cardinal symptoms of depressive disorder. Psychomotor retardation is manifest as poverty of movements, generalized lethargy, and inertia. There appears to be a loss of motivation, with a consequent decline in productivity, which might be described as mental and physical fatigue.

Diminished ability to think or concentrate or indecisiveness nearly every day are depressive symptoms of considerable diagnostic and research interest. In the *DSM-IV* manual, they are included in the diagnostic criterion for major depressive episode.

Atypical depression is diagnosed when there is reactive mood ("mood swings") plus at least two of four additional symptoms: a lifetime pathological sensitivity to rejection, hyperphagia (or overeating), hypersomnia, and leaden paralysis. The latter two are of most relevance to the discussion of disorders of alertness. Hypersomnia describes the tendency to sleep excessively: Some patients may sleep as much as 20 hr a day. Leaden paralysis describes a state in which the patient suffers extreme psychomotor retardation. All physical activity ceases and the patient will spend many hours in apparent stupor.

Depression is treated with drugs, which increase the availability of serotonin and/or norepinephrine either by increasing their production or by blocking their reuptake, thereby making more of the neurochemical available in the synapse to stimulate receptors.

C. Disorders of Consciousness

At the extreme of disorders of alertness are the so-called disorders of consciousness, including coma, persistent vegetative states, and hyperkinetic or akinetic mutism. In the case of coma, the patient cannot be aroused and is unresponsive to internal and external stimuli. In contrast, the persistent vegetative state is differentiated from coma by the presence of cyclic arousal (resembling sleep–wake cycles) but without cognitive alertness or responsivity. Both coma and persistent vegetative state are associated with damage in the brain stem and both conditions are described as deficits of alertness.

In akinetic and hyperkinetic mutism, the deficit is less obviously one of alertness, although patients with either condition are unresponsive and apparently unconscious. Akinetic mutism resembles the persistent vegetative state in that the patient is unresponsive but shows spontaneous eye opening and may show smooth pursuit tracking of visual stimuli. This state has been described as "hypervigilant": The patient appears to be alert and attentive although he or she remains unresponsive. This disorder results from damage to frontal cortical and subcortical areas, such as that which occurs following rupture of the anterior communicating artery. The converse condition appears to be hyperkinetic mutism, in which the patient displays coordinated motor activity but without attention and apparent awareness. Hyperkinetic mutism is seen following damage to posterior attentional circuits of the parietal and occipital lobe, leaving frontal cortex intact. In both cases, the brain stem activating systems are intact: The forebrain executive systems are compromised. Thus, these conditions might represent the dissociation of consciousness (which is impaired) and alertness (which is present).

IX. IS ALERTNESS A USEFUL CONCEPT?

It is both possible and useful to make a distinction between alertness and processes such as arousal, attention, and vigilance. Traditionally, arousal was the term used to encompass all forms of activation, be it the cognitively and spatially specific arousal achieved by covert orienting of attention or the general and nonspecific sympathetic arousal resulting from the perception of imminent danger. Identifying the specific functions of the multiple transmitter

systems, arising in the brain stem to innervate the forebrain, requires a fractionation of the concept of arousal into its components. It is not possible to determine a single neurochemical system that is responsible for alertness: It is likely that alertness is the product of the synergistic activation of multiple transmitter systems. Nevertheless, alertness is a useful concept because it represents another dimension along which cognitive processing varies and further fractionates and refines the traditional concept of arousal.

Georgetown University Medical Center

GLOSSARY

affixes Grammatical word endings (e.g., *ly, ing, ed*).

derivational paralexia A paralexia in which the root morpheme, but not the part of speech, is retained.

functors Grammatical words, including pronouns, prepositions, articles, conjunctions, and auxiliary verbs (e.g., *him*, *the*, *with*, and *are*).

inflectional paralexia A paralexia in which the root morpheme and the part of speech are retained, but the form of the word is incorrect.

orthographic Pertaining to the letters of which a word is composed and the order in which the letters occur.

orthographic paralexia A paralexia in which the response shares at least 50% of its letters with the target word.

paralexia The incorrect production of a word in oral reading.

part of speech Syntactic classification of a word (e.g., noun, verb, adjective, adverb, and functor).

phonologic Pertaining to the pronunciation of the word.

pseudowords Pronounceable nonwords (e.g., *zilt* and *rog*).

semantic Pertaining to the word's meaning.

semantic paralexia A paralexia that consists of a real word that is related in meaning to the target word.

In this article, *alexia* is the term used to refer to acquired disorders of reading, subsequent to brain injury, in persons who had been literate prior to the injury. This is distinguished from dyslexia, which refers to developmental disorders of reading. In other texts, the term *acquired dyslexia* is used synonymously with alexia and is distinguished from *developmental dyslexia*.

I. INTRODUCTION

Alexias are common in patients who have sustained damage to the left hemisphere of the brain and are present in most patients with aphasia. In recent years, several different varieties of alexia have been identified. This is not surprising: Reading is a skill consisting of many cognitive components. Although there are many different models of reading, most agree that certain basic processes must occur: The written symbols are processed perceptually; letters are segregated and identified; orthographic units are matched to stored orthographic representations (knowledge of the letters that comprise a word and the order in which they occur); and the activation of orthographic representations, in turn, leads to activation of phonologic representations (the word's pronunciation) and semantic representations (the word's meaning). Disturbances in these various subcomponents of reading might very well be expected to disturb the process of reading in different ways. The identification of different types of alexia has led to new, more specific, approaches to treatment as well as to more detailed assessments of acquired reading disorders.

II. SYMPTOMS OF ALEXIA

The different types of alexia are distinguished from one another on the basis of two basic features: The

properties of the words that the patient has difficulty reading and the types of *paralexias*, or reading errors, that are produced.

A. Paralexias

The term *paralexia* is applied to an error produced in response to a task requiring the oral reading of a written word. Ordinarily, this term is used only for single-word responses and does not include multiword phrases.

Orthographic paralexias are reading errors in which the response shares at least 50% of its letters with the target word, in approximately the same order. Some examples are shown in Table I. These paralexias have sometimes been called "visual paralexias." This is a misnomer: The overall visual similarity between target word and response is often minimal with regard to overall shape and length (e.g., *political* → "police"). Another reason not to use the term visual paralexia is that in most cases, orthographic paralexias are not caused by visual problems. Orthographic paralexias are produced by patients with all forms of alexia, but the reasons these errors are produced differ between alexias. Therefore, these paralexias are not particularly useful in the classification of an alexia.

Semantic paralexias are reading errors in which the meaning of the response word is related to the meaning of the target word. Semantic paralexias are of many types. The response word may be a synonym, an antonym, a subordinate, a superordinate, a coordinate, or an associate of the target. Examples of semantic paralexias are provided in Table I. By definition, all alexic patients who produce semantic paralexias as more than 5% of their total reading errors are classified as having "deep alexia," which will be discussed later.

Table I
Examples of Paralexias

Type	Example
Orthographic	winter → "water"
	badge → "bandage"
Semantic	river → "stream"
	play → "game"
Derivational	instructive → "instructor"
	strength → "strengthen"
Inflectional	wished → "wishing"
	wants → "want"
Orthographic-then-semantic	sympathy → "orchestra"
	favor → "taste"
Functor substitutions	before → "into"
	his → "our"
Regularization errors	bread → "breed"
	shoe → "show"

Inflectional and derivational paralexias are reading errors in which the root morpheme is retained but the incorrect form of the word is produced. Inflectional paralexias refer to errors in which the correct part of speech is retained (e.g., *happiest* → "happier" and *buy* → "bought"). Derivational paralexias refer to errors in which the part of speech has been changed (e.g., *applaud* → "applause"). Inflectional and derivational errors are always seen in patients with deep alexia. They are often produced by patients with phonologic alexia as well. They are not characteristic of pure alexia, surface alexia, or attentional alexia. Prefix errors may occur in left neglect alexia, and suffix errors may occur in right neglect alexia.

Function word substitutions are errors in which a function word such as a preposition, conjunction, pronoun, or auxiliary verb is incorrectly read as another, seemingly unrelated, function word. Many of these paralexias are easily classified as function word substitutions; there is simply no other way in which the response word and the target word are connected (e.g., *her* → "which"). On other occasions, function word substitutions may be related orthographically (e.g., *her* → "here") or semantically (e.g., *her* → "she"). Although these latter paralexias may indeed represent instances of orthographic or semantic paralexias, they are typically all categorized as function word substitutions. Function word substitutions are produced by all patients with deep alexia, and by some patients with phonologic alexia.

Regularization errors are paralexias that are produced when an alexic patient reads a word as it *would* be pronounced if it were being read via some sort of spelling-to-sound correspondence rules (e.g., the word *come* is read as "comb"). These errors are not always easy to classify because the "rules" that were employed are not always transparent. Regularization errors may occur, sometimes with great frequency, in patients with surface alexia.

Orthographic-then-semantic paralexias are the result of two processing errors. The target word is first altered orthographically, then the altered word is misread semantically. These paralexias may at first appear to be random, unrelated responses until the mediating word is deduced (e.g., pivot → [pilot] → "airplane").

B. Word Properties Affecting Reading Accuracy

Written words differ along many dimensions. Some differences among written words, such as the word's initial letter or physical characteristics such as color, height, or type font, have little relevance to alexia. Other characteristics of words are extremely important in diagnosing and understanding alexia. These include part of speech, concreteness, length, regularity, and familiarity.

1. Part of Speech

For some alexic patients, the probability of reading a word correctly is dependent on the word's syntactic class. What is remarkable is that when a patient shows such a part-of-speech effect, the order of difficulty of the word classes is usually predictable. Nouns and adjectives are typically read best; verbs are read with greater difficulty; and functor words, including prepositions, conjunctions, pronouns, articles, and auxiliary verbs (e.g., *have* and *was*), are read most poorly. Part-of-speech effects are always seen in deep alexia and often in phonological alexia.

2. Concreteness

Another dimension along which words can be divided is the degree to which their referents are concrete or accessible to the senses. This is highly correlated with imageability, the ease with which a word's referent can be imaged. For some alexic patients, words that are highly concrete or imageable (e.g., *chair*) are more likely to be read correctly than words low in imageability or concreteness (e.g., *truth*). Patients with deep alexia always display a concreteness effect, and patients with phonological alexia may show this effect as well.

3. Length

The length of a written word will affect its likelihood of being read correctly for patients with certain types of alexia but not for others. For some patients, particularly those with pure alexia, words containing more letters will be more difficult. For other patients, especially those with phonologic/deep alexia, the number of syllables (not letters) might affect the difficulty of reading the word. For many patients, however, neither of these measures of length will be significantly correlated with reading success.

4. Regularity

This refers to the degree to which a word's pronunciation can be determined by its spelling—that is, whether it can be "sounded out" on the basis of spelling-to-sound correspondences. For some patients, particularly those with surface alexia, words that are highly regular such as *pin* and *tub* are more likely to be read correctly than irregular (also called "exception") words such as *pint* and *touch*.

5. Familiarity

Familiarity, whether or not a word is known to the reader as a real word, affects the reading of some alexic patients. An unimpaired adult reader can read both familiar real words and unfamiliar pronounceable nonwords (pseudowords), such as "rithy" or "Mr. Jamport." The reading of patients with phonologic/deep alexia is sensitive to this variable; real words such as *rot* may be read better than pseudowords such as *bot*.

III. TYPES OF CENTRAL ALEXIA

A. Pure Alexia

The syndrome of pure alexia was first described in the 19th century. The most striking feature of this reading disorder is that the patient retains the ability to write and spell; thus, pure alexia is also known as alexia without agraphia. Patients who have alexia without agraphia cannot read that which they have just written.

A characteristic feature of pure alexia is that patients with this form of alexia retain the ability to recognize words that are spelled aloud to them. That is, although patients with pure alexia have difficulty recognizing written words, they do not have difficulty identifying those same words upon hearing the names of the letters in the word in serial order. In fact, many of these patients discover that they can "read" written words if they name the letters of the words. The use of this compensatory reading strategy has been termed letter-by-letter reading. The ability to identify letters may be impaired early in the course of pure alexia. However, letter-naming ability often recovers over time, or it can be successfully retrained in most cases. The error most likely to be produced is the orthographic paralexia. These errors may be the result of incorrect letter naming or failure to hold on to all letter names in a word while the word is being identified (Table II).

Table II
Central Alexias and Their Characteristic Paralexias

Alexia type	Paralexias
Pure alexia	Orthographic
Surface alexia	Orthographic
	Regularization
Phonological alexia	Orthographic
	Inflectional and derivational
	Function word substitutions
Deep alexia	Orthographic
	Inflectional and derivational
	Function word substitutions
	Semantic
Phonological text alexia	*Errors occur only in text reading*
	Orthographic
	Inflectional and derivational
	Function word substitutions

Table III
Central Alexias and Word Properties Affecting Reading

Alexia	Word properties affecting reading
Pure alexia	Letter length
Surface alexia	Regularity
Phonological alexia	Part of speech
	Concreteness
	Syllable length
	Familiarity
Deep alexia	Part of speech
	Concreteness
	Syllable length
	Familiarity
Phonological text alexia	*Errors occur only in text reading, except PW reading errors*
	Part of speech
	Concreteness
	Syllable length
	Familiarity

Pure alexia is also characterized by a length effect, in which words with more letters are read more slowly and are less likely to be read correctly than words with fewer letters (Table III). The length effect is likely a consequence of the explicit letter-by-letter reading strategy: The more letters that must be identified and named, the longer it must take to do so. There are no effects of concreteness, part-of-speech, regularity, or familiarity either when these patients are attempting to read words or when words are spelled aloud to them.

Patients with pure alexia usually have intact language, although there may be some degree of anomia (difficulty retrieving words), which may be particularly pronounced for colors (color anomia). They frequently have a visual field cut called a right homonymous hemianopia, in which the right side of visual space cannot be seen.

Both the retained ability to spell and write and the retained ability to recognize orally spelled words suggest that orthographic information about words remains intact in patients with pure alexia. Thus, it has been suggested that the disorder reflects a disconnection of visual information from intact language processing areas of the brain.

The anatomy of pure alexia is consistent with the notion of a disconnection between visual and language processing centers of the brain. Pure alexia typically results from a stroke within the distribution of the left posterior cerebral artery or from a tumor located in the posterior left hemisphere of the brain. In most cases, the left occipital lobe is damaged such that the primary visual cortex is destroyed. This accounts for the right homonymous hemianopia. All visual input, then, must be processed initially by the right visual cortex. The results of this processing must then be transferred to the left angular gyrus for orthographic processing. However, this relay of the information is not possible because the lesion also damages the splenium of the corpus callosum, which connects the hemispheres in the posterior part of the brain, or the lesion damages the fibers adjacent to the angular gyrus within the left hemisphere. In either case, the visual information cannot reach the left angular gyrus, and reading fails (Table IV).

B. Surface Alexia

The cardinal feature of surface alexia is the presence of a measurable regularity effect in reading. When presented with a list of words with regular spelling-to-sound correspondences and a second list of words matched to the first list in letter length and frequency but consisting of words with irregular spelling-to-sound correspondences, patients with surface alexia have considerably more difficulty reading the second list. The regularity effect is likely to be even more pronounced when the words are of low frequency.

Some patients with surface alexia produce regularization errors; that is, an irregular word is pronounced (incorrectly) as it would be according to the

Table IV
Alexias and Site of Lesion

Alexia	Lesion site
Pure alexia	Left occipital lobe and splenium of the corpus callosum
Surface alexia	Parietal or temporoparietal, multifocal cortical degeneration, or closed head injury
Phonological alexia	Variable sites, but usually in the distribution of the left middle cerebal artery
Deep alexia	Left frontal extending into the parietal and temporal lobes
Phonological text alexia	Variable sites, but usually in the distribution of the left middle cerebral artery
Attentional alexia	Left posterior tumor or left parietal infarct
Neglect alexia	Typically right parietal lesion

spelling-to-sound correspondence rules of the language. However, not all surface alexic patients produce regularization errors in reading. Indeed, some of these patients produce a large number of errors that appear to be the result of a *misuse* of correspondence rules. Vowels, which typically have more than one pronunciation, are often mispronounced. One common error is the production of the short vowel rather than the long vowel in syllables consisting of vowel–consonant–e (e.g., reading *hate* as "hat"). Consonants with multiple pronunciations may be misread as well (e.g., *get* → "jet").

The patient with surface alexia appears to be unable to access the meanings of written words without first accessing their pronunciations. Comprehension of written words appears to depend on the pronunciation given to the word. Thus, if a written word is read incorrectly, the meaning attributed to that word will correspond to the pronunciation given. For example, if the word *come* is read according to spelling-to-sound correspondence rules, and is thus pronounced so as to rhyme with "home," then the surface alexic patient may interpret the word to mean an implement used for fixing one's hair.

As might be predicted, homophones are the source of a great deal of confusion for surface alexic patients. Intact readers make use of the orthography (spelling) of words such as *for* and *four* to determine that the former is a preposition and the latter a number. The surface alexic patient, upon pronouncing them both identically, may not know which for/four is which.

Indeed, the surface alexic patient frequently relies on the pronunciation of a written word not just to determine its meaning but also to determine whether or not it is a real word. If the patient reads the word *pint* so as to rhyme with *mint*, then the word will be judged to be a nonword, because there is no English word with that pronunciation. The patient is unable to rely on the familiarity of the sequence of letters in a previously known word to determine that it is a real word.

Similarly, pseudowords are not immediately recognized as being nonwords and must be pronounced before such a judgment can be made. Pseudowords that are homophonic with real words (e.g., *hoam*) may be accepted as real words by surface alexic patients.

The reading of patients with surface alexia usually does not show an effect of familiarity. [If anything, there is a reverse familiarity effect, in that pseudowords are read better than many (irregular) real words.] Likewise, effects of concreteness, part of speech, and length are not typically seen in surface alexia. In most reported cases of surface alexia, spelling is impaired in a manner analogous to the reading deficit. That is, words with irregular or ambiguous spellings are likely to be spelled incorrectly more often than words with predictable spellings (lexical or surface agraphia).

Most patients with surface alexia have lesions in the parietal or temporoparietal region of the left hemisphere. Surface alexia has also been described in cases of multifocal cortical degeneration and is frequently seen following closed head injury.

C. Phonological Alexia

The defining feature of phonological alexia is a strong familiarity effect (i.e., a marked deficit in reading pseudowords) in the face of a relatively intact ability to read real words. Although this may seem to have little relevance for reading in the real world (we are rarely called on to read pseudowords), in fact patients with phonological alexia do complain of difficulty reading, although their complaints are often nonspecific.

Some patients with phonological alexia also have difficulty reading functor words (prepositions, conjunctions, etc.) and may have a tendency to delete, add, or substitute affixes (e.g., read *faded* as "fade" or "fading").

An explanation of phonological alexia that accounts for both the primary difficulty reading pseudowords and the secondary difficulty reading functors is that it represents a disturbance in connections between written words (orthography) and their pronunciation (phonology), forcing reading to proceed via direct connection between orthography and meaning (semantics). Most functors and affixes serve primarily a syntactic role and have weak representations within the semantic network. Pseudowords, of course, have no semantic value and thus cannot be read via meaning.

The errors that these patients produce when attempting to read pseudowords often seem to be derived from the target word in some way. Commonly, the initial phoneme (sound) is correct. Often, a word that is orthographically similar to the target word is produced. Some very short pseudowords may be read entirely correctly; long pseudowords are rarely read correctly.

The reading of patients with phonological alexia does not exhibit a regularity effect. If a length effect is seen, it is dependent on the number of syllables or phonologic complexity, not the number of letters. A part-of-speech effect may be seen, particularly for functors, as noted previously. A concreteness effect is occasionally seen in phonological alexia. Patients with phonological alexia do not always display the analogous deficit in writing (phonological agraphia).

The lesion causing phonological alexia is quite variable but is normally located within the distribution of the left middle cerebral artery.

D. Deep Alexia

The reading of patients with deep alexia displays all the alexia symptoms of phonological alexia, with the addition of the defining feature of the disorder, the production of semantic paralexias. When semantic paralexias are produced at a rate that is greater than chance, the entire symptom complex is almost guaranteed to be seen: poor pseudoword reading, a part-of-speech effect in which verbs are read more poorly than nouns, and functors are read more poorly than verbs, a concreteness effect, and the production of derivational errors and functor word substitutions. The pseudoword reading deficit in deep alexia tends to be more severe than that seen in phonological alexia. Responses may be completely dissimilar to the target pseudoword, or no response at all is produced.

It has been suggested that deep alexia represents the (most impaired) end point of a continuum that includes the various manifestations of phonological alexia. As in phonological alexia, the pronunciation of written words cannot be accessed directly; reading proceeds semantically. However, in deep alexia there is an impairment within the semantic reading route that results in the semantic paralexias. This impairment may be within the semantic processing system or in the ability of that system to access the correct phonological code.

The typical lesion that produces deep alexia is a large one, affecting much of the left frontal lobe and extending into the parietal and temporal lobes as well. It has been posited that the symptom complex of deep alexia is actually a manifestation of right hemipshere reading in the presence of a left hemisphere that is greatly damaged. Support for this notion has come from studies of reading in split-brain patients. It has been demonstrated that the right hemisphere of some of these patients can read concrete words but not abstract words or functors and cannot determine the pronunciation of nonwords (ascertained with a rhyme task). This pattern is similar to the reading pattern of patients with deep alexia.

E. Phonologic Text Alexia

Some patients complain of difficulty reading following a stroke or head injury, but the examiner may be unable to find any class of words—or indeed any words at all—that the patient cannot read correctly. However, the accurate reading of words presented singly is not replicated when the words are presented within the context of text. When reading text, these patients tend to produce functor word substitutions, and they make errors on affixed words, as is frequently observed when phonological/deep alexic patients are asked to read single words. Also, like phonological alexic patients, these patients have difficulty reading pseudowords. It therefore appears that the reading problems of these patients are related to the problems seen in patients with phonological alexia. Hence, this reading disorder has been labeled phonologic text alexia.

Patients with phonologic text alexia typically have auditory comprehension deficits as well as reading

comprehension deficits. They also have impaired short-term phonologic memory, as demonstrated by decreased span for recall of digits, words, and pseudowords. The combination of all symptoms associated with phonologic text alexia leads to the proposition that the reading disorder seen in these patients is in some way the result of a deficit in phonologic processing and/or retention of phonologic information.

The paralexias produced by patients with phonologic text alexia in text reading (few errors are produced in single-word reading) are predominantly derivational paralexias and orthographic paralexias; semantic paralexias are not part of this syndrome, nor are regularization errors. A length effect may be observed, but this will be dependent on the number of syllables, not the number of letters, reflecting the phonologic processing deficit.

As with phonological alexia, phonological text alexia is normally the result of a lesion in the distribution of the left middle cerebral artery.

IV. TYPES OF VISUAL ALEXIA

Some acquired reading disorders are not the result of deficits within the language/reading processing systems per se, but rather reflect difficulties at a more peripheral stage of visual processing. Attentional alexia and neglect alexia are the most common of these visual alexias.

A. Attentional Alexia

Attentional alexia, like phonologic text alexia, is seen only when the patient is attempting to read text; the reading of words in isolation is basically intact. However, when viewing a multiword display (typically normal text), the patient appears to have difficulty maintaining the separation between words. Letters from adjacent words somehow infiltrate the word being read, resulting in errors that appear to be similar to those of orthographic paralexias. Attentional alexia does not appear to be a problem specific to reading. Rather, it is part of a more general problem with selective attention. The reported etiologies of attentional alexia include left posterior tumor and left parietal lobe infarct.

B. Neglect Alexia

The term neglect alexia refers to a pattern of reading in which one side of each word and/or one side of a page of text is not read or is misread. Often, although not always, this is seen within the context of a neglect syndrome that is not specific to reading. That is, the patient tends to ignore one side of space, even when not engaged in reading. Typically, neglect is produced by a lesion in the right parietal lobe, resulting in neglect of the left side of space. However, there have been reported cases of right-sided neglect alexia following left hemisphere lesions and even some cases of left-sided neglect alexia following left hemisphere lesions.

Institute of Psychiatry, London, United Kingdom

GLOSSARY

divided attention Involves two or more simultaneous trains of cognitive activity in which the attentional focus has to be split between these activities either by simultaneously maintaining attention or rapidly switching between them.

episodic memory A type of memory involving recollection of specific experiences or episodes or where the context of material is also remembered. It can be contrasted with semantic memory, which is knowledge of the world, independent of the context in which it is acquired.

mental control Processes involved in the control and sequencing of cognitive activity. The term can be used in a similar fashion as executive functioning, which in turn encompasses the control processes relating to cognition.

perseveration The tendency to continue (inappropriately) a particular pattern of behavior or response. This can either occur continuously, such as repeating the same motor action, or after a delay, such as the unintentional repetition of a previously emitted response or idea.

Alzheimer's disease (AD) is the most common dementia, accounting for approximately 65% of cases and resulting in widespread neurodegenerative brain changes and accompanying progressive cognitive decline. The brains of people with AD are atrophic, with the most pronounced loss of brain tissue in the parietal and temporal lobes and with relative sparing of the occipetal, primary motor, and somatosensory cortices. The main histological changes include the presence of neuritic plaques, neurofibrillary tangles, granulovacuolar degeneration, gliosis, and neuronal cells loss. Accompanying these changes are depleted neurotransmitter functioning, affecting the main systems, including cholinergic, noradrenergic, and serotinergic function. A corresponding global reduction in cognitive function is the main feature of AD, but this has distinct patterns and can vary between patients. Cognitive neuropsychological investigations have helped establish the pattern of cognitive decline, mainly through studying groups of AD patients.

I. THE PRODROMAL PHASE

The insidious onset of Alzheimer's disease (AD) means that there is a significant prodromal phase of varying length, with research indicating a length of up to 20

years. During this period, there is an accumulation of neuropathological alterations accompanied by subtle cognitive changes, but not yet detected as AD. The nature of these changes has been investigated by following up a random sample of individuals without dementia in a prospective fashion and determining the characteristics of those who develop AD. Such studies indicate that poor performance on tests of episodic memory are highly predictive of AD. There are also individuals who develop isolated substantial memory impairment in the absence of a diagnosis of dementia who then develop AD. This prodromal phase may last many years. Studies suggest that subsequent AD in individuals with isolated memory impairment can be predicted on the basis of short batteries of neuropsychological tests of episodic memory and mental control. Allied to this is the finding that atrophy of the hippocampus is predictive of subsequent conversion to AD. So too are decreased cerebral perfusion rates in the posterior and anterior cingulate, the hippocampal–amygdala complex, and the anterior thalamus, which are structures comprising the network that is thought to support episodic memory function. The prodromal phase has been studied in individuals at greater risk for developing AD, specifically those who are at risk for autosomal-dominance familial AD. This research indicates that the onset of AD is preceded by measurable decline approximately 2 or 3 years before symptoms are observable and 4 or 5 years before the individual fits the criteria for AD. Again, memory dysfunction is the best predictor of subsequent AD.

II. COGNITIVE DECLINE IN AD

AD is perhaps the most well-known example of a progressive dementia. The trajectory of decline, however, can differ among people. Nevertheless, there is evidence that the decline is not linear, with the rate of decline early on being slower than in the middle phase. It is not clear whether the rate of decline slows again in the later stages, partly because there is a lack of measuring instruments that can measure change across the range of severity of cognitive impairment. Many factors have been investigated regarding whether they influence the rate of decline overall. High levels of education seem to be associated with a lower prevalence of AD. Thus, education has been interpreted as acting as a mitigating factor in relation to the neuropathological changes that occur in AD. Conversely, a lower level of education may act as a risk factor in terms of determining the effects of decreased cerebral functioning. Other factors, such as age of onset and whether or not the person is in an institution or receiving community care, do not appear to have any systematic relationship with severity of dementia.

III. ATTENTION

Attention has been investigated in AD in four main areas: phasic, sustained, selective, and divided attention. Phasic attention involves maintaining a state of readiness to respond to a stimulus for very short periods. This appears to be normal in AD, as shown by the normal facilitatory effect of a warning signal prior to having to respond to a stimulus. For example, when a tone precedes having to press one of two keys, according to the position of a "square" on a computer screen, the speed advantage provided by the tone is normal in AD. Sustained attention or "vigilance" is the ability to attend to a particular sensory input or set of sensory inputs for long time periods. Preservation of vigilance in AD has been shown on various tasks, including that requiring a person to listen to trains of short tones.

Selective attention is the ability to shift attention at the perceptual stage. Within the visual domain this has been studied in relation to spatial attention, or moving the focus of attention between specific locations. Here, the processes of engaging or focusing attention on a location, disengaging, and shifting to another location can be studied. In AD, there is evidence that a deficit exists in disengaging and switching attention. Performance on the Posner selective attention task supports this conclusion. AD has been investigated by employing a task in which a particular response key has to be pressed according to whether a vowel or consonant appears to the left or the right of a central fixation stimulus. An arrow is shown just before the stimulus, pointing to either the left or right side of the screen, predicting the stimulus (valid cue) or pointing in the wrong direction (invalid). Most of the time the cue points in the right direction. In AD, there is a normal advantage when the valid cue is shown, indicating that engaging attention is normal. For the invalid cue, there is a greater increase in response time for AD, indicating problems with disengaging or switching attention away from the invalid cue. Impairments in selective attention have also been shown in relation to stimulus attributes. This has been investigated by showing digits

constructed from arrays of smaller digits and then requiring attentional shifts between the larger digits (global) and the smaller ones (local). This requirement leads to much larger response times in AD. Auditory selective attention has been studied using the dichotic listening task, in which simultaneous presentation of two strings of digits is provided. The normal right ear advantage when recalling the two-digit strings is lost in AD. Additionally, when instructed to recall the left ear first, there is an inability to benefit from a left ear advantage. This is interpreted as indicating that attention cannot be switched at will in AD.

People with AD perform very poorly on tasks that involve divided attention. This has formally been studied by requiring patients to combine tracking a moving node on a visual display unit using a light pen and other distracter tasks, such as pressing a foot pad when a tone is heard or repeating a string of digits. This type of task results in very high levels of interference in AD patients when compared to controls, even if the difficulty level of the tasks is adjusted to ensure that overall the difficulty of each individual task matches the ability of the participant.

IV. EXECUTIVE FUNCTION

The term "executive function" is used to cover a broad category of neuropsychological functions concerned with the sequencing and coordination of mental activity and behavior. These aspects tend to show impairment in the early stages of AD, with considerable impairment in the middle phase. This includes impairment on a range of standard tests, such as the Wisconsin Card Sorting Test, the Stroop Test, Random Generation of Digits, and Verbal Fluency. Although some of the deficits on these types of tasks are due to impairments in other domains of functions (e.g., language in relation to verbal fluency), there does appear to be a core deficit in relation to such functions as mental flexibility, initiation, and response inhibition. It is possible to detect subgroups of AD in which executive dysfunction appears early in a more isolated form, although the impairment tends to be become more general as the dementia progresses. It should be noted, however, that progressive dysexecutive impairment as an early presenting feature is likely to occur in people with frontotemporal dementia rather than AD.

Behavioral signs of executive dysfunction at a more basic level include perseveration and utilization behavior. Various forms of perseveration are seen in AD. These can be elicited using simple tasks, such as performing movement to command or getting the patient to draw alternating squares. The unchecked repetition of movement, sometimes termed continuous perseveration, is thought to be due to a disturbance in motor output in which there is postfacilitation of motor impulses. Operating at a different level are "stuck in set" perseverations, which involve difficulty in switching from one activity to another. A third type, which has been termed recurrent perseveration, is the most common type reported in AD and involves unintentionally repeating a response after a delay, cued by a new stimulus. For example, when a patient is asked to define a series of words, such as in the Wechsler Adult Intelligence Scale Vocabulary test, he or she may produce definition material from earlier items in response to a new item in an inappropriate fashion. It has been found that 88% of patients with AD have produced at least one recurrent perseveration within a standard test battery, whereas in normal older adults this type of error is rarely seen. In utilization behavior, responses are cued by objects in the environment in an exaggerated or inappropriate fashion —for example, being impelled to reach out and grasp proximal objects. Although this has not been studied extensively in AD, it can be observed in patients in the middle or later stages.

V. SHORT-TERM AND WORKING MEMORY

Short-term memory encompasses memory for material or events up to a period of approximately 30 sec. A basic method for assessing this is the memory span procedure, which involves the repetition of sequences of items, for example, words or tapping out a sequence of moves on an array of blocks. This type of memory is only slightly impaired in early AD. A more substantial impairment is observed if a delay is introduced between presenting material and recall and when the delay is filled by a distracter task.

This pattern of short-term memory dysfunction has been best characterized by research that attempted to identify the integrity of the different cognitive subcomponents of short-term memory. In relation to the verbal domain, the functioning of the articulatory loop system is a major component. This acts as a phonological store for verbal material, with a verbal rehearsal mechanism. There is evidence that this system is relatively spared in early AD. This is based on the finding that the phonological similarity effect is normal in AD. The effect relates to the tendency of

phonologically similar letters (e.g., PTCVBG) to be recalled worse than dissimilar letters (e.g., KWYRZQ). The size of the effect reflects the strength of the phonological store, and this effect has been found to be normal in AD, despite an overall reduction in memory span. A related finding is the normal word-length effect, in which longer words are more difficult to remember than shorter ones, reflecting the greater amount of time that the longer words take to be recycled in the articulatory rehearsal mechanism.

A major contributor to short-term or working memory impairment in AD is the divided attention of a person. This is seen in experimental paradigms, such as combining tracking with remembering digits, and also on tasks such as the Brown–Peterson task, in which three verbal items (e.g., letters) have to be remembered over intervals of up to approximately 30 sec whilst the person is distracted by a subsidiary task. When combined with tasks such as counting backwards by three's, there can be a severe impairment, even in the early stages of AD. Also, even simple tasks, such as a simple tapping movement, are sufficient to cause impairment in AD.

VI. LONG-TERM MEMORY

A. Episodic Memory

To many clinicians, an impairment in episodic memory, the inability to recall information or events within spatiotemporal contexts in the period of minutes, hours, or days, is the hallmark of AD. However, it should not be considered as a single distinguishing feature. Episodic memory impairment accounts for the loss of spatial or temporal orientation that can occur early on in AD. Formal testing of this type of memory almost always reveals substantial impairment across a range of tasks, for example, recalling lists of words, sentences, and stories or recognition memory for words, faces, and pictures. From a behavioral standpoint, memory loss has a distinct pattern as the dementia progresses. The following are the stages in the breakdown of memory function in AD.

Early AD: Mild memory lapses occur but cause only a few problems for the person. They are often falsely attributed to other factors, such as the effects of normal aging, stress, or depression. Examples are forgetting errands, failing to forward messages, and becoming disorientated in unfamiliar surroundings. Memory of episodes in the near distant past is poor, including memory of conversations with other people. These types of memory problems do not necessarily indicate a progressive neuropsychological impairment or dementing illness.

Moderate AD: The memory impairment starts to have a very significant effect on daily living activities. Memory errors include becoming disorientated even in familiar surroundings, forgetting familiar people or friends, and confusing the time of day or day of week. The person becomes increasingly unable to keep track of daily events.

Severe AD: Memory errors become more severe and can present safety problems for the person, such as those associated with wandering or forgetting to turn off the gas stove. Close relatives may be forgotten. Marked positive signs become apparent, such as confabulation and paramnesia.

The substantive impairment in episodic memory has been related to the pattern of neurodegeneration in AD. Studies of pure amnesia have implicated the mesial temporal lobe structures in memory functioning, including the hippocampus, the parahippocampal gyrus, and the perirhinal and entorhinal cortices. There is evidence that these structures are more heavily damaged early on in the time course of AD, including neurodegeneration of the hippocampus in which severe changes in the CA1 field are observed. Additionally, neurofibrillary tangles (NFTs) are found in large quantities in the entorhinal cortex (affecting layers II and IV). This structure receives projections from the perirhinal and parahippocampal cortices, which in turn project to association cortex including regions of the frontal, parietal, and temporal lobes. A hierarchical vulnerability of individual cytoarchitectural fields has been established through neuropathological studies in which NFTs appear in highest densities first in the entorhinal cortex and then in the CA1 fields and the association and sensory cortices (Fig. 1). Structural magnetic resonance imaging (MRI) has also shown that loss of volume of the hippocampus is related to episodic memory loss rather than other aspects of cognition (e.g., language and constructional praxis). In addition to mesial temporal lobe involvement, there is evidence that damage to the diencephalon contributes to memory disorder. First, a feature of episodic memory impairment in AD is a lack of sensitivity to the context in which a memory is formed, similar to that found in amnesic patients with diencephalic damage, such as occurs in Wernicke–Korsakoff's syndrome. Second, structural MRI has revealed an association between episodic memory loss and shrinkage of the diencephalic (thalamic) region.

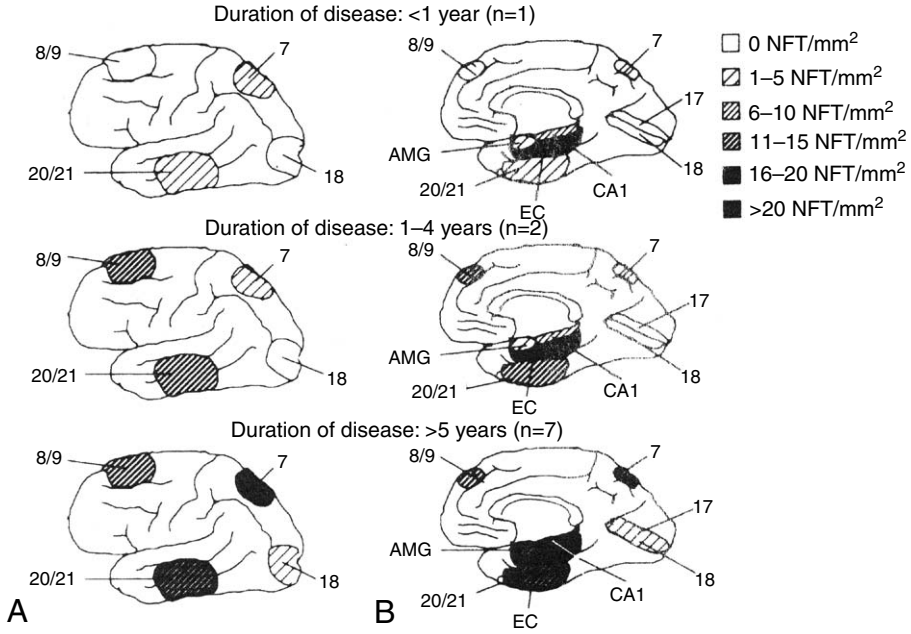

Figure 1 A schematic representation of the relationship between density and distribution of neurofibrillary tangles (NFTs) and duration of AD. (A) lateral view; (B) lateral medial view. The legend gives the density in number of NFTs per millimeter^2 represented by different shadings. EC, entorhinal cortex; AMG, amydala: Numbers refer to Brodman mapping (reproduced with permission from Arriagada *et al*., 1992).

The episodic memory impairment in AD can be seen as an amnestic syndrome overlaid by various processing deficits that further compromise memory functioning. This is supported by the inability of people with AD to make use of semantic processing to aid episodic memory. Normally, memory for material can be improved substantially if it can be better structured during the encoding process or if associative links are made with other material, as in the case of the "depth of processing" procedure in which a semantic orientating instruction is given, such as preceding a word with the question "Is it a type of bird?" In AD there is a failure to take advantage of these types of processes, with no improvement in memory. Nevertheless, when orientating instructions are given when the material is presented and the same orientating instructions are used to cue retrieval, there are memory improvements in early AD. Thus, this fact can be useful in rehabilitation programs relating to memory function.

B. Semantic Memory

The term semantic memory refers to the long-term store of facts, rules, concepts, and associations. The neuronal basis for this type of memory is thought to be diffuse within the neocortex but involving the inferolateral regions of the temporal lobes, with bilateral representation. The vulnerability of this region in AD underpins the loss of semantic memory functioning even at very early stages. Loss of semantic memory should also be distinguished from another disorder, semantic dementia, in which there is an early and marked pure semantic memory impairment. Evidence for the impairment in AD derives from a variety of tests. One is an impairment in verbal fluency, the ability to produce series of words that begin with a specific letter or that belong to a certain category (e.g., fruits). Fewer items are produced within a fixed time period. There is also a problem with object naming, in which the tendency is to produce superordinate or within-category errors [e.g., naming a trumpet a "musical instrument" (superordinate) or a "violin" (within-category)]. These impairments appear to relate to loss of material rather than to a problem accessing it, and they cannot be explained solely on the basis of language impairment. The main supporting evidence for this is that within a particular individual with AD, errors occur relating to the same specific material with different tests. For example, if there is a problem with naming an item, there is more likely to also be a

problem matching the name of the object to a picture of it. This can be true across a range of tests, including naming, matching words and pictures, sorting into categories, and providing definitions in response to being given the name of an item.

In other types of patients with brain damage, sometimes there is a dissociation between the types of semantic memories that are impaired. Specifically, those with focal damage to temporal structures can have difficulties naming living things, whereas those with frontoparietal damage can be impaired with regard to nonliving things. This distinction is mirrored in AD, for which some studies show particular problems with naming living things and some only with nonliving things, whereas others show no difference between the two. It has been suggested that such category-specific impairment depends in part on the stage of the dementia, with the early stages associated with more difficulty with nonliving items, and the pattern reversing as the dementia progresses. However, this is not proven and an alternative idea is that the type of category-specific deficit depends on the relative involvement of either temporal or frontoparietal regions.

The breakdown of semantic memory may explain some of the difficulties that people with AD have in responding appropriately in social or practical situations. There is evidence that impaired semantic memory extends to loss of schema or script knowledge. This refers to memories for typical sequences of events common to the shared cultural experience. For example, this might include "going to the theatre" or "a meal at a restaurant." Script knowledge has been examined in AD, and it has been shown that only the central and most frequent components of a script tend to be recalled, with difficulties in assigning particular activities to certain scripts.

The overall breakdown of semantic memory in AD may explain the clinically observed "emptiness" of thought and vague linguistic utterances, observed more acutely as the dementia progresses into the moderate form.

C. Remote Memory

When interviewing a person with AD, there is often the impression that distant events (e.g., early adult or childhood memories) are remembered better than recent ones. This type of "Remote Memory" has been explored in AD using various techniques and has provided insight into the circumstances in which the very remote memories are stronger. One technique is to present photographs of the faces of people who were famous in different past time periods. On the whole, such studies support the clinical impression, with famous people from the distant past more likely to be remembered, but there is an overall impairment. People with AD tend to do better if asked to say whether a face represents a famous person rather than to name the person or provide the identity; this finding has been taken to indicate that the primary problem is a loss of stored semantic information about the person who is represented rather than difficulties in accessing the name. A second technique consists of to showing pictorially famous scenes and asking the person to recall information about the event. Again, pictures of events in the distant past tend to produce fewer memories in AD.

Another approach is to investigate autobiographical memory, in which personal memories are cued using single words (e.g., "car") or people are asked specific questions about their past. Single-word cueing tends to produce more vague and generic responses. Specific questions, which may be about personal semantic information (e.g., schoolteachers) or episodic (e.g., recollections of the first day at school), result in a higher than normal number of memories about the distant past, similar to the pattern with famous faces. A further variant on this approach is to ask the person to talk about events that have been important in his or her life. In normal older adults, there is a tendency to produce most stories relating to early life, very few stories regarding the middle years, and then a modest increase in the amount of recent stories. In AD this pattern is repeated, but with a downward shift in performance. The result is that the past stories remain prominent, whereas middle-life stories become extremely sparse and there are few recent ones. In other words, people with AD may be left with memories of only salient personal events in early life, which may explain why one of the characteristics of temporal disorientation is that they think they are living in an earlier era.

VII. IMPLICIT MEMORY

A. Conceptual Priming

Conceptual priming is a form of repetition priming in which the subsequent reprocessing of the stimulus

takes place at the meaning or content level of the target stimulus. A main example is word-stem completion, in which the first few letters of a word are represented (e.g., the word "motel" with the stem "mot"). The task is to generate a word beginning with these letters; the fact that the particular word was presented previously increases the chances that it will be produced and not some other word. There is evidence for impairment of this type of task in AD, with the prior presentation of words failing to bias the subsequent production of the same words. This contrasts with "pure" amnesia or Huntington's disease, in which normal priming may occur.

However, there are circumstances in which there is normal conceptual priming, including the use of the homophone spelling bias test. Here, the manner in which a homophone is spelled by a subject can be biased in one direction by presenting semantically related items beforehand that are related to a particular spelling For example, if the word "son" (or "sun") is presented aurally, then it is more likely to be spelled "sun" if it is preceded by the words "moon" and "stars." The semantic context primes the production of the related spelling. This phenomenon has been shown to be as strong in AD patients as in normal subjects. There is also evidence that providing greater support for the original semantic processing of a word can reinstitute the priming effect in AD patients. Specifically, this has been achieved by requiring the subject to complete a sentence that ends in the word used for the priming (e.g., "He hit the nail with a … ." must be completed, where the priming word is "hammer"). A similar procedure that results in normal priming is to require the person to provide the meaning of each of the words that are used as primes. The presence of normal priming effects in certain instances has been interpreted as indicating that whether or not conceptual priming occurs normally in AD depends on the demands on semantic memory. If the demands are high, such as in the lexical priming task, then a partial degradation of semantic memory will cause an impairment.

B. Perceptual Priming

Perceptual priming occurs when processing the perceptual features of a stimulus (e.g., the visual or auditory form) increases the subsequent response time to the same material. Several studies have shown normal "repetition priming" in AD when previously presented material increases the rate at which a geometrically transformed script is read. Similarly, facilitation of the identification of briefly presented words following previous presentation of the same items is normal in AD. This type of learning mechanism may be located within the brain regions responsible for lower level perceptual processes rather than in the temporal–parietal regions, hence the degree of preservation in AD.

C. Perceptual Bias

A related type of learning is the perceptual biasing that can occur within sensorimotor processing in response to repeated activity. For example, lifting a heavy weight for a certain amount of time will bias the judgment of the weight of another item in the direction of thinking it is lighter. AD patients, despite having difficulties explicitly remembering the initially biasing experience, show the normal perceptual illusion. This also applies to the perceptual adaptation test, in which distorting prisms are used to shift the perceived locations of targets, which then have to be pointed to, with feedback given regarding the accuracy of response. In AD, the rate of learning is normal.

VIII. SKILL LEARNING

The ability to learn skilled motor behavior is not impaired in AD patients, at least in the early stages. This is shown by normal rates of learning on a variety of different tests. One is the pursuit rotor test, in which a handheld stylus has to be held so that it maintains contact with a rotating metal disc. Over a series of trials, accuracy increases and the rate of learning is taken as the measure of learning ability. In AD patients, the rate of learning is the same as that in controls, and this is true when the initial error rates on the task are carefully matched across groups by varying the speed of the disc to suit each person. Another task is mirror-reversed reading of text, which in normal circumstances improves with practice. Again, the rate of improvement appears to be normal in AD. In order to test more complex visuomotor skill learning, a serial reaction time test has been used. Here, a typical task consists of four lights being presented and each time a light comes on a key in front of it must be pressed as quickly as possibly. A random sequence is presented, but embedded in this sequence is an order

that is repeated several times. Visuomotor skill learning is shown by the increase in response time following repetition of the sequence, contrasting with a relative decline in response time with novel sequences. In AD, the normal pattern of learning is found, in the context of slower overall responses.

In all of the skill learning tasks described previously, the preserved learning ability suggests that AD patients rely on a different neuranatomical substrate than, for example, episodic memory. Comparison studies have been performed using other neurological conditions. These show a consistent learning deficit in Huntington's chorea, indicating that the neostriatal system is involved at the level of modification of central motor programs following sensorimotor feedback.

IX. LANGUAGE

A disturbance of language function is an intrinsic part of early AD and shows a steady progression in the time course of the dementia. At the early stages, the main feature in everyday language is anomia, accompanied by impoverished and circumlocutious language. As the dementia progresses, problems with comprehension appear to be more pronounced and the content of language becomes more vague, with syntactical and paraphasic errors. At the end stages, language is reduced to a few phases or even muteness. The following are the stages in the breakdown of language functioning:

- Early AD
  - Word-finding difficulties
  - Naming impairment
  - Circumlocutory discourse
  - Some problems with semantics
- Moderate AD
  - Impaired comprehension, particularly with complex material
  - Simplified syntax
  - Content vague and sometime meaningless
  - Paraphasias
  - Verbal perseveration
- Severe dementia
  - Meaningless repetition of words
  - Repetition of nonsense words
  - Mutism

Systematic studies of language function in AD have focused on the different components and suggest a general pattern of disorder. In relation to phonetic or phonemic processing, the processing and production of the sound characteristics, there is relative preservation. Until the advanced stages, phonetic articulation of word and sentence systems is largely intact. To a certain extent this is true for syntactic processing, in the sense that simpler syntactic constructions appear normal. Nevertheless, syntactic simplification in written language has been noted as an early indication of AD. Phonology and syntax contrast markedly with word retrieval impairment, which is manifest in everyday language as an impoverishment of vocabulary associated with difficulties in finding the right words. Nouns tend to be more affected than adjectives, with verbs the least affected. Formal analysis of this impairment has focused on confrontation naming for objects and word fluency. The naming impairment may reflect in part a perceptual difficulty since it is exacerbated if the stimulus is a photograph or line drawing rather than an actual object. Analysis of the errors in naming suggests that they are also semantic in nature, with a breakdown in semantic memory in part underlying the language impairment. Word fluency impairment likewise may reflect a combination of word retrieval, semantic memory, and executive function impairment. The nature of the semantic impairment was discussed previously. Allied to this is a deficit in comprehension of both written and aurally presented material.

The language impairment in AD fits none of the main categories of aphasia, but comparison studies indicate that the closest similarity is with forms of aphasia with more posterior lesions within the neuronal language system (e.g., transcortical sensory dysphasia). This is consistent with the neuropathology of AD, in which the main region of early cortical damage resides in the parietal and temporal lobes.

X. READING

Reading impairment in AD can be better understood in relation to cognitive neuropsychological models of reading processes. A major feature of these models is the identification of three main routes for reading. First, there is a sublexical route that connects the visual analysis of the word via grapheme to phoneme conversion and is used in learning to read. Second, a lexical route involves accessing the word lexicon, but with direct access to the language output system, bypassing analysis of the semantic system. This allows for the identification of words and pronunciation, but

without accessing meaning. Finally, there is input via lexical analysis to the semantic system and then language output.

In AD, the impairment of semantic processing contributes heavily to problems with reading and there is evidence that semantic memory deteriorates before lexical access. For example, in AD, there is more impairment in defining words than in reading comprehension, followed by oral reading of single words. Regular words can be read successfully, but problems occur when attempting to match words to pictures. In AD, there is preservation of reading irregular words, and this is exemplified in the National Adult Reading Test (NART), which is used to estimate the premorbid intelligence of a person with AD. Here, the irregular spellings mean that the grapheme-to-phoneme route cannot be used successfully, with reliance on either the semantic or the lexical route. NART performance is much less affected in AD than performance on other tests that would normally measure intellectual function; thus, it can be used as a premorbid predictor. Nevertheless, with moderate dementia, NART performance does decline and the errors made tend to reflect resorting to using the grapheme-to-phoneme conversion rules to arrive at an incorrect pronunciation. There is also evidence that the ability of AD patients to read NART words can be enhanced by placing them in the context of sentences, as in the Cambridge Contextual Reading Test. This is interpreted as the sentence context either facilitating the reader to identify the word as familiar, which then improves access to the lexical entry, or facilitating the use of a semantic route, resulting in a greater likelihood of correct reading. The reading of nonwords is impaired in AD, unless reading is done in circumstances in which it is possible to draw on orthographically similar words to construct pronunciation. A decline in nonword reading also follows the severity of dementia, indicating that the sublexical route is compromised in line with the dementing process.

Taken together, the pattern of reading ability in AD indicates that the lexical system shows less marked deterioration, with more reliance on the lexical rather than semantic or sublexical route.

XI. WRITING AND SPELLING

Writing becomes impaired early on in AD and is correlated with the severity of overall cognitive decline. This is in turn related to difficulties in accessing semantic information and is reflected in impairment in such tasks as written naming, narrative writing, and the ability to write the correct form of a homophone according to the given meaning. Reduced accuracy can also be attributed to impairments in nonlinguistic factors such as executive control and praxis rather than mainly to a disturbance within language-specific processing. Despite obviously impaired spelling performance, AD does not appear to produce any significant change in the effect of lexical, orthographic, and phonological stimulus variables in writing real words and pseudowords to dictation. For example, there is a normal advantage for spelling words with regular sound-to-spelling correspondence. However, there is a tendency for AD patients to show a slightly increased effect of spelling regularity and to have relatively more difficulty spelling pseudowords than normal controls.

XII. CALCULATION

Impairment in calculation is seen early on in AD. Although the pattern tends to be heterogeneous and inconsistent, there is greater impairment in relation to execution of calculation procedures rather than in answering arithmetic facts (rote-learned calculation outcomes). Within the latter, there is more impairment with multiplication rather than addition and subtraction facts. The deficit in execution has been related in part to the higher executive demand, particularly when the task emphasizes divided attention, such as writing and memorizing. Errors may also be due to problems in organizing and monitoring the sequence of cognitive operations.

XIII. VISUOSPATIAL FUNCTION

Visuospatial impairment in AD may affect either constructional or visuoperceptive ability, and these may reflect the involvement of the dorsal or ventral streams of neuronal processing, respectively. Constructional impairment is unlikely to be a presenting symptom, but it can be detected through formal assessment and may relate to parietal lobe dysfunction, particularly in the right hemisphere. Assessment procedures include the block design subtest from the Wechsler Adult Intelligence Scale, which usually reveals impairment in moderate dementia but can detect difficulties in the mild form. A simpler alternative is to require the patient to draw a series of line drawings, with drawing impairment frequently

observed in early AD. There are some indications that drawing to command (e.g., the patient is requested to "draw a clock") is more sensitive than copying drawings. Additionally, copying three-dimensional figures such as a cube tends to reveal impairment more readily than copying unidimensional figures. Many of these procedures, however, may confound constructional dysfunction with problems of praxis or planning. Visuoperceptual impairment may in part underlie impairment associated with naming objects. This is supported by the fact that naming impairment is increased when photographs of objects or line drawings are used rather than the actual objects.

XIV. EMOTIONAL PROCESSING

The ability to process emotion has been assessed in AD using a variety of tasks, including those relating to the auditory and visual domains. These tasks include recognizing the emotion of audiotaped voices, facial expressions of emotion, gestures, body movements, and videotaped vignettes. There is impairment in AD on these tasks, but this has been found to relate to the other components of the tasks used (e.g., visual processing or abstraction). The lack of primary deficit in processing emotion may explain why people with mild to moderate AD can demonstrate correct emotional responses in social settings, appropriately detecting the emotions of other people.

XV. MOTOR FUNCTIONING

The following are features of motor impairment in AD:

- Pyramidal signs
  - Hyperreflexia
  - Plantar responses
- Extrapyramidal signs
  - Tremor
  - Rigidity
  - Bradykinesia
  - Gait disturbances
- Primitive reflexes
- Apraxia
  - Ideational
  - Ideomotor

Not all people with AD exhibit the full spectrum of deficits. A general feature of AD is that the primary motor cortex is relatively preserved. However, pyramidal signs may be seen in AD; these include hyperreflexia, extensor plantar responses, hyperactive jaw jerk reflex, and ankle clonus. The mechanism for this is unclear but may involve either diffuse white matter or associated vascular dementia. Extrapyramidal signs exist, and the most common are bradykinesia (slowness of movement) and rigidity (increased resistance to passive movement). Tremor is infrequent. Gait abnormalities consist of slowness in walking, with decreased step length, paucity arm swing, and a droop posture, all of which may become more apparent as the dementia progresses. Myoclonus can occur early on, but motor seizures are regarded as happening later. Primitive reflexes of two types, nocioceptive and prehensile, are also seen in AD. The nocioceptive type, which includes the snout reflex, the glabellar blink reflex, and the palmomental reflex, occurs in approximately 20–50% of cases and can be seen early on. Of these, the snout and palmomental reflexes are the most common. The prehensile type, which includes grasping, sucking, and rooting, is less frequent (10–20% of cases) and is associated with late-stage dementia.

The two common types of apraxia are seen in AD, according to the strict definition of this term. Ideational apraxia, which involves impairment of the ability to perform actions appropriate to real objects, is frequently observed in AD, as is ideomotor apraxia. The latter refers to selection of elements that constitute movement, such as in copying gestures and miming usage. It has been estimated that the presence of both ideational and ideomotor apraxia occurs in 35% of patients with mild, 58% with moderate, and 98% with severe AD. Tool action knowledge has also been characterized as conceptual apraxia and found to be dissociable in AD from semantic language impairment.

In the moderate or severe range, another motor feature that can be observed is motor impersistence. This is an impairment in the ability to sustain a voluntary movement (e.g., exerting a steady hand grip or keeping the eyes closed). This is distinguished from apraxia because the movement can be performed and maintained with instruction. This type of motor impairment is strongly related to frontal lobe involvement.

XVI. HETEROGENEITY

The previous description of AD is mostly based on group studies with the aim of establishing general

features of neuropsychological dysfunction. Nevertheless, considerable heterogeneity exists and there is growing evidence for different subforms of AD, defined in terms of their initial presentation. Although a typical pattern is early memory disorder followed by the development of attentional, executive, and semantic memory and praxis and visuospatial impairment, other patterns have been observed. These include early aphasic disorder of fluent and nonfluent type and also early visuospatial or perceptual impairment. These tend to reflect the pattern of neuropathological changes, with the aphasic cases having temporal lobe involvement, those with visuospatial disorders having greater occipetoparietal alterations, and visual cortex involvement in the visual variant cases. It has been estimated that these atypical presentations comprise 14% of patients with AD.

XVII. CONCLUSION

This article shows that AD can be characteractized as an interlocking set of neuropsychological impairments that combine to provide a distinctive profile, considering AD as a single entity. At least in the early stages, areas of relative preservation of function can be identified, and these in turn can be used to optimize functioning. In addition, no person with AD is the same; individuals deviate substantially from the general profile, such that in clinical practice an individual analysis of the presenting deficits and their resultant disabilities should always be considered.

Anger

CHRISTOPHER R. LONG and JAMES R. AVERILL
University of Massachusetts, Amherst

GLOSSARY

aggression In humans, the intentional infliction of harm on another, against their wishes and not for their own good; in other animals, the infliction of harm per se.

executive functioning A superordinate level of cognitive functioning that coordinates goal-directed activities and mediates conscious experience.

localization of function The attribution of a specific psychological process or function to a particular neural structure or brain area.

phrenology A pseudoscience of character analysis popular in the early 19th century based on the mistaken belief that patterns of indentations and protrusions in the skull indicate brain areas that mediate psychological functions.

Type A behavior Behavior characterized by feelings of time pressure, competitiveness, and hostility or chronic anger. Type A behavior has been linked to cardiovascular disease.

Anger is an emotion that involves both an attribution of blame for some perceived wrong and an impulse to correct the wrong or prevent its recurrence. The angry response may or may not involve aggressive behavior.

I. INTRODUCTION

Anger is a complex phenomenon deeply rooted in both our social and biological history. In the fourth century BC, Aristotle observed that

> *Anyone can get angry—that is easy; … but to do this to the right person, to the right extent, at the right time, with the right motive, and in the right way, that is not for everyone nor is it easy; wherefore goodness is both rare and laudable and noble.*
>
> *Nichomachean Ethics*, 1109a25

Elsewhere, writing from the perspective of a "physicist," Aristotle defined anger as a "boiling of the blood or warm substance surrounding the heart" (*De Anima*, 403a30). These two approaches to anger—the social and the physical—are not unrelated. Aristotle was not able to articulate that relation, however, except in abstract, logical terms. His knowledge of the physiological mechanisms was woefully inadequate. Today, advances in neurophysiology allow us to do considerably better.

At first, our knowledge of the relation of anger to the brain might seem a straightforward empirical issue, dependent only on technological advances. However, such an interpretation is only partially correct. As the above passage by Aristotle suggests, anger is inextricably linked to a network of concepts, an implicit folk theory that encompasses notions of action and passion, right and wrong, and retribution and conciliation. Neural mechanisms may be necessary conditions for anger, as they are for all behavior, but they are not sufficient. In this article, we focus

on those necessary conditions, but we do so in a way that also respects the irreducibly social aspects of anger.

II. TWO MEANINGS OF ANGER

The term "anger" is used in two distinct ways, both in everyday discourse and in scientific writings. First, in a generic sense, anger refers to a family of closely related emotions, including annoyance, rage, hostility, contempt, envy, fury, frustration, and jealousy. Second, in a specific sense, anger refers to one emotion among others in the same general class, such as when anger is contrasted with annoyance or rage. It is necessary to distinguish between the generic and specific senses of anger because what is true at one level of generality need not be true at another level.

In its generic sense, anger is often used to indicate almost any aggressive emotional response. Aggression is one characteristic that some episodes of anger share with other emotions in its class (annoyance, rage, hostility, contempt, etc.). However, as a specific emotion, anger is only occasionally accompanied by physical aggression, and even verbal aggression is relatively uncommon. For example, think of the last time you became angry, probably in the past day or two. What did you do? If you are like the majority of people, you likely talked the incident over with the instigator of your anger or with a neutral third party, or else you engaged in a variety of calming activities to "let off steam."

If anger is typically as benign as the above observations suggest, why should we be concerned with it and its underlying neural mechanisms, other than for academic reasons? The answer is threefold.

First, anger can erupt into aggression. When it does, the consequences can be serious both for the angry person and the target. In recent years, major advances have been made in our understanding of the evolutionary and physiological bases of aggression. As are new breakthroughs in the understanding of the neurophysiology of emotional behavior in general, advances in the study of aggression are reviewed in detail elsewhere in this encyclopedia and will only be mentioned briefly here.

Second, the attribution of anger is often used to excuse behavior after the fact. Anger shifts the blame from the aggressor ("I couldn't help it; I was overcome") onto the target ("Besides, he deserved it"). The existence of such a ready-made excuse may facilitate the occurrence of subsequent aggression against the same or other target, as in the case of child and spouse abuse.

Third, anger can cause problems even when no aggression is involved. A person who is unable to express anger in an effective manner may continue to suffer affronts (e.g., harassment in the workplace), leading to chronic stress and associated psychophysiological disorders (e.g., hypertension). In addition, a propensity toward anger and hostility seems to be the component of the Type A behavior pattern that is associated with increased risk for coronary heart disease.

In short, there are good reasons for studying anger and its relation to the brain. It is important to emphasize at the outset, however, that this article focuses on anger as a phenomenon in its own right, distinct from both aggression and emotion in general. This discussion is intended to complement, not replicate or supercede, information provided in the articles in this encyclopedia specifically focusing on aggression and emotion.

III. THE LOCALIZATION OF FUNCTION

To what degree can a complex psychological phenomenon such as anger be localized in the brain? The answer to this question depends in part on the level of organization under consideration. The more elementary the response (e.g., a reflex-like reaction), the more feasible its localization. At higher levels of organization (e.g., an instrumental goal-directed act), the nature of the response depends less on a specific neural structure than on the interaction among different parts of the brain and on the integration of information from a variety of sources, both internal and external.

Historically, there has been a tendency to replace the questions of what is happening and how it is happening with the seemingly more tractable question of where it is happening. In the early 19th century, for example, phrenologists claimed to have identified locations in the brain for a multitude of psychological functions, including everything from verbal ability to love of the picturesque, based on the perceived correlation of relevant behaviors with individual differences in patterns of cranial bulges and indentations. Although the empirical bases on which phrenology presumably rested were soon disproved (e.g., the shape of the skull bears little relation to the shape of the brain),

phrenology remained popular among laypersons well into the 20th century.

Modern researchers have grown much more sophisticated in their ability to assess relationships between the brain and behavior. For instance, by mapping event-related potentials, as well as using imaging techniques such as functional magnetic resonance imaging and positron emission tomography, researchers have recently demonstrated a surprising degree of modularity in brain function. For example, there appears to be specialized neural circuitry for the ability to recognize melody formed by variations in pitch as well as specialized neural circuitry for the ability to recognize the number of objects in an array. In a similar vein, research has demonstrated associations between angry cognitions and certain areas of the brain, often (but not always) the prefrontal cortex, the orbitofrontal cortex, and the bilateral temporal poles.

Before reviewing in detail possible associations between anger and specific areas of the brain, a caveat is worth emphasizing. Recall the example of the recognition of melody. Specialized circuitry for recognizing melodic changes in pitch does not suggest that Beethoven's *Ninth Symphony*, for instance, is somehow hardwired into the brain. Both the composition and the experience of a symphony are dependent on a particular social context as well as any biological predispositions, and the neurological correlates of a symphony are not only established through experience but also variably and widely distributed. Something similar can be said about anger. Specialized circuits likely exist that help mediate aspects of anger. However, as the quotation from Aristotle that opened this article implies, anger also belongs to the realm of moral discourse. A person cannot simply be angry; rather, he or she must be angry at someone for some reason (e.g., a perceived wrong). If anger is to be fully localized, its "place" is as much in the social system (i.e., in the normatively structured interaction between individuals) as it is in the nervous system.

Stated differently, the functions of the nervous system must be identified on their own terms, which include the processing, storage, and retrieval of information and the organization of behavior. The question then becomes: Are some kinds of processes unique to anger (as opposed, for example, to aggression and emotion in general)? No simple answer can be given to a question such as this. The human brain is an exceedingly complex organ that has evolved over millions of years. Past adaptations are seldom discarded but instead are maintained and incorporated into newer systems. Thus, some specialization of function relative to anger undoubtedly exists. There is, however, no reason to believe that a one-to-one relationship exists between a particular process and angry behavior, on the one hand, and another process and nonangry behavior, on the other hand. Rather, depending on the circumstances, the same processes may help mediate angry behavior on one occasion and nonangry behavior on another occasion. Although this complicates analysis, it also yields a major advantage; it means that insights gained in one area of study (e.g., the neural mechanisms involved in memory) can be extrapolated *mutatis mutandis* to other areas, including anger.

IV. THE ORGANIZATION OF ANGER EPISODES

Anger is a hierarchically organized pattern of behavior. In the following discussion, we distinguish five levels of organization, three of which can be observed in infrahuman animals, whereas the other two are specific to humans (Fig. 1). In discussing the infrahuman levels, we focus on aggression rather than anger per se for reasons that will become evident. However, as emphasized earlier, human anger need not—and typically does not—involve aggressive behavior.

Using radio-controlled electrodes implanted in the brains of *Macaca mulatta* monkeys, José Delgado observed the effects of brain stimulation on behavior as the animals roamed freely in their colonies. Stimulation of some brain sites elicited elementary (level I) responses, such as baring the teeth and vocalizations. Stimulation of other sites elicited responses that, although still fragmentary, were more complex and better organized: walking around, circling, climbing, and the like. Such level II responses were sensitive to the environment, but they remained divorced from the remainder of the animal's behavior.

At a still more complex level of organization (level III), one that implicates executive functioning, stimulation could elicit well-coordinated attacks against other members of the colony. However, the occurrence of an attack was not a straightforward response to brain stimulation; rather, it was mediated by past encounters between the stimulated animal and the other members of the colony as indicated, for example, by their relative positions in the troop's dominance hierarchy. When an animal was dominant, stimulation might elicit aggression against subordinate monkeys in the colony. However, if the subordinate monkeys were replaced by more dominant ones, stimulation of the

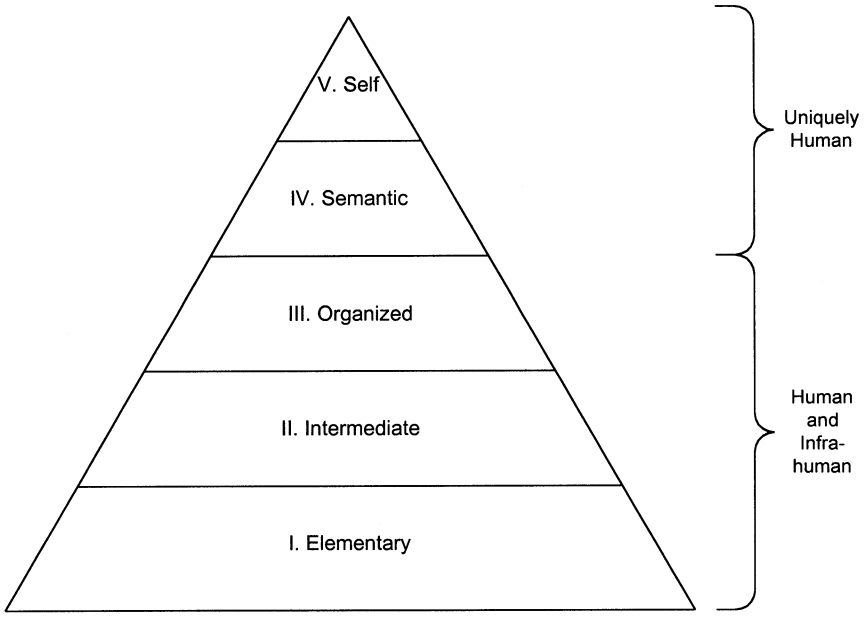

Figure 1 The hierarchical organization of anger episodes.

same animal (and at the same site in the brain) might cause the former aggressor to become the target of aggression by others.

In the particular monkey whose position in the troop's hierarchy was manipulated, the electrode stimulated her right pedunculus cerebellaris medius close to the lateral lemniscus. However, the important detail is not the precise location of the stimulation but that different responses could be elicited depending on the animal's circumstances at the time of stimulation. This exemplifies the point made earlier that a specific mechanism may help mediate angry behavior on one occasion and nonangry behavior on another occasion.

We do not wish to imply that the monkeys studied by Delgado experienced anger, except in a metaphorical sense. As discussed earlier, the concept of anger implies an attribution of blame; and an attribution of blame in turn presumes a network of concepts, for example, of intentionality, right and wrong, and justice and retribution. To the extent that the experience of anger is informed by the concept of anger, a monkey cannot be angry: It can be frustrated and aggressive but not angry.

To differentiate human anger from infrahuman aggression, two additional levels of organization must be considered; namely, the behavior must conform to anger as conceived of by the individual (level IV), and it must be related to the self (level V). To an even greater extent than level III, these distinctly human levels of organization involve executive functions.

V. EXECUTIVE FUNCTIONS AND THE EXPERIENCE OF ANGER

Executive functions coordinate goal-directed behavior and mediate conscious experience. Little direct evidence is available on the neurological mediators of these functions, at least with regard to anger. However, the work of Endel Tulving and colleagues on memory and self-awareness provides some insight. Some of the same capacities required for memory are also required for the full experience and expression of anger. For example, recognizing one's place in a dominance hierarchy, as in the case of Delgado's monkeys described earlier, presumes a memory of past encounters based on associative learning. Knowing the meaning of anger and related concepts, which is a kind of factual knowledge, involves semantic memory. However, objective knowledge of the meaning of anger is not sufficient. In anger, the appraised wrong is experienced personally (subjectively) as an affront to the self. The capacity for self-awareness, which Tulving relates to episodic memory, is thus necessary for the full experience of anger.

The three levels of executive functioning discussed by Tulving and colleagues correspond approximately to the top three levels of organization (III–V) depicted in Fig. 1. All three levels of executive functioning (and their corresponding levels of organization) appear to be localized in the prefrontal cortex. The first level, which can be found in infrahuman animals as well as in humans, interacts directly with posterior cortical and subcortical processes. It is charged with integrating diverse responses into a meaningful sequence, such as when Delgado's monkey's recognition of her subordinate status mitigated her inclination to attack. The second level of executive functioning appears to be localized in a somewhat more anterior portion of the frontal lobes. In addition to mediating semantic memory and factual knowledge, as discussed previously, this level also helps regulate behavior in situations that require novel solutions. Frustration, which is a common occasion for aggression, is one such situation. The third and "highest" level of executive functioning is closely allied with the second. Its distinguishing feature is its ability to relate events to one's own life, not simply in a factual, objective manner but as part of the temporal sequence of events, extending from the past and into the possible future, that comprise a person's sense of self. There would be no anger in the fullest sense—only momentary flaring to the immediate stimulus—without involvement of the self. Tulving and colleagues speculate that this capacity for self-awareness is mediated by processes localized in the most recently evolved anterior portions of the frontal lobes, an area of the brain whose relationship to emotional functioning is currently under investigation, with new findings appearing almost monthly.

Anger is often depicted as a biologically primitive response mediated by subcortical and paleocortical regions of the brain (e.g., the limbic system). It might therefore seem anomalous to suggest that anger is, in an important way, a function of the most recently evolved parts of the brain (anterior frontal lobes). However, this anomaly is not as great as it might at first appear. In the first complete work devoted exclusively to anger, the 4th-century theologian Lactantius used the wrath of God, not animal aggression, as the starting point of his analysis. Also, in traditional ethical teachings, the failure to become angry at perceived wrong was treated as a failure in humanity, not as a sign of superior virtue. In other words, the theoretical conception of anger as a highly evolved psychological function is not incompatible with many long-standing understandings of anger.

VI. RECOGNIZING ANOTHER'S ANGER

In recent years, considerable research has been devoted to specifying the brain mechanisms that help mediate a target's perception of another person's anger. This reflects, in part, methodological considerations: It is relatively easy to ask persons (e.g., brain-damaged patients) to evaluate pictures of angry facial expressions or audio recordings of angry speech; it is difficult to elicit anger in the context of a research study. However, the recognition of anger is an important issue in its own right. As discussed earlier, anger is an interpersonal emotion; it presumes a target as well as an angry person. An inability to recognize another's anger may thus be as disruptive of social relationships as is the inability to express anger appropriately.

The results of research on anger recognition have been variable, allowing few generalizations. The amygdala, the anterior cingulate cortex, and the frontal lobes are areas of the brain frequently implicated in studies of the visual recognition of angry expressions, although these areas are often implicated in the recognition of other emotional expressions as well. Damage to the amygdala has also been associated with difficulty in auditory recognition of anger cues, although several recent studies have called into question the importance of the amygdala in recognizing vocal expressions of emotion.

When interpreting results of research on anger recognition, several considerations must be kept in mind. First, the expressions of anger used in these studies are typically responses (e.g., facial displays) that occur at the organizational level III or below, as depicted in Fig. 1. That is, they are more indicative of aggressive intent than of anger per se. Second, the recognition of an emotional expression need not elicit the same emotion in the perceiver as in the sender; that is, when recognition of an angry expression does occur, the response of the perceiver may be fear or remorse, not anger in return. Third, even when the same emotion (anger) is elicited in the perceiver as in the sender, the brain mechanisms involved in recognition need not be the same as those involved in expression.

VII. IMPLICATIONS FOR REHABILITATION FROM BRAIN INJURY

Life is often unfair, or so it seems. Not surprisingly, people frequently become angry when confronted with life's inevitable misfortunes, including injury due to

accident or disease. For example, a brain-injured patient suffering paralysis or aphasia following a stroke may, like any other patient, experience anger at the seeming unfairness of events. When the anger is misdirected at health care providers, not to mention friends and family, treatment may be disrupted and recovery prolonged. Nevertheless, the anger is understandable, even if unjustified, as the patient comes to terms with a painful event that makes little rational sense.

Such "normal" if misdirected anger must be distinguished from that which results more or less directly from injury to parts of the brain related to aggression. For instance, an injury that results in stimulation of the amygdala may induce an aggressive response that is interpreted post hoc by the patient as anger. As humans, we like to think that our actions are meaningful. When, for extraneous reasons (such as brain injury), we respond in ways that make no sense, we nevertheless impose meaning on the response. Interpreting a brain injury-induced aggressive response as anger is one such meaning-making device. (Recall the earlier discussion of the generic and specific senses of anger. As noted, anger is often used generically to refer to almost any aggressive response.)

One distinguishing feature between normal (albeit misguided) anger following injury and brain injury-induced anger/aggression is that the former is typically manifested soon after the injury's occurrence, and it abates as the patient adjusts to life following the injury. However, differential diagnosis is difficult. Once an aggressive response is interpreted as anger, it is in a sense "normalized"; that is, it is made to conform to the beliefs and rules that help guide normal anger. The underlying condition that produced the aggression may thus be masked.

In short, the assessment and management of anger and aggression in neurological rehabilitation requires careful exploration of the patient's entire repertoire of behavior and the instigating factors. It is easy to be misled by focusing uncritically on a patient's claim that he or she was simply acting out of anger.

The most efficacious treatment of anger and aggression following brain injury requires an individualized rehabilitation program that incorporates an array of neurological, behavioral, and social therapies. In the same way that anger cannot be localized to any specific neural structure, the most effective anger management program will not rely exclusively on any one form of treatment.

Anomia

LISA TABOR CONNOR*,‡ and LORAINE K. OBLER†,‡

*Washington University School of Medicine, †City University of New York Graduate School and University Center, and ‡Boston University School of Medicine

GLOSSARY

aphasia A disorder of language produced by damage to the language zone, usually in the left hemisphere of the brain. Aphasia is not due to the inability to articulate language but is caused by damage to language representations or mechanisms.

circumlocution When a target word cannot be retrieved, a multiword response describing the characteristics of the object it names. For example, "you write with it" for "pen."

confrontation naming A task used to evaluate a person's ability to spontaneously name an object or an action; either a picture or an actual object is presented to the person for him or her to name, or a picture, pantomime, or video enactment of an action is presented to the person to elicit its name.

literal (or phonemic) paraphasia Sound substitutions or additions that result in either an unintended real-word utterance or a nonsense utterance. For example, with the word target *flea*, the utterances *free*, *fleep*, and *flur* would all be classified as literal paraphasias.

perseveration The unintended repetition of an idea, verbal utterance, or motor output.

verbal (semantic) paraphasia Substitution of a real word for a verbal target; if the substituted word is semantically related to a verbal target, such as *leaf* for the intended target *tree*, this would be considered a semantic paraphasia.

Anomia is a profound difficulty in coming up with words in the course of discourse and/or on a naming task, particularly those words that are heavily meaning-laden. This definition presumes both that a word being sought was originally known by the speaker and that the difficulty in retrieval is not due to failed articulation. Anomia is a hallmark of aphasic syndromes and occurs in aphasic persons with fluent, running speech and in aphasic persons with nonfluent, halting speech. That is, all aphasic individuals have word-finding difficulties to some degree. Such difficulties retrieving words are also characteristic of Alzheimer's dementia and, to some extent, of normal aging. This review focuses on the three populations in which anomia, sometimes called dysnomia, is prevalent: persons with aphasia, persons with Alzheimer's disease, and healthy older adults. A review follows of category-, modality-, and grammatical-class-specific anomias and of how these fractionations of word-finding into subtypes inform our understanding of the neuroanatomy of naming. Rehabilitation for anomia and recovery from it are discussed. Finally, a cognitive framework for naming is proposed to provide a means for discussing features of word-finding impairment.

I. ANOMIA IN APHASIA

As mentioned in the article on aphasia (this volume), it is a set of disorders of language. In adults, the aphasias are typically caused by stroke in the left hemisphere of the brain in the perisylvian region. The perisylvian region is bounded by the third convolution of the frontal lobe and the angular gyrus in the parietal lobe,

by the supramarginal gyrus, and by the superior border of the inferior temporal gyrus. Nearly all language deficits are produced by lesions inside the perisylvian region, and lesions outside of this region rarely produce language deficits, at least in right-handed individuals. Both areas traditionally associated with the classic aphasia syndromes, Broca's area in the frontal lobe and Wernicke's area in the temporal lobe, lie inside the perisylvian region.

Aphasic individuals with lesions inside this "language zone" exhibit different characteristics depending upon the location and extent of the lesion. Language deficits may be characterized by severe limitations of verbal and/or written production with relatively well-preserved comprehension (as in Broca's aphasia) or by severe limitations of auditory comprehension with relatively preserved verbal production (as in Wernicke's aphasia). Many other patterns of impairment and preservation of language faculties are possible, and particular combinations are characteristic of other aphasia syndromes. Regardless of whether the person with aphasia exhibits nonfluent speech or fluent speech, however, a common deficit is evident, that is, a difficulty accessing words, anomia. In fact, anomia was recognized in the late nineteenth and early twentieth centuries as a crucial component of aphasia by early aphasiologists such as Broca, Wernicke, Freud, Pitres, Head, and Goldstein. Anomia may be either a central feature of the aphasic picture or more peripheral to other features of language dysfunction. Because of its crucial importance to aphasic syndromes, however, most aphasia assessments begin with examination of the individual's ability to name in conversational speech and to name an object or drawing of an object to confrontation.

Naming is first assessed by eliciting a sample of speech. The speech sample may be obtained by asking the patient open-ended questions like, "What brought you here today?" or by showing a picture of a visual scene and asking the patient for a verbal description of it. Advantages of eliciting speech through a picture description task are that specific targets for naming are present, providing the patient with more structure, and that there may be objective standards for quantifying the patient's impairment in naming. One picture-description task commonly used in the assessment of aphasia is the Cookie Theft Picture Description from the *Boston Diagnostic Aphasia Examination*.

Naming to confrontation is the next step in assessing aphasia. The manner by which confrontation naming ability is tested is quite straightforward. Either an object or a picture or drawing of an object is presented and the patient is asked to say its name. Likewise, an action may be depicted, the examiner can pantomime an action, or a video clip may be shown portraying an action and the patient is asked to say what is happening. A commonly used test of confrontation naming of objects is the *Boston Naming Test*. To examine the nature of retrieval failures in confrontation naming, examiners probe the patient for more information. For example, they may ask "Do you know what this is? Is there another word for that? What is the woman doing?" If the patient is still unable to respond, cues may be given that are related to the meaning of the pictured object. A meaning-based cue, called a semantic cue, is often given if it is unclear that the patient perceives the picture accurately. For example, if shown a picture of a beaver, a cue may be either general in nature, such as "It is an animal," or specific in nature, such as "It builds a dam." If the patient is still unable to respond correctly or if it is clear from the patient's comments that the picture is perceived correctly, a sound-based cue, called a phonemic cue, may be given to aid the patient in producing the correct target. Typically, a phonemic cue consists of a small fragment of the target, such as the initial sound and initial vowel. For instance, if the target is beaver, the cue "bee" would be spoken. In some instances, latencies to produce a picture name may be measured to detect subtle difficulties in initiation or naming difficulties with particular categories of words. The significance of responding to cueing and category-specific deficits in naming will be discussed later in this article.

The characteristics of anomia differ among aphasia classifications. As illustrative examples, consider the features of anomia in Broca's aphasia, Wernicke's aphasia, and anomic aphasia. Anomia plays a dramatic role in Broca's aphasia. Patients with Broca's aphasia have difficulty initiating speech, have nonfluent, agrammatic speech with poor prosody and phrase length, and have particular difficulty producing the "small" function words of the language such as articles and prepositions, as compared to substantive words. Their speech is hesitant and labored, with only critical items related to the meaning of the message being produced, such as nouns and some verbs. Their total output is severely reduced. During confrontation naming, the naming performance of Broca's aphasics may be severely or mildly impaired, but some degree of difficulty will be encountered. Further, the Broca's aphasic may say the name of a previously produced picture even when a new one is presented (a phenomenon called perseveration) or may produce a word that

is semantically related to the target, such as *leaf* for the target *tree*. This latter type of substitution is called a verbal or semantic paraphasia.

Patients with Wernicke's aphasia, by contrast, have "fluent," not labored, fairly grammatical, speech with generally preserved prosody and phrase length. They often have difficulty with confrontation naming tasks, producing verbal paraphasias and word-sound substitutions called literal or phonemic paraphasias. It is often quite difficult to point to specific instances of anomia in the speech of a Wernicke's aphasic because there are no pauses to search for words and the intended meaning of the utterances in free conversation is often unclear. Wernicke's aphasics with severe impairment may produce neologisms, that is, nonsense words that have been hypothesized to reflect word-finding difficulties. A common feature of running speech in milder Wernicke's aphasics, like that of other fluent aphasics such as conduction, anomic, or transcortical sensory aphasics, is circumlocution, the verbal description of a target that the patient is unable to retrieve. In addition, Wernicke's aphasics fill their discourse with words "empty" of content (e.g., *thing*, *something*, *do*), again, probably reflecting difficulty in accessing the substantive nouns and verbs they intend. Severe Wernicke's aphasics are unaware that their speech does not make sense to the listener and may be frustrated that the message is not comprehended. Wernicke's aphasics also tend to perseveratively repeat ideas, particular phrases, or individual words or nonsense words.

Anomic aphasics have a severe word-finding impairment with little evidence of other language difficulty; that is, comprehension and repetition are both well-preserved. The anomia in anomic aphasia is characterized by circumlocution and a keen awareness of retrieval failure. The person with anomic aphasia may be quite frustrated at the inability to produce the desired target. The speech output of an anomic aphasic is still classified as "fluent" even though word-finding difficulties may be quite frequent, because phrase length is in the normal range with circumlocutions consisting of many words in a run and prosody is unimpaired.

II. CATEGORY-SPECIFIC, GRAMMATICAL-CLASS-SPECIFIC, AND MODALITY-SPECIFIC ANOMIAS

In addition to general difficulties retrieving lexical targets in aphasia, considerable attention has been devoted to concomitant category-specific dissociations in naming in aphasia. Several dissociations have been reported, including disproportionate deficits in naming natural objects compared to manmade objects as well as the converse, in retrieving proper names versus common nouns, in naming to visual confrontation as compared to auditory or tactile confrontation, and in naming actions versus objects and the converse. Evidence for semantic category-, grammatical-class-, and modality-specific anomias will be reviewed in turn.

A. Semantic-Category-Specific Anomia

Though reports of both category-specific sparing and deficits arose earlier than the seminal work of Warrington in the 1970s, Warrington and her colleagues brought attention to the increasing number of reports that words from different semantic categories may be unequally affected in aphasia. They began a series of systematic investigations into the selective preservation and impairment of semantic categories, seeking the best way to understand the islands of impairment that their patients exhibited. In early work they focused on the abstract versus concrete dimension and then later focused on the natural versus manmade object dimension. Many studies of semantic-category-specific deficits followed. Although at first it appeared that these more broadly defined categories captured the nature of the impairments in these patients, it became apparent through studies reported by other investigators that many exceptions arose that could not be readily incorporated into such broad categories. For instance, reports surfaced of patients with selective impairments in finding the names of fruits and vegetables but no other living things, impairments of only animal names, and selective impairments of naming facial emotional expressions. To further complicate the issue, there is a loose correspondence between lesion location and the nature of the semantic impairment, such that lesions both inside and outside the classical zone of language produce semantic category impairments, for example, an animal-naming deficit associated with the left inferotemporal region and a tool-naming deficit associated with the left parietal region. However, it is difficult to argue that these impairments arise with any consistency when a particular region is involved. Semantic-category impairments are intriguing both as behavioral phenomena and as challenges to models of language

representation in the brain; however, we are still quite a long way from understanding them.

B. Grammatical-Class-Specific Anomias

The early grammatical-class dissociation observed in the anomias was that between content-laden (''substantive'') words and functors, those ''small words'' like ''if,'' ''is,'' and ''who'' that convey primarily syntactic information. Patients with a type of aphasia called agrammatism, of course, produce predominantly substantives and few functors. However, agrammatism itself traditionally has not been considered primarily an anomic problem. Rather, problems with retrieving substantives (nouns, verbs, adjectives, and, perhaps, adverbs) in running speech or on confrontation naming constitute anomia.

Like the category-specific anomias, grammatical-class dissociations in naming have been reported that include noun–verb dissociations and proper-name-retrieval failures. Unlike semantic-category dissociations, however, noun–verb retrieval dissociations are more tightly coupled with particular lesion territories. That is, individuals with selective impairment of object naming have left posterior language-zone lesions of the temporal cortex, whereas individuals with selective impairment of action naming have left anterior language-zone lesions of the frontal cortex. The controversy in the domain of noun–verb naming dissociations lies in what these lesions represent in terms of the language system. If the anterior area is associated with verb problems and the posterior area is associated with noun problems, how can we account for the category-specific problems discussed earlier? One possibility is that they arise from smaller lesions than the one that results in general problems with nouns. A second possible explanation is that both the representations for semantics and phonology remain intact for nouns as well as for other substantives but that there is a disconnection between specific semantic centers and the store of the phonological shapes of names. In addition, this second theory assumes that the distribution of semantic and phonological representations for nouns is separate from that for verbs, nouns being distributed throughout the temporal lobe and verbs being distributed throughout the frontal lobe.

In addition to noun–verb dissociations, evidence for specific deficits in proper-name retrieval has been reported primarily by Semenza and colleagues. Lesions of the left temporal pole are associated with this deficit. In individuals with proper-name impairments, common nouns are largely preserved. Even names that would have been well-known before the aphasia are markedly more difficult to access. Indeed, some patients have been reported to have a dissociation between their ability to retrieve proper names for people and that for geographic locations and landmarks. The explanation offered for such dissociations has been that proper names, especially those for people, have limited associations to other items in the lexicon. For example, the occupation baker has associations to other occupations and to what bakers do and produce, whereas the last name Baker refers more arbitrarily to the individual or family one happens to know with that last name. For geographical locations and landmarks, the name may be associated more strongly with other information about that place, for example, one may associate the Eiffel Tower with everything one knows about Paris and France.

C. Modality-Specific Anomia

Whereas the term anomia has classically been associated with problems locating the names of things presented visually, there is a substantial set of cases that have been reported in the literature in which modality-specific factors are evident in accessing or producing substantives. Among the different modalities of presenting the targets are touch, taste, smell, and hearing (e.g., the sound of a bell ringing to elicit the noun ''bell''). Optic aphasia, for example, nicely demonstrates that naming impairments may be specific to a particular sensory modality. In optic aphasia, the person is unable to name an object presented visually but has minimal difficulty naming that same object presented through another modality. A picture of an apple may be met with naming impairment, but once the person has touched or smelled an apple the name is readily retrieved. As is the case with grammatical-class-specific anomia, a particular lesion along the pathway either from visual association areas and the semantic representations for objects or from visual association areas and motor output areas for speech is posited to explain the phenomenon. In addition, patients have been reported for whom it is not the modality of input that results in a dissociation but, rather, the modality of output. For example, an individual may be markedly more anomic when asked

to speak the name of a target than when asked to write it or vice versa.

Cases of modality-specific anomia have lead to theorizing about the extent to which there is one underlying lexicosemantic system for all modalities. Instances with dissociations among modalities suggest rather that there may be multiple systems of input in order to get to the phonological (or orthographic) shapes of words and for outputting them via speech or writing.

III. ANOMIA IN ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is the most studied of the dementia-producing diseases that can have anomia as a salient symptom. Dementia (see the article on it in this volume) may be defined as a progressive cognitive decline resulting from a number of diseases. Such a cognitive decline characteristically may include more language disturbance (as in Alzheimer's disease in all but very-late-onset instances) or less language disturbance (as in the dementia associated with perhaps one-third of the individuals with Parkinson's disease). When a language disturbance is evident, anomia is invariably a part of it. The naming problems associated with the dementias may or may not be termed anomia by different scholars; however, the phenomenon is quite similar to that found in the aphasias. What underlies the problem, however, appears to be different. First, the cognitive problems underlying the dementia regularly include a variety of memory problems, so one may argue that the difficulty with outputting a name results from the memory problem rather than from a more strictly linguistic problem. At the anatomical level, moreover, the dementias are associated not with sizable, isolatable lesions such as those of the aphasias but rather with multiple lesions at the cellular level, thus suggesting that it is a systemic problem rather than an area contributing to some more or less specific aspect of naming that is impaired when anomia manifests itself.

Linked to the cognitive decline crucial for a diagnosis of dementia is a marked component of semantic impairment evident in the dementias, most particularly in AD. The term "semantic" here is meant to be distinct from the term "phonological" (or "orthographic") in that the borders of meaning of a word seem to become more permeable, or less specific information about the meaning of the word is available. This can be well-demonstrated by a task such as one to probe the semantic attributes of a word. For example, when a patient cannot remember the name penguin, one might ask about superordinate information (e.g., is it a tree? an animal?), coordinate information (e.g., is it a dolphin? a robin?), and subordinate information (e.g., does it eat fish? does it live in a cool climate?). Whereas people with anomia resulting from the aphasias can access all three types of information without difficulty, anomics with AD can, at one point in their cognitive decline, access only the superordinate information and later may even have problems with that. Such semantic problems, however, act in conjunction with more purely lexical-access problems. These may be more severe than those associated with normal age-related problems that the patient would be expected to evidence.

One of the ways one tests for the problem lying at the retrieval stage, as mentioned earlier, is by giving phonemic cues. For patients with AD, these may not be helpful as they are for normal elderly individuals with naming problems. Indeed, patients with AD may appear to "free associate" to the phonological cue: for a picture of a trellis, one says "tre…" and the patient may respond "trend." Of course such a response does not positively assure that the problem lies at the lexical level; rather, it may be due to inattention to the task. An alternate indication is to look at the consistency with which the patient can name an item over time. If the patient cannot name the trellis one day but can the next, this argues that the item's representation itself is not impaired, but rather retrieval of it is. An additional factor that enters into the naming errors of patients with AD is perceptual difficulty. That is, pictures may draw inappropriate answers ("cucumber" for "escalator") as the patient is drawn to the overall shape or to a subcomponent of the picture.

IV. ANOMIA IN NORMAL AGING

Whereas there are clear-cut naming problems associated with old age, the term anomia may be even less appropriate to describe them than the naming problems of Alzheimer's disease, perhaps because they are so much more subtle than the naming problems of aphasia. Indeed the term "dysnomia" (here referring to a transient naming problem rather than a permanent disorder) may more accurately portray the naming problems of aging in that it implies a more fleeting problem rather than an enduring impairment. Phenomenologically, older adults report word-finding

difficulties as they age (including more frequent tip-of-the-tongue experiences), and, in fact, laboratory-based studies have confirmed this report. In particular, older adults find the retrieval of proper names increasingly difficult. Whereas the literature confirms that proper nouns are particularly difficult with advanced age, difficulties with nouns and verbs are evidenced as well. There are some reports in the literature that noun retrieval is disproportionately impaired relative to verb retrieval with age, but more recent evidence suggests that, in carefully matched sets of nouns and verbs, the retrieval deficit associated with age, which becomes significant around age 70 years, is equivalent for both types of substantives.

Cross-sectional studies as a rule demonstrate significant naming problems for groups of older adults starting in the decade of the 70s. Longitudinal studies point to subtle declines in naming as early as the 40s. With normal aging, however, there is substantial variability across individuals within any given age cohort; some 80-year-olds perform like some 30-year-olds in a naming task. Education does seem to have long-term protective benefits in this regard. Results from the ability of older adults to rapidly choose a correct name on a multiple-choice task for items that they were unable to spontaneously retrieve, as well as being able to retrieve the correct name for an object once given a phonemic cue, suggest that the deficit in lexical retrieval for older adults lies in accessing the phonological shape of the target word. However, there is a suggestion that subtle semantic degradation may be involved as well from research examining the consistency of naming a given item over a series of test sessions.

Theoretical accounts for dysnomia in aging have centered around the well-described phenomenon of cognitive slowing. In particular, Burke and her colleagues have put forward an account of age-related naming deficits that combines cognitive slowing with the clear-cut deficit in accessing the phonological shape of a target word. Their model suggests that aging produces slowing, or "transmission deficits," across the board in the semantic and phonological networks that underlie lexical retrieval. The phonological system is relatively more affected, however, because, as activation spreads throughout the network, semantic activation for a particular target converges on the appropriate lexical node, but the activation must then diverge from the lexical node to the many phonological nodes that constitute the word. Because general slowing is at play in aging, the amount of activation that has accrued at the lexical node is less for older adults than for younger adults and, thus, when the activation spreads to the phonological nodes, it expires before crossing the threshold for word production.

V. TREATMENTS AVAILABLE FOR ANOMIA

Naming abilities in aphasics recover over time. Indeed, it appears that there may be slow progressive recovery in the ability to name objects and actions over time even years after the aphasia-producing incident and long after treatment has ended. However, some aphasics who have, according to all aphasia tests, fully recovered from their aphasia, nevertheless report feeling that they cannot always find the words they need in conversation.

Despite the apparent spontaneous recovery of naming abilities over time, treating them is quite difficult. Attempts at drilling items, which work well for second-language acquisition in some normal individuals, have no long-term effects for aphasic patients. More successful, by contrast, are efforts to affect the processes that interfere with naming. For example, perseveration of a previous verbal response may prevent access to an otherwise intact name. Therefore, treatments that focus on reducing perseveration may be helpful in "deblocking" verbal naming. One such treatment developed by Helm-Estabrooks and colleagues involved bringing perseveration to the awareness of aphasic individuals and teaching them to actively suppress the item that they were about to incorrectly produce and to then ask the therapist for a cue as to the correct name for the target. This treatment is not, however, a treatment for naming per se but rather an means to prevent an incorrect response from intruding upon the production of the correct name.

Another deblocking technique for severely impaired aphasics is the Voluntary Control of Involuntary Utterances program also developed by Helm-Estabrooks and colleagues. This method is appropriate for use in individuals who have quite restricted verbal ability, perhaps limited to a few stereotypical responses, but whose productions are inappropriate to the context. This type of off-target responding occurs only in cases of severe verbal production deficit. An example of this would be the case where the patient says "cat" when shown a picture of a pencil. The fact that the patient clearly has access to the name "cat" indicates that it is a candidate for remapping to its appropriate semantic representation. The idea underlying this program is that speech that is generated automatically

and without voluntary control can be retrained to be uttered voluntarily in an appropriate context. The clinician starts with a very small vocabulary of items, perhaps as few as five or six, for which the patient can successfully read the name of an object presented with its picture (e.g., the patient says "cat" to a picture of a cat) and expands the functional vocabulary over time by first introducing emotionally salient words and expanding outward from there to include new items. This technique tends to deblock other vocabulary, enabling the clinician eventually to expand functional naming to as many as a few hundred items.

Techniques have also been put forward to enable a less severely impaired patient to use partial utterances to cue a correct response. Often it is the case that, once a phonemic cue is given, an aphasic patient will be able to use that cue to generate the remainder of the word. Because this technique is only appropriate for a particular target, the goal is to get the patient to apply a systematic approach to retrieving the appropriate cue that will "bootstrap" the target response. An alphabetic search strategy is one means by which to generate the appropriate cue (and many aphasics have spared ability to recite fixed sequences like the alphabet), or mentally generating semantic associates to the target may lead to the recovery of the initial phonemes.

VI. COGNITIVE FRAMEWORK FOR NAMING

In order to arrive at a cognitive framework for naming that accounts for a majority of the available data from aphasia, aging, and Alzheimer's disease, a basic three-stage model of naming like that of Levelt consisting of a visual object-recognition stage, an access-to-semantic-information stage, and finally a phonological-realization stage needs to be expanded considerably. First, a lexical level needs to be inserted between the semantic and phonological levels to satisfy constraints of mapping distributed semantic and phonological representations onto one another. In addition, due to modality-specific deficits such as those found in optic aphasia, it is clear that a single semantic system blind to input modality will not suffice. Therefore, it is necessary to propose two levels of semantic analysis: one dealing with modality-specific features of an object and a second dealing with supramodal features such as an object's function. Moreover, on the basis of data from normal aging, it is necessary to include in a model of confrontation naming a means to describe the process by which the information is passed from one level of representation to another and how that information could be disrupted or affected by changes in the processing abilities of the individual. Finally, information about semantic-category dissociations and the degradation of semantic knowledge with Alzheimer's disease requires that there be a hierarchical representation of semantic attributes. Therefore, what initially appeared to be a simple and straightforward three-stage model of naming is complicated by what we know about how the components and processes of naming are affected by aging, disease, and neurological accident. Even with all of the additions to and modifications of the simpler model, many behavioral phenomena associated with anomia, as well as their neurological underpinnings, are as yet unexplained.

GLOSSARY

akinetic mutism The inability to initiate movement following surgical removal of or infarcts to the anterior cingulate cortex.

allele Refers to a sequence variant of a particular gene. Each person carries a genome sequence that is approximately 0.1% different from any other human (excluding identical twins and family members). These differences in the sequence of a gene give rise to multiple alleles of a gene in a population and can lead to variations in observable traits. The sequencing of the human genome shows the most common sequence differences (available at http://www.cshl.snp.org).

automatic processing A term used to describe cognitive processes that can be done rapidly, in parallel, and that require no attentional resources.

cingulate epilepsy syndrome Seizures confirmed in the anterior cingulate cortex that result in excessive activity of this region, impair consciousness, and alter affective state and expression. Patients with such seizures may display psychopathic or sociopathic behaviors.

cognitive conflict Interference due to competing stimuli, memories, decisions, tasks, thoughts, or actions.

cognitive control The ability to resolve conflict among competing or interfering thoughts and actions.

error-related negativity (ERN) A negative deflection in the event-related potential following incorrect responses during choice reaction time tasks observed during scalp electrophysiological recordings.

gene A portion of the human genome that contains the instructions and code for the production of a protein. The publication of the sequence of the human genome reveals approximately 35,000 genes (available at http://genome.ucsc.edu/).

gene association study The statistical methods used to determine whether variation in the sequence of a particular gene correlates with variation in an observable trait.

heritability (h^2) A term that describes the extent to which variation in a trait (e.g., cognitive performance) among members of a population is determined by inherited genetic variation. h^2 can vary between 1 (high) and 0 (low). h^2 can be estimated in a number of ways but most conveniently by comparing the correlation in performance of identical (monozygotic or MZ) vs fraternal (dizygotic or DZ) twins. Higher correlation among MZ twins suggests that genetic factors contribute significantly to the variation among individuals for that trait.

The anterior cingulate cortex is a region of the brain thought in to be involved in actions guided by sensation, cognition, and emotion. This article provides evidence for anterior cingulate cortex function from both human and animal studies using neuroimaging, electrophysiology, lesion, and genetic methodologies.

I. NEUROANATOMY

The anterior cingulate cortex is situated around the rostral portion of the corpus callosum. This region has numerous projections into the motor cortex and, thus, advantageously sits where it may have a significant contribution in the control of actions. Basically, the anterior cingulate has been implicated in sensory, cognitive, and emotionally guided actions. A description of the morphology, cytoarchitecture, and

connectivity of the anterior cingulate cortex is provided in order to help specify biological constraints on any theory of anterior cingulate function.

A. Morphology

The anterior cingulate cortex lies bilaterally on the medial surface of the frontal lobes around the rostrum of the corpus callosum, bounded by the callosal sulcus and the cingulate sulcus (see Fig. 1). The cingulate sulcus is consistently observed and typically remains unsegmented from its rostral extent to its termination at the marginal ramus in the parietal lobe across individuals. However, the precise morphology of the anterior cingulate cortex is extremely variable. In particular, a second paracingulate sulcus is observed to run parallel to the cingulate sulcus in many subjects, more frequently so in the left hemisphere than the right.

On the basis of cytoarchitecture and differential patterns of connectivity, the anterior cingulate cortex has been divided into ventral (Brodmann's areas 25 and 33), rostral (BA 24 and 32), and caudal (BA 24′ and 32′) regions. Area 24 has been further decomposed into a, b, and c subdivisions. Despite the variable morphology of cingulate cortex, there are some consistencies in the distribution of areas on the cortical surface. Thus, area 33 lies in the rostral bank of the callosal sulcus, with areas 25, 24a,b, and 24′a,b typically lying on the gyral surface and area 32 lying in the rostral part of the cingulate sulcus. Caudally, areas 24c and 24′c usually form the ventral bank of the cingulate sulcus, facing area 32′ on the dorsal bank. The paracingulate gyrus, when present, comprises areas 32 rostrally and 32′ caudally.

B. Cytoarchitecture

Brent Vogt and colleagues at Wake Forest University have characterized the cytoarchitectural divisions within the anterior cingulate cortex. In common with cortical motor areas, layer IV, the major input layer from sensory cortices, is absent from the anterior cingulate cortex proper (areas 33, 25, and 24). Because layer IV is also called the internal granular layer the anterior cingulate cortex is described as agranular.

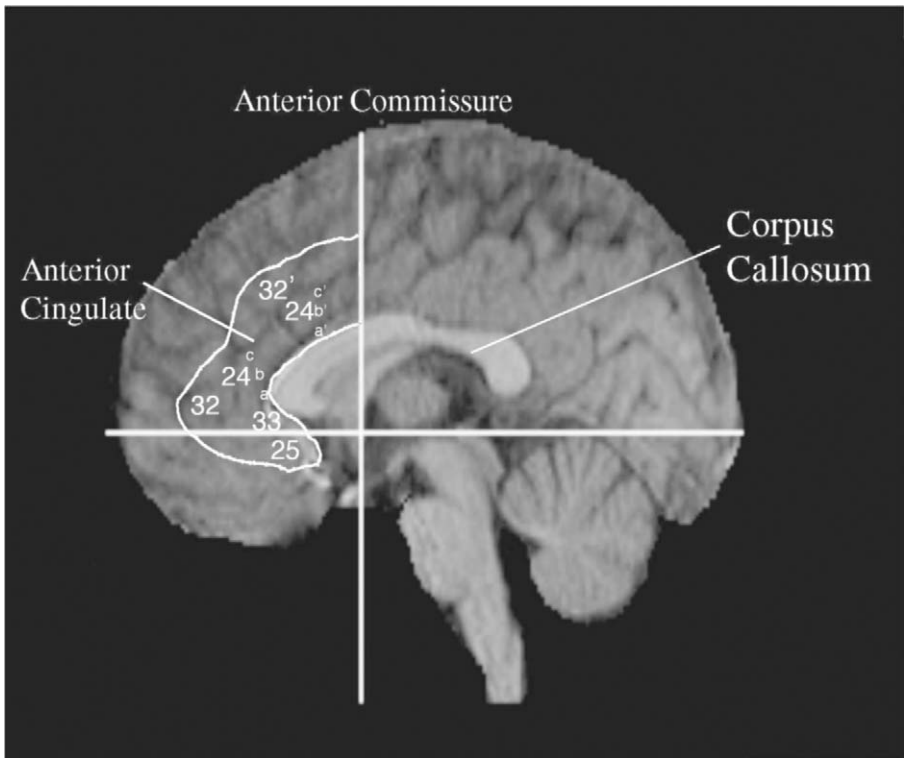

Figure 1 Anatomy of the anterior cingulate cortex.

In contrast, cingulocortical transition area 32 is characterized by a dysgranular layer IV that is attenuated in area 32′. Area 32 can also be distinguished from area 24 by the presence of large pyramidal neurons that form a layer IIIc. In area 32′, these pyramidal neurons are even larger.

Anterior cingulate cortex in general is characterized by a prominent layer V. Ventral areas 25 and 33 are poorly differentiated, although a laminar structure is apparent in a thin layer V and undifferentiated in layers II and III. Area 24 is characterized by a neuron-dense layer Va with prominent pyramidal cells and has a clear division between layers II and III. Area 24′ can be distinguished from rostral area 24 by its lower neuron density and thinner layer V. The a, b, and c subdivisions of areas 24 and 24′ are marked by generally increasing differentiation of cortex away from the corpus callosum. A further division in the most caudal sulcal region of the anterior cingulate cortex, area 24c′g, has been identified as containing gigantopyramidal neurons in layer Vb.

C. Connectivity

Investigations in nonhuman primates have shown the anterior cingulate cortex to be connected with a diverse range of cortical and subcortical areas. This brain region receives afferents from more thalamic nuclei than any other cortical region and also receives diffuse monoaminergic innervation of serotonin (5-HT), dopamine, and norepinephrine from the raphe nucleus, locus ceruleus, and ventral tegmental area, respectively. The overall pattern of connectivity reveals a broad distinction between autonomic functions and affect in ventral–rostral areas and between motor functions and cognition in more caudal areas of the anterior cingulate cortex.

1. Rostral–Ventral Regions

The ventral and rostral regions of the anterior cingulate cortex are closely connected with brain regions concerned with autonomic and visceromotor function. Ventral area 25 projects directly to the medulla, and areas 25, 24, and 32 may also influence autonomic function and affect via their reciprocal connections with the amygdala and insula, regions that project directly to the medulla. Ventral–rostral anterior cingulate cortex connects with other areas implicated in autonomic function—including the periaqueductal gray matter, orbitofrontal cortex, and nucleus accumbens of the ventral striatum—as well as having reciprocal connections with the hippocampus and parahippocampal regions and auditory areas of the superior temporal cortex.

2. Caudal Regions

a. Sulcus In contrast to the visceromotor involvement of ventral–rostral regions, caudal areas within the cingulate sulcus are associated with motor function. Peter Strick of the University Pittsburgh and colleagues have identified three separate cingulate motor areas that differ in cytoarchitecture and connectivity. Two of these regions lie just caudal to the anterior cingulate cortex as defined earlier and lie on the dorsal (CMAd) and ventral (CMAv) banks of the cingulate sulcus. A third, more rostral area (CMAr) is within area 24c.

The cingulate motor areas project directly to the spinal cord, together making up as much as 21% of the total frontal lobe projection. The motor involvement of cingulate cortex is further demonstrated by its projection to ventral motor nuclei of the thalamus and to the dorsal striatum (caudate nucleus and putamen). In addition, all cingulate motor areas have reciprocal, topographically organized connections with primary motor, premotor, and supplementary motor cortices. CMAd has the largest corticospinal neurons and sends the largest projection to the spinal cord and primary motor cortex. It receives input from the pallidum via the thalamus, as well as from parietal area 5. CMAv has smaller pyramidal neurons and receives input from thalamic regions innervated by the cerebellum, as well as from parietal areas 5 and 7, pre-SMA (area 6aβ), and prefrontal area 46. Finally, CMAr has the smallest projection to the spinal cord and primary motor cortex. It receives input from the pallidum (via a different thalamic relay than CMAd), parietal area 7, pre-SMA, and area 46. Thus, the anterior cingulate cortex is advantageously connected in such a way as to have a significant role in the control of actions.

b. Gyrus The connections of the anterior cingulate cortex are not limited to direct autonomic and motor functions. For example, area 24b receives input from the medial thalamic nuclei responsible for relaying nociceptive information from the spinal cord to the cortex. Nociceptive neurons in these nuclei have large, bilateral receptive fields. Area 24 projects, in turn, to the periaqueductal gray matter, both directly

and via the parafascicular nucleus of the thalamus. This pattern of connectivity, together with the high level of opiate receptor binding observed in cingulate cortex, implicates the anterior cingulate cortex in pain processing.

3. Intracingulate Connections

The combination of results from anterograde and retrograde labeling studies reveals strong interconnections within the ventral–rostral and caudal sulcal regions but very few projections between these regions. Thus, injection of a retrograde tracer in area 25 labels neurons in rostral area 24 and vice versa, but neither injection labels neurons in caudal gyral or sulcal areas. Similarly, small injections in the cingulate sulcus label many other neurons in this area, but very few in area 25 or rostral area 24. Reciprocal connections appear to exist between sulcal and gyral regions in caudal anterior cingulate cortex, but these gyral regions have a limited connection with rostral–ventral anterior cingulate cortex.

II. ANIMAL STUDIES

Studies of animal behavior begin to outline the roles of the anterior cingulate cortex in autonomic, affective, pain, and motor functions that were identified earlier with regard to the connectivity of this region.

A. Autonomic Function

Stimulation in area 24 has been shown to elicit almost every type of autonomic response—including changes in blood pressure, heart rate, respiratory rate, pupillary dilation, skin conductance, thermoregulation, and gastrointestinal motility—as well as causing changes in adrenal cortical hormone secretion (ACTH). Stimulation in the cingulate cortex can also lead to vocalizations. The evoked activity is usually linked to the role of the anterior cingulate cortex in visceromotor, as opposed to skeletomotor, function because the vocalizations are limited in number and have affective content.

Although lesions to the anterior cingulate cortex have little or no effect on baseline autonomic function, there is evidence that the anterior cingulate cortex is involved in autonomic conditioning (i.e., the development of autonomic responses to stimuli that are predictive of events, such as electric shocks, that evoke autonomic responses). Neurons in the anterior cingulate cortex show changes in activity as animals learn such contingencies, and lesions of the anterior cingulate cortex greatly reduce autonomic changes induced by the presentation of predictive stimuli. Lesions of the anterior cingulate cortex also change affective responses in more complex situations. Changes following ablation have been characterized in terms of blunted affect, reduced aggression, decreased motivation, and the disruption of mating and social behavior.

B. Skeletomotor Functions

Lesions in the anterior cingulate cortex can cause contralateral motor neglect. Stimulation of the CMAs evoke skeletomotor movements, although with lower probability and a higher stimulation threshold than the primary motor cortex. The evoked movements are typically fast, brief, limited to a single joint, and demonstrate a topographical organization. Complementary to these findings, single-unit recordings have shown that neuronal activity in the CMAs precedes voluntary movements. Neurons in CMAr are more activated during self-paced than stimulus-triggered movements and may precede the movement by long lead times (0.5–2 sec). In contrast, activity in the caudal CMAs shows less specificity to self-paced movements and is characterized by shorter lead times preceding the movement. Findings have linked CMA activity, particularly in CMAr neurons, to reward-based response selection tasks. Different CMA neural populations are active during the learning of new reward contingencies and during the execution of familiar, well-learned responses.

C. Pain

Neurons in area 24b of the rabbit anterior cingulate cortex are activated in response to painful stimuli. Like the nociceptive neurons in the medial thalamic nucleus that innervate the anterior cingulate cortex, area 24b neurons have large receptive fields that are often bilateral. The neurons are specific to nociceptive information, i.e., they are not activated by nonpainful somatosensory stimulation, and they show some specificity to the nature of the painful stimulus. These neurons are also activated during the learning of responses that lead to the avoidance of painful stimuli.

Lesions in the anterior cingulate cortex retard such learning and have been shown to reduce pain sensitivity in monkeys.

D. Learning

Apparent in the preceding discussion is the role of the anterior cingulate cortex in learning novel behaviors, whether as a conditioned response to predictors of painful stimuli, as an instrumental response to avoid such stimuli, or in response to reduced reward. Of interest in this context is the dopamine projection to cingulate cortex from the ventral tegmental area. The ventral tegmental dopamine system is known to be involved in processing rewarding or salient stimuli: Neurons in this area increase firing in response to unpredicted rewards and reduce firing if an expected reward is withheld. Consistent with the notion that dopamine is involved in adaptive behavior in the anterior cingulate cortex, this region, in common with other dopamine-innervated regions, supports self-stimulation. The properties of cortical self-stimulation differ, however, from those of medial forebrain structures—e.g., having longer acquisition times and lower sensitivity to amphetamine modulation—which may question a simple relationship between reinforcement learning in these systems.

III. NEUROIMAGING STUDIES

A small number of studies have used invasive techniques to study anterior cingulate function in humans, recording from or stimulating cingulate neurons during neurosurgery. Stimulation in ventral–rostral areas has been found to evoke autonomic changes in blood pressure and heart rate, visceromotor responses including salivation and vomiting, emotional responses including fear, agitation, and euphoria, and vocalizations with affective content. Anterior cingulate stimulation has also been shown to evoke motor responses of the face, hands, and legs, evidence, perhaps, of areas in the human brain corresponding to the CMAs seen in nonhuman primate anterior cingulate cortex. Recordings in caudal regions have revealed neurons with activity that is modulated during attention-demanding tasks such as arithmetic and generating lists of words. Other neurons, in further caudal and inferior regions, show sensitivity to painful stimuli. Overall, the findings are consistent with those reported in the previous section. However, these invasive studies are necessarily infrequent, and their interpretation is complicated by the neuropsychological condition of the patients involved that necessitated the surgery. Therefore, the preceding findings notwithstanding, much of the current understanding of anterior cingulate function has stemmed from more noninvasive imaging methods that can be applied in neurologically intact subjects.

Most neuroimaging studies of anterior cingulate function have used positron emission tomography (PET) or functional magnetic resonance imaging (fMRI). Both techniques rely on a subtractive methodology, comparing activation in brain areas across different experimental conditions that are designed to isolate specific processes. Such comparisons reveal areas of activation—areas more activated in the experimental than in the control condition—and, less commonly, areas of deactivation. These methodologies have very good spatial resolution on the order of millimeters, but relatively poor temporal resolution on the order of seconds to minutes. Electrophysiological recordings, on the other hand, have poor spatial resolution, but excellent temporal resolution on the order of milliseconds. Findings based on either PET, fMRI, or electrophysiological recordings regarding the role of the anterior cingulate cortex in human behavior are described later by relative region. For the most part, rostral and ventral regions have been linked with affective behavior, and more dorsal and caudal regions have been linked to cognitively driven actions. A major debate regarding the function of this region has resided in the domain of cognition primarily.

A. Affect

Activation in the rostral–ventral anterior cingulate cortex has been observed in normal subjects under a variety of conditions, including (1) when asked to recall sad memories and to view faces with sad expressions compared with recalling neutral memories and viewing neutral faces; (2) when anticipating an upcoming painful electric shock compared with resting activation; and (3) when exposed to scenes or words with emotional content compared with scenes and words with neutral content. Corresponding activations are observed in symptom provocation studies involving phobic, anxious, and obsessive–compulsive patients. These tasks have been characterized as having affective, emotional content, and therefore it is unsurprising that activations in the amygdala and orbitofrontal cortex are commonly observed to

co-occur with those in the anterior cingulate cortex. Often these paradigms require the subject to induce an affective state or think of emotional information that is contrary to the subject's current affective state. Moreover, some of these paradigms require the subject to attend to nonaffective attributes such as the color of an emotionally salient word (e.g., "Murder") rather than the word itself. Performance on such tasks is worst when the stimuli have emotional content versus neutral content and the rostral–ventral anterior cingulate cortex is activated

Deactivation in the rostral–ventral anterior cingulate cortex—often accompanied by deactivation in orbitofrontal and amygdala regions—has been observed in many of the attention-demanding tasks found to activate caudal regions of the anterior cingulate cortex. For example, Wayne Drevets of the National Institute of Mental Health and Marchus Raichle of Washington University have shown decreased activity in the ventral anterior cingulate cortex, amygdala, and orbitofrontal cortex—all areas implicated in emotional processing—during the performance of demanding cognitive tasks. Conversely, they have shown decreases in dorsal anterior cingulate cortex and dorsolateral prefrontal cortex activity—areas implicated in cognitive processing—during emotion-related tasks.

B. Cognition

Caudal anterior cingulate cortex has been found to be activated in a wide range of cognitive tasks. On the basis of their review of 29 PET studies, Peter Strick and colleagues drew a broad distinction between the most caudal area of the anterior cingulate cortex, area 24c′g, lying on and just posterior to the line of the anterior commissure and more anterior regions (areas 24′ and 32′). The former region is commonly activated during simple and/or familiar movements (typically in comparison with resting conditions involving no movements), movements that are associated with activity in the SMA but not lateral prefrontal areas. By contrast, areas 24′ and 32′ tend to be activated during the execution of more complex response selection tasks alongside activations in the pre-SMA and lateral prefrontal areas. On these grounds, Picard and Strick identified the caudal cingulate zone with CMAd observed in primates and tentatively correlated CMAr and CMAv with the anterior and posterior sectors, respectively, of the more rostral region activated by complex tasks.

A variety of complex tasks have been found to be associated with cingulate activity. Tasks that require subjects to respond to one stimulus in the presence of distracting, irrelevant information reliably result in such activation. For example, during Stroop task performance, the anterior cingulate cortex is more activated when subjects are required to name the ink color of a nonmatching color word (e.g. "Blue" written in red ink) than when naming the ink color of a stimulus that is not a color word. The anterior cingulate cortex is also activated when subjects are required to withhold responding in the context of speeded response tasks (e.g., no go and stop signal trials as compared with go trials) and when subjects must saccade away from rather than toward a target stimulus. Activity in corresponding regions is observed during the learning of new motor sequences or new noun–verb associations (compared with activity during the performance of familiar sequences or associations), following a switch to a new task (compared with repeated task performance), during free recall of remembered lists (compared to rest), when generating words that start with certain letters (compared to rest or repeating words seen or heard), and when required to make a decision based on degraded information (compared with undegraded information). As mentioned earlier, the performance of many of the tasks that activate the caudal anterior cingulate cortex is associated with corresponding deactivations in the rostral anterior cingulate cortex. Similarly, deactivations in the caudal anterior cingulate cortex have been observed during the performance of some of the tasks with affective content described earlier.

Attempts have been made to characterize the kinds of tasks that activate caudal anterior cingulate cortex to infer the function of this region. In general, the activating tasks have been categorized as difficult or complex or as eliciting multiple competing responses. Following from these observations, caudal anterior cingulate cortex has been variously attributed a role in attention or executive processes, in the decision process to select or initiate a response to "funnel" to motor areas, and in the monitoring of ongoing performance.

Whereas there is potentially significant overlap in these differing theories—e.g., performance monitoring can be considered as an important executive function in regulating response selection—there is evidence that the anterior cingulate cortex plays a direct role in performance monitoring. First, scalp electrophysiological recordings reveal a negative deflection in the event-related potential following

incorrect responses during choice reaction time tasks, a finding reported independently by Falkenstein and colleagues in Dortmund and by Gehring and coworkers in Illinois. This error-related negativity (ERN or Ne) begins around the time of the response and peaks roughly 100 msec after (see Fig. 2). The ERN has a midline frontocentral distribution on the scalp, and the anterior cingulate cortex is consistently found to be its most likely neural generator. The amplitude of the ERN wave varies as a function of the force with which the error is produced and the probability that the error is corrected, suggesting that the ERN relates somehow to error processing. Crucially, the observation of an ERN following performance feedback and following failures to withhold a response when required—errors that cannot be corrected—suggests that the ERN, a presumed electrophysiological index of anterior cingulate function, is related to performance monitoring rather than to the process of response selection itself.

Caudal anterior cingulate cortex is not uniquely activated following errors, as fMRI studies have shown this region to be activated even on correct trials. When subjects respond correctly, moreover, the activation observed is larger when there is response conflict—e.g., when distractor information presented is associated with a different response than target information—leading to the suggestion that the anterior cingulate cortex monitors for conflict rather than errors per se. Studies of response conflict provide a second line of evidence for the role of the anterior cingulate cortex in performance monitoring. For example, in a given task condition, if attention is effectively engaged to filter out irrelevant information, conflict will be low. In contrast, if attention is low, conflict will be high. When within-condition contrasts are made for subsets of trials with high attention–low conflict and subsets with low attention–high conflict, the anterior cingulate cortex activation is found to

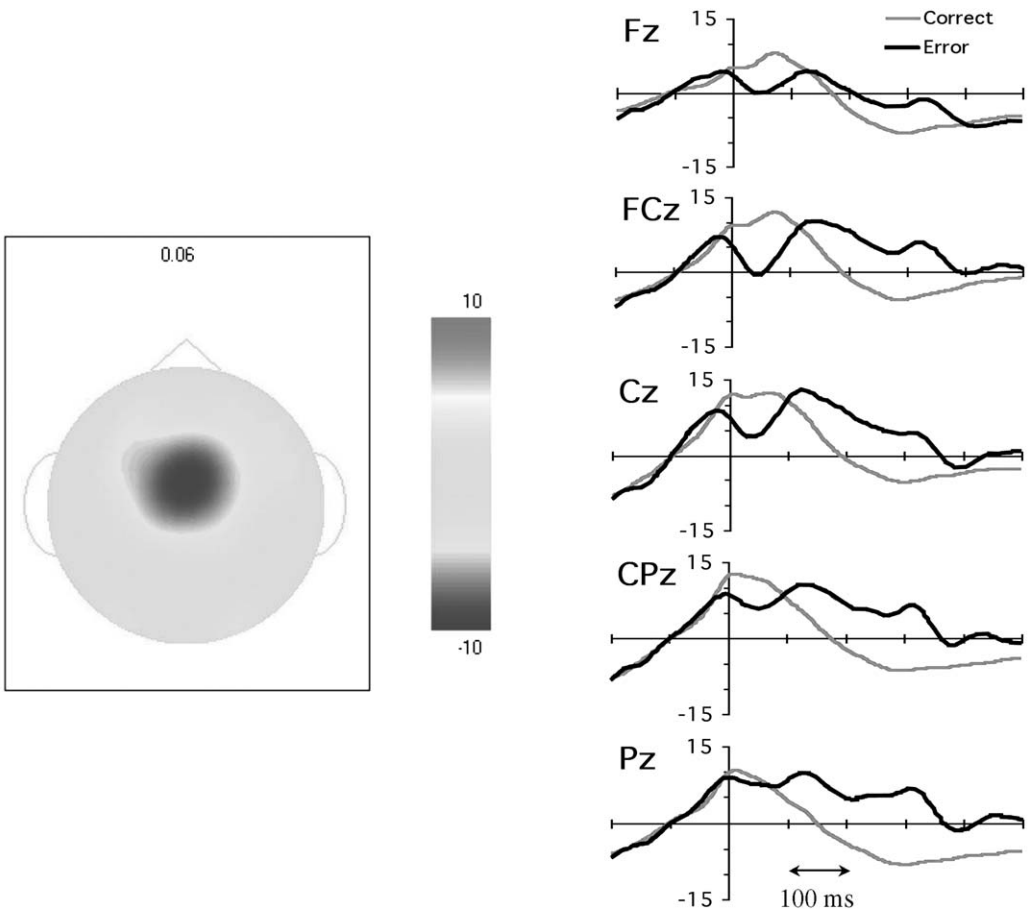

Figure 2 Scalp distribution and electrical tracing of the error-related negativity (ERN).

follow the degree of conflict rather than the level of attention, consistent with the monitoring hypothesis.

C. Pain

Comparisons of activations associated with painful versus nonpainful stimulation commonly reveal foci within posterior portions of the anterior cingulate cortex, in regions caudal and inferior to those observed in complex cognitive tasks. The anterior cingulate cortex is typically thought to be involved in processing the affective or motivational significance of painful stimuli. For example, the anterior cingulate cortex can be selectively activated by an illusion of pain (the "thermal grill," in which spatially interleaved warm and cool bars produce the illusion of noxious cold), compared with activations associated with either warm or cool components in isolation. This result suggests the involvement of the anterior cingulate cortex in subjective pain rather than the sensory coding of intensity. Consistent with this hypothesis is the finding that hypnotic suggestion to selectively manipulate ratings of pain unpleasantness while keeping perceived intensity constant positively correlated with activation in a caudal gyral region of the anterior cingulate cortex.

Studies of pain processing have, on occasion, revealed activation in rostral–ventral anterior cingulate cortex and in the caudal region usually activated during complex cognitive tasks. The former finding may reflect an affective or autonomic response to pain or the anticipation of pain. The latter finding may reflect cognitive processing of pain: such activations are observed, for example, when subjects are required to pay attention to the painful stimuli in order to keep count of the number of changes in stimulus intensity. Alternatively, the activity observed in the anterior cingulate cortex in response to pain may be associated with the representation of competing actions to make in response to the painful stimulus, such as avoidance versus tolerance of pain.

IV. CLINICAL STUDIES

The anterior cingulate cortex—not surprisingly given its involvement in cognitive and affective processes—has been implicated in a number of psychiatric disorders. This region has been shown to play a role in a number of human syndromes and disorders, providing neuropsychological evidence for its function in complex behaviors.

A. Epilepsy

Perhaps the clearest example of support for the role of the anterior cingulate cortex in movement, affect, and social behaviors is that of cingulate epilepsy syndrome described by Brent Vogt and others. Excessive activity in cases with seizures confirmed in the anterior cingulate cortex may impair consciousness and alter affective state and expression. Patients with such seizures may also display psychopathic or sociopathic behaviors.

B. Psychiatric Disorders

A number of psychiatric disorders have been linked with abnormalities in the function of the anterior cingulate cortex. Activity is elevated in this region in obsessive–compulsive disorder, tic disorder, and depression, and normalization of activity in this region occurs with behavioral and pharmacological treatment of these disorders in some cases. With severe forms of these disorders, such as with obsessive–compulsive disorder, cingulotomies have been shown to be effective in relieving the symptoms.

Other psychiatric disorders that have been associated with abnormal functioning of the anterior cingulate cortex include attention deficit hyperactivity disorder (ADHD) and schizophrenia. These patients show reduced activity in portions of the anterior cingulate cortex, particularly in caudal regions. Both attention deficit hyperactivity disorder and schizophrenia have been linked with poor dopaminergic modulation of prefrontal circuitry. Given the strong dopaminergic projections to the anterior cingulate cortex, these findings are consistent with a disruption in the modulation of anterior cingulate activity. Finally, individuals with psychopathic or sociopathic behaviors show less activity in the anterior cingulate cortex following errors in performance than do individuals without these characteristics, as evidenced in the ERN literature. This finding is consistent with the cingulate epilepsy literature mentioned previously.

C. Cingulotomies

Surgical removal of or infarcts to the anterior cingulate cortex provide further evidence for its role in

responsiveness to pain, movement (e.g., akinetic mutism), regulation of autonomic activity, and internal emotional responses, consistent with evidence from animal and imaging studies. Clearly, whether the lesion is more caudal or rostral affects the behaviors observed. Surgical removal of this region has been shown to diminish symptoms associated with severe cases of obsessive–compulsive disorder as described earlier and in cases of chronic and severe pain. One hypothesis for the involvement of anterior cingulate cortex in pain or obsessions is associated with attention to the pain or obsession; however, this interpretation has been called into question specifically with regard to pain.

V. DEVELOPMENT

The anterior cingulate cortex, like other prefrontal regions, undergoes a prolonged developmental process relative to sensorimotor regions. Pasko Rakic, Jean-Pierre Bourgeois, and others at Yale University have shown that, even though neurogenesis is completed in the anterior cingulate cortex (area 24) before the visual cortex, synaptogenesis occurs later. Synaptic density in area 24 then remains at a high level until sexual maturity. Speculations relating the development of this brain region to behavior have been proposed by Michael Posner and Mary Rothbart of the University of Oregon on the basis of behavioral data from infants and children on tasks thought to require the anterior cingulate cortex. B. J. Casey at the Sackler Institute in New York and colleagues have used MRI-based morphometric studies of this region to relate its size and symmetry to behavioral development. More recently, Casey has used functional MRI studies for this purpose.

A. Behavioral Studies

Behavioral studies suggesting development of the anterior cingulate cortex use behavioral tasks shown to activate this region in imaging studies with adults using Strooplike or go–no go tasks. The assumption is that, if a child can perform the task, then the anterior cingulate must be mature enough to support the behavior. Accordingly, one may track the development of behavioral performance on these tasks across ages to determine the degree of development of the brain structure. A substantial increase in the ability to perform these Stroop-like tasks occurs across the ages of 2–5 years. This evidence is inferential and not conclusive of a specific structure–function relation between the development of the behavior and the anterior cingulate cortex. Clearly, maturation of this region alone is not occurring in isolation of other brain systems' maturation.

B. MRI-Based Morphometry

MRI-based morphometric measures show a correlation between size of the right anterior cingulate region and performance on an attention switching task in 6- to 18-year-olds (see Fig. 3). The larger the anterior cingulate region, the faster the performance on the attention switching task that required the subject to switch from attending to color to attending to shape, alternating from trial to trial. This region did not correlate with a simple nonswitching attentional task, suggesting its involvement in tasks that have attentional conflict or require cognitive control. Even after correcting for total brain size and estimated IQ, the correlation remained significant, suggesting that the association was not a general one but specific to this brain region. Yet this association is indirect in that the two measures are assessed at different time points.

C. Functional Neuroimaging Studies

Perhaps the most direct evidence of development of the anterior cingulate cortex and behavioral regulation comes from an fMRI study of children between the ages of 7 and 11 years and young adults. In that study, Casey showed an increase in MR signal intensity in the anterior cingulate cortex as a function of increased number of errors on a go–no go task (Fig. 4). This task required the subject to override a compelling response. Those individuals experiencing the most difficulty with this task showed increased activity in this region. However, in this study, only regions of the prefrontal cortex were examined; thus, again the question may be raised as to how specific this region is to behavioral regulation in children. Other regions including portions of the basal ganglia and projections to and from these regions may be likely candidates. Interestingly, this study demonstrated a dissociation of prefrontal regions from anterior cingulate cortex function, with ventral prefrontal regions correlating with accuracy and the anterior cingulate regions correlating with errors. Thus, whereas the anterior cingulate may index errors or response conflict, the

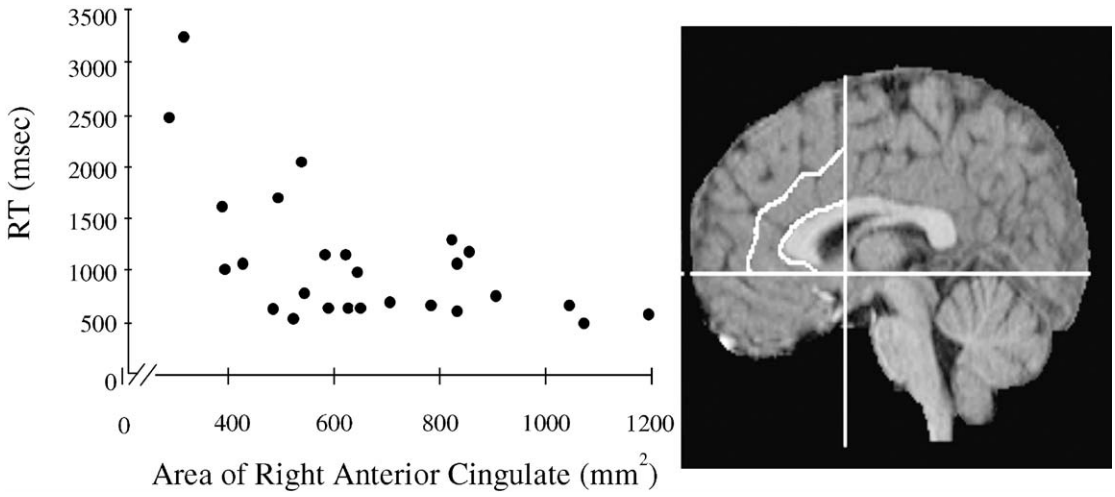

Figure 3 Reaction times during performance of an attention shifting task in children between the ages of 6 and 18 years as a function of the size of the anterior cingulate cortex.

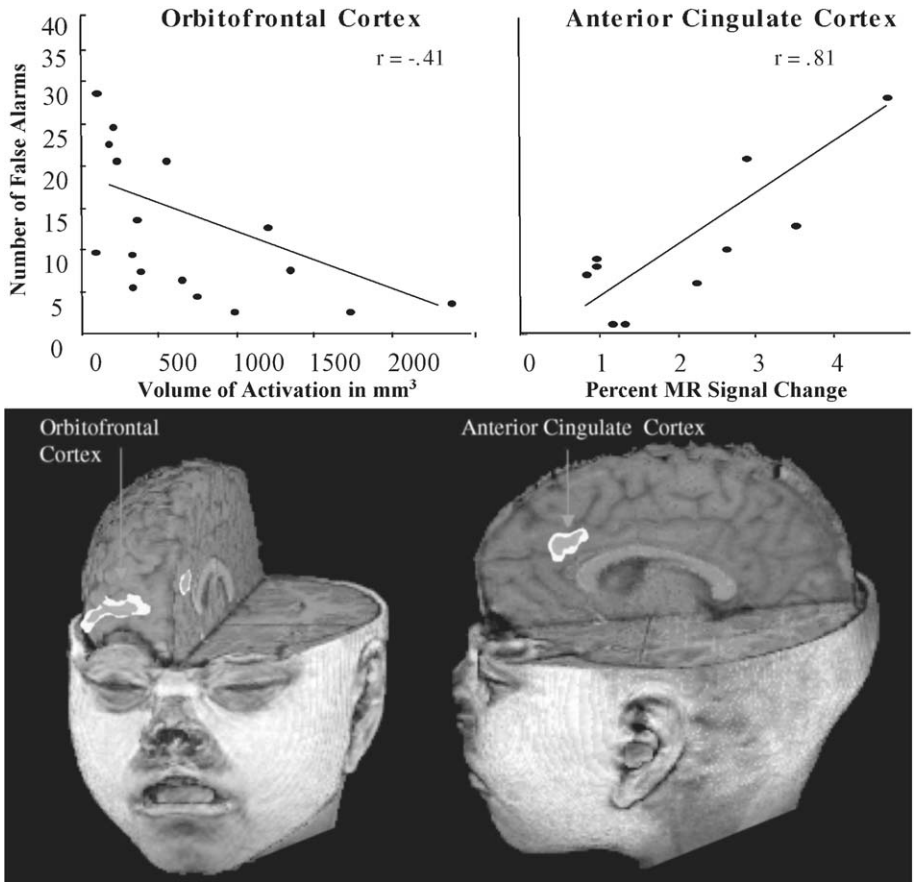

Figure 4 Location, volume, and percent change in MR signal intensity as a function of the number of errors for the ventral prefrontal and anterior cingulate cortices.

ventral prefrontal region indexed the degree of conflict resolution on this task. A similar dissociation has been shown in dorsolateral prefrontal cortex and anterior cingulate cortex on a version of a Stroop task more recently by MacDonald and Carter at the University of Pittsburgh.

VI. GENETICS AND EVOLUTION

As described, the anterior cingulate cortex has been implicated in a number of psychiatric disorders. Interestingly, all of these disorders show familial patterns of inheritance, increased risk among first degree relatives of affected patients, and increased concordance in identical vs fraternal twins. The *heritability* (see Glossary) has been estimated for schizophrenia (0.6), attention deficit hyperactivity disorder (0.79), obsessive–compulsive disorder (0.68), and major depression disorder (0.6). Estimates of heritability have been extended to specific cognitive functions in normal populations as well. Tasks that activate the anterior cingulate cortex, such as spatial working memory, divided attention, and attentional set shifting, have been examined in identical and fraternal twin populations and have high heritabilities. These findings suggest that genetic factors play a role in behaviors associated with anterior cingulate abnormalities and normal anterior cingulate function. These genes may be important for the establishment of proper connectivity during pre- and postnatal development and/or for proper physiological homeostasis under stressful or injurious conditions. Of the approximately 35,000 *genes* (see Glossary) in the human genome, it remains a challenge to identify the genes of critical importance.

A. Candidate Genes

Several candidate genes have already emerged. Gene expression studies in mice and humans have identified many genes whose expression is enriched in the anterior cingulate cortex. For example, the *neurotrophin-3* (*NT3*) gene, a molecule involved in the growth and survival of developing neurons, shows enriched expression in the anterior cingulate cortex during development. Support for the role of *NT3* in anterior cingulate development and function comes from the results of a *gene association study* (see Glossary) showing that variation in the *NT3* gene was associated with schizophrenia. Similarly, the *neurotensin* (*NTS*) gene shows enriched expression in the cingulate cortex at birth. Gene association studies on the promoter of the *neurotensin receptor* (*NTSR1*) have also shown associations with schizophrenia. Other genes whose expression is enriched in the developing cingulate cortex include *Emx2* and *ER-81*. Mutations in the *Emx2* gene have been shown to cause schizencephalies, but it remains to be seen whether less severe genetic variations give rise to subtle cognitive impairments. The *fragile-X mental retardation* gene (*FMR2*) is also enriched in limbic cortex and is associated with mild mental retardation.

B. Dopamine-Related Genes

The expression of the *dopamine D4 receptor* (*DRD4*) gene in the anterior cingulate cortex is of particular interest. As reviewed by Williams and Rakic from Yale University, the anterior cingulate cortex contains high levels of DA innervation in layers II–VI. Dopaminergic axonal fibers arising from the VTA form axon–axononal connections and allow large regions of this cortical area to be globally regulated. The cingulate cortex contains interneuron populations expressing *dopamine D2 receptor* (*DRD2*) and *DRD4* receptors and pyramidal neurons expressing *dopamine D1 receptor* (*DRD1*) receptors. Whereas most DA receptors are expressed widely throughout the brain, *DRD4* shows its highest levels of expression in the frontal and cingulate areas. Interestingly, a polymorphism in the cytoplasmic loop of the *DRD4* gene has been associated with attention deficit hyperactivity disorder. Similarly, a specific polymorphism of the *dopamine D3 receptor* (*DRD3*) and *DRD2* genes was associated with schizophrenia, as were the *dopamine β-hydroxylase* (*DBH*) and *catechol-O-methyl transferase* (*COMT*) genes. Figure 5 illustrates the various alleles (see Glossary) of the *DRD4* gene in normal volunteers based on DNA samples from cheek cells. Basic genotyping studies of this format no doubt will increase given the publication of the human genome in *Science* and *Nature*.

Gene expression studies have also shown that the anterior cingulate cortex is highly sensitive to environmental stress. Anoxia, maternal separation, amyloid protein expression, and drug abuse all induce hypometabolism, gliosis, and programmed cell death in the anterior cingulate cortex. Exposure to stress induces the expression of *glucocorticoid receptor* (*GR*), a transcription factor that mediates the cellular response to stress as shown by Bruce McEwen of Rockefeller University. Stress-induced excitatoxic damage has

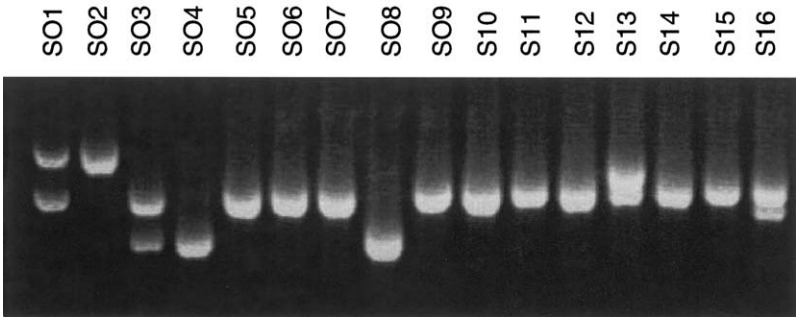

Figure 5 Genotyping of the *DRD4* gene in 16 healthy adults using DNA samples from cheek cells.

been noted in the anterior cingulate cortex in schizophrenia. Specifically, Francis Benes of Harvard Medical School has shown that dopaminergic innervation of interneurons in layers II and V is increased in post mortem analyses of schizophrenia. Under normal conditions, the synaptic contacts on local interneurons that utilize *DRD2* receptors result in inhibition of cell activity. The hyperinnervation of interneuronal *DRD2* contacts is suspected to disable local inhibition of pyramidal cells and lead to excess glutamatergic signaling and excitotoxicity in downstream brain areas. Because this type of excitotoxic damage is mediated by the *GR* gene, it is likely that genetic variation in this gene and/or its downstream targets explains the phenomenon of a gene × environment interaction seen in many psychiatric disorders.

C. Evolution

Knowledge of how genetic factors modulate cingulate development and function may shed light on the unique evolutionary history of this area in humans. The anterior cingulate arises from the medial (limbic) and medial–dorsal telencephalic pallium. These cortical regions show remarkable evolutionary conservation among mammals, birds, and reptiles in contrast to dorsal telencephalic pallium or neocortex, which is highly divergent in volume and microstructure. For these reasons, the cingulate gyrus is often referred to as a phylogenetically "ancient" structure. Whereas this appears to be true in the case of most mammals, analyses of cingulate cortical microstructure in humans show a remarkable leap of recent evolution. Betz, in 1881, first noted the presence of large motor neurons in the cingulate region of humans but not in other great ape species. Similarly, Patrick Hof and John Allman have found spindle cells, so named for their elongate and gradually tapering morphology, predominantly in layer Vb in the medial wall of the cingulate gyrus. These cells are not seen in old world primates but are found in bonobos, chimpanzees, and humans. Phylogenetic studies comparing human and primate genomic sequence data have attempted to explain this recent evolutionary leap. Studies of the role of the *DRD4* gene in human evolution and migration show a high correlation (0.8) between the frequency of the exon III seven-repeat allele and miles of migration. Migration was estimated for ethnic groups around the world as the human population expanded out of Africa. The *DRD4* gene has undergone strong positive selection during primate evolution. Additional studies of genes that contribute to the development and physiology of the cingulate gyrus may shed light on the evolution of this important brain area. Most importantly, many of these genes may serve as useful molecular targets for pharmacologic intervention for the treatment of psychiatric disorders.

VII. CONCLUSIONS

In sum, the anterior cingulate cortex appears to play an important role in autonomic, affective, and cognitive behavior. The precise nature of its role is still uncertain and a number of questions remain unanswered. For example, is the anterior cingulate cortex organized by function or by domain? In other words, do different regions of the anterior cingulate cortex function according to different rules or mechanisms, or is there a common underlying function that applies to all domains of behavior including the domains of sensation (e.g., pain), affect, and cognition? The anterior cingulate cortex appears both anatomically and functionally well-situated to integrate information across these domains. Paus and others have demonstrated somatotopic organization of the cingulate cortex and suggest that this region modulates and funnels cognitive and motor

commands to the motor system. One could interpret this view as the cingulate having a specific function that only differs across regions in terms of the type of information guiding the action. Although Paus' work was specific to motor and cognitive commands, it may be plausible to modify this theory to accommodate the domain of emotion and emotionally guided actions (e.g., to avoid or approach an aversive or appetitive stimulus). A potential caveat in this line of thinking is the inverse relation frequently observed between the affective and cognitive portions of the anterior cingulate gyrus in imaging studies.

Clearly, the anterior cingulate cortex plays an important role in attention and behavioral regulation, and Posner and colleagues have been at the forefront of such speculations. However, the question remains in the cognitive literature as to whether the anterior cingulate's primary function is one of executive control, whereby the cingulate functions as a controller to resolve conflict, or one of detection, whereby the anterior cingulate monitors for errors or conflict. A number of groups have begun to dissociate these functions in adult and developmental neuroimaging studies that attribute conflict detection to the anterior cingulate cortex and conflict resolution to other regions like the prefrontal cortex. Either way, the structure is critical for guiding complex cognitive actions. Its specific role in behavior will be further specified with the refinement of biologically plausible computational models that will help constrain interpretations of the electrophysiological and imaging data. Recently, Matthew Botvinick of the University of Pittsburgh has developed such a model, which seems to clarify the role of the anterior cingulate cortex in cognitive conflict and dissociates conflict from cognitive control. How well this model of anterior cingulate function will hold up within the domains of sensation and affect remains unanswered. However, it is the case that paradigms of affective processing often require the subject to induce an affective state or think of emotional information that is contrary to or in conflict with the subject's current affective state. Moreover, affective paradigms have conflicting responses built in as with the emotional Stroop task, which requires the subject to name the color of the emotionally salient word "Murder" when reading the word is the more compelling response. Likewise, in the case of pain research, one can imagine the inherent response conflict associated with the competing representations to avoid vs tolerate a painful stimulus. Each of these examples provides a plausible role of the anterior cingulate in monitoring unresolved conflict across the domains of emotion and pain. Clearly, exciting work and theory development on anterior cingulate function will continue with the advancements of noninvasive neuroimaging and genetic methodologies in combination with computational and animal models.

Anxiety

ERIC VERMETTEN, DENNIS S. CHARNEY, and J. DOUGLAS BREMNER
Yale University

GLOSSARY

amygdala Almond-shaped collection of three nuclei in the anterior portion of the temporal lobe, central portion of the 'limbic' system, also called the 'emotional brain'.

anxiety The apprehensive anticipation of future danger or misfortune accompanied by a feeling of dysphoria or somatic symptoms of tension, when there is no true threat.

fear Feelings of anxiety associated with real external threat.

hippocampus A brain structure consisting of grey matter, receiving highly processed sensory information from the cerebral cortex, playing an important role in learning and memory.

locus coeruleus Dark blue-pigmented cell structure containing norepinephrine in the brain stem above the fourth ventricle projecting to all parts of the CNS, also called the 'alarm bell' of the brain.

panic disorder Disorder characterized by one or more episodes of abrupt, intense anxiety, i.e., a panic attack and persistent apprehension about the recurrence of these episodes.

phobic disorder Disorder of long lasting and persistent anxiety for a thing or situation that compels one to avoid the feared stimulus.

posttraumatic stress disorder Disorder of persistent re-experiencing of a traumatic event in dreams and memories; persistent avoidance of stimuli associated with the event, and increased arousal. The disorder occurs after exposure to a traumatic event that coincided with intense fear, helplessness or horror.

For more than a century scientists have wondered about the basis of fear and anxiety in the brain; however, only recently have clinicians developed neuroanatomical hypotheses to explain specific anxiety disorders. Although anxiety disorders affect a large portion of the population, relatively little is known about the neurobiological correlates of fear, anxiety, and anxiety disorders. Despite the lack of direct neurobiological data regarding anxiety disorders, tremendous advances have been made in understanding the neurobiology of stress and the response to threat. The neurobiology of stress and fear responsivity can give important clues to the neurobiological underpinnings of anxiety. Whether fear is due to an actual external threat (e.g., to be killed) or internal threat (e.g., hypoxia), a neutral but mislabeled cue now categorized as threat related, or an imagined threat, the brain responds in a similar fashion. Researchers in the clinical neuroscience of anxiety disorders have applied animal models of stress to humans with anxiety disorders, testing hypotheses derived from animal studies in human subjects with anxiety disorders. Based on these studies a working model for a neural circuitry of anxiety and fear can be described. This article reviews neural correlates of fear and anxiety and the clinical neuroscience of human anxiety disorders. Connections will be made between neurobiology, functional neuroanatomy, and the clinical presentation of patients with anxiety disorders. This work is

ongoing and many of the models proposed may be subject to modification and revision as our knowledge base in this exciting area continues to expand.

I. THE EXPRESSION OF FEAR AND ANXIETY

Emotion is composed of several elements, including affective valence and arousal. Fear, like anger, is a protective emotion. It is a feeling of agitation and anxiety caused by the presence or imminence of danger and refers to a state or condition marked by this feeling. Fear has evolved as a vitally important physiological response to dangerous situations that prepares one to evade or confront a threat in the environment. Fear has played a critical role in survival, and therefore efficient fear responses have been selected through evolution.

Anxiety is the subjective sensation that accompanies the body's response to threat that is similar to the fear reaction but in which there is no real threat. Panic is the sudden onset of an overpowering feeling of fear or discomfort that occurs suddenly, and it is associated with increased heart rate, sweating, trembling, shortness of breath, feeling of choking, nausea, dizziness, derealization, fear of losing control and fear of dying, numbness, and chills. For some individuals, the frequency, duration, intensity, or context of anxiety are extreme and can interfere with normal development and functioning.

Anxiety differs from fear in that the fear-producing stimulus is either not present or not immediately threatening, but in anticipation of danger the same arousal, vigilance, physiologic preparedness, negative effects, and cognitions occur. Different types of internal or external factors or triggers act to produce the anxiety symptoms of panic disorder (PD), agoraphobia, posttraumatic stress disorder (PTSD), specific phobias, generalized anxiety disorder (GAD), and the prominent anxiety that commonly occurs in major depression.

As one of the most readily accessible and perhaps easily understood of the major symptoms of mental disorders, anxiety may often take the concrete form of intense fear that is experienced in response to immediately threatening experiences, such as being involved in a near deadly car accident or witnessing a violent bank robbery. Experiences like this are typically accompanied by strong emotional responses as well as physical symptoms, such as rapid heartbeat, increased perspiration, cold hands or feet, hot flushes, sensations of shortness of breath, lightheadedness, trembling, restlessness, muscle tention, feelings of fear or dread, of increased gastrointestinal motility, and urge to urinate. Psychiatrists consider anxiety as an excessive alarm response system when there is no real threat—a pathological expression of fear responses.

The appropriate regulation of fear is critical to the survival of virtually every higher organism in every environment. However, the mechanisms that regulate fear may break down in a wide variety of circumstances, leading to excessive or inappropriate expression of anxiety. Specific examples include phobias, panic attacks, and generalized anxiety. In phobias, high-level anxiety is aroused by specific situations or objects that may range from concrete entities such as snakes to complex circumstances such as social interactions or public speaking. Panic attacks are brief and very intense episodes of anxiety that often occur without a precipitating event or stimulus. Generalized anxiety represents a more diffuse and nonspecific kind of anxiety that is most often experienced as excessive worrying, restlessness, and tension occurring with a chronic and sustained pattern. In each case, an anxiety disorder may be said to exist if the anxiety experienced is disproportionate to the circumstance, is difficult for the individual to control, and interferes with normal functioning. In obsessive–compulsive disorder (OCD), individuals experience a high level of anxiety that drives their obsessional thinking or compulsive behaviors. When such an individual fails to carry out a repetitive or ritualistic behavior such as hand washing or checking, there is an experience of severe anxiety. Thus, although the outward manifestations of OCD may seem to be related to other anxiety disorders, there appears to be a strong component of abnormal regulation of anxiety underlying this disorder. Since OCD is in many ways distinct from the other anxiety disorders, it is not addressed in detail in this article. PTSD can occur after an individual has responded with intense fear, helplessness, or horror after having been exposed to a traumatic event that involved actual or threatened death or serious injury or a threat to the physical integrity of oneself or others. The characteristic symptoms that result from such a traumatic event include the persistent reexperience of the event in dreams and memories, persistent avoidance of stimuli associated with the event, and increased arousal.

The clinical acceptance of the heterogeneity of anxiety disorders suggests that there are distinct neurobiological substrates for each. This seems to be most true for PD and PTSD, and clinicians have developed neuroanatomical hypotheses that are related to these specific anxiety disorders.

II. PREVALENCE OF ANXIETY DISORDERS

The American Psychiatric Association first recognized anxiety disorders in 1980 as a separate group of psychiatric disorders. The concept of neurosis (neurasthenic neurosis, anxiety neurosis, phobic neurosis, and obsessive–compulsive neurosis) in previous classifications was abandoned because it was considered too vague. Anxiety disorders now include PD, PTSD, social phobia, specific phobia, OCD, and GAD. Anxiety disorders are by far the most common of psychiatric disorders (25%), followed by affective disorders (17%).

In the past decade, large epidemiological studies have provided information about the prevalence of anxiety disorders in the general population. A landmark epidemiological study in the United States in 1994 found lifetime prevalence rates for all anxiety disorders combined to be 19.2% for men and 30.5% for women. Phobic disorders are the most common diagnosis in broad-based assessments of psychiatric disorders in the community (affecting about 13% of individuals at any point in their lives), whereas PTSD affects 8% of the general population, GAD 5%, and PD and OCD each about 1%. Even apart from the considerable comorbidity between the anxiety disorders, comorbidity rates between anxiety disorders and depressive disorders are high (especially PD with agoraphobia, social phobia, and OCD), ranging from 30% for coexisting in time to 60% lifetime. Comorbidity rates between GAD or PTSD and other psychiatric disorders are even higher, about 80% for GAD and 90% for PTSD (lifetime).

Anxiety disorders have a disabling impact on daily life and are associated with considerable morbidity for the individual patient. They also impose a substantial economic impact on our society as a whole. Twenty-three million people suffer from an anxiety disorder in the United States. The total cost of anxiety disorders in this society is estimated to be $42.3 billion per year as direct and indirect expenses. PTSD and PD have the highest rates of service use. There are no obvious reasons to assume that the picture for other countries is very different (Table I).

Table I
Lifetime Prevelance Rate of Anxiety Disorders[a]

Disorder	Rate (%)
Social phobia	13
Specific phobia	12
PTSD	8
GAD	5
PD	1
OCD	1

[a]Based on results of the National Comorbidity Study, USA (1994).

III. ETIOLOGY OF ANXIETY AND ANXIETY DISORDERS

In broad terms, the likelihood of developing anxiety involves a combination of life experiences, psychological traits, and/or genetic factors. Anxiety disorders are so heterogeneous that the relative roles of these factors are likely to differ. Some anxiety disorders, such as PD, appear to have a stronger genetic basis than others, although no single gene is responsible for any anxiety disorder in the majority of cases. Quantum trait loci (QTL) have been successfully applied in plant and nonhuman genetics, relating dimensional traits to genes. QTL provide a means of combining molecular and quantitative approaches to complex behavior genetics.

Other anxiety disorders are more rooted in stressful life events. It is not clear why females have higher rates than males for most anxiety disorders, although some theories have suggested a role for the gonadal steroids. Other research on women's responses to stress suggests that women experience a wider range of life events (e.g., those happening to friends) as stressful compared with men, who react to a more limited range of stressful events, specifically those affecting themselves or close family members. To delineate the contributions of the environment, population-based research is important in future research.

IV. FUNCTIONAL NEUROANATOMICAL MODELS OF FEAR AND ANXIETY

A. History of Neuroanatomical Modeling of Fear and Anxiety

There has been a long history of hypotheses related to the neurobiology of human anxiety. The central role of a subcortical network of brain structures in emotion in

general was hypothesized by Papez in 1937. In 1949, MacLean coined the term "limbic" system, integrating Papez's original circuit (hypothalamus, anterior thalamus, cingulate gyrus, and hippocampus) and other anatomically and functionally related areas (amygdala, septum, and orbitofrontal cortex). Over the years, various regions have been added or removed from this "emotion" processing circuit. Papez hypothesized that several telencephalic and diencephalic structures which form a border ("limbic" = border) around the diencephalon constituted a circuit, which controlled the emotions. He suggested that blockage of information flow at any point along this circuit would cause disorders of affect (i.e., mood). Removal of the cerebral cortex of the cat, leaving only subcortical regions including amygdala, thalamus, hippocampus, and hypothalamus, resulted in accentuated fearful responses to potentially threatening or novel stimuli, accompanied by signs of diffuse sympathetic activation such as increased blood pressure, sweating, piloerection, and increased secretion of epinephrine from the adrenal medulla. This behavioral response was termed "sham rage". In this situation the animal behaves aggressively with little or no provocation. These experiments led to the hypothesis that subcortical brain structures above the level of the midbrain, such as the hypothalamus, hippocampus, cingulate, entorhinal cortex, and thalamus, mediate human anxiety responses. When the amygdala was also removed, as described by Kluver and Bucy, a typical "psychic blindness" occurred, indicating that these animals had good visual acquity but were "blind" to the psychological significance of stimuli. They showed no fear responses; the lesioned cat remained unprovoked, neither aggressive nor fearful of the appearance of a dog. Thus, the amygdala was added to these limbic brain structures and given a pivotal importance in emotional memory and fear responsivity.

B. Limbic System

The critical role of the limbic system is its participation in the experience of emotions, moods, and consolidation of short-term into long-term memory. It receives input from various regions of cortical structures, such as the gustatory (through the solitary nucleus) and olfactory areas (the olfactory bulb), and major inputs from the brain stem. One of these brain stem inputs comes from the locus coeruleus (LC), a relatively small group of pontine neurons near the central grey. The second area of brain stem input comes from the thalamus.

Since the 1980s, when the prevailing view was that excess discharge of the LC with the acute stress response was the major contributor to the etiology of anxiety, its role has become more balanced and in tune with the contribution of other circuits and systems in fear responsivity. It appeared that the acute stress response relates to arousal and vigilance rather than anxiety. With anxiety, the concern about the stressor is out of proportion to the realistic threat. Anxiety is often associated with elaborate mental and behavioral activities designed to avoid the unpleasant symptoms of a full-blown anxiety or panic attack. Also, anxiety is usually longer lived than arousal. Moreover, anxiety can occur in isolation without exposure to an external stressor.

Although technological developments have contributed to a more differentiated assessment of brain structures involved in anxiety, the past decade has seen considerable research on the role of the amygdala. This has led to hypotheses that the amgygdala plays a critical role in the elaboration of anxiety, panic, and related symptoms of arousal and fearful avoidance. However, the role of mental imagery and conscious memory recall in the development of anxiety suggests that other cortical areas, such as hippocampus and frontal cortex, must play a role in anxiety since the amygdala does not have the capacity for conscious recall, and research findings are consistent with a role for these structures in anxiety disorders. Moreover, the role of specific neurochemical systems has become clearer. Long-term dysregulation of these systems is strongly associated with the development of anxiety disorders, including PD, PTSD, and phobic disorders. In the mediation of symptoms of the anxiety disorders, these neurochemical and neurotransmitter systems act on a substrate of specific cortical and subcortical brain areas.

C. Animal Research in Fear and Anxiety

Animal tests of fear and anxiety are used both to screen new compounds for potential anxiolytic action and to study their neural substrates. Until the mid-1970s, animal tests consisted of delivering shocks as a punishment, most often for an operant lever-press response. These tests were developed as screening tests for the pharmaceutical industry. Matching particular tests of fear and anxiety to particular anxiety disorders

is an extremely difficult task. The social interaction test (placing rats in an unfamiliar or brightly lit environment), the elevated plus-maze (placing the animal on an elevated open arm), predator exposure stress, forced swim, and social defeat or subordination stress are models of fear and anxiety.

In the wide range of approaches used to study fear and anxiety in animal studies, two sets of tests probe their responses. The first set uses models of conditioned fear; the second uses models of unconditioned fear. Both models presuppose that aversive stimuli, such as foot shock or novelty, induce a central state of fear, which can be quantified through specific behavioral and physiological measures (restlessness, avoidant behaviors, body temperature, body posture, tremor, and sweating). Animals display fear responses to aversive events, such as being forced to swim in cold water, predator exposure, or being given electric foot shock.

Typically, if a caged rat is subjected to electrical foot shock, a protective defense system is engaged. It is likely to flee if an exit is available (fear) or attack a cagemate if there is one (anger). If the shocks are repeated randomly and uncontrollably it is likely that it will cower helplessly and later become dull and unresponsive (learned helplessness or depression). On the other hand, in conditioned fear experiments, after repeated pairings of an aversive stimulus with a formerly neutral cue, animals will experience this state of fear even when only the cue is present. The model of conditioned fear provides a critical survival-related function in the face of threat by activating a range of protective behaviors. Classical fear conditioning experiments and experiments in which anxiety is induced by other means (conditioned models and unconditioned models of fear) have expanded our understanding of mechanisms of fear and anxiety and are currently our best approaches as models for human anxiety disorders.

Using animals to measure the effects of chronic stress on neurochemical systems assumes that animal models of the anxiety disorders are directly applicable to human anxiety disorders. However, if there is any validity to our differentiation of unique disorders of anxiety and depression, then it is not possible that, regarding animal models, ''one size fits all.'' These limitations of animal models have to be borne in mind and are useful in guiding research in anxiety disorders. PTSD, PD, and phobic disorders have been found to have many phenomenological and neurobiological characteristics and can benefit from the application of animal models of stress.

V. KEY BRAIN STRUCTURES MEDIATING FEAR AND ANXIETY BEHAVIORS

The brain structures that constitute a neural circuit of fear and anxiety should have the following features:

1. There is sufficient afferent sensory input to permit assessment of the fear- or anxiety-provoking nature of the external threat or internal stress.
2. Neural interactions among the brain structures capable of incorporating an individual's prior experience or memory into the appraisal of stimuli. These interactions are important in the attachment of affective significance to specific stimuli and the mobilization of adaptive behavioral responses.
3. Efferent projections from the brain structures should be able to mediate an individual's neuroendocrine, autonomic, and motor response to threat as well account for the pathological reactions that result in anxiety-related signs and symptoms.

To underscore its survival importance, many brain areas with redundant circuits are involved to subserve this important constellation of behaviors. Critical brain structures capable of incorporating an individual's prior experience or memory into the appraisal of stimuli are amygdala, LC, hippocampus, thalamus, hypothalamus, periaqueductal grey (PAG), and prefrontal cortex. Alterations in neurochemical and neurotransmitter systems that mediate the stress response also play a role in anxiety. Important neurotransmitters are corticotrophine-releasing factor (CRF), adrenocorticotrophic hormone (ACTH), norepinephrine (NE), epinephrine, dopamine, cortisol, benzodiazepines (Bzs), opioids, and other neurochemical systems.

A. Amygdala

The amygdala is a large nucleus (actually a complex of at least three nuclei) that lies in the temporal lobe just lateral to the uncus. All its nuclei have a distinct cytoarchitectonic and chemoarchitectonic organization. The amygdala has a close anatomical and functional relationship with the hippocampal formation (projections to hippocampal neurons) and together they form the two major subcortical telencephalic limbic areas. The central nucleus of the amygdala projects to a variety of brain structures via the stria terminalis and the ventral amygdalofugal pathway. One pathway is from the central nucleus to the brain

stem startle reflex circuit (nucleus reticularis pontis caudalis). Pathways from the amygdala to the lateral hypothalamus affect peripheral sympathetic responses to stress. Lesions of the central nucleus of the amygdala have been shown to completely block fear conditioning, whereas electrical stimulation of the central nucleus increases acoustic startle. Electrical stimulation of the amygdala in cats resulted in peripheral signs of autonomic hyperactivity and fear-related behaviors seen in the wild when the animal is attacked or is attacking, including alerting, chewing, salivation, piloerection, turning, facial twitching, arching of the back, hissing, and snarling, associated with an increase in catecholamine turnover. Electrical stimulation of the amygdala in human subjects resulted in signs and symptoms of fear and anxiety, including an increase in heart rate and blood pressure, increased muscle tension, subjective sensations of fear or anxiety, and increases in peripheral catecholamines. These findings demonstrate that the amygdala plays an important role in conditioned fear and emotional responding. There are also important connections between cortical association areas, thalamus, and amygdala that are important in shaping the emotional valence of the cognitive response to stressful stimuli. In addition to thalamocorticoamygdala connections, direct pathways from thalamus to amygdala, could account for fear responding below the level of consciousness.

The paradigm of conditioned fear has been utilized as an animal model for stress-induced abnormalities of emotional memory and recently further neuroanatomically differentiated. Long-term activation using diffuse cues shows that this relies more on the bed nucleus of the stria terminals, whereas with the use of explicit cues, long-term activation was processed in the central nucleus of the amygdala. This may represent a brain distinction between "real fear" and "anxiety."

The amygdala is also involved in modulating peripheral stress responses. The reciprocal projections to the bed nucleus of the stria terminalis are among the major corticotropin-releasing hormone (CRH) containing systems in the brain. On the basis of chemoarchitecture and hedology, this sometimes is referred to as "extended amygdala."

B. Locus Coeruleus

The LC is located in the dorsal pontine tegmentum. LC neurons utilize norepinephrine (NE) as their neurotransmitter and have been implicated in the control of vigilance. That is, they seem to fire just before an experimental animal begins to pay attention to the novel sensory stimuli. The LC accounts for most of the noradrenergic input to the limbic system. Manipulation of noradrenergic function alters fear and anxiey behaviors, therefore supporting the longstanding notions of the critical role of the LC in anxiety and fear. The LC shows heterogeneity of transmitter content: the catecholaminergic neurons contain noradrenaline and also peptides such as neuropeptide Y (NPY) and galanin. Stimulation of the LC results in a series of responses very similar to those observed in naturally occurring or experimentally induced fear. Drugs have been used (e.g., yohimbine and piperoxone) that activate LC by blocking α_2-adrenergic autoreceptors. Increases in LC function are accompanied by sympathetic activation; the greater the activation, the greater the correlation. Decreasing the function of the LC (interacting with inhibitory opiates, benzodiazepines, and α_2 receptors on LC) results in a decrease in fearful behavior. The LC–NE network helps determine whether, under threat, an individual turns attention toward external sensory stimuli or to internal vegetative states.

C. Hippocampus

The hippocampus plays a key role in memory function and also in the context of fear. An important aspect of the fear response is incorporation of a person's prior experience (memory) into the cognitive appraisal of stimuli. The hippocampus and adjacent cortex mediate declarative memory function (e.g., recall of facts and lists) and play a role in integration of memory elements at the time of retrieval and in assigning significance for events within space and time. The hippocampus is also involved in mediating emotional responses to the context of a stressor—for example, in animal studies timely lesions of the hippocampus disrupted the formation of emotional memories of the context (i.e., the box) where the stressor (i.e., electric foot shock) took place. With long-term storage, memories are believed to be shifted from hippocampus to the neocortical areas, where the initial sensory impressions take place. The shift in memory storage to the cortex may represent a shift from conscious representational memory to unconscious memory processes that indirectly affect behavior. "Traumatic cues" such as a particular sight or sound reminiscent of the original

traumatic event will trigger a cascade of anxiety- and fear-related symptoms, often without conscious recall of the original traumatic event. Lesions in the hippocampus have little effect on classically conditioned modality-specific fear, in contrast to the amygdala. Projections from the amygdala to the hippocampus could permit the experience of fear to modulate or influence short-term memory function, attaching cognitive significance to fear-inducing events and facilitating memory traces that enable the individual to rapidly initiate adaptive behavioral responses. Recent research has shown that the hippocampus is particularly vulnerable to stress possibly through the effects of increased levels of glucocorticoids. Glucocorticoids have also been shown to augment extracellular glutamate accumulation. Other factors besides glucocorticoids, such as brain-derived neurotrophic factor (BDNF), trkB mRNA, and nerve growth factor, which have a regulatory effect on neuronal morphology and proliferation, may mediate stress-induced alterations in hippocampal morphology. Stress-induced damage has been shown to be associated with an increase in levels of CRF mRNA in the paraventricular nucleus (PVN) of the hypothalamus as well as a decrease in the sensitivity of rats to dexamethasone suppression of hypothalamic–pituitary–adrenal (HPA) function.

D. Thalamus

The thalamic nuclei relay sensoric information from auditory, visual, and somesthetic systems to the cortex and limbic forebrain. An exception is the olfactory system, which does not relay information through the thalamus. Processing of threatening stimuli involves the relay of sensory signals to limbic forebrain directly from thalamus and cortex.

E. Hypothalamus

Many of the neuroendocrine and autonomic changes resulting from stress, fear, and anxiety can be understood from the projections that the hypothalamic nuclei receive from many limbic and brain stem structures. Their projection is to sympathetic regions in the spinal cord and medulla. The hypothalamus is important in the regulation of neuropeptide release and sympathoadrenal outflow associated with fear and anxiety. Stress results in increased production and turnover of NE in the hypothalamic nuclei. Stimulation of LC results in increased NE turnover in the PVN and supraoptic nucleus (SON), and helps PVN and SON synthesize enkephalin, vasopressin, and oxytocin—hormones whose levels are increased by stress. There is evidence that stress induces changes in cholecystokinin (CCK) and substance P, concentrated in the hypothalamus.

F. Periaqaeductal Grey

PAG is a key brain region involved in initiating fear-related behaviors. Lesions of the PAG reduce fear-related behaviors. It has been suggested that the amygdala signals the degree of threat to the PAG. Immediate threat may activate vigorous defense behaviors and nonopioid analgesia; less immediate threat or conditioned stimulus (CS) presentation predicting danger may produce freezing behavior and opioid analgesia.

G. Cortex

The cognitive response to threat involves placing the threatening object in space and time. Specific cortical brain areas are involved in these functions; for example, parietal cortex is involved in determining where an object is located in space; posterior portions of the cingulate have connections to parietal cortex, hippocampus, and adjacent cortex (important in visuospatial processing); prefrontal cortex is also involved in memory and cognition and with parietal cortex has important dual reciprocal connections with all the subcortical areas; and the dorsolateral prefrontal cortex has a range of functions, including declarative and working memory as well as planning of action, whereas the parietal cortex plays an important role in spatial memory. The medial prefrontal cortex (mPFC) and parietal cortex probably work in concert in the alerting and planning aspects of the stress response that is critical for survival. mPFC, including anterior cingulate (Brodmann area 32) and subcallosal gyrus (areas 24 and 25), is involved in selection of responses for action and emotion. This area and other medial portions of the prefrontal cortex, including orbitofrontal cortex, modulate emotional and physiological responses to stress, specifically in the effectiveness of the individual's behavior (e.g., the capacity to inhibit and change behavior in the face of threat) and are

discussed in more detail later. Lesions of the mPFC increase resistance to extinction of fear-conditioned responses. The reciprocal interactions between subcortical limbic structures and orbitofrontal cortex may point to interaction in learning and unlearning of the significance of fear-producing sensory events and the choice and implementation of behaviors important for survival. Lesions in the prefrontal cortex cause profound changes in affect, mood, and social behavior.

mPFC areas (areas 24, 25, and 32) modulate emotional responsiveness through inhibition of amygdala function. It has projections to the amygdala, which are involved in the suppression of amygdala responsiveness to fearful cues. Dysfunction of these areas can be responsible for the failure of extinction to fearful cues, which is an important part of the anxiety response. Area 25 also has direct projections to brain stem and is involved in regulation of peripheral responses to stress, including heart rate, blood pressure, and cortisol response. Lesions of this area in animals result in impairments in mounting the peripheral glucocorticoid and sympathetic response to stress. Human subjects with lesions of medial prefrontal cortical areas (e.g., the famous case of Phineas Gage) have deficits in interpretation of emotional situations that are accompanied by impairments in social relatedness. Other case studies of humans with brain lesions have implicated mPFC in "emotion" and socially appropriate interactions. Auditory association areas (temporal lobe) have also been implicated in animal studies as mediating extinction to fear responding.

VI. NEURAL CIRCUITS IN ANXIETY AND FEAR

The major afferent arm of neural circuitry includes exteroceptive sensory systems of the brain, consisting of serially organized relay channels that convey directly or through multisynaptic pathways information relevant to the experience of fear. The sensory information contained in a fear- or anxiety-inducing stimulus is transmitted from peripheral receptor cells in the eyes, ears, nose, skin, the body's own visceral information (e.g., blood glucose, arterial pressure, and CO_2 levels), or any combination of these. Except for olfactory information, which goes directly to amygdala and enthorhinal cortex, these sensory inputs are relayed through the dorsal thalamus to amygdala and cortical brain areas, such as primary visual (occipital), auditory (temporal), or tactile (postcentral gyrus) cortical areas. Input from peripheral visceral organs is relayed through the nucleus paragigantocellularis and nucleus tractus solitarius in the brain stem to LC and from there to unimodal and polymodal cortical association areas. Another projection from the brain stem to the limbic system comes from the midbrain region of the ventral tegmental area. This nuclear group contains some of the few dopaminergic neurons found in the brain. Information that reaches primary sensory areas is then processed by secondary cortical association areas, often physically adjacent to the primary sensory areas from which they receive information. These brain areas send projections to multiple brain structures, including amygdala, hippocampus, entorhinal cortex, orbitofrontal cortex, and cingulate gyrus, that are involved in mediating this visual memory and attached emotion.

As this primary sensory input comes into the brain stem and midbrain, it is matched against previously stored patterns of activation and if unknown, or if associated with previous threat, an initial fear response begins, consisting of affective, behavioral, and somatic responses. A wave of neuronal activation in key brain stem and midbrain nuclei is formed by activation of different neurotransmitters, neuromodulators, and neuropeptides, resulting in patterns of neuronal activation which move from brain stem through midbrain to thalamic, limbic, and cortical areas. At the level of the thalmus and the limbic areas (the amygdala also receives information directly from the thalamus) specific patterns of neuronal activity result in the actual sensation of anxiety. The pivotal role of the amygdala is supported by the fact that it receives afferents from thalamic and cortical exteroceptive systems as well as from subcortical visceral afferent pathways. At the subcortical and cortical level, more complex cognitive associations are made, allowing for interpretation of that internal state of anxiety (e.g., the neuronal interactions between amygdala and orbitofrontal cortex enable the individual to initiate adaptive behaviors to threat based on prior experience and the nature of the threat). Cortical, limbic, midbrain, and brain stem-based neuronal activity may subsequently be involved in various aspects of anxiety regulation or dysregulation.

VII. NEUROENDOCRINE, AUTONOMIC, AND MOTOR RESPONSES

Efferent projections from the brain structures need to be able to mediate an individual's neuroendocrine,

autonomic, and motor response to threat. They also need to account for the pathological reactions that result in anxiety-related signs and symptoms. The organism must rapidly effect peripheral responses to threat, which are mediated by the sympathetic and parasympathetic systems. Structures involved in these responses include the amygdala, LC, hypothalamus, PAG, and striatum. The hypothalamus coordinates the information it receives from various brain regions to patterns of sympathetic responses. Stimulation of the lateral hypothalamus results in sympathetic system activation with increases in blood pressure and heart rate, sweating, piloerection, and pupil dilatation. Activation of the paraventricular nucleus of the hypothalamus promotes release of a variety of hormones and peptides. Its activation in anxiety and fear is thought to rely on stimulation from hypothalamus via projections from the amygdala and LC. The PAG also serves to regulate the sympathetic function, which accounts for parallel activation of the peripheral sympathetic system and the LC. The n. vagus and splanchnic nerves are projections from the parasympathetic system. The n. vagus receives information from the lateral hypothalamus, PVN, LC, and amygdala. The splanchnic nerves receive afferent input from LC. This innervation from the parasympathetic system relates to visceral symptoms associated with fear and anxiety such as gastrointestinal and genitourinary disturbances.

The amygdala has strong projections to most areas of the striatum, including nucleus accumbens, olfactory tubercle, and part of the caudate and putamen. The dense innervation of the striatum and prefrontal cortex by the amygdala indicates that the amygdala can powerfully regulate both these systems. Adaptive mobilization of the motor response to threat probably involves pathways between cortical association areas and the striatum and also the amygdala and the striatum. These interactions between amygdala and the extrapyramidal motor system may be important in generating motor responses to threatening stimuli, especially when they are related to prior experiences.

The cerebellum has a well-known role in motor movement, suggesting that this region is involved in planning for action; however, recent imaging studies are consistent with a role in cognition as well. Connections between parietal and prefrontal cortex are required in order to permit the organism to rapidly and efficiently execute motor responses to threat. These areas have important innervations to the precentral (motor) cortex, which is responsible for motor responses to threat. The striatum (caudate and putamen) modulates motor responses to stress. The dense innervation of the striatum and prefrontal cortex by the amygdala indicates that the amygdala can regulate both these systems. These interactions between the amygdala and the extrapyramidal motor system may be very important for generating motor responses to threatening stimuli, especially those related to prior adverse experiences.

Thus, preparation for responding to threat requires integration between brain areas involved in assessing and interpreting the potentially threatening stimulus. Brain areas involved in response (e.g., prefrontal cortex and anterior cingulate) play an important role in the planning of action and in holding multiple pieces of information in "working memory" during the execution of a response. Parietal cortex and posterior cingulate are involved in visuospatial processing that is an important component of the stress response. Motor cortex may represent the neural substrate of planning for action.

A. HPA Axis

The HPA axis is a component of the response system in fear and anxiety. The HPA axis has important functional interactions with the NE system that facilitate a sophisticated range of responses to stress. Stimulation of the lateral hypothalamus results in sympathetic system activation producing increases in blood pressure and heart rate, sweating, piloerection, and pupil dilatation. Stress stimulates release of CRF from the PVN of the hypothalamus into the portal bloodstream. CRF is transported to the anterior lobe of the pituitary, where it stimulates the release of ACTH and ultimately the release of cortisol from the adrenal cortex. High levels of circulating cortisol act through a negative feedback pathway to decrease both CRF and NE synthesis at the level of the PVN. Glucocorticoid inhibition of NE-induced CRF stimulation may be evident primarily during stressor-induced cortisol release and not under resting conditions. High levels of cortisol likely inhibit the effects of NE on CRF release from the PVN, serving to restrain the stress-induced neuroendocrine and cardiovascular effects mediated by the PVN. CRF increases activity of the LC; CRF injected into the LC intensifies anxiety-related responses. CRF serves as an excitatory neurotransmitter in the LC, which contributes to a pathway for the behavioral effects of CRF.

The mechanism responsible for transient stress-induced hyperadrenocorticism and feedback resistance

may involve a downregulation of glucocorticoid receptors. High glucocorticoid levels decrease the number of hippocampal glucocorticoid receptors, resulting in increased corticosterone secretion and feedback resistance. Following stress termination, when glucocorticoid levels decrease, receptor numbers are increased and feedback sensitivity normalizes.

The effects of chronic stress on ACTH and corticosterone secretion vary depending on the experimental paradigm. In nonhuman primates, adverse early experiences induced by variable maternal foraging requirements result in profound behavioral disturbances (more timid, less social, and more subordinate) years later. Adult monkeys raised in the variable foraging maternal environment were also hyperresponsive to yohimbine and had elevated levels of CSF and decreased CSF cortisol levels in adulthood. These observations suggest that early adverse experience permanently affects the HPA axis.

B. Norepinephrine

Norepinephrine release in the brain represents an important part of the immediate stress response, reacting within seconds. The majority of noradrenergic cell bodies are located in the brain stem, in the LC, with axons that extend throughout the cerebral cortex and to multiple subcortical areas. Neurons in the LC are activated in association with fear and anxiety states and the limbic and cortical regions innervated by the LC are thought to be involved in the elaboration of adaptive responses to stress. Stressors such as a cat seeing a dog result in an increase in firing of neurons in the LC and enhanced NE release in the hippocampus and mPFC. Exposure to chronic stress also results in a potentiation of NE release with subsequent stressors. Consistent with these findings, noradrenergic stimulation resulted in decreased metabolism in hippocampus (consistent with high levels of NE release) and relative failure of activation in mPFC in PTSD patients but not normal subjects. There was also a pattern of a relationship between this metabolic response and increased panic anxiety.

C. Dopamine

The dopamine innervation of the mPFC appears to be particularly vulnerable to stress. Sufficiently low-intensity stress (such as that associated with conditioned fear) or brief exposure to stress increases dopamine release and metabolism in the prefrontal cortex in the absence of overt changes in other mesotelencephalic dopamine regions. Low-intensity electric foot shock increases *in vivo* tyrosine hydroxylase and dopamine turnover in the mPFC but not the nucleus accumbens or striatum. Stress can enhance dopamine release and metabolism in other areas receiving dopamine innervation, provided that greater intensity or longer duration stress is used. Thus, the mPFC dopamine innervation is preferentially activated by stress compared to mesolimbic and nigrostriatal systems, and the mesolimbic dopamine innervation appears to be more sensitive to stress than the striatal dopamine innervation.

D. Serotonin

Although less studied, in conditioned fear experiments animals demonstrated an increase in serotonin (5-HT) turnover in different brain areas, with preferential release in mPFC. Serotonin antagonists produce behavioral deficits resembling those seen following inescapable shock. Chronic stress increases cortical 5-HT_2 receptor binding and reduces hippocampal 5-HT_{1A} receptor binding. Drugs that enhance serotonin neurotransmission are effective in reversing this behavioral "learned helplessness." Injection of serotonin into the frontal cortex after stress exposure reverses behavioral deficits.

The effect of stress in activating serotonin turnover may stimulate a system that has both anxiogenic and anxiolytic pathways within the forebrain. A primary distinction in the qualitative effects of serotonin may be between the dorsal and median raphe nuclei, the two midbrain nuclei that produce most of the forebrain serotonin. The serotonergic innervation of the amygdala and the hippocampus by the dorsal raphe are believed to mediate anxiogenic effects via 5-HT_2 receptors. In contrast, the median raphe innervation of hippocampal 5-HT_{1A} receptors has been hypothesized to facilitate the disconnection of previously learned associations with aversive events or to suppress formation of new associations, thus providing resilience to aversive events.

E. Benzodiazepine

Alterations in Bz receptor function are involved in the stress response and anxiety. Animals exposed to stress

develop a decrease in Bz receptor binding in different brain sites. Decreases in Bz receptor binding are also associated with alterations in memory. Bz receptors are present throughout the brain, with the highest concentration in cortical grey matter. Bzs potentiate and prolong the synaptic actions of the inhibitory neurotransmitter γ-aminobutyric acid (GABA). Central Bz receptors and GABA receptors are part of the same macromolecular complex. These receptors have distinct binding sites, although they are functionally coupled and regulate each other in an allosteric manner. Administration of inverse agonists of Bz receptors results in behavioral and biological effects similar to those seen in anxiety and stress. These effects are blocked by administration of Bzs or pretreatment with the Bz antagonist flumazenil.

F. Neuropeptides

Several neuropeptides also mediate the response to stress. CCK is an anxiogenic neuropeptide present in the gastrointestinal tract and the brain that has recently been suggested to be a neural substrate for human anxiety.

Stress is associated with an increase in endogenous opiate release with decreased density of mu opiate receptors, which may mediate the analgesia associated with stress. Other neuropeptides under investigation that appear to play a role in the stress response are neuropeptide Y, somatostatin, and thyrotropin. Stress also has important effects on the immune system.

VIII. APPLICATION OF THE MODEL OF THE NEURAL CIRCUITRY OF ANXIETY AND FEAR TO ANXIETY DISORDERS

The primary goal of research in the clinical neuroscience of anxiety disorders is to apply findings related to the effects of stress on the brain in animals to patients with anxiety disorders. Different methods contributed to the working model of the neural circuitry of anxiety and anxiety disorders that is presented here. The neural circuits mediating symptoms of anxiety disorders can be studied by measuring neurotransmitters and hormone levels in blood, urine, and saliva; by assessing behavioral and biochemical responses to pharmacological challenge to specific neurochemical systems; by measuring key brain structures with structural neuroimaging; by provoking disease-specific symptoms in conjunction with functional neuroimaging; or by using imaging to measure neuroreceptors.

Among the most characteristic features of anxiety disorders such as PTSD and PD is that "anxiogenic" memories (e.g., of the traumatic experience or first panic attack) can remain indelible for years or decades and can be easily reawakened by all sorts of stimuli and stressors. The strength of traumatic memories relates, in part, to the degree to which certain neuromodulatory systems, particularly catecholamines and glucocorticoids, are activated by the traumatic experience. Release of these stress hormones modulates the encoding of memories of the stressful event. Experimental and clinical investigations provide evidence that memory processes remain susceptible to modulating influences after information has been acquired. Long-term alterations in these catecholaminergic and glucocorticoid systems may also be responsible for symptoms of fragmentation of memories, but also for hypermnesia, amnesia, deficits in declarative memory, delayed recall of abuse, and other aspects of the wide range of memory distortions in anxiety disorders. With long-term storage, memories are shifted from hippocampus to the neocortical areas, where the initial sensory impressions take place. The shift in memory storage to the cortex may represent a shift from conscious representational memory to unconscious memory processes that indirectly affect behavior. Traumatic cues such as a particular sight or sound reminiscent of the original traumatic event will trigger a cascade of anxiety and fear-related symptoms will ensue, often without conscious recall of the original traumatic event. In patients with PTSD, however, the traumatic stimulus is always potentially identifiable. Symptoms of anxiety in panic or phobic disorder patients, however, may be related to fear responses to a traumatic cue (in individuals who are vulnerable to increased fear responsiveness, through either constitution or previous experience), where there is no possibility that the original fear-inducing stimulus will ever be identified.

Thus, patients with anxiety disorders have symptoms that reflect a more or less continuous perception of threat with unconscious processed fear responses. The animal model of contextual fear conditioning represents a good model for these symptoms. Preclinical data suggest that the hippocampus (as well as BNST and PAG) plays an important role in the mediation of contextual fear, and that increased responding to CS is due to hippocampal dysfunction. Hippocampal atrophy in PTSD, as described

previously, therefore provides a possible neuroanatomical substrate for abnormal contextual fear conditioning and chronic symptoms of feeling of threat and anxiety. Interestingly, in light of studies showing abnormal noradrenergic function in PTSD, the BNST has some of the densest noradrenergic innervation of any area in the brain.

The startle reflex has been the subject of the few fear conditioning studies that have been performed in humans. Startle is a useful method for examining fear responding in experimental studies involving both animals and humans that is mediated by the amygdala and connected structures. Patients with combat-related PTSD were found to have elevated baseline startle compared to controls in some studies but not others. In the patient group, there were asymmetry of baseline startle response and increased heart rate responses during measurement of startle. From other studies it is clear that unconscious emotional processes are involved in fear conditioning (e.g., patients with anxiety disorders have demonstrated greater resistance to extinction of conditioned responses to angry facial expressions, but not to neutral facial expressions, compared to controls). In the neural circuitry, damage to the amygdala does not prevent patients from learning the relationship between the CS and the unconditioned stimulus (UCS), but it abolishes conditioned autonomic responses. In contrast, damage to the hippocampus does not affect conditioned autonomic responses but does prevent learning of the CS–UCS association. Further evidence for unconscious processes stems from backward masking techniques, which prevent conscious awareness of a stimulus. Using such a technique, fear conditioning to a certain class of stimuli called fear-relevant stimuli (e.g., spiders and snakes) proves to be mediated by preattentive automatic information-processing mechanisms. These automatic mechanisms may be mediated in part by direct thalamic–amygdala connections. Thalamoamygdala pathways that bypass the cerebral cortex may trigger conditioned responses before the stimulus reaches full awareness, providing an explanation for unconscious conditioned phobic responses to fear-relevant stimuli.

A. Alterations in Neurochemical Stress Response Systems in Patients with Anxiety Disorders

1. CRF/HPA Axis

Anxiety disorder patients have long-term alterations in neurochemical systems that are involved in mediating the stress response and are sensitive to chronic stress. The findings in PTSD and PD (most extensively studied of the anxiety disorders) are summarized in Table II.

Specific alterations in cortisol and HPA axis function are associated with PTSD. An increase in neuronal CRF release is a possible explanation for the clinical findings that have been reported for this disorder, with resultant blunting of ACTH response to CRF, increased central glucocorticoid receptor responsiveness, and resultant low levels of peripheral cortisol due to enhanced negative feedback. Interestingly, nonhuman primates with variable foraging mothers (a model for early life stress) had elevated CSF and CRF and decreased CSF cortisol levels in adulthood, which is more similar to PTSD than to depression.

Evidence for dysfunction of CRF or HPA systems in PD has been inconsistent. Normal levels of CRF in CSF of PD patients have been found, blunted ACTH responses to CRF (indicating chronic elevations in CRF) have been reported in some studies, and both normal and elevated rates of cortisol nonsuppression following dexamethasone have been reported. Urinary-free cortisol results have been inconsistent. Elevated plasma cortisol levels were reported in one study but not in others. In 24-hr secretion of ACTH and cortisol in PD, only subtle abnormalities were seen. Patients had elevated overnight cortisol secretion and greater amplitude of ultradian secretory episodes.

2. Catecholamines

There is extensive evidence indicating that NE plays a role in human anxiety and is dysregulated in anxiety disorders. PTSD and PD seem to have similar alterations in noradrenergic function. However, the causes of the two syndromes may differ, with PD associated more with genetic factors and PTSD with the effects of severe psychological trauma.

Heightened autonomic or sympathetic nervous system arousal was found in children but also in combat veterans with chronic PTSD. They showed higher resting mean heart rate and systolic blood pressure, as well as greater increases in heart rate, when exposed to visual and auditory combat-related stimuli compared with combat veterans without PTSD, patients with GAD, or healthy subjects. The PTSD patients showed hyperreactive responses to combat-associated stimuli but not to other stressful noncombat-related stimuli. They also showed elevated NE and epinephrine in 24-hr urine in comparison to normal

Table II

Evidence for Neurobiological Alterations in CRF/HPA Axis, Catecholaminergic Systems, and Other Neurotransmitter Systems[a]

	PTSD	Panic
CRF/HPA axis function		
Alterations in urinary cortisol	+/−[a]	+/−
Altered plasma cortisol with 24-hr sampling	+ (decrease)	+ (increase)
Supersuppression with DST	+	−
Blunted ACTH response to CRF	+ +	+/−
Elevated CRF in CSF	+	+
Increased lymphocyte glucocorticoid receptors	+ +	NT
Catecholaminergic function		
Increased resting heart rate and blood pressure	+/−	+/−
Increased heart rate and blood pressure response to traumatic reminders/panic attacks	+ + +	+ +
Increased resting urinary NA and Epi	+	+ +/−
Increased resting plasma NA or MHPG	−	−
Increased plasma NA with traumatic reminders/panic attacks	+	+/−
Increased orthostatic heart rate response to exercise	+	+
Decreased binding to platelet-2 receptors	+	+/−
Decrease in basal and stimulated activity of cAMP	+/−	+
Decrease in platelet MAO activity	+	?
Increased symptoms, heart rate, and plasma MHPG with yohimbine noradrenergic challenge	+	+ + +
Differential brain metabolic response to yohimbine	+	+
Other neurotransmitter systems		
Serotonin		
Decreased serotonin reuptake site binding in platelets	+ +	
Decreased serotonin transmitter in platelets	−	
Blunted prolactin response to buspirone ($5HT_{1A}$ probe)	−	
Benzodiazepine		
Increased symptomatology with Bz antagonist	−	+ +
Cholecystokinin		
Increased anxiety symptoms with CCK administration	NT	+ +
Anxiolytic effect of CCK antagonist	−	
Opiate		
Naloxone-reversible analgesia	+	
Increased plasma β-endorphin response to exercise	+	
Increased endogenous opiates in CSF	+	
Altered serotonin effect on cAMP in platelets ($5HT_{1A}$ probe)	−	
Neuropeptide Y		
Altered plasma levels	+ (decrease)	+ (increase)
Thyroid		
Increased baseline thyroxine	+	
Increased TSH response to TRH	+	
Somatostatin		
Increased somatostatin levels at baseline in CSF	+	

[a]Findings of decreased urinary cortisol in older male combat veterans and holocaust survivors and increased cortisol in younger female abuse survivors may be explainable by differences in gender, age, trauma type, or developmental epoch at the time of the trauma. + indicates the availability of studies; NT = not tested.

controls and patients with other psychiatric disorders. Relative elevations of the NE metabolite, MHPG, were found in their nighttime samples. No differences were found in baseline levels of plasma NE when compared with healthy subjects. This noradrenergic hyperreactivity in patients with PTSD may be associated with the conditioned or sensitized responses to specific traumatic stimuli. Women with PTSD secondary to childhood sexual abuse had significantly elevated levels of catecholamines (NE, E, and DA), cortisol and catecholamine metabolites, metanephrine, vanillylmandelic acid, and HVA in 24-hr urine samples.

The release of glucocorticoids or other stress-related factors (e.g., stress-induced decreases in BDNF) is shown to result in hippocampal damage with lasting deficits in verbal declarative memory dysfunction in PTSD. Although hippocampal volume reduction appears to be specific to stress-related anxiety disorders, PD patients have been shown to have alterations of parahippocampal gyrus and other portions of extrahippocampal temporal lobe that may underlie declarative memory deficits that are also seen in PD. Increased cortisol release with stress in both PTSD and PD may result in amnesia and cognitive dysfunction associated with these disorders. Excessive release of NE with stressors in anxiety disorder patients is predicted to result in decreased function of neurons which may be related to both cognitive dysfunction and increased anxiety with stress. In addition, given the known role of the hippocampus in contextual fear, lasting damage to the hippocampus may contribute to excessive anxiety and fear responding in these patients. Finally, since the hippocampus is involved in integration of individual aspects of memory at the time of memory retrieval, hippocampal dysfunction may lead to memory fragmentation and amnesia.

Evidence for noradrenergic responsivity is also manifested on the level of peripheral NE receptor function. A decrease in platelet adrenergic α_2 receptor number as measured by total binding sites for the α_2-antagonist [^{3}H]rauwolscine and greater reduction in number of platelet α_2 receptors after exposure to agonist (epinephrine) may reflect chronic high levels of NE release which lead to compensatory receptor downregulation and decreased responsiveness. Although there is inconsistent evidence for elevations in NE at baseline in PTSD, there is evidence for increased noradrenergic responsivity in this disorder. Studies have also shown alterations in the α_2-receptor and cyclic AMP function in patients with PTSD, which were similar to those in PD. Patients with combat-related PTSD compared to healthy controls had enhanced behavioral, biochemical (NE metabolite MHPG), and cardiovascular (heart rate and blood pressure) responses to the α_2 antagonist, yohimbine, which stimulates central NE release. Moreover, neuroimaging with positron emission tomography (PET) demonstrated that PTSD patients have a cerebral metabolic response to yohimbine, consistent with increased NE release.

Alterations in sleep function may be secondary to altered pontine function and noradrenergic dysregulation in PTSD. Sleep dysfunction has been documented following acute fear and appears to be related to development of chronic anxiety disorders. PTSD patients have been found to have decreased total sleep time, increased "microawakenings," and increases in phasic rapid eye movement activity relative to controls. These abnormalities may play a role in nightmares in this patient population.

Abnormal regulation of brain noradrenergic systems is also involved in the pathophysiology of PD. Evidence for baseline elevations in heart rate and blood pressure, as well as plasma NE, in PD has been conflicting. PD patients had increased heart rate responses to orthostatic challenge when compared to normal subjects. Patients with PD were found to have elevations in baseline plasma epinephrine. One study found increased NE with lactate-induced panic attacks but another did not find an increase with spontaneous panic attacks. PD patients are very sensitive to the anxiogenic effects of yohimbine, in addition to having exaggerated plasma MHPG, cortisol, and cardiovascular responses. Responses to the α_2-adrenergic receptor agonist, clonidine, were also abnormal in PD patients. Clonidine administration caused greater hypotension, greater decreases in plasma MHPG, and less sedation in panic patients than in controls. Clonidine significantly, but only partially, attenuated lactate panic symptoms, indicating that noradrenergic neuronal activity cannot fully account for lactate-induced panicogenesis. Growth hormone response to clonidine (used as a probe of central α_2-adrenergic receptor function) was blunted in PD versus normals. These findings persist despite clinical recovery with fluoxetine treatment.

Few studies have examined noradrenergic function in patients with phobic disorders. In patients with specific phobias, increases in subjective anxiety, and increased heart rate, blood pressure, plasma NE, and epinephrine have been associated with exposure to the phobic stimulus. This finding may be of interest from the standpoint of the model of conditioned fear, in

which a potentiated release of NE occurs in response to a reexposure to the original stressful stimulus. Patients with social phobia have been found to have greater increases in plasma NE in comparison to healthy controls and patients with PD. In contrast to PD patients, the density of lymphocyte α adrenoceptors is normal in social phobic patients. The growth hormone response to intravenous clonidine (a marker of central α_2 receptor function) is blunted in social phobia patients.

There is evidence for a role for dopamine in human anxiety states. A higher incidence of anxiety disorders including panic attacks occurs in patients with Parkinson's disease. A higher concentration of the dopamine metabolite, homovanillic acid, in plasma in PD has been found in patients with high levels of anxiety and frequent panic attacks. Recently, patients with PD were shown to have a greater growth hormone response to the dopamine agonist apomorphine than patients with depression. However, some negative studies also exist. As noted previously, elevations in dopamine were found in 24-hr urine of patients with PTSD. There have been no studies of dopamine function in social phobia.

3. Other Neurotransmitter Alterations

a. Serotonin Clinical studies of serotonin function in anxiety disorders have had mixed results. Although there are only a limited number of studies of serotonergic function in PTSD, there is a large body of indirect evidence suggesting that this neurotransmitter may be important in the pathophysiology of trauma-related symptomatology. In humans, low 5-HT functioning has been associated with aggression, impulsivity, and suicidal behavior. Patients with PTSD are frequently described as aggressive or impulsive and often suffer from depression, suicidal tendencies, and intrusive thoughts that have been likened to obsessions. Patients with PTSD were found to have a predominance of "reducing" patterns to auditory-evoked potential paradigms compared to normal controls. One explanation for these findings is low serotonergic activity in PTSD. This hypothesis gains further support from the observation that serotonin reuptake inhibitors have been found to be partially effective in treating PTSD symptoms such as intrusive memories and avoidance symptoms. A subgroup of patients with PTSD exhibited a marked behavioral sensitivity to serotonergic provocation with *m*-chlorophenylpiperazine (mCPP), a probe of postsynaptic 5-HT_{1C} and 5-HT_2 receptor functions, raising the possibility of pathophysiologic subtypes among traumatized combat veterans.

To date, pharmacologic challenge studies of 5-HT in PD have also been unable to establish a definite role for 5-HT in the pathophysiology of panic. Challenges with the 5-HT precursors, L-tryptophan and 5-hydroxytryptophan (5-HTP), did not discriminate between PD and controls on neuroendocrine measures. Conversely, tryptophan depletion was not anxiogenic in unmedicated PD patients. However, challenge with the 5-HT-releasing agent fenfluramine has been reported to be anxiogenic and to produce greater increases in plasma prolactin and cortisol in PD compared to controls. Studies with mCPP have produced equivocal findings. Increases in anxiety and plasma cortisol in PD patients compared to controls have been reported with oral but not IV administration of mCPP. When the selective 5-HT_{1A} partial agonist ipsapirone was used as a challenge agent, ACTH, cortisol, and hypothermic responses to ipsapirone were blunted in PD patients, but anxiety responses did not differ from controls. These data implicate 5-HT_{1A} receptor subsensitivity in the pathophysiology of PD.

In several case reports the synthetic amphetamine analog MDMA has been associated with panic attacks and in some cases with the induction of PD. MDMA acts as both an indirect dopamine agonist and a potent 5-HT releaser and agonist.

b. Benzodiazepine Despite the preclinical support for the involvement of Bz systems in stress, clinical investigations of the function of this system in patients with anxiety disorders have been difficult to design. The inability to identify variables measurable in living human subjects who reflect central Bz system function has contributed to the paucity of research in this area. However, evidence from clinical studies performed to date suggests a possible role for alterations in Bz receptor function in disorders of anxiety and stress.

Pharmacologic challenge studies with the Bz receptor inverse agonist FG7142 induced severe anxiety resembling panic attacks and biological characteristics of anxiety in healthy subjects. Both oral and intravenous administration of the Bz receptor antagonist flumazenil to patients with PD resulted in an increase in panic attacks and subjective anxiety in comparison to controls. Flumazenil, however, had no anxiogenic effects in PTSD. Bz-induced changes in sedation and cortisol levels, as well as saccadic eye movement velocity, have been suggested to be indicative of Bz receptor-mediated actions. PD patients were found to

be less sensitive than controls to diazepam using saccadic eye movement velocity as a dependent measure, suggesting a functional subsensitivity of the GABA–Bz supramolecular complex in brain stem regions controlling saccadic eye movements. Other evidence for alterations in Bz receptor function in PD patients includes a diminished sensitivity to suppression of plasma NE, epinephrine, and pulse following administration of diazepam in comparison to controls.

Patients with GAD have been found to have decreases in peripheral-type Bz receptor binding as assessed by [^{3}H]PK11195 binding to lymphocyte membranes, although the relationship to central Bz receptor function is unclear. In addition, reduced binding to [^{3}H]PK11195 has been reversed with Bz therapy in patients with anxiety disorders. Healthy subjects exposed to the stress of war have also been found to have a decrease in binding of Bz receptors on peripheral mitochondria during the stressful period before and during war relative to the period after the war, which was correlated with an improvement of anxiety after the end of the war. Mixed findings are reported on peripheral Bz receptor binding in PD patients. Studies examining GABA, which is functionally related to Bzs, have not found differences in plasma levels between PD patients and controls at baseline.

Studies have begun to use neuroimaging to examine central Bz receptor function in anxiety disorders. [^{123}I]Iomazenil binds with high affinity to the Bz receptor and can be used with single photon emission computed tomography (SPECT) to image the Bz receptor in human brain. SPECT has been used to show a decrease in [^{123}I]iomazenil uptake in frontal, temporal, and occipital cortex in PD patients relative to comparison subjects. These studies were limited by the use of nonquantitative methods for estimation of Bz receptor binding, the absence of medication-free subjects, psychiatric comorbidity within PD patients, and/or the use of diseased patients for comparison groups. SPECT iomazenil quantitation of Bz receptor binding, comparing volumes of distribution of receptor (related to the ratio of receptor number and affinity) in patients with PD and controls resulted in a reduction in Bz receptor binding in left hippocampus and precuneus in PD. Elevated levels of anxiety were correlated with decreased binding in the frontal cortex. When PET and [^{11}I]flumazenil were used in the measurement of Bz receptor binding, global decreases in PD patients were found, with the greatest magnitude in the right orbitofrontal cortex and insula. Recently, a decrease was found in Bz receptor binding in prefrontal cortex (area 9) in patients with combat-related PTSD compared to matched healthy controls. These findings were consistent with animal studies of stress showing decreased binding in the frontal lobe and hippocampus.

c. Cholecystokinin The neuropeptide CCK has been shown to be anxiogenic in human subjects. In healthy volunteers intravenous administration of CCK4 (a tetrapeptide that crosses the blood–brain barrier more readily than CCK8) has been shown to induce severe anxiety or short-lived panic attacks. The anxiogenic effect of CCK was blocked by the Bz lorazepam, although this may merely be pharmacological opposition and not true antagonism. PD patients were found to be more sensitive to the anxiogenic effects of CCK4 and a closely related peptide, pentagastrin. These effects were blocked by CCK antagonists. Imipramine antagonizes the panicogenic effects of CCK4 in PD patients. The mechanism is unclear but may relate to the ability of imipramine to downregulate β-adrenergic receptors since propranolol antagonizes the anxiogenic actions of CCK4. Levels of CCK in the CSF are lower in PD patients than in normal subjects, indicating the possibility of enhanced function of CCK receptors. The mechanism responsible for the enhanced sensitivity to CCK4 has not been elucidated. Patients may have an elevated production or turnover of CCK or increased sensitivity of CCK receptors. Since CCK has important functional interactions with other systems implicated in anxiety and fear (noradrenergic, dopaminergic, and Bz), these interactions need to be evaluated in PD patients. CCKB receptor antagonists are now being tested as antipanic drugs.

d. Opiates Only a few studies have examined opiate function in PTSD. Some studies report lower AM and PM plasma β-endorphin levels. In studies that found no differences in plasma levels of methionine enkephalin, degradation half-life was significantly higher in the PTSD group. In a pharmacological challenge of the opiate system, PTSD patients showed reduced pain sensitivity compared to veterans without PTSD following exposure to a combat film. This was reversible by the opiate antagonist naloxone and could be explained by increased release of endogenous opiates with stress in PTSD. Levels of endogenous opiates in cerebrospinal fluid were found to be elevated in combat-related PTSD. Symptoms of avoidance and numbing are thought to be related to a dysregulation of opioid systems in PTSD. The use of opiates in chronic PTSD may also represent a form of

self-medication. Animal studies have shown that opiates, by acting to decrease firing of LC neurons, are powerful suppressants of central and peripheral noradrenergic activity. If, as suggested earlier, some PTSD symptomatology is mediated by noradrenergic hyperactivity, then opiates may serve to "treat" or dampen down that hypersensitivity and accompanying symptoms. On the other hand, during opiate withdrawal when opiates are decreased and noradrenergic activity is increased, PTSD symptoms may become acutely exacerbated. In fact, many symptoms of PTSD are similar to those seen during opiate withdrawal.

e. Neuropeptide Y Low doses of NPY administered intraventricularly have proven to have anxiolytic effects in several animal models of anxiety. Disturbed NPY transmission might have a role in symptoms of anxiety. In PD elevated plasma levels of NPY have been found. In PTSD, lower levels were found.

f. Thyroid In the early part of the twentieth century, Graves first described cases of hyperactivity of the thyroid gland, with neuropsychiatric symptoms of anxiety, palpitations, breathing difficulties, and rapid heart rate, in a series of cases of individuals who were recently exposed to traumatic stress. Although the relationship between stress, neuropsychiatric symptoms, and thyroid disease has continued to be clinically observed, to date there have been no systematic epidemiologic studies of the relationship between stress and thyroid disease. Thyroid hormone has a range of actions, including energy utilization within the cell (important in stress), and stress results in long-lived elevations in thyroid hormone. Elevated levels of T3 were reported in patients with combat-related PTSD.

B. Panicogenic Effects of Lactate

In the late 1960s an observation was made by Pitts and McClure that intravenous infusion of lactate produced panic anxiety in susceptible individuals but not in normal subjects. Subsequently, the reliability of panic provocation by sodium lactate has been well established. Lactate response appeared to be specific for PD compared with other anxiety disorders and psychiatric conditions. Moreover, treatment of panic with imipramine blocked the effects of lactate.

However, the panicogenic mechanism of lactate has not been established. One theory is based on the fact that systemic alkalosis caused vasoconstriction of cerebral vessels, which in turn induced cerebral ischemia, with an increase in the intracellular lactate:-pyruvate ratio. Furthermore, infused lactate resulted in a rapid passive elevation in the lactate:pyruvate ratio in localized brain regions outside the blood–brain barrier, such as the chemoreceptor zones. These two mechanisms lowered the intracellular pH in medullary chemoreceptors. In PD patients there is dysregulation (greater sensitivity to alterations in pH) in this region; thus, a panic response is triggered. This theory predicts that panic could be triggered in any subject if medullary pH was changed sufficiently.

The limitations of the model include the fact that it is not yet known whether the pH changes in the local circulation are mirrored intracellularly. Physiological effects of sodium bicarbonate have revealed a paradoxical intracellular acidosis, so the same may be true of lactate. There has been no clear evidence that intracellular acidosis initiates neural activity, as the theory requires. Second, the model predicts that hypoxia is a profound stimulus for chemoreceptor stimulation, and hyperventilation is belied by experiments in which removal of CO_2 from inspired air leads to loss of consciousness without anxiety or air hunger.

A second major hypothesis is that lactate's panicogenic effect occurs via the induction of a metabolic alkalosis. Infused lactate is metabolized to bicarbonate that is further metabolized to CO_2, which quickly permeates the central nervous system. This central buildup of CO_2 increases the ventilatory rate via a direct stimulation of ventral medullary chemoreceptors. Increasing brain pCO_2 concentration has been shown to be a profound stimulus for LC activation, which could cause panic via central noradrenergic activation.

Although this lactate–CO_2 theory has considerable appeal, initial studies with the isomer D-lactate indicate that this may not be the whole explanation. This isomer is found to also be panicogenic but is not metabolized to CO_2. Comparisons of the behavioral effects of lactate and bicarbonate infusion demonstrate provocation of panic in susceptible patients; however, bicarbonate is less anxiogenic than lactate. This finding argues against alkalosis alone being the panicogenic stimulus. Stimulation of respiratory centers to produce increased ventilation, hypocapnia, and respiratory alkalosis was the common factor in producing panic by both infusions.

Panic can also be provoked by increases in pCO_2 (hypercapnia). This can be done slowly, such as by rebreathing air or by breathing 5–7% CO_2 in air.

Alternatively, panic attacks can be provoked by breathing only one or two deep breaths of 35% CO_2. Hyperventilation and increased CO_2 hypersensitivity have also been posited as an explanation for symptoms of PD. According to the model, elevated levels of pCO_2 lead to activation of the vagus nerve, which through the nucleus tractus solitarius stimulated the LC as well as hyperventilation. Increased tidal volume drove down pCO_2, with increased respiratory alkalosis, and symptoms of panic. Hyperactive chemoreceptors lead to hyperventilation in order to keep down pCO_2, which results in panic symptomatology. A corollary model to the hyperventilation hypothesis stated that PD patients suffered from a physiologic misinterpretation of a suffocation monitor, which evoked a suffocation alarm system. This produces sudden respiratory distress, followed quickly by hyperventilation, panic, and an urge to flee. This model posited that hypersensitivity to CO_2 is due to the deranged suffocation alarm systems. The central problem with these models is that it is difficult to determine whether hyperventilation is a primary or secondary phenomenon in PD. Also, there is no evidence of hyperventilation at baseline in PD patients. There are many potential panicogens in PD, and there is no evidence that hyperventilation is more robust than other agents such as noradrenergic stimulation with yohimbine.

C. Contributions from Neuroimaging Studies

For an overview of findings in imaging studies see Table III.

1. Structural Neuroimaging

Digital processing of magnetic resonance imaging (MRI) of the brain can quantify three-dimensional volumes of brain structures. Nonquantitive studies found evidence of abnormalities in temporal lobe in patients with PD, and one quantitative study found decreased volume in the hippocampus. A reduction in hippocampal volume has been reported in several studies in patients with PTSD (Fig. 1).

This hippocampal volume reduction has been positively correlated with verbal memory deficits. Considering the role the hippocampus plays in the integration of memory elements, which are stored in primary sensory and secondary association cortical areas at the time of retrieval, these findings suggest a possible neural correlate for symptoms of memory fragmentation and dysfunction in PTSD.

2. Functional Neuroimaging

Functional brain imaging studies have examined brain metabolism and blood flow at rest and during stress/symptom provocation in patients with anxiety disorders. Patterns of regional blood flow that are evoked reflect the engagement of neural structures in fear and anxiety responses. PET has been used to measure the closely related processes of brain metabolism (using radiolabeled glucose or [^{18}F]2-fluoro-2-deoxyglucose) and blood flow (with radiolabeled water or [^{15}O]H_2O), whereas SPECT was used to measure brain blood flow (with [^{99m}Tc]HMPAO). An increase in the function of neurons in a specific area is reflected by an increase in metabolism and a shunting of blood flow toward the area that can be measured with these imaging techniques.

Pharmacologic and cognitive provocation of PTSD symptom has been used in order to identify neural correlates of PTSD symptomatology and of traumatic remembrance in PTSD. Administration of yohimbine (which increases NE release) resulted in increased PTSD symptoms and anxiety in the PTSD group. NE had a U-shaped curve type of effect on brain function, with lower levels of release causing an increase in metabolism and very high levels of release actually causing a decrease in metabolism. Yohimbine causing a relative decrease in metabolism in patients with PTSD in orbitofrontal, temporal, parietal, and prefrontal cortex—all brain areas which receive noradrenergic innervation. Normal controls demonstrated a pattern of increased metabolism in these areas. PTSD patients (but not normals) had decreased hippocampal metabolism with yohimbine. These findings were consistent with an increased release of NE in the brain following yohimbine in PTSD and PET metabolism studies showing an inverse-U relationship between anxiety and cortical function, with low levels of anxiety causing an increase in cortical metabolism and high levels causing a decrease in cortical metabolism.

Several studies have used PET in challenge models that vary from reading narrative scripts to exposing patients to slides or slides and sounds of traumatic material. In these studies [^{15}O]H_2O was used to examine brain blood flow during the cognitive challenge which provoked PTSD symptoms and traumatic remembrance. Control subjects typically demonstrated increased blood flow in anterior cingulate during these conditions. When women with histories of childhood abuse were read personalized scripts of their trauma history, blood flow correlates of exposure

to these scripts showed decreased blood flow in mPFC (areas 24 and 25) and failure of activation in anterior cingulate (area 32), with increased blood flow in posterior cingulate and motor cortex and anterolateral prefrontal cortex. These areas are known to modulate emotion and fear responsiveness through inhibition of amygdala responsiveness. At the same time, these women also had decreased blood flow in the right hippocampus, parietal, and visual association cortex. These findings replicated findings in combat veterans with PTSD exposed to combat-related slides and sound (Fig. 2).

One study found amygdalar activation, but overall findings of amygdalar activation are mixed. These findings point to a network of related regions as mediating symptoms of anxiety. Dysfunction of the

Figure 1 Part of an MRI scan of the hippocampus in a normal control and patient with combat-related PTSD. The hippocampus is visibly smaller in PTSD. Overall, there was an 8% reduction in the right hippocampal volume in PTSD.

mPFC areas may represent a neural correlate of a failure of extinction to fearful stimuli in PTSD. Posterior cingulate plays an important role in visuospatial processing and is therefore an important component of preparation for coping with a physical threat. The posterior cingulate gyrus has functional connections with hippocampus and adjacent cortex, which led to its original classification as part of the limbic brain.

Findings from imaging studies may also be relevant to the failure of extinction to fear responding that is characteristic of PTSD and other anxiety disorders. Following the development of conditioned fear, as in the pairing of a neutral stimulus (bright light, CS) with a fear-inducing stimulus (electric shock, UCS), repeated exposure to the CS alone normally results in the gradual loss of fear responding. Extinction to conditioned fear has been hypothesized to be secondary to the formation of new memories that mask the original conditioned fear memory. The extinguished memory is rapidly reversible following reexposure to the CS–UCS pairing even 1 year after the original period of fear conditioning, suggesting that the fear response did not disappear but was merely inhibited. The extinction is mediated by cortical inhibition of amygdala responsiveness. mPFC has inhibitory connections to the amygdala that play a role in extinction of fear responding. Auditory association cortex (middle temporal gyrus) also has projections to amygdala that seem to be involved in extinction. Anterior cingulate activation represents a ''normal'' brain response to traumatic stimuli that serves to inhibit feelings of fearfulness when there is no true threat. Failure of activation in this area and/or decreased blood flow in adjacent subcallosal gyrus may lead to increased fearfulness that is not appropriate for the context.

In PD activation studies have revealed the involvement of many brain areas, depending on the condition and the paradigm. However, the orbitofrontal cortex/anterior insula and the anterior cingulate are implicated in all the studies and may represent the nodal point between somatic and cognitive symptoms of panic but also any other form of anxiety. Most studies of binding at the Bz–GABA(A) receptor are difficult to interpret because of substantial methodological problems; however, regional and/or global reductions are the most consistent finding in PD.

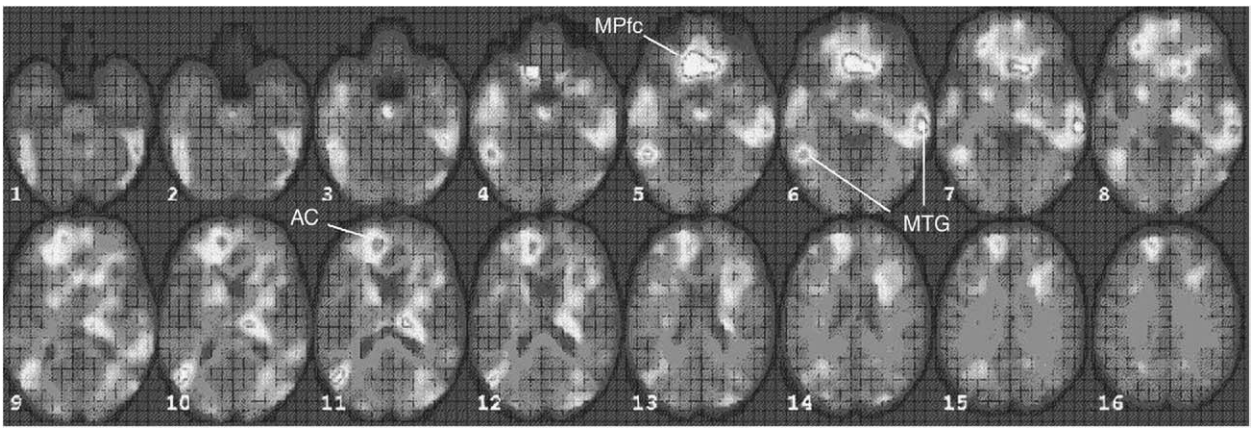

Figure 2 Anxiety response in O^{15} PET scanning in veterans with PTSD during memories of war using audiovisual cues of war. There is decreased blood flow in the medial prefrontal cortex, medial temporal gyrus, and anterior cingulate indicative of a failure of inhibition of limbic structures such as amygdala (areas displayed with z score > 3.00; $p < 0.001$).

IX. A WORKING MODEL FOR THE NEURAL CIRCUITRY OF ANXIETY DISORDERS

Anxiety disorders are characterized by dysfunction of an interrelated neurochemical and neuroanatomical system. PTSD and PD share many biological and phenomenological similarities that allow them to be considered related. Phobic disorders and GAD are still in early stages of investigation. Although phenomenologically they are similar to PTSD and PD, it is premature to include them in a model for human anxiety disorders. PTSD is related more to the deleterious effects of environmental stress, whereas PD is not as clearly related to stress and may be related more to genetic variability in anxiety. In stress-related anxiety disorders (i.e., PTSD), PTSD symptoms as well as cognitive dysfunction associated with PTSD may be linked to hippocampal dysfunction. A model can be created which incorporates informatiom from animal and clinical research relevant to these disorders, keeping in mind that working models are subject to modification with new information, and that generalizations involving causality should be seen as merely speculative when derived from clinical studies that are by their very nature cross sectional. For a schematic model of the neural circuitry see Fig. 3.

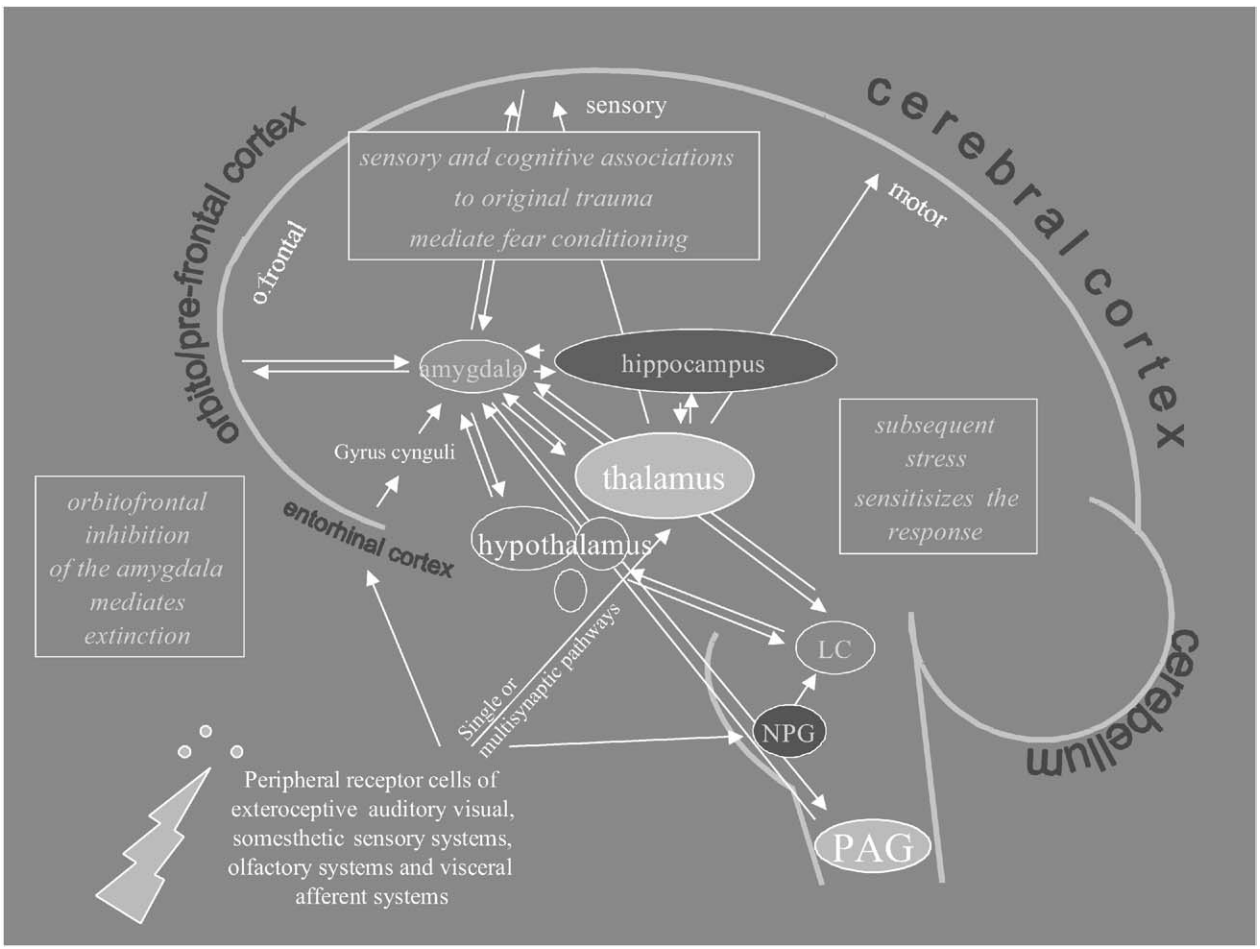

Figure 3 A schematic model of the neural circuits involved in the afferent input of fear- and anxiety-inducing stimuli and the processing of the stimuli. The amygdala plays a pivotal role in the assessment of danger and the response. The LC is a critical component in both afferent and efferent systems, mainly through NE release. The amygdala receives input from PAG, LC, thalamus, hippocampus, association cortices, entorhinal cortex, and visceral pathways. Input from mPFC is involved in determining the significance of fear-producing sensory events, the choice and implementation and the type of behavior, and the extinction of conditioned fear responses. States of stress and fear result in a rapid increase in firing of neurons in the LC, with release of NE transmitter in different target sites in the brain. This results in an increase in attention and vigilance, as well as enhancement of memory recall, which can be life saving in threatening situations. Patients with anxiety disorder, however, develop long-term alterations in the function of this system. The fear response is dependent on previous experience, sensitization, fear conditioning, and extinction of previous fear responses.

A biological model to explain pathological human anxiety should involve both brain stem circuits and cortical and subcortical regions involved in memory and modulation of emotion. The evidence is consistent with chronically increased function of neurochemical systems (CRF and NE) that mediate the fear response in anxiety disorders. Although it is clear that activity at the central portion of the HPA axis is increased, responses at other portions of the HPA axis, including the pituitary and adrenals, and the long-term effects on the hormonal final product (cortisol), are less clear. Increased NE and CRF released in the brain act on specific brain areas, including hippocampus, mPFC, temporal and parietal cortex, and cingulate, that are dysfunctional in human anxiety disorders. Other neurochemical systems, including Bzs, opiates, dopamine, CCK, and NPY, also play a role.

Emotion is a phenomenon uniquely associated with our species. Moving up in terms of species complexity, the most salient change in brain architecture is the massive increase in cortical gray matter, especially frontal cortex. It is therefore not surprising that this frontal lobe plays a role in modulation of emotionality. The medial portion of prefrontal cortex serves to inhibit more primitive limbic processing and thus has an important role in modulation of human emotion in general and also in fear responsivity and anxiety. Amygdala and LC both play a pivotal role in fear processing and anxiety. Hippocampal dysfunction also plays an important role in the development of symptoms of anxiety. mPFC (areas 24 and 25) and anterior cingulate (area 32) have inhibitory inputs that decrease amygdala responsiveness and have been hypothesized to mediate extinction of fear responding. Activation of this area has been shown to be a normal response to stress or increased emotionality. Dysfunction in this area may mediate increased emotionality and failure of extinction to fear inducing cues in anxiety disorders. Evidence to support this idea includes failure of normal activation in this area with yohimbine-induced provocation of anxiety in both PTSD and PD and failure of activation/decreased blood flow with traumatic cue exposure in PTSD. Again, potentiated release of NE with stressors in PTSD and PD is expected to be associated with a relative decrease in function of neurons in this area.

Studies performed to date are encouraging because many findings from animal studies have been successfully applied to human anxiety disorders. The past decade has seen an exciting expansion of research in the field of fear and anxiety. Future research will need to continue to apply findings from the revolution in neuroscience to further understand fear processing, anxiety, and human anxiety disorders.

Aphasia

MARTHA TAYLOR SARNO
New York University School of Medicine

GLOSSARY

anosognosia A lack of awareness and recognition of a condition or disease.

apraxia of speech An articulatory deficit characterized by awkward and labored articulation, sound distortions, and substitutions in the absence of impaired strength or coordination of the speech organs.

dysarthria A speech impairment resulting from pathology of the motor speech system in which the articulation, rate, resonance, loudness, voice quality, or other acoustic aspect of speech are affected.

neologism A meaningless word.

phonology The system of speech sounds.

prosody The melody, stress, and intonation of speech.

Aphasia is an acquired communication disorder caused by damage to the brain that is manifest in an impairment of the ability to transmit or exchange information and feelings, especially in speaking, and it may also affect writing, comprehension of spoken language, and reading. There are more than 1 million individuals in the United States with aphasia and approximately 84,000 new cases each year. The aphasia population comprises approximately 15% of the adult speech–language impaired population. Aphasia is most prevalent among individuals older than the age of 65 who have suffered a stroke, and in a smaller number it may be the result of head trauma or tumors. Aphasia is also sometimes present in the early stages of Alzheimer's disease.

I. HISTORICAL ASPECTS OF APHASIA

The cerebral lesions that cause aphasia are generally in the left cerebral hemisphere. Some early Greek medical literature noted speech impairment associated with cerebral damage but little was made of the connection between aphasia and the left cerebral hemisphere until the late 19th century when Paul Broca, a surgeon and anthropologist, reported the autopsy findings of the brains of two patients with aphasia. Twenty-five years before Broca made his observations known, Gustav Dax published a paper written by his father, Marc Dax, in which he presented a mass of evidence supporting the discovery that aphasia was due to lesions of the left hemisphere.

Efforts to localize aphasia in its many forms continued throughout the 19th and 20th centuries by medical scientists such as Wernicke and Lichtheim in Germany, Pierre Marie in France, and Henry Head in Britain. Head took issue with the idea that specific areas of the cortex were responsible for the complex functions necessary for human communication. Among those who contributed to the understanding of aphasia in the early 20th century were Kurt Goldstein, a German neurologist; Weisenburg and McBride in the United States; Alajouanine, Ombredane, and Durand in France; and Roman Jakobson, a noted linguist who had emigrated to the United States.

In the early 1960s, Norman Geschwind, a neurologist at the Boston Veteran's Administration Hospital and director of its aphasia center, reinterpreted the works of earlier investigators and stimulated renewed interest in the study of aphasia. His interpretation of aphasia as the result of neural disconnection and concurrent advances in radiologic technology

facilitated the neuroanatomical study of aphasia. In this same era, D. Frank Benson (1967) reported findings from one of the first studies that systematically correlated neuroimaging with the symptoms of aphasia. Benson's work provided radiologic confirmation of the distinction between posterior left hemisphere lesions resulting in "fluent" aphasia and posterior lesions with "nonfluent" aphasia using radiologic data. The emergence of such measures as computerized tomography, magnetic resonance imaging, single-emission computed spectography, positron emission tomography, and functional MRI in the last half of the 20th century increased the understanding of the relationships between lesion localization and the signs and symptoms of aphasia. Although the evolution of neuroimaging techniques has had a great impact on the study of the neural basis of aphasia, the autopsy studies that preceded them have withstood the test of time (Fig. 1).

The contemporary study of aphasia has been influenced by the involvement of many disciplines including the late 20th century emergence of speech–language pathology, neuropsychology, behavioral neurology, and neurolinguistics. Each field has brought its particular perspective, expertise, and body of knowledge to bear on the study of aphasia. The founding of the Academy of Aphasia in 1962 and the publication in this period of new journals that address issues bearing on the study of aphasia, such as *Cortex*, *Brain and Language*, and *Aphasiology*, reflected an increased interest in the condition.

II. SYMPTOMS AND CLASSIFICATION

A. The Nature of Communication Behavior

When an individual generates an idea that he or she wants to verbalize, certain physiologic and acoustic events must take place in order for it to be transformed into words and sentences. The message is converted into linguistic form at the listener's end. The listener, in turn, fits the auditory information into a sequence of words and sentences that are ultimately understood. The system of symbols that are strung together into sentences expressing our thoughts and the understanding of those messages is referred to as language.

Language is made up of phonology, the system of speech sounds that are combined to form the syllables that comprise words; a lexical system, or vocabulary of words, used to communicate information; the grammar, or syntax, that determines the sequence of words that are acceptable as utterances; and semantics, or the meaning system. When communicating using speech, we also employ stress and intonation, referred to as prosody, to help make distinctions among questions, statements, expressions of emotions, shock, exclamation, and so forth.

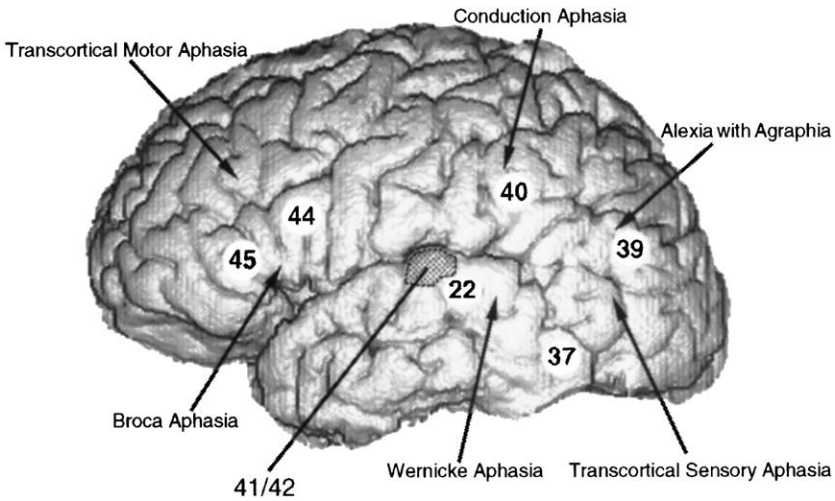

Figure 1 Lateral view of the left hemisphere of a normal adult brain using thin contiguous MR slices and Brainvox. Brodmann's areas 44 and 45 correspond to the classic Broca's area, and area 22 to Wernicke's area. Areas 41 and 42 correspond to the primary auditory cortex; these are located in the depth of the sylvian fissure and cannot be seen in a lateral view of the brain. Area 40 is the supramarginal gyrus; area 39 is the angular gyrus. Area 37, principally located in the posterior sector of the second and third temporal gyrus, does not have correspondence in gyral nomenclature. [reproduced with permission from Damasio, H. (1998). Neuroanatomical Correlates of the Aphasias. In *Acquired Aphasia*, 3rd ed., (M. T. Sarno, ed.), p. 45. Academic Press, San Diego.]

B. Types of Aphasia

Aphasia is generally of sudden onset and is sometimes present during the acute phase of an illness and then disappears in a matter of hours or days. In this context, the term aphasia is used when its symptoms persist for more than 1 month.

An exception to the typically sudden onset of aphasia occurs in primary progressive aphasia (PPA), a diagnosis that is being made with increasing frequency. PPA is usually gradual in onset, sometimes emerging over a period of years, and may evolve into a dementia or Alzheimer's disease.

Individuals with aphasia may show evidence of impairment in any or all language systems ranging from a virtually total inability to communicate using the speech code, but with preserved ability to communicate through the use of gestures, facial expression, and pantomime, to a mild, barely perceptible language impairment.

There is a group of distinct aphasia syndromes that have a high correlation with the location of anatomical lesions. However, it is not always possible to classify patients according to these syndromes. In fact, estimates of the proportion of cases that can be unambiguously classified range from 30 to 80%.

The determination of the aphasia syndrome that best fits depends primarily on identification of the characteristics of speech production combined with a judgment of fluency. Speech output that is hesitant, awkward, interrupted, and produced with effort is referred to as nonfluent aphasia, in contrast to speech produced with ease of articulation, at a normal rate, with preserved flow and melody but that may be lacking in coherence, which is referred to as fluent aphasia. Fluency judgments are generally derived from an extended conversation with a patient.

1. Fluent Aphasia

Fluent aphasia is characterized by fluent speech produced at a normal rate and melody, accompanied by impaired auditory comprehension. It is generally associated with a lesion in the vicinity of the posterior portion of the first temporal gyrus of the left hemisphere. When fluent aphasia is severe, the individual may substitute sounds and words with such frequency and magnitude that speech may be rendered meaningless. Some produce nonsense words, referred to as neologisms or jargon aphasia. Those with fluent aphasia tend to have greatest difficulty retrieving the substantive parts of speech (i.e., nouns and verbs) and also tend to manifest impaired awareness. They do not generally evidence paralysis or weakness of the right arm and leg.

a. Wernicke's Aphasia The most common variety of fluent aphasia is Wernicke's aphasia, characterized by fluently articulated speech sometimes marked by word substitutions and accompanied by impaired auditory comprehension. Individuals with Wernicke's aphasia may produce what appear to be complete utterances, use complex verb forms, and speak at a rate greater than normal that is sometimes referred to as press of speech. Their communication behavior, profile of language impairment, and lack of physical impairment may lead to a psychiatric diagnosis (Fig. 2).

b. Conduction Aphasia Conduction aphasia is also one of the fluent aphasias, but unlike Wernicke's aphasia, auditory comprehension is generally more intact. A deficit of word and sentence repetition prevails and is marked by phonemic paraphasic errors—that is, the production of inappropriate, although precisely articulated speech sounds.

c. Transcortical Sensory Aphasia Individuals with transcortical sensory aphasia have fluent speech output marked by substitutions of words and severe impairment of aural comprehension. Transcortical sensory aphasia is distinguishable from Wernicke's aphasia by a preserved repetition performance. Also, those with transcortical sensory aphasia often "echo" questions, a behavior referred to as "echolalia."

d. Anomic Aphasia The primary characteristic of anomic aphasia is a pervasive difficulty in word retrieval in the presence of fluent, well-articulated, and grammatically correct output and intact auditory comprehension. Anomic aphasia is often the mildest form of aphasia and is sometimes the recovery end point of other types of aphasia. It may also characterize the early stages of primary progressive aphasia.

2. Nonfluent Aphasia

Nonfluent aphasia is characterized by limited vocabulary, sometimes restricted to nouns, verbs, adverbs, and adjectives; slow, hesitant speech production, awkward articulation; and a restricted use of grammar with normal or near-normal auditory comprehension. Individuals with nonfluent aphasia are often referred to as agrammatic since they tend to have a pervasive

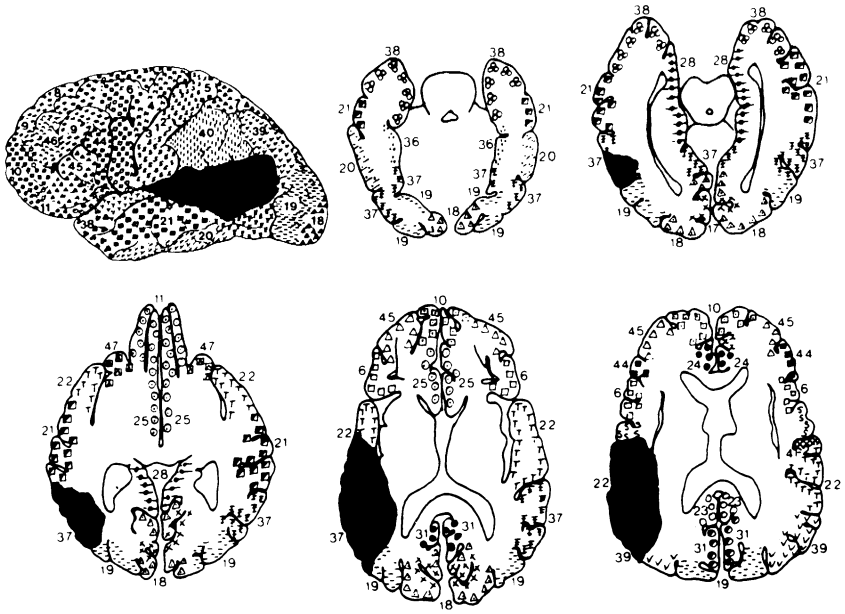

Figure 2 Magnetic resonance template from a patient with Wernicke's aphasia (WG0988). The lesion involved the posterior sector of the left superior and middle temporal gyri but did not extend into the parietal lobe. [reproduced with permission from Damasio, H. (1998). Neuroanatomical Correlates of the Aphasias. In *Acquired Aphasia*, 3rd ed., (M. T. Sarno, ed.), p. 50. Academic Press, San Diego.]

grammatical impairment as the result of difficulty in retrieving less substantive parts of speech (i.e., prepositions, articles, and pronouns).

Nonfluent aphasia is usually associated with a high degree of deficit awareness and impaired motor function on the right side of the body (hemiplegia–paresis). The intact deficit awareness generally present in nonfluent aphasia may produce a significant degree of frustration.

a. Broca's Aphasia The most common type of nonfluent aphasia is Broca's aphasia, which is characterized by awkward articulation, restricted vocabulary, and grammatical forms in the presence of normal or near-normal auditory comprehension. Writing performance generally mirrors speech production and reading may be less impaired than speech and writing. In the majority of individuals with Broca's aphasia, awareness of deficit is good and paralysis on the right side of the body (hemiplegia) is present (Fig. 3).

3. Apraxia of Speech

The term apraxia refers to an impairment in the ability to carry out physical movements in the absence of paralysis or sensory impairment to the body part. Apraxia of speech (AOS), a term synonymous with verbal apraxia and speech dyspraxia, is seldom manifest independent of Broca's aphasia, however mild. It is an articulatory deficit characterized by awkward and labored articulation, distortion of phoneme production, and sound substitutions in the absence of impaired strength or coordination of the motor speech system. Unlike individuals with dysarthria, an impairment of speech associated with pathology of the motor speech system, individuals with AOS do not have difficulty performing nonspeech movements of the oral musculature.

a. Transcortical Motor Aphasia This type of aphasia is characterized by nonfluent speech, intact repetition, impaired auditory comprehension, and a tendency to perseverate and substitute both sounds and words.

4. Global Aphasia

When aphasia is severe in all modes of communication, rendering a person markedly restricted in participating in verbal interactions, it is referred to as global aphasia. Individuals who manifest global aphasia are often able to produce serial or automatic speech (i.e., counting in series, reciting the days of the week, reciting prayers, singing the words to songs, and using common everyday greetings). Global aphasia is generally associated with extensive cerebral damage, often in both hemispheres.

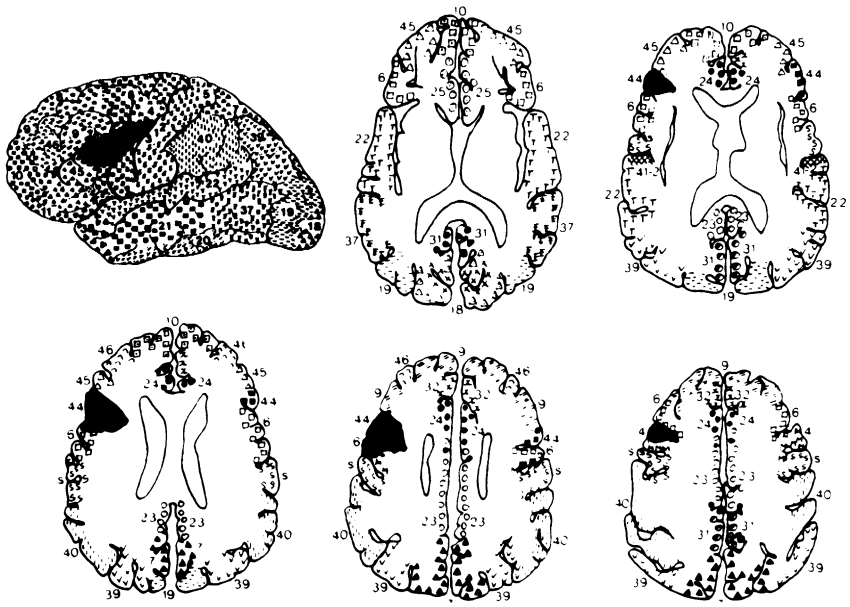

Figure 3 Computerized tomographic template from a patient with Broca's aphasia (MW0018). The lesion involved only the superior sector of Broca's area (area 44) and the premotor region (area 6) immediately above it. [reproduced with permission from Damasio, H. (1998). Neuroanatomical Correlates of the Aphasias. In *Acquired Aphasia*, 3rd ed., (M. T. Sarno, ed.), p. 55. Academic Press, San Diego.]

5. Primary Progressive Aphasia

The onset of language impairment in primary progressive aphasia (PPA), unlike the classic aphasia syndromes, begins gradually. It is often associated with degenerative disease, such as spongiform encephalopathies and Pick's disease. Typically, the condition begins with the gradual onset of word retrieval difficulties, especially for nouns and/or verbs. Although individuals with PPA may appear to be free of cognitive deficits for some time, language deficits other than word-finding difficulties, especially the cognitive symptoms of dementia, usually begin to emerge over time.

C. Classification Nomenclature

Different investigators and clinicians have used different terms to classify the aphasia syndromes, often reflecting a difference in perspective. For example, the classic designation expressive and receptive aphasia was introduced by clinicians Weisenburg and McBride (1935), whereas Luria used the terms efferent, afferent motor, and dynamic aphasia, reflecting a physiological approach. The classification scheme of Goodglass and Kaplan (1972) is currently used (Table I).

III. THE ASSESSMENT OF APHASIA

A. History of Aphasia Assessment

Formal aphasia testing was relatively unknown until the early l920 s when Henry Head and Weisenburg and McBride published the first aphasia tests. Until then, aphasia was assessed primarily on the basis of clinical observations and examination.

B. Purpose of Assessment

The purpose of aphasia assessment varies according to the demands of particular clinical settings and includes the need to

1. Screen patients in the hospital setting in order to determine the presence/absence of aphasia and the need for comprehensive evaluation
2. Perform an in-depth evaluation in order to determine a diagnosis/clinical description
3. Identify areas of deficit and preserved performance for rehabilitation assessment
4. Make recommendations for treatment if indicated
5. Develop a treatment plan
6. Render a prognosis

Table I
Classification Systems Schemes[a]

Boston	Head	Goldstein	Weisenberg and Mcbride	Luria	Wepman
Anomia	Nominal aphasia	Amnesic aphasia	Amnesic aphasia	Acoustic–amnestic aphasia	Semantic aphasia
Wernicke's aphasia	Syntactic aphasia	Sensory aphasia	Predominately receptive aphasia	Acoustic aphasia	Pragmatic aphasia
Broca's aphasia	Verbal aphasia	Motor aphasia	Predominately expressive aphasia	Efferent motor aphasia	Syntactic aphasia
Conduction aphasia		Central aphasia		Afferent motor aphasia	
			Expressive–receptive aphasia		
Transcortical sensory aphasia (isolated speech area syndrome)					
Transcortical motor aphasia				Dynamic aphasia

The examiner includes an assessment of the individual's motivation, expectations, psychosocial status, and ability to cope with the demands of the rehabilitation process. Baseline measures obtained at the first assessment are used to measure progress over time.

In addition to the described general measures of aphasia, tests of specific linguistic performance, such as the use of syntax, vocabulary, frequency of word usage, pauses, hesitations, length of utterances, and rate of speech, are derived from a free speech sample or a narrative elicited in response to the tasks of describing a picture or telling a story.

C. Aphasia Test Requirements

Adequate measures of aphasia adhere to the same general requirements of all tests; that is, they must be reliable, valid, and standardized. Several issues arise in the design of tests for use with the brain damaged, especially those with aphasia, including the range of item difficulty, overlap of aphasia examinations with intelligence tests, and the effectiveness of the test in measuring progress.

D. Aphasia Measures

Comprehensive language tests designed to assess aphasia are usually structured around specific domains of performance: visual confrontation naming; a spontaneous or conversational speech sample that is analyzed for fluency, articulation, phrase length, prosody, word substitutions and omissions; repetition of digits, single words, multisyllabic words, and sentences of increasing length and complexity; comprehension of single words and sentences that require yes–no responses and pointing on command; word retrieval; reading and writing.

Some of the most widely used aphasia measures are the Boston Diagnostic Aphasia Examination, the Neurosensory Center Comprehensive Examination for Aphasia, the Western Aphasia Battery, the Minnesota Test for Differential Diagnosis of Aphasia, and the Multilingual Aphasia Examination.

Screening tests include the Sklar Aphasia Scale and the Reitan Aphasia Screening test. Tests of specific language performance include the Shewan Auditory Comprehension Test for Sentences, the Boston Naming Test, Controlled Oral Word Association, the Discourse Comprehension Test, the Reporter's Test, and the Token Test. A listing of aphasia assessment instruments is provided in Table II.

E. Functional Communication Assessment

In addition to measuring specific linguistic performance, a comprehensive aphasia assessment also

Table II
Differential Diagnosis of the Main Types of Aphasia[a]

Type of aphasia	Speech	Comprehension	Capacity for repetition	Other signs	Region affected
Broca's	Nonfluent; effortful	Intact or largely preserved	Impaired	Right hemiparesis (arm and leg); patient aware of defect and may be depressed	Left frontal (lower, posterior)
Wernicke's	Fluent; abundant; well-articulated; melodic	Impaired	Impaired	No motor signs; patient may be anxious, agitated, euphoric, or paranoid	Left temporal (posterior and superior)
Conduction	Fluent with some articulatory deficits	Intact or largely preserved	Impaired	Often none; patient may have cortical sensory loss or weakness in right arm; right-sided facial weakness may be seen	Left supramarginal gyrus or left auditory cortex and insula
Global	Scant; nonfluent	Impaired	Impaired	Right hemiplegia may be present without hemiplegia	With hemiplegia: massive left perisylvian lesion Without hemiplegia: separate frontal and temperoparietal damage
Transcortical					
motor	Nonfluent; explosive	Intact or largely preserved	Intact or largely preserved	—	Anterior or superior to Broca's area; may involve part of Broca's area
Sensory	Fluent; scant	Impaired	Intact or largely preserved	—	Area surrounding Wernicke's area, posteriorly or interiorly
Atypical					
"Basal ganglia"	Dysarthric, but often fluent	Impaired	May be intact or Impaired	Right hemiparesis (arm and leg)	Head of caudate nucleus; anterior limb of capsule
Thalamus	Fluent; may be logorrheic	Impaired	Intact or largely preserved	Attentional and memory defects in acute phase	Anterolateral thalamus

includes supplementary measures of "functional communication."

This category of measures provides information about the individual's actual use of residual communication skills in everyday life, in contrast to performance, which is a response to the presentation of specific tasks in a structured testing situation. Ordinary everyday behaviors, such as making telephone calls, using everyday greetings, and reading the newspaper, have been noted to reflect another dimension of communication behavior that is often not elicited in the performance of a specific, structured task. The notion of a "functional" dimension of communication behavior emerged from the rehabilitation medicine setting in the late 1950s when it was observed that many patients with aphasia communicated with different degrees of skill depending on whether they were communicating in a natural, interactive speaking situation or in structured, task-oriented conditions.

Since then, many rating scales designed to assess the functional communication dimension of aphasia have been published, including the Functional

disorder. Study results differ as to whether or not the older, more frequently used language is more preserved or whether there is little difference in the accessibility of an individual's primary and secondary languages.

Several tests have been translated or adapted for use with bilingual patients and are listed in Table III. The Multilingual Aphasia Examination (MAE) was designed to provide fully equivalent forms in several languages but best results are obtained when it is administered by someone fluent in both languages (Table IV).

G. Other Factors

Aphasia test results can be affected by many nonlanguage factors that need to be considered in the interpretation of test findings. These include acute confusion, agitation, drowsiness, depression, distractibility, lack of cooperation, and attention deficits.

Given the complexity and broad scope of human communication that encompasses both verbal and nonverbal domains (i.e., facial expression and body language), aphasia tests cannot be sufficiently comprehensive or sensitive to the full impact of aphasia on communication behavior. The interpretation of aphasia test results requires an interpretation of the findings in the context of the individual's premorbid communication functioning, his or her perceived impairment, compensatory skills, educational and vocational history, and overall psychosocial status. Most important, the unique, personal nature of communication behavior makes it difficult to make decisions regarding diagnosis, classification, and rehabilitation management based on test findings alone.

H. Related Disorders

Certain associated disorders are generally present in the majority of individuals with aphasia. These include deficits in writing, reading, and calculation. Patients with Broca's aphasia, for example, tend to have difficulty with prepositions, articles, and conjunctions not only in speaking but also when writing or reading, that may range from mild to severe. This include difficulty reading aloud, reading certain parts of speech, greater ease reading longer than shorter words, confusion over word meanings (i.e., reading the word "wife" for "sister"), difficulty copying letters, and writing small words or words with a low frequency of occurrence. Letter deletions, substitutions, and additions may also be present. Those with calculation disorders in addition to aphasia may show deficits in all four basic arithmetic operations.

1. Peripheral Field Deficits

A common physical consequence of damage to the brain is visual deficits involving the peripheral field of vision. The peripheral fields of vision refer to what we see out of the "corners" of our eyes when looking straight ahead. In the case of someone with a left hemisphere cerebral lesion, the individual may have absent vision in the right peripheral field of both eyes and this can further complicate the reading process for someone with aphasia.

I. Intelligence and Aphasia

Aphasiologists continue to debate the relationship between aphasia and intelligence. The boundaries of cognition and language are difficult to determine. Some argue that aphasia is simply a component of the cognitive system. Others view thought and language as independent of each other. Cognitive slowing (i.e., a greater than normal amount of time required to perform cognitive processing) decreased activation and initiation, and response latencies, deficits of spatial relations, abstract reasoning, and visual perception have all been identified as symptoms that may be present in aphasia. Some of these may be coincidental to the anatomical proximity of cerebral areas that govern language and cognition.

From an operational perspective, clinicians generally view aphasia as a language processing disorder that is not a thinking disorder. Those with aphasia often state that they know what they want to say but cannot adequately access language. This dichotomy can be observed in the deaf population, in which normal thought processing is present but the ability to convert thought to language is impaired.

The term anosagnosia refers to a lack of awareness and recognition of a condition or disease and is sometimes present in individuals with aphasia.

J. Artistry and Aphasia

Aphasia affects performance in the arts in different ways. Musical skill is not always affected, probably owing to its cerebral control areas being located in the

right rather than left hemisphere. However, among talented musicians there appears to be different representation in the brain for musical abilities.

In the visual arts, the average individual appears to lose some ability but the very talented continue to function without apparent difficulty. This is not the case among professional writers, in whom aphasia has a profound effect on performance.

K. Aging and Aphasia

Some language changes that are characteristic of aphasia are also present in the normal elderly. For example, the most frequently reported age-related language changes in the normal elderly are word finding difficulties and the comprehension of complex sentences.

Elderly individuals with Broca's aphasia, on average tend to be significantly younger than the median age of people with Wernickes aphasia. Ninety-five percent of aphasias in individuals younger than 30 years of age are of the nonfluent type, whereas only 45% of aphasias are nonfluent in individuals over the age of 60. Results of studies addressing the predictive effect of age on prognosis for recovery are controversial.

L. Acquired Aphasia in Children

Use of the term aphasia has unfortunately been applied to children who have not yet developed age-appropriate language skills. The term developmental aphasia is often used for this population and is more appropriate.

Acquired aphasia in children differs from that in adults in several important ways. When aphasia is acquired in childhood, the child's stage of both central nervous system development and language development at the time of brain damage must be considered. In adults an assumption is made that language was fully developed at the time of disruption, whereas in children a determination must be made as to which of the observed deficits represent aphasia and which represent aspects of language that have not yet emerged.

Children with acquired aphasia generally recover more rapidly and completely than adults. However, there is no single correlation between age at lesion onset and outcome. Furthermore, long-term studies suggest that residual and long-standing linguistic symptoms appear to be present in many children who have acquired aphasia.

M. Aphasia Secondary to Traumatic Head Injury

The majority of patients have been in vehicular accidents (closed head injuries), with a smaller number receiving gunshot or other penetrating wounds (open head injury). Unlike the pathophysiology of stroke, the majority of those who have suffered traumatic head injury do not have focal cerebral lesions but suffer diffuse injury to the cerebral white matter that is apparently the result of shearing and stretching of nerve fibers at the moment of impact.

Classic aphasia symptoms as a result of traumatic head injury are not uncommon, especially when there is a history of loss of consciousness. A characteristic of acute aphasia after trauma is the pervasiveness of anomia. Nonaphasic language processing deficits are a common finding in the closed head injury population. It is generally reported that aphasia secondary to head injury has a better prognosis for recovery than aphasia secondary to stroke.

N. Psychosocial Aspects of Aphasia

The psychosocial consequences of aphasia represent one of the most significant effects of the condition since communication using language, especially speech, is one of the most fundamental of human behaviors. The effect of aphasia on the individual's sense of self, identity, and quality of life is considerable. The ability to initiate and maintain personal relationships, which are dependent on communication, often leads to social isolation for the person with aphasia. Generally, those with nonfluent disorders tend to be more aware, frustrated, and depressed than those with aphasia of the fluent type.

The psychological reactions to aphasia are believed to be influenced to some degree by premorbid personality, level of achievement, and values. As a result of its negative effect on interpersonal activity and quality of life, aphasia is frequently referred to as a social disability. By far the most commonly mentioned psychological reaction is depression. Difficulty in coping with being socially different, feelings of loss, grief, and lowered self-esteem are also pervasive. Family members also suffer from the effects of role changes, caregiving, the impact on the family's sources of gratification, and difficulties in communication.

O. The Natural Course of Aphasia

When aphasia has persisted for several months, a complete recovery to a premorbid level of communication function is unlikely. The temporal course of aphasia from its sudden onset, acute stage, and subsequent phases of recovery evolves along separate pathways depending on whether one is referring to the individual's communication skills, psychological state, social functioning, compensatory skill level, or level of adjustment.

In the period immediately following onset, a degree of natural recovery referred to as spontaneous recovery takes place in the majority of individuals. There is a lack of concensus as to how long this period lasts, ranging from 2 to 6 months postonset.

It is generally agreed that, with some exceptions, major improvements in communication occur in the first 12–24 months following onset. Gradual changes, however, have been reported for many years thereafter, especially in compensatory, alternative skills that are used more effectively over time.

Age, gender, education, and handedness do not appear to affect recovery. Comprehension tends to recover more than expressive communication. Some individuals recover many communication skills but are left with an anomia. Several studies report that for the more severe aphasias recovery of communication skills begins later than for the mild and moderately impaired.

P. Recovery and Rehabilitation

1. History of Aphasia Rehabilitation

Reports of recovery of function were documented as early as the 16th century. In the late 19th and early 20th centuries, the literature related to the rehabilitation of aphasia was almost exclusively in German. Much of this was the result of World War I experience when rehabilitation centers for the brain injured were established particularly in Germany. During World War II, several specialized, comprehensive programs were developed in military medical centers in the United States for veterans with aphasia secondary to head injuries. In the period immediately following World War II, concurrent with the birth of rehabilitation medicine as a medical specialty and the emergence of speech–language pathology as a health-related profession, treatment services for civilians with aphasia began to emerge.

2. Approaches to Aphasia Rehabilitation

Treatment approaches have generally followed one of two models: a substitute skill model or a direct treatment model. Both models are based on the assumption that the processes that subserve normal performance need to be understood if rehabilitation is to succeed. Treatment methods are categorized according to whether they are primarily indirect stimulation–facilitation or direct, structured, and pedagogic in nature. Comprehensive, specialized treatment programs for aphasia generally offer both individual and group therapy using a multimodal approach depending on language symptoms and psychosocial needs.

A primary goal in the management of aphasia is to train the individual to use communication strategies appropriate to the type and severity of impairment in order to substitute or circumvent impaired language processing. However, aphasia rehabilitation goes beyond the development of communication strategies by helping the person and his or her intimates facilitate communication, enhance social interaction, and adjust to the alterations and limitations imposed by the disability. This social disability model considers all the factors that contribute to an individual's life experience, value systems, expectations, needs for fulfillment, level of activation and initiation, social isolation, physical endurance, associated physical and neuropsychological deficits, and emotional state in the intervention process.

Professional responsibility for the language rehabilitation of the individual with aphasia has traditionally been the domain of the speech–language pathologist. In many cases, effective intervention requires a team of several health professionals, including neuropsychologists, occupational therapists, physical therapists, social workers, and vocational counselors. These services are usually available in rehabilitation medicine facilities and centers specializing in the rehabilitation of communicative disorders.

Those experienced in the rehabilitation of aphasia generally agree that no single technique or approach can ameliorate aphasia completely once it is established. Therefore, rehabilitation approaches tend to be eclectic and include a broad spectrum of techniques. Computers are frequently used as a facilitation and training tool for the restoration of language skills by reinforcing through the provision of feedback and frequent repetition and practice. Software designed specifically for the rehabilitation of aphasia and/or facilitation is available. Alternative/augmentative systems are also used for selected individuals.

Meta-analyses of the efficacy of aphasia treatment reported by Robey and Whurr *et al*. indicated (i) that clinical outcomes showed a clear superiority in the performance of those who received treatment by a speech–language pathologist; (ii) the more intensive the treatment, the greater the change; (iii) the outcome is best when treatment is begun in the acute stage of recovery; (iv) treatment for the moderately severe and severe can have a major impact when it is begun in the chronic stage; and (v) treatment in excess of 2 hr per week yields greater gains than less intensive treatment.

Aphasia rehabilitation is viewed as a process of patient management in the broadest sense. The process is complex and encompasses many domains ranging from the neurolinguistic and cognitive to the pragmatic, functional, emotional, and social. As a result, despite several decades of clinical research addressing intervention issues, there is no defined philosophy of aphasia rehabilitation.

Not all individuals with aphasia have access to rehabilitation services, especially in the currently constrained health service delivery situation. As a result, there is a critical need for access to information about aphasia, guidelines and training for the provision of treatment at home by family members, and access to social opportunities and peer support.

A movement to develop advocacy/educational organizations for people with aphasia began in Finland in 1971, followed by Germany in 1978, the United Kingdom in 1980, Sweden in 1981, and Montreal, Quebec, in 1988. In the United States, the National Aphasia Association was founded in 1987 as an advocacy organization that sponsors a national network of aphasia support groups called aphasia community groups, provides educational publications about aphasia, maintains a website (www@aphasia.org), and sponsors conferences and newsletters.

Apraxia

KENNETH M. HEILMAN and LESLIE J. GONZALEZ-ROTHI
University of Florida College of Medicine

GLOSSARY

apraxia A disorder of implementing programs that instruct the motor neurons how to position one's hand and arm to interact with a tool or object, to orient the limb toward the target of the limb's action, to move the limb in space, to determine the speed of the movement, to order a series of acts leading to a goal, and to utilize the mechanical advantage that tools afford.

conceptual apraxia A loss of mechanical knowledge.

conduction apraxia Patients with this form of apraxia are more impaired at imitation than pantomiming to command.

dissociation apraxia Patients have a modality-specific apraxia (e.g., verbal command). Unlike patients with ideomotor and conduction apraxia, patients with this form of apraxia have almost flawless imitation and correctly use actual objects.

ideational apraxia The inability to carry out a series of acts that lead to a goal, an ideational plan.

ideomotor apraxia Patients with ideomotor apraxia make the most severe errors when asked to pantomime transitive acts to verbal command. When imitating their performance may improve but frequently remains abnormal. When using actual tools their performance may improve even further, but often their performance remains impaired. Patients with ideomotor apraxia make primarily spatial and temporal movement errors.

limb kinetic apraxia Patients with limb kinetic apraxia have a loss of the ability to make finely graded, precise, individual finger movements.

The pyramidal motor system, together with motor units, can mediate an infinite number of movements. Therefore, to successfully manipulate environmental stimuli the pyramidal motor neurons must be guided by movement programs. The programs must instruct the motor neurons how to position one's hand and arm to interact with a tool or object, to orient the limb toward the target of the limb's action, to move the limb in space, and to determine the speed of the movement. To successfully interact with the environment, one must also know how to order components of an act to reach a goal and the mechanical advantage that tools afford. Disorders of this control system are called apraxia.

I. HISTORY

In 1871, Heymann Steinthal first used the term "apraxia" for a loss of motor skills. Steinthal thought that apraxia was a defect in "the relationship between movements and the objects with which the movements were concerned." Despite this 19th-century description of apraxia, not many important advances were made until the beginning of the 20th century with the work of Hugo Liepmann, who described three forms of apraxia: limb kinetic, ideomotor, and ideational. After World War I there was a loss of interest in continental European neurology and little interest in apraxia. However, after seeing a patient with a callosal disconnection, Norman Geschwind, in his classic paper "Disconnection Syndromes," renewed interest in apraxia. In this brief review, we describe the three form of apraxia described by Liepmann as well as three other forms of apraxia he did not discuss.

II. APRAXIA TESTING

In order to be classified as being apraxic, the inability to perform skilled purposeful movements should not be caused by sensory loss or by more elemental motor disorders such as weakness, rigidity, tremors, dystonia, chorea, ballismus, athetosis, myoclonus, or seizures. Cognitive, motivational, and attentional disorders may also be associated with an inability to perform skilled acts. Therefore, before diagnosing apraxia, a patient must undergo a detailed neurological examination, including testing of cognitive function. Although the presence of cognitive behavioral disorders does not preclude that the patient may also have apraxia, before diagnosing apraxia the clinician should be certain that these behavioral disorders do not fully account for their patient's inability to perform skilled acts.

Testing praxis involves selectively varying input and task demands. When possible, the same items should be used for all the following subtests. First, patients should be requested to pantomime/gesture. Both transitive (e.g., ''Show me how you would slice bread'') and intransitive gestures (e.g., ''Wave good-bye'') should be tested. Independent of the way in which patients perform to command, patients should be asked to imitate the examiner performing, both with meaningful and meaningless gestures. Independent of the results of the pantomime to command and imitation tests, the patient should also be allowed to see and hold actual tools or objects and to demonstrate how to use them. In addition to having a patient pantomime to verbal command, the examiner may also want to have the patient pantomime in response to seeing pictures of tool or the objects on which tools work. The examiner should learn if the patient can name or recognize transitive and intransitive pantomimes made by the examiner and discriminate between well-performed and poorly performed pantomimes that are performed by the examiner. Lastly, the examiner may want to learn if the patient knows the mechanical advantage that tools afford and if the patient can substitute or even fabricate tools to solve mechanical problems.

III. TYPES OF LIMB APRAXIA

There are six major forms of limb apraxia: limb kinetic, ideomotor, dissociation, conduction, ideational, and conceptual. Each of these forms of apraxia is defined by the nature of errors made by the patient, and each of these disorders also has different mechanisms. In this article, we discuss the clinical presentation of each of these apraxic disorders. Although constructional apraxia and dressing apraxia also involve the limbs, these disorders are strongly associated with visuoperceptual–visuospatial disorders and will not be discussed here.

A. Limb Kinetic Apraxia

In 1920, Liepmann found that patients with limb kinetic apraxia have a loss of the ability to make finely graded, precise, individual finger movements. Tasks such as finger tapping and pegboard may be impaired. The patient may have difficulty picking up a straight pin from the top of a desk using a pincer grasp of the thumb and forefinger. Limb kinetic apraxia usually affects the hand that is contralateral to a hemispheric lesion.

Liepmann thought that limb kinetic apraxia was induced by lesions that injured the primary motor and sensory cortex. In 1968, it was demonstrated that monkeys with lesions confined to the corticospinal system show similar errors.

B. Ideomotor Apraxia

Patients with ideomotor apraxia (IMA) make the most severe errors when asked to pantomime transitive acts to verbal command. When imitating, their performance may improve. When using actual tools their performance may improve even further, but often their performance remains impaired. Patients with IMA make primarily spatial and temporal movement errors. Spatial errors include postural, spatial trajectory, and spatial orientation. One of the most common postural errors is using a body part as a tool, despite being instructed not to use emblems of tools. When not using their body parts as tools, patients with IMA will often fail to position their hands as if they were holding the tool or object.

Whereas normal subjects will orient their hands to an imaginary target of that tool's action, patients with IMA often fail to orient their forelimbs to an imaginary target. IMA spatial trajectory errors are caused by incorrect joint movements. Apraxic patients will often stabilize a joint that they should be moving and move joints that should not be moving. Patients

with apraxia may be unable to coordinate multiple joint movements to get the desired spatial trajectory. It has been noted that patients with IMA may also make timing and speed errors.

In right-handed individuals, IMA is almost always associated with left hemisphere lesions, and in left-handed people IMA is usually associated with right hemisphere lesions. IMA is associated with lesions in a variety of structures, including the corpus callosum, the inferior parietal lobe, convexity premotor area, and the supplementary motor area. In 1907, Liepmann posited that the left hemisphere of right-handed people contains movement formulas (memories of how to make these skilled movements) or what are called praxicons, and that the callosal lesions may disconnect these movement formulas from the right hemisphere's motor areas. Years later, it was proposed that the movement representations first posited by Liepmann were stored in the left parietal lobe of right-handed people and it was demonstrated that destruction of the left parietal lobe produces both a production deficit (apraxia) and a gesture/pantomime comprehension/discrimination disorder. In contrast, apraxia induced by premotor lesions, lesions in the pathways that connect premotor areas to motor areas, and lesions in the pathways that lead to the premotor areas from the parietal lobe may also cause a production deficit. However, unlike parietal lesions, which destroy the movement representations, these more anterior lesions do not induce gesture comprehension and discrimination disorders. The medial premotor cortex or supplementary motor area (SMA) appears to play an important role in mediating skilled movements. The SMA receives projections from parietal neurons and projects to motor neurons. Several patients with left-sided medial frontal lesions that included the SMA demonstrated an IMA when tested with either arm. Unlike patients with parietal lesions, these patients could both comprehend and discriminate between well-performed and incorrectly performed pantomimes.

C. Conduction Apraxia

Patients with IMA are generally able to imitate better than they can pantomime to command. However, one patient was reported who was more impaired when imitating than when pantomiming to command. Because this patient was similar to the conduction aphasic who repeats poorly, this disorder was termed conduction apraxia. Whereas the lesions that induce conduction aphasia are usually in the supramarginal gyrus or Wernicke's area, the lesions that induce conduction apraxia are unknown. The mechanism of conduction apraxia may be similar to that of conduction aphasia, such that there is a disconnection between the portion of the left hemisphere that contains the movement representations (input praxicon) and the parts of the left hemisphere that are important for programming movements (output praxicon).

D. Dissociation Apraxia

In 1973, Heilman described patients who, when asked to pantomime to command, looked at their hand but failed to perform any recognizable actions. Unlike patients with ideomotor and conduction apraxia described previously, these patients' imitation and use of objects were flawless. In addition, when they saw the tool or object they were to pantomime, their performance was also flawless. Later, others not only reported similar patients but also other patients who had a similar defect in other modalities. For example, when asked to pantomime in response to visual or tactile stimuli, some patients were unable to do so, but these patients could pantomime to verbal command.

Patients with dissociation apraxia may have callosal lesions. In those patients with callosal lesions, it has been proposed that, whereas language was mediated by their left hemisphere, the movement representations (praxicons) were stored bilaterally. Therefore, their callosal lesion induced a dissociation apraxia only of the left hand because the verbal command could not get access to the right hemisphere's movement representations. Whereas these patients with callosal disassociation apraxia were not able to correctly carry out skilled learned movements of the left arm to command, they could imitate and use actual tools and objects with their left hand. Using actual objects and imitating does not need verbal mediation and the movement representations stored in their right hemisphere can be activated by visual input.

Dissociation apraxia may also be associated with left hemisphere lesions. These patients probably have an intrahemispheric language-movement formula, vision-movement formula, or somesthesia-movement formula dissociation such that, depending on the type

of dissociation, stimuli from one of these modalities (e.g., language) are not capable of activating the movement representations or praxicon, but stimuli in other modalities (e.g., vision) are able to activate these representations. The locations of the lesions that cause these intrahemispheric disassociation apraxias are not known.

E. Ideational Apraxia

In the early 1900s, the inability to carry out a series of acts, an ideational plan, was studied and termed ideational apraxia. When performing a task that requires a series of acts (such as making a sandwich), patients have difficulty sequencing the acts in the proper order.

It was noted that most of the patients with this type of ideational apraxia have a degenerative dementia. Frontal lobe dysfunction is also often associated with temporal order processing deficits, and the inability to correctly sequence a series of acts may be related to frontal lobe degeneration. Patients who select the wrong movement (content errors) have also been diagnosed as having ideational apraxia, but in order to avoid confusion these errors may be classified as conceptual apraxia.

F. Conceptual Apraxia

To perform a skilled act, two types of knowledge are needed—conceptual knowledge and production knowledge. Whereas dysfunction of the praxis production system induces ideomotor apraxia, defects in the knowledge needed to successfully select and use tools and objects are termed conceptual apraxia. Therefore, patients with ideomotor apraxia make production errors (e.g., spatial and temporal errors), and patients with conceptual apraxia make content and tool selection errors. Patients with conceptual apraxia may not recall the type of actions associated with specific tools, utensils, or objects (tool–object action associative knowledge) and therefore make content errors. For example, when asked to demonstrate the use of a screwdriver by either pantomiming or using the tool, the patient with a loss of tool–object action knowledge may pantomime a hammering movement or use the screwdriver as if it were a hammer. Content errors (i.e., using a tool as if it were another tool) can also be induced by an object agnosia. However, researchers have reported a patient who could name tools (and therefore did not have an agnosia) but often used these tools inappropriately. Patients with conceptual apraxia may be unable to recall which specific tool is associated with a specific object (tool–object association knowledge). For example, when shown a partially driven nail, they may select a screwdriver rather than a hammer. This conceptual defect may also be in the verbal domain such that when an actual tool is shown to a patient, the patient may be able to name it (e.g., hammer), but when a patient with conceptual apraxia is asked to name or point to a tool when its function is described, he or she may not be able to correctly point to it. Patients with conceptual apraxia may also be unable to describe the functions of tools.

Patients with conceptual apraxia may also have impaired mechanical knowledge. For example, if they are attempting to drive a nail into a piece of wood and there is no hammer available, they may select a screwdriver rather than a wrench or pliers (which are hard, heavy, and good for pounding). Mechanical knowledge is also important for tool development. Patients with conceptual apraxia may also be unable to correctly develop tools.

In 1920, Liepmann thought that conceptual knowledge was located in the caudal parietal lobe, but in 1988 researchers placed it in the temporal–parietal junction. Later, a patient was reported who was left-handed and rendered conceptually apraxic by a lesion in the right hemisphere, suggesting that both production and conceptual knowledge have lateralized representations and that such representations are contralateral to the preferred hand. Further evidence that these conceptual representations stored in the hemisphere that is contralateral to the preferred hand derives from the observation of a patient who had a callosal disconnection and demonstrated conceptual apraxia of the nonpreferred (left) hand. Researchers studying right-handed patients who had either right or left hemisphere cerebral infarctions found that conceptual apraxia was more commonly associated with left than right hemisphere injury. However, they did not find any anatomic region that appeared to be critical, suggesting that mechanical knowledge may be widely distributed in the left hemisphere of right-handed people. Although conceptual apraxia may be associated with focal brain damage, it is perhaps most commonly seen in degenerative dementia of the Alzheimer's type. It was also noted that the severity of conceptual and IMA did not always correlate. The observation that patients with IMA may not

demonstrate conceptual apraxia and patients with conceptual apraxia may not demonstrate IMA provides support for the postulate that the praxis production and praxis conceptual systems are independent. However, for normal function these two systems must interact.

Area V2

DANIEL J. FELLEMAN
University of Texas, Houston Medical School

GLOSSARY

callosal connections Pathways that link the two cerebral hemispheres. In the visual system, many callosal pathways link the representations of the vertical meridian in each hemisphere. The representation of the vertical meridian, and thus the location of callosal pathways, forms the border between many cortical areas.

chemoarchitecture The study of the anatomical subdivisions of the brain based on the differential distributions of various neurotransmitters or other chemicals.

cortical area A subdivision of the cerebral cortex that is based on a combination of physiological and anatomical criteria. These criteria in the visual system include a topographic representation of visual space, a distinct cyto-, myelo-, pigmento-, or chemoarchitecture, a distinct pattern of cortical and subcortical connections, distinct receptive field properties of constituent neurons, and a distinct behavioral deficit following its lesion or deactivation.

cytoarchitecture The study of the anatomical subdivisions of the brain based on the size, shape, density, and laminar organization of neurons.

magnetic resonance imaging A collection of imaging techniques that provide either anatomical (MRI) or functional (fMRI) views of the organization of the brain.

myeloarchitecture The study of the anatomical subdivisions of the brain based on the laminar distribution and density of myelinated axons.

pigmentoarchitecture The study of the anatomical subdivisions of the brain based on the size, density, and laminar distribution of cells based on their content of pigment-containing granules.

positron emitted tomography A brain imaging technique that utilizes positron-emitting compounds (often O^{15}-labeled water) to detect functionally active brain regions during the performance of a specific task.

topographic mapping The analysis of the organization of the visual system based on the systematic representation of visual space within each cortical area. Most cortical areas adjoin each other at the representation of either the vertical or horizontal meridian. Two parameters of visual space are extracted for each recording site during topographic mapping: eccentricity and polar angle.

Area V2 is an extrastriate visual area located immediately adjacent to the primary visual cortex in the occipital lobe. This article will describe the known anatomical features of V2 and discuss physiological studies of its topographic organization and functional properties. These studies are discussed with respect to similar studies performed in nonhuman primates.

I. EARLY VIEWS OF THE ORGANIZATION OF HUMAN VISUAL CORTEX

Early views of the functional organization of visual cortex were based largely on two different types of criteria. First were behavioral criteria evaluated following brain injury to large or more restricted portions

of the occipital lobe. Complete lesions of the occipital cortex in monkeys and dogs led to "Rindeblindheit" or complete cortical blindness. However, small lesions of occipital cortex led to "Seelenblindheit" or psychic blindness, in which dogs were capable of seeing and avoiding objects but no longer recognized what they saw. By the end of the nineteenth century, similar observations were made following brain injury in humans.

Second were the anatomical criteria that included the analyses of the cytoarchitecture, myeloarchitecture, pigmentoarchitecture, and, finally, the myelogenesis of the optic radiations. The most widely recognized study of the cytoarchitecture of the occipital lobe was performed by Brodmann, who described three subdivisions of occipital cortex. He identified an area 17, largely contained within the calcarine sulcus, that was identified by a highly differentiated laminar structure in which layer 4 was subdivided into three sublaminae, IVA, IVB, and IVC. Area 17 is also known as striate cortex primarily because of the dense band of myelin, called the stria of Gennari, which is located in layer 4B. Brodmann also described two belts of cortex that surrounded area 17 that he named area 18, the occipital area, and area 19, the praeoccipital area. Unfortunately, the cytoarchitectural characteristics of areas 18 and 19 in humans were not well-specified in this study.

Von Economo and Koskinas described a tripartite organization of occipital cortex that they based on quantitative measurements of laminar widths and cell-packing density. Their areas OC (area striata), OB (area parastriate), and OA (area peristriata) correspond largely with Brodmann's areas 17, 18, and 19. Area 18 is easily recognized at the border with striate cortex (OC) and is characterized by a high cell density in layers II and IIIa, low density in layer V, and large cells in layer 6. A distinct population of very large pyramidal cells in layer IIIc of area OB characterizes the border of area OB with OC. This region, OBγ or limes parastriatus gigantocellularis, is located in the region of OB cortex that contains the representation of the vertical meridian. In macaque monkeys, this region has been shown to contain a population of pyramidal cells that are immunoreactive to SMI-32, many of which were shown to project across the corpus callosum. Furthermore, in humans lacking a corpus callosum, this population of large pyramidal cells in layer IIIc is greatly reduced. The cytoarchitectonic characteristics of area 18 (or OB) at the border with area 17 (OC) are illustrated in Fig. 1A. This border is distinct in many respects, including the changes in

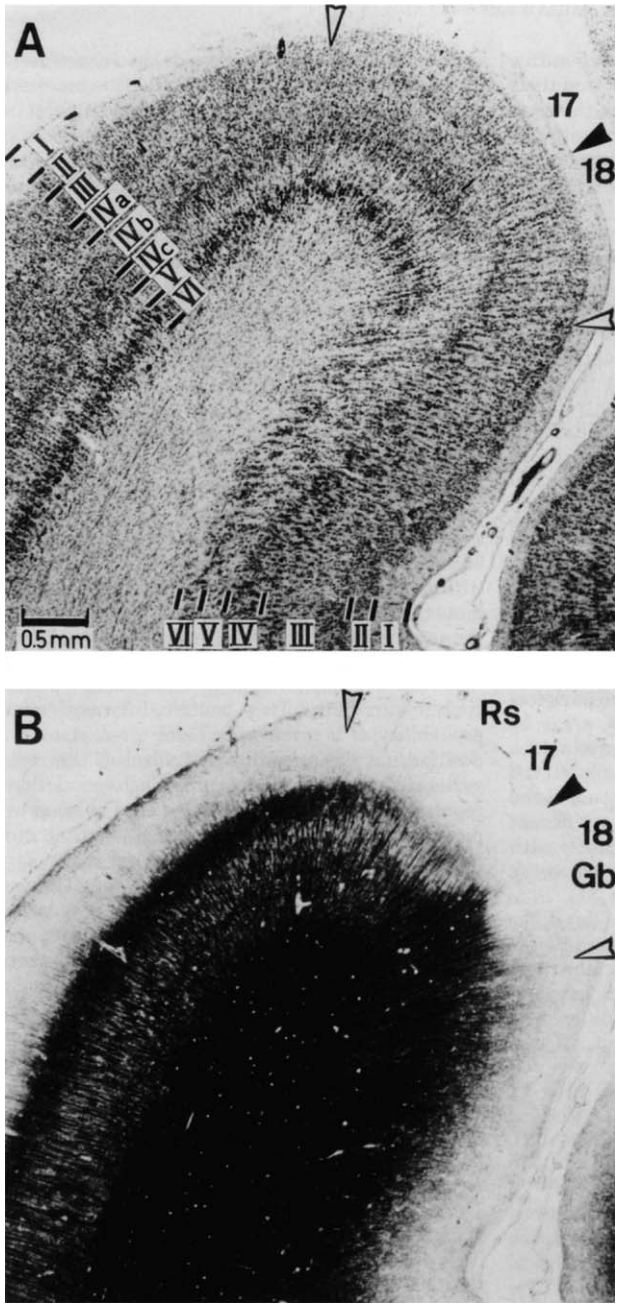

Figure 1 Architecture of the 17 (OC)–18 (OB) border. (A) Cytoarchitectonic characteristics of the 17–18 border region. Black arrow-head indicates the border. Open arrowhead in area 17 indicates the limit of the fringe area, Randsaum. Open arrowhead in area 18 indicates the limit of the border tuft region, Grenzbuschel. Layers indicated according to Brodmann. (B) Myeloarchitectonic characteristics of the 17–18 border. Area 17 is characterized by a dense band of fibers in layer IVB, the stria of Gennari. The inner band of Baillarger begins to emerge within 17 and becomes dense within area 18. A dense border tuft of radially oriented fibers is located in area 18 just across the 17–18 border. From Amunts *et al.* (2000).

width, density, and sublamination of layer IV, the density of layer VI, and increased in density in layer II. This border region is quite complex when viewed in sections stained for myelin (see Fig. 1B). Although the 17–18 border can be recognized by the change in myelin density in the infragranular layers with the emergence of the inner band of Baillarger, the myeloarchitecture of the more superficial layers is more complex. The region of area 17 just within the 17–18 border is known as the fringe area Randsaum (Rs) of Sanides and Vitzthum. Within the fringe area, the inner band of Baillarger, which is not prominent within area 17 proper, begins to emerge. On the other side of the 17–18 border, a narrow band of radially oriented fibers becomes prominent. This region is known as the border tuft, or Grenzbuschel (Gb), of Sanides and Vitzthum. This border tuft is located within von Bonin and Koskinas' area OBγ, which corresponds to the callosal recipient–origin region of OB.

The anterior border of area OB is more difficult to describe, although von Economo and Koskinas were able to use quantitative criteria to describe the overall organization and possible subdivisions within area OA (OA_1, OA_2, and OA_m). More recently, a clear separation of layers II and IIIA in 19 and a decrease in the cell density of layer IIIB in 19 have been used to distinguish area 18 from area 19.

The location and extent of Brodmann's areas 17, 18, and 19 and von Economo and Koskinas' areas OC, OB, and OA are illustrated in lateral and medial views of the human brain in Fig. 2. Similarly, the striate, parastriate, and peristriate subdivisions of occipital cortex, based on the pigmentoarchitectonic of Braak (see later discussion), are illustrated. In the medial view of the hemisphere, Brodmann's area 18 is wider than von Bonin and Koskinas' area OB. Similarly, on the lateral occipital surface, area 18 is described to occupy a $\sim$1 cm wide swath, whereas area OB barely extends onto this surface.

Although the border of area 18 with striate cortex is easily distinguished in fresh brain tissue due to the presence of the densely myelinated stria of Gennari in layer IVB and in Nissl-strained sections due to the characteristic sublamination of layer IV, the anterior border of area 18 has proven difficult to discern using traditional cytoarchitectonic criteria. However, the pigmentoarchitectonic method was able to characterize the lipofuscin distribution in striate cortex and distinguish several subdivisions of extrastriate cortex. This method identified parastriate cortex that forms a belt or horseshoe that surrounds V1 except at its most

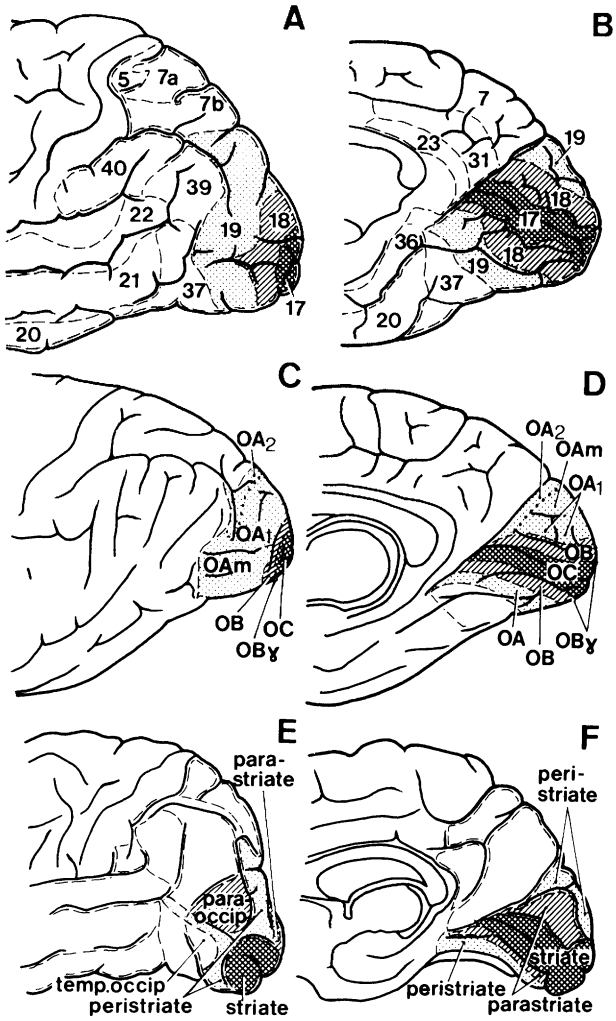

Figure 2 Cytoarchitectonic maps of the human visual cortex. (A, B) Brodmann, 1909; (C, D) von Economo and Koskinas 1925, and (E, F) myeloarchitectonic map by Eliot Smith, 1907. From Zilles and Clarke (1997).

anterior extent. The most striking characteristic of parastriate cortex was the presence of a tripartite external teania (pigmentoarchitectonic layer IV). The upper portion (pigmentoarchitectonic IVA or pIVA) is lightly stained, the middle portion (pIVB) is densely stained, and the lower portion (pIVC) is lightly stained. This pattern is distinctive, forms a precise border with striate cortex, and extends for approximately 10 mm from the V1 border. The pigmentoarchitectonic characteristics of the border between striate and parastriate regions are illustrated in Fig. 3. The parastriate region corresponds largely to area 18 of Brodmann, so it is unclear whether it only contains area V2 or whether it contains additional visual areas

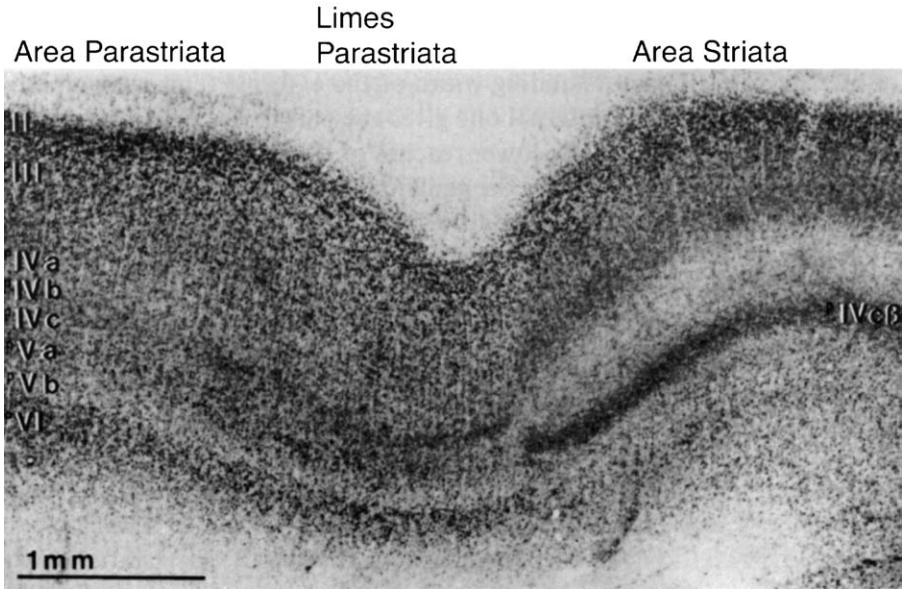

Figure 3 Pigmentoarchitectonics of the border region between area striata and area parastriata. Area striata (right) is characterized by a densely pigmented layer 4Cβ that ends abruptly at the border with area parastriata (left). Area parastriata is characterized by a tripartite layer 4 divided into pIVa, pIVb, and pIVc. The border region (limes parastriatus) contains a collection of densely pigmented cells in layers IVc and Va. From Braak (1980).

such as V3 and VP (see later discussion). In order to address this question, it will be necessary to combine this pigmentoarchitectonic approach with studies of interhemispheric connections in post mortem brain tissue or to combine *in vivo* topographic mapping with post mortem pigmentoarchitectonic analyses.

The third anatomical criterion that distinguished a tripartite subdivision of visual cortex was based on the developmental pattern of myelination of the optic radiation. Three zones were described: a projection zone that was myelinated at birth, an intermediate zone that myelinated 1 month later, and finally a terminal zone that myelinated later yet. The projection zone was shown to correspond to the area containing the stripe of Gennari, the striate cortex. The surrounding two zones together were considered to contain visual association cortex.

II. MORE RECENT VIEWS OF THE ORGANIZATION OF VISUAL CORTEX IN NONHUMAN PRIMATES

The distinction of three subdivisions of visual cortex was a widely held concept until the 1970s and 1980s, when seminal anatomical and electrophysiological mapping studies demonstrated that primate visual cortex consists of a large number of areas that are not simply belts of cortex surrounding striate cortex. They recognized that area V2 is a constant feature of organization of primate (and mammalian) visual cortex. V2 is seen as a belt of cortex that surrounds striate cortex, V1, and appears to correspond largely to area 18 of Brodmann or area OB of von Bonin. However, area 18 is somewhat larger in width than area V2; therefore, it might contain portions of areas such as V3, VP, and perhaps V3A. When electrophysiological mapping is compared with studies of interhemispheric connections, it is revealed that the border between V1 and V2 is coincident with a dense band of callosal connections that demarcates the superior and inferior vertical meridians. Anterior to this dense callosal band is a large callosal-free region that contains area V2, V3 in dorsal cortex, and VP in ventral cortex. A second dense band of callosal connections is observed along the anterior borders of areas V3 and VP, again coincident with the representation of the inferior and superior vertical meridians, respectively. Therefore, the representation of the horizontal meridian is located within this callosal-free zone because areas V2, V3, and VP contain split representations of the horizontal meridian, which form their common border. Similarly, the mapping

studies indicated that the cortex that makes up Brodmann's area 19 contains a number of distinct visual areas rather than a single third-tier area. Specifically, area MT is separated from area V2 by at least one other cortical area, V4 (or DL, the dorsolateral visual area).

Several convergent criteria are generally used to identify cortical subdivisions. Traditionally, a distinctive cyto- or myeloarchitecture has been used to identify specific cortical subdivisions. Second, a representation of visual space, a cortical map, is usually identified with a visual area. Third, areas are defined by a unique set of receptive field properties within their population. Fourth, areas are defined by a specific behavioral loss following their lesion or temporary inactivation. Finally, areas can be defined by a unique pattern of corticocortical and/or cortical–fugal connections.

V2 in nonhuman primates has been characterized by most, if not all, of these criteria. For example, V2 in macaque monkeys has a distinct appearance, most notably its cytochrome oxidase dense stripes. These appear as repeating thin and thick stripes that are separated by cytochrome oxidase pale zones. The distinction of thick and thin stripes is more difficult in macaques than in squirrel monkeys, but the thick stripes can be distinguished by their high immunoreactivity to the CAT-301 antibody. V2 contains an overall representation of the contralateral visual hemifield with the representation of the vertical meridian forming the posterior border with V1 and the representation of the horizontal meridian forming the anterior border with area V3 in dorsal cortex and VP (V3v) in ventral cortex. Furthermore, each of the cytochrome oxidase stripe compartments (thin, pale, and thick) contains a separate representation of the visual hemifield. Macaque V2 contains neurons with a wide range of stimulus specificities. A high proportion of cells located within the cytochrome oxidase thin stripes demonstrate selectivity for stimulus color and lack orientation selectivity, whereas a high proportion of cells located in the pale and thick stripes demonstrate orientation selectivity. Some cells located within the pale and thick stripes are also selective for illusory contour stimuli. In addition, a substantial proportion of V2 cells in awake fixating macaque monkeys exhibit selectivity for complex visual features such as noncartesian gratings.

Macaque V2 makes connections with a variety of cortical areas or modules within areas. The cytochrome oxidase thin stripes of V2 receive a preferential input arising largely from the cytochrome oxidase blobs of V1. Similarly, the cytochrome oxidase pale stripes receive feedforward input from the interblobs of V1. Finally, the V2 thick stripes receive feedforward input almost exclusively from layer IVB of V1. Thick stripes make feedforward connections primarily with areas V3 and MT. V2 makes feedback connections to each of these V1 compartments. Thin stripes and interstripes make dense projections that remain largely segregated into discreet zones of area V4. Areas V3A and VP receive input from V2 compartments that have not been identified. Finally, V2 makes weak projections to area TEO in posterior inferotemporal cortex. Each of these higher areas makes feedback projections to V2, demonstrating that V2 is located at the second level within a complex cortical hierarchy that contains reciprocal pathways.

The behavioral and perceptual contributions of macaque area V2 have been difficult to assess primarily due to the difficulty in limiting lesions to V2 and the need for appropriate controls. These limitations were overcome in one study that made ibotenic acid lesions of parafoveal lower field V2 and compared them to similar lesions in area V1 of fixating, behaving monkeys. In contrast to area V1, lesions of V2 led to no appreciable deficits in acuity or contrast sensitivity. V2 lesions did lead to significant deficits in orientation discrimination of lines made of collinear dots embedded in noise or of texture elements in an array. These results indicate that V2 is not needed for some low-level discriminations but may be essential for tasks involving more complex spatial discriminations, especially those that involve segregating features from a noisy background.

III. ANATOMICAL CHARACTERIZATION OF HUMAN AREA V2

A. Callosal Connections Identify the Borders between Human Visual Areas

Clarke and Mikossy studied the organization of human occipital cortex using cyto- and myeloarchitecture and their relationships to callosal connections. In addition to the easily identified cytoarchitectonic border of V1 with V2, this border is demarcated by a dense band of callosal connections that is bordered anteriorly by a large acallosal zone (see Fig. 4). On the basis of studies in macaque monkeys, these acallosal zones are thought to contain the lower and upper field representations of area V2, as well as the lower field

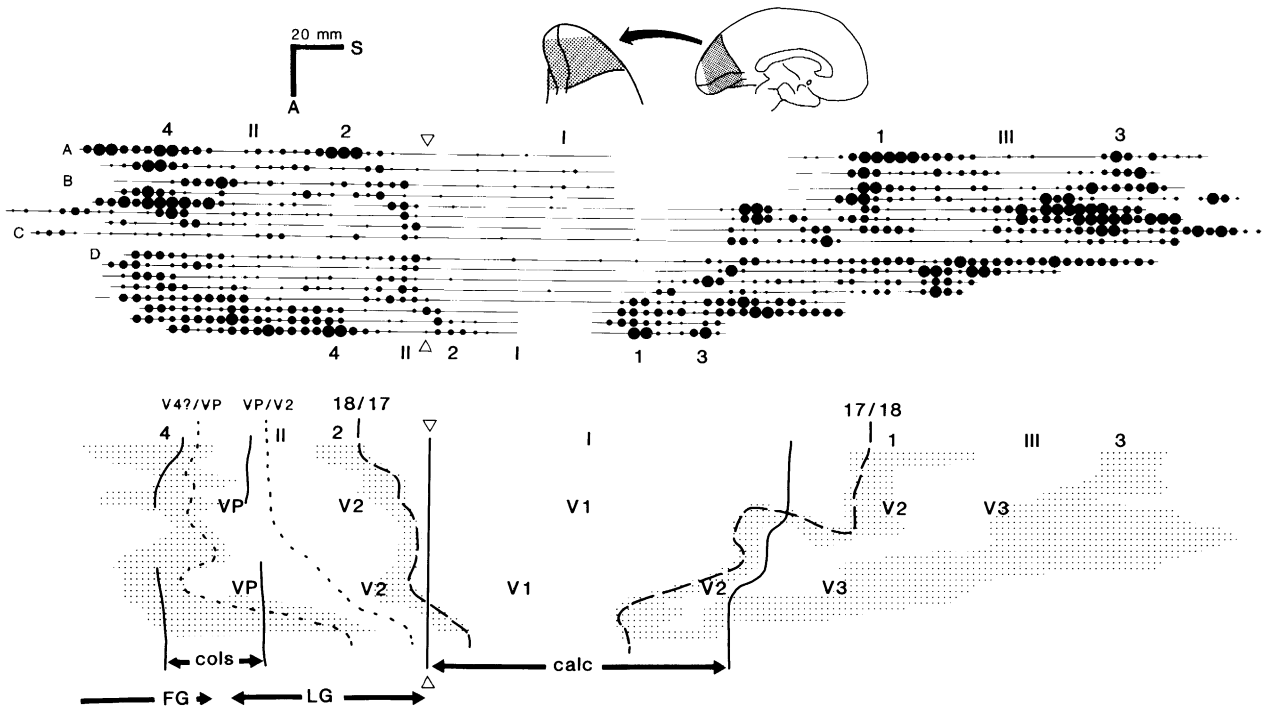

Figure 4 (Top) Flat reconstruction of the medial occipital lobe illustrating the tangential distribution of callosal afferents within the gray matter. The reconstructed region corresponds to the shaded portion of the brain insets and also includes cortex buried within the calcarine and other sulci. Sixteen sections are reconstructed with the callosal afferents projected to a point halfway between the pial surface and white matter. The density of degenerating fibers is represented by the different sizes of filled circles. (Bottom) Stippling shows dense regions of callosal afferents. The large callosal-free region labeled I corresponds to area V1. The 17–18 border (heavy dashed line) is marked to a narrow dense band of callosal afferents (regions 1 and 2). A second callosal-free zone is located anterior to region 2 in ventral cortex (region II) and anterior to region 1 in dorsal cortex (region III). These callosal-free zones is contain representations of the horizontal meridian. Anterior to the callosal-free zones is a second dense band of callosal afferents found in ventral cortex (region 4) and in dorsal cortex (region 3). These anterior bands correspond to a second representation of the vertical meridian. The ventral callosal-free zone contains areas V2 and VP and is located within area 18. Similar arguments can be made for areas V3 and V3A in dorsal extrastriate cortex. From Clarke and Miklossy (1990).

representation in area V3 and the upper field representation in area VP. A second dense callosal band marks the anterior border of this acallosal zone, just as is observed at the anterior borders of areas V3 and VP in macaque monkeys.

The border between V2 and presumably V3 in dorsal occipital cortex was difficult to identify on the basis of cytoarchitecture or myeloarchitecture, although macaque V3 has a distinctive pattern of dense myeloarchitecture. In contrast, the ventral acallosal zone can be subdivided into densely myelinated V2 posteriorly and poorly myelinated VP located anteriorly. This border also corresponds to a decrease in CO activity in VP as compared to area V2. Therefore, area V2 is contained within cytoarchitectonic area OB of von Economo, whereas area VP is contained with cortex of the OA_1 subtype of area peristriata. On the basis of the published map of callosal afferents, area V2 ranges from approximately 10 mm to more than 20 mm in width.

B. Quantitative Cyto- and Myeloarchitecture of V2

In an effort to provide quantitative criteria for the distinction of area V2 from other cortical areas, image-processing techniques have been used to assess the cytoarchitectonic and myeloarchitectonic organizations of area V2 and to compare them with those from areas V1 and V4. According to this approach, Nissl-stained sections are digitized and the profiles of cell bodies are segmented according to gray level. A gray level index is then used to quantify the areal fraction of cortex occupied by stained cell bodies. Figure 5A illustrates the gray level index in areas V1, V2, and V4.

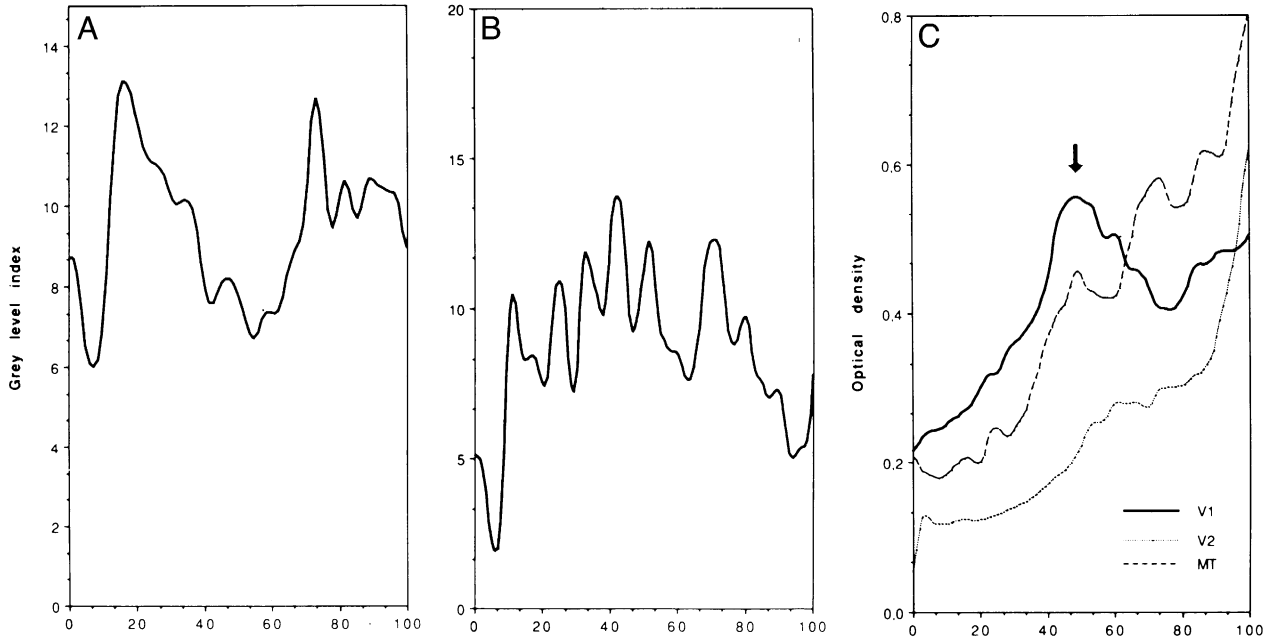

Figure 5 Distribution of the gray level index (GLI) in areas V1 (1) and V2 (2). The differing profiles indicate the different laminar patterns of cytoarchitectonic features in these two areas. Distribution of myelin densities in areas V1, V2, and MT. From Zilles and Schleicher (1993).

V1 is characterized by a bimodal GLI that peaks in layers II–III, drops in layer IVB, peaks again in layer IVC, and finally falls off in layers V and VI. In area 18 (V2, just across the V1 border), a different pattern is observed with multiple peaks extending across the depth of the cortex and no distinctive cell-sparse zone as observed in layer IVB of V1. Finally, a similar multipeaked pattern was observed in area V4 of the fusiform gyrus.

Similar quantitative techniques have been used to quantify the distribution of myelin in sections of areas V1, V2, and MT stained by the Gallyas method for myelin. All three areas show an increase in the density of myelin from the upper to the lower cortical layers. In V1, a distinct peak is found in the middle of cortex corresponding to the stria of Gennari. V2 can easily be distinguished from V1 by the overall lower density of myelin and the clear lack of the stria of Gennari (see Fig. 5B).

Quantitative cytoarchitectonic and myeloarchitectonic methods have been used to determine the variability of areas 17 and 18 when transformed into the Talairach stereotaxic coordinate system. For example, five male and five female brains were obtained at autopsy, fixed in 4% formalin for several months, and imaged with MRI at high resolution. The brains were then cut at 20 μm and sections were analyzed quantitatively every 1200 μm. The borders between areas 17 and 18 and between areas 18 and 19 were determined using the gray level index to quantify neuronal density across cortical layers. These histological borders were then transferred to MRI sections using both linear and nonlinear fluid transformations. Finally, the MRI-reconstructed brains were transformed into a standard format. Figure 6 illustrates the surface rendering of areas 17 and 18 on sagittal views of the MRI reconstructions of the 10 brains used in this study. It is apparent that area 18 is highly variable in location and extent across these 10 brains. This variability can be expressed by the center of gravity and standard deviation of the Talairach coordinates for area 18. Thus, area 18 has a maximum variability of the center of mass of 5 mm in the z plane, and this variability is almost half as large in the x plane.

C. Cortical Connections of Area V2

The organization of corticocortical connections between areas V1 and V2 in human visual cortex has been studied using the neuronal tracer DiI (1,1′-dioctadecyl-3,3,3′,3′-tetramethylindocarbocyanine perchlorate) in aldehyde-fixed post mortem brain tissue. DiI injections

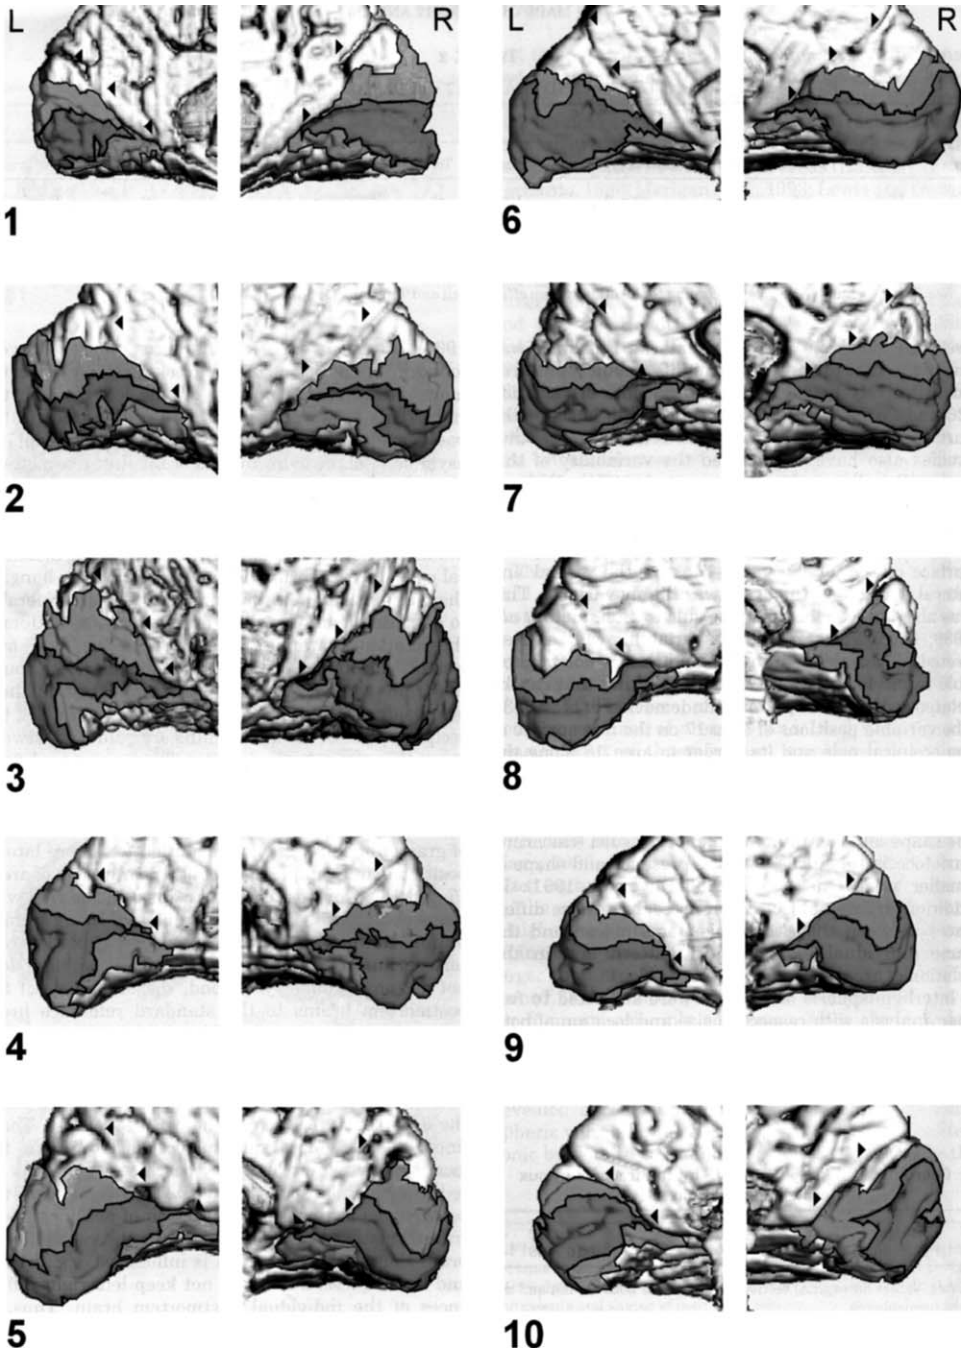

Figure 6 Surface rendering of the two hemispheres from 10 brains illustrating the variability in the locations of areas 17 and 18. From Amunts *et al.* (2000).

were placed either in area V1, identified by the presence of the stria of Gennari and cytochrome oxidase blobs, or in area V2, identified by the presence of cytochrome oxidase stripes. Following V1 injections, labeled fibers enter the white matter and then ascend into the gray matter of area V2. These fibers then either terminate in layers III and IV or travel horizontally through the gray matter to terminate a short distance away in V2 (Fig. 7A). Injections of DiI into V2 led to a different pattern of fiber projections. Rather than coursing through the white matter underlying V1, fibers coursed through the gray matter to terminate in layers I, II, III,

IVB, V, and VI and avoided terminating in layers IVA and IVC (Fig. 7B). The projections to layers IVB and V were highly clustered, forming 0.3-mm-wide clusters with a spacing of 0.6–1 mm. Some of the V2 injections failed to produce labeling of layer IVB. Presumably these V2 injections failed to hit the V2 thick stripes so the projections to layer IVB would not have been expected (Fig. 7C).

DiI injections into area V2 also produce clustered intrinsic projections. Figure 7D illustrates a transverse section throughV2 with an injection site in the superficial layers and clustered projections extending through layers II–V. The spacing of these intrinsic projections is approximately 1 mm, which is smaller than the distance between functional modules identified through cytochrome oxidase histochemistry (see later discussion).

The development of these feedforward and feedback connections between areas V1 and V2 has been studied using the DiI technique in post mortem brains ranging in age from 37 weeks of gestation to 4 postnatal months. At 37 weeks of gestation, injections to area V2 led to the labeling of fibers that originated only from deep cortical layers of V2 and ran through and perhaps terminated in layers V and VI of area V1. At 9 postnatal days, injections of V1 label fibers that are restricted to the deep layers of V2. No fibers were seen to terminate in superficial layers, but a few fibers ended in growth cones in layer IV. Injections of V2 produced both retrogradely labeled cells and anterogradely labeled fibers. Retrogradely labeled cells were observed in layers IVB and VI but not in supragranular layers II and III. Thus, feedforward projections first mature from layers IVB and VI, and the supragranular

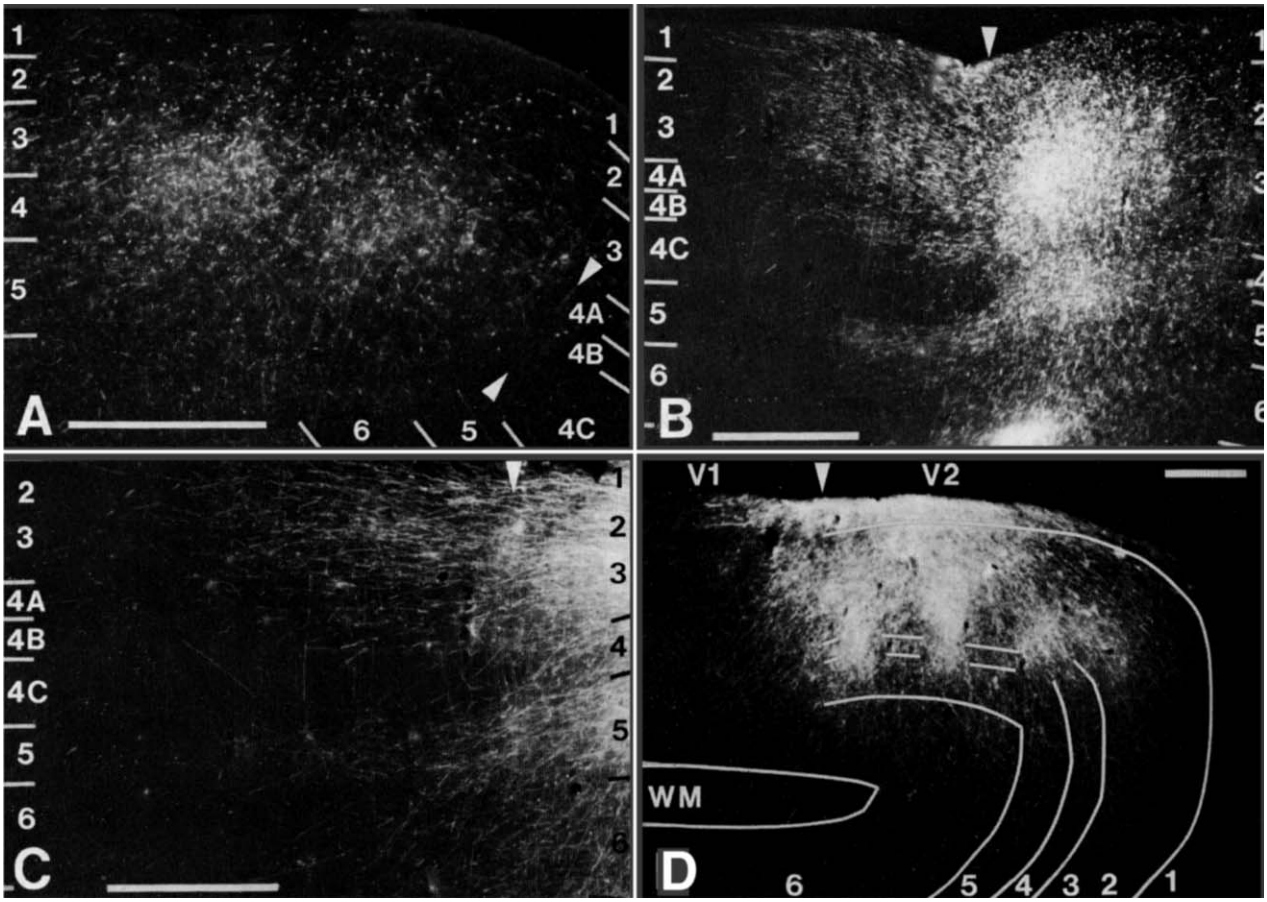

Figure 7 Extrinsic and intrinsic connections of area V2. (A). Transverse section through V1 and V2 showing clustered terminations in layers III and IV of V2 following an injection of DiI into V1. (B) Projections from V2 to V1. DiI injection was made into V2 (right of arrowhead), and labeled fibers and terminals are observed in layers I, II, III, IVB, and V of V1. (C) Projections from V2 to V1 that avoid layer IVB. DiI injection in V2 is located at the right of the arrowhead. Fibers are seen coursing from the injection site to terminate in layers I, II, III, and V of V1. (D) Intrinsic connections of V2. Transverse section showing projections following DiI injection into superficial layers of V2. Clustered projections extend from the injection site to terminate in layers II–V. Bar=1 mm. From Burkhalter and Bernardo (1989).

projections, characteristic of adults, are not yet formed by 9 postnatal days. At 9 postnatal days, feedback projections from V2 to V1 are characterized by horizontally oriented fibers in deep layers V and VI, which contain vertical branches that reach into layer IVB. Some feedback fibers were observed in supragranular layers, but these were usually obliquely oriented fibers that ramify in layer I.

At 7 postnatal weeks, feedforward projections from V1 to V2 begin to show the adult pattern of labeling. That is, labeled fibers enter V2 not only from the deep cortical layers but also from the superficial layers and begin to terminate in layers III and IV. In contrast, the feedback projections from V2 to V1 remain largely immature at 7 postnatal weeks. Feedback fibers terminate in layers I, IVB, V, and VI, just as was observed at 9 postnatal days. Fibers were still not observed in layers II and III, as in the adult. Nevertheless, there was some development of these feedback pathways in that more fibers were observed coursing through layers II and III to terminate in layer I. In addition, fibers in layer IVB were often oriented horizontally and some innervation of layer IVA was observed.

At 4 postnatal months, the projection from V1 to layer IV of area V2 became denser. Feedforward projections from V1 to V2 begin to take on the adult appearance at 4 postnatal months. At this time, injections of V2 produced retrograde labeling of neurons in layers II, III, IVB, V, and VI. In contrast, feedback projections from V2 to V1 are still immature at this time. Fibers were seen to terminate densely in layers I, IVB, V, and VI, but the projections to layers II and III remain weak at this time. Thus, at 4 postnatal months, the feedforward projections from V1 to V2 appear more mature than the feedback projections from V2 to V1. At 2 years of age, feedforward projections from V1 terminate in layers III and IV of V2. This projection is similar to that observed at 4 postnatal months but is more dense. Similarly, the feedback projection from V2 terminated densely in layers II, III, IVB, and V of area V1 and more weakly in layers I and VI. Similar to adults, this feedback projection was highly clustered with $\sim$0.3-mm-wide clusters separated by $\sim$0.3-mm-wide gaps.

The development of long-range *local* connections within areas V1 and V2 has been studied using the DiI technique in fixed prenatal and postnatal post mortem brains. At 37 weeks of gestation, injections of V2 give rise to labeled fibers in layers II, III, and V that extend horizontally for several millimeters. By 9 postnatal days, these fibers become denser and tend to form irregular clusters close to the injection site. In contrast, at 4 postnatal months, local connections within V1 are largely immature. Injections of V1 give rise to horizontally oriented fibers within layers IVB, V, and VI, whereas the labeling of layers I, II, and III is sparse. Thus, although V1 layer II–III neurons begin to project to area V2 by 4 postnatal months, they have yet to form the adult pattern of local horizontal connections within V1.

The intracortical connections of V2 with a more rostral region of human extrastriate cortex have been studied in post mortem brain tissue following a naturally occurring infarct in area 19. A $\sim$1-cm-wide infarct was found in the superior lateral extrastriate cortex of a 92-year-old female who died of natural causes. The brain was recovered shortly after death and was later processed for degenerating axons. On the basis of previous studies of the interhemispheric connections of extrastriate cortex in humans, the infarcted region is located anterior to area V3A in a region that perhaps corresponds to area V6 of macaque monkeys. Dense regions of degenerating axons were found within 2–5 mm of the infarct and were distributed to more distant cortical regions, including areas V1, V2, V3, VP, V3A, and V4. Dense projections were seen in superior portions of V1, V2 and V4 and in areas V3 and V3A, whereas weaker projections were seen in inferior portions of V1, V2, V4, and in area VP. These results suggest that the infarct affected cortex that represented the inferior visual field, yet appeared to have extended into cortex that contained a representation of the superior visual field. In V2, the degenerating fibers were localized primarily in the infragranular layers, but, in its densest region, extended into the middle cortical layers. This pattern of labeling is suggestive of a feedback projection from the infarct to area V2. A similar laminar pattern of labeling was also observed in V1 and in extrastriate areas V3, VP, V4, V3A, and V5.

D. Evidence for a Modular Organization of Human Area V2

The distinction of area V2 from V1 and the identification of functional subunits in both of these areas have been facilitated greatly through the examination of the differential distribution of cytochrome oxidase histochemistry in nonhuman primates. Cytochrome oxidase blobs or puffs have been identified in supragranular striate cortex that represents regions of higher degree metabolic activity than the surrounding

interblob zones. Subsequent investigations using microelectrode, 2-deoxyglucose autoradiography and optical recording techniques have linked these different anatomical modules within V1 with distinct physiological properties. Cells in V1 blobs tend to be monocular, express a lack of orientation selectivity, and possess a higher degree of color selectivity. In addition, V1 blobs tend to be located at the center of ocular dominance stripes.

V2 is also characterized by a unique pattern of cytochrome oxidase histochemistry in a wide range of nonhuman primate species. In V2, increased densities of CO are observed to form elongated stripes that are oriented perpendicular to the V1–V2 border. In squirrel monkeys, these stripes can readily be observed to alternate in a regular thick–thin pattern, separated by intervening interstripe zones of low CO activity. The alternation in stripe width as well as the overall regularity of stripe alternation is less obvious in macaque monkeys as well as in humans (see later discussion).

A periodic pattern of cytochrome oxidase activity in human visual area V2 was first described in 1984. This pattern was similar to that observed in macaque monkeys but differed in size, periodicity, and overall homogeneity. Like nonhuman primates, area V2 can be identified by the presence of CO-dense stripes in layers III–V (see Fig. 8). These stripes form a regular pattern of dense stripes that are oriented perpendicular to the V1 border. The dense stripes are 1.0–2.75 mm in width and are separated by CO-pale zones that are 1.5–2.75 mm in width.

Unlike nonhuman primates, human V2 CO stripes are more globular than homogeneous in structure. These globular zones are 580–1400 μm in width and form stripes that have a spacing of 1500–2300 μm. These CO density dimensions were reported to be rather variable across individuals. Interestingly, CO stripes in V2 can be observed in neonatal tissue at a time when CO blobs are not present in area V1. Furthermore, although the CO densities formed rough stripes oriented perpendicular to the V1 border, the demarcation of thick and thin stripes, which is readily observed in squirrel monkeys and less so in macaque monkeys, generally is not possible in humans. However, it is possible to distinguish these stripes from each other in humans through the use of CAT-301 immunoreactivity.

CAT-301 is a cell-surface proteoglycan that is observed at high density in several levels of the macaque visual system that are related to the magnocellular thalamocortical pathway. The distribution of

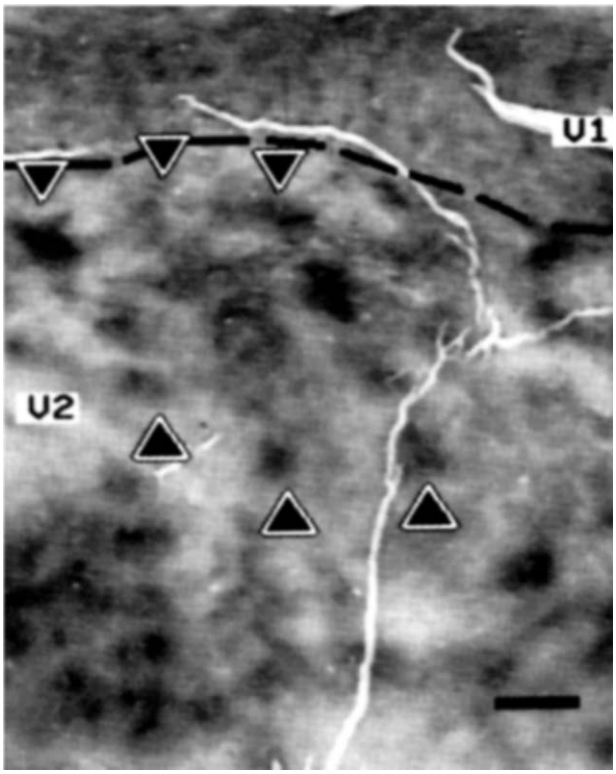

Figure 8 Cytochrome oxidase stripes in human V2. Three prominent stripes are seen in this section through layer 4. Individual stripes consist of dense patches separated by pale zones that are aligned in rows. Bar=2 mm. From Tootell *et al*. (1993).

CAT-301 immunoreactivity has been observed in cross-sectional and tangential tissue blocks of human visual cortex. Labeled cells in V2 are distributed in two distinct bands: one located in layer 3 and a second in layer 5 (see Fig. 9A). The periodicity of CAT-301 is best revealed in tangentially sectioned tissue. CAT-301 stained dense clusters of neurons in V2, which formed stripes that were 1–3 mm wide and 1.5–3 cm long and oriented perpendicular to the V1–V2 border (see Fig. 9B). These dense stripes were separated by approximately 4–8 mm. Because CAT-301 immunoreactivity identifies the CO-dense thick stripes of macaque area V2, it seems likely that this CAT-301-ir in human V2 also recognizes thick stripes. It is important to point out that these CAT-301-dense regions appear distinctly stripelike, whereas studies of V2 using CO tend to identify CO-dense clusters rather than stripes.

In addition to cytochrome oxidase and CAT-301 staining, myelin staining of unfolded, tangentially sectioned portions of V2 with the Gallyas stain reveals stripes that are 6–8 mm apart. This spacing is consistent with the labeling of one set of stripes, either

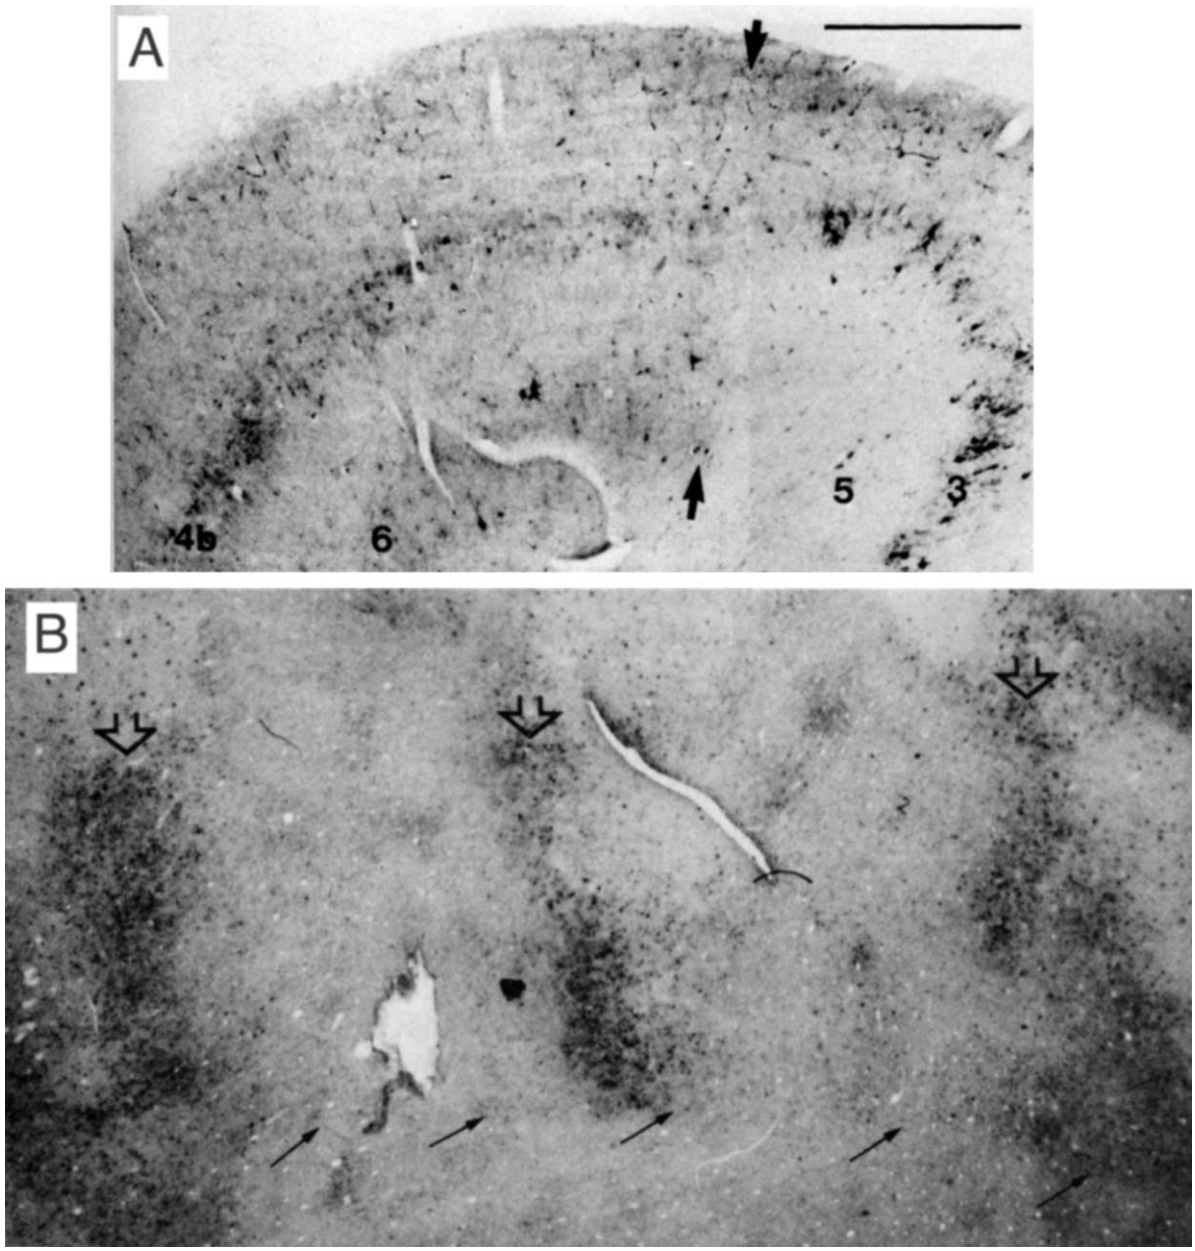

Figure 9 CAT-301 immunoreactivity in human area V2. (A) Laminar distribution of CAT-301-ir neurons in V1 (left) and V2 (right). V1 contains two bands of labeled cells corresponding to layers IV and VI. The laminar pattern changes at the V2 border, where CAT-301-ir cells are located in a dense band in layer III and a lighter band in layer V. Arrows indicate the V1–V2 border. Bar=1 mm. (B) Tangential distribution of CAT-301-ir cells in area V2. Thick bands of CAT-301-ir cells run orthogonal to the V1–V2 border. Bar=1 mm. From Hockfield *et al.* (1990).

thin or thick stripes. Alternatively, the myelin staining may reflect the pale CO compartments that have been reported to contain higher myelin densities in squirrel monkey V2. The pattern of myelin staining in unfolded V2 is illustrated in Fig. 10.

The distinctiveness and regularity of CO densities end at the anterior border of V2 and allow for an assessment of the overall size of V2 in humans. At the foveal representation, V2 is relatively narrow at 1–1.5 cm wide. In both dorsal and ventral cortex, the width

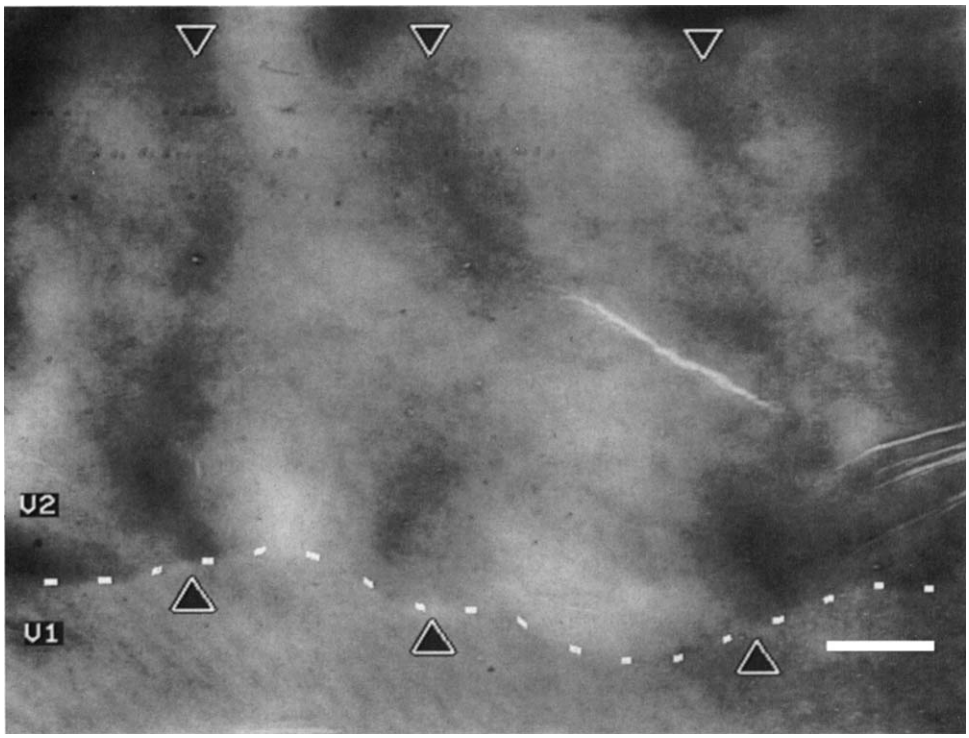

Figure 10 Myelin staining in human area V2. Composite image of four aligned sections spanning layers 3–5. Three myelin dense stripes are observed running orthogonal to the V1–V2 border (dashed line). Bar=2 mm. From Tootell and Taylor (1995).

of V2 increased to 1.8–3.4 cm at parafoveal eccentricities. These features of the modular organization of area V2 are summarized in Table I.

IV. NEUROCHEMICAL CHARACTERIZATION OF HUMAN AREA V2

The distinctive border between areas V1 and V2 has facilitated greatly the determination of the laminar distributions of neurotransmitter receptors in area V2 of humans. [^{3}H] Glutamate and NMDA receptors (labeled by [^{3}H]TCP, [^{3}H]glycine, or [^{3}H]dizocilpine binding) are densely distributed in layer IVC of V1 but are not densely distributed in layer IV of V2. In contrast, kainate receptors (determined through binding of [^{3}H]kainate) are not observed in layer IVC of V1 but are labeled in layer IV of V2. In addition, dense labeling of NMDA and AMPA receptors is observed in layer III of V2, whereas weaker labeling is observed in layers III–IVA of V1. Similarly, weak labeling of kainate receptors is observed in layer III of V2, whereas no labeling is observed in layer III of V1. Finally, whereas dense labeling of kainate receptors is observed in layers V and VI in both areas V1 and V2, weak AMPA receptor labeling is observed in layer V of V1 that is not observed in layer V of V2. These results are summarized in Table II.

In addition to the distribution of glutamate receptors, the distribution of $GABA_A$ receptors distinguishes area V2 from area V1. $GABA_A$ receptors are distributed in a bimodal pattern in V1 and a unimodal pattern in V2. This is due to a lack of $GABA_A$ receptor binding in layer IVB and weak binding in layer III of V1, whereas layers II–IV of V2 show dense $GABA_A$ binding.

Acetylcholine receptors have different laminar distributions in areas V1 and V2. Nicotinic receptors, determined through the binding of [^{3}H]oxotremorine, have their highest densities in layers V and VI in both areas V1 and V2. In V1, binding sites are also apparent in layer IVC, whereas in V2, binding sites are observed in layers I and II. Muscarinic, M_1 receptors, determined through the binding of [^{3}H]*N*-methylscopolamine, show their highest densities in layers II and III of

Table I
Modular Organization of V2[a]

Structure	Size (mm)
Width of dense CO stripes	1–2.75
	0.5–0.7
Width of CO interstripes	1.5–2.75
	0.5–0.7
Diameter of "globular" CO zones	0.580–1.4
Distance between globular CO zones within stripes	0.85–1.85
Distance between CO stripes	1.5–2.3
Length of CO stripes	15–25, 10–15 foveal, 18–34 intermediate, eccentricity
Width of CAT-301 stripes	1–3
Distance between CAT-301 thick stripes	4–8
Length of CAT-301 stripes	15–30
Width of myelin-dense stripes	~2
Distance between myelin-dense stripes	6–8
Length of myelin-dense stripes	12+
Cycle width between like stripes	6–8

[a]This table summarizes the modular features of human area V2 revealed through anatomical methods. An alternating dense and pale stripelike pattern is revealed when V2 is processed for the visualization of cytochrome oxidase (CO). This anatomical feature allows for a comparison of the organization of human V2 with that of nonhuman primates. The length of these cytochrome oxidase stripes provides an anatomical marker for the width of area V2. The pattern of immunoreactivity for CAT-301-provides a means for distinguishing the CAT-301-dense CO thick stripes from the CAT-301-pale CO thin stripes. V2 is also characterized by an array of myelin-dense stripes that may correspond to either the CO thin or thick stripes.

Table II
Neurotransmitter Receptor Distribution in Human V2[a]

Adrenergic α_2	–	+	–	+	–	–

[a]Distribution of glutaminergic, gabaergic, cholinergic, serotonergic, and adrenergic receptors as a function of cortical layer in human V2.

both areas V1 and V2. In V1, weaker binding is observed in layers IVC and V, whereas in V2 a high density of binding is observed in layer IV. Muscarinic, M_2 receptors, visualized through the binding of [^{3}H] pirenzepine, show a high density in layers II and III of both areas V1 and V2. A high density of receptors is seen in layer IVC of V1 and in layer IV of V2. Weaker binding is observed in layer V of area V1 and in layer VI of V2.

Adrenergic receptors also show a differential regional pattern between areas V1 and V2. Overall, α_1 receptors have a higher mean density in area V2 than in V1. This uneven distribution is largely due to the high density of α_{1B} receptors in area V2. The peak α_1 density is found in layers II and III, with lower densities in layers I, IV, V, and VI. In contrast, the α_{2A} receptors show a higher density in area V1 than in V2. This difference is largely due to the high density of α_{2A} receptors in area V1. In V2, the highest density of α_{2A} receptors is found in layers II, V, and VI, peaking in layer VI.

The distribution of serotonergic receptors can also be used to distinguish area V2 from area V1. 5-HT_1 binding sites have a higher density in area V1 than in V2. 5-HT_{1A} binding sites have a similar laminar distribution in both areas, peaking in layers I and II. 5-HT_2 binding sites, determined through [^{3}H]keranserin autoradiography, have a high density in layer 4C of V1, and layers II and V have the higher density in area V2. 5-HT_{2A} receptor mRNA has its highest density in layer IVC of area V1, lower densities in layers III and II, and lowest densities in layers IVB, V, and VI. In V2, 5-HT_{2A} receptors show their highest densities in layers III and V, and lower densities were found in layers II and IV.

The distribution of nicotinamide adenine dinucleotide phosphate-diaphorase (NADPH-d) immunoreactivity has been used to distinguish area V2 from area V1. NADPH-d immunohistochemistry labels both the neurophil and several sizes of neurons in both the gray and white matter. In V1, NADPH-d activity in the neuropil is most dense in layer IV, and regions of high activity can be observed to extend into the

supragranular layers. In V2, the NADPH-d-background activity is more diffuse, extending from layer IV into the supragranular layers. NADPH-d-positive cells in areas V1 and V2 can be subdivided into large gray matter cells (16 × 16 μm soma size) with round, oval, or pyramidal cell bodies with sparely spinous dendrites, large white matter cells (12 × 19 μm soma size) with oval cell bodies that are horizontally oriented and contain spinous dendrites, and small gray matter cells (3.6 × 4 μm soma size) with stellate shape. The small cells are distributed in layers II–VI of areas V1 and V2 and they are most numerous in layer IV.

Area V2 also contains a rich complement of neurons and fibers immunoreactive for neuropeptide Y. In both areas V1 and V2, immunoreactive pyramidal and nonpyramidal cells are found in layers I–VI. The nonpyramidal cells are either bipolar, bitufted, or multipolar aspiny cells. In layers II and V, most immunoreactive cells are pyramidal in shape. In addition to these cells located in the cortical gray matter, the majority of neuropeptide Y immunoreactive cells are located in the underlying white matter. Many of these cells are located just below the border of layer VI, whereas other cells are located deeper within the white matter. Immunoreactive fibers are found in two plexuses: one in layers I and II and a second in layer V. This pattern is distinct from that seen in area V1, where a third plexus in layers IVB and IVC is observed. Many of these immunoreactive fibers are found to surround small blood vessels, suggesting that they play a role in the regulation of cerebral blood flow. The localization of neuropeptide Y in both aspinous and spinous pyramidal cells suggests that it plays a role in both inhibitory and excitatory neurotransmission. The localization in layer III and V pyramidal cells suggests that this peptide is involved in cotransmission in long-range corticocortical and corticofugal pathways.

Calcium-binding proteins parvalbumin (PV), calbindin (CB), and calretinin (CR) have been reported to be colocalized in GABAergic neurons in human visual cortex. In general, these GABAergic cells are interneurons of the chandelier and basket cell types located in layers II and IV (PV), double bouquet cells of layers II–III and V (CB), or bipolar and fusiform cells in layers II and III (CR). In addition, some pyramidal cells in layers II–III are immunoreactive for calcium-binding proteins. In some cases, more than one calcium-binding protein has been localized in individual cells in areas V1 and V2 of human visual cortex. In area V2 (area 18 near the V1 border), 3.28% of cells are immunoreactive for both PV and CR, whereas 7.39% of cells are immunoreactive for both CR and CB. The colocalization of PV and CB is rare in both areas V1 and V2. In addition to the single- and double-labeled cells located within the gray matter of V2, single- and double-labeled fibers were observed in the underlying white matter. These labeled fibers may belong to projection neurons from the lateral geniculate nucleus or pulvinar because these cells are often immunopositive for calcium-binding proteins.

Many parvalbumin immunoreactive neurons are surrounded by extracellular lattice coatings called perineuronal nets that are stainable with lectins such as *Wisteria floribunda* agglutinin (WFA). Areas V1 and V2 differ in the density, laminar distribution, and target cells of WFA immunoreactivity. In V1, WFA staining is largely distributed in two bands; one located in layer IVB and the second in layer VI. Lighter staining is observed in layers II and III. In V2 a different laminar pattern of labeling is observed. Dense labeling is observed in layers IIIB–IIIC, and less intense labeling is observed in layer V. In addition to these laminar differences, areas V1 and V2 differ in the size of neurons that were enveloped by WFA finding. In both areas, medium-sized cells (13–21 μm) are the most commonly enveloped cell type. In V1 a greater percentage of small cells (5–12 μm) are labeled in layers II–III, IVA, IVB, and IVC. In contrast, a larger percentage of large cells (22–30 μm) are labeled in layers IIIB, IIIC, and V of area V2. Finally, layer VI of V1 contains a larger proportion of labeled large cells.

The density and laminar distributions of neurons that are immunoreactive to SMI-32 that recognizes nonphosphorylated neurofilament proteins, also provide a basis for distinguishing area V1 from area V2. In area V1, densely stained SMI-32 immunoreactive neurons are found in layer 4B and the Meynert cells of layer VI. In addition to these large cells, smaller immunoreactive cells are found in layers III, V, and VI. In area V2, SMI-32 immunoreactivity is found in the large cells of layers III and V (see Fig. 11A). Area V2 also contains a population of SMI-32 immunoreactive cells that are affected in cases of Alzheimer's disease. Although area V2 contained significantly less neuritic plaques and neurofibrillary tangles than prefrontal and temporal cortex, a significant loss of SMI-32 immunoreactive neurons is found in layers III and VI of area V2 (average loss of 18%). These results reinforce the view that Alzheimer's disease preferentially affects neurons with long corticocortical axons such as those in layers III and VI of V2 that project to distant extrastriate cortical areas or to subcortical targets (Fig. 11B).

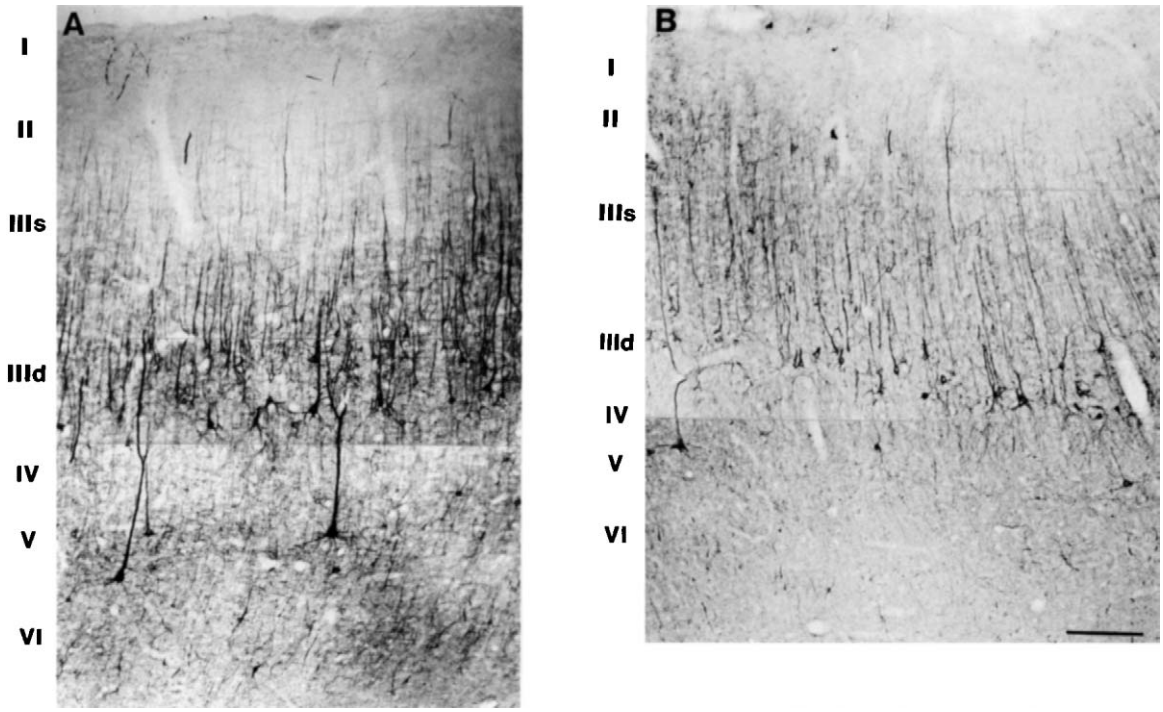

Figure 11 Photomontage of SMI-32 immunoreactivity in human area 18. (A) Normal cortex. Large SMI-32-ir neurons are present in layers IIId and V. (B) V2 in Alzheimer's disease is characterized by a major loss in the density of SMI-32-ir neurons in layers IIId and V. From Hof and Morrison (1990).

V. TOPOGRAPHIC MAPPING OF HUMAN VISUAL CORTICAL AREAS

Functional magnetic resonance imaging (fMRI) has been used to map the location, extent, and topographic organizations of several cortical areas in the human visual system. Signals used by fMRI are thought to represent local changes in blood flow that serve as an indirect marker for the activation of pools of neurons. Eccentricity and polar angle coordinates in several visual areas (V1, V2, V3, VP, and V3A) are usually mapped using phase-encoded, contrast-reversing checkerboard stimuli that were presented as a rotating hemifield (polar angle) or expanding annulus (eccentricity). To maximize attention and arousal and, thus, maximize activity in extrastriate cortex, subjects typically are required to fixate and report changes in the location of a small centrally located stimulus.

Spin echo imaging is used to acquire functional brain maps, whereas gradient-recalled images are generally used to acquire anatomical data that are used for the reconstruction of three-dimensional models of the brain, which then served as input to one of several brain-flattening algorithms to build unfolded cortical maps or inflated brain reconstructions. Figure 12A illustrates the representation of eccentricity in the visual cortex for three subjects in both three-dimensional and two-dimensional reconstructions of the occipital cortex. These cortical maps illustrate the representation of eccentricities ranging from 1.4° to 24° as color-coded bands that extend both dorsally and ventrally from the collateral sulcus (ventrally), to the calcarine sulcus, and then onto the exposed lateral surface of cortex. The representation of polar angle in occipital cortex from these three subjects is illustrated in Fig. 12B. Regions of cortex activated are color-coded yellow when the hemifield checkerboard is located within 5° of the superior vertical meridian, purple when within 5° of the horizontal meridian, and orange when within 5° of the inferior vertical meridian. Because the vertical and horizontal meridians form the borders of many visual cortical areas in macaque monkeys, these data formed the basis for identifying the borders between cortical areas in the human occipital cortex. A large purple region located within the calcarine sulcus corresponds to the horizontal meridian representation of area V1. This region is bordered dorsally by an orange region corresponding to the inferior vertical meridian representation at the border between areas V1–V2. In ventral cortex, V1

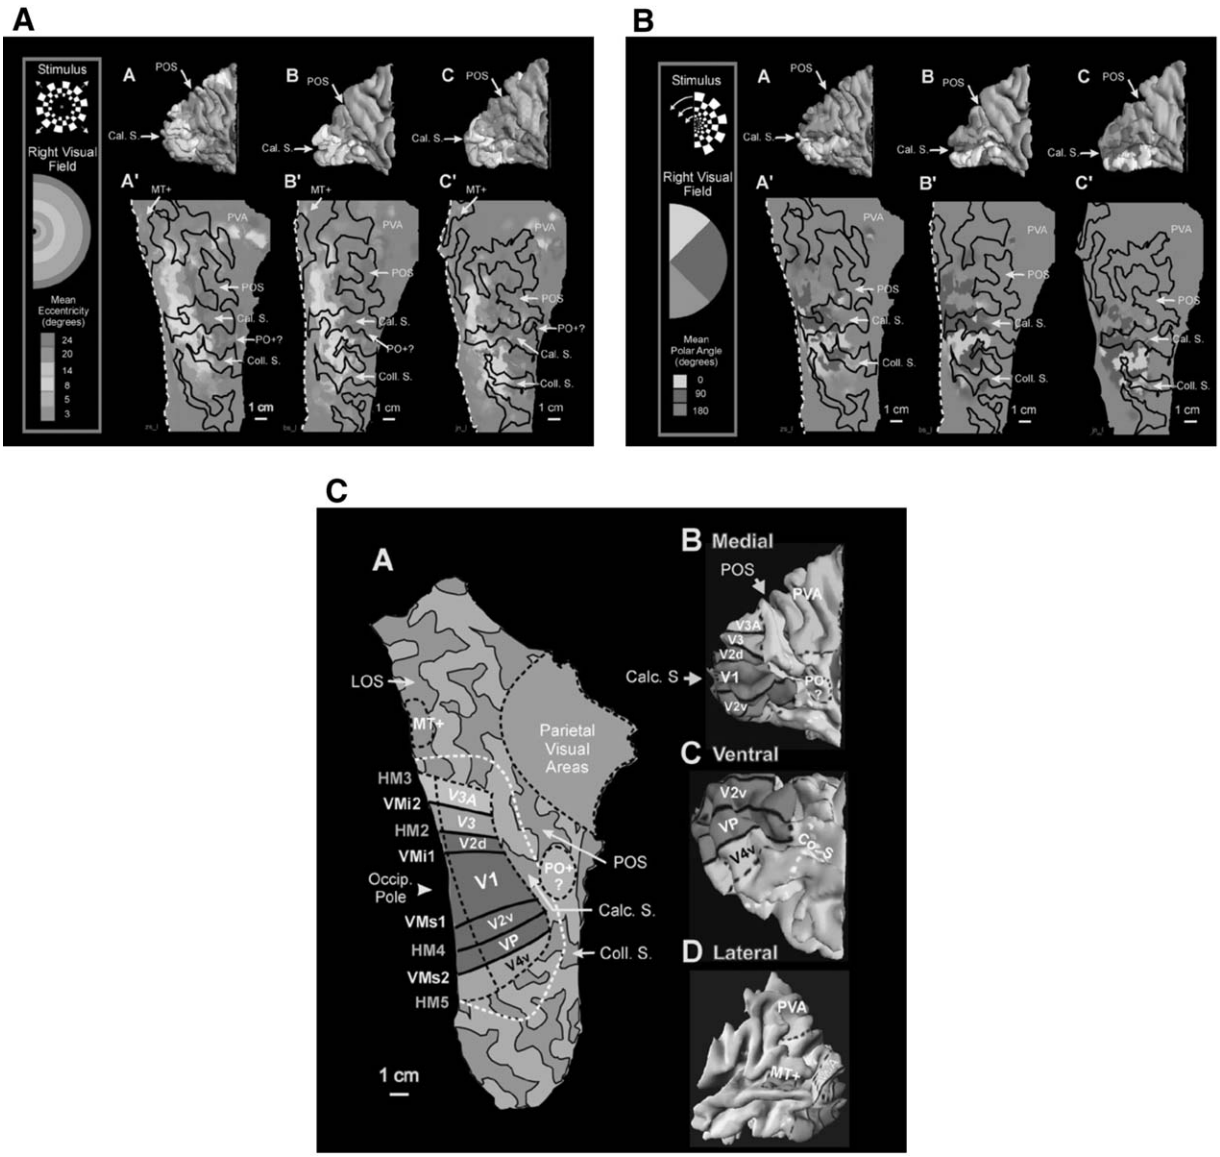

Figure 12 Mapping of visual topography in human visual cortex. (A) Representation of visual field eccentricity from 3° to 30°. Visual stimuli and their representational shades are represented on the left. The locations of activations for three subjects are illustrated on surface reconstructions of the occipital pole (top) and on unfolded cortical maps (bottom). (B) Representation of polar angle determined through activation from rotating checkerboard hemifield (left). (C) Combined visual field topography from three subjects illustrating the multiple representations of the horizontal and vertical meridia found in each subject (left), the localization of the 3–24 isoeccentricity contours (right), and their average overlap (middle). (D) Summary of the topography of human visual cortical areas V1, V2, V3, VP, V3A, and V4v. Area V1 is located in the fundus of the calcarine fissure and is bordered by the representations of the superior and inferior vertical meridia. Area V2 is located both dorsal and ventral to area V1. The anterior border of dorsal V2 is formed by a representation of the horizontal meridian (HM2), and the anterior border of ventral V2 is formed by a second representation of the horizontal meridian (HM4). From DeYoe *et al.* (1996).

is bordered by a yellow band that corresponds to the representation of the superior vertical meridian at the ventral V1–V2 border. The width of V2 can be calculated by determining the location of the next representation of the horizontal meridian that corresponds to the border between areas V2 and V3 in dorsal cortex and between V2 and VP in ventral cortex.

Figure 12C illustrates the average organization of eccentricity and polar angle from the three subjects illustrated in the two previous parts. Area V2

corresponds to a band of cortex that extends from the vertical meridian representation at the border of V1 to the horizontal meridian representations at the border with area V3 in dorsal cortex and VP in ventral cortex. According to this view, area V2 is approximately 1–1.5 cm wide in the region from 1.5° to 24° of eccentricity. This estimate is in agreement with the value of 1–1.5 cm for foveal V2 based on the extent of CO stripes observed in unfolded and flattened human occipital cortex. At more peripheral regions corresponding to intermediate eccentricities, the CO stripes of V2 extend from 1.8 to 3.4 cm. Thus, a potential discrepancy exists between the width of V2 derived from fMRI topographic mapping studies and the width of V2 reported from CO architecture at intermediate eccentricities.

The amount of cortical tissue devoted to the representation of a given portion of the visual field (mm^2/deg^2) is described by the cortical magnification function (CMF). This magnification function varies as a function of eccentricity, with larger values typically found for central visual fields. The calculated CMF for many topographically organized cortical areas is based upon measurements derived from fMRI mapping. The CMF derived for V2 is described by the function $25.19(0.09 + E)^{-1.53}$, where E is eccentricity in degrees.

Areas V1, V2, and several other extrastriate cortical areas have been localized on a surface-based map of the entire cerebral cortex based on the visible man data set. This method provides a convenient method to represent topographic mapping data and functional activation data in a common format that is readily converted to the Talairach stereotaxic space. Figure 13A illustrates the locations of areas V1, V2, V3, VP, V3A, and V4v in the visible man based on topographic mapping data. The uncertainties of the extents of these visual areas are illustrated by question marks on the surface map. Figure 13B illustrates the locations of these areas on a surface model of the visible man's right hemisphere. The lateral view in Fig. 13B illustrates the remaining uncertainty of the foveal projects of these areas. The surface-based atlas also provides a convenient format for the illustration of activation foci from functional studies of color, motion, form, and face processing derived from a wide variety of sources. Corbetta and colleagues have performed a comprehensive study of perceptual processing in the human occipitotemporal cortex. Figure 13C illustrates the location of these activation foci for perceptual tasks involving color, motion, and form processing. Color-processing tasks activated several foci within ventral and dorsal V2; one focus was localized to dorsal V2 in a motion-processing task, whereas three foci were localized to V2 in a form-processing task. Tasks involving the processing of faces do not preferentially activate V2 but instead tend to engage areas in the inferior temporal cortex.

VI. VARIABILITY IN THE LOCATION AND SIZE OF V2 IN HUMANS

PET and MRI imaging have been used to investigate the location and variability of areas V1, V2, VP, V3A, and V4 defined through functional topographic mapping. During PET imaging, 11 subjects viewed dynamic random dot patterns that were arranged as "bowties" along either the horizontal or vertical meridian. Regional blood flow (rCBF) was calculated as deviation from the rest condition for stimulation of either the vertical or horizontal meridian sectors. The resultant PET images were then normalized into the Talairach and Tournoux stereotaxic space. The MRI images from each subject were similarly normalized to Talairach space, and the PET data were coregistered with the MRI anatomical images. The center of area V2 was calculated as the midpoint between the representations of the horizontal and vertical meridia in both dorsal and ventral cortex. The borders of area V2 were consistently observed in the right hemisphere of all 11 subjects and in the left hemisphere in 10 of 11 subjects. Table III summarizes the mean location and standard deviation of the center of gravity of area V2 in the three Talairach coordinates. Overall, the center of gravity of V2 has a mean standard deviation of approximately 5 mm, but it is more consistently localized in the x plane (SD=4.075 mm) and least consistently localized in the z plane (SD=5.975 mm).

VII. VISUAL FIELD DEFECTS ASSOCIATED WITH DAMAGE TO AREA V2 (AND V3)

The organization of area V2 described by functional topographic mapping indicates that area V2 adjoins area V1 along the representation of the vertical meridian in both dorsal and ventral cortex. The anterior border of V2 corresponds to the horizontal meridian, which is split such that the inferior horizontal meridian is located in dorsal cortex and the superior horizontal meridian is located in ventral extrastriate cortex. Area V3 adjoins V2 along the representation of the horizontal meridian in dorsal cortex, whereas area VP adjoins V2 along the representation of the

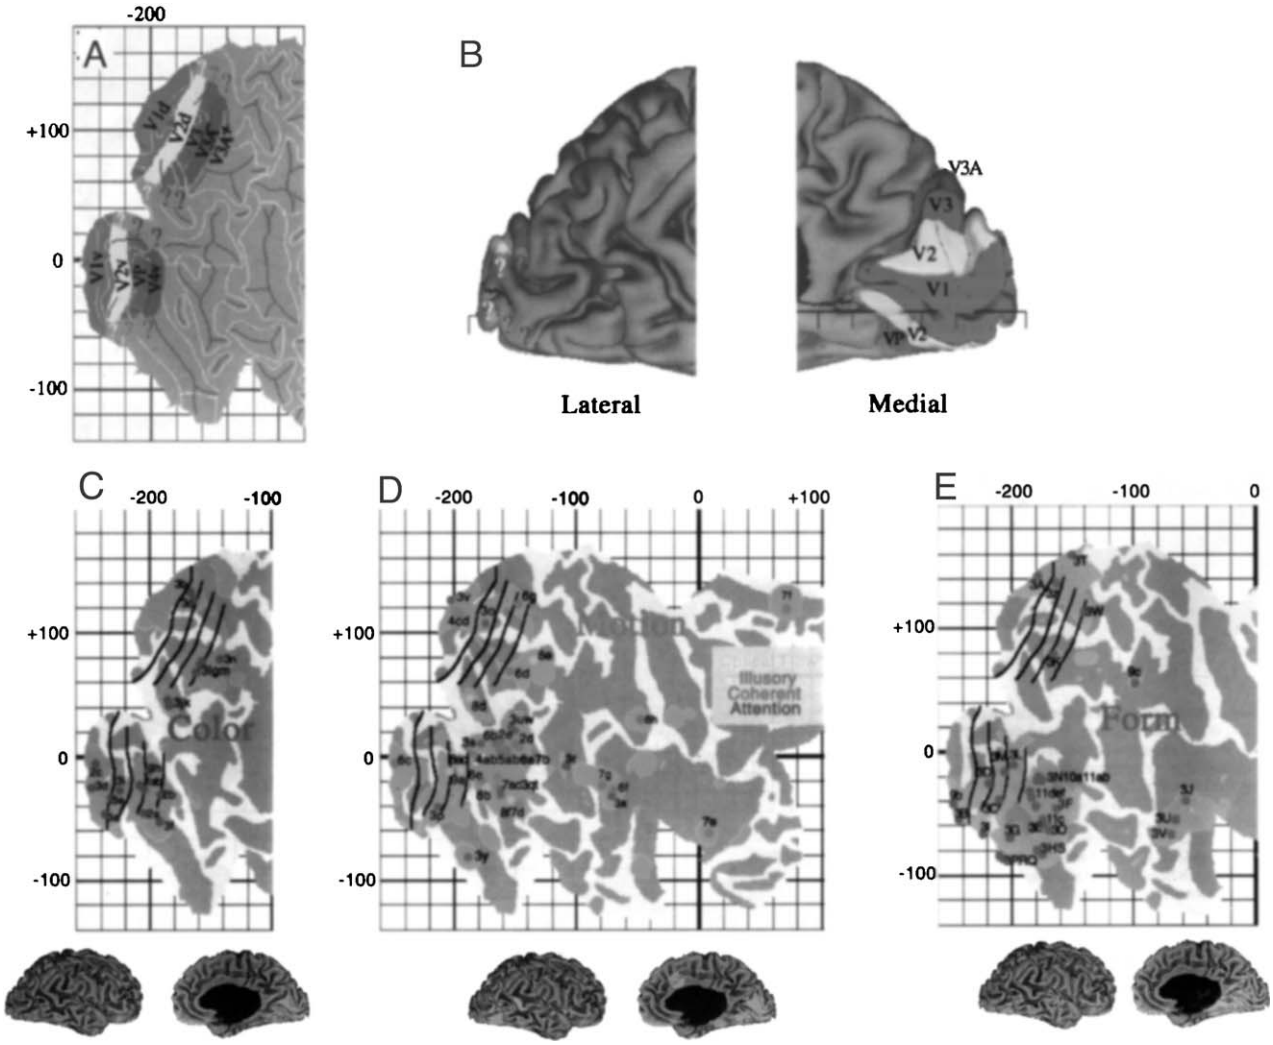

Figure 13 Location and functional mapping onto a surface-based map of human cerebral cortex. (A) Locations of visual areas V1, V2, V3, VP, V4v, and V3A on a surface-based atlas based on fMRI topographic mapping studies. (B) Locations of visual areas projected onto the surface visible man cerebral cortex. (C) Locations of functional activation loci from color-processing tasks (from Corbetta *et al*., 1990). (D) Motion-processing tasks. (E) Form-processing tasks. From Van Essen and Drury (1997).

horizontal meridian in ventral cortex. This is the same topographic organization that has been reported for areas V2, V3, and VP in macaque monkey extrastriate visual cortex. Homonymous quadrantic visual field defects have been observed in two patients with astrocytomas of the extrastriate occipital cortex. Both patients had lower field quadrantanopias that extend up to, but not beyond, the horizontal meridian. Such quadrantanopias have been reported previously and were attributed to lesions of the calcarine cortex. The precise border of the visual field defect at the horizontal meridian is not likely to be caused by lesions of V1 because the border between the lower and upper visual fields is congruent and a lesion is unlikely to precisely respect this border. Instead, quadrantic visual field defects are likely to represent injury to areas V2–V3 (VP) where the horizontal meridian is split into dorsal and ventral halves. Therefore, quadrantic visual field loss may be a hallmark of lesions of early extrastriate cortical areas such as V2, VP (VP), or V4.

In another case, homonymous quadrantanopia was associated with cerebral diplopia (polyopia). This patient had an embolic infarction of the left inferior

Table III
Localization of Human V2 in Talairach Coordinates[a]

V2 component	X plane	Y plane	Z plane
Right V2v	-7.7 ± 4.2	-75.3 ± 5.1	-7.5 ± 4.9
Right V2d	-11.7 ± 4.6	-91.5 ± 4.3	2.7 ± 8.6
Left V2v	7.8 ± 4.0	-71.1 ± 5.9	-3.3 ± 5.9
Left V2d	8.2 ± 3.5	-87.6 ± 4.3	6.1 ± 4.5

occipital lobe anterior to the primary visual cortex. Similar to the lesions described earlier, this lesion produced a superior visual field quadrantanopia that precisely respected the horizontal meridian. Thus, this lesion is likely to represent damage to ventral extrastriate areas V2 and/or VP. This patient had severe defecits in form and color recognition within the affected quadrant. In addition, the patient reported diplopic images within this quadrant. Although the mechanism of cerebral diplopia is not understood, it is possible that the loss or disruption of feedback signals from extrastriate areas V2 and/or VP to area V1 is responsible for this perceptual anomaly.

VIII. FUNCTIONAL PROPERTIES OF HUMAN AREA V2

A. Disparity Processing

Positron emission tomographic methods have been used to identify visual areas involved in the processing of small horizontal disparities. In one such study, subjects were presented either random noise patterns or Julesz-type stereograms. The difference in the regional blood flow patterns was taken to indicate regions of cortex involved in the analysis of the stereogram patterns. The resultant regional blood flow patterns were then mapped onto the corresponding anatomical sections derived from magnetic resonance imaging. Statistically significant cortical activation was observed over a large region of occipital cortex that involves areas 17, 18, and 19.

B. Chromatic and Motion Processing

Early positron emitted tomographic (PET) studies of the functional organization of visual cortex in humans have concentrated on determining the location and specialization of the human homologs of macaque monkey areas V4 and MT. In a color-processing study aimed at identifying human homologs, regional cerebral blood flow (rCBF) measures were made while subjects viewed either chromatic or gray Mondrian patterns. Two statistically significant foci of activation were observed in the visual cortex: one in the occipital pole corresponding to V1–V2 and a second area in the lingual and fusiform gyrus corresponding to V4. In a motion-processing study aimed at identifying human MT, rCBF measures were made while subjects viewed either stationary or moving small black squares. Again two statistically significant foci were observed: one corresponding to V1–V2 and the second at the junction of the parietal and occipital cortices corresponding to area MT. Given the spatial resolution of the PET technique and the similarity of response properties in V1 and V2, these authors were unable to distinguish activation in V2 from that in V1. Nevertheless, this focus was active in each of the four stimulus conditions tested. Thus, V1–V2 were found to participate in both chromatic and gray scale analyses as well as in stationary and moving square analyses.

C. Illusory Motion Processing

The role of areas V1 and V2 in the processing of illusory motion has been studied using PET to measure rCBF. Subjects viewed two different gray scale images based on *Enigma* designed by I. Leviant. The first consisted of concentric gray rings separated by interrupted black and white spokes. Viewing of this image produces the illusion of rotary motion within the rings. In the second image the spokes continued through the concentric rings and the illusion of rotary motion is not observed. This study revealed strong activation of area MT but little or no activation of areas V1–V2. Thus, these lower cortical areas do not appear to participate in the perception of illusory motion.

D. Higher Order Motion Processing

The role of area V2 in the processing of first- and second-order motion in the human visual cortex has

been investigated using fMRI. Retinotopic mapping of visual cortex was first accomplished using contrast-reversing checkerboard hemifields or wedges. Then various first-order and second-order motion and static control stimuli were presented while subjects fixated on the center of the concentric ring stimuli. Regions of interest (ROI) were then applied to the different cortical areas on two-dimensional cortical maps, and the response magnitude for each stimulus condition was determined for each ROI. Areas V1 and V2 responded to all stimuli that contained dynamic flicker and did not prefer stimuli that contained second-order motion signals. This contrasts with the responses in areas V3, VP, V3A, V3B, and MT that demonstrated strong preferences for second-order motion. Thus, the responses in area V2 were governed by local changes in luminance rather than the higher order motion cues.

E. Illusory Contour Processing

Experiments conducted in macaque monkeys indicate that area V2 contains neurons that are selective for illusory contour stimuli, whereas such responses are weak or not present in area V1. In order to determine which areas in human visual cortex are responsive to illusory contours, fMRI techniques were applied to map the areal distribution of responses to illusory contours of the Kanizsa and displaced grating types. Kanizsa stimuli were compared with aligned and rotated inducers, and the resultant activations were mapped onto retinotopically defined visual areas. For individual subjects, Kanizsa stimuli produced robust activations in intermediate level visual areas V3A, V4, V7, and V8 but not in areas V1, V2, V3, or VP. When an across-subject analysis with restricted regions of analysis (ROIs) was applied to these data, a small, but statistically significant response was also observed in these lower visual areas. When displaced grating stimuli were used to produce illusory contours, strong activations were observed in the intermediate cortical areas and weaker activations were seen in areas V1, V2, V4, and VP. Thus, in agreement with previous single-cell and optical recording in macaque monkeys, area V2 contains neurons responsive to illusory contours based on displaced grating stimuli. Unlike the work in macaques, area V1 contained illusory contour responses that were indistinguishable from those observed in area V2. In addition, these results indicate that human area V2 contains a weak, yet significant signal representing stimuli of the Kanizsa type. In contrast, higher cortical areas contained much stronger responses to both types of illusory contours.

F. Texture Segregation Processing

fMRI has been used to study the role of area V2 in texture segregation. Topographic mapping of human visual cortex was first performed to distinguish topographically organized visual areas V1, V3A, V4, and TEO. In ventral cortex, areas V2 and VP could not be distinguished from each other in all subjects, and, thus, the relevant data must be attributed to this amalgam. Subjects were presented blank displays or oriented line texture displays that were either homogeneous or contained checkerboard patterns that were defined by oriented line element boundaries. In area V4 of all subjects, the checkerboard pattern evoked a larger fMRI response than did the uniform texture display. Similarly, a statistically greater fMRI response to the checkerboard pattern was observed in area V2–VP of one subject, but this significance was not achieved when all subjects were combined ($p < 0.08$). In area V1, the difference in responses between the homogeneous texture and the checkerboard texture was not significant. A texture segregation index was used to characterize the difference in responses to structured and unstructured textures. The greatest differential response to structured textures occurred in higher cortical areas V4, TEO, and V3A. However, the positive finding in V2–VP for one subject and the near-statistical significance in the pooled data suggest that V2 (VP) may be where the analysis of large-scale texture patterns first begins.

G. Global Object Processing

The role of various visual cortical areas in the processing of the global features of objects was studied using fMRI by presenting images of natural objects or highly scrambled versions of the same images. The visual areas of interest were first determined through the traditional mapping of the representations of the horizontal and vertical meridians that delineate the borders between areas. Then a series of full field, blank field, half field (upper or lower), or scrambled images were presented to subjects. Whereas this study concentrated on the sensitivity of the lateral occipital area (LO) to the scrambling of images, important information was acquired about areas V1, V2, and V3. As a

group, these areas were well-activated by the natural object images and did not show a reduction in activity with image scrambling. Thus, these lower tier visual areas appear to be responsive to the local orientation and contrast within a stimulus array rather than selective to the global properties of the natural image.

H. Visual Learning and Imagery

It has been hypothesized that cortical areas involved in visual perception are also involved in the recall of images. This hypothesis has been tested using both fMRI and PET. In one study, subjects alternately viewed LED displays of flashing squares or were asked to imagine the display pattern. A region of high activity during the stimulation condition was observed in the posterior occipital cortex that was reported to include both areas V1 and V2. This same region showed strong, yet weaker activation during the imagine condition in five of the seven subjects tested. These results suggest that areas V1 and V2 are involved in the recall or imagination of visual stimuli.

A second study reached a different conclusion using a different paradigm that allowed the assessment of the role of various cortical regions in visual learning, recall, and recognition. Subjects were presented various colored geometric patterns and were tested for their learning of the pattern contents. PET imaging was used to assess the cortical regions involved in the learning phase as well as in the recall and recognition of these learned patterns. Due to the limited spatial resolution of the PET method and the lack of topographic mapping in these experiments, it was not possible to assign activation foci to specific cortical areas. However, it was possible to compare the activations across learning, recall, and recognition conditions. Early cortical area V1 and adjacent pericalcarine areas (such as V2) were activated in the learning phase of this experiment. In contrast, no cortical regions in the occipital lobe were activated significantly during the recall of learned patterns. In addition, V1 and adjacent pericalcarine fields were activated during the recognition task, where learned patterns were presented intermixed with similar novel patterns. These results suggest that areas V1 and V2 are not involved in visual recall, but instead higher cortical and limbic areas are involved in this complex process. The differences in the results between this study and the first study appear substantial and may be attributable to methodological differences.

I. Effects of Attention

Studies in several areas of occipital and inferotemporal cortices in monkeys have indicated that spatially direct attention can modulate the activity of individual neurons. These studies indicate that, when two stimuli are presented in a neuron's receptive field, the neuron's response is dictated by the attended stimulus. This result has been interpreted as a reduction in the suppressive effect of the second stimulus when attention is directed to the first stimulus in the receptive field. This modulatory effect was observed both in the stimulus-evoked activity and in the spontaneous activity when no stimulus was present.

The role of attention in the activity of area V2 in human visual cortex has been investigated using fMRI with paradigms that are largely identical to those used in single-unit investigations in monkeys used to study stimulus-evoked activity and background modulation. To study the effect of attention on evoked activity, fMRI were investigated in areas V1, V2, VP, V4, and TEO during conditions of sequential or simultaneous stimulus presentation both with and without spatially directed attention. The suppressive effect of simultaneous stimulation with four different stimuli increased from area V1 to area TEO. In addition, the magnitude of the response in both the simultaneous and sequential conditions was increased when attention was directed to the visual stimuli in areas V2, V4, and TEO, but not in area V1. To study the effect of attention on spontaneous activity, the baseline activity prior to stimulus presentation was measured with and without spatially directed attention. A baseline shift index (BSI) was used to quantify this difference in activity during the expectation period prior to stimulus presentation. A statistically significant BSI was observed for all cortical areas studied including areas V1 and V2. Thus, area V2 showed an increase in both stimulus-evoked activity and background activity under conditions of spatially directed attention. Interestingly, area V1 showed a significant effect of attention on background activity but not on stimulus-evoked activity. The increase in background activity during spatially directed attention is similar to the results observed in single-unit recording in areas V2 and V4 of awake macaque monkeys.

Thus, functional imaging techniques have been used to study the role of area V2 in a range of perceptual and cognitive tasks. These functional properties of human V2 are summarized in Table IV. This table represents the beginning of detailed investigations about the function of area V2. Future work will ask more specific

Table IV
Perceptual and Cognitive Functions of Human V2[a]

questions about the specific roles that V2 plays in these perceptual tasks. Important questions remain concerning the spatial ranges in which V2 performs motion, form, and color analyses and whether these analyses can be attributed to individual functional compartments in V2.

IX. FUTURE INVESTIGATIONS

Future investigations of human area V2 will utilize new techniques to address several anatomical issues related to two- and three-dimensional mapping and several physiological issues related to compartmental organization. Current methods of two-dimensional and three-dimensional mapping techniques can be expected to be used to provide more complete reconstructions of the distributions of several anatomical markers. For example, although cytochrome oxidase stripes have been visualized in limited portions of V2, it has not yet been possible to map the complete distribution of human V2 cytochrome oxidase stripes. Similarly, the distribution of immunoreactivity for CAT-301, characteristic of the magnocellular compartment of V2, has been observed in limited regions of flattened V2, and it will be possible to reconstruct its complete distribution in three-dimensional reconstructions of histological sections and on unfolded cortical maps. These same approaches can be applied to the localization of a variety of other anatomical markers, such as the distribution of callosal afferents and the distribution of immunoreactivity for SMI-32 or various neurotransmitters.

The previously described anatomical studies are primarily concerned with the distribution of anatomical markers in individual brains that have been first imaged by MRI, then sectioned and stained, and then reconstructed back into three-dimensional models and two-dimensional maps. Additional investigations will expand these single-subject reconstructions to build a standardized brain and standard map. These investigations will build upon existing methods of brain warping and map warping to allow for a probabilistic mapping of these anatomical variables.

Future investigations will explore further the connections that area V2 makes with cortical and subcortical targets. One approach might use highly diffusible markers, with greater efficacy than DiI, to trace axonal pathways. Another approach might use physiological methods of microstimulation combined with fMRI to detect cortical targets activated following local magnetic or electrical stimulation. Finally, the more recently developed method of diffusion tensor magnetic resonance imaging might be employed to study the organization and targets of axonal fascicules that leave V2 for other cortical areas.

Future functional studies will provide better insight into the role that human V2 plays in various aspects of visual perception. These studies are likely to proceed along three different fronts. The first of such studies will utilize refined psychophysical methods, in conjunction with fMRI, to better identify the role of V2 in color, form, motion, texture, and illusory contour processing. The overall goal of such experiments will be to distinguish the perceptual contribution of V2 that is distinct from those of area V1 and higher cortical areas. This work will proceed in parallel with similar investigations in macaque monkeys using microelectrode and fMRI techniques.

The second type of future physiological studies will employ fMRI techniques to study the temporal organization of processing in the visual cortex. These studies will explore the temporal sequence of color, form, motion, and texture processing as these signals radiate out of V1. Although it is clear that the visual cortex is organized in an anatomical hierarchy, little is known about the timing of information flow within this hierarchy. Thus, whereas different stimulus attributes are processed by different compartments in V2

and by different cortical areas, it remains unclear, for example, whether fast motion processing via area MT interacts with slower form- and color-processing elements via feedback to area V2.

The third type of future physiological investigation will employ state of the art fMRI techniques to explore the functional properties of the modular compartments of human V2. Previous fMRI studies of human V2 have summed signals across large expanses of cortex to yield a picture of the role V2 plays in perception. Future studies will be directed at the modular segregation of such signals. Current fMRI methods have begun to address the compartmental organization of visual cortex. The visualization of presumed ocular dominance columns in human V1, which are approximately 1 mm in width, increases the likelihood that the larger V2 modules can be similarly visualized.

Finally, better functional localization of visual cortical areas such as V1, V2, V3, VP, V4, and MT in individual brains will allow more highly detailed solid models necessary for the interpretation of multisource electrical or magnetic evoked potentials. The resolution of these multisource models will allow a wide variety of studies that can examine the dynamics of visual perception.

Arousal

RICHARD T. MARROCCO and BRENT A. FIELD
University of Oregon

GLOSSARY

agonist A drug that activates the same receptor as does the natural neurotransmitter.

antagonist A drug that blocks the activation of a receptor.

electroencephalograph The electrical activity of the brain measured from the surface of the scalp.

G protein-coupled receptors Cell surface receptors that are activated by substances in the synaptic cleft but are coupled to channels by multiple chemical messengers that open the channels from within the cell.

ligand-gated receptors Cell surface receptors that are activated by chemical substances in the synaptic cleft (ligands) and are coupled directly to channels in the cell's membrane.

neuromodulatory transmitter A neuroactive substance found in the peripheral or central nervous system that causes long-lasting changes in excitability of the postsynaptic cell.

Arousal is the ability to mobilize metabolic energy to meet environmental or internal demands on behavior. As such, it is an organismal property that is found throughout the animal kingdom, including those species with very rudimentary nervous systems. For example, in jellyfish, arousal may be produced by the diffusion of activating substances within the body wall that increase metabolic activity. In insects, activating substances may be generally mobilized within ganglia and released onto specific target structures from single neurons. In marine mollusks, repeated application of a noxious stimulus to the skin causes a withdrawal response that grows in magnitude over time. Although termed sensitization, it is associated with global changes in metabolism and is probably the precursor to the arousal response in higher organisms. The anatomy and physiology of arousal are similar among primitive vertebrates and highly complex mammals. Although the arousal response in humans is present at birth, research suggests that some components of the response are recognizable *in utero*. Arousal responses in neonates are frequent and associated with hunger and discomfort. The soothing voice of the parent is usually the first external stimulus to exert control over the arousal response. The major developmental changes in the arousal response are the growth of inhibitory processes that control and shape the response and an increase in the range of internal and environmental stimuli that activate these processes.

I. HISTORY

The concept of arousal dates well back into the histories of many linguistic groups. According to *Webster's Dictionary*, the root *arouse* was used in English as far back as 1593. The first scientific investigation into arousal appeared in the 1860s. Arousal from sleep was measured by determining from how high an object needed to be dropped for the subject to awaken. Kohlshütter reported that sleep depth increased up to 1 hr post-sleep onset and then decreased through the remainder of the night.

Modern work on arousal systems began in the era after World War I, when viral epidemics occurred that caused damage to the brain stem and produced "sleeping sickness," which was characterized by a profound hypoarousal. About two decades later, the first evidence for arousal centers in the upper brain stem was obtained from experimental animals. Perhaps the most cited work in this area of medicine is that of Moruzzi and Magoun. The major conclusion of their work was that brain stem influences modulated thalamocortical neurotransmission. Although the details of this conclusion have changed substantially, the core idea published more than 50 years ago was essentially correct.

In the past two decades, progress in understanding arousal systems has been advanced most dramatically through neurochemistry. It is now clear that the arousing structures of the brain stem and hypothalamus have neurochemically distinct profiles, and the neurotransmitters in each may use distinct intracellular pathways to regulate the excitability of cortical neurons. Most, if not all, of these neurotransmitters show increased turnover during the aroused state and, conversely, drugs that stimulate the release of these substances cause increased cortical arousal. In addition, these neuroactive substances regulate cells of other arousing structures as well, making it all but certain that variations in behavioral states result from a change in the patterns of activity between the arousing structures.

The potential complexity of these patterns of activity is impressive. As will be discussed later, the arousing structures release five major neurotransmitter substances that bind to at least 33 pre- and postsynaptic receptor types. Although found in very low concentrations within the axon terminals, nine additional neuroactive substances, including neuropeptides and adenosine triphosphate (ATP), are coreleased and bind to many postsynaptic sites. Both classes of substances are undoubtedly important for the patterns of arousal. Ultimately, understanding how the arousal response occurs depends on knowing which neurotransmitters are active and where they are exerting their effects.

II. NEUROCHEMISTRY

The major neuroactive substances we discuss are noradrenaline (NA), dopamine (DA), acetylcholine (ACH), serotonin (SE), and histamine (HA). Most of these neuromodulatory transmitters (collectively referred to as NMTs) are located in brain stem or forebrain nuclei and modulate both subcortical and cortical structures. NA (also known as norepinephrine) is contained in many cell groups of the pons but the locus coeruleus is the critical structure for cortical arousal. DA-containing cells reside in the pontine tegmentum and the cortex receives dopaminergic fibers from the ventral tegmental region. ACH neurons are found in the pontine pretrigeminal area and the basal forebrain. SE (also called 5HT) neurons are located along the medullary midline in the raphe nuclei. HA is manufactured by cells of the hypothalamus.

Other neuroactive substances also influence brain arousal, but are different from the NMTs in one or more ways. Adenosine is an amino acid that inhibits other NMTs and is found in many locations throughout the brain. Unlike the other NMTs, however, it is neither a classical neurotransmitter, because it is not released synaptically, nor is it contained in cells that reside in the brain stem. Adrenaline (epinephrine), which resides in brain stem neurons and uses the same receptors as NA, does not project to the cortex and is generally thought to contribute little to conscious arousal. Adenosine and adrenaline will not be discussed further. Glutamate is occasionally listed as an NMT. Glutamate is contained in the terminals of the thalamocortical neurons and provides the synaptic inputs that drive cortical cells. We take the view, however, that arousal is a modulation of the thalamocortical inputs, not the action of the inputs themselves, and we do not include glutamate as an NMT.

This article reviews neuroscientific research conducted within the past 20 years on the roles of each NMT in arousal and identifies, where possible, patterns of activity among the arousing structures that are correlated with behavioral states. We begin by defining the terms that will be used and by describing the physiological indices used to assess arousal tone. We then provide an overview of the anatomical components of the arousal systems and their associated NMTs. For each NMT, its anatomy, its effects on target cells, and its role in specific behaviors will be discussed. We then attempt to integrate the properties of these systems and show how they shape and modulate behavior. We will not discuss the connections between arousal and sexual or consummatory behavior.

III. TERMINOLOGY

A review of the arousal literature reveals that a variety of terms are used to define aspects of arousal. *Arousal*

and *alerting* are often used interchangeably, as are *arousal* and *behavioral state*. In this article, we take the position that the changes in nervous system excitability may differ significantly in duration. We refer to changes lasting a few milliseconds to a few seconds as shifts in *alertness*. We refer to changes lasting from seconds to minutes as *vigilance*, for lack of a better word. Our use of vigilance is different than that in the signal detection literature, in which it refers to the readiness to detect infrequent events in noise. We use vigilance to describe the physiological reactions to environmental events that accompany shifts in focal attention, an increased readiness to respond, and increased activity in the sympathetic nervous system. The events are often cognitive demands on the organism, including emotional valence, task difficulty, and stimulus novelty. Relatively speaking, we consider alerting to be a phasic process and vigilance a tonic process. The term arousal is used in a more general sense to refer to any changes in nervous system excitability regardless of duration.

IV. AROUSAL INDICES

The most common index of arousal is the cortical electroencephalogram (EEG), which can be recorded from the scalps of most mammals. The electrical activity recorded at the scalp represents the summed voltages produced by extracellular neuronal activity beneath the recording electrode. Neuronal electrochemical currents are filtered by the skull and surrounding tissues as the currents spread passively to the recording device. Consequently, the exact location of a particular voltage change is difficult to determine.

The electrical voltage of the EEG ranges from a few microvolts in the aroused state to several hundred microvolts in deep, slow-wave sleep. Therefore, EEG voltage is inversely correlated with behavioral arousal. EEG frequency varies directly with arousal, with the highest values (50–60 Hz) associated with the highly aroused state and the lowest values (2 Hz) seen in comatose states. Both overt behavior and EEG characteristics tend to change gradually during the day. One exception to this is during sleep, when abrupt transitions between slow-wave sleep and rapid eye movement (REM) sleep occur. The EEG characteristics of REM sleep are nearly identical to those of the alert state and reflect episodes of dreaming.

The EEG can also be used to measure alerting and vigilance by measuring changes in electrical activity immediately following an environmental stimulus, a shift of attention, or a change in the task at hand. Although arousal state may be recognizable from a single, 3- to 5-sec epoch of the EEG, it is usually necessary to average tens or even hundreds of short (e.g., 300 msec) segments of the EEG following the external stimulus to measure the change caused by alerting.

Many other measures have been used extensively, including electrodermal responses, changes in blood chemistry, and even early gene expression. A discussion of these issues is beyond the scope of the current review, but excellent treatments may be found in texts on psychophysiology.

There are pitfalls in relying on any single measure of arousal. For example, alerting caused by fear-evoking stimuli causes an increase in heart rate and other autonomic indices. In contrast, phasic alerting caused by orienting toward a nonthreatening stimulus causes a slowing of the heart and other internal organs. Thus, a complete understanding of the arousal response requires a consideration of the pattern of responses and the context in which they occur.

V. ANATOMICAL SUBSTRATES OF AROUSAL

Behavioral arousal is caused by an interplay between the peripheral and central nervous systems. The central nervous system (CNS) evaluates external stimuli for meaning and initiates or modulates activity in the peripheral and central systems. Peripheral arousal is the result of activation of the autonomic nervous system, which affects internal organs directly and skeletal musculature indirectly. One of the main functions of the sympathetic branch of the autonomic nervous system is to liberate adrenaline into the bloodstream. Adrenaline increases alertness and energy expenditure, which are then sensed by the CNS. Thus, peripheral and central arousal are interdependent contributors to the control of behavioral arousal.

A. EEG Arousal Is Controlled by Interconnections between the NMTs, Thalamus, and Cortex

1. Two Modes of Thalamic Activity

Changes in the EEG during arousal are produced by an interaction of the NMTs with the cortex and thalamus. The NMTs control the strength and pattern of the coupling between the thalamus and the cortex.

During rest or sleep, thalamic reticular neurons (Fig. 1) emit rhythmic bursts of action potentials within a narrow range of frequencies (4–8 Hz). The bursting pattern is maintained as long as these cells are slightly hyperpolarized. Hyperpolarization may be caused by the release of SE in the thalamus by the brain stem raphe nuclei. Thalamic burst activity, known as the burst mode, is relayed to the cortex, where it produces cortical burst activity. On the scalp, this pattern is recorded as high-voltage, slow-wave cortical activity, known as the synchronized EEG.

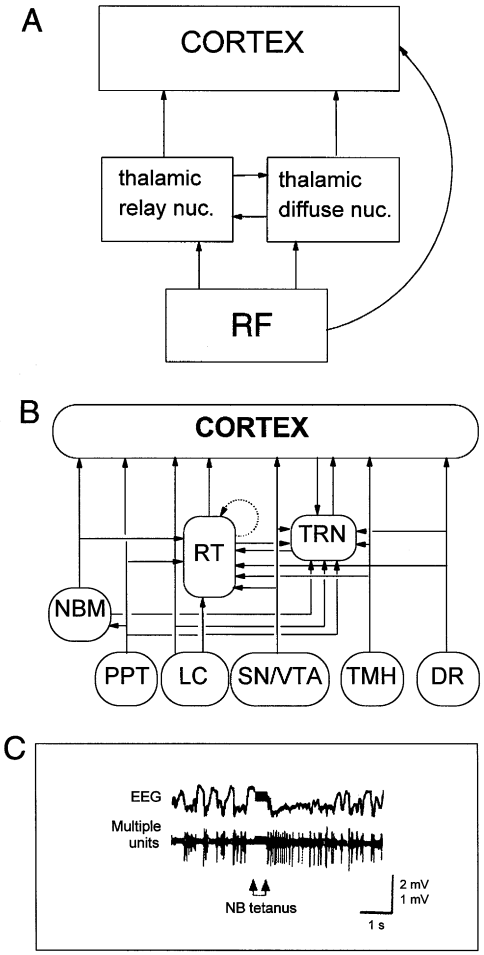

Figure 1 (A) Early model of arousal systems, circa 1972. The RF was considered a unitary structure that modified processing in sensory thalamic relay structures, nonsensory diffuse nuclei, and the cortex. The two groups of thalamic nuclei were mutually interconnected. (B) Contemporary view of arousal systems. Each NMT (bottom) sends influences to both the RT and the TRN. The RT contains oscillatory circuits (dotted line) that produce the rhythmic activity of the brain. (C) Electrical activity recorded in the cortex and the effects of electrical stimulation (tetanus) of the cholinergic NBM. The EEG switches from high-voltage slow waves to low-voltage fast activity. Individual cells show burst activity prior to tetanus and single spike activity for several seconds after tetanus [reproduced with permission from Metherate *et al.*, (1992). *J. Neurosci.* **12**, 4701–4711. Copyright Society for Neuroscience]. RF, reticular formation; NBM, basal nucleus of Meynert; PPT, peduncolopontine tegmental nucleus; LC, locus coeruleus; RT, relay thalamic nucleus; SN/VTA, substantia nigra/ventral tegmental nuclei; TMH, tuberomamillary hypothalamic nucleus; DR, dorsal raphe nucleus; TRN, thalamic reticular nucleus.

In contrast, the low-voltage, fast-wave activity, known as the desynchronized EEG, results when NMTs suppress the hyperpolarizing influences on thalamic neurons and shift the thalamic activity into the single-spike mode. This activity is initiated by ACH that is released from the terminals of basal forebrain neurons. The frequency spectrum of rhythmic activity increases substantially and high frequencies (40–60 Hz) may be frequent. Similar patterns are engendered in cortical neurons and the EEG records of this activity are seen during REM sleep and waking states. Although high-frequency EEG activity has been characterized as desynchronized, it may simply be synchronized to higher frequencies. The mechanisms underlying the burst and single-spike mode are discussed in-depth later.

2. Models of NMT Modulation of Thalamocortical Activity

The mechanisms underlying EEG desynchronization have been of great interest for decades. Early studies in the 1940s and 1950s by Moruzzi and Magoun and others showed that stimulation of the midline thalamus caused a desynchronized EEG pattern in anesthetized cats. Based on these results, two systems for the control of cortical arousal were hypothesized: the generalized thalamocortical system, composed of the midline and intralaminar thalamic nuclei, and the specific (relay) thalamocortical system. The relay system carries sensory information to the cortex, but its cortical influence is modulated by the generalized system. The general system has also been called the ascending reticular system and the diffuse thalamocortical projection system.

The arousal systems must work in unison to control behavior, but the arousal response is not necessarily stereotyped. In some circumstances, the EEG and other indices of arousal may be uncorrelated with behavioral or physiological responses. Specific behavioral contexts are important in determining the patterns of motor, autonomic, emotional responses. For example, intense fear may cause overt, widespread changes in muscular locomotor activity and produce escape responses. Alternatively, there may be a

complete lack of overt activity but widespread covert changes in muscle tone, such as occurs during "freezing" behavior. These qualitative changes may indicate an underlying shift in dominance from one transmitter system to another. Thus, it is more appropriate to view arousal as a flexible response to changing environmental demands rather than as a reflexive, fixed pattern of activity.

B. Arousal State Depends on Excitatory and Inhibitory Actions Mediated by a Variety of Receptors

1. Peripheral Nervous System

In the peripheral autonomic nervous system (ANS), phasic or tonic arousal is associated with a shift from anabolic to catabolic metabolism. Anabolic changes are mediated by ACH, which generally has an inhibitory effect on target organs; catabolic, excitatory changes are mediated by two catecholaminergic transmitters, adrenaline and NA. Thus, the peripheral nervous component of arousal level is determined by an interplay between ACH, NA, and adrenaline.

2. Central Nervous System

There is a more complex interplay between excitatory and inhibitory forces in the CNS compared to the peripheral system due to a greater number of NMTs and their associated receptors. Most of the arousal-related substances may be excitatory or inhibitory or both, depending on the specific receptor–ion channel complex they stimulate. The latency and duration of these effects are quite varied. Another difference is that structures in the CNS are not innervated by two neurotransmitters substances with opposite effects. In most cases, cortical cells are contacted by NMT axons that have similar postsynaptic effects. Opposing actions may be mediated by two NMTs on a single cell but they are likely mediated by inhibitory interneurons.

3. Receptor Families

Transmitters produce receptor-mediated, postsynaptic responses in two ways. First, ligand-gated receptors are directly coupled to ion channels in the postsynaptic membrane. The binding of the ligand produces short latency and short duration effects. Second, G protein-coupled receptors are linked to second messenger systems such as protein kinases or adenylate cyclases. In this type of system, the binding of the ligand can produce a variety of biochemical reactions that result in longer latency and longer duration effects. The effects of ACH 5HT are mediated by either ligand-gated or G protein-coupled receptors. The effects of NA, HA, and DA are G protein coupled only. Next, we provide a more detailed description of the individual neuroactive substances and their interactions with receptors.

C. Noradrenaline

1. Projections of the NA System Are Highly Divergent

NA is supplied to the forebrain by neurons in seven medullary nuclei. The cortex is innervated by one of those nuclei, the locus coeruleus (LC). LC axons travel to the cortex in the dorsal tegmental bundle and show a spectacular pattern of branching that delivers NA to many separate areas. In each area, the fibers approach the cortical mantle from the underlying white matter, project upward, and give off collaterals in almost all laminae.

NA influences cortical neurons through α and β adrenoceptors. These receptors are differentially distributed across cortical laminae and cortical areas. Each receptor is activated by unique ligands, triggers distinct intracellular second messenger systems, and mediates different physiological responses in postsynaptic neurons. In the visual cortex, for example, stimulation of β receptors (β_1 and β_2 subtypes) with sotalol produces mostly short- and long-term inhibitory effects on cells in lower cortical laminae. Stimulation of α receptors (both α_1 and α_2 subtypes) with phentolamine produces only short-duration excitatory effects on cells in the upper cortical laminae.

In the primate visual cortex, greater NA innervation is seen in the superficial and deep laminae than in the middle laminae. This suggests that NA has a greater influence on cortical outflow than cortical inflow. Perhaps NA may be important in regulating the amplification of signals sent to other cortical areas.

2. Cellular Effects of Noradrenaline May Be Excitatory or Inhibitory

In vivo application of NA onto cortical and thalamic relay cells produces a slow depolarization of the membrane and an inhibition of the potassium con-

ductance. This makes the cell react more strongly to its inputs. The effects on the cell's spontaneous activity are more variable. Reductions in activity are seen that effectively increase the salience of evoked responses compared to the unstimulated activity. Thus, the effect of NA is not expressed until a sensory stimulus is present. In other cells, elevations in spontaneous activity are seen. No increase in salience occurs in these cells and decreases in salience may occur. NA's effects on single cells is complex and probably depends on the unique distribution of receptors on each cell. It is to be expected that NA will have complex effects on networks of neurons, but this expectation has not been tested.

What events cause NA to be released onto postsynaptic targets? NA neurons appear to respond phasically to the appearance of nonarousing environmental stimuli and in conjunction with shifts of attention, but they respond more tonically to arousing stimuli (e.g., threatening or appetitive stimuli). In addition, tasks requiring intense focusing of attention are accompanied by a steady rate of firing in LC neurons. When attention wanders, the tonic activity of LC neurons increases and becomes more variable. These results suggest that the rate of LC activity may be positively correlated with attentional lability. Conversely, focused attention reduces the likelihood that the organism will be alerted by unexpected stimuli. This relationship will be discussed later with regard to recent studies of alerting.

The release of NA may also be produced by the application of cholinergic agonist to the LC. This manipulation causes excitation in LC neurons and a reduction in low-frequency EEG activity, similar to that seen during natural arousal. However, it has little effect on the 10- to 30-Hz components that are enhanced during natural arousal. Perhaps isolated stimulation of the LC fails to activate other NMTs that produce increased high-frequency activity during natural arousal.

3. Cortical Arousal May Be Altered by Local Factors

As would be expected from its anatomical organization, stimulation of the LC causes release of NA at many cortical and subcortical sites simultaneously. This has been confirmed empirically and suggests that NA release is governed by activity in LC cell bodies. In many other experiments, however, NA release is regulated by factors near the terminals of LC neurons. In the visual cortex, physiological experiments demonstrate that the release of NA in the visual cortex by visual stimulation depends on the efficacy with which the visual stimulus affects the electrical activity in nearby cortical neurons. The same stimuli are ineffective in evoking LC neuronal activity. These results suggest that the release of NA from visually nonspecific LC neurons may be determined by excitation in nonnoradrenergic, cortical cells. In the frontal cortex, local administration of glutamate causes the release of NA from the terminals of LC neurons.

All these observations can be explained by postulating two kinds of control over the LC neurons. The first is produced by synaptic inputs to dendrites or cell bodies, which cause global release of NA. The second is produced by the local regulation of NA release from individual LC terminals, which would account for the local physiological effect of visual stimulation. Indeed, the second type of control, which occurs in the absence of impulse activity generated in the cell bodies, may be the basis for interactions between many neurotransmitter systems. For example, cholinergic and glutamatergic control of DA and NA release and noradrenergic control of ACH by preterminal modulation of transmitter release have been demonstrated.

4. Behavioral Effects of Altering CNS Noradrenaline Are Diverse

Systemic administration of NA agonists and antagonists has both peripheral and central nervous effects. Here, we limit the discussion to drugs that alter CNS arousal. The stimulants methylphenidate and amphetamine increase the levels of both NA and DA by stimulating α_2, D_1, and D_2 receptors and blocking reuptake of DA and NA into the presynaptic cleft. These drugs also increase alerting and vigilance to environmental stimuli.

The effects of nonstimulant drugs on arousal may be more complex. For example, clonidine, an α_2 agonist, causes deficits in stimulus alerting in nonhuman primates. Subjects are impaired in using the timing of the stimulus onset to help them respond to visual targets in a rapid fashion. This effect is due to stimulation of presynaptic receptors, which reduces brain NA. Clonidine also ameliorates the memory deficits of aged monkeys by increasing the levels of brain NA through stimulation of postsynaptic receptors. It probably increases their alertness as well. The differences in outcomes may be due primarily to the amount of drug present near the synapse. Low doses stimulate postsynaptic receptors and higher doses stimulate postsynaptic and presynaptic receptors.

The results may also depend on the age of the subject and the type of task used.

In humans, the brain locations at which NA regulates changes arousal are of great interest. Recent efforts to identify these sites using functional magnetic resonance imaging of brain activity have shown that the thalamus is especially important in mediating the interaction between changes in arousal and the performance of cognitive tasks requiring sustained attention.

D. Dopamine

1. Dopaminergic Neurons Project Mainly to Subcortical and Frontal Cortical Areas

DA is supplied to the cerebral cortex primarily by cells of the pontomedullary region termed area A10, whose axons travel in the median forebrain bundle and bifurcate to innervate the frontal and motor cortices. There is a rostral–caudal gradient of terminals across the hemispheres, with the highest densities in the frontal lobe and virtually no DA in the occipital lobe. DA neurons from the substantia nigra innervate the corpus striatum. The rest of the brain receives DA from seven other brain stem dopaminergic nuclei.

2. Dopamine's Cellular Effects Resemble Those of Noradrenaline

The cellular effects of DA application are similar to those of NA. There is a generalized reduction of spontaneous activity in neurons with DA receptors and overall increases or decreases in evoked activity. No changes in signal-to-noise ratios are reported. DA neurons typically are active during shifts in behavioral states. Brief bursts of activity are recorded following behaviorally arousing stimuli. Inhibition of activity is reported for periods of sustained, focal attention. Thus, DA neurons are more active during the shifting of arousal or attention than during sustained arousal.

Recent work investigated which of several DA receptors may mediate arousal. D_2 receptor agonists produce cortical desynchronization and an increase in locomotor activity in rats. If both D_1 agonists and antagonists are coadministered, the rat shows no signs of increased arousal. However, administration of a D_1 antagonist blocks the effect of arousing stimuli but does not produce sedation. Thus, an increase in D_1 receptor activity may underlie increases in arousal.

Stimulation of D_2 receptors produces desynchronization but has a less dramatic effect on locomotor activity. These effects are not entirely blocked by coadministration of D_2 antagonists. As in the case of D_1 antagonists, administration of D_2 antagonists alone fails to produce sedation. However, simultaneous blockade of both D_1 and D_2 receptors produces sedation and EEG synchronization.

Thus, it appears that activity mediated by D_1 or D_2 dopaminergic receptors may underlie increases in arousal. Decreases in the activity of either receptor type, however, are not sufficient to decrease the organism's arousal. Rather, activity in both D_1 and D_2 receptors must be decreased simultaneously for a decrease in arousal to be measured.

3. Dopamine Modulates Behavioral Action

The literature linking DA to behavior is vast. Although DA has been implicated in many behaviors, the common theme in behavioral pharmacological studies is motoric. That is, the sensory- and memory-related components of behavior are less affected than the response components by manipulations of DA levels. These observations are consistent with the extensive dopaminergic innervation of the corpus striatum, a key structure for movement. In addition, there are dramatic instances of DA involvement in degenerative diseases that produce major movement deficits. For example, Parkinson's patients, whose midbrain DA neurons have been lost, exhibit severe deficits of voluntary and involuntary action. Also, involuntary movements (tardive dyskinesia) are side effects of drugs that block DA receptors in schizophrenic patients. Lastly, people who abuse stimulants that affect the DA system may show stereotyped, rhythmic hand and head movements. Interestingly, stimulant abuse may also cause a model paranoid psychosis, including delusional behavior, hallucinations, and a hyperattentional state. Clearly, DA's effects may be apparent in brain systems that are not obviously motoric. DA's involvement in other behaviors is seen in normal subjects as well.

DA's effects on attention in normal subjects depend on the task the subject must complete. For example, the shifting of attention may be evoked in humans by cues (arrows) that point in the direction of a location to be attended. Administration of droperidol, a D_2 antagonist, slows overall reaction times to visual stimuli and increases the time required to reorient attention when it is focused on the wrong target location. These results are consistent with the motoric

theme as long as the movement of attention is treated as covert motor activity.

Other human studies use D_2 antagonists to examine the orienting of attention to cues that physically appear near the location at which a target appears. No specific effects on attention are found for these drugs, but there is a generalized slowing of responses to all targets. Studies of animals lacking dopaminergic cortical projections on one side of the brain also show generalized motor deficits in reacting to visual stimuli. Taken together, DA appears to play a role in the motor activity required to react to the targets in general but not in attention *per se*.

E. Acetylcholine

1. Projections of the Cholinergic System Are Relatively Punctate

There are six distinct sources of ACH in the cerebrum. Cortical ACH is supplied primarily from the basal forebrain nucleus and secondarily from the ansa lenticularis and substantia innominata. Recent work has examined the degree of divergence in the axonal projections of basal forebrain neurons. The patterns are distinctly different than those seen for noradrenergic or dopaminergic neurons. Neighboring cortical locations are almost always innervated by different cholinergic neurons. Indeed, the axon terminals of single basal forebrain neurons often synapse entirely within single cortical columns, the smallest anatomical division of the cortex. Although some divergence is occasionally seen, the bulk of the cholinergic projections to the cortical mantle show extremely limited divergence.

The effects of ACH are mediated by nicotinic and muscarinic receptors, which mediate excitatory effects on cortical neurons. Muscarinic receptors are more numerous than nicotinic receptors and are found mostly on postsynaptic cells. Nicotinic receptors are more often presynaptic than postsynaptic. Both types of cholinergic receptors are found throughout the neocortex and are most dense in the lower cortical laminae. Some subcortical areas, such as the optic tectum, seem to contain only nicotinic receptors.

2. The Most Common Cellular Effect of ACH Is Excitation

Both direct application of ACH and electrical stimulation of the basal forebrain nuclei produce rapid firing in cortical neurons (Fig. 1C). Unlike direct application, basal forebrain stimulation causes extracellular ACH to increase simultaneously at widely separated locations in the cerebral cortex. The breadth of this effect is what one would expect from cholinergic anatomy. Is the same pattern evident during natural arousal? The answer is yes: A robust increase in cortical extracellular ACH is measured during the transition between sleep and wakefulness. Does damage to the basal forebrain impair arousal? This answer is also yes because damage to basal forebrain neurons causes synchronized cortical activity. Thus, the release of ACH from the terminals of basal forebrain neurons is both necessary and sufficient for cortical arousal and also mediates the changes in EEG activity.

Knowing how ACH changes the patterns of the cortical EEG is only half the problem. ACH's role in regulating the neural interplay between the thalamus and the cerebral cortex must also be understood. McCormick provides an excellent summary of these regulatory effects. For example, cholinergic stimulation of neurons in the lateral geniculate nucleus (LGN) causes cortical cells to switch from a burst mode to a single-spike firing mode and thereby produces visual cortical EEG desynchronization. This switch is caused by the reduction of three potassium-sensitive currents that excite the cell. In addition, ACH inhibits the LGN interneurons that inhibit the LGN cells that project to the cortex. Thus, cholinergic influences directly excite and disinhibit cortical neurons. During drowsiness, the production of cortical synchrony depends on removal of cholinergic stimulation and stimulation of inhibitory LGN interneurons by noncholinergic NMTs.

The pedunculopontine area of the brain stem is the source of thalamic cholinergic modulation. Stimulation of this area produces arousal-like effects in thalamic cells and a desynchronized EEG pattern in the cortex. Pedunculopontine-mediated cortical arousal is not dependent on the basal forebrain system since blocking the nucleus basalis Meynert does not abolish the effect. Especially intriguing is the specific augmentation of the high-frequency (25–45 Hz) components of the EEG. These components are thought to be important in arousal or attentive visual fixation and pattern recognition, and they are not produced by LC stimulation.

The central role of ACH in arousal is also supported by pharmacological studies. Cholinergic agonists (e.g., carbachol and bethanecol) increase cortical ACH and EEG desynchronization. Interestingly, cholinergic antagonists (atropine and scopolamine) reduce cortical ACH and increase EEG synchrony, but they

produce an alert, wakeful behavioral state. This finding illustrates that there are occasional dissociations between the physiological and behavioral indices of arousal and reiterates that the EEG alone may not give a complete picture of the dynamics of the arousal response.

3. Acetylcholine Improves Cognitive Function

Through the manipulation of the brain's chemical environment, researchers have found that ACH plays a key role in such cognitive functions as learning, memory, and attention. This view is consistent with our view that cholinergic activation, by virtue of its broad excitatory actions, facilitates behaviors by maximizing information processing in brain systems.

As an example of ACH's cognitive benefits, nicotine has been shown to improve visuospatial attention shifting in the cued target detection (CTD) task described previously. Attentional orienting is faster in monkeys given injections of nicotine and in humans who smoke cigarettes. The effect in monkeys is reversed by the nicotinic antagonist mecamylamine, suggesting that it is specific to the nicotinic synapse. Blockade of the muscarinic receptors has a similar effect on the CTD.

If the cholinergic system is involved in arousal, then neurons of the basal forebrain system should become active in tasks that demand increased arousal or attention. In fact, neurons of the basal forebrain nucleus respond during a behavioral choice task that requires either the execution of a hand movement or withholding of the response. Most neurons responded during both tasks, indicating that their activity was linked to some aspect of the decision process or to increased arousal preceding the response.

F. Serotonin

1. Serotonin's Projections to the Brain Are Widespread

There are nine sources of SE within the brains of mammals. All lie in the brain stem and those from the dorsal raphe nucleus comprise 80% of the SE innervation of the cerebral cortex. SE projections contact all the major cortical areas of the brain, but whether individual serotonergic neurons send signals to all areas of the cortex (as do NA neurons) or to more restricted areas (as do cholinergic neurons) is not known. In the visual cortex, the terminals of SE neurons are found in layers avoided by NA neurons.

Current classification schemes list seven main types of serotonergic receptors (5HT-1–5HT-7), each of which has several subtypes. The subtypes appear to be located in different areas of the brain, suggesting that they have different functions. For example, only 5HT-1 receptors are found in large numbers in the hippocampus, suggesting that they are involved in the storage of information.

2. Serotonin's Effects on Cells

The effects of application of SE to cortical neurons depend on the receptor types stimulated. 5HT-3 receptors are ionotropic and applied SE produces immediate excitation of the cell, probably by activation of sodium currents. All other SE receptors are G protein coupled and applied SE produces either excitatory (inhibition of K^+ currents) or inhibitory (activation of K^+ currents) responses that have slower onsets and longer duration than those responses seen in 5HT-3 neuron).

3. Serotonin Plays a Major Role in a Wide Variety of Behaviors

SE is found in the tissues of vertebrates, invertebrates, plants, and fruits. In vertebrates, it is found in many organ systems (e.g., gastrointestinal tract, lungs, and skin) and the peripheral and central nervous systems. It is the precursor for the melatonin produced in the pineal gland.

SE plays a role in many behaviors, including eating, sleeping, and emotional balance. For example, deficits in CNS SE are associated with depression. Interestingly, there is evidence that women have only half as much SE as men, which may correlate with the increased incidence of female depression. Drugs that block the reuptake of SE into the neuron may dull the appetite, alter sleep patterns, and alleviate depression. The range of symptoms successfully treated with SE-altering drugs is remarkable.

Activity in serotonergic neurons of the dorsal raphe nucleus was once thought to trigger slow-wave sleep (SWS). However, recent work has shown that stimulation of the dorsal raphe nucleus increases extracellular SE and its metabolites, electrocortical arousal, and REM sleep. Thus, increased synaptic serotonin appears to be linked with REM sleep, rather than SWS, and perhaps arousal during the awake state. Since SWS alternates with REM sleep, inhibition of the

raphe nucleus or blockade of SE receptors should result in fewer episodes of slow wave cortical activity. This interpretation, however, is inconsistent with sleep patterns observed in mice that are born lacking one subtype of serotonergic receptor (5HT-1B). During their sleep periods, these animals spend more time in REM sleep and less time in SWS than do wild mice. Thus, evidence suggests that SE exerts an inhibitory influence on REM sleep.

G. Histamine

1. The Distribution of Histamine in the CNS Is Widespread

HA neurons, originating in five nuclei within the tuberomamillary nucleus of the hypothalamus, innervate almost every structure in the brain stem and cerebral cortices. The densest innervation is to the hypothalamus and septum. Somewhat lower densities are found in the cortex and amygdala, and the lowest is seen in the hippocampus, brain stem, and cerebellum. At least three types of HA receptors (H_1–H_3) have been identified in the brain. In addition, HA is present in nonneural mast cells of the brain.

2. The Cellular Effects of HA Resemble Those of NA and ACH

The effects of HA on cells can be inhibitory or excitatory, like the majority of NMTs. Although the ionic mechanisms of these effects are less well-known than those of NA or ACH, at least some of the excitation is produced by reductions in K^+ currents, leading to a faster recovery after an action potential. For example, application of H_2 agonists to thalamic and cortical neurons causes excitation by reducing the afterhyperpolarization currents; H_1 agonists may increase excitation by producing slow depolarizations. However, H_3 receptors are probably located on histaminergic terminals and limit HA release by autoreceptor inhibition.

3. Histamine's Action Depends on the Receptors It Stimulates

HA administered intravenously or intracerebrally induces an EEG arousal response and spontaneous locomotor behavior, including exploration and grooming. These changes are blocked by H_1 antagonists, an effect consistent with the cellular effects of these drugs. H_3 agonists cause animals to spend a longer amount of time in SWS and the increased time can be blocked by either H_3 agonists or H_1 antagonists.

The dynamics of the cortical EEG are mediated normally by thalamic mechanisms. Application of HA to thalamic neurons results in a slow depolarization of the membrane produced by reductions in K^+ currents. This switches synchronized activity of individual neurons to the single-spike mode of repetitive firing. Recent evidence indicates that HA's major contribution is to the regulation of arousal rather than the control of alerting or vigilance.

Part of HA's effects may be due to interactions with cholinergic neurons of the basal forebrain and laterodorsal tegmentum as well as the LC. Application of HA excites basal forebrain and tegmental cholinergic neurons through stimulation of H_1 and H_2 receptors. These findings suggest that ACH and HA may synergistically increase cellular and behavioral arousal.

H. Interactions between the NMTs Are Common

Many of the results of the behavioral studies cited previously are interpreted as though a single NMT system was affected by the experimental drug. These interpretations are true in an approximate sense only. Even if drugs bind tightly and selectivity to a single receptor (they frequently do not), more than one neuroactive substance may be affected through simple postsynaptic effects and reuptake mechanisms. For example, if NA is infused into cortical tissue-containing cells and axon terminals of DA neurons, microdialysis of that tissue records increases in both NA and DA. The NA increase is expected since it was added by the experimenter. However, what caused the increase in DA? The increase cannot be caused by the action of NA on receptors on dopaminergic cell bodies because none are present. The answer is that both NA and DA are recycled into the presynaptic terminal of the DA neuron, which causes the synaptic release of DA to increase. Thus, drugs applied by the systemic route are likely to interact with several neurotransmitter systems. Indeed, there are only a few instances in which a single transmitter fails to affect all other transmitters.

Other examples of cross talk can be found between cholinergic and monoaminergic systems. For example, applications of nicotine in the vicinity of the axon terminals of noradrenergic neurons facilitate noradrenergic release and glutamatergic neurotransmission. In addition, GABA, an inhibitory neurotransmitter,

exerts tonic inhibition on the cholinergic system. Lastly, both DA and SE regulate the release of ACH in the cortex.

I. NMT Systems Share Many Properties

Many of the cells and cell groups within the ascending systems share common properties. Indeed, the arousing systems differ in the neuroactive substance they release but otherwise produce similar net effects on cortical tissues. The similarities between NMT systems are summarized as follows:

Projections: The cell bodies reside in the brain stem and project rostrally to cortex and subcortical structures. Each system influences thalamic and cortical structures, and both NA and SE systems project caudally to the spinal cord as well. Several of the systems affect pathways to the cortex at two or more locations.

Anatomical connections: Each system makes synaptic contacts with multiple cortical areas. The noradrenergic and serotonergic neurons have the broadest divergent connections, followed by lesser divergence in the cholinergic, dopaminergic, and histaminergic systems.

Cortical innervation: A given cortical area is usually innervated by two or more systems. In the posterior cortex, the inputs from different NMTs may be interdigitated across the cortical laminae. In more anterior regions, this lamination is much less evident.

Multiplicity of receptors: Each system exerts its effects on families of neurotransmitter receptors that produce a variety of pre- and postsynaptic effects. In the cortex, receptors subtypes are frequently located in different cortical laminae. The action of the transmitter on these receptors produces either excitatory or inhibitory effects, but the onset and duration of these responses vary widely.

Phasic and tonic responses: Many of the cells in the ascending systems register simple sensory events by phasic responses and more complex external and internal events and overt behaviors with variations in tonic activity. In addition, several (e.g., NA, ACH, and SE) have spontaneous activity that increases with increasing arousal.

Global and local effects: Arousing systems are capable of both global and local control of target structures. In other words, they are capable of influencing either narrow or broad areas of the cerebrum as conditions dictate. This is due, in part, to topographic projections within many of these systems so that restricted input leads to restricted output. Generally, global control may be mediated by postsynaptic effects. Within nontopographic systems (e.g., the LC), modulation of the preterminal receptors produces a spatially limited release of neurotransmitter.

Interactions: The arousal systems facilitate not only intrinsic subcortical and cortical activity but also other arousal systems. They may also inhibit activity in another system. For example, activity in the LC is inhibited by the cholinergic system during REM sleep.

J. Despite Similarities, Arousing Systems Also Display Unique Properties

There are considerable differences in the biochemical pathways through which NMTs act on target neurons. NMTs linked directly to ligand-gated mechanisms (e.g., 5HT-1 and glutamate) produce fast postsynaptic responses with short durations. In contrast, those linked to second messenger systems (ACh, NA, DA, SE, and HA) have slower onsets and longer duration. The latter systems may be further divided into classes based on the postsynaptic currents they activate. For example, muscarinic receptor stimulation causes a decrease in K^+ currents, β-adrenergic receptor activation decreases Ca^{2+}-activated K^+ currents (I_{AHP}), and 5HT receptor stimulation causes a decrease in the voltage-sensitive K^+ current I_M.

VI. BEHAVIOR

We now discuss the roles of the NMT systems in the global regulation of brain activity and behavior. To understand these roles, it is necessary to synthesize a large body of data. This is best done by the construction of frameworks or theories that link consistent observations and generate testable predictions. One theory suggests that during arousal, each NMT system provides control over synchronization frequency for different areas of the brain. According to this view, the entire brain shows similar resting frequencies; high-frequency activity appears locally in those parts of the brain that are controlling behavior. Support for this theory is lacking. Studies that examine correlations between neurons during sensory stimulation have

found only brief periods of synchrony. The high-density arrays of EEG electrodes that are currently available or the newer magnetoencephalographic technology can be used to test this hypothesis.

Another hypothesis that has received substantial empirical support is that each NMT system mediates different response components of behavior. This hypothesis arose from research conducted with an attentional task known as the five-choice, serial RT task. This task allows independent assessment of error rate, frequency of premature responses, number of response omissions, and response latency. Using this task, the effects of damage to NMT systems are tested in a highly systematic manner. It was found that cholinergic lesions impair the ability to discriminate visual targets (increased error rate). In contrast, NA lesions impair accuracy of responding, especially in the presence of distracters. Lesions of DA systems impair overall speed and probability of responding. Finally, 5HT lesions produce a reduction in premature responding. It is likely that some of the deficits are due to changes in alerting as well as alterations in attentive behavior.

The primary deficits in one response measure were accompanied by minor changes in the other measures. Perhaps this is due to incomplete independence of the measures. For example, impulsive responding to incorrect stimuli should increase error rates and decrease response latency. In any case, the results are consistent with the central tenet of this review that patterning of activity within NMTs is responsible for distinct aspects of aroused behavior.

A. Properties of Arousal Systems Explain Some Aspects of Behavioral Performance

It is important to understand not only how the NMTs are associated with different kinds of behavior but also how their activity causes variations in a specific behavior. The classic description that relates arousal to cognitive performance is Yerkes–Dodson law, which states that the optimal performance on cognitive and motor tasks depends on a moderate level of arousal or vigilance. Low and high levels produce suboptimal performance. When graphed, Yerkes–Dodson law resembles an inverted U. The decline in performance at high levels of arousal suggests the recruitment of inhibitory processes that reverse the beneficial effects of optimal arousal.

The most likely neural structure that mediates vigilant behavior is the LC. Optimal vigilance means that sensory information is processed efficiently and irrelevant stimuli are ignored. Two properties of the LC/NA system seem well suited to the task. First, application of NA to cortical cells causes an increase in the signal-to-noise ratio, as discussed previously. Second, by increasing NA at sensory sites, the LC filters out signals that differ only slightly from the background activity. Therefore, better filtering of meaningful stimuli is a natural consequence of optimal arousal levels.

LC neurons also show "baseline" activity that varies monotonically with arousal level in the absence of vigilant behavior. One consequence of this tonic activity is that increased release of NA onto thalamic neurons increases their activity in a monotonic manner. These increases are passed on to cortical neurons and presumably account for better performance. What causes the decline in performance with high arousal? There are several possibilities, including higher thresholds for β receptor-mediated inhibition, recruitment of inhibitory GABA interneurons, and stimulation of presynaptic (α_2) autoreceptors. A definitive answer to this question remains to be provided.

Another quantitative aspect of performance to be explained is that in repetitive tasks, performance worsens over time. In one such task, printed letters are rapidly presented to human observers who report when a letter is repeated. Performance of this task varies with arousal level. Early in the task period, subjects are vigilant and performance is high; later, it is lower, presumably a result of the decline in arousal. Drugs that affect NA increase arousal and improve performance, decreasing the number of missed pairs. This suggests that the signal was more detectable, which is consistent with the cellular effects of NA.

B. Recent Studies of Alerting Implicate Noradrenaline

Most of the foregoing discussion focused on the roles of NMTs in arousal and vigilance. However, the LC/NA system is also involved in alerting in that it reacts phasically to unexpected environmental stimuli. If the LC is damaged, alerting responses to intense, novel stimuli are impaired.

A particularly attractive paradigm for studying alerting is the cued target detection task developed by Michael Posner. This task, which was developed to study covert movements of attention, investigates the

effects of visual cues on reaction times to peripheral targets. Two cues, valid and invalid, are included to assess the impact of spatial information on the speed of covert orienting. Two additional cues, neutral and no-cue, are included as controls to specifically assess alerting effects. The difference in reaction times between valid and invalid trials is termed the validity effect, and the difference between neutral and no-cue trials is known as the alerting effect. The question is how altered levels of NA or DA affect the validity and alerting effects. The results confirm that lowered levels of NA produced by α_2 receptor blockers significantly reduce the size of the alerting effect. α_2 agonists have the opposite effects. None of these substances alter the validity effect. These results are also consistent with those of studies using cellular monitoring of LC activity, which suggest that LC activity is associated with attentional lability. That is, when the subject attends to the fixation point, presentation of the peripheral stimulus evokes a major LC response because it is unexpected and located away from the current focus of attention. The presence of the adrenergic agonist, however, reduces LC activity and produces a state of attentional fixity within which reaction times are slowed.

VII. REGULATION OF AROUSAL SYSTEMS

Arousal systems are regulated not only by external stimuli and other arousal systems but also by control systems of the brain. For example, the frontal cortex, particularly the orbitofrontal area, regulates the thalamic reticular nucleus and the cholinergic, basal forebrain structures. Patients with lesions in this area show deficits in arousal. Cortical control is probably not limited to cholinergic modulation. Recent work in the noradrenergic system suggests that the frontal cortex regulates impulse activity in LC neurons as well. The frontal cortex also exerts an influence on the limbic system, which regulates emotional arousal. In the condition known as akinetic mutism, patients may be immobile for hours but when aroused are capable of a wide range of behaviors. This condition is a result of lesions in the mediodorsal frontal cortex and damaged connections with the limbic system. The anterior cingulate region is also important in the self-regulation of arousal through its connections with the cholinergic basal forebrain. In summary, the frontal cortex acts as an executive to regulate the brain stem influences on cortical excitability.

VIII. SUMMARY

Arousal is a physiological and behavioral response to external or internal events (threat, pain, reward, etc.). The arousal response can be divided into three categories based on the duration of response: short-term alerting, long-term vigilance, and longer term arousal. Each category represents an interplay of mechanisms in the peripheral and central nervous systems. Arousal is a result of the release of modulatory neurotransmitters that control target structures (e.g., brain and internal organs) that contain a large variety of receptors. Although all the arousal neurotransmitters can induce EEG arousal, they play different roles in behavioral arousal. The noradrenergic system mediates alertness to sensory events and regulates the vigilant state of the organism. The cholinergic system increases behavioral and cognitive arousal, thereby facilitating attention and the encoding of information. The dopaminergic system facilitates the execution of appropriate behavioral responses to external and internal events. The serotonergic system mediates motivational behaviors such as food consumption and sexual behavior, maintains adequate activation of mood, and regulates REM sleep. Histamine's function is less clear but, like acetylcholine, it regulates cortical and subcortical excitability.

Artificial Intelligence

DEREK PARTRIDGE
University of Exeter, United Kingdom

GLOSSARY

cognitive level A viewpoint in which structures and mechanisms to support a scientific interpretation of intelligent behavior bridge the gap between neurophysiology and intelligent behavior. Structures and mechanisms at the cognitive level may or may not be found to have a simple mapping to the structures and mechanisms of brain anatomy.

heuristic A rule of thumb used to generate adequate solutions to intractable problems.

knowledge base A set of ''if–then'' rules and facts that captures the information necessary to support intelligent activity within some circumscribed domain.

neural network A computational system composed of highly interconnected simple processing units that operate in parallel to process all incoming activity values, compute an output activity value, and send it to all directly connected neighboring units. A unit's output value transferred by each interunit link is modified by the ''weight'' (a real number) associated with each link. It is this set of link weights that is altered during the initial network training.

Artificial intelligence (AI) has no firm definition. The term refers to attempts to simulate or replicate with computer systems functions that are normally assumed to require intelligence when manifest in humans. The goal of AI is to reproduce some aspect of human intelligence within a computer system. Thus, the bulk of AI work consists of programming computers, although significant engineering can be involved in important subareas such as robotics. Intelligence is thus seen as running the right program on an adequate computer, and the grand goal of AI is to write that program.

I. APPROACHES

There are a variety of approaches to the question of what aspect of human intelligence to attempt to simulate or replicate with a computer system. The basic division, which is particularly germane for brain scientists, is whether the approach is to reproduce functional equivalence with no regard for the mechanisms and structures of the human brain or whether it is important to reproduce structure as well as function.

A. Functional Equivalence

Within a functional equivalence approach to AI the goal is to reproduce (or supercede) some aspect of human intelligence, such as medical diagnosis or chess playing, by using whatever means are available. It is believed, for example, that the best human chess players examine only a few of the many possible move sequences that may be available at any given point in a game. The success of chess-playing computers has been founded on very fast exploration of thousands of possible move sequences. The result is very high-quality chess games from these machines but based on

mechanisms that would not appear to be used by humans who exhibit equally impressive chess-playing behavior.

The bulk of work in AI has taken this purely functional approach for two good reasons. First, the mechanisms underlying human intelligence tend to be options for debate rather than secure knowledge. At the cognitive level, the mechanisms and structures, such as short-term and long-term memories, are by their very nature difficult to describe in detail with certainty. Also, although details of brain physiology may be asserted unequivocally, the uncertainty lies in their roles in the production of the aspects of human intelligence being reproduced. The second reason for neglect of structure and mechanisms is the suspicion that the human brain may not be an optimum architecture on which to build intelligence. Its basic design evolved long before it was required to support intelligent behavior, and there are many seemingly obvious weaknesses in the human brain when viewed as a computational machine, such as error-prone memory retrieval. Therefore, most of the work in AI must be viewed as attempts to reproduce some aspects of intelligence without regard for the way that the human brain might be thought to be operating to produce human intelligence.

B. Structural Equivalence

For those researchers of AI who do claim some measure of structural validity to their work, two levels of structure and mechanisms may usefully be distinguished: the cognitive level and the level of brain anatomy. At the cognitive level, the psychologist posits structures and mechanisms to account for the observed behavior, and although these objects may have no clear implementation in terms of brain anatomy, it is a requirement that such a mapping could be plausibly found. The other level of structure is that of brain anatomy: the structures and mechanisms that can be physically observed, probed, and generally examined. At the cognitive level, we deal with abstract structures such as short-term memory and mechanisms such as forgetting caused by attention shift. At the physical level the structures may be an observed pattern of interconnectivity of neurons, and the mechanisms may be pulse frequency between the component neurons. Neither level is simple, nor are they always distinct, but this twofold division is a useful approximation.

1. Abstract Structure: Cognitive Science

The majority of AI work that has not eschewed structural equivalence has accepted a structural model of the brain at the cognitive level, and much of the AI work in this subarea is also known as cognitive science. Alternatively, most of the AI work in this subarea is aimed at evaluating and exploring cognitive models of human intelligence.

2. Physical Structure: Cognitive Neuroscience

There is a relatively small but growing body of work in AI that does accept constraints that derive from anatomical knowledge of brain structure and function. The impetus for this type of approach to AI has been the surge in interest and activity based on computation with neural networks. A neural network is a computational system that is founded on simple communication between highly interconnected networks of simple processing elements, i.e., a computational basis that appears to reflect some aspects of brain physiology. Conventional programming is also used to construct AI models of this type, but it tends to be restricted to the reproduction of a limited aspect of human intelligence. A system might, for example, attempt to reproduce certain aspects of human learning behavior based on a model of synaptic facilitation at the molecular level.

II. COMPUTATIONAL PARADIGMS

In addition to the type of approach taken, work in AI can be distinguished by the computational paradigm used. By this I mean the style of computational mechanism, both in general and in the specific class of programming language used (e.g., procedural versus declarative languages).

A. Classical Programming

Classical or conventional programming has dominated AI (as all other forms of computer usage). It is characterized by the processes of first deriving an algorithmic procedure for achieving some desired goal within the accepted constraints and then casting this algorithm into a machine-executable form [i.e., the classical task of writing (or coding) a program]. Typically, the elements of the program are the conceptual objects of the problem [e.g., a small array

of storage locations might be labeled short-term memory (STM)], and the algorithmic mechanisms programmed will directly implement the conceptualizations of the way the model works (e.g., subparts of the program using STM will be direct implementations of storing and removing objects from the STM object in the program). In this classical usage of computers, the speed and accuracy of the computer are used to perform a series of actions that could, in principle, be performed by hand with a pencil and paper. The main drawback from an AI perspective is that the programmer must decide in advance exactly what detailed sequence of actions will constitute the AI system.

1. Procedural Programming

Most programming languages are procedural languages; that is, they permit the programming to specify sequences of action, procedures, that the computer will then execute. Several programming languages have a particular association with AI. One such language is LISP, which dominated the early decades of AI. LISP serves the needs of AI by being a general symbol-manipulation language (rather than a numeric computation language such as FORTRAN); it is also particularly useful for AI system development because it demands a minimum of predefined conditions on the computational objects, which permits maximum freedom for changing program structure in order to explore an AI model by observation of the computational consequences. This flexibility minimizes automatic error checking and can lead to fragile programs that may also be large and slow to execute. It is thus not a favored language and method for mainstream computing, in which the emphasis is on fast and reliable computation of predefined procedures.

2. Rule-Based Systems

Early in the history of AI it was realized that the complexity of AI models could be reduced by dividing the computational procedures and the objects they operate on into two distinct parts: (i) a list of rules that capture the knowledge of some domain and (ii) the mechanisms for operating on these rules. The former part became known as the knowledge base and the latter as the inference engine or control regime. The following might be a simple rule in a chess-playing system: IF a potential exchange of pieces will result in the opponent losing the more valuable piece THEN do the exchange of pieces.

The general form of such rules is IF ⟨condition⟩ THEN ⟨action⟩. When the ⟨condition⟩ is met, then the ⟨action⟩ is executed, which generally results in new conditions being met and/or answers being generated. The control regime might be that the first rule whose condition is satisfied is executed, with this simple control repeated until some goal is achieved or no rules can be executed. This strategy for building AI systems became inextricably linked with the AI subarea of expert systems.

3. Logic Programming

Development of the knowledge-base and inference-engine division was formalized in the idea of logic programming. The basis for logical reasoning, which has always been an attractive foundation on which to build AI, is a set of axioms and the mechanism of logical deduction, and this pair map easily onto the knowledge base and inference engine, respectively. This particular development was implemented in detail in the logic programming language PROLOG, which became a popular AI language in the 1970s, especially in Europe and Japan.

B. Neural Computing

Neural networks are computational structures that are composed of many simple, but highly interconnected, processing units or nodes. Each interconnection, or link, is associated with a weight that is a number that controls the strength of the link; for example, with the weight as a simple multiplier, positive weights larger than 1.0 will increase the activity value from one node to the next. There are many varieties of neural network in use and most are trained in order to generate the desired system. Training consists of adapting an initial set of link weights (initially set as random numbers) so that the network reproduces a training set of input–output pairs—the training set, a set of examples of the behavior that we wish to simulate. The training procedure (which consists of adjusting the link weights until the network reproduces the training set) is an automatic algorithmic process. The training cycle typically consists of inputing a training pattern, executing the network, calculating the error between what the network computes and the correct result for this particular input, and adjusting the link weights to reduce this error. It is not usually possible (and not desirable) for a given network to reproduce the training set exactly. Training is thus repeated until a

measure of the error between network performance and training set is acceptably small. The training algorithms usually guarantee that this error will not increase with further training, but there is no guarantee that it will always be reducible to the desired value.

This process of AI system development—random initialization and repetitive training—is clearly different from that of classical programming and it does not always succeed. At best, training only promises a local minimum error, which means that training can become stuck with no further improvement from successive repetitions of the training cycle, but the network is a poor approximation to the training data.

Figure 1 presents a neural network known as a multilayer perceptron. It is a system designed to predict risk of the bone degradation disease osteoporosis. It can be used to prioritize patients for screening in order to improve early detection of the disease. The inputs are 15 risk factors (measured from a given patient) and the single output is a measure of how likely the patient is to develop osteoporosis, with 1.0 the highest likelihood and 0.0 the lowest. Approximately 500 patients both with and without osteoporosis were used to train the network, and it proved to be approximately 72% correct on a set of 200 previously unseen cases.

The network structure and mechanisms illustrated in Fig. 1 bear little more than a tenuous analogical relationship to actual brain structures. Other uses of neural computing have accepted more realistic constraints from neuroanatomy. Figure 2 presents a simplified version of a system that was designed to recognize shape from shading (i.e., to reproduce the human ability to perceive a three-dimensional shape from a two-dimensional pattern of light and dark). The neural net system used was built from hexagonal arrays of formal neurons that were configured to mimic the various known receptor types in the optic tract (e.g., circular receptive fields).

Although AI systems constructed with neural computing methods are necessarily approximations, they offer the advantage of not requiring a prior problem specification. For many AI subareas the details of how the input information is transformed into an "intelligent" output are incompletely understood. In fact, the essence of the problem is to develop such an

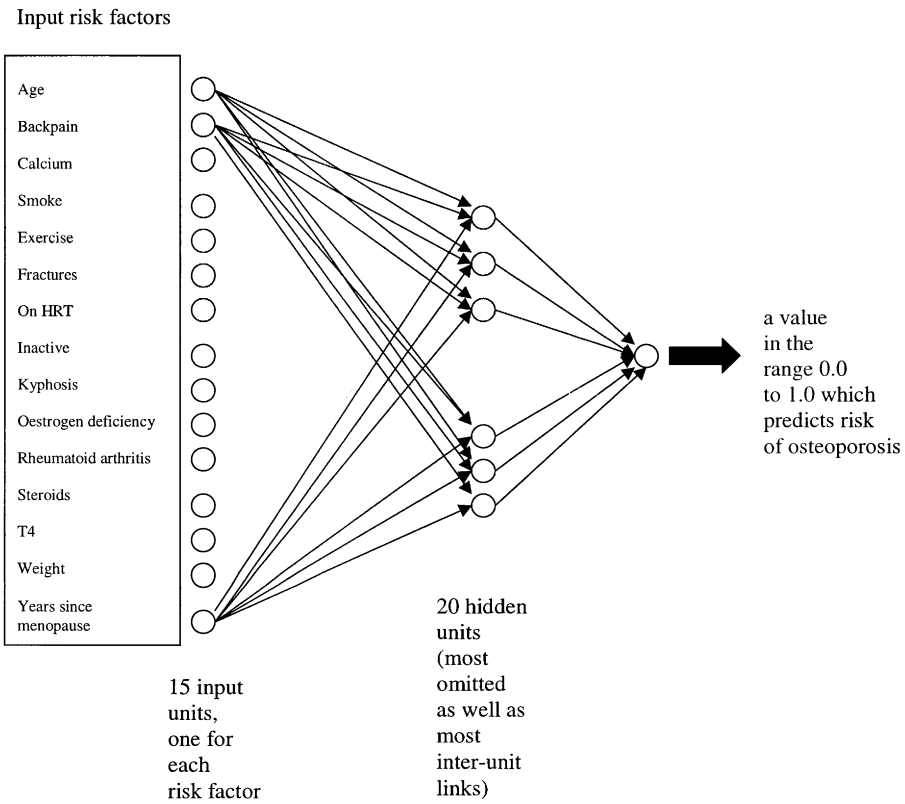

Figure 1 A multilayer perceptron.

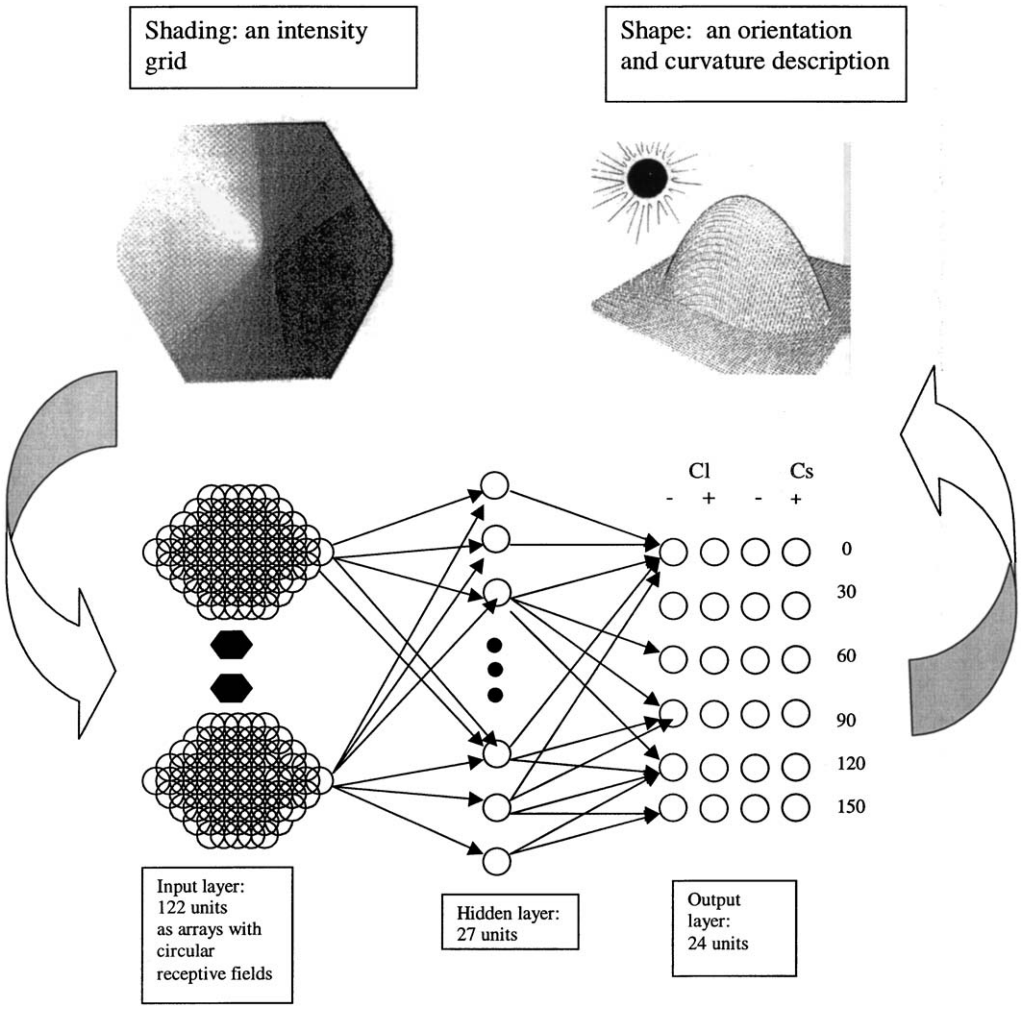

Figure 2 A system designed to recognize shape from shading. [Adapted from Lehky and Sejnowski (1988). Network model of shape from shading: Neural function arises from both receptive and projective fields. *Nature* **333,** 452–454.]

understanding. A data-driven technology, such as neural computing, that enables the construction of a system from a set of examples is thus particularly useful.

Neural computing is a powerful technology but it tends to suffer from lack of transparency: Trained neural networks are resistant to easy interpretation at the cognitive level. In the trained neural network illustrated in Fig. 1, for example, all the individual risk factors are totally and equally (except for the individual link weightings) intermingled in the computation at the hidden layer (all input nodes have a connection to every hidden-layer node). Therefore, how is each risk factor used in the computation of disease risk? It is impossible to determine from the neural net system; its computational infrastructure cannot be ''read off'' as it can be for a classical program. However, different styles of explication are emerging: It is possible, for example, to associate a confidence with each network prediction based on an analysis of the particular input values with respect to the set of values used for training.

Another result of the total intermingling of all the input features and the fact that the internal structure of a neural network is nothing but units with different combinations of weighted links in and out is that no conceptually meaningful representation can be isolated within the computational system. In the osteoporosis system, for example, the input feature ''age'' is assessed in comparison to some threshold in order to add its contribution to the final outcome. However, no comparison operations or threshold values are evident within the trained network. It is usual to say that such

computational mechanisms use distributed representations. In contrast to neural networks, there are other inductive, or data-driven, technologies that operate directly at the cognitive level.

C. Inductive Methods

An inductive method of system building is one that produces a generalized computational system from a set of specific examples. Neural computing offers one general class of inductive method, and rule-induction algorithms provide another. From a set of examples, a rule-induction algorithm will construct a decision tree, which is a computational system that embodies general rules that encapsulate the classifications (predictions, decisions, diagnoses, etc.) provided in the set of examples. Just as with neural networks, a decision tree cannot always be constructed, and when it can it is unlikely to be 100% correct even when classifying the training examples.

Decision trees tend to train faster than neural networks, but they tend to be more dificult to train to low error because they are more sensitive than neural networks to the choice of input features. However, the final decision tree is structured as sequences of decisions at the cognitive level; therefore, these computational systems may admit an interpretation and an understanding of the computational details of the problem in terms of cognitive-level features.

Figure 3 presents part of a decision tree for predicting whether an aircraft will level off at the flight level it is approaching or not. Such trees have been automatically generated using several thousand examples of aircraft leveling and not leveling at various flight levels at London's Heathrow Airport. The examples consisted of radar tracks (sampled at 4-sec intervals) and the particular flight level that was being approached (e.g. 7000-ft level, which is FL7000). Various features are extracted from the radar tracks; for example, in Fig. 3 d45 is the vertical distance traveled by the aircraft between radar points at interval 4 and interval 5 before the flight level is reached.

The internal structure of this (simplified) decision tree is composed of branch choices, and the tree leaves are the predicted outcomes (i.e., level off or non-level off). The branch choice at the top of the illustrated tree tests feature d45: If the value of d45 for the sample to be predicted is less than or equal to 100 feet, then the left branch is taken; otherwise, the right branch is taken and non-level off is immediately predicted.

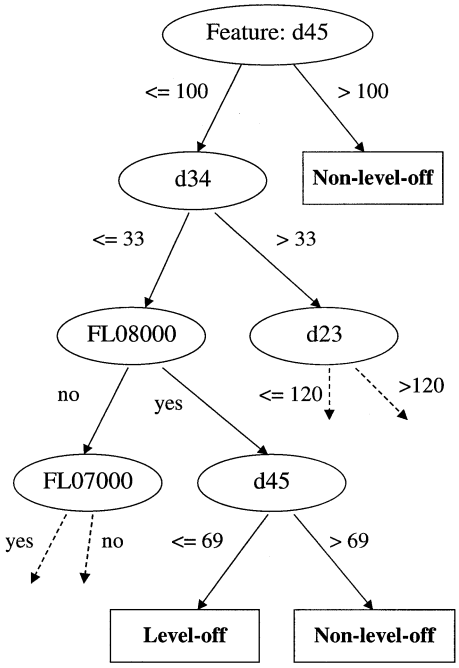

Figure 3 Partial decision tree for predicting whether an aircraft will level off at a certain flight level.

III. SUBDIVISIONS

Intelligence, even if we limit interest to human intelligence rather than intelligent possibilities in some abstract sense, is a broad topic. From the early days of AI (1950s and 1960s) when initial attempts, which dealt with many aspects of intelligence, were revealed to be far too ambitious, the history has been one of scaling down. Consequently, the field of AI has been subdivided into many (often more or less isolated) aspects of intelligent behavior.

A. Knowledge Representation

There is a long-held belief in AI that knowledge is crucial to intelligent behavior. If a system does not have a significant fund of knowledge (about the world or about some particular subarea), then no matter how sophisticated the reasoning, intelligent behavior will not be forthcoming. Quite apart from the difficult questions of what knowledge is needed and how much of it is needed, there is an initial question of how that knowledge must be structured, or represented, within an AI system.

1. Semantic Networks

One enduring belief about how knowledge should be structured is that there should be much and various interconnectivity between the elements of knowledge, whatever they may be. Concepts should be associated with each other with various strengths and according to various relationships. Words, for example, seem to be associated in our brains by semantic similarity and by frequency of cooccurrence.

A representational scheme known as semantic networks is one attempt to provide the necessary associativity. A semantic network is a set of nodes and links between them in which each node is labeled with a concept and each link is labeled with a relationship between the concepts. This scheme can be effective for small and static domains. However, in the wider fields of intelligent behavior it is evident that both the relationships and their strengths are context dependent, which implies that the semantic network must be dynamically reconfigurable. The concept ''chair,'' for example, might be represented in terms of physical relationships as having legs (usually four), a seat, and a back (not always). In terms of functional relationships, it is used for sitting on. However, there are chairs with no legs (e.g., when suspended), and there are chairs that must not be sat on (e.g., in a museum). Neither of these situations would be expected to disrupt normal intelligent behavior, but such exceptional circumstances as well as a detailed computational realization of common qualifiers, such as ''usually,'' cause major problems in AI systems.

Dynamic reconfigurability is the first example of adaptivity, of learning, which seems to be fundamental to intelligent behavior but is a source of great difficulty in computational systems. Neural networks have a fundamental ability to adapt and learn: (they are constructed by adapting the link weights to learn the training examples), but they are severely limited in scope and do not begin to approach the apparent complexities of human learning. In AI, this is considered as yet another subfield, machine learning.

2. Knowledge Bases

A further drawback of the semantic network representation of knowledge is the complexity of the representation. For example, if a node is removed from a network, then all links to it (or from it) must be removed or redirected to other nodes. Therefore, explicit representation of the desired associativity actually works against efforts to introduce dynamic adaptivity.

A knowledge base, or rule base, is a representation of the knowledge as a set of facts and rules that capture much the same information as a semantic network but do so with a set of distinct elements (the individual facts and rules). This does make the addition and deletion of knowledge elements (and hence adaptivity of the knowledge as whole) computationally much simpler. The cost is that relationships between the rules are no longer explicit within the representation. They reside implicitly in the rule ordering in conjunction with the searching strategies.

3. Expert Systems

Despite the loss of explicit representation of the interrelationships between the various elements of knowledge, knowledge bases have become firmly established as a useful way to represent knowledge in relatively limited, fixed, and well-structured domains of human endeavor. They have provided the basis for the large and relatively successful subfield of expert systems.

An expert system reproduces (or even exceeds) human capability in some specialized domain, some area of human expertise. Initially, the use of knowledge bases with appropriate control strategies so dominated the expert systems subfield that this representational scheme was used to define an expert system. Subsequently, it has been accepted that it is the reproduction of intelligent activity within a very limited domain that characterizes an expert system, whatever the means of realization. However, it is not uncommon to find the terms expert system and knowledge base used with virtual synonymity.

B. Machine Learning

The ability to adapt to changing circumstances (i.e., to learn) appears to be fundamental to the nature of intelligence. However, the construction of computer programs is a difficult and demanding exercise that usually requires that much time be spent on what is euphemistically called debugging—tracking down and eliminating errors in a program. The intricacies and complexity of debugging can escalate dramatically if a program is self-modifying (i.e., if it learns), because learning changes some aspects of the original program. This means that when a programmer needs to delve into a learning program to alter or correct its behavior, he or she first has to understand the detailed results of the learning in addition to the complexities of the basic

program as originally written. Consequently, most AI systems have little or no learning behavior built into them. Explorations of mechanisms to support adaptive behavior tend to be pursued as an end in themselves, and these explorations constitute the AI subarea of machine learning.

1. Rote Learning

Rote learning is the process of memorizing specific new items as they are encountered. The basic idea is simple and easy to realize within a computer program: Each time a new and useful piece of information is encountered, it is stored away for future use. For example, an AI system might be designed to recognize faces by extracting a variety of features (such as distance between the eyes) from an image and searching for a match within a database of 1000 stored feature sets. If it finds a match, it has recognized the person; if not, it reports "unknown person." In this latter case, the person or some human operator can provide the necessary details of this unknown person, and the system can enter the details in its database so that next time this person is presented to the system he or she will be correctly recognized.

However, every rote learning event increases the size of the database, and speed of recognition (as well as accuracy if new faces are similar to old ones) will decrease as the size of the database grows. Depending on the application of this system, certain new faces may be seen once and never again, in which case rote learning wastes time and space. Alternatively, this new face may be commonly seen at first but may over time become rare and ultimately no longer seen. In the first case, rote learning is immediately detrimental to system performance, and in the second case it becomes detrimental over time.

Rote learning (and in general any sort of learning) implies some compensating mechanism of forgetting, which suggests that the apparent human weakness of imperfect recall may be a fundamental necessity to long-term intelligence. AI has largely been preoccupied with learning mechanisms usually without the compensating mechanism of forgetting.

The second general point is that most situations change over time, so an AI system with any longevity will have to be able to track and react appropriately to the natural drifts in the problem domain. This is not an easy problem to solve. The fundamental difficulty is one of distinguishing between short-term variation and long-term drift when both short term and long term are ill-defined context-dependent quantities. If after appearing twice a day, a face is not seen for a week, should it be deleted? There is no correct answer and probably no more than guidelines even if the full details of the application of this face recognition system are known.

Therefore, a good rote learning system must exhibit flexibility and sophistication. It cannot simply store every new event and delete every one that is not used during some specified period of time. Human intelligence appears to embody some mechanisms of partial recall that, like forgetting, may not be weaknesses; for example, learned faces may gradually fade over time if not used but may be more quickly and easily reestablished if they reappear before they have been totally forgotten.

Neural networks, in which input information is blended and distributed across the network (distributed representation), do offer hope of a mechanism for partial learning and forgetting. Currently, however, sophisticated control of such abilities proves elusive. Classical programs appear to be less amenable to schemes for partial representation.

2. Parameter Optimization

If a problem-solving procedure can be specified in terms of a set of parameters, then mechanisms of machine learning can be used to reset, or learn, optimum values for these parameters. To grossly oversimplify the face recognition system introduced previously, identification of a face might be based on the distance between the eyes (DE), the length of the mouth (LM), and the depth of the forehead (DH). However, what is the relative importance of each of these features? They are probably not exactly equally valuable in the recognition task. The system can learn this information. Suppose we define recognition score as follows:

$$\text{Recognition score} = X \times \text{DE} + Y \times \text{LM} + Z \times \text{DH}$$

where X, Y, and Z are the parameters that determine the relative importance of the three features for face recognition. By trying different values for these parameters against recognition speed and accuracy for a test set of faces, the system can set them to optimal values. Therefore, from some arbitrary first-guess values for X, Y, and Z, optimal values have been learned and a better recognition score will be computed.

Quite apart from the issue of problem drift, this technique presents many difficulties. First, the form of the initial equation severely constrains what can be

learned, and it might be a poor choice. The most important features might have been omitted because their importance was not recognized. More subtly, there may be interactions between features such that attempts to optimize each parameter independently lead to a highly suboptimal system. Finally, this mechanism offers very little scope for the system to learn anything that was not foreseen explicitly by its designer.

3. Inductive Generalization

As discussed previously, inductive generalization is the process by which a general principle is extracted from a set of instances. It is the basis for several computing technologies (neural networks and rule-induction algorithms). It can also be viewed as a method for machine learning quite independent of the technology used to implement it.

The inductive technologies described in Section II are thus ways of building an AI program by learning from a set of examples. Further interest in this general idea has arisen because the inductive technologies are each based on a specific class of induction algorithm, and many other types of induction algorithm remain to be explored and possibly developed into new computational technologies.

There is an unlimited scope for further developments in this subarea of machine learning because there are an unlimited number of ways to extract generalities from a set of instances, and there is no correct way. Inductive generalization is a fragile procedure. The classic illustrative example derives from philosophy: Suppose you see a large white waterbird and are told it is a swan, and then you see another that is also white, and then another, and so on. How many specific instances of white swans do you need to see before it is safe to generalize to the rule that all swans are white? The answer is that the inductive generalization can never be guaranteed no matter how many white swans you see. However, a single sighting of a black swan can tell you that your generalization is false; it represents an apparent contradiction to your rule.

However, you might choose a different interpretation of the black swan sighting. The first being that it is not a swan because it is not white. In this case you have transformed your initial tentative generalization into a firm rule that is used to further interpret the world. An intelligent agent must do this eventually because this is the whole purpose of generating such generalizations. A different rejection of the black swan sighting might be based on the idea that your generalization is essentially correct, it just needs refining—and this is always possible to do. The black swan sighting might have been on a Saturday, so a new (and now uncontradicted) version of your rule might be that all swans are white except on Saturdays.

This last, somewhat absurd dodge is particularly instructive because it highlights the problem of what features to extract from the instances to include in the generalized rule. We know that a swan's color does not depend on the day of the week, but an AI system, with its necessarily limited knowledge, might not know this to be true.

Therefore, the difficulties in contructing algorithms for inductive generalization are determining what features (from the infinitely many possible ones, such as "3 PM on a cloudy day") to extract to focus the generalization on and determining when features from two instances are sufficiently similar. For example, most swans will not appear pure white, and we must accept that swans that are shades of gray or discolored due to dirt are all still essentially the same color (i.e., white). At what point do we have to admit that a bird's plumage is not sufficiently similar to white, and that the bird is thus an exception to our rule? This, like so much else in AI, is an ill-defined and context-dependent issue.

C. Vision and Perception

Sight, although not essential, appears to be an important component of human intelligence. AI vision systems have many potential applications, from automated security camera systems to automatic detection of pathological images in medicine. Because of the accessibility (and assurance of general functional commitment) of the optic tract, mammalian visual systems offer some of the best opportunities for basing AI systems on neuroanatomical data rather than cognitive-level abstractions. Figure 2 is one example of an attempt to build an AI vision system with regard to neuroanatomy.

1. Pattern Recognition

Pattern recognition usually refers to attempts to analyze two-dimensional images and recognize (i.e., label) within them prespecified subareas of interest. Mathematics and statistics feature strongly in this subarea by providing algorithms for noise reduction, smoothing, and segmentation. Processing of images at the pixel level leads naturally into the classic

bottom-up approach to pattern recognition. In this strategy, the idea is to associate areas in the image of similar texture or intensity with features of interest and to associate discontinuities with boundaries that might be developed to circumscribe features of interest. When the image has been segmented, segments may be collected into recognizable objects or may represent the expected objects.

This final process of labeling image segments may be classically programmed or may be learned through a set of examples and the use of an inductive technology. This latter approach has been found to be valuable when it is difficult to specify exactly what is to be labeled (e.g., a tumor in a radiogram), but many examples are available that can be used to train a system.

It has been argued, however, that an intelligent agent generally sees what it expects to see; this is the top-down approach to vision. In this case, an image is scanned with an expectation of what the system wants to find in the image. The image need only be processed where and to whatever depth necessary to confirm or reject the expectation. In the bottom-up approach, it is anticipated that the features will emerge from the image, and in the top-down approach it is hoped that knowing what one is looking for will facilitate quick and accurate recognition or rejection. Of course, it is possible to combine bottom-up and top-down processing.

2. Image Understanding

One point of distinction in AI vision systems is that of finding and labeling objects in an image (from a stored list of possibilities) as opposed to the development of an understanding of an image. The latter, somewhat ill-defined goal seems to be what an AI vision must achieve, and it probably involves some object labeling as a constituent process. Image understanding is the placement of an image in a global context. A pattern recognition system, for example, might find and label a tree, sky, clouds, and grass in an image, whereas an image understanding system might declare that the image is a countryside scene in some temperate climatic zone, perhaps land used for grazing cows or sheep (an implication of the short-cropped grass).

Sophisticated image understanding has not been achieved, except in some very restricted subdomains (e.g., automatic monitoring of the configuration of in-use and free gates at a specific airport terminal). The inductive technology of neural computing has been trained to assess the crowdedness of specific underground station platforms.

In the latter case, a neural net system can only be trained to generate answers in one-dimension, i.e., it can assess crowdedness but no other characteristic of the people such as category (e.g., business or tourist). Other neural nets might be trained to assess other desired features but this implies that the important features are decided in advance of system construction and that a general understanding will only be gained from a set of trained networks. This approach to image understanding implies that a classically programmed harness system will be needed to collect and combine the outputs of the individual neural networks.

Image understanding, however it is achieved, is expected to require substantial knowledge of the world within which the image is to be interpreted. In the previous example of a rural scene, the only basis for drawing the implication about cows and sheep must be knowledge of why grass is cropped in the countryside (as opposed to a lawn, for which the grazing implication is likely to be wrong) and which grazing animals are likely to be responsible in a temperate climate.

Thus, intelligent image understanding will require image processing, pattern recognition, and a knowledge base together with an appropriate control strategy, and all must be smoothly integrated. Like so much else in AI, image understanding beyond very limited and heavily constrained situations is currently beyond the state of the art.

D. Natural Language Processing

Human language, which is generally recognized to be a phenomenon quite distinct from (and in advance of) any known animal communication mechanism, is often considered to be a characteristic feature of intelligence. The Turing Test for AI hinges on whether a computer system can communicate in natural language sufficiently well that a human observer is likely to mistake it for another person; If so, then we must concede that the system exhibits AI. From this widely accepted viewpoint, natural language understanding, both analysis and synthesis, is the key to AI. This view is defensible because, as with image understanding, natural language understanding implies many other AI subfields—a knowledge base, inferential control strategies, adaptivity, and so on.

Natural language processing (NLP), computational linguistics, computational semantics, cognitive linguistics, and psycholinguistics are interrelated areas within which AI work on language processing may be found.

1. Spoken or Written

A first issue for any proposed AI NLP system is the modality of the input (and output): Will the language be written or spoken. Speech, and thus sound waves, as the input medium is normally viewed as a separate pattern recognition task (i.e., the recognition of words within the sound wave pattern). This is not an easy task but considerable progress has been achieved in recent years, particularly with systems that employ some inductive technology and can be trained to the particular idiosyncrasies of a user's voice. Many relatively cheap systems are commercially available for speech recognition, but they do not extend (other than trivially) to language understanding. This is a different and separate subfield, and it typically requires that the language utterances be typed.

2. Syntactic Analysis and Grammars

The formal basis of language appears to be syntactic structure, and such structure is defined with a grammar. Prior to AI, linguists formulated specific grammars to capture the allowable structures of various languages, and they also formulated classification schemes such that a given grammar (and hence the language it purports to specify) could be assigned to a class.

Formal definitional schemes, such as these grammars, were ideal for computerization and were seized on by the first computational linguists. Simply stated, the expectation was that computers could apply such grammars to check the correctness of a sentence in, for example, English, and also determine the syntactic category of each word. From this point a dictionary of word meanings could be applied, and a meaning for the sentence could thus be generated. Even the most optimistic did not think that this would yield perfect understanding, but they thought it would be good enough, for example, to add the dictionary of meanings from another language and thus translate from one language to another. However, like all other aspects of AI, it was not this simple.

Much human communication, especially spoken communication, is ungrammatical. We often communicate in broken structures; furthermore, neither we nor those we speak to appear to be unsettled by or even notice the ungrammaticalities. In addition, there is no fixed grammar for any living language precisely because any language in use evolves and is modified by those who use it. Further complicating this is the fact that a widely used language develops differently at different points in its range. This leads to dialects and eventually to distinct different languages. These problems do not bode well for any AI system that aspires to deal with the NLP problem beyond the confines of a small, well-defined, and fixed subset of some language.

Consequently, there was a movement among NLP workers to develop systems that were not based on a complete and correct prior syntactic analysis. Efforts in this direction have been founded on finding main verbs and then using these to seek parts of the surrounding sentence that fulfill the anticipated roles. Therefore, for example, if a sentence in English contains the word "hit" the implication will be that the subject of the sentence will be a potential "hitter" (which probably requires an animate object) and that the object of the sentence will be something that "is hit." In addition, the sentence could have the role of "what was used for the hitting" specified and introduced by a word such as "with."

Clearly, some initial syntactic analysis can be used to build a framework of further syntactic expectations that may be further constrained by semantic expectations. Continuing the previous example, the hitter is likely to be an active animate object (a person rather than a ball or a bat, which might also be mentioned in the sentence). A shift to consider such constraints on words, rather than simply grammatical categories such as verb or noun, leads us into the realm of semantics.

3. Semantics

Words have meanings, and so it seems reasonable that the NLP researcher might expect to build up through word meanings to sentence meanings, paragraph meanings, and complete document meanings. However, words sometimes have a variety of meanings. Consider the sentence, "The pig is in the pen". The meaning of the word "pen" here must be "enclosure" rather than "writing implement" or "female swan." The semantics of "pen" is disambiguated by the meaning of the sentence as a whole, so the sentence meaning cannot simply be built up from word meanings.

In general, NLP requires a complex interaction between expectations at all levels that yields a most likely meaning when all (or a maximum) of the mismatches have been eliminated. In the previous example sentence the mismatch between large animal "pig" being inside small writing implement "pen" is eliminated by consideration of the enclosure meaning of "pen." However, suppose this sentence is followed by another: "When will that bird learn to stop

swallowing the children's toys." A whole new semantics for the previous sentence emerges, but only if this latter sentence is taken as a further comment on the first sentence and not as a break to a new topic.

Decades of work on AI NLP systems has resulted in progress, but it has also revealed the complexity of language. The surprise is not that we cannot make computers understand anything beyond small and well-defined language subsets, but that we as humans all intercommunicate freely in an unbounded medium. Part of the answer, of course, is that miscommunication occurs, and that communication is seldom perfect (whatever that might mean) because it does not need to be.

4. Pragmatics

If the NLP problem is not daunting enough already, consider that what we might term the direct or explicit meaning of a string of words may bear little relation to the "real" meaning. Said in an ironic tone, "That's smart" may mean "that was a stupid thing to do." Ultimately, the meaning of a natural language utterance is colored by the predisposition of the listener, then by what the listener thinks the utterer is intending to convey, and then by what the listener thinks the utterer thinks the listener will think. There is, of course, no end to this sequence of presuppositions. The utterer may bring an entirely equivalent but quite different suppositions to bear on what he or she intends to mean. Pragmatics is the collection of all these factors beyond and outside of language that influence meaning. AI NLP systems have hardly come to grips with any aspects of pragmatics other than in the context of theoretical analyses of pragmatic issues.

5. Machine Translation

Due to the commercial value of adequate machine translation (MT), attempts to construct such systems occurred at the birth of AI NLP. Another impetus for MT springs from the potential of such systems to begin to solve the difficult question of whether some text has been adequately understood. For example, in English-to-Russian and a Russian-to-English translation systems, a given utterance in English can be translated into Russian and then translated back to English. In which case, the question of whether the two systems extract accurate meanings can be simplified (without major distortion given the current state of the art) to one of meaning preservation: Does the initial English sentence say the same thing as the final English sentence?

MT systems have been in use for years but only in niche applications either in simple and restricted applications or where a first crude translation is valuable. The former case might be technical manuals that are written according to simple, well-defined structures using a small, well-defined vocabulary. The latter situation might arise as a precursor to human refinement of the documents.

6. Machine-Readable Dictionaries

One spin-off from MT work has been the computerization of dictionaries. Words with their various meanings can be stored in a computer for fast access by any other computer system such as a word processor or by an inquiring human. This is little more than a fast form of the traditional book dictionary, but appropriate computerization can offer much more. A computerized dictionary can be proactive in suggesting words and even phrases, which implies an AI aspect to certain operations.

E. Robotics

The idea of a robot embodies the ultimate goal of AI, and robots have been designed and built since AI's inception.

1. Moving, Sensing, and Reasoning

One feature of the early years of AI was that researchers did not appreciate the depth and difficulty of the problems they faced. Many early robotics systems were mobile machines with a variety of sensors (vision, infrared, tactile, etc.). They were also supposed to analyze their situation and solve problems (such as how to traverse realistically cluttered rooms and corridors). They were conceived as crude simulations of complete humans with the hope that refinements and additions would improve the similarity year by year. This did not happen; instead, each component problem escalated into a full-blown subarea of AI.

2. Hand–Eye Systems

One common simplification of the robotics problem has been to construct hand–eye robots. These systems attempt to integrate visual processing and manipulation of the seen objects. This difficult task requires pattern recognition and some degree of image

understanding to be integrated with fine motor control and tactile feedback.

Industrial companies such as automobile manufacturers employ a dazzling array of robotics systems but these include little or no AI. The elaborate welding systems are preset to weld at specific points in three-dimensional space. The problem of fast, accurate welding is then reduced to one of engineering the means by which the parts to be welded are moved to precisely the correct placement.

3. Cognitive Systems

Some of the most imaginative and ambitious work on AI robots is being done at one of the long-term bastions of AI. At the Massachusetts Institute of Technology, research teams are developing various systems to implement cognitive robotic functions (e.g., an attentional system for social robots).

IV. PHILOSOPHICAL PERSPECTIVES

The field of AI has always spurred extensive philosophical controversy. Can human intelligence be no more than the right algorithm running on a biological computer, sometimes called wetware as distinct from the hardware of modern computers? There are various arguments that human intelligence must be more than this. Is the spiritual or emotional dimension of humanness an essential ingredient of intelligence, or are such aspects merely side issues that humanity happens to exhibit?

Whatever the outcome, some assert that an intelligent machine can never really feel like we do, enjoy the taste of strawberries or the thrills of love, so it must always fall short of full human intelligence. At best, machine will only simulate such feelings, and this is a far cry from actually experiencing them as a human does.

A distinction is sometimes drawn between strong AI and weak AI. The former is a machine intelligence that encompasses all aspects of human intelligence (whatever they may be), whereas the latter category only aims to reproduce limited aspects of intelligence.

Further controversy centers on the notion of intelligence as an abstract concept within which human intelligence is just one (the only one we currently know) particular manifestation. In this view, arguments for the nonoptimality of human intelligence emanate from several sources: Empirical evidence of, for example, imperfect memory suggests that certain specific improvements should be possible, and the realization that the basic ''machinery'' of the brain was not designed to support intelligent activity but evolved for other purposes is also suggestive of nonoptimality. Given a custom-designed machine executing a similarly crafted suite of computational procedures, an AI that supercedes the human version in terms of speed, accuracy, etc. should be possible.

In opposition to this viewpoint, evolution may have produced a set of compromises that is optimal for intelligence on Earth. It is plausible that imperfect memory, for example, is an unavoidable negative outcome from a system that would be seriously disadvantaged by the clutter of useless memories if it forgot nothing. Similarly, feelings and emotions might be vital signals of what courses of action to pursue, and what ones to avoid, in a world full of choices that must be made on incomplete evidence.

What claim can there be that a machine is intelligent just because it behaves as if it is? The famous Turing Test (devised in 1950 by the mathematician Alan Turing) rests on the idea that if a machine behaves as if it is intelligent then we must concede that AI has been achieved. This opens the more general issue of whether and to what extent form can be inferred from function: By observing what a system does, can we determine anything about how it is doing it? If we ignore the physical components of the brain (as most AI work does), then what can we expect to deduce about the detailed mechanisms that constitute intelligence based only on observations of intelligent behavior?

Finally, there are challenges to the accepted wisdom that intelligence is, or can be exhibited by, **any** algorithmic procedure running on **any** modern digital computer. There may be something about the determinism and definiteness of this combination that is totally at odds with the seemingly unconstrained openness of human intelligence. Objections of this nature tend to be founded on either the known limitations of formal systems (such as abstract algorithms) or the apparent difficulties posed by certain aspects of human intelligence (e.g., free will).

V. CONCLUSIONS

In the field of AI, there is a range of often autonomous subfields. This occurred as a reaction to the extreme difficulty revealed by all approaches to the more global goal of complete AI. It is a classic divide-and-conquer approach to excessive complexity, but can it work for AI?

On the negative side, note that investigations within most (if not all) subfields seem to reveal that knowledge of the world and sophisticated contextual awareness are essential for high-quality AI. In other words, real progress in each subfield seems to require major progress in every other as a corequisite, if not a prerequisite.

On the positive side, there are some clear indications that intelligence is not all-or-nothing. There are many examples of intelligent humans who lack sight, speech, and hearing. In addition, there is a case to be made for the modularity of mind both from localization of functional components of intelligence in specific anatomical regions and from observed phenomena such as optical illusions. Many optical illusions remain compelling illusions even when the basis for the illusions is physically demonstrated or explained. This persistence might be interpreted as an absence of close integration between visual processing and reasoning abilities.

One pervasive conundrum is that a broad and deep knowledge of the world appears repeatedly in the subfields of AI as a necessity for intelligent activity, with an associated implication that more knowledge supports higher levels of intelligence. However, from a computational perspective more information (in a larger knowledge base) must lead to more searching for relevant pieces, which takes more time. Stated succinctly, the more you know, the slower you go. This is true for AI systems but not, it seems, for humans. In fact, the growth of a human's expertise is often associated with a faster performance rather than a slowdown. Why? For some, the answer is that classical programming on conventional computers is the wrong basis for intelligence. Therefore, other computational paradigms are being explored. For others, the answer is less radical but no less obscure: Information cannot just be added on, it must be properly integrated and indexed in sophisticated ways.

A final general point of difficulty is that intelligence in humans is characterized by tentative conclusions and sophisticated recovery from errors. We do not always get things right, but we can usually readjust everything appropriately once we accept the error. In AI systems, the compounding of tentative conclusions is difficult to manage and recovery from error is often no easier because we typically have to foresee each source of error and supply a recovery procedure that will always work.

One general conclusion to be drawn from this survey is that AI has not been as successful as is popularly believed. One rejoinder to this common charge is that as soon as an AI problem has been solved by the construction of a programmed system, that problem ceases to be called AI. There is some truth in this, but not much. The real AI problems of adaptivity, natural language understanding, image understanding, and robotics are still out there and waiting to be solved.

Work in AI does not undermine a belief in humanity by aspiring to mechanize it. Quite the contrary—the more one examines the problems of intelligence, the more one's admiration grows for a system that seems to solve all of them at once, often effortlessly.

GLOSSARY

Alexander's disease Alexander's disease is a leukodystrophy in which there is accumulation within the astrocyte cytoplasmic processes of beaded inclusions, i.e., Rosenthal fibers which contain alpha-B crystallin. The relationship between these abnormal astrocytes and demyelination characteristic of this pathology is not yet clear.

blood–brain barrier The blood–brain barrier is a physical and physiological barrier impeding the passive diffusion of solutes from the blood into the extra-cellular space of the central nervous system. It is also a brain–blood barrier. The highly impermeable tight junctions between endothelial cells forming the capillaries in the central nervous system are responsible for the blood–brain barrier functions. Astrocyte perivascular processes or end-feet form a virtually continuous sheath around the vascular walls. Astrocytes are involved in the induction of the blood–brain barrier property of central nervous system endothelial cells.

gap-junctions Gap-junctions are a group of diverse channels that vary in their permeability, voltage-sensitivity and potential for modulation by intra-cellular factors. They provide a pathway for the selective exchange of small molecules. Astrocytes are connected to each other by gap-junctions which are localized between cell bodies, between processes and cell bodies and between astrocyte end-feet that surround blood vessels. Thus activities of neighboring cells can be synchronized.

glial cells Glial cells are present in the central nervous system and distinct from neurons. They include astrocytes, oligodendrocytes and microglia. Interactions between neurons and glial cells are important during neuronal development and for the normal functioning of the nervous system. Dysfunction of glial cells is involved in many degenerative diseases of the nervous system.

glioma Glioma are the most frequent malignant tumors of the brain. Most of them are of astrocytic origin.

gliosis Astrocytes have a capacity to react mainly in relation to an injury in the central nervous system and constitute reactive gliosis. This reaction is characterized by hypertrophy of astrocytes. There is also an increase in astrocyte intermediary filament numbers and in their constituent the glial fibrillary acidic protein GFAP. There may also be a proliferation of astrocytes, occurring in general close to an acute lesion, but it is not constant. Astrogliosis is observed as a secondary process during aging as well as in many pathological conditions such as Alzheimer disease, brain trauma, ischemia, and multiple sclerosis in demyelinated areas. The physiological role of astrogliosis remains controversial with respect to the beneficial or detrimental influence of reactive astrocytes on central nervous system recovery.

radial glia Radial glia are a particular category of the astrocyte family. Radial glia fan out from the ventricular and subventricular zones where the cell bodies reside, and they extend to the pial surface. During development, radial glia are necessary to neuronal migration to the cortex. After migration has begun to subside, these cells assume a variety of transitional forms and transform into star-shaped astrocytes.

The astrocyte is a major glial cell type of the central nervous system. Astrocytes are star-shaped cells which extend

processes terminating in end-feet at the pial surface or on blood vessels. Other cells with a different morphology have key-constitutents of astrocytes, such as glycogen particles and a protein of astrocyte intermediary filaments, the glial fibrillary acid protein (GFAP); thus they are part of the astrocyte family. Among them are embryonic glial fibers (radial glia) necessary for neuronal migration. Development of neuronal pathways and synaptic functions require interactions with astrocytes. Astrocytes help to maintain synaptic functions by buffering ion concentration, clearing released neurotransmitters, and providing metabolic substrates. Their dysfunction is implicated in neurodegenerative diseases. The major brain tumors (glioma) appear to be of astrocytic origin.

I. INTRODUCTION

Virchow (1846) was the first to find cells other than neurons in the brain. He thought that it was the connective tissue of the brain, which he called "nervenkitt" (nerve glue) (i.e., neuroglia). The name survived, although the original concept radically changed. Two main types of glial cells were originally described in 1893 by Andriezen: protoplasmic in gray matter and fibrous in white matter. They were both later proven to be astrocytes and their first clear description was provided by Ramon y Cajal in 1913; he showed that they were independent from neurons and capillaries. In 1928, using staining techniques based on silver carbonate impregnation, as introduced by Golgi, Rio Hortega found two other cell types, the oligodendrocyte (first called interfascicular glia) and another cell type that he distinguished from the two macroglial cells (i.e., macroglia) and that he called microglia.

Astrocytes with oligodendrocytes and microglia constitute the glial cells (Fig. 1) in the central nervous system (CNS). The importance of glial cells is suggested by their increasing number in relation to the evolution of species, from 25% in the *Drosophila* brain to 65% in murine species and 90% in man. Astrocytes

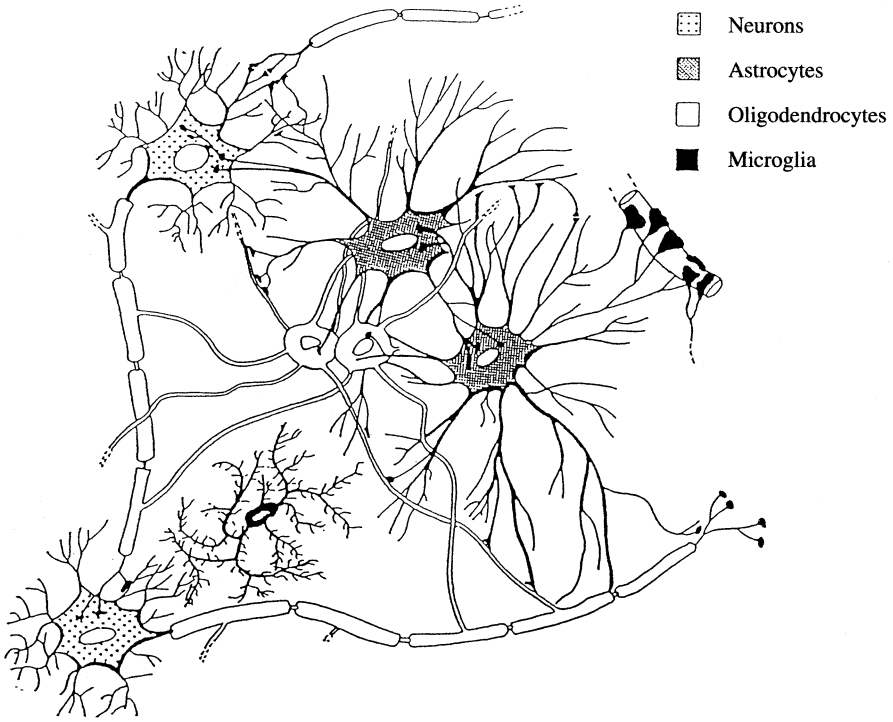

Figure 1 Schematic representation of the different types of glial cells in the CNS and their interactions among themselves and with neurons. Astrocytes are stellate cells with numerous processes contacting several cell types in the CNS: soma, dendrites, and axons of neurons and soma and processes of oligodendrocytes and other astrocytes. Astrocytic feet also ensheath endothelial cells around blood capillaries, forming the blood–brain barrier, and terminate to the pial surface of the brain, forming the glia limitans. Oligodendrocytes are the myelinating cells of the CNS. Many interactions between glial cells, particularly between astrocytes in the mature CNS, are regulated by gap junctions, forming a glial network (adapted from C. Giaume and L. Venance, 1995, *Perspect. Dev. Neurobiol.* **2,** 335–345).

present a wide range of functions: They participate to brain construction and energy metabolism, and they also participate in the formation and maintenance of the blood–brain barrier. Their organization and functions are modulated by circadian rhythms, parturition, lactation, and osmotic stimulation. They respond to many changes in the cellular and extracellular environment. Astrocytes are also directly or indirectly involved in pathological states.

The diverse roles of these cells are still being unraveled and may be more complex than previously thought. Indeed, recently it was shown that astrocytes possess a calcium-dependent form of excitability, and that they are involved in the functional modulation of synaptic activity. The existence of a coordinated and continuous bidirectional neuron–astrocyte signaling provides a new view of the physiology of these glial cells.

II. THE ASTROCYTE FAMILY

Astrocytes are a family of cell types that share certain morphological and functional similarities as well as biochemical and immunological features. Astrocytes are star-shaped cells, the processes of which occupy 25% of the volume of the CNS and extend into the surrounding neuropil (network of intermingled and interconnected processes of neurons). They have an electron-lucent cytoplasm and several distinguishable morphological characteristics. First, as shown by electron microscopy, they contain intermediate filaments of 10 nm (gliofilaments) that were referred to as fibrils in the gold-sublimate preparations. Intermediate filaments are more abundant in the fibrous astrocyte population of the white matter region; they occur in bundles and contain mainly a specific protein, the glial fibrillary acidic protein (GFAP). Second, they contain numerous glycogen particles. Third, their processes terminate on blood vessels (arterioles, veinules, and capillaries) as perivascular end feet, participating in the blood–brain barrier formation, and/or extend expansions toward the surface of the brain where they constitute a glial limiting membrane (the glia limitans). By filling cells intracellulary with horseradish peroxidase or lucifer yellow, it was shown that astrocytes may have 50–60 branching processes that terminate in end feet at the pial surface or on blood vessels. Some of these processes extend to considerable distances (i.e., 300–400 μm). The subpial astrocyte processes present a well-organized palisading pattern in the adult CNS. A basal lamina separates the plasma membrane of the end feet from the blood vessels and also the glia limitans from the pial elements. Fourth, astrocytic processes are connected by gap junctions, mainly at the level of perivascular end feet, or the glia limitans. Finally orthogonal arrays, as observed by freeze-fracture microscopy, are present on the surface of perivascular end feet or subpial astrocytes of the glia limitans; because they are so characteristic of astroglial cell membranes, they are used as a marker in freeze-fracture replicas. Orthogonal arrays may represent sites at which some material is transported across membranes at the interface between the blood and the cerebrospinal fluid compartments.

In addition to the two main classes of astrocytes, protoplasmic in gray matter, and fibrous in white matter, there are also astrocyte subtypes in the olfactory bulb. Embryonic radial cells (radial glia) and cells that may be considered morphologically and biochemically as adult divergent forms of embryonic radial glia (i.e., Müller cells of the retina, Golgi–Bergmann cells of the cerebellum, pituicytes, pineal astrocytes, ependymal cells, and tanycytes) are considered to belong to the astrocyte family. Ependymal cells and tanycytes are considered by others as a separate group of glial cells although certainly closely related to astrocytes.

- Olfactory bulb ensheathing cells are specialized ensheathing cells. They are found in the pathway known as the rostral migratory stream (RMS), in which they accompany the olfactory neurons in their migration from the olfactory epithelium to the olfactory bulb. They remain in the adult since neurons keep multiplying and differentiating in this area of adult neurogenesis. They share both Schwann cells and astrocytic characteristics.
- Embryonic radial glial cells (radial glia) fan out from the ventricular and subventricular zones, where their cell bodies reside, to the pial surface, where they terminate with conical end feet.
- Golgi epithelial cells and their Bergmann glial fibers are generated from radial glia in the molecular layer of the developing cerebellum, where they form characteristic palisades. They may therefore share with radial glia phenotypic traits that allow them to guide the external granular cell migration in the cerebellum. However, in the adult, the Bergmann glia have lost their radial glia characteristics.
- Müller cells are bipolar radial glial cells spanning the entire depth of the retina. They comprise the principal glial cells of the retina in most vertebrate

species. Microvilli from their apical process project into the subretinal space surrounding the photoreceptors. Secondary processes from their main trunk form extensive sheaths that surround neuronal cell bodies, dendrites, and, in the optic fiber layer, the axons of ganglion cells.

- Ependymal cells are located along the internal cavities of the CNS (cerebral ventricles and ependyma). They possess microvilli and ciliated processes that contribute to the movement of the cerebrospinal fluid. In some areas of the ventricular system, ependymal cells give rise to the choroid plexus, which secretes cerebrospinal fluid. Tanycytes are a special category of ependymal cells with numerous microvilli; they are devoid of cilia at their apical surfaces. They are associated with the circumventricular organs (i.e., the choroid plexus, the subcommissural organ, the subfornical organ, neurohypophysis, median eminence, pineal gland, and area postrema).

In fact, there are many astrocyte subpopulations, not only in regard to their shape and ultrastructural characteristics but also with respect to their biochemical properties, such as the receptors they express and the enzymes they carry. There are also morphological variations of astrocytes according to certain physiological states as well as pathological changes (e.g., gliosis, which occurs in gray and white matter regions), mainly in reaction to certain pathological states.

III. CHARACTERISTIC COMPONENTS OF ASTROCYTES

All the biochemical and molecular characteristics of astrocytes will not be described here. We limit discussion to those that have given specific insights toward our understanding of this cell type.

A. Glial Fibrillary Acidic Protein

GFAP is an intermediate filament protein expressed in astroglia. It was first isolated from multiple sclerosis brain, in which astrocytes are very reactive. Intermediate filaments constitute major components of the cytoskeleton of eukaryotic cells as 10-nm filaments. On the basis of differences in size and amino acid sequences, GFAP together with vimentin and desmin are classified as type III intermediate filament proteins. They are composed of three distinct regions: an amino-terminal head region, a central rod region, and a carboxy-terminal tail region. The rod regions are highly conserved among intermediate filament proteins, whereas size and amino acid sequences vary in the other regions. GFAP shows some species-specific amino acid heterogeneity and its molecular weight ranges from 48 to 51 kDa. Despite these minor differences, it is a highly conserved molecule. Soluble forms of the protein are assembled to form dimers; two dimers form protofilaments, which assemble to form the 10-nm filaments. Phosphorylation and dephosphorylation of specific amino acid residues in the head region are involved in the regulation of GFAP assembly. GFAP is observed in all cells of the astrocyte family, including ependymocytes, and is very abundant in tanycytes. Although GFAP has been found in the peripheral nervous system (e.g., in nonmyelinating Schwann cells) as well as in non-CNS tissues, GFAP immunocytochemistry is a main tool to study normal development of astrocytes and their reaction following injury and disease where it is upregulated.

B. Other Specific Components of Astrocytes and Cells of the Astrocyte Lineage

Nestin is a protein the expression of which specifically distinguishes neuroepithelial stem cells (from which the name nestin originated) from other more differentiated cells in the neural tube. Nestin defines a distinct sixth class of intermediate filament protein, closely related to neurofilaments. Nestin is expressed by glial precursors such as radial glia and in the cerebellum by immature Bergmann fibers; it is also expressed by adult Bergmann fibers recapitulating developmental stages when placed in the presence of embryonic neurons. During neuro- and gliogenesis, nestin is replaced by cell type-specific intermediate filaments (i.e., neurofilaments and GFAP, respectively). Nestin expression is reinduced in reactive astrocytes in the wounded adult brain. In adult subventricular zone (SVZ) of adult mice, ependymocytes strongly express nestin and vimentin and lightly express GFAP.

Vimentin, a type III intermediate filament subunit present in most tissues of many vertebrates, is also found in brain. In the mouse, it is expressed in oligodendrocyte precursors, radial glia, and astrocytes before the onset of GFAP expression. Both *in situ* and in culture, vimentin and GFAP may coexist in certain astrocyte subclasses, such as tanycytes and ependymocytes. In vimentin knockout mice, the GFAP

network is disrupted in those astrocytes that normally coexpress vimentin and GFAP (i.e., Bergmann glia of cerebellum and astrocyte subpopulations of the corpus callosum).

Glycogen particles are present in radial glia and mature astrocytes, and they represent the storage form of glucose. Glutamine synthetase (GS) catalyzes the conversion of glutamate to glutamine in the presence of ATP and ammonia. By immunocytochemical methods, its presence has been demonstrated in the cytoplasm of astrocytes. Although some authors have found GS immunoreactivity in a discrete population of oligodendroglia, it remains for most authors an astrocyte marker. Its important function in neuron physiology will be described later.

S100 proteins are Ca^{2+}- and Zn^{2+}-binding proteins found at high concentration in the mammalian brain. It is now known that the S100 family of calcium-binding proteins contains approximately 16 members, each of which exhibits a unique pattern of tissue/cell type-specific expression. There are two 10-kDa isoforms of S100, alpha and beta. In the brain, the beta isoform is most abundant and is synthesized by and released from astrocytes. The S100 beta molecule is considered a calcium-binding protein of astroglia.

IV. ASTROCYTE CELL LINEAGE

Mammalian species acquire their full complement of cortical neurons during the first half of gestation. Radial glia is established early in development at the time of neurogenesis, during the early gestational period, and accompanies neuroblasts during their migration to the cortex. In late gestational and early postnatal mammalian brain, the SVZ is the major source of astrocytes and oligodendrocytes, although astrocytes may also develop from radial glia. Remarkable recent data suggest that cells of the astrocyte lineage could have neural stem cell potential.

A. Embryonic Radial Glia

The radial glia was first revealed by the Golgi silver impregnation at the turn of the twentieth century and later described by Rakic in the early 1970s. They have a highly organized palisading cytoarchitecture, in relation to their role in neuronal migration from the ventricular zone to the cortical layers. In the developing CNS, cell bodies of the radial glia lose their ventricular insertion and migrate toward the brain surface. In the monkey, these glial cells appear during the first third of gestation, first in the spinal cord and then in the diencephalon, the telencephalon, and the cerebellum. During the peak of neurogenesis, there are two distinct classes of proliferative cells: those expressing GFAP that will give rise to radial glia and those not expressing this marker (i.e., neuroblasts). These $GFAP^+$ and $GFAP^-$ cells are intermixed in the ventricular and subventricular zones, which illustrates that glial and neuronal cell lines coexist within the early fetal proliferative zones and that the onset of glial phenotypic expression occurs prior to the last division of neuroblasts. Expression of embryonic radial glial identity requires the presence of extrinsic soluble signals is in embryonic forebrain, including neuronal factors.

By using a Golgi technique, Schmechel and Rakic showed in the monkey brain that radial glia transforms into astrocytes. Radial glial cells assume a variety of transitional forms during the process of this transformation into mature astrocytes. This transformation occurs in different areas of the CNS at a specific embryonic age and is initiated after neuronal migration has begun to subside. The bipolar radial cell becomes transformed into the astrocytic multipolar form; this may occur directly or with a monopolar radial form as an intermediate state of transformation (Fig. 2). The number of astroglial cells increases at an accelerated pace after neurogenesis is complete.

A recent discovery suggests that in the developing CNS, radial glial cells may have the potential to self-renew and to generate both neurons and astrocytes; these data led to the concept that a lineage relationship between these two cell types underlies the radial organization of the neocortex.

B. Astrocytes Derived from SVZ Precursors

In the mammalian cortex, both neurons and glia arise from the proliferating neuroepithelial cells of the telencephalic ventricular and subventricular zone. The SVZ is a mosaic of multipotential and lineage-restricted precursors in which environmental cues influence both fate choice and all surviving cells. In the adult brain, SVZ astrocytes could be neural stem cells.

The generation of astrocytes directly from SVZ cells was suggested by morphological observations

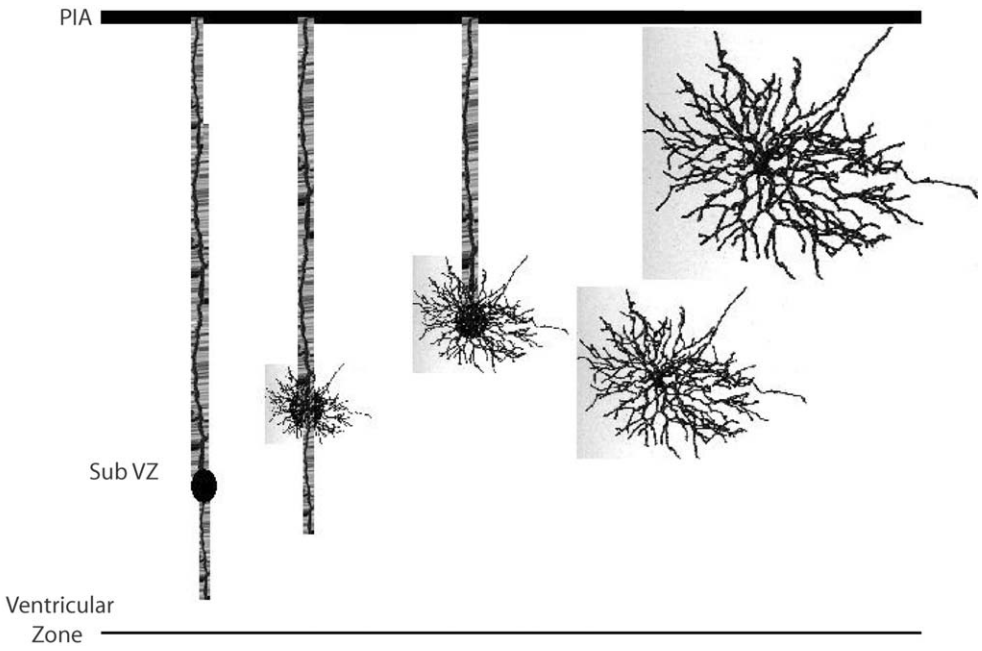

Figure 2 Morphogenetic transformation of fetal radial glial cells into various astrocytic forms [adapted from P. Rakic, 1995, in *Neuroglia* (H. Hettenmann and B. Ransom, Eds.), pp. 746–762, Oxford Univ. Press, New York].

providing evidence for separate astrocyte and oligodendrocyte lineages while these cells are still proliferating. Moreover, because angiogenesis and astrogenesis occur over a similar period of time during neurogenesis, it has been suggested that the growth of blood vessels may even drive the selection of astrocytic fate by a progenitor cell; at the time at which vessel growth is completed, fewer progenitors may be directed toward an astrocytic fate, allowing more to differentiate into oligodendrocytes.

C. Type 2 Astrocyte Phenotype

Since the early 1980s, glial research has centered around an oligodendrocyte type 2 astrocyte progenitor (0-2A) first discovered in culture of the optic nerve. 0-2A progenitors in culture generate oligodendrocytes constitutively but can give rise to process-bearing astrocytes (so-called type 2 astrocytes) when treated with 10% fetal calf serum. Attempts to find cells *in vivo* with the type 2 astrocyte phenotype during normal development have failed. Most astrocytes are generated prenatally and during the first postnatal week, before oligodendrocyte formation, suggesting that there is not a second wave of type 2 astrocytes *in vivo* as suggested by previous *in vitro* studies. Franklin and Blakemore noted that the apparent discrepancies between the data obtained *in vitro* and *in vivo* highlights an important aspect of the approach *in vitro*. When a progenitor cell is grown in tissue culture, the environments to which it can be exposed are restricted only by the imagination of the experimenter. By exposing the cell to a variety of signals, the differentiation potential of the cell can be examined. In contrast, during development, a progenitor cell is exposed to a restricted sequence of signals that are spatially and temporally programmed.

D. Influence of Growth Factors and Hormones

As shown for radial glial cells, neuronal factors influence the development of astrocytes. In tissue culture systems, primary astrocytes respond to the presence of neurons by withdrawing from the cell cycle and extending complex $GFAP^+$ processes. In contrast, in the absence of neurons, astrocytic cells have a flat fibroblastic appearance with little or no processes formation.

Many trophic factors act on cells of the astrocyte lineage *in vivo* such as bone morphogenetic proteins

(BMP), ciliary neurotrophic factor (CNTF), fibroblast growth factor (FGF), epidermal growth factor (EGF), platelet-derived growth factor (PDGF), and leukemia inhibitory factor (LIF). Most of these have been shown to be involved in proliferation and differentiation of cells of the astrocytic lineage and provided by neighboring neurons, with PDGF appearing to be the link in the sequence of cell–cell interactions responsible for matching numbers of neurons, astrocytes, and blood vessels during development.

The thyroid hormone T3 regulates the number of astrocytes and the maturation of Bergman glial cells. Neuroactive steroids also regulate astroglia morphology, at least in hippocampal cultures from adult rats.

V. PARTICIPATION OF ASTROCYTES IN BRAIN CONSTRUCTION

A. Neurons

1. Neuronal Migration and Neurite Formation

In 1911, Ramon y Cajal perceived the functional importance of radial glia as directional guides for migrating immature nerve cells. The concept of glial guidance first described by Rakic in 1971, and derived from the observation of a tight association between migrating granule cells and Bergmann fibers in the developing molecular layer of the cerebellum, underlies a commonly used mechanism for the positioning of young postmitotic neurons in developing brain. Neuronal migration is a key step in neural morphogenesis since inadequately located neurons may not establish the appropriate connections, and this may lead to neuronal death or to functional deficits of synaptic circuits. The close structural relationship between radial glia and migrating neurons consist in a radial unit. Radial glial fibers are present in large numbers during peak periods of neuronal cell migration in each structure of the developing primate nervous system. During the entire period of cell migration to the neocortex, a single radial process can guide several hundreds of neurons that originated from the same position in the ventricular zone, the so-called proliferative unit. Although the migrating neuron encounters myriad processes in various orientations, it remains constantly apposed to radially oriented fibers. Thus, there is a vertical columnar organization of the brain. From counts on samples of ventricular zones, it has been determined that the total number of ontogenetic columns is several millions. The remarkable expansion of the cortical surface during evolution can be explained by an increase in the number of proliferative units, as a single round of cell division doubles the number of ontogenetic columns and therefore the number of cells in the cortex. Within each column, neurons generated earlier occupy deeper positions; therefore, those arriving later have to pass them, along the glial radial fiber, to become situated more superficially. This constitutes an ''inside-out'' sequence of time of origin of neurons in the cerebral isocortex. There is a neuronal leading process along the glial guide, and the neuronal cell body is the site of adhesion of the migrating neuron.

Neuronal cell migration requires the cooperative interaction of adhesion and recognition molecules, which may be expressed by neurons and radial glial cells. Migratory granule neural cells in the cerebellum produce a cell adhesion molecule, astrotactin, that enables them to ride the glial scaffold. The blockage of astrotactin curtails neuronal migration *in vitro*. Although at this stage some of the numerous molecules involved in neuronal migration have been identified, the exact mechanisms involved in the selection of a pathway, migration, and departing from this pathway remain obscure.

In the adult mammalian forebrain, neuronal precursors born in the SVZ of the neonatal and adult rodent brain are able to migrate 3–8 mm from the walls of the lateral ventricle into the olfactory bulb, where they differentiate into olfactory interneurons. This migration depends on a persistent manifestation of the RMS that was first reported in the developing rodent brain. This tangentially oriented migration occurs without the guidance of radial glial or axonal processes. The cells are closely associated, forming elongated aggregates called ''migration chains'' that are ensheathed and moved within channels formed by the processes of specialized astrocytes. However, the role of these astrocytic tunnels is unclear. If the migration of neuroblasts by chain migration is a glial-independent movement, these glial cells may provide *in vivo* a permissive environment and directional cues for migration to the olfactory bulb, restricting the dispersal of neuroblasts outside the migratory stream or isolating the migrating cells from the surrounding parenchyma.

Neurons have the intrinsic property of generating two distinct sets of processes, one axon and multiple dendrites. Some of the mechanisms underlying polarized sorting of membrane and cytosolic proteins are similar in neurons and other polarized cells, such as epithelial cells. The axonal membrane of neurons

shares properties with the apical membrane domain of epithelial cells, whereas the soma and the dendritic arbor of neurons corresponds to the basolateral domain of epithelial cells. Glial cells can control neuronal shape. It was recently shown in culture that the dendritic branching of GABAergic neurons requires signaling from living astrocytes. Among several mechanisms, neurite outgrowth can be promoted by regulating the degradation of the extracellular matrix by protease inhibitors, such as the glia-derived nexin.

2. Astrocyte Boundaries and Neural Pathways

Throughout neurogenesis, the diverse neural cell populations have to establish their correct pathways to find their proper locations and establish correct connections with neural partners. Moreover, the formation of the adult architecture of neuronal networks is essentially based on directed neurite extension. Growth cones have to find their way to their target region by crossing permissive substrates and diffusible factors and avoiding repulsive ones. Glial cells have been proposed to provide some pathways for axon growth in mammalian brain. Therefore, interactions with molecules secreted in the extracellular matrix by glial cells have been implicated in the formation of boundaries separating anatomically defined regions in the CNS. Within the developing nervous system, such boundaries are present in numerous regions of the CNS, such as the diencephalic/telencephalic junction, the optic chiasm, the midline of the developing forebrain, and the cerebral commissures. Among the components of the extracellular matrix, many are synthesized during development by glial cells such as tenascin-C and -R, thrombospondin-1, and laminin as well as a variety of proteoglycans; these molecules can act as either promoters or inhibitors of neural cell migration and neurite outgrowth. When functional patterns have formed and appear to be stabilized, these boundaries are no longer detectable, but can be reexpressed in reaction to injury. Astroglial maturation is accompanied by a decrease in expression of molecules such as laminin, NCAM, L1, and heparan sulfate proteoglycan, which are known to promote axonal outgrowth. In parallel, the maturation of astrocytes is accompanied by an increase in the synthesis of molecules known to inhibit neurite outgrowth, such as chondroitin sulfate proteoglycan and tenascin.

B. Brain Vessels and Blood–Brain Barrier

The blood–brain barrier is a physical and physiological barrier impeding the passive diffusion of solutes from the blood into the extracellular space of the CNS. The blood–brain barrier is also a brain–blood barrier. In mammals and most vertebrates, the blood–brain barrier is a complex cellular system consisting of endothelial cells, pericytes, perivascular microglia, astrocytes, and basal laminae. Interactions of all these cells seem necessary for the induction and maintenance of the specialized functions of the blood–brain barrier which protect the brain from toxin, viruses, and macromolecules. The highly impermeable tight junctions between endothelial cells forming the capillaries in the CNS of higher vertebrates are responsible for the blood–brain barrier functions. Astrocyte perivascular processes or end feet form a virtually continuous sheath around the vascular walls and are nearly as extensive as the vascular endothelial covering. Astrocytes end feet at the pial surface, which form the glia limitans, constitute a boundary around the entire CNS that helps to separate neural elements from mesodermal tissues.

During vascularization in early embryonic development, angioblasts (precurseurs of endothelial cells) invade the CNS neural tissues. When astrocytes differentiate, they extend processes on vessels and they induce blood–brain barrier differentiation in endothelial cells. Conversely, interactions of astrocyte progenitors with developing blood vessels may have a role in differentiation of astrocytes. In this context, it has been demonstrated in the retina that the vascular endothelial growth factor synthesized by astrocytes and Müller cells was an important inducer of endothelial cell growth and blood vessel development; therefore, astrocytes are critical in establishing the correct number of blood vessels in the brain. Recently, it has been shown that astrocytes isolated from GFAP knockout mice are unable to induce blood–brain barrier properties in endothelial cells.

VI. GLIAL NETWORK

Although many astrocytic processes ensheath most of the synapses within the CNS, other astrocytic processes are connected to each other by gap junctions. The main astrocytic gap junction protein is connexin 43, but others may be present. *In situ*, morphological studies have shown that astrocyte gap junctions are

localized between cell bodies, between processes and cell bodies, and between astrocytic end feet that surround blood vessels (Fig. 1). Gap junctions are a group of diverse channels that vary in their permeability, voltage sensitivities, and potential for modulation by intracellular factors. Thus, junctional coupling may provide a pathway for the selective exchange of small molecules (less than 1–1.4 kDa) such as ions, cyclic nucleotides, and small peptides. Gap junctions could potentially give rise to hierarchical signaling systems, in which cells of one class can transfer second messengers to cells of a second class but not vice versa. Although less frequently observed, gap junctions also occur between astrocytes and oligodendrocytes as well as between oligodendrocytes. Thus, the astrocytic syncytium extends to oligodendrocytes, allowing glial cells to form a "generalized glial syncytium." This large glial network extends radially across gray and white matter regions, from the spinal canal and brain ventricles to the glia limitans and the capillary epithelium.

Homologous coupling could synchronize the electrical activity of neighboring cells that serve the same functions, thereby generating a functional network. In this regard, intercellular coupling is believed to facilitate one of the major functions of astrocytes—maintaining the ionic balance of the extracellular fluid—by providing a vast cytoplasmic reservoir for the spatial buffering of ions taken up from the extracellular space. In particular, K^+ released from active neurons would enter neighboring glial cells and be redistributed by current flow through the glial syncytium. Heterocoupling between astrocytes and oligodendrocytes has been proposed to serve K^+ buffering around myelinated axons.

VII. CALCIUM SIGNALING IN THE ASTROCYTE NETWORK AND BETWEEN ASTROCYTES AND NEURONS

A seminal observation was made in the early 1990s by Cornell Bell and collaborators, who found that in the presence of glutamate, Ca^{2+} waves propagate *in vitro* at a velocity of about 15–20 μm/sec following complex routes of hundreds of micrometers through the astrocyte syncytium. Cornell Bell and collaborators proposed that networks of astrocytes may constitute a long-range signaling system within the brain. Since then, several critical steps involved in intercellular calcium signaling have been identified, and it is likely that gap junction communications play a key role in this process. Nevertheless, alternative mechanisms for Ca^{2+} wave propagation may involve extracellular messengers, such as ATP, released by stimulated cells. Propagation of calcium signals from astrocytes to neurons has recently been observed in astrocyte and neuron cocultures as well as *in situ* on acute rat brain slices. Elevation of cytosolic calcium in astrocytes induces glutamate release from neurons, which in turn signals back to neurons. Although different from neuronal excitability, astrocytes do indeed exhibit a form of excitability mediated by intracellular calcium spikes and oscillations as well as intercellular calcium waves that propagate through the glial syncytium in response to firing of glutamatergic neurons. The astrocytic Ca^{2+} excitability may be functionally analogous to the action potential that neurons use for communication, thereby enabling a bidirectional communicating network between neurons and astrocytes.

VIII. PARTICIPATION OF ASTROCYTES IN BRAIN HOMEOSTASIS AND NEURON–GLIA INTERACTIONS

A. Lipids

Apolipoproteins arise from local synthesis or filtration from plasma, although the respective amount remains unclear. According to current views, apolipoprotein E (apoE) is the main apolipoprotein produced and secreted by astrocytes within the brain parenchyma. ApoE is presumably involved in the redistribution of lipids among cells. Other apolipoproteins appear to be involved in brain lipid transport and homeostasis, such as ApoJ and ApoD. ApoD is found mainly in oligodendrocytes and astrocytes. Irregular lipoprotein metabolism, possibly related to special isoforms, may be involved in several neurodegenerative diseases, especially Alzheimer's disease.

B. Energy Metabolism: Glucose

In the brain, astrocytes are situated in a key position between microvessels, neurons, and oligodendrocytes (Fig. 1). If one considers the narrow extracellular space between brain cells, it appears that the substrates for the generation of energy must cross the astrocytes to reach their metabolic destination in neurons. Glucose

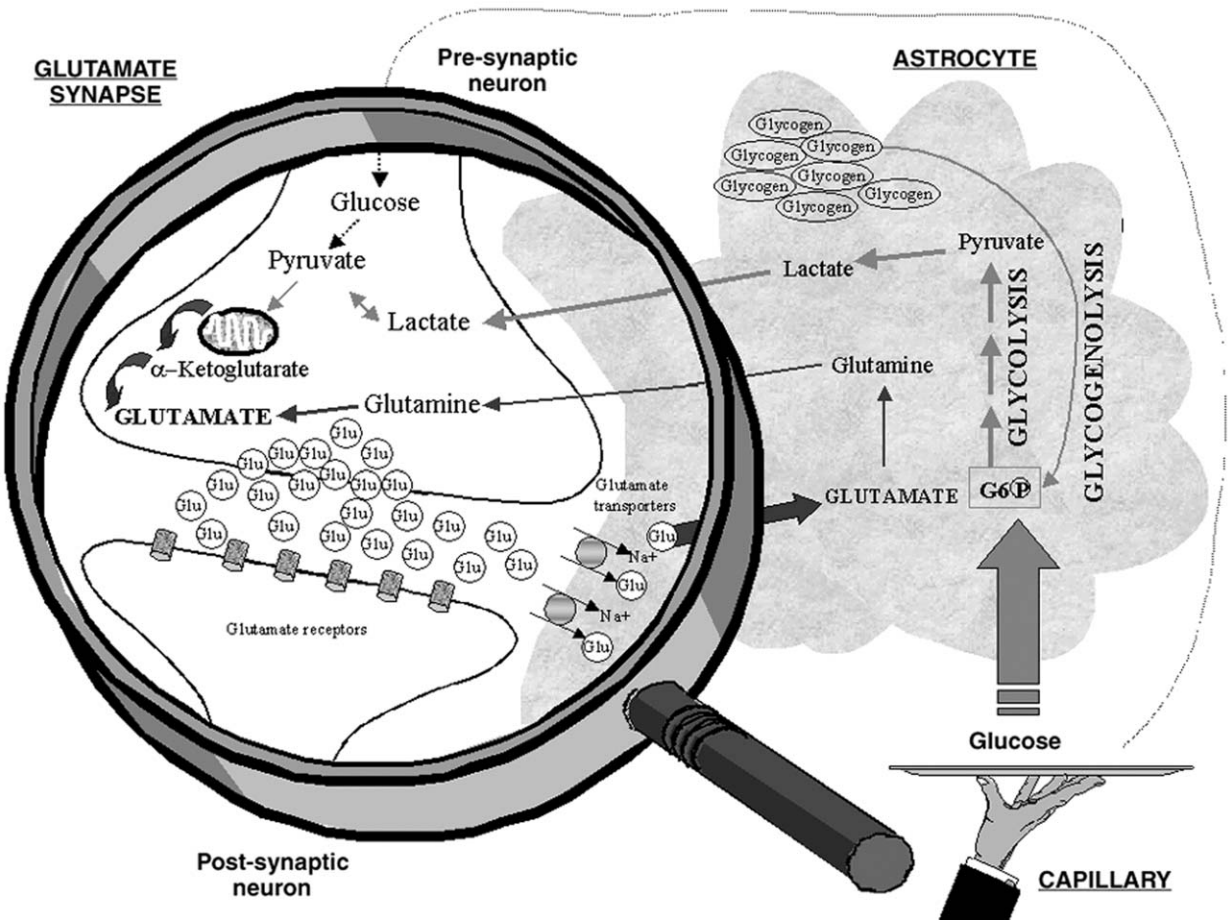

Figure 3 Metabolic coupling between neurons and astrocytes at glutamatergic synapses. Presynaptically released glutamate depolarizes postsynaptic neurons by acting at specific receptor subtypes. The action of glutamate is terminated by an efficient glutamate-uptake system located primarily in astrocytes. Glutamate is cotransported with Na^+, leading to activation of the astrocyte Na^+/K^+-ATPase, which in turn stimulates glycolysis (i.e., glucose utilization and lactate production). Lactate, once released by astrocytes, can be taken up by neurons and serve them as an adequate energy substrate. In accord with recent evidence, glutamate receptors are also shown on astrocytes. Glycogenolysis is also a source of lactate by glycogenolysis to glucose-6-phosphate (G6P), followed by steps of glycolysis. Direct glucose uptake into neurons under basal conditions can also occur. (adapted from Magistretti *et al*., 1999).

is the main energy source in the CNS; although neurons are able to take up glucose and phosphorylate it, at a basic level the tight coupling between the function and the energy metabolism of this cell type requires astrocytes (Fig. 3). First there is a transport of glucose into astrocytes by specific transporters; gap junction permeability also controls the uptake and distribution of glucose in astrocytes and in this way may regulate brain metabolism. Glycogen is also a source of energy in the brain, in which it is localized almost exclusively in astrocytes, to an extent that it can be considered a marker for this cell type. Its level is finely tuned by synaptic activity. Glycogenolysis is also activity dependent. Several neurotransmitters, such as noradrenaline, serotonin, histamine, the vasoactive intestinal peptide, and the purine adenosine, promote glycogenolysis as shown in studies of slices from different brain areas. The glucosyl residues of glycogen appear to also be broken down to lactic acid.

The discovery that glucose is taken up by glial cells was first demonstrated in the CNS model of the honeybee drone retina, in which an analog of glucose [2-deoxyglucose (2-DG)] was quantitatively shown to be taken up and phosphorylated by hexokinase in glial cells during light stimulation. The same coupling also occurs in the mammalian retina. It has been demonstrated in culture of astrocytes that glutamate stimulates 2-DG uptake and phosphorylation and that there

is a tight coupling between Na^+-dependent glutamate uptake and glucose utilization (Fig. 3). Noradrenaline and arachidonic acid also stimulate glucose uptake by astrocytes.

There is mounting evidence that lactate, resulting from the glycolytic processing of glucose in astrocytes, is the preferred energy source for neurons, particularly during situations of high energy demand. In astrocyte cultures, there is a glutamate-evoked lactate release that correlates with glutamate-evoked glucose utilization, indicating the role of glycolysis in this process. A similar process is observed in preparations of freshly isolated Müller cells still attached to photoreceptors, even in the presence of millimolar concentrations of glucose. When such a preparation is maintained in darkness to stimulate neurotransmitter release, lactate derived from glial glycolysis is transferred from Müller cells to photoreceptors, where it serves to fuel mitochondrial oxidative metabolism and possibly the resynthesis of the neurotransmitter pool of glutamate. There is a saturable lactate transporter in neurons. Pyruvate gives rise to lactate in astrocytes through a different lactate dehydrogenase enzyme than that in neurons; thus, there is evidence for an astrocyte–neuron lactate shuttle. In astrocytes, lactate could also be released from the metabolism of amino acids such as glutamate.

In human, glucose metabolism can be studied using (^{18}F) fluoro-2-deoxyglucose (FDG) by positron emission tomography (PET). FDG–PET imaging supports the notion that astrocytes markedly contribute to the FDG–PET signal; this view does not challenge the validity of the 2-DG-based techniques to monitor neuronal activation since the uptake of the tracer into astrocytes is triggered by a neuronal signal (i.e., the activity-dependent release of glutamate).

Although there is no proposal for other neurotransmitters, the well-studied model proposed for glutamatergic synapse can be extended to other neurotransmitters systems, such as the primary inhibitory transmitter γ-aminobutyric acid (GABA) that flows in a similar neurotransmitter cycle between neurons and astrocytes.

C. Neurotransmitter Transporters and Receptors

1. Glutamate Transporters

L-Glutamate is the major excitatory neurotransmitter in mammalian CNS. High-affinity glutamate transporters are believed to be essential both for terminating synaptic transmission and for keeping the extracellular glutamate concentration below neurotoxic levels. Many glutamate transporter subtypes are known and may display different functions in different neural subtypes. GLT-1 and GLAST transporter subtypes were shown to be selective markers of all astrocytic plasma membranes. GLAST transporter is expressed from radial glia through mature astrocytes during spinal cord development. Astrocytic membranes facing capillaries, pia, or dendrites express less glutamate transporters than those facing nerve terminals, axons, and spines, suggesting that the localizations of these glutamate transporters are tightly regulated.

The coexpression of GLAST and GS was specifically demonstrated in Müller cells, astrocytes, and retinal pigment epithelium, three cell types developmentally related in the retina. No neuronal or microglial staining was observed. Astrocytes are known to metabolize extracellular glutamate into glutamine, which constitutes the basis for the ''glutamate–glutamine'' cycle. In the brain, the major site of glutamine synthesis is astrocytes, in which GS is localized. Glutamine synthesis also requires glutamate, ammonia, and ATP. Glutamine released from astrocytes has very low affinity for glutamate receptors and therefore remains available for the synthesis of glutamate in neurons by the phosphate-activated glutaminase. Overall, once degraded in neurons, glutamine provides an important precursor source for amino acids, such as glutamate and GABA. Net synthesis of the neurotransmitter glutamate and GABA can take place from glutamine, α-ketoglutarate, or another tricarboxylic acid cycle intermediate together with an amino acid as the donor of the amino group. The latter may also be synthesized in astrocytes and taken up by neurons.

Glutamine synthesis is important for the detoxification of ammonia. During hepatic encephalopathy and other hyperammonemic states, the ability of the brain to fix excess blood levels of ammonia produced may be limited. Ammonia inhibits glutamine efflux from astrocytes, which probably contributes to astrocyte swelling and alteration of calcium homeostasis. The reduction of the extracellular space following astrocyte swelling may result in an increase in the extracellular concentration of ions, especially calcium that could affect neuronal excitability. Swollen astrocytes also release glutamate, which might also contribute to excitotoxicity. These data suggest that glial glutamate transporters provide the majority of functional glutamate transport and are essential for both maintaining

low extracellular glutamate and preventing chronic glutamate neurotoxicity.

2. Glutamate Receptors

Glutamate receptors were the first neurotransmitter receptors identified in astrocytes by studies showing that excitatory amino acids (glutamate, aspartate, and kainate) directly induce depolarization of astrocytes in culture. Glutamate induces complex changes in $[Ca^{2+}]_i$ characterized by intracellular waves and oscillations, mediated by different ionotropic (AMPA/kainate and NMDA) and metabotropic glutamate receptors (mGluRs).

3. Glycine Receptors

Glycine receptors are also regionally restricted in subclasses of neurons, and their adjacent astrocytes in the spinal cord, suggesting interplay between these two cell types.

4. GABA Transporters

GABA transporters play a key role in the termination of GABA transmission and in the regulation of extracellular GABA concentrations. It was recently shown that astrocytic processes, identified by their immunoreactivity for GFAP, express specific GABA transporters. This specific GABA uptake system is restricted to astrocytes near GABAergic synapses.

5. Benzodiazepine Receptor and Natural Ligands

Mitochondrial benzodiazepine receptors (MBRs) also called peripheral-type benzodiazepine receptors, are extremely abundant in steroidogenic cells and astrocytes. MBR ligands stimulate progesterone synthesis by isolated mitochondria due to MBR translocation of cholesterol, its precursor, from the outer to the inner mitochondrial membrane. The endogenous natural ligands for MBR have been termed "endozepines" because they displace benzodiazepines from their binding sites on GABA A receptors and MBR. All endozepines are so far derived from a 10-kDa polypeptide called diazepam binding inhibitor, which can generate through proteolytic cleavage several biologically active peptides. One of them, an octadecaneuropeptide, is found in high concentrations in glial-rich parts of the brain and is a much more potent inhibitor of [^{3}H]diazepam binding in glial cells than in neurons. MBR and progesterone synthesis are also increased in reactive glial cells.

D. Modulation of Synaptic Activity

As previously mentioned, astrocytes possess many of the characteristics that would allow them to play an active role in the regulation of neuronal activity, particularly in synaptic transmission. Astrocytes tightly surround synapses; they possess ion channels and receptors for various neurotransmitters and are therefore in a good position to regulate the molecular environment of their associated neuronal set. As discussed previously, two mechanisms, not mutually exclusive—gap junction coupling and neurotransmitter release—may mediate the propagation of Ca^{2+} waves in the astrocyte network. Other neurotransmitters, such as norepinephrine and GABA, have also been shown to evoke $[Ca^{2+}]_i$ increases in astrocytes from hippocampal slices, indicating that neuron/astrocyte signaling is not restricted to glutamatergic synapses. Moreover, it has been shown that astrocytes are in turn able to release glutamate and activate the neighboring neurons. Glutamate released from astrocytes can activate either neuronal NMDA receptors or mGluRs and in this way facilitate or depress synaptic activity. Overall, when releasing glutamate, presynaptic neuronal endings signal not only to postsynaptic neurons but also to perisynaptic astrocytes, which can reply by releasing glutamate and inducing $[Ca^{2+}]_i$ changes in the same or in different neurons. This activation of astrocytes by synaptically released glutamate is finely tuned, depending on the intensity and frequency of neuronal activity, indicating plasticity of the astrocyte response.

Other transcellular messengers, such as nitric oxide (NO) and arachidonic acid or its metabolites, are involved in the interactions between neurons and astrocytes. For instance, astrocytes as well as neurons respond to glutamate by releasing arachidonic acid, which in turn participates in the Ca^{2+}-dependent glutamate release by astrocytes. Arachidonic acid and ATP also stimulate glycogenolysis in astrocytes; these molecules are involved in the metabolic cross talk between astrocytes and neurons. Glial cells also produce NO in response to cytokines released in inflammatory conditions, thereby affecting the reuptake of glutamate by astrocyte. In this context, excessive NO production in the brain has been correlated with neurotoxicity and the pathogenesis of

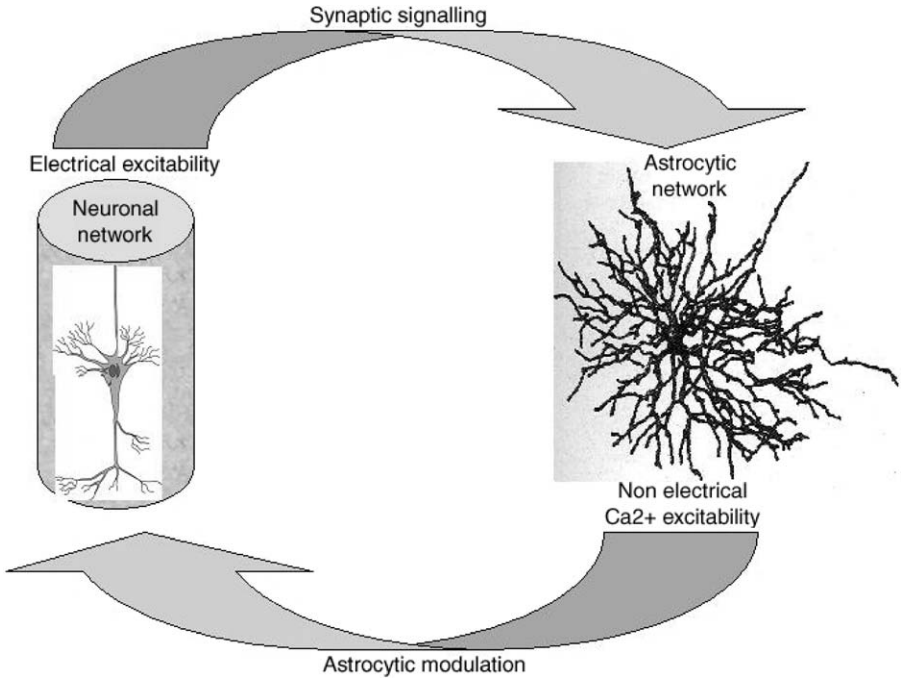

Figure 4 New role for astrocytes: processing of information in the CNS (adapted from S. Smith, 1994, *Curr. Biol.* **9,** 807–810).

several neurodegenerative diseases, such as Alzheimer's disease.

Prostaglandins (PGs) are synthesized in astrocytes and also induce a Ca^{2+}-dependent glutamate release. In many brain pathologies or injuries, PG levels have been reported to increase, suggesting that the dysregulation of PG-dependent glutamate release from astrocytes could participate in neurotoxic cascades. These data again indicate the existence of an integrated glutamatergic cross talk between neurons and astrocytes that may play critical roles both in synaptic plasticity and in neurotoxicity.

Another aspect recently evaluated is the role of glial cells in synaptogenesis. In glia-free cultures, retinal ganglion cells form synapses with normal ultrastructure but display little spontaneous synaptic activity and high failure rates in evoked synaptic transmission. In contrast, when cocultured with glial cells, retinal ganglion cells show an increase in the number, frequency, and amplitude of spontaneous postsynaptic currents and also fewer transmissions failures.

Therefore, although lacking the excitability associated with neurons, glial cells are more actively involved in brain function than had been previously thought. Indeed, it appears that glia is intimately associated with neurons through an exchange of signals regulated by the same types of receptors as those found in neurons (Fig. 4).

IX. PHYSIOLOGICAL PLASTICITY OF ASTROCYTES IN THE ADULT CNS AND NEURON–GLIA INTERACTIONS

In certain regions of the adult CNS, astrocytes display a morphological and functional plasticity in relation to particular physiological states, such as circadian rhythms, parturition and lactation, and osmotic stimulation, as well as to pathological states.

A. Neuron–Glia Interactions in the Hypothalamus and the Pituitary

Although the close anatomical association of glia and neurons is a familiar notion, we are only beginning to appreciate that this association is dynamic and modifiable. A neuronal system, which well exemplifies this is the hypothalamoneurohypophysial system, in which neurons and glial cells undergo physiologically linked morphological changes throughout life. Thus, during conditions that enhance neurohormone secretion

(parturition, lactation, and prolonged osmotic stimulation), glial coverage of oxytocinergic neurons markedly diminishes and their surfaces are left in extensive juxtaposition. Concurrently, there is formation of new synapses, which are predominantly GABAergic and which couple two or more oxytocinergic neurons simultaneously; glutamatergic synapse numbers also increase significantly. The same stimuli induce similar changes in the posterior pituitary, in which retraction of pituicyte processes from posterior pituitary neurons and growth and multiplication of neurosecretory axon terminals lead to an increase neurohemal contact. These structural changes do not permanently modify the anatomy of the system since upon cessation of stimulation neuronal juxtapositions and shared synapses disappear, and they reappear upon new stimulation. Activity-related changes in the conformation of glia, neurons, and synaptic inputs also occur in other hypothalamic–neurosecretory systems, such as the arcuate nucleus in relation to varying estrogen level.

B. Circadian Rhythms

The suprachiasmatic nucleus (SCN) of the anterior hypothalamus is the site of the endogenous clock controlling circadian rhythms in mammals. Within the SCN, there is a circadian fluctuation in GFAP immunoreactivity distribution, in parallel with energy metabolism, electrical activity, and peptide synthesis, thus implicating astrocytes in the mechanism of the circadian clock. Neurons of the SCN display endogenous circadian oscillations of spike-firing rates *in vivo* as well as in slice preparations. Propagating waves of increased Ca^{2+} moving through the astrocytic network were noted in the isolated SCN following glutamate stimulation; glutamate inputs from retinal ganglion cells to the SCN could be the trigger for Ca^{2+} waves in these astrocytes *in vivo*.

X. ASTROCYTE AND PATHOLOGICAL STATES

A. Human Defects in Neuronal Migration

In the human, the major neuronal migrations that form the cortical plate occur by the 16th week of gestation, and late migrations from the germinal matrix into the cerebral cortex continue until 5 months postnatally. The external granule layer of the cerebellar cortex continues to migrate until 1 year of age. Abnormalities of these migratory processes have pathological consequences.

The neural tube of the early human embryo is poorly vascularized. It may rely on the glial processes to transport nutrients between the ventricular system and the glycogen-rich meningeal tissue. Any pathological event, such as ischemia or hypoxia, that interrupts or distorts the radial glial fiber system between the ependymal and pial surfaces of the brain may create abnormalities of neuronal migration. If a premature infant suffers a subependymal hemorrhage, the radial glial process that is guiding neurons to the surface may retract from the cortical surface after its cell somata is destroyed. An immature neuron already in migration along this process may have escaped destruction within the zone of hemorrhage, but it is able to migrate only as far as the end of the glial guide fiber. The migrating cells in the company of several others whose radial fibers are also retracted for the same reason create a group of heterotopic cells that are unable to complete their journey. They mature *in situ* but are unable to establish their intended synaptic relations; consequently, there is a faulty synaptic circuitry. Failure of migrating cells to reach their proper destination may be referred to as neuronal ectopia. Incidental findings at autopsy may be related to the development of an epileptic focus.

In an animal model of Down's syndrome, the trisomy 16 mouse, there is a reduction of radial units in early telencephalic development, explaining the reduction in the final telencephalic size. Most mammals, including all primates, develop convolutions to provide a large cortical surface without incurring a concomitant increase in cerebral volume. Abnormal convolution patterns of the infant brain (i.e., pachygyria, lissencephaly, and polymicrogyria) are the result of faulty neuronal migration and are associated with an abnormally laminated cortex. Some of these are being characterized at the molecular level. The recently sequenced human gene for astrotactin, is a candidate for unsolved neuronal migration disorders in man. Even small perturbations can produce defects; abnormally migrated neurons and glia via a rupture of the glia limiting membrane have been found in the perisylvian cortex of some dyslexic brains.

B. Gliosis

Astrocytes have a capacity to react mainly in relation to an injury to the CNS and constitute reactive gliosis. Although there may also be associated proliferation

and reactivity of microglial cells, the term gliosis is classically related to astrogliosis. This reaction is characterized by hypertrophy of astrocytes, both cytoplasmic and with enlarged nuclei, associated with a profusion of long, thick cytoplasmic processes. There is also an increase in gliofilament number and their constituent, GFAP. The gliotic reaction may also consist of hyperplasia, with the proliferation occurring close to an acute lesion; in other cases, the proliferation of astrocytes may be discrete, even absent, and its degree seems to depend on the kind of lesion, the region, and the state of development of the brain. The proliferation of astrocytes, when it occurs, could originate from multipotential stem cells or glial precursors still widely present in adult CNS. There could also be dedifferentiation of mature astrocytes, which could explain the expression or overexpression of molecules during the first stages of astrogenesis by recapitulation of ontogenic stages.

There are two types of reactive astrocytes. One is isomorphous gliosis, in which there is a regular pattern of astrocytes that are parallel to degenerating axons—for instance, in Wallerian degeneration, in which glial fiber organization preserves a normal structure. This is observed in slowly degenerative lesions or at distance from a lesion. There is also an anisomorphic gliosis in which proximal reactive astrocytes, close to a lesion, form a dense mesh with no discernable pattern. Astrocyte reactivity is more intense in gray matter than in white matter, in which there is already a higher level of GFAP expression. Other markers of astrocytes are also expressed by reactive astrocytes, such as GS and S100 beta. Activated S100 beta$^+$ astrocytes are dramatically increased in the brains of patients with Alzheimer's disease and in the Alzheimer-like neuropathological changes observed in Down's syndrome. This could favor calcium-mediated events in Alzheimer's disease, such as excessive phosphorylation of the tau protein present in neurofibrillary tangles, that could ultimately result in the neuronal cell death characteristic of this disease. The concomitant considerable increase in GFAP, even in regions that do not present the Alzheimer pathology, may reflect the prominent role played by astrocytes during this pathology. Interestingly, in Alzheimer's disease the production of β-amyloid precursor protein (APP) is increased in reactive astrocytes, as is the ApoE isoform, which is associated with the pathophysiology of APP metabolism. In this way, reactive astrocytes may be involved in the processing of APP, perhaps contributing to β-amyloid deposition in Alzheimer's disease.

Gliosis is also a secondary process observed during aging as well as in many pathological conditions affecting neural cells, such as brain trauma, ischemia, experimental autoimmune encephalomyelitis (EAE), and demyelinated areas of multiple sclerosis. The correlation of AIDS dementia with a high level of astrocytic expression of adhesion proteins such as VCAM-1 and ICAM-1 may be involved in cellular dysfunction. In myelin mutants, such as the *jimpy* mouse and the *md* and the *taiep* rat, gliosis is severe; nevertheless, axonal growth is not impaired.

The physiological role of astrogliosis remains controversial with respect to the beneficial or detrimental influence of reactive astrocytes on CNS recovery. On the one hand, the very dense network of processes built up in the scar by reactive astrocytes suggests that the scar tissue may fulfill important functions as a barrier isolating and protecting the intact tissue from the lesions, from which toxic molecules could be released. On the other hand, molecules expressed in lesion scars on the astroglial cell surface or secreted molecules render the reactive astrocyte a less favorable substrate, which could be inhibitory to neuritic outgrowth. Proteoglycans such as chondroitin sulfate proteoglycans may act as inhibitors of neurite outgrowth by attenuating the potential for axon elongation that could occur due to a concomitant expression of growth-promoting molecules such as laminin in regions of reactive gliosis. There also seems to be regional differences in the capacity for the gliotic astrocytes to secrete inhibitory molecules.

In the injured brain, the release of immunoregulatory cytokines by cells around lesion sites may be a mechanism contributing to the induction of gliosis. Molecular signaling may occur between lesioned neurons, glia, inflammatory cells, fibroblasts, and meningeal cells. Among these gliosis signaling molecules are macrophage inflammatory protein (MIP)-1α and MIP-1β, tumor necrosis factor-α, transforming growth factor-β, bFGF, interleukin-1, LIF, and CNTF.

C. Protective Role of Astrocytes

Glial cells may be involved in the differential vulnerability of dopaminergic neurons in Parkinson's disease; this is supported by the inverse relationship between the degree of neuronal loss and the density of astroglial cells initially present in these groups. For instance, even in the substantia nigra, the density of astroglial cells is lowest in the area where dopaminergic

neurons degenerate. Astrocytes may protect dopaminergic neurons from degeneration by metabolizing dopamine and scavenging oxygen free radicals that are associated with dopamine metabolism. Glutathione peroxidase and catalase are involved in the detoxification of H_2O_2 by astroglial cells.

Astrocytes may also protect neurons by secreting neurotrophic factors, although the respective role of astrocytes and neurons in this secretion *in vivo* remains unclear. Astrocyte synthesize metallothionein proteins, which present a neuroprotective role in inflammatory conditions.

According to their role in the reuptake of neurotransmitters, astrocytes are also involved in the control of glutamate-induced neurotoxicity. Astrocyte-specific glutamate transporters play a pivotal role in the clearance of glutamate synaptically released and therefore in the maintenance of glutamate at a physiological level, thus avoiding excitotocity.

D. Alexander's Disease and Its Animal Model

Alexander's disease is a leukodystrophy in which there is accumulation within the astrocytic cytoplasmic processes of eosinophilic, beaded inclusions, the Rosenthal fibers, which contain small heat shock proteins (e.g., α-B crystallin). The pathophysiological mechanisms responsible for this disease, and the relation between affected astrocytes and the demyelination characteristic of this pathology, have not been identified. Astrocytes of transgenic mice overexpressing GFAP contain cytoplasmic inclusion bodies identical histologically and antigenically to the Rosenthal fibers seen in Alexander's disease. Mice in the highest expressing lines die by the second postnatal week. Recently, sequence analysis of DNA samples from patients representing different Alexander's disease phenotypes revealed that most cases are associated with nonconservative mutations in the coding region of GFAP. Alexander's disease represents the first example of a primary genetic disorder of astrocytes, one of the major cell types in the CNS. Therefore, the GFAP-overexpressing transgenic mice provide an animal model for studying the interactions between astrocytes, oligodendrocytes, and myelin. Another important role of astrocyte in myelin maintenance and blood–brain barrier function was revealed by the study of an other animal model, the GFAP-deficient mouse, in which the white matter is poorly vascularized and the blood–brain barrier is structurally and functionally impaired.

E. Gliomas

Malignant gliomas are extremely invasive tumors; they are the most common type of malignant brain tumors in adults (40%). Most of them are of astrocytic origin. Despite aggressive treatment assays such as surgery, chemotherapy, and radiotherapy, mean survival rates for this disease are less than 1 or 2 years, depending on the clinical grade of the disease. Gene therapy has been used to kill tumor cells in animal models; the classic example of this strategy is the retroviral transfer of the herpes simplex virus thymidine kinase (TK) gene to tumor cells followed by treatment with the antiviral compound gancyclovir to kill cells expressing TK. This strategy was successful in rodents due to the bystander effect, in which cytotoxicity is transferred from cells expressing TK to non-TK-expressing cells. Unfortunately, it did not present any therapeutic effect in humans, presumably because of the low infection rate within human tumors and also because of the dissemination of the tumor cells in the human brain, impairing the bystander effect observed in rodent tumors.

Recently, attenuated, nonneurovirulent versions of herpes simplex virus have been used and have been shown to kill glioma cells in culture, and they have also been implanted in rodents. These viruses are currently in clinical trials. The pathophysiological mechanisms of gliomas have not been clearly identified.

XI. CONCLUSIONS

The importance of glia has become increasingly clear with the development of molecular biology and cell culture techniques. With technical progress, the roles of glia in neuronal migration in the development of neuronal pathways as well as in synaptic functions have been deciphered. Increasingly, the molecules involved in developmental processes and in the adult are being identified; molecules necessary for the migration of neurons on radial glia or Bergmann cells are made by neurons or glia with multiple interactions. Molecular studies of developmental mutants and human pathologies have led to the identification of the involvement of glia in numerous defects of migration that lead to microcephaly and other developmental diseases.

In many cases, axonal guidance seems to involve preformed glial pathways that may remain and create glial boundaries. Increasingly these neuroglial interactions are being identified in relation to neuronal

functions. Because of their mobility and plasticity, glial cells appear to be increasingly involved in the functions of the cabled neuronal network (Fig. 4). Synapses throughout the brain are ensheathed by astrocytes. Astrocytes help to maintain synaptic functions by buffering ion concentrations, clearing released neurotransmitters, and providing metabolic substrates to synapses. As recently reviewed, glia should be envisaged as integral modulary elements of tripartite synapses because they are now playing an active role in synaptic transmission and are fully involved in neuron–astrocytes circuits in the processing of information in the brain. They are indispensable in obtaining nutrients from the blood and helping to maintain the blood–brain barrier. For energy metabolism, these glial cells take up glucose from the brain capillaries and transform it into lactate and other fuels absolutely necessary for the neurons to function. The metabolic coupling between glia and neurons is increasingly obvious in view of the development of the methods of investigation, even *in vivo*; astrocytes contribute to the deoxyglucose signal in PET, which may give new insights into the interpretation of this signal in neurological and psychiatric disorders. Astrocytes are necessary to avoid the excitotoxic role of glutamate through the glutamate–glutamine cycle, which is pivotal, as are probably other neurotransmitter cycles. One of the recent developments is the way in which communication can occur through glial cells by calcium waves; this seminal discovery has been followed by a wealth of work demonstrating that calcium signaling can extend even to neurons and can be bidirectional. It is possible that astrocytes may provide new means of communication in the nervous system and new pathways not yet clearly defined. No doubt, there are enormous gaps to fill in relation to their functions *in vivo*: hints have been provided, for example, by the observation that they are modulated by circadian rhythms and hormonal states.

Although myelin repair and synaptic remodeling and regeneration can occur, many enigmas still remain, especially in humans, in which the factors may be different from those in the murine species. Thus, studies in primates and *in vivo* systems cannot be omitted at this stage in view of therapeutic implications.

The dysfunction of glial cells is possibly at the origin of many of the degenerative diseases of the nervous system and the major brain tumors (glioma). Although the neuroimmunological role of astrocytes as antigen presenting cells is still unclear in the CNS under *in vivo* conditions, their role in neurodegenerative diseases seems increasingly evident because they are implicated in the suppression of oxidative stress. No doubt, in the near future, we will understand more about the cross talk between glial cells and neurons in normal and pathological states. Already, abnormal astrocytes and oligodendrocytes appear to be involved in cognitive functions as evidenced from leukodystrophies related to oligodendrocyte or astrocyte genetic disorders. Recently, the primary genetic defect of Alexander disease was demonstrated in astrocytes where mutations of GFAP lead to a secondary demyelinating disease, enlightening the pivotal role of astrocyte on oligodendrocyte and myelin maintenance.

Progress in neuroscience has shown that neurons and glia do not represent just the addition of independent compartments and that the cooperation of both cell populations is essential for development and functions of the nervous system. As mentioned by Peschanski, the time has come for "neurogliobiology" because neurons and glia (including astrocytes, oligodendrocytes, and microglia) in the nervous system are undissociable partners.

Attention

SHAUN P. VECERA and STEVEN J. LUCK
University of Iowa

GLOSSARY

attentional blink Following the identification of a target in a rapid sequential stream of stimuli, there is temporary impairment in identifying a second target stimulus that occurs shortly after the first. It is as if attention has ''blinked'' after identifying the first target, preventing subsequent target detection.

binding problem The problem of determining which elementary visual features, such as color, shape, or size, belong to the same stimulus. Spatial attention allows elementary features to be bound or grouped together.

grouped-array representation A spatial representation that contains perceptual grouping information. Image features (e.g., line segments) are grouped to form larger structures, such as surfaces or regions.

neglect (also extinction) A neuropsychological disorder of visual attention that follows damage to the posterior parietal region. Patients with neglect fail to attend to events on the side of space opposite the lesioned hemisphere. As patients recover from neglect, they demonstrate extinction, a form of transient neglect that occurs when events occur on both sides of space simultaneously.

object-centered representation A representation of an object that encodes the properties of the object, such as parts, relative to a reference point on the object itself, such as a principle axis.

visual search The process used to find a visual target (i.e., how you find what you are looking for). Both elementary visual features, such as color, shape, or size, and focal visual attention combine to guide the search for a target.

At any given moment, the sensory systems in your brain are receiving thousands of simultaneous environmental inputs. Some of these inputs are relevant to your current behavior and others are irrelevant. The visual words printed on a page are relevant to reading, but the visual impression of the desk on which the pages lie is irrelevant to reading. Furthermore, some of the inputs in one modality have correspondences with inputs in another modality, as in the link between a person's visual appearance and the speech uttered by that individual. Because we cannot process all inputs simultaneously, there must exist processes that select some inputs and filter out others. These processes collectively are referred to as ''attention.''

The study of attention has a long history in both the cognitive and brain sciences. Although early research implicitly assumed that attention is a single, monolithic process, an emerging view that we endorse is that there are multiple forms of attentional selection. Attention can select stimuli at specific locations in vision, audition, or touch; attention also can select entire objects, not just locations. Furthermore, attention selects not only stimulus inputs but also mental functions such as behavioral goals or tasks: You can attend to the task of reading instead of the task of identifying a font type. To understand attention requires studying these multiple forms of selection, their similarities and dissimilarities, and their neural foundations.

I. CONTROL OF VISUAL SPATIAL ATTENTION

A. Multiple Constraints on Selection: A Framework

Perhaps the most complete understanding of attentional selection is in the visuospatial domain, in which stimuli at specific locations are selected for processing. What are the critical parameters that determine those inputs that receive attention and those that do not? This is the question of attentional control.

There are different parameters or processes that can influence attentional control. Two general classes of control are top-down sources that arise from the current behavioral goals and bottom-up sources that arise from sensory stimuli present in a scene. These two sources can be illustrated by considering visual search, the act of looking for a visual target among distractors (e.g., finding a friend's face in a crowd). In a typical visual search task, observers are instructed to search for a particular target, such as a black vertical line, that appears in a field of distractors (Fig. 1). The target description can be conceptualized as a "template" temporarily stored in memory that can influence visual search in a top-down manner; as an observer, you would actively attempt to look at black and vertical items. The scene presented in a visual search task provides the bottom-up information that is searched; this information indicates where objects are located and which features are present at each location. Effective visual search would require finding a balance between the top-down information and the bottom-up information. An example of an effective search is searching for a single feature, such as a black vertical line among white vertical lines (Fig. 1a). In this example of a feature search, color uniquely defines the target, and the bottom-up information is consistent with the top-down information in constraining where an observer should search. A less efficient search would involve searching for a conjunction of features, such as a black vertical line among black horizontal lines and white vertical lines (Fig. 1b). In this search, any single piece of bottom-up information is not unique to the target item, so the bottom-up constraints are weaker than in the feature search. Top-down constraints would be required to resolve the competition among the input items. In general, the control of spatial attention can be viewed as a "biased competition" model: Competition among bottom-up inputs is biased (i.e., some of the inputs are favored) by top-down inputs, such as a target template.

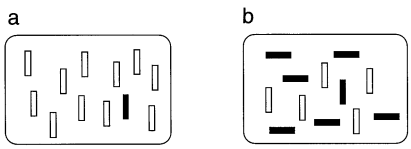

Figure 1 Sample visual search task: search for a black vertical line. (a) Feature search in which the target pops out from a homogeneous background. (b) Conjunction search in which the target does not pop out because the distractors share both black and vertical features with the target.

How is visual search controlled, particularly when search is inefficient and not determined by bottom-up information? Two possible control modes have been hypothesized for visual search. The serial search account proposes a sequential control of attention in which attention shifts from one item to the next until the target is found. The parallel search account proposes that attention is allocated to every item simultaneously, with less attention available for each item when a large number of items must be searched simultaneously. Much debate has surrounded the serial/parallel dichotomy, and current perspectives on the issue focus on the efficiency of search and not on an absolute dichotomy. Although there is evidence for a serial control process, this serial control process must be implemented in the brain's parallel hardware. Furthermore, if multiple attention systems exist, then some forms of attentional control may be more serial and others may be more parallel.

The control of spatial attention has also been examined by directing attention to a location before a target event occurs. In these "spatial precuing" tasks, observers are required to detect or identify a target item that appears at a peripheral location. Before the target appears, one location is precued by an arrow pointing to the location, a flash of light at the location, or some similar means. The subsequent target usually appears at the cued location (a "valid" trial), although it may occasionally appear at an uncued location (an "invalid" trial). Because the cue is usually valid, observers are motivated to attend to the cued location, and observers typically detect valid location targets more quickly and accurately than invalid location targets.

The type of precue used can bias attentional control to favor bottom-up factors or top-down factors. For example, if the precue is an abrupt luminance change (e.g., a flicker in the visual periphery), attention is automatically captured by the bottom-up input, irrespective of the observer's intentions. Such "exogenous" cues are extremely difficult to ignore and they

are not interfered with by concurrent tasks such as a memory task. In contrast, if the precue is a symbol such as a centrally presented arrow that points to a location, attention will move to the cued location only if the observer wants to shift attention, and when attention does move it moves more slowly. These "endogenous" cues are not automatic: They can be ignored, and they are interfered with by concurrent tasks. Because endogenous cues are dependent on task-related goals and observers' expectancies, they involve top-down control processes. In many spatial precuing tasks, the control of attention involves a balance between bottom-up and top-down factors. Although bottom-up onset cues capture attention, they may be influenced by top-down attentional control settings (e.g., expectations of where the target will appear).

B. Neuroanatomy of Control

1. Neuropsychology: Neglect and Extinction

There are undoubtedly several cortical and subcortical areas that participate in the control of spatial attention. The pulvinar nucleus of the thalamus, for example, is involved in filtering or suppressing irrelevant stimuli in a cluttered display. However, the cortical region that plays the most significant role in the control of spatial attention is the posterior parietal region. Damage to the parietal region (especially the right parietal region) in humans results in a profound attentional impairment referred to as neglect. Neuropsychological patients with neglect fail to pay attention to stimuli falling on the side of space opposite the lesion (the contralesional side). For example, a patient with damage to the right parietal lobe may fail to acknowledge a person sitting on the left, may fail to eat food on the left half of a plate, and may fail to read words on the left half of a page. Neglect occurs soon after damage to the parietal region. As a patient recovers and the neglect becomes less severe, patients can process a single stimulus presented in the contralesional visual field. These recovering patients show another disorder, however, referred to as extinction: When two stimuli are presented simultaneously in opposite visual fields, patients will extinguish, or fail to notice, the stimulus in the contralesional field. In other words, extinction patients exhibit neglect of contralesional stimuli only in the presence of ipsilateral stimuli. Both neglect and extinction appear to be disruptions of the ability to control spatial attention and deploy it to the contralesional field.

Neglect can be observed in spatial precuing tasks. In these tasks, extinction patients can detect and identify targets presented in the contralesional visual field; furthermore, these patients can use exogenous precues to allocate attention to the contralesional field prior to the appearance of the target. However, when a precue appears in the ipsilesional field and a target appears in the contralesional field, these patients are much slower to detect the target than when the contralesional field is cued and the target appears in the ipsilesional field. That is, they are impaired primarily when they are cued to the good field and then the target appears in the bad field. A straightforward interpretation of these results is that the contralesional and ipsilesional sides of space compete for attention. A bottom-up factor, such as a spatial precue, can bias the competition in favor of the cued field. The effect of parietal damage is to weaken the ability of the contralesional field to compete for attention. When both the cue and the target are in the same field, there is no competition and the target can be detected quickly. However, when the good field is cued and the target appears in the bad field, the good field wins the competition for attention even though the target is in the bad field, leading to abnormally slow responses.

What aspect of attentional control, bottom-up or top-down, is disrupted in these patients? Although parietal-damaged patients appear to have intact perceptual processing, the disorder of attention appears to involve bottom-up control parameters: Attention is not captured effectively by contralesional inputs. Furthermore, some forms of top-down attentional control appear to be intact in parietal-damaged patients. These patients can make use of top-down expectancies or task-relevant goals. For example, a contralesional stimulus may not be extinguished if the ipsilesional stimulus is irrelevant to a task and the patient is instructed to ignore this ipsilesional stimulus. Presumably, the top-down control of attention is intact in these patients and biases attention to select the relevant item in the bad field.

2. Neuroimaging Studies

Neuroimaging studies also indicate a central role for the posterior parietal lobe in spatial selection. Because the whole brain can be examined using some of these techniques, other brain regions that influence spatial attention can be observed. Observing multiple neural sites simultaneously may be useful for isolating the sources of bottom-up and top-down control.

Separate neuroanatomical sources for two forms of control is suggested by positron emission tomography (PET) studies of performance in the spatial precuing task. Observers were presented with sequences of visual targets that appeared in a predictable sequence that would engage endogenous attentional allocation. The predictable sequences were leftward or rightward appearances of the target; the target first appeared near fixation to the left or right and then continued to move in the same direction in a majority of the trials. For example, if the first target first appeared slightly to the right of fixation, the second target would likely occur to the right of the first target's position; similarly, the third target would likely occur to the right of the second target, and so forth. A predictable sequence allows observers to anticipate the next target location and endogenously allocate attention to that expected location. Thus, the peripheral targets in this task involve both exogenous and endogenous components—the appearance of the target is an exogenous luminance change and the predictable sequence allows observers to anticipate the next target and allocate attention endogenously. Two neural regions of interest exhibited increased blood flow during this task: the superior parietal lobe near the postcentral sulcus (near Brodmann's area 7) and the superior frontal cortex (near Brodmann's area 6).

To distinguish the superior parietal and superior frontal areas by their sensitivity to the exogenous and endogenous components, observers performed a control task. This control task presented the same peripheral targets in a predictive sequence, but instead of detecting these peripheral targets observers detected targets presented at fixation. Exogenous orienting would occur to the peripheral targets, even though these targets were irrelevant to the observers' task. However, endogenous attention would be directed to the central targets because these were the task-relevant stimuli. When endogenous shifts of attention were eliminated in this manner, the superior frontal areas were no longer active, but the superior parietal areas continued to be active. These results suggest that superior parietal regions are involved in the exogenous, bottom-up control of spatial attention and that superior frontal regions are involved in the endogenous, top-down control of spatial attention.

The bottom-up control of spatial attention coordinated by the superior parietal lobe appears to involve spatial selection only. If other visual attributes are selected, such as a color or a shape, the superior parietal lobe does not appear to show increased blood flow as measured by PET, although other extrastriate visual areas are activated in response to different visual attributes. For example, in searching for a target defined by color, blood flow increased in the left dorsolateral occipital lobe and in the left collateral sulcus. Searching for a target defined by movement or by shape resulted in increased blood flow in other extrastriate areas. Thus, there appears to be a large network of extrastriate visual areas that each mediate bottom-up aspects of attention to different stimulus attributes. Furthermore, PET results suggest that each of these areas could receive feedback from frontal lobe areas—areas that may represent task-relevant goals useful for allowing one stimulus attribute (e.g., color) to be selected from an image containing many attributes (e.g., color, shape, and movement).

There may exist some extrastriate visual regions that participate in attentional control across different visual attributes. Recent functional magnetic resonance imaging (MRI) results have found activation in two parietal lobe areas across three very different attention tasks: (i) a spatial shifting task similar to that described previously, (ii) an object matching task in which observers reported whether two attended objects were the same or different, and (iii) a nonspatial conjunction task in which observers searched for a target letter in a sequential stream of colored letters. These two parietal subareas seem to be involved in a wide range of visual selection, contrary to the PET results discussed previously that demonstrated no parietal involvement in visual search for targets defined by color, shape, or motion.

However, there is a resolution to the apparent discrepancy between a general attentional involvement of parietal areas and a spatial-specific role for parietal areas: Parietal lobe attention areas may control the suppression of visual distractors. Functional MRI studies that exhibit parietal activation across attention tasks required irrelevant stimuli to be ignored; PET visual search studies that did not exhibit parietal activation across tasks involved displays containing only task-relevant stimuli. In the biased competition account, parietal lobe areas may receive feedback from frontal lobe areas that allow parietal regions to suppress distractors and act as a "gate" for other extrastriate visual areas.

C. Neurophysiology of Control

As with neuroanatomical studies of attentional control, there has been a substantial amount of research

on single-neuron recordings from a range of brain areas. Those regions relevant to the biased competition framework are regions in the parietal and frontal lobes; other important areas, such as the superior colliculus or pulvinar, will not be reviewed here.

Many neurophysiological studies investigate overt spatial attention, in which the eyes overtly move to an attended location, in contrast to covert spatial attention, in which the eyes do not move. One consequence of overt shifts of spatial attention is that stimuli in a visual scene occupy different retinal locations from one eye movement to the next. Covert spatial attention appears to shift before the overt eye movement, allowing the representation of a visual scene to be updated prior to the eye movement. Neurons in the parietal lobe appear to play a role in controlling the focus of spatial attention.

Evidence for parietal lobe involvement in covert shifts of spatial attention derives from single-unit recordings from the lateral intraparietal (LIP) area in monkeys. Neurons in LIP have topographically mapped receptive fields that respond to visual stimulation (Fig. 2a). When a monkey makes an eye movement to a new location, the receptive field of a LIP neuron will also fall in a new location (Fig. 2c). Prior to the eye movement, however, a LIP neuron will respond to visual stimuli at a location based on the planned eye movement that has not been executed (Fig. 2b). That is, the receptive fields of LIP neurons are remapped in anticipation of an eye movement. This shift of the LIP representation of space may provide the neural mechanism for covert shifts of attention that precede and anticipate overt shifts involving eye movements.

The ability of LIP neurons to update their representation of space implies that this area receives inputs regarding the intended eye movement. This input likely comes from the frontal eye fields (FEFs), suggesting that updating the spatial representation is based on endogenous, top-down factors. Neurons in LIP are also able to alter their firing based on exogenous, bottom-up factors, such as the abrupt appearance of a stimulus in a LIP neuron's receptive field. The appearance of a new stimulus inside a LIP neuron's receptive field results in a large increase in the neuron's firing rate. However, if an eye movement brings a stationary stimulus into the neuron's receptive field, only a weak neural response is produced. The abrupt appearance of a stimulus is the critical parameter for evoking a large neural response: If a stimulus appears shortly before an eye movement (approximately 400 ms), there is a large neural response when the eye movement brings the new stimulus into the LIP neuron's receptive field. The "newness" or salience of the stimulus, indicated by the recency of its appearance, in part controls the response of LIP neurons and, presumably, covert spatial attention.

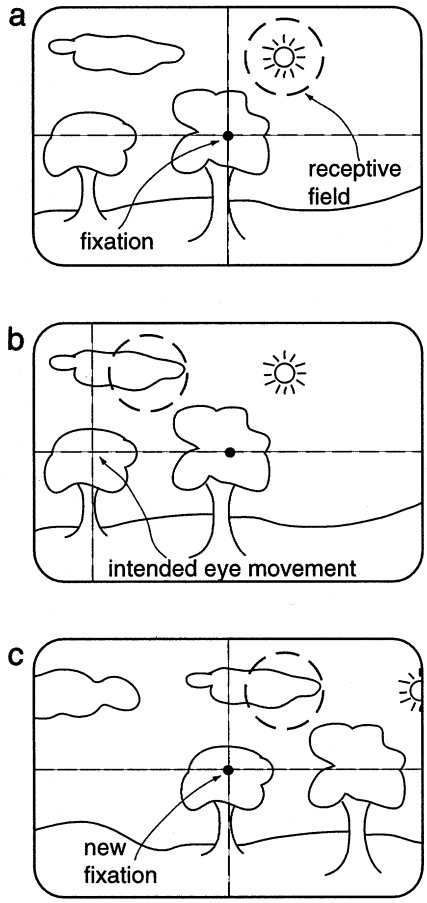

Figure 2 Remapping of receptive fields in area LIP in response to an intended eye movement. (a) The center tree is fixated, and the sun falls within an LIP receptive field. (b) An eye movement to the other tree is planned, and the LIP neuron's receptive field is remapped in accordance with the intended movement. The cloud falls within the receptive field, even though the eyes remain fixated on the center tree. (c) The eye movement is performed, allowing the second tree to be fixated.

Finally, consistent with neuroimaging data, frontal lobe areas participate in the control of attention. In visual search, the FEF is involved in selecting the target to which an eye movement will be directed. Monkeys viewed displays that contained a target that differed from a field of distractors by one feature (Fig. 1a); they were trained to make an eye movement to this target. Prior to the saccade, FEF neurons discriminated target items from distractor items. If the target fell within a FEF neuron's receptive field, the neuron

responded vigorously; if a distractor fell within the receptive field, the neuron responded weakly. Additional studies demonstrated that the enhanced firing of these FEF neurons was not in response to a bottom-up capture of attention by the odd item in the display. Other monkeys were trained to make eye movements to a target defined by color (e.g., make an eye movement to any white target). If a monkey trained to move to a white target viewed Fig. 1a, this monkey would respond by generating an eye movement to any of the white bars. Despite the presence of multiple targets in this situation, FEF neurons continue to show larger firing rates when targets fall in their receptive fields than when the single distractor falls within their receptive field.

In addition to FEF, other areas in prefrontal cortex participate in attentional selection. Many studies implicate dorsolateral prefrontal areas in selection; these studies examined search tasks in which the monkey first sees a cue object that depicts the target for which the monkey must search. Following the presentation of the cue, a display of objects appeared, and the monkey had to search for and remember the location of the target object. During the presentation of the search array, the activity of neurons in the dorsolateral prefrontal cortex was sensitive to the visual attributes of the target only; the distractors were effectively filtered out and did not influence the response of prefrontal neurons. Complementary studies have been performed in extrastriate regions such as the inferior temporal cortex with similar results. The selectivity to target attributes occurs earlier for prefrontal neurons than for inferotemporal neurons, suggesting that target selection first occurs in frontal areas and provides the top-down target template that guides selection in extrastriate areas.

II. EFFECTS OF VISUAL SPATIAL ATTENTION ON PERCEPTION

A. Types of Effects

Having previously discussed how spatial attention can be controlled to focus on an item, we now turn to the effects of attention: How is an attended stimulus processed differently from an ignored stimulus? For example, the representation of an attended item could be either enhanced or suppressed relative to distractor items. An attended item could also integrate all the visual attributes of the attended stimulus (e.g., the color, shape, and size of the stimulus).

1. Locus of Selection: Where Does Attention Have Its Effect?

Since the beginning of attention research, many studies and theories have examined whether attention operates at an early stage of processing (early selection) or at a late stage (late selection). The early selection account proposes that attention operates prior to stimulus identification. Thus, in a visual search task (Fig. 1), an item would be selected first by directing attention to its location and then fully identifying it (e.g., ''black vertical line''). The late selection account proposes that attention operates after all stimuli have been identified to some degree; in visual search, all the items would be recognized in parallel and only the target item would be selected for storage in working memory and for control over behavior.

Under a biased competition account in which multiple forms of attentional selection occur, the early versus late debate has no absolute answer; some forms of attentional selection necessarily will occur earlier or later than others, allowing for both early and late selection. The main issue then becomes determining where effects occur for a given type of attention, such as spatial attention.

Numerous behavioral studies of spatial attention have supported an account in which items are selected at an early sensory level. If a spatial precue orients spatial attention to a region of space, targets appearing at that location (validly cued targets) are detected faster and more accurately than targets appearing elsewhere (invalidly cued targets). Using a signal detection theory approach, performance in such luminance detection tasks can be traced to changes in perceptual sensitivity, independent of changes in response bias. These changes in the sensitivity of perceptual processes also have implications for the second possible effect of spatial attention—that of sensory gain control.

2. Sensory Gain Control

One hypothesized effect of spatial attention is that it may control the gain or amplification of sensory information transmission. Sensory amplification may increase the signal-to-noise ratio between attended and unattended items. As with an early locus for attentional effects, behavioral evidence supports a sensory gain control effect of spatial attention. Because spatial

precues produce a change in perceptual sensitivity, it appears that spatial attention enhances or increases the gain of target items that appear at an attended location.

3. Binding the Attributes of Objects

Another potential effect of spatial attention is that it binds together the various attributes of a stimulus. In cluttered visual scenes that contain many objects (Fig. 1b), the presence of different attributes such as color and orientation is confusing: How does a viewer know that the color "black" belongs to a vertical line when both the color black and vertical lines are present? This question illustrates the binding problem: the difficulty of knowing which attributes belong together by virtue of being aspects of a single object.

Spatial attention may provide the "glue" that binds together the attributes of objects. The probability of binding errors (misconjunctions of feature attributes) can be increased by presenting brief displays while attention is broadly distributed. In such a situation, if a display contained a blue triangle and a red square, observers may occasionally report perceiving a red triangle or a blue square. If observers focus spatial attention on a region in response to a peripheral precue, illusory conjunctions are less likely for objects that appear at the cued location than for objects that appear at an uncued location. Focused spatial attention thus appears to bind together the features of objects.

B. Neuropsychological Evidence

Results from neuropsychological patients with damage to their parietal lobes support the role of spatial attention in solving the binding problem and conjoining the features of objects. In one representative study, an extinction patient was shown two letters in either the contralesional or ipsilesional visual field. One of the letters was a target (F or X) and the other was a distractor (O). The letters were colored, and the patient was instructed to name both the color and the identity of the target letter (i.e., was it F or X and what color was it?). In this task there are two types of errors. The first is a feature error, in which either letter name or color is reported incorrectly. For example, if the patient was presented with a blue F and a red O, reporting a yellow F would be a feature error. The second type of error is a conjunction error, in which a feature of the distractor letter O "migrates" to the target letter, forming an illusory conjunction. For example, if the patient was presented a blue F and a red O and reported a red F, the color of the red O was misconjoined with the target letter F. The extinction patient studied showed many conjunction errors in the contralesional field compared to the ipsilesional field. However, similar numbers of feature errors were made in the contralesional and ipsilesional fields, indicating that feature perception was similar in both fields. Presumably, the damaged parietal-based spatial attention system is unable to permit a correct conjunction of features such as color and shape; the individual features are represented, however, allowing for accurate reports of the features.

Other patients with damage to the parietal lobe attention areas show inabilities to bind features correctly. Patients with bilateral damage to the parietal lobe have Balint's syndrome, which is characterized by an inability to perceive multiple shapes simultaneously (simultanagnosia); Balint's patients can perceive only one object at a time. Recent reports indicated that Balint's patients may show higher than normal rates of illusory conjunctions. If shown a display containing a red X and a blue T and asked to report the name and color of the first letter seen, these patients may often report seeing a blue X and a red T. These misconjunctions even occur when the display is present for several seconds.

C. Physiological Evidence

Neurophysiological and electrophysiological studies have overwhelmingly supported the early locus of selection and sensory gain effects of spatial attention. An early locus for spatial attention has been demonstrated with event-related potential (ERP) studies in which the electroencephalogram is time locked to the appearance of a visual stimulus. The experimental paradigm used most often in these studies is illustrated in Fig. 3a. At the beginning of each trial block, observers are instructed to attend to either the left or the right visual field while maintaining fixation at the center of the screen. Stimuli are then presented rapidly and sequentially to the left and right visual fields, and observers are required to respond when they detect an infrequently occurring target stimulus in the attended field. By maintaining the same sequence of stimuli from trial block to trial block and varying whether the left or right field is attended, it is possible to compare

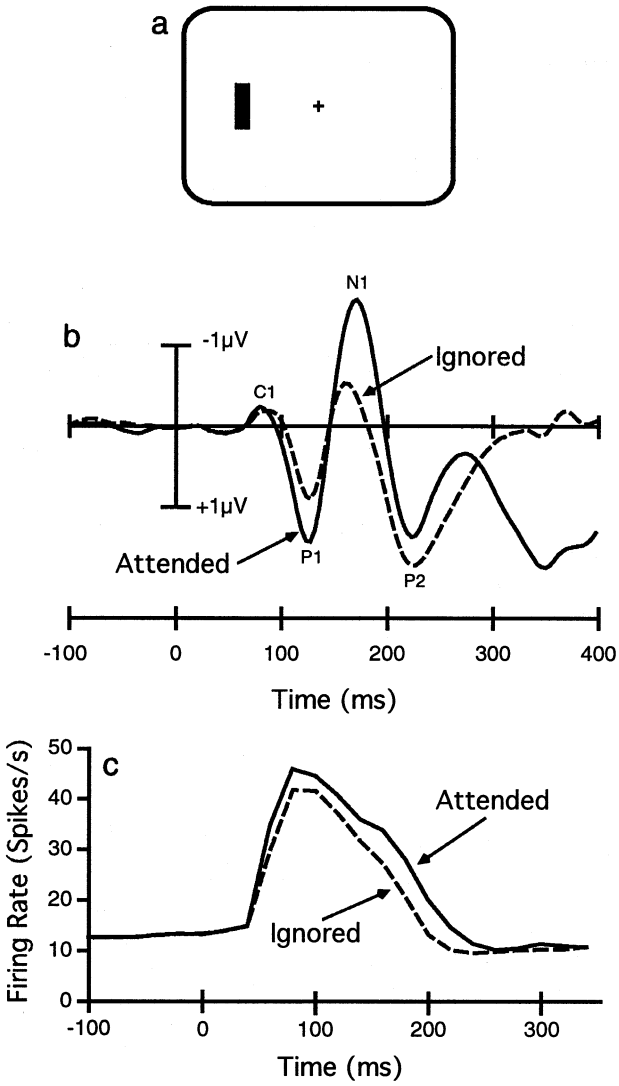

Figure 3 ERP and neurophysiological results from a spatial attention. (a) Observers attend to the left or right side of space, and targets appear at either the attended or ignored location. (b) ERP results show larger P1 and N1 components when targets appear at the attended location than at the ignored location. (c) Neurophysiological results from a representative neuron in area V4. When a target falls within the neuron's receptive field, the neuron fires more vigorously when the target's location is attended than when it is ignored.

the response to the same physical stimulus when it is presented at an attended versus an ignored location.

As shown in Fig. 3b, the ERP waveform recorded over occipital scalp sites in this paradigm consists of a series of positive and negative peaks or components. The earliest component, which is called the "C1 wave" and is observed only under certain conditions, is typically unaffected by attention. Although it is usually difficult to determine the neuroanatomical site at which an ERP component is generated, it is known that the C1 wave is generated in primary visual cortex (area V1), and the finding that the C1 wave is unaffected by spatial attention indicates that the initial volley of V1 activity is not influenced by attention (although V1 activity appears to be modulated by attention at later time points, presumably due to feedback).

The C1 wave is followed by the P1 and N1 waves, both of which are typically larger in amplitude for attended location stimuli than for unattended location stimuli. The P1 effect typically begins before 100 msec poststimulus and combined PET/ERP studies have indicated that it is probably generated in the ventral extrastriate cortex. Moreover, this effect is present for target stimuli, nontarget stimuli, and completely task-irrelevant probe stimuli. Together, these factors indicate that the P1 modulation reflects an effect of attention on sensory processing, supporting early selection models of visual–spatial attention. The N1 effect appears to reflect a modulation of visual discrimination processes, although the precise nature of this effect and its neural origins are not clear.

This paradigm has also been modified for use with single-neuron recordings in monkeys, and a similar pattern of results was obtained (Fig. 3c). Attention had no effect on responses in area V1, but in area V4 (an intermediate visual processing region) attended location stimuli evoked higher rates of neural firing than did ignored location stimuli. Moreover, the effect of attention began at 60 msec poststimulus, which was the same time as the onset of stimulus-related activity in these neurons. However, spatial attention produces no changes in the tuning curves of the neurons. Thus, under certain conditions, attention acts as a preset filter that controls the amplitude of the sensory response in intermediate-level areas of visual cortex.

III. ATTENTION TO OBJECTS

A. Demonstrations of Object-Based Attention

In addition to selecting regions of space, recent research has demonstrated that objects can be attended and selected independently of their locations. Although some investigators have argued that attention is object-based instead of space-based, the emerging consensus is that space-based and object-based attentional systems coexist. A more subtle issue,

however, is whether the objects selected by attention are low-level retinotopically defined regions formed by gestalt grouping processes or higher level invariant objects formed by object representation processes. Again, the emerging consensus is that both types of object selection may exist.

1. Grouped Array Selection

One mechanism for object-based attention involves attending to perceptual objects that are defined in a spatial reference frame—a "grouped array." The grouped array is a spatiotopic map in which locations or features are grouped according to gestalt principles such as similarity (e.g., features similar in color group with one another), closure (e.g., features that form closed shapes group with one another), or figure-ground relations (e.g., figures are closer to the viewer and are more salient than grounds). Selection from a grouped array representation involves attending to the locations of items that are grouped together.

Results from several behavioral studies are consistent with grouped array selection. Two strategies have been used to study this form of object selection. One strategy is to manipulate whether stimulus objects, such as letters, are grouped together based on secondary features, such as a common color or direction of motion. For example, if observers are asked to attend and categorize a target letter presented at fixation, their responses are influenced by adjacent flanking letters. Flanking letters that are consistent with the response to the target decrease observers' response times, and flanking letters that are inconsistent with the response to the target letter increase response times. The effect of flankers depends on object grouping factors: Flankers that group with the target letter influence responses more strongly than flankers that do not group with the target (Fig. 4). Presumably, the gestalt grouping principles define a set of letters as a related group, and this group is attended as a single unit. The flankers within this single perceptual group then decrease or increase response times to the target letter. Grouping effects on targets and flankers have been reported with several gestalt principles, including similarity, common fate, connectedness, and good continuation.

A second strategy for studying object-based attention is to manipulate whether two attended features fall on the same object or on different objects or, alternatively, whether attention shifts within an object or across objects. One widely used paradigm is illustrated in Fig. 5. In this paradigm, observers view

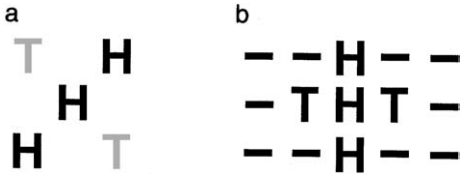

Figure 4 Displays used to study the influence of gestalt organization on visual attention. Observers report whether the central letter is an H or a T. (a) Grouping via similarity; the nontarget Hs group with the target H. Because the flankers that group with the target are compatible with one another, observers would classify the target letter quickly. (b) Grouping via good continuation; the nontarget Ts group with the target H. Because the grouped flankers are incompatible with the target H, observers would classify the target letter slowly.

two rectangles oriented either horizontally or vertically. One end of one of the rectangles is precued with a brief flash, and this precue is followed by a target that requires a keypress response. The target usually appears at the cued location; when it appears at an uncued location, it may appear within the same object as the cued location or in the other object. Both of these uncued locations are the same spatial distance from the

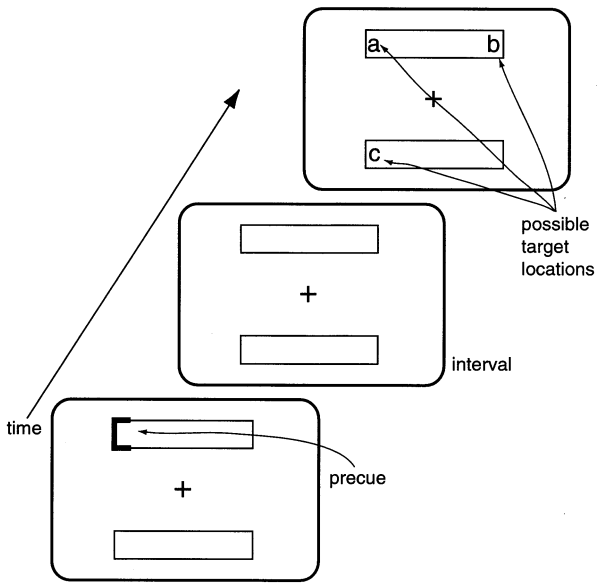

Figure 5 Spatial precuing task used to study object-based attention. Two rectangles appear, and the end of one is precued with a peripheral flash. After a delay, a target appears at one of three locations: a, a validly cued target; b, an invalidly cued target that appears in the cued object; c, an invalidly cued object that appears in the uncued object. Observers more quickly detect invalidly cued targets appearing in the cued rectangle faster than those appearing in the uncued rectangle.

precued region and the target is equally unlikely to appear at either of them, but observers are faster to respond to targets appearing in the uncued end of the cued rectangle than in either end of the uncued rectangle. Thus, attention appears to cover the entire cued rectangle even though only one end was cued. Similar results have been obtained with tasks that do not require spatial precues. In displays containing two rectangles that are overlapped to form an "X," observers are faster to discriminate features on the same rectangle than on different rectangles even though the spatial distances are similar.

Note that spatial location is centrally important in selection from a grouped array because this representation is spatiotopic. A handful of studies have demonstrated the importance of location by manipulating both grouping principles and spatial position. These studies have demonstrated that both grouping principles and spatial position influence attentional selection. In the cued detection task depicted in Fig. 5, moving the rectangles closer to one another reduces the cost of switching attention from the cued rectangle to the uncued rectangle, although attention continues to shift faster within an object than between objects. On the basis of such results, it may be possible to explain many demonstrations of "object-based attention" as occurring within a spatially formatted representation.

2. Object-Centered Selection

A second mechanism for object-based attention involves attending to objects that are defined in an object-centered reference frame, which represents the parts and features of an object in relation to a reference point on the object. Coding parts and features in reference to the object allows the relative positions of the parts and features to be constant as the object changes spatial position and retinal size. A person's head is above the torso irrespective of where the person appears (e.g., left or right visual field) or how distant the person is from the viewer.

Because an object-centered reference frame is relatively insensitive to spatial position, spatial manipulations should not influence this form of object-based selection. There is evidence for selection from a late, object-centered representation from a discrimination task that requires observers to focus attention on a single object or divide attention between two objects —a box and a line (Fig. 6). Observers report the values of two features, such as whether a gap is on the left or right side of a box. Sometimes, the two features are located on the same object (both features on the box) and sometimes on different objects (one feature on the box and one on the line). Performance is object-based in this task because features on the same object are reported more accurately than are features on different objects. However, unlike grouped array selection, performance in this task is not influenced by the spatial distance between the box and line, suggesting the objects are selected and not the locations occupied by the objects.

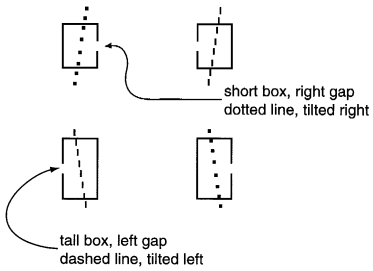

Figure 6 Object stimuli used to study object-based attention. Observers are more accurate in reporting attributes from the same object (e.g., box height and side of gap) than attributes from different objects (e.g., box height and tilt of line).

B. Neuropsychology of Object-Based Attention

1. Object-Centered Neglect

As with most neuropsychological studies of spatial attention, investigations of object-based selection have focused on patients with neglect following damage to the parietal lobe areas. Two key findings from neglect patients have implications for the neural basis of object selection. The first finding is that some of these patients exhibit object-centered neglect. The second finding is a hemispheric difference between object and spatial attention in patients with neglect.

Some patients with right parietal lobe damage (left neglect) neglect not only the left side of space but also the left side of an object, even when that object is located in the good (ipsilesional) visual field. Left neglect of objects can be observed when patients are asked to compare two novel objects and determine if they are the same or different. If the two objects are identical on their right sides but different on their left sides, neglect patients will incorrectly report that the objects are the same. Neglect patients continue to show this error when both objects are rotated 45° clockwise

to place the differing feature in the good right visual field. If neglect occurred for spatial coordinates only, rotating part of the objects into the nonneglected visual field should have allowed the patients to notice the difference between the two objects. Because the neglected region of the object follows the object as it is rotated, the neglect must be defined relative to a reference point on the object, such as the object's principal axis (i.e., midline).

Although object-centered neglect has been the focus of many recent studies, these effects are not present in all neglect patients, which raises two points. First, failure to find object-centered neglect in some patients may occur because visual neglect is not a unitary disorder. Second, and more interesting, object-centered neglect may be unobservable because of the stimulus objects used. Objects that do not posses a strong principal axis or do not have well-defined left and right sides (a "canonical handedness") may not have a single object-centered reference point, which could prevent object-centered neglect. For example, a symmetric letter such as "A", does not have a canonical handedness because the left and right sides are identical; there is no need for the visual system to represent the sides of a symmetric letter differently. Asymmetric letters (e.g., "F") have a canonical handedness, and the visual system must represent the differences between the two sides. Accordingly, object-centered neglect is less likely for symmetric letters than for asymmetric letters, suggesting that the object's handedness may influence the allocation of visual attention.

Finally, what type of object representation is involved in object-centered neglect—a grouped array or an object-centered representation? As noted previously, the common assumption is that object-centered neglect occurs within an object-centered reference frame. However, recent simulation results from connectionist models demonstrate that object-centered neglect could arise from a spatiotopic grouped array representation. These simulations indicate that perceptually organized input to a damaged attentional system may be sufficient to demonstrate object neglect; no object-centered coordinates, principle axis, or canonical handedness need to be computed to explain the findings from neglect patients.

2. Lateralization of Object and Spatial Attention

The second finding from neglect patients relevant to object attention is an apparent hemispheric difference between object-based attention and spatially based attention. Patients with damage to the right parietal lobe most often present with hemispatial neglect in which the left side of space is ignored. (Patients who demonstrate object-centered neglect also exhibit spatial neglect.) Left neglect can also be demonstrated in these patients by using object-based attention tasks. For example, in the task shown in Fig. 5, left neglect patients are slower to detect targets in the contralesional visual field than in the ipsilesional visual field. However, left neglect patients show preserved object-based attention: They detect targets in the cued rectangle faster than targets in the uncued rectangle, and this object-based effect is found in both the contralesional and ipsilesional visual fields. In contrast to patients with left neglect, patients with damage to the left parietal lobe (right neglect) appear to have deficits in object-based attention. Right neglect patients also show slower target detection in the contralesional visual field than in the ipsilesional field. However, these patients exhibit larger object attention effects in the contralesional field; it is more difficult for these patients to switch attention from the cued rectangle to the uncued rectangle in the contralesional field than in the ipsilesional field. These hemispheric differences between object-based and spatially based attention have been supported by research with a split-brain patient. In performing the cued detection task shown in Fig. 5, this patient had greater difficulty switching attention from the cued rectangle to the uncued rectangle when stimuli were presented in the right visual field (left hemisphere) than when stimuli were presented in the left visual field (right hemisphere).

3. Other Patient Groups

Finally, a few patient groups besides neglect patients have been studied to understand object-based attention. For example, studies with a visual form agnosic reported impaired object-based attention but intact spatial attention following diffuse damage to the occipital cortices. Patients with visual form agnosia fail to perceive objects because of damaged early level visual areas. Although these patients have intact sensory processes (e.g., acuity and color perception), they are unable to organize visual features using the gestalt principles. The damage to perceptual organization processes impairs the ability to form perceptual groups, which prevents any object-based component of visual selection. Despite having impaired object-based attention, spatial selection appears to be intact following diffuse occipital damage, suggesting that

object grouping processes appear to be dissociable from spatial selection processes. Thus, the parietal lobe attention system is not the only cortical system involved in mediating object selection.

C. Physiology of Object-Based Attention

In addition to the focus on parietal lobe involvement in neuropsychological studies of object selection, physiological studies have implicated other cortical areas in object attention. Multineuron recordings from macaque primary visual cortex (area V1) have implicated this area in object-based attention. Specifically, attending to one of two objects in a display results in enhanced firing for neurons whose receptive fields contain features of the attended object. Monkeys viewed scenes containing two objects (simple curves); one of the objects was connected to the fixation point, and monkeys were trained to attend to this object. The monkeys' task was to make an eye movement from the fixation point to the opposite end of the attended curve. Segments of the curves fell within receptive fields of V1 neurons. The neuronal responses were larger when a receptive field contained a segment of the attended curve than a segment of the unattended curve. This object-based attentional modulation in area V1 is important because previous studies of spatial attention were equivocal in finding V1 attentional modulation. Neurons in V1 exhibit attentional modulation when an object can act as the recipient or focus of attention; neurons in V1 do not appear to exhibit attentional modulation with blank displays or nonorganized cluttered displays. These neurophysiological findings are consistent with results from visual form agnosia, in which diffuse damage to early cortical visual areas (possibly V1) impaired object-based attention. Thus, there is growing evidence to support a central role for early cortical areas in perceptual organization and object attention.

Neurophysiological results have also suggested that object selection can occur in the oculomotor system as well as in purely sensory areas. Neurons in the supplementary eye field (SEF), located on the dorsomedial surface of the frontal lobes, appear to represent object-centered spatial selectivity for the direction of eye movements. That is, these neurons seem to code for spatial positions within an object, such as the left side of the object. Macaque monkeys were trained to make eye movements to the onset of a target spot. The target appeared in one of three conditions: alone in an otherwise blank display, at the left end of an object (a rectangle), or at the right end of an object. The absolute direction of the eye movement was identical in all three conditions; that is, the monkeys' eyes moved in exactly the same direction and same distance across these conditions. Although the eyes moved identically, a subset of SEF neurons fired at higher rates when eye movements were executed to a specific region of the object, regardless of its absolute spatial location. For example, some neurons responded vigorously to eye movements to the right side of the object; the same eye movement that landed on the left side of the object resulted in a smaller neuronal response. Thus, SEF neurons code for locations within an object; how these locations are coded—in a spatial reference frame such as the grouped array or in an object-centered coordinate frame—is unknown.

Finally, ERP studies with humans have investigated object-based selection. When viewing displays containing two superimposed surfaces (two transparent surfaces of different colored dots that rotate in opposite directions), observers can selectively attend to one of the two surfaces despite their spatial superimposition. If observers are instructed to attend to one of the surfaces, changes to the attended surface will produce evoked potential components with larger amplitudes than stimuli presented on the unattended surface. Specifically, changes on the attended surface generate larger P1 and N1 components compared to changes on the unattended surface. The similarity of these effects to the spatial attention effects described previously suggests that some object-based effects may be generated by neural processes shared with spatial attention. Attentional selection may be occurring from a grouped array in which motion segregation cues allow the two dot surfaces to be separated from one another in depth.

IV. ATTENTION TO OTHER MODALITIES

A. Selection beyond Vision

Beyond locations and objects in the visual modality, stimuli from other modalities can be selectively attended. This observation is evident from studies of selective attention in the 1950s and 1960s in which listeners attended one of two different speech signals arriving simultaneously in each ear. To determine how effectively attention could be restricted to one signal,

listeners were required to repeat (''shadow'') the speech in the attended channel. This shadowing procedure was the main behavioral technique for studying selective attention for decades. Studies of auditory attention supported early selection of stimuli; words spoken into the unattended ear are effectively filtered out. For example, if listeners are instructed to tap a key when they hear the word ''tap,'' they almost always tap when the word is presented to the attended ear and almost never tap when the word is presented to the unattended ear. Words presented to the unattended ear are filtered at an early level of processing prior to word identification; if filtering occurred later, after word identification, listeners should have tapped when the word tap was spoken in the unattended ear. However, the early attentional filter appears to be leaky in that salient material on the unattended channel, such as the listener's name, can deter attention from the attended channel.

An early locus for auditory selective attention has been confirmed with ERP studies. The general procedure is similar to that used to study spatial attention (described previously). Listeners hear a sequence of auditory tone pips, half presented to the left ear and half to the right ear. Listeners pay attention to the tones in one ear and press a button whenever an infrequent target tone is presented to the attended ear. Many studies using this procedure have found that the early ERP waves are larger for tones presented in the attended ear than in the ignored ear, consistent with a sensory gain effect of auditory attention. This enhancement of the voltage amplitude occurs temporally early, with the effect beginning as early as 20 msec after stimulus onset, well within the period of sensory-level processing. Moreover, the attentional enhancement was present for both targets and nontargets presented in the attended ear, indicating that selection occurred before the stimuli were identified. In addition, magnetoencephalographic studies have shown that these effects arise in or near primary auditory cortex. The results from auditory attention experiments are similar with results from visual attention experiments in suggesting an early selection account of attention in both modalities.

B. Cross-Modal Coordination of Attention

The existence of attentional selection in different modalities raises a basic question: Is there a single, supramodal attentional system that mediates selection across multiple modalities, or are there individual attentional systems for each modality that have some degree of cross talk with one another? Results from neuropsychological patients with neglect support a supramodal view of attention. Neglect patients have difficulty attending to both visual and auditory stimuli opposite the lesioned hemisphere, suggesting that parietal lobe attentional processes operate on a representation of space that codes both visual and auditory stimuli. Similar results have been reported from multimodal versions of the spatial precuing task. In the multimodal version of this task, neglect patients are asked to detect a lateralized visual stimulus. This visual target is preceded by a lateralized precue presented in either the visual or the auditory modality. Neglect patients show similar orienting behavior to both types of precues; specifically, neglect patients have difficulty disengaging attention from precues presented on the good (ipsilesional) side of peripheral space irrespective of the cue's modality. These results support a supramodal representation for parietal lobe attentional processes.

Further strengthening the supramodal view of attention, neglect patients also fail to attend to somatosensory stimuli presented on the bad (contralesional) side of peripheral space. However, somatosensory neglect could be explained by contralesional sensory deficits that accompany brain damage; inputs from the contralesional side of the body may be weaker than inputs from the ipsilesional side of the body. A convincing demonstration of somatosensory neglect was provided by testing neglect patients' ipsilesional hands, which have no sensory loss. The patients were touched simultaneously on the left and right sides of their right wrist and asked to report where they were touched. There were two key findings. First, left neglect patients failed to notice being touched on the left side of their right wrists, demonstrating that somatosensory neglect can occur in the absence of sensory deficits. Second, the attentional impairment for detecting contralesional touches occurred whether patients' hands were facing with the palm downward or facing with the palm upward. The neglect did not follow the rotation of the hands but instead remained fixed on the left side of the wrist. These results indicate that the attentional deficit did not occur in somatosensory coordinates, such as always neglecting the thumb side of the wrist or always neglecting the left side of the body. Instead, neglect occurred in abstract spatial coordinates that represent the left and right sides of a limb independent of that limb's orientation. This ''limb-centered'' somatosensory neglect bears a

striking similarity to the object-centered neglect observed in the visual modality: The neglected region is not necessarily defined by the patients' midline but by the midline of a stimulus (an object or a limb).

Finally, both behavioral and ERP studies with neurologically normal observers have extended the operation of selective attention across different modalities. There appear to be strong cross-modal links in spatial attention that allow observers to spatially attend a region and select stimuli occurring in different modalities. In behavioral studies, observers visually cued to one side of space detect more quickly both visual and auditory targets on the cued side of space than on the uncued side of space; this cued location advantage occurs when the modality of the target is unpredictable. Thus, spatial attention appears to operate across modalities. Behavioral studies have also attempted to decouple attentional shifts across modalities by varying the occurrences of auditory or visual targets. Can auditory spatial attention be allocated to a different region than visual spatial attention if an auditory target is expected at one location and a visual target is expected at another location? The answer to this question seems to be "no." If observers voluntarily shift auditory spatial attention to one region to detect a highly probable auditory target, visual spatial attention seems to follow. The same result holds for shifts of visual spatial attention; auditory attention will follow visual attention when visual attention is voluntarily shifted to a region to detect a highly probable visual target. ERP studies have reported similar results. For example, if observers are required to monitor a location for an infrequently occurring visual target, larger evoked responses are generated by both visual and auditory nontarget stimuli at the attended location than at the unattended location.

One caveat from the cross-modal studies of attention is that although visual and auditory attention appear to operate in concert, the effects across modalities are not equivalent to effects within a single modality. Larger attentional effects are found when the cue and target appear in the same modality than in different modalities. Such an observation cannot be explained with a strong supramodal account of spatial attention. The strong supramodal account would predict that each sensory modality could cause an equivalent shift of spatial attention, which would provide enhanced processing at the attended location across all modalities. However, cross-modal studies cannot distinguish between linked unimodal attention systems and a supramodal system that receives differentially weighted inputs from each modality. Furthermore, a supramodal system may be an emergent property of the connections that link modality-specific attentional systems. Consistent with the multiple attentional systems in the visual modality, there are likely to be both unimodal and supramodal attentional mechanisms for the coordination of attention across sensory modalities.

V. ATTENTION TO TASKS

A. Performing Multiple Tasks Simultaneously

In addition to coordinating the processing of sensory stimuli, attention must participate in the coordination of tasks. There are many situations in which humans must perform multiple tasks concurrently, as such having a conversation while driving. Performance is impaired when multiple tasks are performed concurrently, even when the tasks are highly practiced, as with driving and speaking. Attentional processes may be involved in selecting an individual task for current behavior, with a cost in performance occurring when attention is either divided or switched between multiple tasks.

The biased competition model we used to describe spatial attention can also be applied to performing multiple tasks such as the Stroop task, in which different tasks must be performed in different blocks of trials. In the Stroop task, observers view words that name colors (e.g., "red" or "blue") presented in different colors of ink. The words can be written in a compatible ink color ("red" written in red ink) or in incompatible colors ("red" written in blue ink). Observers perform one of two tasks—either reading the word or naming the ink color. Because word reading is more practiced than ink color naming, observers can read words with little effect of the ink color; observers can just as quickly read color words printed in a compatible ink color as color words printed in an incompatible ink color. In contrast, color naming is highly influenced by the word; observers are slower to name ink colors used to print an incompatible word ("red" printed in blue ink) than ink colors used to print a compatible word ("red" printed in red ink). In the Stroop task, the top-down task demands (i.e., the task observers are asked to perform) and the bottom-up stimulus features (the word and ink color) both guide behavior. The color naming task is difficult because the bottom-up inputs are stronger for words

than for ink colors. Thus, there is a stronger bias for word reading than for color naming, allowing the word reading task to compete more effectively for the control of behavior.

One difficulty in using the Stroop task to study attention to tasks is that one of the tasks, word reading, is much easier than the other. An attentional phenomenon that demonstrates competition between two equally difficult tasks is the "attentional blink." In the attentional blink task, observers view a stream of approximately 20 stimuli presented one at a time at a rate of about 10 stimuli per second; observers are asked to detect two targets from this stream. For example, the first target (T1) may be a number that observers must classify as even or odd, and the second target (T2) could be a letter that observers must classify as a consonant or vowel. Observers make both responses at the end of the stimulus stream. Observers often fail to identify T2 if it appears shortly after T1; if T2 appears somewhat later, observers more accurately report its identity. The temporary impairment in identifying T2 is referred to as the attentional blink because it is similar to the consequence of a T1-triggered eyeblink (i.e., a brief period during which subsequent targets cannot be detected).

The attentional blink does not appear to be caused by sensory-level interference between the two targets. Instead, the failure in reporting T2 is more central, resulting from a failure to store T2 in a durable form that can be reported at the end of the stimulus stream. In terms of a biased competition account, top-down task constraints related to the T1 task may bias this item to be coded into working memory. After T1 begins to be encoded into working memory, the task bias can begin to switch to the T2 task, but this reconfiguration takes time. Thus, if T2 appears soon after T1, it may not be efficiently encoded into working memory and may be overwritten by the next item in the input sequence. At the end of the stimulus sequence, reporting T2 is difficult because of this shallow encoding into working memory—T2 is identified but not reported, suggesting that selection may operate relatively late in the visual processing stream (i.e., after stimulus identification).

B. Neural Mechanisms

1. Attentional Blink and Neglect

As with almost every other type of attentional selection, the attentional blink appears to involve the parietal lobe attention system. Patients with damage to the right parietal lobe show a prolonged attentional blink. Compared to normal observers, these patients need longer intervals between T1 and T2 or T2 will be missed. This suggests that neglect is not only a disorder of visuospatial attention but also reflects more general attentional processes. Thus, the parietal lobe attention system may involve several types of attentional "gating," ranging from sensory gating to task gating, which allows the parietal lobes to participate in both early (sensory) selection and late (task) selection.

2. Human Electrophysiology of the Attentional Blink

Perhaps more than any other methodology, ERP studies of the attentional blink have elucidated the mechanisms of this form of selection. Recent ERP studies have demonstrated that the attentional blink occurs late in visual processing, after stimulus identification, consistent with the view that failure to recognize T2 is due to poor encoding of this item into working memory.

To determine if the attentional blink involves sensory-level attention processes, early ERP components were studied. Observers participated in a standard attentional blink task, but a task-irrelevant probe was presented simultaneously with T2. This irrelevant probe, a flashed visual stimulus, elicited the P1 and N1 components that are involved in spatial selection. If the attentional blink is due to suppressed sensory processing, P1 and N1 components should also be suppressed for irrelevant probes presented during the window of the attentional blink. However, no suppression of the P1 and N1 waves was observed, even though behavioral performance exhibited a strong attentional blink. There was no evidence for sensory suppression during the attentional blink period, indicating that the mechanisms of spatial attention are different from the mechanisms of the attentional blink.

Although early sensory processes measured by P1 and N1 are not responsible for the attentional blink, later perceptual processes may be. An additional experiment addressed whether the T2 item was recognized completely; complete recognition of the T2 item would indicate that the attentional blink was not due to any form of perceptual suppression, early or late. This study investigated the N400 ERP component. The N400 is typically elicited by words that mismatch a previously established semantic context. For example, an N400 would be generated by the last word in the sentence "The man drank his coffee with cream and

dog'' because ''dog'' is inconsistent with the semantic meaning of the sentence. If an N400 is elicited by a word, then the word must have been identified; otherwise, a semantic comparison with the context would have been impossible.

In the N400 attentional blink study, the T2 stimulus was a word. Each trial began with a semantic context word, and the T2 word was either semantically related or unrelated to this semantic context word. When the T2 word semantically mismatched the context word, an N400 component was produced, even if the T2 word occurred during the window of the attentional blink such that observers could not report the word. This result indicates that the T2 word was identified during the attentional blink window, and the failure of observers to correctly report the word reflects a failure to store the word in working memory. Thus, the attentional blink occurs after identification, consistent with a late-selection account of attention.

VI. SUMMARY

Attention is necessary for eliminating sensory inputs or behavioral tasks that are irrelevant at a specified time. Although there may be multiple forms of attention, some neural sites, such as the parietal lobe, are involved in many aspects of attention. The control and effects of these multiple forms of selection are quite varied, however. The integration of top-down behavioral tasks or goals and bottom-up stimulus factors may allow the attentional system to be highly flexible and allow a small subset of components to have varied effects.

Auditory Agnosia

HENRY A. BUCHTEL
University of Michigan and VA Healthcare System, Ann Arbor

GLOSSARY

apperceptive agnosia Disturbance of the basic analysis and elaboration of sound energy arriving at the ear and up through sensory pathways.

associative agnosia Loss of the ability to link a stimulus to meaningful associations (meaning).

audiogram A graphical representation of a person's ability to hear sounds of different frequencies.

pure word deafness A form of auditory agnosia in which the disorder is limited to the understanding of spoken language.

Auditory agnosia refers to the loss of the normal ability to derive the meaning from an auditory stimulus. Careful testing is needed before the cause of the agnosia can be determined.

I. OVERVIEW

Auditory agnosia is a rare condition in which the individual has an isolated deficiency in comprehending sounds despite a normal or nearly normal audiogram. The patient is usually unable to recognize both spoken words and environmental sounds. If only the comprehension of spoken language is affected, the disorder is called *verbal auditory agnosia* or *pure word deafness*. If only environmental sounds are affected, the person is said to have *nonverbal auditory agnosia*. Typically, these patients are able to read, write, converse intelligently, and name objects. They can also use prosodic information (e.g., the melody or intonation in a speaker's voice) to identify emotional content and even syntax (e.g., that a person has asked a question rather than having made a statement).

II. VARIETIES OF AUDITORY AGNOSIA

There are two major classes of auditory agnosia. If the disorder affects only the comprehension of spoken language, it is called *pure word deafness*. If the person has difficulty only with environmental sounds, the condition is called nonverbal auditory agnosia.

III. APPERCEPTIVE DEFICITS

If the person with auditory agnosia is unable to extract meaning from a stimulus because the initial analysis (perception) of the stimulus is flawed, then the higher cognitive mechanisms that would ordinarily assign meaning will not have sufficient information to perform adequately. Thus, central mechanisms for extracting meaning could be intact but unable to carry out their functions because the information that they receive is defective. An analogy might be a noisy telephone line. A person trying to understand speech coming over the line would not have a sufficiently clear signal to allow the information transfer to occur.

IV. ASSOCIATIVE DEFICITS

If the initial analysis of the stimulus appears to have been carried out normally and the person is still unable to extract meaning, then it is likely that the person is suffering from an associative disorder. What is lacking is a link between the information and stored knowledge concerning its meaning. The patient's perceptual experience might be similar to that of a person who had previously known a foreign language well but who has now forgotten the meaning of a particular word. Such a person would be able to hear the word clearly and may even recognize that it represented a meaningful collection of sounds, but its meaning would be lost to the listener.

V. NEUROLOGICAL SUBSTRATE OF THE DISORDER

The damage responsible for these disorders is usually caused by cerebrovascular disease, usually embolic stroke, that involves the midportion of the first temporal gyrus bilaterally (at least one case has been reportedly caused by a hemorrhage in an auditory structure in the brain stem, the inferior colliculi). If caused by unilateral damage, the lesion is usually deep in the posterior temporal lobe of the hemisphere dominant for speech (usually the left hemisphere). In such cases, there may be signs that any residual abilities that are present depend on right hemispheric linguistic abilities. For example, the person may report hearing a word that is semantically related to the actual word spoken (''horse'' for ''pony''). Some authors have suggested that damage to the primary auditory cortex produces pure word deafness (agnosia for spoken language only), whereas damage to the auditory association cortex produces difficulties with nonspeech sounds. Damage to both regions would produce global auditory agnosia. The pattern of disabilities in auditory agnosia differs from that of the more common Wernicke aphasia in that the receptive language disturbance is limited to the auditory domain while the patient's spoken language is relatively good. In early accounts of the syndrome, a normal audiogram led to the assumption that basic auditory analyses (apperception) were normal and that the disorder arose because of an inability to link the sound to its meaning (association). This interpretation can still be found in current texts and the syndrome is frequently attributed to a disconnection of auditory cortex from Wernicke's area, with the possible implication that both are capable of normal functioning.

VI. BEHAVIORAL ASPECTS OF AUDITORY AGNOSIA

Although apperceptive functions are usually assumed to be normal in individuals with auditory agnosia, behavioral evidence has been accumulating that the audiogram in patients with auditory agnosia is not an adequate measure of their ability to analyze the kinds of sounds critical for speech. With more sophisticated auditory tests, several abnormalities have emerged. For instance, many such patients have difficulty determining the temporal order of sounds and they may require a greater than normal sound intensity to make very brief sounds audible. Some but not all patients also have difficulty discriminating the loudness of stimuli and their location in space. Disturbances of temporal resolution (order of sounds) and two-click discrimination have also been described. To illustrate some of these associated hearing deficits, the following case is one that might previously have been judged to exemplify an associative auditory agnosia.

A. Case LD

At the age of 49 years, this individual suffered a cerebral stroke in the distribution of the left middle cerebral artery. His right leg and arm were partially paralyzed and his speech was moderately disturbed. The right-sided weakness resolved within several days but the speech deficits slowly resolved over the next year, at which time his naming and ability to understand spoken and written words were normal and he returned to work. About 6 months later, he suffered a second stroke, this time in the right cerebral hemisphere. This stroke evolved over the next 48 hr. Initially, he was globally aphasic and could neither understand commands nor repeat simple sentences. Spontaneous speech was occasionally clear but interspersed with jargon. The motor system appeared to be relatively unaffected apart from an extensor left plantar response, but over the next 24 hr a dense left-sided hemiparesis developed, which resolved by 48 hr. His language disturbances persisted. A computerized tomography scan 3 months later indicated that the infarction had been in the right posterior temporal region. When examined 6 months after the second stroke, the only remaining physical abnormalities were a mild left lower facial weakness, mild left hyperreflexia, and extinction of pin prick in the right face, arm,

and leg with bilateral simultaneous stimulation. Neuropsychological testing at this time demonstrated that his IQ was in the average range. His spoken language was generally correct in content but had a loud, explosive quality. Despite a relatively normal audiogram, he was severely deficient in understanding spoken language and environmental sounds. In fact, in the absence of contextual cues he was never observed to understand a single spoken word. He was also unable to repeat words, letters, numbers, phonemes, or nonsense sounds. He did only slightly better than chance at determining whether two letters spoken successively were the same or different. In contrast, he was able to point correctly to a picture in an array when a word for one of the pictures was spoken. If he heard the name of the object, he pointed correctly to its picture and said the word. If he heard an associated word (e.g., "gambling" when confronted with an array of three objects including a picture of dice), he said the word of the picture while pointing to it ("dice") but never uttered the semantically related word.

The patient gave no indication that his hearing was defective, consistent with the audiogram, and he claimed that he could hear all the sounds presented to him. However, several subtle lower level abnormalities emerged during testing that could account for his auditory agnosia. First, reaction times to brief (30-msec) suprathreshold tones were very slow (averaging about 380 msec), whereas reaction times to longer (100-msec) tones were within the normal range for his age group (averaging about 250 msec). Reaction times to visual stimuli were also in the 250-msec range for both 30- and 100-msec stimulus durations (Fig. 1). Since consonants in speech have durations in the 30- to 40-msec range, slow processing of such sounds could clearly lead to problems understanding speech. Second, the patient required almost a quarter of a second of silence between two brief (30-msec) tones in order to be hear them as separate (Fig. 2). This suggests that the sound of the first tone persisted in his auditory system long after its offset. If so, the resulting "avalanching" of sounds while listening to someone speak would clearly interfere with comprehension.

The previous case is an example of auditory agnosia in which the loss of comprehension may have had an apperceptive rather than associative origin. In this patient the disorder was probably the consequence, at least in part, of a very slow analysis of brief sounds and an independent or derivative slow decay of sounds in the auditory system. Because only supplementary tests demonstrated the possible apperceptive nature of his deficit, it is possible that many other cases of auditory agnosia that were attributed to an associative deficit may also have involved a disruption of lower level language decoding functions.

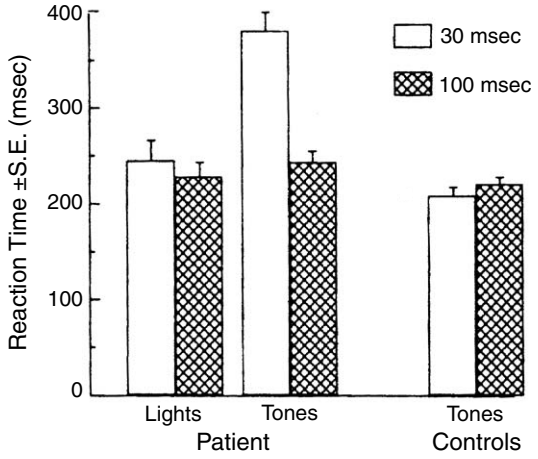

Figure 1 Simple reaction times to tone and light stimuli for the patient (left) and for tones for control subjects at the same intensity above threshold (right). Reaction times were slow for the patient when 30-msec tones were used, whereas changing the duration of light stimuli had only a minor effect. Control subjects have similar reaction times for both 30- and 100-msec tone durations. [From Buchtel and Stewart (1989). Auditory agnosia: Apperceptive or associative disorder? *Brain Language* **37,** 12–25].

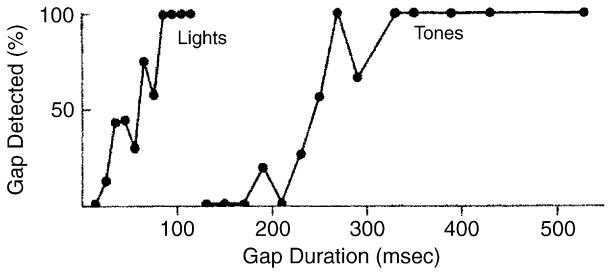

Figure 2 Gap detection: The patient needed almost 300 msec between two 30-msec tones before he could reliably tell that there were two stimuli rather than one. Sensitivity to successive light stimuli was normal. [From Buchtel and Stewart (1989). Auditory agnosia: Apperceptive or associative disorder? *Brain Language* **37,** 12–25].

Auditory Cortex

ROBERT J. ZATORRE
McGill University

GLOSSARY

aphasia A loss or disruption of normal language ability resulting from cerebral damage.

binaural Pertaining to processing of sound combinations coming from the two ears.

formant A resonant frequency band in the acoustic spectrum.

formant transition A change in formant frequency, usually related to speech in which rapid changes in the position of the vocal articulators result in such transitions.

Heschl's gyrus Cortical region in the superior temporal gyrus that contains primary auditory cortex.

planum temporale Cortical area located on the superior temporal gyrus behind Heschl's gyrus.

medial geniculate nucleus Principal thalamic nucleus for the auditory system.

tonotopy The systematic topographical arrangement of neurons sensitive to particular acoustic frequencies.

Wernicke's area A region in the left posterior temporoparietal cortex that plays a role in speech and language processing.

The human auditory cortex may be defined as those regions of the neocortex, situated mostly on the superior and lateral surfaces of the temporal lobe, that contain neurons responsible for processing sound. This article describes the anatomy and physiology of this area, with emphasis on properties that are specifically related to human auditory processing. The role of the auditory cortex in behavior will be considered, particularly in relation to the analysis of speech sounds. Related issues concerning morphological and functional hemispheric asymmetries will also be discussed.

I. ANATOMY

A. Gross Morphology

The auditory cortex consists of several distinct fields that differ in terms of their cytoarchitecture, connectivity, and physiological response properties. In primates, three major subdivisions may be identified, which are usually referred to as core, belt, and parabelt regions. The correspondences and homologies between these regions in human and other primates have not been completely worked out. However, it is well established that in humans the primary auditory cortex is located within Heschl's gyrus (HG), a relatively well-defined gyrus located transversely on the superior temporal gyrus, deep within the Sylvian fissure (Figs. 1 and 2). It is not uncommon for more than one HG to be present in one or both hemispheres, but there is no consistent pattern of asymmetry, as had been once thought. The right HG is shifted anteriorly by approximately 6 mm compared to the left. The primary area is confined mostly to the medial half to two-thirds of HG (the first HG when there is more than one), although in some individuals it may extend into Heschl's sulcus, which forms the posterior border of HG.

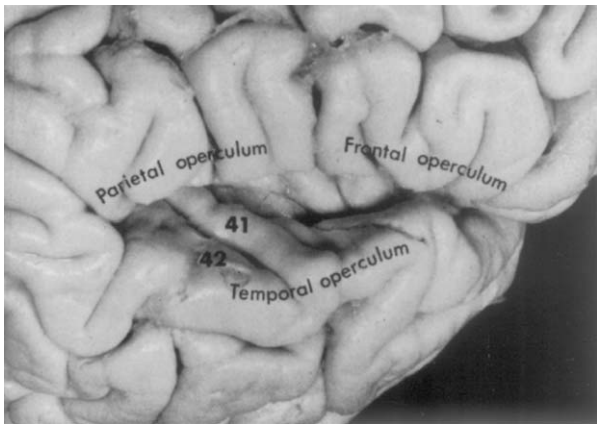

Figure 1 Anatomical specimen showing a lateral view of the right cerebral hemisphere with the lateral (Sylvian) fissure opened to reveal the hidden surface of the superior temporal gyrus. Heschl's gyrus is visible as the prominent transverse convolution, marked 41. The planum temporale is located posterior to Heschl's gyrus and is marked 42. Numbers correspond to cytoarchitectonic definitions according to Brodmann (reproduced courtesy of Charles C. Thomas, Publisher, Ltd., Springfield, Illinois from E. A. Kahn *et al*., 1969, *Correlative Neurosurgery*).

The precise boundaries of the belt and parabelt fields of the human auditory cortex have not been established, but it appears that auditory regions extend from HG both posteriorly and anteriorly along the superior temporal gyrus (STG) as well as onto the lateral aspect of the gyrus and into the superior temporal sulcus, as occurs in the macaque (Fig. 3). There is also evidence that auditory cortex may be found within the temporoparietal opercular area and even in some portions of the posterior insula bordering the medial portion of HG. However, there are no clearly established sulcal or gyral boundaries that correspond to these fields.

Posterior to HG is the planum temporale (PT), an approximately triangular region along the STG, bordering the Sylvian fissure (Fig. 1). This area, defined on the basis of its gross morphology, has been proposed to be important in language processes. Anterior to HG along the STG is an area sometimes referred to as the planum polare, which is likely to contain unimodal auditory cortex as well. The lateral aspect of the STG and the upper bank of the superior temporal sulcus may be considered as part of the parabelt auditory cortex as well. Beyond these regions lie areas that may have multimodal functions, notably cortex within the lower bank of the superior temporal sulcus and/or the middle temporal gyrus that may integrate auditory and visual information.

B. Cytoarchitecture

The core auditory region within HG, which in turn may be further subdivided, consists of koniocortex. Its laminar organization is characteristic of primary regions in other modalities; it is granular, with a thick, well-defined layer IV containing pyramidal cells. It is also densely myelinated and has high reactivity to cytochrome oxidase and acetylcholinesterase. This area is approximately coextensive with area 41 in Brodmann's cytoarchitectonic map of the human brain and with area TC according to the parcellation of von Economo and Koskinas. It is also sometimes referred to as A1 in the neurophysiological literature.

The cytoarchitectonic organization of the rest of the human auditory cortex is not well known, but studies in monkeys have helped to provide a model to which human data may be compared. The core, belt, and parabelt areas mentioned previously have been best defined in the macaque (Fig. 3). In that species the core region may be further subdivided into at least two and likely three separate areas based on the slightly different characteristics of their neuronal organization as well as on physiological response properties. It is likely, but not proven, that a similar organization exists in the human brain.

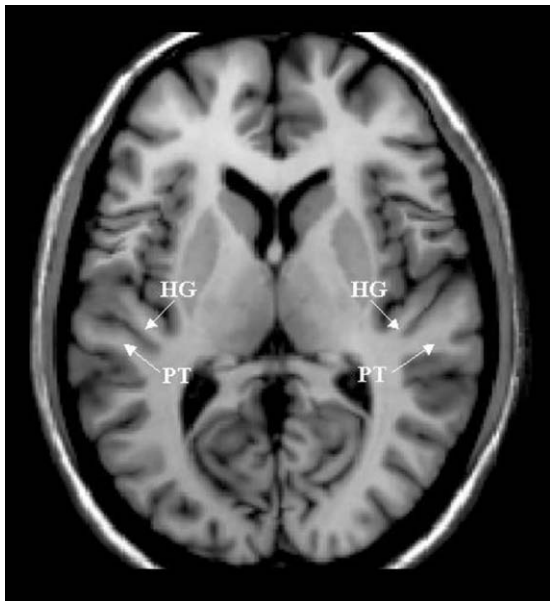

Figure 2 Magnetic resonance image of a normal human brain showing a horizontal section through the region of Heschl's gyrus (HG) and the planum temporale (PT).

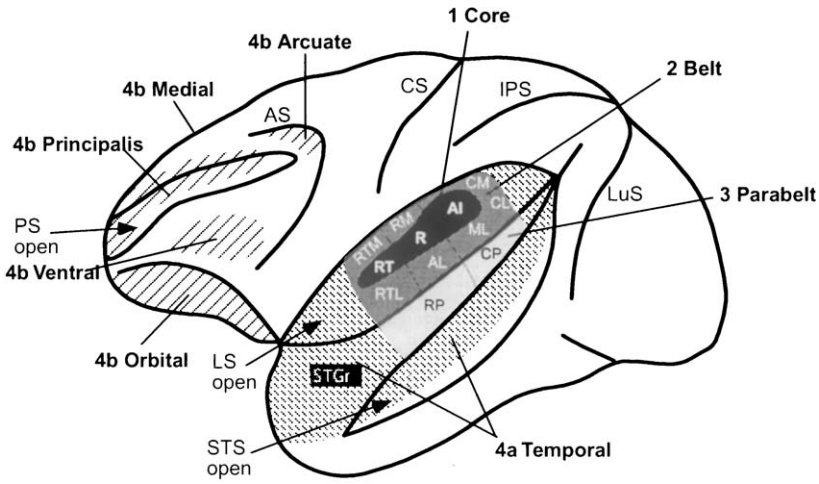

Figure 3 Levels and regions of auditory cortical processing in the macaque monkey. The areas shown are located on the superior temporal gyrus and in the depths of the superior temporal sulcus (STS), which has been opened to show the extension of auditory-related cortex into this sulcus. Level 1 represents the core (darkest shading) and includes tonopically organized regions A1, R, and RT; level 2 represents the belt areas (moderate shading) that encircle the core; level 3 represents the parabelt areas RP and CP (light shading), found in the upper bank of the STS; level 4a (stippling) represents putative auditory cortical areas outside the parabelt region, including the rostral area STGr; and level 4b (light hatching) represents frontal lobe cortex involved in auditory processing (reproduced with permission from Kaas *et al.*, 1999).

C. Connectivity

The input to the auditory cortex in the macaque comes from several subdivisions of the medial geniculate nucleus (MGN), which in turn receives the most important auditory projections from midbrain and brain stem auditory nuclei. The ventral subdivision of the MGN sends projections to all core areas, whereas the belt and parabelt areas receive primary projections from the dorsal and medial divisions of the MGN.

Corticocortical connections exist within and between the core, belt, and parabelt regions in a topographic and hierarchical arrangement. Neurons that respond to specific frequencies tend to be interconnected most heavily with neurons of the same frequency selectivity in other cortical fields. Removal of the A1 core region does not abolish responses in the more rostral core area (field R) in the macaque, indicating that parallel inputs exist to this region. However, belt regions immediately posterior to the core areas in the macaque appear to receive important inputs from the core area since excision of the core region results in abolition of responses to pure tones. Other, more anterior and lateral belt areas do continue to respond to sounds, however, even after removal of the primary region, as shown by evoked-potential responses recorded in human epilepsy patients.

The parabelt area is closely connected to the belt region but receives few if any direct inputs from the core areas. In addition to its thalamic inputs from the dorsal and medial portions of the MGN, the parabelt area receives inputs from other nuclei, including the pulvinar. Although the connectivity of the human auditory cortex is not well-known, it is note worthy that depth-electrode stimulation in human neurosurgical patients indicates that unidirectional connections exist from primary regions to more lateral and posterior areas, in accord with the corticocortical patterns described for monkeys.

Reciprocal cortical connections also exist between regions in the two hemispheres. The principal interhemispheric fibers pass through the midregion of the corpus callosum. Two features of this connectivity are worth noting. First, as with intrahemispheric connections, the projections are topographically organized, with neurons of the same frequency selectivity most highly interconnected. Second, the binaural response properties are important determinants of interhemispheric connectivity: Neurons that respond to stimulation of either ear tend to be heavily interconnected, whereas those units that are inhibited by input to one ear but not the other tend to have sparse interhemispheric projections.

Connections between the auditory cortex and several other cortical and subcortical structures have also been explored, but again little is known about these connections specifically in the human brain. In monkeys, there are important efferent connections between auditory regions and midbrain nuclei, particularly the inferior colliculus, as well as the basal ganglia.

Connections between auditory regions and the frontal lobe are topographically organized, with posterior regions of the STG projecting primarily to dorsolateral frontal cortices, whereas anterior and ventral auditory areas project preferentially to ventrolateral and orbital regions of the frontal lobe. Similar fibers have been described in gross anatomical studies in humans; one of these, the arcuate fasciculus, interconnects posterior STG regions with frontal cortices in and around Broca's area and is thought to play an important role in speech perception and production.

II. PHYSIOLOGY

The vast majority of information concerning neurophysiology of the auditory cortex derives from animal studies. To what extent these findings apply directly to humans is not known; moreover, human auditory cortical neurons may exhibit properties that are not found in other species, considering humans' specific ability to process complex sounds such as speech and music. Nevertheless, it is likely that much of the basic organization of the auditory cortex is at least similar to a first approximation between monkeys and humans.

A. Tonotopy

Tonotopic organization refers to the systematic topographical arrangement of neurons as a function of their response to tones of different frequencies. Tonotopy is a feature of the cortex but is also found throughout the auditory neuraxis, from the most peripheral level, at the basilar membrane of the cochlea as well as throughout most brain stem nuclei, midbrain, and thalamic levels. In primary auditory cortex, A1, single-unit recordings indicate that the majority of neurons demonstrate frequency selectivity, which is typically measured by establishing frequency threshold tuning curves for different frequencies of stimulation. The frequency for which a given neuron responds at the lowest intensity level is referred to as the characteristic frequency or best frequency. These best frequencies have been shown to be organized along a linear dimension of A1. In the human auditory cortex, it has been well established with electrophysiological and functional imaging techniques that high frequencies are represented in the most medial portion of HG, with lower frequencies represented more laterally along the gyrus. In monkeys, the more anterior field R is also known to exhibit tonotopy, but its frequency representation is reversed with respect to A1 so that the boundary between the two corresponds to low frequencies. This arrangement is similar to that of visual cortical regions that are adjacent to one another, which show similar reversals in the retinotopic organization of visual input.

B. Complex Response Properties

Although neurons in A1 typically show clear frequency selectivity, many of these neurons display more complex properties. Even neurons with the same best frequency may display different tuning functions. For example, some have very wide receptive fields, meaning that they respond well to tones over a wide frequency range, whereas others are more narrowly tuned. Still others have multiple best frequencies so that they respond strongly to two separate frequencies but not necessarily to frequencies in between. These features are thought to arise from interactions with convergent excitatory and inhibitory inputs from various afferent sources, as described previously. Thus, unlike auditory nerve fibers, whose tuning curves primarily reflect the mechanical tuning properties of the basilar membrane, cortical neurons display properties that are the result of neural interactions and thus represent higher order processing.

Beyond the core regions, the degree of tonotopic organization appears to break down. Some of the cortical fields adjacent to A1 have some tonotopic organization, but in belt and parabelt areas this organization is either absent or only weakly present. Neurons in these areas tend to have complex response properties and are generally not well characterized by simple frequency tuning curves. In the lateral belt areas, neurons tend to discharge with higher rates to narrowband noise bursts than to pure tones, in contrast with core area neurons whose discharge rates are typically highest for pure tones. In addition, the lateral belt neurons tend to have preferred bandwidths; that is, they respond best to sounds that cover a particular frequency range and less well to sounds that cover greater or lesser ranges. These properties suggest that neural integration over specific frequency ranges is occurring, most likely as a result of converging inputs from neurons in the core areas.

In several animal species, it has been shown that many auditory neurons respond not only to frequency information but also to temporal properties of the

stimulus. There are neurons that respond primarily with excitation to the onset of the stimulus but are insensitive to its offset or vice versa. Other neurons have more sustained responses throughout the period of stimulaion, and still others respond with inhibition or with a combination of these features. Some neurons have been described in unanesthetized monkeys with very complex receptive field properties that take into account both spectral and temporal information. For example, there may be excitation to a particular frequency region during some time period, whereas another frequency region elicits inhibition for a different time period.

There are also neurons sensitive to frequency modulation. These changes in frequency that can be either monotonic (e.g., frequency glides, where the frequency changes in a consistent direction) or periodic (when the frequency moves up and down at regular time intervals, such as in vibrato). Also, neural responses that follow amplitude modulation, or changes to the amplitude envelope of a sound, have been described. These changes may also be of a periodic nature (e.g., in a tremolo), or responses may occur to abrupt changes in envelope, such as occur when an object strikes another object. These abrupt changes are also found in human consonant speech sounds. Because of their dynamic response properties, it is possible that these types of neurons may play a role in processing complex sounds such as vocalizations, which contain time-varying energy distributed in distinct spectral bands (formants). It is highly likely that similar neural responses occur in humans for processing of speech sounds.

In human studies, the distinction between primary and extraprimary fields, as determined from anatomical data such as that reviewed previously, is generally supported by physiological data. For example, the core region located in HG is seen to respond with the shortest latencies to clicks in depth-electrode recordings, whereas surrounding areas have longer latencies, consistent with the idea that information is passed from one region to the next in a hierarchical arrangement. Also, functional imaging shows that the core areas respond well to stimuli such as noise bursts, whereas the surrounding regions generally respond to stimuli with more complex properties. Also relevant are cortical stimulation studies in which the cortex is stimulated while patients undergo neurosurgery. These observations have shown that stimulation of HG generally leads to nonspecific percepts, such as buzzing or hissing. In contrast, stimulation of anterior and lateral STG regions sometimes results in complex auditory hallucinations. In some cases, subjects report hearing music, speech, or voices quite vividly. These observations are consistent with the idea of a hierarchical arrangement between primary and extraprimary areas.

C. Binaural Properties

Many auditory cortical neurons are sensitive to differences in the way a sound reaches the two ears. These interaural differences are primarily of two types: intensity and time of arrival. Both these properties arise as a consequence of the distribution of sounds in space and the acoustics of how such sounds arrive at the two ears. Consequently, these differences are the cues used by the auditory nervous system to compute the spatial position of sounds. Physiological responses that correspond to these two features have been described in several different locations in the auditory core, belt, and parabelt regions. Many cortical neurons are very sensitive to slight differences in interaural intensity, whereas others respond differentially to interaural timing differences. These neurons tend to respond preferentially to sound sources located in the contralateral spatial hemifield, although there are also many units that show broad spatial tuning, extending into both hemifields.

Although there is evidence that neurons sensitive to similar spatial positions are located within cortical columns, there appears to be no topographic representation of space in the auditory cortex. Thus, unlike the visual system in which retinal position, and hence space, is coded by retinotopic mechanisms, the representation of auditory space is not topographically organized. However, recent evidence suggests that auditory space may be represented by population codes based on neural activity rates. Cortical neurons are also sensitive to auditory motion and sometimes respond preferentially to one direction of motion in the azimuthal plane.

III. BEHAVIORAL ASPECTS

The anatomy and physiology of the auditory cortex set the stage for understanding its role in behavior. This role has been traditionally elucidated by studying the effects of cortical damage on various perceptual tasks, either in experimental animals or in patients with brain lesions. Recently, this information has been

supplemented by the development of functional neuroimaging techniques, such as positron emission tomography, functional magnetic resonance imaging (fMRI), and magnetoencephalography.

A. Cortical Deafness

It has been known since at least the late 19th century that lesions to the superior temporal region in dogs, monkeys, and other species entail disorders of auditory perception. Early studies of dogs with cortical damage to this area showed, for example, that they failed to orient to sounds or respond to them normally. However, it was evident even from these early observations that such animals were not really deaf, in the sense that they did show some reaction to sounds. Furthermore, there seemed to be fairly rapid recovery in many cases, making the issue difficult to study. Recently, it has been shown in controlled experimental studies that bilateral ablation of A1 results in a profound loss of hearing sensitivity for a certain period of time, but that recovery does take place so that after a few weeks or months the animals have only a mild disturbance of sound detection. However, problems in more complex domains of auditory processing do remain, as described later.

Corresponding observations in human cases of so-called cortical deafness were also made in the early 20th century; patients with apparently complete loss of the ability to identify or discriminate sounds were described, but these individuals were usually not deficient in detecting the presence of sound. These dissociations have become much better understood in the past two decades. The concept of cortical deafness has been refined and usually refers to patients who suffer damage to auditory cortices in both hemispheres and who have profound difficulties in identifying sounds or recognizing speech. These patients usually have only mild or no threshold detection deficits, in accord with animal studies, and may also show no consistent disturbance in simple discrimination tasks for frequency or intensity. These phenomena indicate a functional dissociation since the inability to identify sounds is independent of the ability to detect the presence of sound. Thus, these cases support the idea that the auditory cortex is necessary for higher order processes but not for simply detecting or reacting to sounds. Cortical deafness contrasts with comparable cases in vision or in the somatosensory domain since lesions to the primary cortices in these modalities typically result in a nearly complete loss of conscious perception of light or touch.

B. Pitch Perception

The role of stimulus frequency in tonotopically organized cortex suggests that the cortex plays an important role in the processing of frequency and, hence, of pitch. However, the relation between pitch and frequency is not simple since pitch is a perceptual entity that is affected by many different aspects of the stimulus. Thus, the effects of lesions of auditory cortex on pitch depend on the nature of the task and stimuli used.

In many animal studies, it has been shown that complete destruction of A1 and surrounding areas bilaterally entails only transient difficulties in simple frequency discrimination tasks. Even when threshold differences in frequency between pure tones are measured, damage to A1 has no effect in tasks in which the animal must discriminate between the same tone presented twice and two tones of slightly different frequency. Similar results have been demonstrated in human patients with lesions of auditory areas. The conclusion from these studies is not that auditory cortex plays no role in pitch perception but, rather, that these simple discrimination tasks do not require the processes carried out by cortical structures.

Many studies have revealed that cortical mechanisms are important for pitch processing under conditions in which stimuli or tasks make certain demands. For example, the phenomenon of residue pitch, or missing fundamental pitch, apparently depends on cortical processes. This effect occurs when a complex tone is presented in which little or no energy is present at the fundamental frequency. Under certain conditions, it is possible to hear the pitch corresponding to the fundamental frequency, even in its absence, as a consequence of the frequencies of the remaining harmonics that are multiples of the fundamental frequency. This percept, which requires integration of information from several harmonics to abstract the missing element, is affected by damage to A1 in cats. It has also been shown in human patients that damage to HG in the right hemisphere leads to disturbances in the same type of pitch task.

Another example of pitch processing that is dependent on cortical function relates to the situation in which the processing of pitch cannot be done on the basis of a simple change detection. In animal

experiments, for example, lesions of at least some portions of auditory cortex impair the ability to respond to the cessation of a pitch from a set (i.e., detecting that ABAB has changed to AAAA), whereas the reverse order is not affected by such lesions. The important factor here is that it is easier to detect a change when a new element is added than when some of the same stimulation remains in both cases. Similarly, cortical lesions impair cats' ability to discriminate simple pitch patterns (e.g., ABA from BAB), whereas there is no difficulty in discriminating AA from AB.

A similar example from human studies is that the threshold for discriminating the pitch of two tones is unimpaired following lesions of HG in a simple same/different task, in which the subject must simply indicate that a change has or has not occurred [i.e., AA (same) vs AB (different)]. However, patients with damage to the right HG suffer a fourfold increase in threshold for a very similar task that requires identifying which of two tones is higher, whereas damage to the left HG has no effect. In this task the two stimuli in a trial are always different (AB or BA); hence, it is insufficient to merely detect that a change has occurred, as in the prior task. Instead, the two stimuli must be represented at a higher level of abstraction because the relation between them on some ordered scale is required to obtain the correct answer. This can only be accomplished if the appropriate cortical mechanisms are intact. Note that in these studies damage to the left HG has little or no effect, reflecting a hemispheric specialization discussed in greater detail later.

C. Spatial Localization

The ability to localize sounds in space is a function that appears to depend on the integrity of the primary auditory cortex. The presence of cortical neurons sensitive to interaural differences would be consistent with this functional role. Experimental studies in animals provide the most consistent data. In many species, unilateral destruction of A1 leads to a disturbance in localizing sound sources in the contralateral field. This deficit can be quite specific; for example, if the damage is to a restricted frequency band in the cortex, the animal will be unable to localize within that frequency band but will be unimpaired at other frequencies. Discrimination of sound sources at different locations is sometimes still possible even after complete destruction of A1, however, if the behavioral response entails a simple discrimination rather than responding to a true position in space. Thus, these findings support the concept that auditory cortex is necessary to construct a representation of auditory space rather than merely computing interaural acoustic differences, which is accomplished at earlier levels of the auditory system.

Data on human auditory spatial localization are not as clear as those from controlled animal studies. Patients with unilateral or bilateral hemispheric lesions have often been described who show deficits in localizing sound sources in space, but the precise nature of the damage and type of deficit are not well correlated. Some studies report greater localization problems in the hemifield contralateral to the lesion, but other findings indicate that deficits may exist in both auditory hemifields after damage to the right cerebral hemisphere, which is known to play an important role in spatial processing generally. However, it is important to distinguish the effects of large hemispheric lesions that affect parietal and frontal lobes as well as auditory cortex from more restricted damage to the superior temporal region. The former are likely to result in generalized spatial processing impairments and hemispatial neglect, whereas the latter result in selective auditory localization problems.

Neuroimaging findings indicate that perception of moving sounds or registering the visual position of auditory targets, engages parietal cortex, in keeping with the known role of these areas in spatial processes. Another important finding is that patients with complete removal of one hemisphere early in life show only very mild disturbances of auditory localization, in contrast with the severe effect of much more restricted lesions of auditory cortex occurring in adulthood. Therefore, there may be considerable plasticity in the functional role of auditory cortices—a finding not suspected from the animal literature, perhaps because most such studies are done only in the acute phase and in adult animals, thus not allowing for plasticity to manifest itself.

IV. COMPLEX FUNCTIONS

A. Pattern Perception

It was previously mentioned that cortical damage in both animals and humans leads to deficits in discriminating pitch patterns, particularly when the elements in the pattern are rearrangements of individual elements. This type of finding is indicative of the

important role played by auditory cortical regions in processing complex sound patterns. In animals, these patterns are especially important for functions such as responding to conspecific vocalizations, but they are also relevant for interpreting many sounds from the environment.

Many aspects of pattern detection appear to occur automatically, as indexed by electrical and magnetic changes measured from STG. Auditory cortical areas appear to be highly sensitive to changes or deviations from a background, even when subjects are not listening to the stimulus but are engaged in another task. The cortex responds to simple deviations in frequency or intensity but also to subtle changes in more complex patterns, indicating that the auditory system is specialized to some extent for ongoing pattern analysis and detection of novelty. Such a mechanism inplies an important survival value since changes in the auditory environment could signal danger or an event needing attention.

In humans, the perception of speech is among the most complex types of patterns that must be processed and will be discussed later. Another example of pattern perception that is related to speech, but is independent of it, pertains to the processing of voices. Human voices contain characteristic acoustic features that are unlikely to exist in other environmental sounds. Recently, it was proposed on the basis of fMRI data that regions in the upper bank of the superior temporal sulcus may be specialized for processing auditory information related to the perception of voices. These parabelt regions would be well situated to extract higher order stimulus features according to the hierarchical nature of the inputs to these areas.

Another important example of complex auditory pattern perception concerns music. Music, which appears to be both unique to and ubiquitous in the human species, offers a particularly rich source of information concerning human auditory cortical processing. Cases of specific loss of musical functions following brain damage have been described dating back to the 19th century. Recently, detailed studies of patients with bilateral damage to auditory cortices have revealed that certain specific aspects of musical function, notably involving discrimination of pitch patterns, may be selectively abolished while leaving other auditory functions, including speech, intact. These findings lead to the conclusion that aspects of music may have a distinct neural substrate, independent of other processing domains.

Studies of patients with unilateral damage to the anterior STG have generally shown that discrimination of melodic patterns is most affected by damage to the right STG, although usually milder disturbance may also be seen after left STG lesions. These findings are in accord with the data reviewed previously indicating that aspects of low-level pitch processing are affected by right HG damage. Thus, whereas more fundamental aspects of auditory processing are dependent on the core regions, damage outside of the core area results in impairments in higher order processes. Deficits in processing tonal patterns are also described following damage to right auditory cortical areas when the stimuli consist of complex spectral elements, such as musical chords, or when the discrimination entails differences in the distribution of spectral energy, such as when changes in harmonic structure affect the timbre of musical instruments. Functional imaging data also suggest that core and belt areas of the right STG are involved in tonal processes. Imaging studies have found neural activity changes, often bilaterally but usually greater on the right, in these areas in tasks requiring analysis of pitch or of pitch patterns, including melodies and chords (Fig. 4).

These findings extend to other types of tasks as well, including situations in which tones must be retained over brief time intervals. In this type of task, working memory mechanisms are involved. Working memory is important for all types of complex auditory processing since sounds necessarily unfold over time, and a mechanism must therefore exist for holding auditory information on-line so that relationships between elements can be appreciated. In the case of melodies, working memory for pitch involves belt areas of the right auditory cortex, as shown both by lesion studies and by functional imaging studies in normal listeners. The latter studies have also shown that pitch judgments depend on interactions between auditory regions and frontal lobe cortices since frontal cortical regions become more active when tones must be retained over time intervals filled with distractor tones. Together, these findings support the idea of a hierarchy of processing, with basic aspects of pitch analysis being carried out in the core areas in HG, and more complex processes important for pattern analysis dependent on cortical areas in the belt region anterior and possibly posterior, to HG. The perceptual analyses carried out within these regions in turn must interact with frontal lobe regions, presumably via the connectivity described previously, for situations in which working memory is important.

Another example of a complex function is auditory imagery, or the ability to imagine sounds in the absence

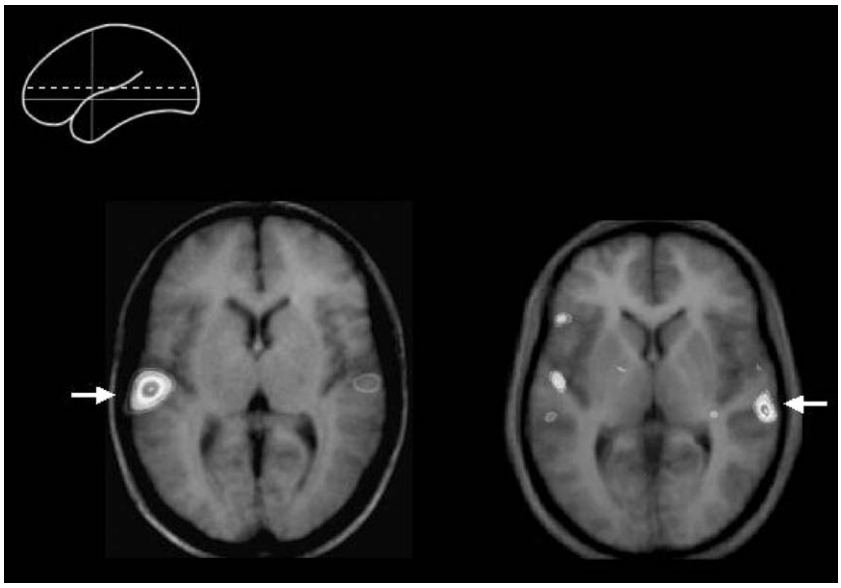

Figure 4 Positron emission tomography scans showing neural activity in superior temporal regions in response to auditory stimulation. Each image shows a horizontal slice through the temporal cortex at the position indicated by the dotted line in the inset. Changes in cerebral blood flow (arrows) are superimposed on structural magnetic resonance images. The left image shows increased activity in the left planum temporale in response to hearing speech sounds compared to a control condition of acoustically matched noise bursts. The right image shows bilateral activity in belt areas of the superior temporal gyrus, with stronger activity on the right side, in response to hearing tonal melodies.

of real auditory stimulation. This phenomenon has been studied in the context of musical imagery as well as imagery for speech. Several studies using functional imaging, as well as behavioral lesion techniques, have shown that auditory cortical areas, especially those in the right STG, are involved in the subjective experience of imagining a melodic pattern. Thus, there is an overlap between the cortical areas recruited for perceiving a sound and imagining it. An example of a similar phenomenon has been described for silent lip reading, which results in cortical activation of HG and surrounding areas, particularly on the left. This functional overlap between cortical zones involved in perception and imagery has also been described in the visual modality. These findings suggest that sensory information may be re-evoked by mechanisms that engage the sensory cortices that are initially involved in processing perceptual information from the environment.

B. Speech Perception

The uniquely human ability to perceive and produce speech sounds is among the most complex cognitive functions to which the auditory system contributes. The precise role of auditory cortical structures in speech is not fully understood, but considerable progress has been made in the past decade. Studies in monkeys have uncovered neural response features that may be considered as evolutionary precursors to human speech analysis—for example, the sensitivity of certain neurons to formant transitions, found in both human speech and monkey vocalizations, or the fact that some neurons respond to specific abrupt changes in sound envelope that correspond to some consonant speech sounds. However, the complexity of speech decoding goes beyond these low-level features since speech is combinatorial in nature, meaning that words in all natural languages consist of permutations and combinations of a limited set of sounds, called phonemes, which are by themselves not meaningful. The ease with which all normal humans understand the complex sound patterns inherent to speech and the fixed developmental sequence for language acquisition, strongly suggest that a specific neural specialization underlies this ability.

It has been clear for more than a century that one aspect of this specialization is that the left cerebral hemisphere plays a more important role in speech processing than the right in the majority of individuals. Classical studies of aphasic populations not only revealed a lateralization but also indicated that cortical

regions in the STG posterior to HG were especially important for the perception of speech sounds since damage to these areas, traditionally referred to as Wernicke's area, typically results in disruption of speech comprehension. The precise role of these areas has not been clear, however, because the precise location of the damage was often not well-known and because patients with such damage often display complex linguistic disorders that go beyond perception of speech sounds. Moreover, damage to frontal lobe language regions can often lead to speech perception deficits. The boundaries of the speech-related areas in the temporal lobe were further defined in the 1950s by Penfield, who tested neurosurgical patients under local anesthesia with the cortical stimulation technique. Penfield and others identified that disruption of speech could often be elicited by stimulation not only of the left posterior STG but also of regions in the middle temporal gyrus as well as the inferior parietal lobe (Fig. 5).

Recently, functional imaging studies have begun to reveal the organization of speech-related auditory cortical areas. The results of most of these studies are in agreement that speech sounds engage auditory areas both anterior and posterior to HG, but that the greatest differential response is in the left posterior temporal area (Fig. 4). The extent to which these specific areas respond uniquely to speech sounds *per se*, as opposed to certain acoustic characteristics that are present in speech, remains a matter of current research. It has also been proposed from imaging research that regions in the left STS and middle temporal gyrus respond specifically to auditory words.

Depending on the nature of the task, different patterns of activity have been noted. In particular, imaging studies have indicated that in addition to posterior temporal areas, left premotor areas may also be active when the task requires discrimination of speech phonemes. This effect has been attributed to the engagement of articulatory processes that may be involved in some aspects of speech processing. According to this view, which is not universally accepted, speech decoding is not solely dependent on analysis of the acoustic waveform but also depends on comparison of the auditory input with internal motor representations of the vocal gestures necessary to produce the sound.

Conversely, functional neuroimaging studies have also suggested that the area of the planum temporale can also be active during articulation even in the absence of auditory stimulation, for example, when auditory input is blocked by masking noise or when viewing lip and mouth movements, as mentioned previously. These findings thus challenge the conventional view that the posterior temporal speech zone is exclusively dedicated to speech perception, and that the frontal region is devoted to speech production. These regions may instead form part of an interactive

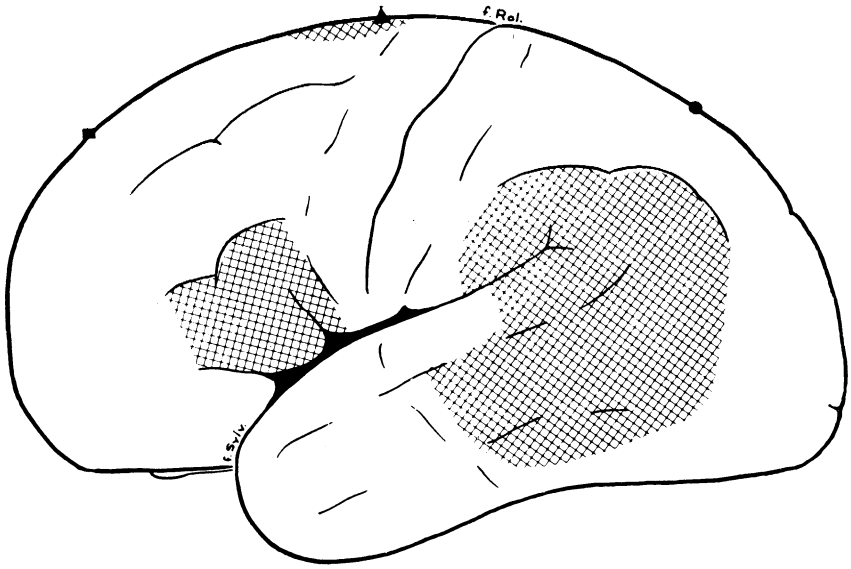

Figure 5 Diagram illustrating areas of the left cerebral hemisphere that cause disturbance of speech when stimulated electrically during neurosurgical procedures (reproduced with permission from W. Penfield and L. Roberts, 1959, *Speech and Brain Mechanisms*. Princeton Univ. Press, Princeton).

functional network, including other brain areas, that is involved in speech processing.

Much recent attention has been devoted to the idea that speech perception may depend on cortical mechanisms specialized for processing rapidly changing acoustic patterns. Because the perception of certain consonants in speech depends on small temporal differences (on the order of 20 msec), it has been proposed that the temporal resolution of the left auditory cortex is higher than that of the right, and that this factor underlies the hemispheric specialization for speech processing. Evidence in favor of this view derives from electrophysiological and functional imaging studies, which tend to show a greater response from the left than the right auditory regions to sounds that are separated by very brief time intervals, that contain short, abrupt changes in stimulus energy, or that contain rapid changes in formant transitions. Also, in at least some studies, patients with damage to auditory regions on the left have increased temporal discrimination thresholds, as do populations of children with certain developmental language acquisition disorders. It is thus possible that at least some aspects of hemispheric specialization for language arise from differences in processing at the level of primary and surrounding auditory cortices in the left and right hemispheres.

V. STRUCTURAL ASYMMETRIES

The considerable body of data indicating that the human auditory cortices are specialized for different types of processing in the left and right hemispheres has led to the search for possible structural correlates of this lateralization. The region of the PT has been one focus of such research since many studies have indicated that it differs across the two cerebral hemispheres. This asymmetry has traditionally been characterized as one of size, with the left PT being larger than the right in approximately 65–80% of brains. It is also known that similar asymmetries exist in the brains of newborns. These findings have been widely interpreted as providing a basis for the specialization of left posterior STG regions for auditory language processing. However, there is only limited evidence directly linking structural to functional asymmetries.

Considerable evidence also exists for hemispheric differences in the shape of the superior temporal region. It is well-known that the right Sylvian fissure angles upward more steeply on the right side, and that the point at which it begins to ascend is more anterior than on the left. Therefore, the apparent size difference of the PT may at least partly be a consequence of hemispheric differences in morphology rather than size.

Evidence exists that certain cytoarchitectonic regions within the PT may be larger on the left, but because there is no established relationship between the cytoarchitecture and the gross anatomical features on which the PT is defined, it is difficult to determine how measurements of the PT are related to cytoarchitectonically defined areas. The search for structure–function correlates is further complicated by the fact that the incidence of structural asymmetry in the PT is far lower than the incidence of left hemisphere language organization, which is estimated to be on the order of 95–98% of the population.

Other structural asymmetries in addition to the PT have also been described in auditory cortices. Recent evidence from both *in vivo* MRI studies and postmortem histological studies indicates that a greater volume of white matter underlies the left HG and surrounding cortex than the equivalent areas on the right (Fig. 2). In addition, there is evidence that myelination of axonal fibers on the left side is thicker, which would be compatible with the hypothesis that the left auditory cortices are specialized for faster neural transmission, as required for perception of speech signals.

VI. PLASTICITY AND REORGANIZATION

In the past several years, much research has revealed that the functional characteristics of the auditory cortex are not necessarily static but instead may be influenced by environmental experience. It has been shown that many properties of cortical neurons may change as a function of such experience, and that reorganization may occur when there is a change in the normal sensory input.

The most dramatic changes in auditory cortex organization are evident when there is loss of a sensory modality, such as occurs in blind or deaf individuals. In experimental animals, it has been shown that early loss of vision entails an increase in auditory-sensitive neurons in some cortical areas. Also, some of these neurons respond with a higher degree of accuracy to sounds in specific spatial positions than do similar neurons in normal animals. This latter observation is most likely responsible for the behavioral

advantage that is sometimes seen in blind humans and other species for navigating in space with the use of auditory cues.

Reorganization of auditory cortex may also occur when it is deprived of its normal afferent input due to cochlear or other damage to the periphery of the auditory system. For example, if the afferent input from a restricted area of the basilar membrane is disrupted, the tonotopic organization of the cortex is also altered, with frequencies corresponding to the damaged region diminishing, while adjacent tonal regions increase their representation. Damage to one ear also changes the response properties of neurons that are normally sensitive to binaural cues.

In cases of complete deafness, on the other hand, there is evidence from both human and animal studies that auditory cortical regions may respond to visual cues, although the nature of the processes involved has not been worked out. However, it has been shown in some animal species that when optic nerve inputs are rerouted to the medial geniculate nucleus during early phases of development, auditory cortical areas begin to show some of the structural and functional characteristics of visual cortex, implying that these features are driven by the nature of the stimulation that is received rather than by epigenetic factors exclusively.

Other evidence of plasticity in the auditory cortex derives from studies examining changes associated with learning and conditioning paradigms. For example, a tone stimulus results in greater cortical activation when it has been conditioned to precede an air puff to the eye than when it is presented in isolation. This increased activity disappears once the tone is no longer paired with the air puff and it is specific to the frequency used for conditioning. Such findings indicate that auditory cortical activity reflects not only the characteristics of the stimulus but also its associative value and hence the importance of the stimulus in a given situation.

In monkeys, cortical tonotopic organization may be influenced by training the animal to respond to a particular frequency, which induces an increase in the representation of that frequency in the tonotopic map at the expense of adjacent regions. The degree of expansion correlates with behavioral performance. These findings indicate that far from being fixed, neural response properties are dynamic and subject to considerable influences based on environmental input. These types of modifications are likely to be important for speech perception as well; infants begin to respond differentially to the phonemes of the language around them by 6 months of age, which is likely related to learning-induced changes in auditory cortical processing. Changes to cortical organization as a consequence of experience have also been noted in studies of musically trained individuals, who show a higher amplitude of cortical magnetic response to piano tones compared to pure tones, whereas musically untrained subjects do not. This type of finding tends to be strongest in individuals whose training started early in life, indicating that plasticity is greatest during development, although it may still occur in the adult organism.

VII. CONCLUSION

The human auditory cortex has attracted considerable attention in the past decade, and much progress has been made. The advent of structural and functional imaging techniques has facilitated the detailed study of the human auditory cortex and has permitted comparison with knowledge derived from other species. It seems clear that distinct auditory cortical areas exist in the human brain, but their boundaries and functional properties have yet to be identified. It also appears that important differences exist in auditory cortical functions in the two hemispheres. Finally, recent work has emphasized the modifiable nature of auditory cortical organization, yielding a complex and dynamic view of this important sensory system.

Auditory Perception

WILLIAM A. YOST
Loyola University, Chicago

GLOSSARY

auditory scene analysis The analysis of multiple sound sources into auditory perceptions of the individual sources using cues such as spatial separation, temporal modulations, spectral profiles, harmonicty and temporal regularity, and common onsets and offsets.

central auditory nervous system The anatomical parts of the brain stem and cortex devoted to auditory processing.

frequency The frequency of a periodic quantity, in which time is the independent variable. Frequency is the number of periods occurring in unit time. Unless otherwise specified, the unit is hertz.

hearing Determining the sources of sound.

intensity The magnitude of sound measured in a specified direction at a point is the average rate of sound energy transmitted in the specified direction through a unit area normal to this direction at the point considered.

loudness Subjective attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from soft to loud.

masking The process by which the threshold of audibility for one sound (signal) is raised by the presence of another (masking) sound.

peripheral auditory system The outer ear, middle ear, inner ear, and auditory nerve bundle.

pitch Subjective attribute of auditory sensation in terms of which sounds may be ordered on a scale extending from low to high.

spatial hearing The ability to locate a source of sound in three-dimensional space based on only acoustic cues.

Hearing, like all of our senses, allows us to determine objects in our world. Objects can vibrate, producing sound, and our sensitivity to that sound allows us to know something about the sound-producing sources. Often, many sources produce sound at the same time, and we parse this complex auditory scene into perceptions of its constituent sound sources. The sounds from these many sources are combined into one complex sound field. When the auditory system receives this complex sound field, the auditory periphery provides a neural code for the physical variables of the sound field: intensity, frequency, and time. This neural code is further processed by the central nervous system providing the neural substrates for the perceptions of the individual sound sources that originally generated the sound field. This article reviews the physics of the three physical variables of sound (intensity, frequency, and time); describes the peripheral auditory system and perceptual data related to processing intensity, frequency, and time; describes the central auditory system; and discusses the variables that influence sound source determination.

I. THE SOUND FIELD

A. Sound

Any object that has inertia and elasticity can vibrate and as a consequence can produce sound. Vibrations have three main variables: amplitude, frequency, and time. The simplest vibration is harmonic motion as described by a sinusoidal relationship between displacement and time shown in Fig. 1. Amplitude describes the distance through which a vibrating object travels, and it is related to intensity. Frequency is the inverse of

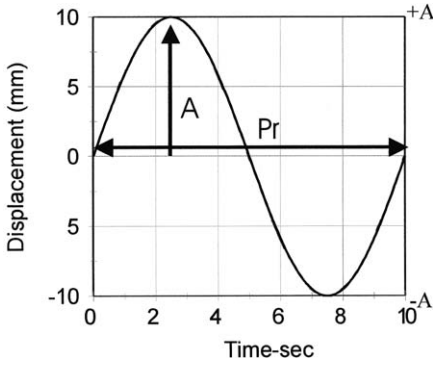

Figure 1 A sinusoidal relation between displacement and time. The period (Pr) is the time it takes to complete one cycle, and A is the peak amplitude. Period is 10 msec, frequency is 100 Hz, peak amplitude is 10, and starting phase is 0°.

period and describes how often per unit of time the object oscillates. Starting phase describes the relative starting point of the vibration.

A powerful theorem, Fourier's theorem, states that any arbitrary physical vibratory pattern consists of a sum of sinusoidal vibrations (Fig. 1). Sinusoidal vibration is a basic unit of vibration, and thus of sound. It is therefore not surprising that much of what is known about hearing has been derived from the study of sinusoidal vibrations and sounds. The sinusoidal relationship is written as $A(t)=A \sin(2\pi ft+\theta)$, where $A(t)$ is the instantaneous amplitude, A is the peak amplitude, f is frequency, t is time, and θ is the starting phase.

1. Intensity

The amplitude of vibration can be expressed as the instantaneous amplitude [$A(t)$], peak amplitude (A), peak-to-peak amplitude, or the root mean square amplitude. When an object vibrates it can produce pressure, which is proportional to amplitude. A vibrating object can also produce work. Work is measured in units of power or energy. Sound intensity is the measure of sound magnitude in units of power or energy. Thus, sound magnitude can be expressed in units of amplitude (displacement), pressure, or intensity (power or energy).

The dynamic range of sound intensity over which the human auditory system functions is approximately 10^{13}. In order to deal with this large dynamic range, sound intensity is often converted to decibels (dB) by $\text{dB}=10 \log_{10}(I_1/I_0)$ or equivalently $20 \log_{10}(p_1/p_0)$ since sound intensity (I) is proportional to pressure (p) squared. Therefore, in decibels the dynamic range of hearing is 130 dB ($10 \times \log_{10}10^{13}=130$ dB). It is common to use 20 (μPa) as the referent pressure (p_0) in calculating decibels since the threshold for hearing sinusoidal sounds is approximately 20 μPa. When this reference is used, the sound is measured in dB sound pressure level (SPL); therefore, a sound level of 50 dB SPL is a sound that is 50 dBs more intense than 20 μPa, (i.e., 50 dB higher than the level of the softest sound humans can detect).

2. Frequency

Frequency (f) is measured in hertz (Hz), where f in Hz=1/Pr, when Pr is the period of vibration and is measured in seconds (Fig. 1). A vibration that oscillates with a frequency of n Hz goes through n complete vibratory cycles in 1 sec. Many animals can hear over a range of sinusoidal frequencies from a few hertz to tens of thousands of hertz. The human range of hearing is approximately 20–20,000 Hz.

3. Starting Phase

The starting phase (θ) of vibration is measured in angular units of degrees or radians. When a sinusoid completed one cycle, it has gone through 360° (2π radians) since sinusoidal motion can be derived from the projection of a point on a rotating circle. The sinusoidal motion that begins at zero amplitude at time zero, as shown in Fig. 1, is defined as having zero starting phase. All other possible starting phases are relative to this zero starting phase condition. Humans are only sensitive to changes in starting phase in certain situations.

B. Sound Propagation

Air is the common medium for sound propagation for human hearing. The molecules of air are in constant random motion and the density of the molecules dictates the static air pressure. If an object is vibrating in this space, the outward vibration of the object causes the molecules that the object initially makes contact with to be pushed in the direction of the object's outward motion. This will cause a condensing of the molecules, thus increasing the air molecule density at the location of the condensation. This increased density leads to an increase pressure. When the object moves in an inward direction air molecules will tend to fill the vacated space evenly (a property of the gas

laws), resulting in a rarefaction of molecules and, hence, a lowering of the density of molecules. The lower density leads to a lower pressure. The distance between successive condensations (or rarefactions) is the wavelength (λ) of sound, such that $\lambda = c/f$, where c is the speed of sound in the medium and f is frequency in hertz.

These areas of increased (condensations) and decreased (rarefactions) pressures of the sound wave radiate out from the vibrating source in a spherical manner. As the sound travels from the source the density at condensations and rarefactions decreases, since the area of the sphere is increasing. This results in a loss of pressure as the sound travels from the source, and this pressure loss is proportional to the distance squared (called the inverse square law).

In most spaces sound will encounter obstacles as it travels from its source to its destination. The sound wave can be absorbed at an obstacle's boundary, transmitted to the medium of the obstacle, reflected from the obstacle's surface, or diffracted around the obstacle. All these have significant consequences for hearing in the real world. For instance, a reflected sound wave may encounter the originating sound wave (or other reflections). The reflected wave may reinforce or cancel the originating sound wave. Locations of reinforcement will cause areas of increased sound pressure, whereas areas of cancellation lead to decreases in sound pressure. Often, the pattern of reinforcements and cancellations sets up a standing wave pattern such the standing wave vibrates at its resonant frequency causing enhanced intensity at this resonant frequency. The resonant frequency is inversely proportional to the size of the environment in which the standing wave occurs. This is the principal on which woodwinds, horns, and organ musical instruments operate. The pitch of the sound is proportional to the resonant frequency of the standing wave set up in the "pipe." Not only can standing waves exist in our acoustic environment but they can also exist in the ear canal and other parts of the auditory system.

In other cases, an object may cause a sound shadow in which there is an area of reduced pressure on the side of the object opposite from the sound source. The size of this sound shadow is a joint function of the wavelength of the sound and the size of the object such that to a first approximation sound shadows exist when the object's dimension are close to those of the sound's wavelength. The fact that the head produces a sound shadow plays a significant role in sound localization.

C. Sound Analysis

The auditory system is a sound analyzer and our models of this analysis are based on physical systems. Frequency is the primary aspect of sound that is analyzed by the auditory system. Consider listening to several notes played together on a piano. Often, it is relatively easy to determine the different pitches. However, the sound that arrives at the auditory system is one complex waveform that is a sum of all the frequencies that make up this composite sound (recall the role of Fourier's theorem). The primary frequencies of this complex sound are those corresponding to the basic vibration of each piano string that is struck when the various piano keys were pressed. These primary frequencies produce the perceived pitches of the various notes. The fact that we perceive these pitches means that the auditory system has determined the various frequency components that made up the complex waveform that arrived at the auditory system as a single sound.

When the waveform is described in terms of the pressure or displacement waveform (Fig. 1), it is being described in the time domain. If it is described in terms of the frequency components that constituent the waveform, it is being described in the frequency domain. Figure 2a shows a complex waveform in the time domain. This waveform is the sum of three sinusoids. The amplitude and phases of these three sinusoids are shown in the amplitude and phase spectra as a function of frequency. These spectra form the frequency domain description of the complex wave.

The most general model for frequency analysis by the auditory system is filtering. Although there are not actual physiological filters in the auditory system, the results of the biomechanical and neural actions of the auditory periphery behave as if there were. The important filter for the purposes of auditory analysis is the bandpass filter, in which all frequency components of a complex sound that are within the passband of the filter are passed unaltered and those components with frequencies higher and lower than the passband have their levels attenuated and their starting phases altered (actually, the components outside the passband are delayed, resulting in a phase shift). The levels will decrease as a constant roll-off ratio in dB/octave changes in frequency from the cutoff frequencies of the passband (an octave is a doubling of frequency).

Bandpass filters can be used to estimate the amplitude spectrum of a complex waveform. If the waveform contains frequency components that are in the

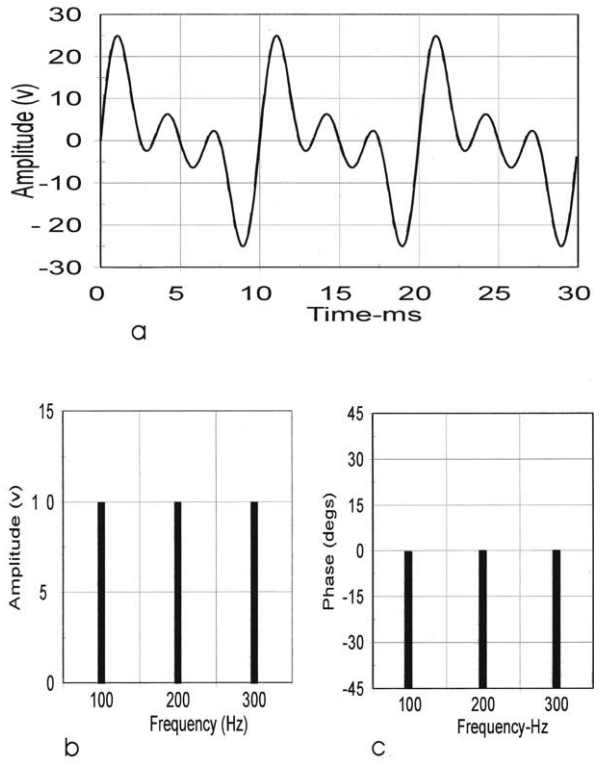

Figure 2 (a) The sum of three sinusoids with frequencies of 100, 200, and 300 Hz produces the time domain waveform. The frequency domain representation is described by the amplitude (b) and phase (c) spectra.

passband of a bandpass filter, then the filter's output will be high compared to the case in which the stimulus does not contain frequency components in the filter's passband. Thus, a series of filters, each with a different passband region (assuming that the passbands are very narrow), can be used to analyze a complex waveform to obtain an estimate of the waveform's amplitude spectrum. Filters with high levels at their output indicate that there are frequency components in the complex waveform near the spectral region of the filters' passbands. Thus, a function relating the magnitude of the filters' output to the spectral region of their passbands is an estimate of the sound's amplitude spectrum. The narrower and steeper the filters' passbands become the better the filters estimate the sound's amplitude spectrum. The equivalent filters in the auditory system have very narrow passbands with steep slopes.

Most real sound analysis systems, including the auditory system, are nonlinear. A consequence of nonlinearity is that frequency components exist at the output of a nonlinear processor that were not present in the input. For instance, if the input consists of the sum of two frequency components, f_1 and f_2, the nonlinear output contains frequencies equal to $mf_1 \pm nf_2$, where $n = m = 1, 2, 3, 4$, etc. The frequency components that are integers of f_1 and f_2 (nf_1 and mf_2) are harmonics, and if they are audible they are called aural harmonics. The terms $mf_1 + nf_2$ are summation tones, and the terms $mf_1 - nf_2$, are difference tones. The cubic difference tone, $2f_1 - f_2$ ($m = 1$, $n = 2$), is a significant nonlinear auditory component. A nonlinear processor will distort its input due to the addition of the nonlinear frequency components to the originating input components.

II. THE PERIPHERAL AUDITORY SYSTEM

Figure 3 displays the major parts of the auditory system: outer ear, middle ear, inner ear, and the central nervous system. The outer ear collects the sound for delivery to the middle ear, which allows air pressure to effectively vibrate the fluids and tissues of the inner ear. The inner ear serves as the auditory biological transducer translating vibration into a neural code for intensity, frequency, and temporal structure. The central nervous system processes this neural code, allowing for sound source determination.

A. Outer and Middle Ears

As sound travels to the outer ear, it passes over the torso, head, and especially the pinna. All these structures attenuate and delay the passage of the sound to the outer ear, and the attenuation and delay depend on the interaction between the size of the structures and the wavelength of the sound, such that high-frequency sounds are affected more than low-frequency sounds. These transformations alter the spectrum of the originating sound and are called head-related transfer functions (HRTFs). HRTFs are significant for sound localization.

The outer ear canal has a resonant frequency near 4000 Hz (i.e., standing waves exist within the outer ear), and as such sounds with frequency components near 4000 Hz are more intense in the ear canal than are other frequency components. The middle ear ossicles (bones) provide further enhancement in sound level in the region of 2000–5000 Hz. All these increases in sound level are necessary if air pressure is to produce an effective vibration within the inner ear. The inner

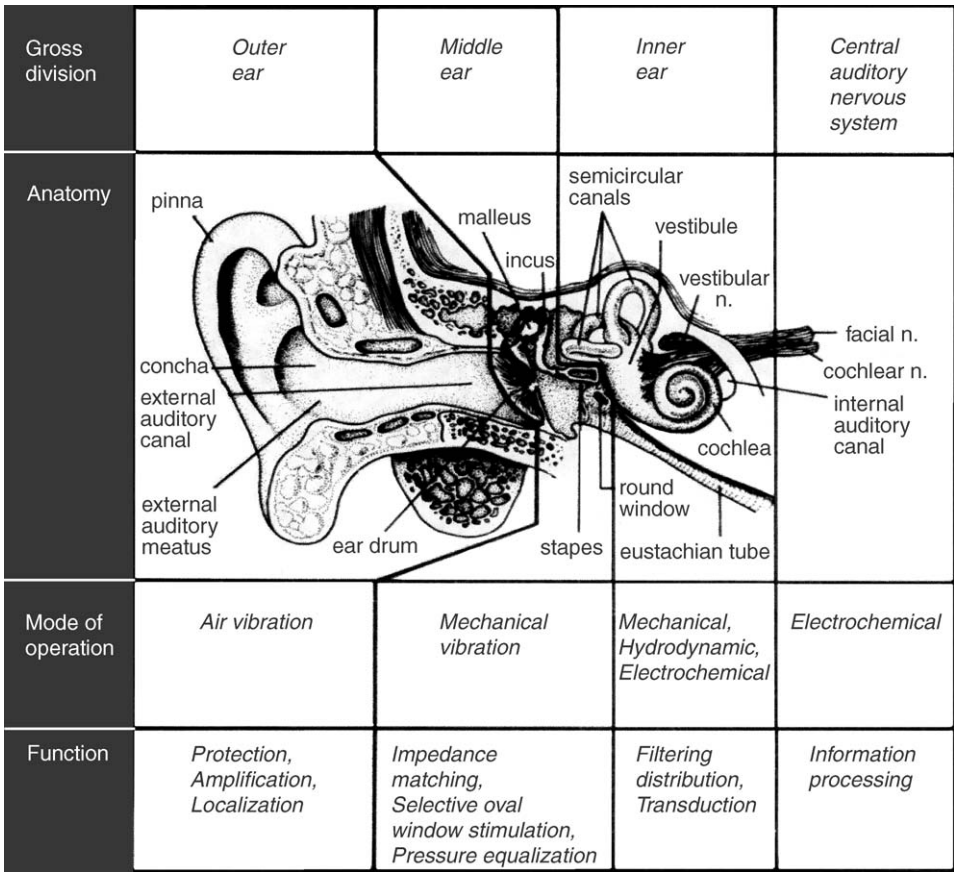

Figure 3 The four major divisions (outer ear, middle ear, inner ear, and central auditory nervous system) of the auditory system, their mode of operation, and their function are shown (from Yost, 2000).

ear is a fluid-filled space containing neural structures and their support. These inner ear structures offer significant impedance to the transmission of vibration from the air-filled outer ear to the inner ear. The resonance of the outer ear and the increases provided by the ossicular chain provide an impedance match between air and the fluids and structures of the inner ear so that over a significant portion of the audible range of hearing, changes in air pressure impinging on the auditory system are efficiently transmitted to the inner ear with no loss in sound level. Damage to the ossicular chain leads to significant hearing loss because of the loss of this crucial impedance matching function.

B. Inner Ear

The inner ear contains the neural structures for both the sense of balance (the vestibular system) and hearing. The auditory part of the inner ear consists of the cochlea, a tube that wraps around itself three or four times (depending on species) in a snail-like coil. The footplate of the stapes (the medial-most ossicular bone) pushes in on the oval widow at the base of the cochlea. The cochlear tube contains an inner tube, the cochlear partition, that is a sealed structure running the length of cochlea except at the top (apex), where there is an opening (the heliocotrema) between the cochlear partition and the end of the cochlea.

Figure 4 shows a schematic diagram of a cross section of the cochlear partition, the inner tube of the cochlea. Along the bottom membrane, the basilar membrane, lie the inner and outer hair cells, the neural elements for hearing, and their supporting structures. Figure 5 shows a view looking down on the top of the hair cells, revealing the hairs (stereocillia) from which the hair cells derive their name. In mammals there are three rows of outer hair cells and one row of inner hair cells. When the fluids of the inner ear are vibrated by

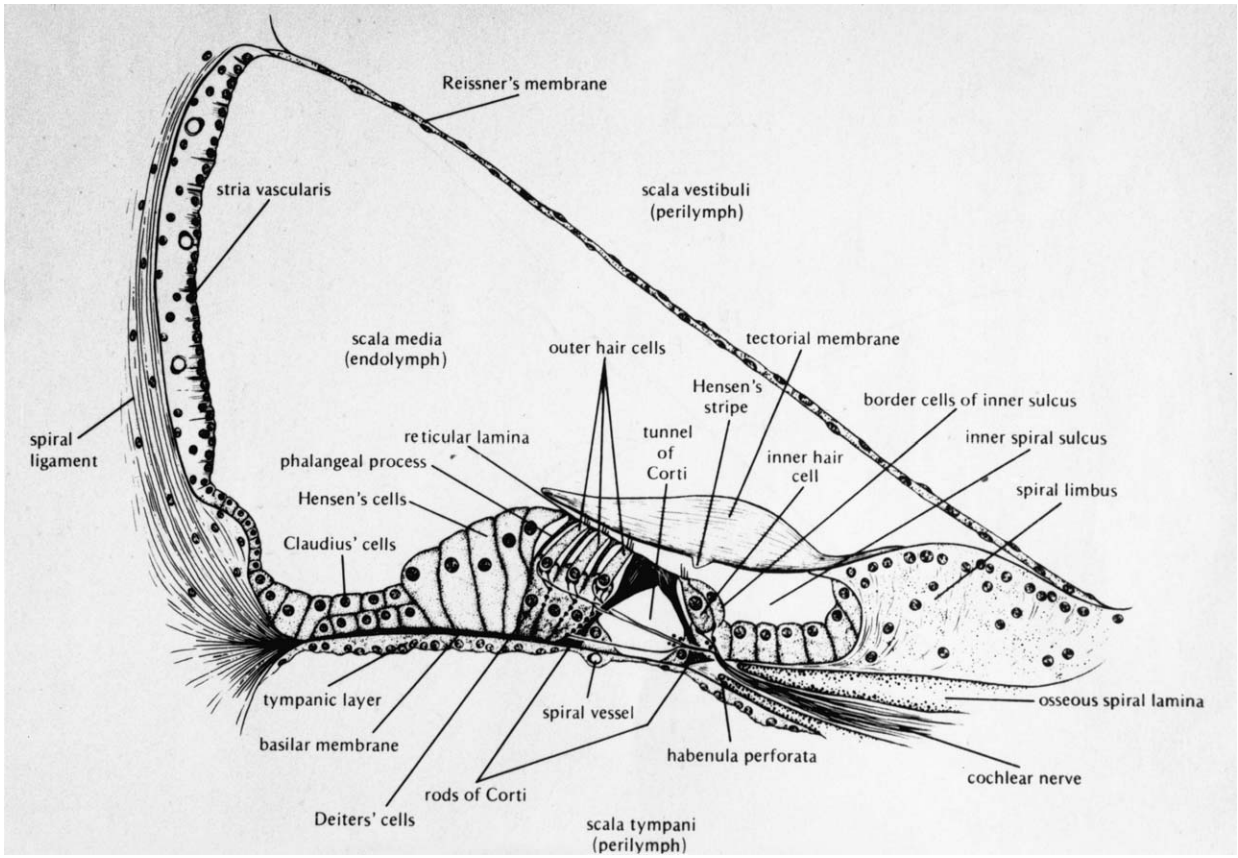

Figure 4 A cross-section of the cochlear partition of the cochlea is shown (from Yost, 2000).

the ossicular chain, a wave motion occurs within the cochlea that causes a differential movement between the basilar membrane on which the hair cells sit and the tectorial membrane at the top of the hair cells. This differential movement causes the stereocillia to shear (a type of bending), and this shearing ignites a generator potential in the hair cell causing an action potential in the auditory nerve fiber attached to the hair cell at its bottom.

This cochlear wave motion is a crucial part of the biomechanical action of the inner ear. The wave is a traveling wave (Fig. 6), such that the region of maximum vibratory displacement along the cochlear partition from base to apex is frequency dependent. High frequencies produce a wave that travels only partway from the base to the apex, thus producing maximum displacement near the cochlear base. Low frequencies cause the wave to travel to the apex, producing maximum displacement at or near the apex. Thus, the area of maximum cochlear partition vibration is distributed along the cochlear partition according to the frequency content of the originating sound. Since the hair cells are distributed from base to apex, those whose stereocillia will be maximally sheared depend on the sound's frequency content. Thus, hair cells are able to signal where, along the cochlear partition, the maximal displacement occurs and, hence, they code for the frequency content of sound. If the stereocilla of hair cells near the base are maximally sheared, the sound contains high frequencies, whereas maximal stereocillia shearing for hair cells near the apex code for low frequencies. Neural discharge rate is directly proportional to the amount of stereocillia shearing and, thus, to the displacement of the cochlear partition.

The frequency selectivity of this vibratory traveling wave is very sharp, the basilar membrane vibration is extremely sensitive, and the vibratory motion is a compressive nonlinear function of sound level. The exquisite frequency selectivity, high sensitivity, and important nonlinear function of the cochlear biomechanical traveling wave are only possible because of the way in which the inner and outer hair cells function. The inner hair cells are the biological transducers that

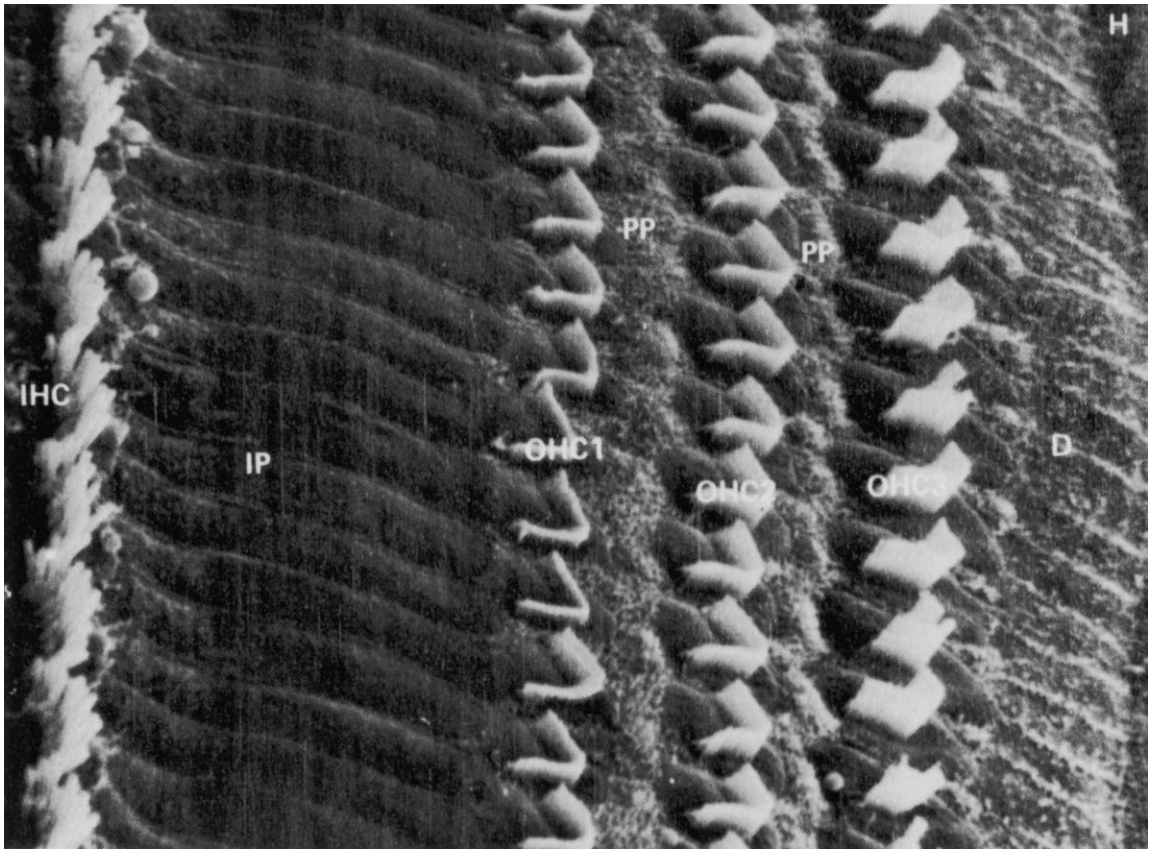

Figure 5 A scanning electron micograph showing the tops of the hairs and the stereocilla of the three rows of outer hair cells (OHC) and the one row of inner hair cells (IHC). H, IP, PP, and D are supporting structures within the cochlea (from Yost, 2000).

provide the neural code transmitted to the central auditory system by the auditory nerve. Each auditory nerve fiber is connected to a few inner hair cells and 90% of the auditory nerve fibers innervate the inner hair cells. The outer hair cells change size (primarily length) as a result of the vibration of the cochlear partition and the consequential outer hair cell stereocillia shearing. Because the length of the outer hair cells changes, this presumably alters the connections between the basilar and tectorial membranes, which would affect the biomechanical vibration of the cochlea. If the outer hair cells are damaged, the frequency selectivity and the sensitivity of the biomechanical vibration are compromised, suggesting the importance of outer hair cell motility in effective cochlear functioning. The fact that the outer hair cells are motile and this motility feeds back into the biomechanical action of the cochlea suggests that the outer hair cells provide an active mechanism that serves as a type of cochlear amplifier allowing the inner hair cells to provide a highly sensitive, very frequency selective, and compressively nonlinear code for the frequency, intensity, and timing of the acoustic input.

C. Auditory Nerve

Each auditory nerve fiber in the auditory portion of the VIII cranial nerve innervates a small number of inner hair cells, with nerve fibers near the center of the auditory nerve bundle coming from the cochlear apex and those on the outside of the bundle coming from the cochlear base. Thus, the fibers in the auditory nerve bundle are topographically organized on the basis of their cochlear innervation, and they transmit the neural code for sound from the cochlea to the cochlear nucleus in the auditory brain stem.

The neural response of auditory nerve fibers increases in firing rate over a 30- to 40-dB range. Each

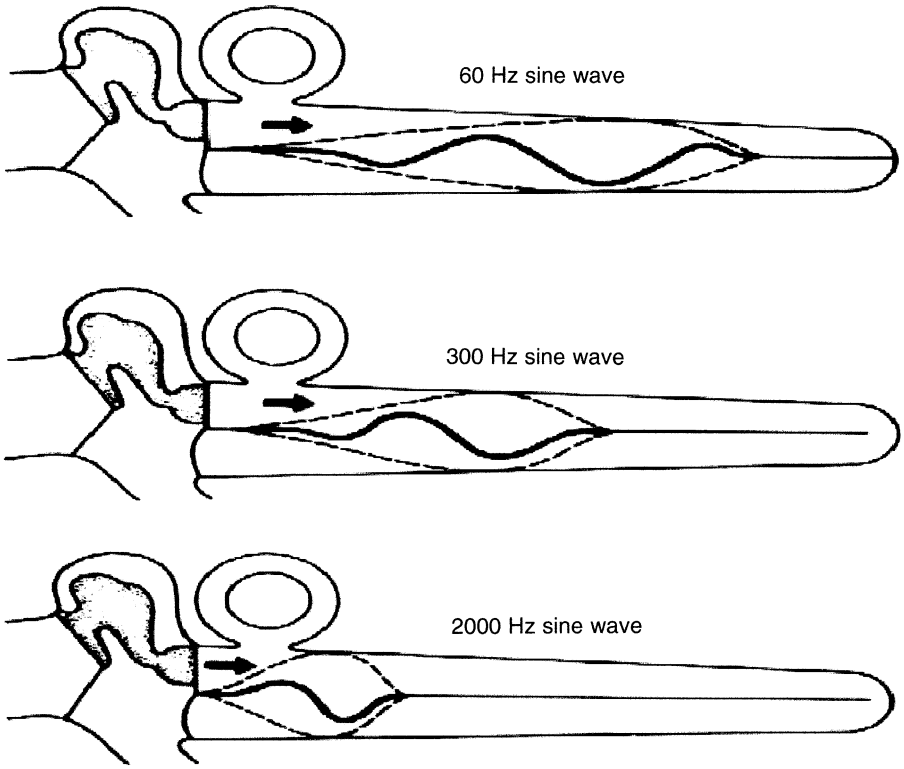

Figure 6 A schematic diagram of the traveling wave for three frequencies. The solid line is an instantaneous traveling wave, whereas the dotted curve represents the envelope of the traveling wave outlining its overall shape. The cochlea is shown as if it were unrolled. For low frequencies, the traveling wave travels to the apex, where maximal stimulation occurs. For high frequencies the wave travels a short distance from the base and maximal displacement is at the base (from Yost, 2000).

nerve fiber is highly selective to the frequency of the sound, reflecting the selectivity of the traveling wave (Fig. 7). Thus, each nerve fiber carries information about a narrow region of the spectrum and as such each fiber is tuned to a particular frequency. Because of the relationship between the location along the cochlear partition that each nerve fiber comes from and the activity of the traveling wave, auditory nerve fibers are tonotopically organized so that fibers near the middle of the nerve bundle carry information about low frequencies and those toward the outside of the bundle carry high-frequency information. The tuning curves of Fig. 7 are obtained by determining for each frequency the tonal level necessary to elicit a threshold neural discharge rate. The frequency that requires the lowest level to reach this threshold (the tip of the tuning curve) is the tuning curve's center frequency (CF).

The nerve fibers discharge in synchrony (Fig. 8) to the pressure waveform, such that the neural output represents a half-wave rectified version of the stimulus waveform. Thus, the neural output of the auditory nerve can follow the temporal structure of the waveform up to frequencies of about 5000 Hz. The upper frequency limitation of such temporal resolution is dictated by the refractory properties of neuronal function.

Figure 9 represents the output of a computational model that simulates the properties of the auditory periphery. Each line represents the aggregate neural response of fibers tuned to particular frequencies (low frequencies for fibers coming from the cochlear apex at the bottom of Fig. 9 and those for high frequencies coming from the cochlear base at the top). The model uses bandpass filtering to simulate the frequency selectivity of the tuning curves (Fig. 7), and a model of the hair cell–nerual interaction that provides a rectified, compressed, and adapted version of the filtered sound is used as the cochlear simulation. Thus, Fig. 9 represents the neural information flowing from the cochlea to the auditory brain stem for the vowel /e/, as in the word bead. The vertical bands of high output represent those fibers that are firing to the regions of

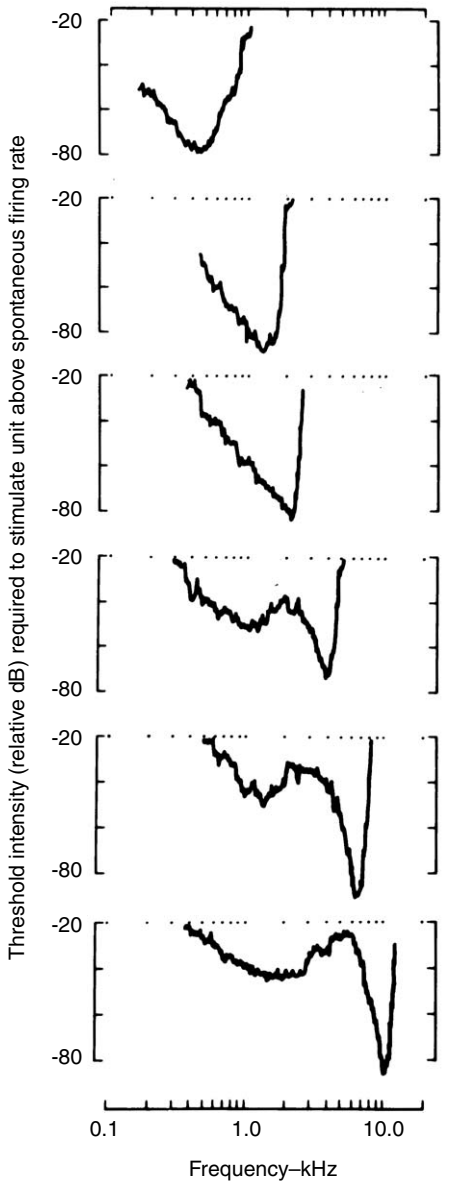

Figure 7 Tuning curves for auditory nerve fibers showing the responsiveness of different auditory nerve fibers to tones of different frequencies (from Yost, 2000).

the spectrum where the most energy occurs in the vowel's spectrum (i.e., the vowel formants), and the changes over time represent the temporal structure of the vowel waveform, most notably the periodic modulation due to the opening and closing of the vocal cords. Thus, Fig. 9 represents a simulation of the neural code for frequency, intensity, and timing provided by the auditory periphery.

III. THE AUDITORY BRAIN STEM AND AUDITORY CORTEX

The bilateral auditory neural pathway goes from the auditory nerve to the cochlear nucleus, the olivary complex, the inferior colliculus, the medial geniculate, and then the auditory cortex. There are numerous connections within and between these nuclei and from nuclei on one side of the brain to those on the other side. There is also a rich array of descending, efferent fibers that modulate the flow of neural information in the auditory pathway.

The tonotopic organization seen in the auditory nerve is preserved throughout the auditory brain stem and cortex, often being represented several times within a nucleus. The phase locking of neural elements to the temporal waveform is preserved in some centers but not in others. The exact nature of the tuning and phase locking can vary from nucleus to nucleus.

The cochlear nucleus (CN) contains three main regions (the dorsal cochlear nucleus, the anteroventral cochlear nucleus, and the posteroventral cochlear nucleus) with a rich array of neuronal cell types and physiological function. There is no detailed understanding of the auditory function of the CN, but there is ample evidence that there are strong inhibitory circuits that might provide a lateral inhibitory network for sharpening spectral contrasts in complex sounds. There are neurons and circuits that appear to integrate information both from auditory nerve fibers that carry similar information about the frequency content of sound (i.e., integrate information from neurons with tuning curves with similar CFs) and from auditory neurons that carry information about different frequencies in a sound (i.e., integrate information from neurons with tuning curves with different CFs). There are also circuits that preserve the exact temporal structure of complex sounds.

The olivary complex represents the first brain stem site at which there is strong bilateral convergence. Thus, the olivary complex [the medial superior olive (MSO) and the lateral superior olive (LSO)] is most likely responsible for the binaural processing of interaural time differences (in the MSO) and level differences (in the LSO) that are crucial for sound localization, especially in the horizontal or azimuthal plane.

The inferior colliculus (IC) is anatomically divided into three areas (central nucleus, dorsal cortex, and paracentral nucei). IC neurons appear to be tuned not only tonotopically but also to other stimulus conditions, such as the amplitude-modulated pattern of

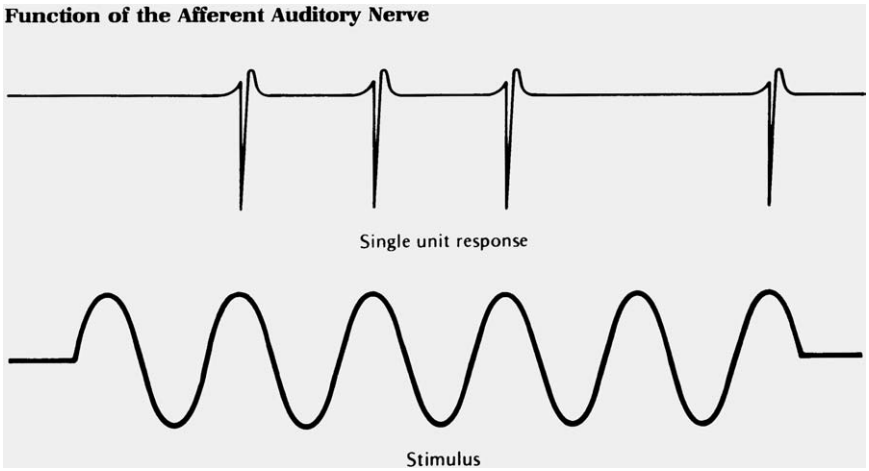

Figure 8 Auditory nerve discharges appear in synchrony with the stimulus waveform, such that when the nerve discharges it does so when the waveform reaches a peak (from Yost, 2000).

complex sounds and to the binaural cues of interaural time and level. It is possible that neural maps of auditory space might exist at the level of the IC. Work in the bat and the barn owl has provided useful models for better understanding the auditory function of the auditory brain stem.

The human auditory cortex is located deep within the Sylvian fissure and contains several areas, with A1 being the major auditory cortical center. As elsewhere in the auditory central nervous system, there is a rich array of fiber types and physiological responses in the cortex. Often, cortical neurons will only respond to particular stimulus waveforms (e.g., to a complex sound but not to a pure tone). However, with the exception of the barn owl and bat, the auditory function of different parts of the auditory cortex has not been well established. There is evidence that, like at the level of the IC, cortical neurons, perhaps organized in columns, are tuned to the amplitude modulation pattern. There is also evidence for auditory spatial maps in the auditory cortex.

The central auditory nervous system is a complicated system of many neural centers and countless number of interconnections that are organized in complex ways. It has been argued that the crucial information for hearing must be computed from the neural code provided by the auditory periphery, and the complexity of the central auditory nervous system represents the hardware for this computation.

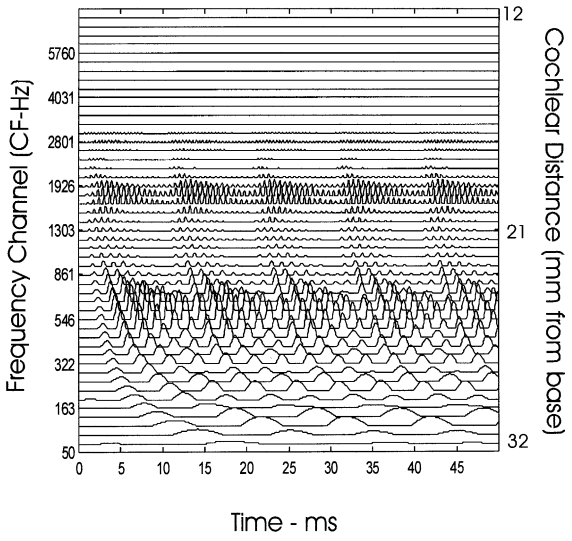

Figure 9 The output of a computational model of the auditory periphery indicating the neural code of the vowel /e/ that flows to the auditory brain stem. Each line represents the aggregate neural response of fibers tuned to the same frequency. Concentration of activity in the vertical direction represents the spectral code for hearing and structure in the horizontal direction represents the temporal code. The model simulates the actions of the outer ear and middle ears, the inner ear, and the auditory nerve.

IV. PERCEPTION OF THE SOUND FIELD

A. Absolute and Difference Thresholds

As noted previously, the key function of the auditory periphery is to code for the frequency, intensity, and temporal structure of sound. Auditory systems of all animals are sensitive to only a limited range of frequencies. Figure 10 displays the auditory thresholds

of humans to sinusoidal sounds of different frequencies. These thresholds of audibility can be obtained in one of two ways: The sounds can be presented over headphones [the minimal audible pressure (MAP) method] or over loudspeakers in a room with the listener [the minimal audible field (MAF) method]. When thresholds of audibility are measured, on average there is a 6-dB difference between MAP and MAF thresholds, which is due to diffraction of sound around the head and the calibration procedures used to obtain the MAP and MAF thresholds. The upper limit of hearing (e.g., the level at which sound becomes uncomfortably loud) is about 130 dB SPL. Thus, the dynamic range of hearing is about 130 dB in the frequency region between 500 and 4000 Hz. Humans can detect sound with frequencies ranging from 20 to 20,000 Hz, although hearing sensitivity, starting with the high frequencies, decreases with age.

The thresholds of hearing depend on the sound's duration. For durations less than approximately 300 msec, the energy of the sound determines threshold. Thus, long sounds require less sound power for detection than do short sounds. For durations greater than 300 msec, the ability to detect sinusoidal sound remains constant for signals of constant power. The duration at which the power of the signal no longer changes for detection threshold is used as an estimate of the integration time for detection.

Humans are sensitive to about a 0.2% change in frequency over a significant part of the range of hearing. For instance, one can discrimination between a 1000- and a 1002-Hz sinwave based on the frequency difference. An approximately 0.5-dB change in level is also discriminable over a significant part of the range of hearing. Thus, sensitivity to frequency and sound intensity (not expressed in decibels) is approximately proportional to frequency or level. This proportionality is referred to as Weber's fraction or law, and to a first approximation the auditory system displays a constant Weber fraction for frequency and level.

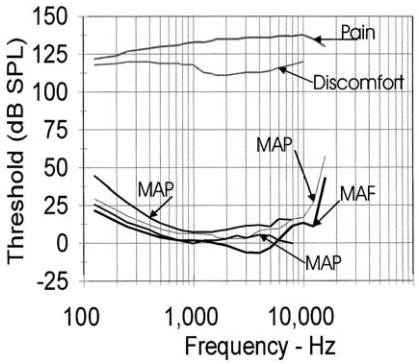

Figure 10 The absolute thresholds of hearing for MAP and MAF measures of audibility. Three different MAP measures are shown, representing measures with three different types of headphones. Thresholds of pain and discomfort are shown as estimates of the upper limit for the dynamic range of hearing.

The ability to discriminate sounds with changing levels from steady sounds is described by the temporal modulation transfer function (TMTF). The TMTF is measured by asking listeners to discriminate between a noise whose amplitudes are sinusoidally modulated and a noise with no amplitude modulation. The TMTF describes the depth of modulation (the difference in the changing amplitude) required to discriminate amplitude-modulated noise from unmodulated noise as a function of the rate of the amplitude modulation. The TMTF has a low-pass characteristic because as the rate of amplitude modulation increases beyond about 50 Hz the threshold for detecting amplitude modulation decreases. That is, it is more difficult to detect changes in the amplitude of modulated noise when the amplitude is changing faster than 50 times per second.

B. Masking

Most sounds do not occur in isolation. Sounds from different sources interact such that sound from one source may interfere with the detection of sound from a target or signal source (i.e., masking occurs). A masker only provides significant masking of the signal when the masker and signal have about the same frequency. Figure 11 shows results from a psychophysical tuning curve masking experiment. In the middle masking contour, the signal was a brief (10-msec), 1000-Hz tone presented at a low level, about 20 dB above its unmasked (absolute) detection threshold. The level of the masker is varied until the listeners in the experiment are at threshold in their ability to discriminate the signal-plus-masker presentation from the masker-alone presentation. At the tip of the psychophysical tuning curve, when the masker and signal have the same or nearly the same frequency, a very low-level masker interferes with discrimination, indicating an effective masker. When the frequency of the masker differs from that of the signal, a greater masker level is required for masked threshold, indicating that for these larger separations in frequency the masker is not an effective masker. Similar functions are

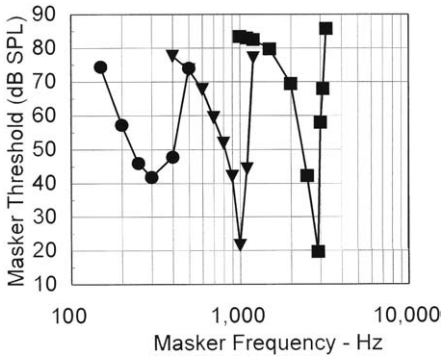

Figure 11 Psychophysical tuning curves for three signal frequencies [250 (●), 1000 (▲), and 3000 (■) Hz] showing the level of the tonal masker required for threshold detection of the tonal signal (from Yost, 2000).

obtained when the frequency of the signal is changed in different experiments.

These experiments suggest that only masker frequencies near that of the signal are critical for masking. A noise masker is a complex sound containing a continuum of frequencies. Experiments have been conducted in which the noise is filtered with a bandpass filter centered on the frequency of the sinusoidal signal and the detection of the signal is measured as a function of narrowing the bandwidth of the filter. The detection threshold remains constant until the filter bandwidth reaches a critical bandwidth, and further decreases in filter bandwidth lower the signal threshold, indicating that the signal is easier to detect. This result is consistent with the assumption that there is an internal filter centered on the signal frequency, and it is the power of the noise masker coming through the internal filter that determines signal detection threshold (Fig. 12). Several different types of noise-masking experiments can be performed to estimate the width of this internal, critical band filter. The width of the estimated critical band is proportional to signal frequency such that critical bandwidth increases with increasing frequency. The critical bandwidth is approximately 130 Hz wide when the signal is 1000 Hz, and it is 1100 Hz wide when the signal is 10,000 Hz. The similarity between the psychophysical tuning curves (Fig. 12) and neural tuning curves (Fig. 7) suggests that the internal, critical band filters are based on the tuning properties of auditory nerve fibers.

Maskers also mask signals occurring before a pulsed signal (forward masking) and after the signal (backward masking). For a fixed temporal separation between pulsed signals and maskers, there is usually more masking in forward than in backward masking.

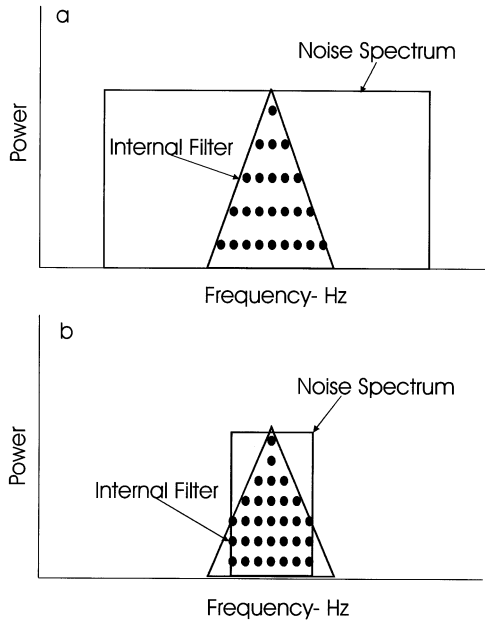

Figure 12 (a) The maximum power comes through the internal filter for a broadband noise resulting in maximal masking. (b) Less power comes through the internal filter for a narrowband noise resulting in less masking.

When the signal is shorter than the masker and when it occurs at the very beginning or the very end of the masker, there is more masking (masking overshoot) than when the brief signal occurs in the temporal middle of the masker.

C. Loudness and Pitch

The physical properties of sound include intensity and frequency. Subjective attributes of sound include loudness and pitch. Although loudness is highly correlated with intensity and pitch is highly correlated with frequency, changes in frequency can cause perceived loudness changes; similarly, changes in intensity can lead to perceptual differences in pitch.

Figure 13 displays equal loudness contours, where each contour represents the level and frequency of tones that are judged equally loud. For instance, the curve labeled 40 phons represents the levels and frequencies of tones that are all equal in loudness to a 40-dB SPL, 1000-Hz tone; the 80-phon curve represents the frequencies and levels required for equal loudness judgments to a 80-dB SPL, 1000-Hz tone. Equal loudness contours are used to define the phon as a decibel measure of loudness level. A tone that is x

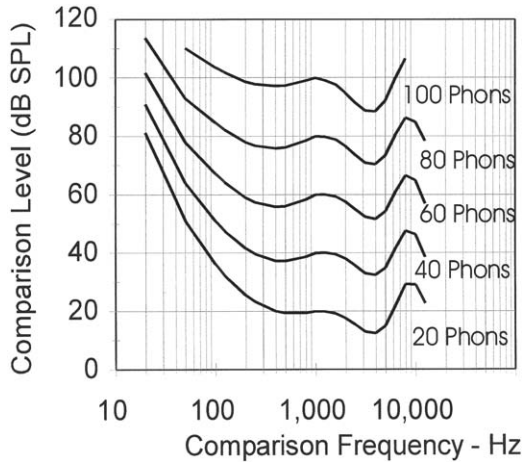

Figure 13 Equal loudness contours showing the level of a comparison tone required to match the perceived loudness of a 1000-Hz standard tone presented at different levels (20, 40, 60, 80, and 100 dB SPL). Each curve is an equal loudness contour. Based on International Standards Organization Standard ISO, R-532 (1981).

phons loud is judged to be equally loud to an x dB SPL, 1000-Hz tone.

Pitch is measured in hertz, and the most often used scales of pitch are musical scales. Musical scales are based on octaves, where an octave is a doubling of frequency (e.g., 440 to 880 Hz is one octave). The octave is divided into 12 equal logarithmic steps (semitones), with each semitone containing 100 cents. Thus, in a musical scale an octave is divided into 1200 logarithmic steps called cents. The musical note scale (A, B, C, D, E, F, G with or without sharps and flats) is also used as a pitch scale.

The perception of pitch exists even when there is no energy in a sound's spectrum at frequencies that correspond to the perceived pitch. These pitches are often referred to as complex, virtual, or missing fundamental pitches. The latter name is derived from the following type of stimulus conditions: a complex sound consisting of six tones added together with equal levels and with frequencies of 400, 500, 600, 700, 800, 900, and 1000 Hz. Independent of the phases of the individual tones, this complex sound has a salient perceived pitch of 100 Hz. Note that all the tones are harmonics of 100 Hz (integer multiples of 100 Hz), but 100 Hz is "missing" (hence the term missing fundamental pitch). Also note that there is no energy in this sound's spectrum in the region of the reported pitch (100 Hz). The temporal waveform of this stimulus can produce an amplitude modulation of 100 Hz, but neither simple measures of the periodicity of the amplitude modulation nor those of the spectral structure of these complex sounds are able to predict complex pitch, suggesting that pitch processing involves more complex operations than simple temporal or spectral mechanisms.

Due to the nonlinear properties of the transduction of sound by the auditory periphery, pitches associated with nonlinear distortion products are often perceived. For instance, a complex sound consisting of 700- and 1000-Hz, equal-amplitude tones may produce pitches in addition to those of 700 and 1000 Hz. In many conditions, listeners also report pitches of 400, 1400, and 2000 Hz for primary stimuli with frequencies of 700 and 1000 Hz. The pitches of 400, 1400, and 2000 Hz are nonlinear distortion products caused by nonlinear peripheral transduction. The 1400- and 2000-Hz pitches are aural harmonics (the second harmonics of 700 and 1000 Hz). The 400-Hz pitch results from the cubic difference tone, which is twice the lower frequency minus the higher frequency ($2f_1 - f_2 = 2 \times 700 - 1000 = 400$). The cubic difference tone is often the most salient distortion product.

Sounds can have many other subjective attributes. The spectral complexity of sound is often correlated with a sound's timbre. Sounds differ in timbre if the sounds are perceived as different even though they have the same perceived loudness, pitch, and duration. Thus, the perceptual difference between a violin and viola playing the same musical note, with the same loudness and duration, is a timbre difference.

V. AUDITORY SCENE ANALYSIS

Previous sections described the perceptual attributes of the sound field but did not discuss the cues used to determine sound sources, especially when there are many sound sources. In addition to each sound source contributing perceptual attributes to the sound field, the spatial location of sound sources can be determine based on sound alone. Clearly, spatial separation could be one cue used to determine sound sources. Other cues include temporal modulation, spectral profiles, harmonicity and temporal regularity, and onsets and offsets.

A. Spatial Hearing

The location of a sound source can be determined entirely on the basis of the sound produced by the source despite the fact that sound does not have spatial properties. A sound source can be located in each plane

in three-dimensional space (azimuth or the left–right plane, vertical or the up-down plane, and distance or the near–far plane). It appears that the auditory system uses different acoustic cues to compute the source's location in each plane.

A sound arriving at a listener's ears from a source lying in the azimuth plane will reach one ear before it reaches the other ear, resulting in an interaural time difference that increases as the sound source is moved further away from midline toward one ear. The sound arriving at the far ear will be less intense than that arriving at the near ear because for a wide range of frequencies the head produces a sound shadow lowering the level at the distal ear. As with the interaural time difference, the interaural level difference also increases as the sound moves in azimuth toward one ear. Thus, interaural time and level differences are the cues used to locate sound sources in the azimuthal plane. At midline, sound sources separated by as little as 1° of visual angle can be discriminated. Interaural time differences as small as 10 microseconds and interaural level differences as small as 0.5 dB can be discriminated. Due to the interaction of sound with the dimensions of the head, the interaural differences are frequency dependent, such that sound sources producing sounds with low frequencies or slow amplitude modulations are located on the basis of interaural time differences, and sounds produced with high frequencies are located on the basis of interaural level differences (the duplex theory of sound localization).

If the head does not move, a sound directly in front of a listener will produce no interaural time and level differences, as would all sounds lying on a plane that runs from in front to directly overhead, directly behind, and directly below (this vertical, midsagital plane is one cone of confusion in which all locations on a cone of confusion produce the same interaural differences). If interaural differences were the only cues used for sound localization, then all sound sources located on a cone of confusion would be perceived at the same location. Although differentiating sound sources located on cones of confusion is more difficult when the head is kept stationary than when it is not, sound sources located at different points on a cone of confusion are perceived at different spatial locations. Thus, cues in addition to interaural differences appear necessary for determining vertical location.

The HRTF described previously occurs because the spectrum of a sound traveling from a source to the tympanic membrane is altered by the body structures (especially the pinna) that the sound must pass over. The spectral alteration and, hence, the spectral characteristics of the HRTF depend on the location of the sound source relative to that of the body and head. The HRTF therefore contains potentially useful information about sound source location. The spectral alterations resulting in the HRTF, especially in high-frequency regions, provide cues for vertical sound localization. In particular, there are HRTF spectral valleys and peaks in regions above 3000 Hz that vary systematically as a function of vertical location. These high-frequency HRTF spectral valleys and peaks are the potential cues for vertical sound location.

Sound location acuity is best in the azimuth plane, poorer in the vertical direction, and even poorer for judgments of distance. The distance of a source can be inferred from loudness differences, assuming one compensates for the other variables that cause a sound's level to change. Distance location is also dependent on the ratio of reflected sound (in reverberant environments) to the amount of sound coming directly from the source. The more relative reflected sound there is, the closer the sound is likely to be.

Most animals locate sounds in reverberant spaces very well, suggesting that the source of the actual sound is not often confused with the location from which reflections (echoes) occur. The sound from the source will reach the listener before that from any reflection because the path of the reflected sound is longer. Thus, our ability to locate sound sources accurately in reverberant environments is most likely due to the earlier arriving sound from the source taking precedent over later arriving reflected sound. Indeed, studies of the precedence effect (or law of the first wavefront) suggest that later arriving reflected sound is suppressed relative to earlier arriving direct sound.

Sounds presented binaurally over headphones are often lateralized within the head as opposed to being localized in the external environment. However, if careful attention is paid to altering the stimuli to reflect the spectral complexity of the HRTF before presenting sounds over headphones, then listeners can perceive virtual sounds in the external environment at locations appropriate for the HRTF-altered stimuli delivered to both headphones.

Segregating different sound sources might be aided by our sound-localization abilities. The ability to determine sound sources based on spatial separation has been referred to as the "cocktail party effect," referring to our ability to attend to one voice at a cocktail party out of many voices and other competing sounds sources. The threshold for detecting a masked signal presented with one set of interaural differences of time and level is lower if the masker has a different

set of interaural differences than if the signal and masker share the same interaural differences. Since interaural differences are used to determine a sound's azimuthal location, the stimulus conditions described previously can be restated: The signal is at one azimuthal position and the masker at another. Thus, the signal is easier to detect if it is at a different location than the masker. The difference in detection thresholds due to interaural differences of time and level between the signal and masker are referred to as binaural masking-level differences (BMLDs or MLDS). MLDs suggest that spatial separation can serve as an aid for sound source determination. However, spatial separation by itself is not a necessary and sufficient condition for sound source determination. The sound of an orchestra recorded by a single microphone played over a single headphone will provide no interaural differences, and yet such a condition interferes little with one's ability to identify the musical instruments (sound sources) in the orchestra.

B. Temporal Modulation

Sounds from most sources vary in amplitude (amplitude modulation) and/or frequency (frequency modulation) over time, and often the modulation of one sound source may differ from that of another sound source. Thus, in some cases the ability to process sound from a source must be resilient to modulations, and in other cases differences in modulation might help segregate one sound source from another. It appears as if frequency modulation per se is not a useful cue for sound source segregation, but amplitude modulation may be.

Much the work on auditory scene analysis has been done in terms of a paradigm referred to as auditory stream fusion or auditory stream segregation. A typical experiment may involve two tones of different frequencies (f_1 and f_2) that are turned on and off (turning a sound on and off is a form of amplitude modulation). Suppose that a tone of frequency f_1 is turned on and off out of phase with a tone of frequency f_2. Thus, the frequencies alternate back and forth between f_1 and f_2. Under some conditions, listeners report that they perceive a single sound source whose pitch is alternating. In other conditions, they report perceiving two separate sound sources, each with its own pulsating pitch, as if there were two auditory streams consisting of the two sources running side by side. The conditions that lead to stream segregation (the perception of two sources) as opposed to stream fusion (one source) provide valuable information about the cues that may be used by the auditory system to sort the various sound sources in a complex auditory scene. Spectral differences are potent for stream segregation, but differences in spatial parameters (e.g., interaural time differences), modulation patterns, and timbre can also support auditory stream segregation.

Sounds that share a common pattern of amplitude modulation (AM) are most likely produced by a single sound source than by different sources. Thus, common AM is a potential cue for sound source determination. When a complex masker contains two spectrally separated masking stimuli (e.g., two narrow bands of noise in different regions of the spectrum), the detection of a signal whose frequency is at the spectral center of one of the maskers is dependent on the similarity of the pattern of AM imposed on the two masking stimuli. If both masking stimuli have the same AM pattern (the maskers are comodulated), then detection threshold is lower than if the AM patterns are not the same (maskers are not comodulated). The difference in detection threshold due to comodulation is called comodulation masking release (CMR), as shown in Fig. 14. Models of CMR often assume that comodulation aids the auditory system in determining the quiet periods in the masker when the signal would be easier to detect.

Another example of the role of common amplitude modulation concerns the detection of a change in the depth of AM (not unlike experiments measuring the TMTF). The ability to detect a change in the depth of AM of a tone with a particular carrier frequency (probe tone) is not changed if a second, unmodulated tone, of a different carrier frequency is added to the probe tone. Since tones of different frequencies do not interfere with each other in masking experiments, this is not a surprising outcome. However, if the two tones are modulated with the same pattern, detection of the depth of AM imposed on the probe tone is more difficult, as shown in Fig. 15. The elevation of the threshold for detecting a change in AM depth due to comodulation is referred to modulation detection interference (MDI). It is as if the common modulation fuses the two tones as being produced by a single source, making it more difficult to process the AM of either component of this single source. If so, making the modulation patterns different should no longer allow the two tones to be fused as if they were produced by a common source and the amount of MDI should decrease, which is what happens as shown on the right of Fig. 15.

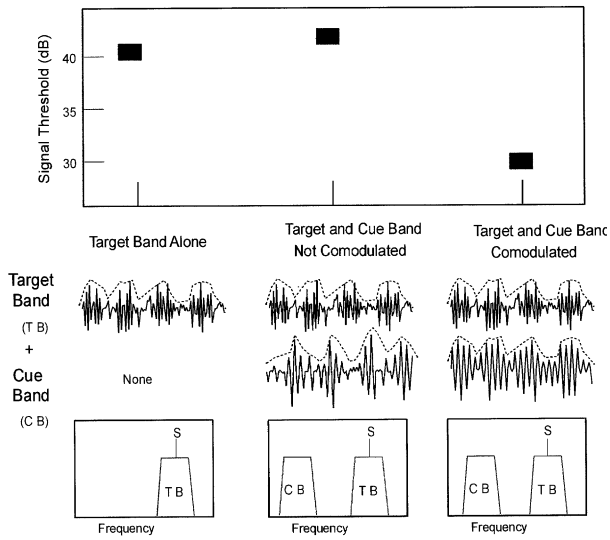

Figure 14 Both the basic CMR task and results are shown. (Bottom) The time domain waveforms for the narrowband maskers (target and cue bands) and the amplitude spectra for the maskers and the signal are shown in a schematic form. The dotted line above each time domain waveform depicts the amplitude modulated envelope of the narrowband noises. The listener is asked to detect a signal (S) which is always added to the target band. In the target band-alone condition, the signal is difficult to detect. When a cue band is added to the target band such that it is located in a different frequency region than the target band and has an amplitude envelope that is different (not comodulated with) from the target band, there is little change in threshold from the target band-alone condition. However, when the target and cue bands are comodulated, the threshold is lowered by approximately 12 dB, indicating that the comodulated condition makes it easier for the listener to detect the signal. The waveforms are not drawn to scale (from Yost, 2000).

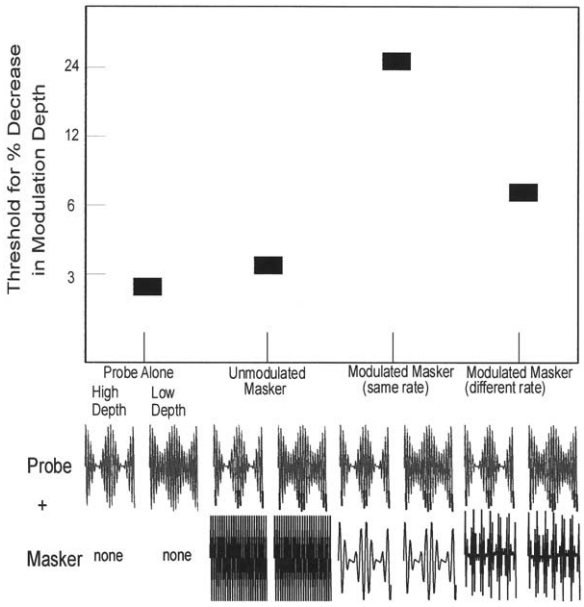

Figure 15 Both the basic MDI task and results are shown. The basic task for the listener is depicted at the bottom. The listener must detect a decrement in the depth of probe amplitude modulation (difference between low and high depth). When just the probes are presented, the task is relatively easy. When an unmodulated masker tone with a frequency different from that of the probe is added to the probes, thresholds for detecting a decrease in probe modulation depth are not changed much from the probe-alone condition. However, when the masker is modulated with the same rate pattern as the probe, the threshold for detecting a decrement in probe modulation depth increases greatly, indicating that modulation depth is difficult to detect when both the probe and the masker are comodulated. When the masker is modulated, but with a different rate (shown as a faster rate in the figure) than that of the probe, the threshold for detecting a modulation depth decrement is lowered. The waveforms are not drawn to scale (from Yost, 2000).

Experiments in CMR and MDI demonstrate the ability of the auditory system to integrate information across a sound's spectrum and experiments in stream segregation describe temporal integration over time. Both spectral and temporal integration are requirements for analyzing complex auditory scenes in the real world.

C. Spectral Profiles

The spectrum of the sound from one source will differ from that of another source. Experiments in spectral profile analysis measure the auditory system's sensitivity to changes in the amplitudes of the spectral components of a complex sound. The schematic diagrams on the bottom of Fig. 16 display different spectra used in a spectral profile experiment. The spectra consist of several tonal components logarithmically spaced in frequency. As can be seen, the center frequency component has a greater level than the flanking components. The listener's task is to discriminate between presentations of spectral profiles in which the center component has a level increment and complex sounds in which all components have the same level. The level of the increment in the center component is adjusted until threshold discrimination is achieved. A key element in these experiments is that the overall level of each complex sound is randomly varied over a very large range. The overall level of randomization makes it difficult for the listener to use the overall change in stimulus level or the change in level of just the level-incremented component (the center component) as the cues for discrimination. The listener appears to use the relative change in level that exists in the complex. That is, the change in level of the center component compared to the other, equal-level

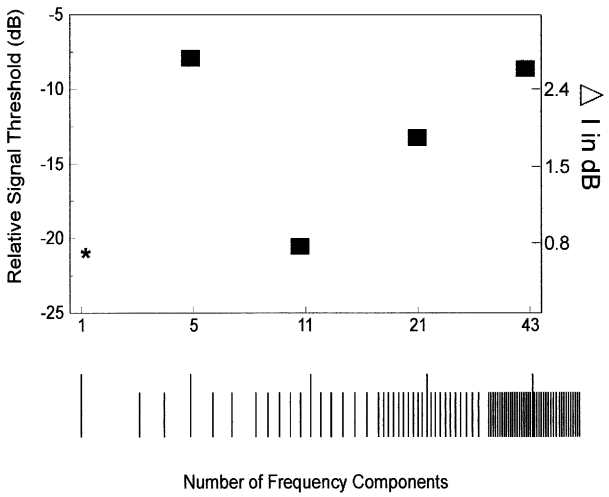

Figure 16 Results from a profile analysis experiment in which the number of masker frequency components surrounding a 1000-Hz signal component increased from 4 to 42. The thresholds for detecting an increment in the 1000-Hz signal component (the center component) are shown in decibels relative to that of the rest of the masker component intensity. The asterisk indicates the typical threshold for detecting a level increment of a single, 1000-Hz tone. The level of the signal is expressed in terms of the signal-to-background level. (from Yost, 2000).

side frequency components is the discrimination cue. As the data in Fig. 16 show, listeners are almost as good at detecting the change in relative level of the center component of the complex sound when there are 11 components as when this center component is presented as a single sound with no flanking components. When there are a few widely spaced components it is more difficult to judge the relative level change. When there are many, densely packed components, discrimination is also difficult, most likely because the components are close enough in frequency to directly mask each other. Studies of profile analysis describe the stimulus conditions that allow the auditory system to detect small changes in spectral shape that would be crucial for sound source determination.

In profile experiments the overall level was randomized. If other forms of randomization are used to make the stimulus conditions vary from trial to trial (e.g., the frequency content of a masker is varied from stimulus to stimulus), there is often considerably more masking than when the uncertainty about the stimuli is small. The extra masking resulting from stimulus uncertainty is referred to as informational masking, distinguishing this form of masking from that which occurs due to the direct interaction of the masker and signal.

D. Harmonicity and Temporal Regularity

Many sound sources vibrate with a fundamental frequency having many harmonics (e.g., voiced speech, musical instrument, and sounds from motors). These harmonically related spectra usually have temporally regular waveforms. As discussed previously, stimuli with harmonic structure or temporal regularity often produce a complex pitch. This unitary pitch can be used to characterize a complex sound. However, it is not always the case that mixing two complex sounds, each with a different fundamental, results in the perception of two pitches that could be used to segregate the two complexes. For instance, a sound source consisting of a 300-Hz fundamental and its harmonics could be mixed with a sound source consisting of a 410-Hz fundamental and its harmonics. In many situations, the auditory system does not analyze the complex mixture into two sources, one with a 300-Hz pitch and one with a 410-Hz pitch. In these cases, the auditory system appears to process the complex mixture synthetically.

In other conditions, a change in the fundamental component of a complex sound can be an aid to sound source segregation. For instance, if two different speech vowels are computer generated so that they have the same fundamental frequency (reflecting the periodicity of the vibrating vocal cords), listeners may have difficulty identifying the two vowels. However, when the two vowels also have different fundamental frequencies, vowel identification is possible. Thus, harmonic relationships and temporal regularity can be cues for sound source determination, but not in all cases.

E. Onsets and Offsets

A powerful cue for segregating one sound source from a mixture of other sounds is temporal asynchrony. If the sound from one source begins or ends at a different time than other sounds from other sources, the differences in onsets or offsets allow listeners to determine the various sound sources. For instance, in the case described previously in which listeners may not perceive two complex pitches (e.g., 300 and 410 Hz) when two different harmonically related stimuli are mixed, listeners report perceiving the two pitches if one complex harmonic stimulus is presented slightly before the other stimulus. Although both stimuli may be played together for most of their duration, a small onset asynchrony can assist complex pitch segregation.

The onset (attack) and offset (decay) characteristics of the playing of many musical instruments are crucial variables for the characteristic timbre of the instruments. These timbrel differences can also aid sound source segregation. The ability to represent the proper attack and decay properties is a key element in musical instrument synthesis.

Thus, the auditory system appears to compare information across the spectrum of sound and over time to process complex sounds so that sound sources can be determined and segregated one from the other. Interaural differences, amplitude modulation, harmonicity, temporal regularity, relative amplitude differences (spectral profiles), and common onsets and offsets are some of the variables that allow the auditory system to determine sound sources in our environment, especially when several sound sources exist at the same time.

GLOSSARY

cerebellum Also known as the "little brain," the cerebellum is divided by the primary fissure into anterior and posterior lobes. Other fissures further segment these lobes into several smaller lobules. A thin longitudinal strip traverses the midline and is known as the vermis. The cerebellar cortex contains several different neuron types, including Purkinje neurons, the sole output source. Functionally, the cerebellum has been traditionally viewed as involved only in motor control; however, a new understanding has come to include multiple cognitive functions, such as language and attention.

chromosomes Long thread-like associations of genes found in the nucleus of all eukaryotic cells. Chromosomes consist of DNA and protein.

event-related potential technique A neuroimaging method that records electrical activity from the scalp via electrodes as an individual performs a task. Signal amplitudes and latencies are believed to represent net electrical fields associated with the activity of a population of neurons.

functional magnetic resonance imaging A neuroimaging technique that uses the differing magnetic susceptibility of oxyhemoglobin and deoxyhemoglobin in the blood to detect when and where oxygen is used in the brain, typically as an individual performs a cognitive task.

gene A sequence of DNA that indirectly produces a protein and is located on chromosomes.

genetic linkage analysis with disorder loci The preferential association of a particular gene, or set of genes, with a particular disorder than would be expected by chance alone.

gliosis The presence of glial cells in unexpected locations in neuronal tissue usually as the result of injury or insult.

limbic system A constellation of cortical and subcortical brain structures thought to be instrumental in memory and emotion. Traditionally, the limbic lobe includes the parahippocampal gyrus, the cingulate gyrus, and the subcallosal gyrus; subcortical structures include the hippocampus, amygdala, and parts of the hypothalamus.

magnetic resonance imaging A noninvasive technique used to produce high-resolution images of body tissues, especially soft tissues such as the brain. A large magnet is used to polarize hydrogen atoms in the tissues and radio frequencies are used to measure the nuclear magnetic resonance of the protons within the tissue.

pleiotropy The condition in which a single gene or gene pair exerts effects on multiple functions and/or in multiple cell types often at different times.

repetitive behaviors and stereotyped patterns Interests, motor movements (e.g., arm flapping and rocking), and rituals that are performed repetitively and inflexibly and do not serve any apparent function.

Autism is a biological disorder with a clinical onset in the first years of life that persists, to varying degrees, throughout life. It is characterized by abnormality in reciprocal social interaction, communication, and language development as well as by repetitive and stereotyped behavior. These abnormalities are caused by defects in multiple areas of the brain. The prevalence is 1:600, making it one of the most common neurobiological disorders of infancy and early childhood. It is one of five pervasive developmental disorders (PDDs), along with Rett's syndrome, Asperger's syndrome, child-

hood disintegrative disorder, and pervasive developmental disorder not otherwise specified (PDD-NOS), listed in the *Diagnostic and Statistical Manual IV*. Taken together, the prevalence of a PDD is 1:160. The degree to which autism, Asperger's, and PDD-NOS disorders with behavioral profiles that overlap, may be variants on a single biological theme, or constitute unique etiologies, is still under debate.

I. INTRODUCTION

Leo Kanner first described the developmental disorder known as autism more than 50 years ago. Although his central observations of social aloofness, linguistic abnormalities, and restricted interests in individuals with this disorder are still valid, a new understanding of autism has come to include the idea of heterogeneity; differences in symptom profile and severity, onset, collateral conditions, and potential etiologies as well as developmental course and outcome vary considerably both within and across individuals with this disorder. It is this heterogeneity that not only makes autism an interesting and complex disorder but also provides clues to an appropriate scientific path for investigating this disorder. Tying this work together has been the relatively new use of structural magnetic resonance imaging (MRI) and functional neuroimaging technologies [functional MRI (fMRI), positron emission tomography (PET), and event-related potential (ERP)] that afford insights into the neurobiology that mediates the complex symptom profile seen in affected individuals. Data from structural *in vivo* MRI and autopsy studies support the idea that autism is a disorder with multiple loci of neuroanatomic abnormality; some individuals show abnormalities in the amygdala, frontal lobes, parietal lobes, hippocampus, corpus callosum, and brain stem, whereas others do not. Several brain regions, such as temporal and occipital lobes, have yet to be thoroughly investigated. One structure, the cerebellum, has been shown to be abnormal in 95% of the cases studied at autopsy, a consistency not found with any other structure. However, cerebellar defects cannot singly account for the diverse symptoms seen in autism but, rather, may act in concert with dysfunction in other neural systems. It is the idea of multiple damaged systems operating in a behaviorally and biologically heterogeneous disorder that forms the foundation for the discussion of autism that follows.

II. CLINICAL ONSET AND DIAGNOSIS

A. Characteristics in the First Years and Clinical Onset

Despite the almost complete consensus that autism is a disorder with a biological onset prenatally or shortly after birth, behavioral indicators during the first 2 years of life are elusive. Difficulties in developing a clinical profile of autism at such young ages are due to the fact that most children do not receive a diagnosis until age 2–4; therefore, reliable early indicators may be missed. Some information, however, has been made available based on retrospective analyses of home videos taken of children before the diagnosis of autism has been made. Such retrospective videotaped studies have demonstrated that autism can be distinguished from normal at least as early as 1 year based on differences in social behaviors, such as looking at the face of another or orienting in response to his or her name, and in joint attention behaviors, such as pointing, showing objects to others, and alternating gaze between object and person. Given that these types of social and joint attention behaviors may not yet be present or are difficult to reliably assess in young infants (e.g., 3 months of age), scientists are now searching for indicators for infants at risk for autism. It is well-known that the cerebellum is critical for motor control and, combined with the finding that the majority of individuals have cerebellar abnormalities, it has been suggested that one potential early indicator may relate to observable motor executions. Investigations of motor patterns can be easily assessed in newborns and infants, and new research in fact suggests that abnormalities in motor behavior may be seen as early as 4 months of age in infants later diagnosed as autistic. Specifically, deviancies in major motor milestones, such as lying, righting, sitting, crawling, and walking, have been reported based on precise movement analysis systems (e.g., Eshkol–Wachman). Although only one study has utilized movement analyses, results indicated that all autistic infants studied showed some form of movement abnormality. It is quite possible that early behavioral indicators of autism may be found in basic perceptual and motor systems.

1. Neurobiological Findings and Hypotheses

Currently, the strongest evidence addressing the question of the time of biological onset comes from

postmortem and MRI evidence indicating that cerebellar and brain stem anatomical abnormalities most likely have a prenatal onset. Reduction in Purkinje neuron numbers is typically present without accompanying gliosis, a finding indicative of an early (prenatal or early postnatal) onset for this defect. In the first prospective MRI study of autism, Hashimoto and colleagues found cerebellar vermis hypoplasia in infants who were subsequently confirmed to be autistic. Regression analyses of growth curves for the neocerebellar vermis in autistic patients indicate a perinatal or prenatal onset of the vermis hypoplasia. Finally, evidence from a single postmortem autism case has been interpreted as an indication that maldevelopment in the brain stem may begin as early as the first trimester.

B. Diagnosis

Although biological abnormalities are becoming increasingly better understood in autism, currently this disorder is diagnosed exclusively based on behavioral characteristics. Traditionally, the *Diagnostic and Statistical Manual IV* (*DSM-IV*) has been the guide used for making diagnostic decisions about the presence or absence of autism. A burgeoning interest in early identification in autism, however, has prompted the need for instruments that will both reliably and validly diagnose autism at the youngest ages possible. The ability for the *DSM-IV* to meet this need has been questioned by many scientists. For example, part of the *DSM-IV* criteria relates to language abnormalities, and given that language is minimal at young ages (for both autistic and normal children), children suspected of having autism could not be reliably diagnosed with this instrument. In order to meet this need, a relatively new diagnostic tool, the Pre-Linguistic Autism Diagnostic Observation Schedule (PL-ADOS) developed by Catherine Lord and colleagues, has been utilized with children suspected of having autism and can be used to reliably diagnose autism as young as 18 months of age. The PL-ADOS is distinct from the *DSM-IV* because it focuses on behaviors that are indicative of young children with the disorder, such as abnormalities in gesture or joint attention.

Early identification in autism is essential not only for early treatment but also for investigations of neurodevelopmental processes in autism. The overwhelming abundance of past research has concentrated predominantly on samples of adults with autism. The use of diagnostic tools with toddlers suspected of having autism, such as the PL-ADOS, for the first time allows researchers not only the ability to obtain information at young ages in the disorder but also, the opportunity for longitudinal investigations of behavioral and neurobiological growth and development, beginning at a period when brain development in autism is not only quite active but also undiscovered.

III. SYMPTOM PROFILE AND NEURAL BASES

A. Social Abnormalities

1. Characteristics

When Leo Kanner was deciding on a name that might most aptly characterize his original 11 cases, he chose the term autism, derived from the Greek work ''autos'' or self. His choice likely emerged from the strong sense of a preference for isolation, or the self, to the company of others observed in all his cases.

Indicators of social abnormalities are noted early in autism, quite often as early as the first few months of life. Parents often remark that as infants, their autistic children stiffened when held, failed to make prolonged eye contact, and did not cry for help or consolation. A robust early indicator of social abnormality is a near absence of joint attention, or the coordination of attention between object and person, a skill that emerges in normal infants toward the end of the first year of life. As a category, joint attention behaviors may include pointing and showing objects and the use of eye contact and direction of visual gaze to and from an object and person. Normal infants and toddlers use such gestures regularly. Autistic infants and toddlers, on the other hand, rarely use such gestures and, given that joint attention is considered a precursor to normal language development, it is not surprising that this deficit compounds into not only later deficits in social behavior but also severe deficits in language development.

As the autistic infant matures, social abnormalities become even more apparent and include decreased rates of eye contact, difficulties in expressing and identifying emotion, lack of social initiations, lack of maintaining interactions with others, and lack of an ability to demonstrate empathy. Early studies of social abnormality in autism were largely quantitative: Children with autism were shown to initiate interactions, play with peers, make eye contact, or maintain prolonged interactions with others less than normal

children. Current investigations of social behavior have not only refined and brought greater detail to our understanding of the nuances involved in social dysfunction in autism but also aim to test psychological theories or hypotheses about the role that such abnormalities might play in the course of the disorder.

One such example comes from the idea that individuals with this disorder either lack or have an underdeveloped "theory of mind" (TOM), or an inability to develop mental representations for the contents of other people's minds. By age 4, normal children can typically correctly perform simple TOM tasks, whereas most autistic individuals, with mental ages at or above 4 years, cannot, suggesting that this deficit may not be due solely to general developmental delay. Social intelligence, or TOM, comprises our ability to interpret others' mental states (thoughts, desires, beliefs, and intentions), to use this information to interact in groups, to empathize, and to predict others' thoughts and behaviors. The TOM hypothesis of autism, posited by Simon Baron-Cohen, speculates that not only is this deficit central to the symptomatology of autism and may explain social, communicative, and imaginative abnormalities but also it may be independent from general intelligence.

2. Brain–Behavior Findings

Social dysfunction in autism is severe and persistent and likely involves abnormalities in multiple neural regions, including those involved in face perception, emotion processing, orienting to social cues, and attention regulation. New functional neuroimaging studies provide the first evidence that one brain region traditionally involved in face perception (i.e., fusiform gyrus), an important constituent of social behavior, may have abnormally reduced levels of functional activation in autism (Fig. 1). Furthermore, it appears that activation to faces may instead aberrantly occur in neighboring regions or atypical locations within the fusiform gyrus; the reason for such functional relocation is unclear. One possibility is that limited exposure to faces in patients with autism (perhaps due to innate preference, biases of processing style, or learning) results in an underdevelopment or maldevelopment of face processing systems. Interestingly, recent research has reported increased fusiform gyrus activation after normal subjects were trained to be experts in identifying a novel set of nonsense objects, suggesting that the fusiform gyrus may be an area involved in the processing of extremely familiar objects or objects associated with a particular area of expertise, such as faces. In autism, limited social interactions, and eye contact in particular, could then explain decreased rates of fusiform activation. If so, early intervention strategies could be developed to help autistic toddlers and children acquire the necessary "expertise" for more normal utilization of this cortical region.

The amygdala is necessary to recognize the emotion of fear and blends of emotions, information critical to engaging in successful social interchanges. Anatomic abnormality (increased neuron density) of the amygdala has been described by one research group in nine postmortem autism cases, and two *in vivo* MRI studies have reported reduced amygdala volume in a small sample of adolescent patients. Although not conclusive, such initial evidence of structural defect in the amygdala sets the stage for future anatomic research and functional neuroimaging studies aimed at confirming and further elaborating its role in emotional processing deficits in autism.

Anatomic and functional defects in a third structure, the cerebellum, may contribute to deficits in orienting to social cues and regulating attention during rapid social interchanges when the source of critical social, emotional, and linguistic information shifts. Studies of autistic children show that they orient more slowly than normal to social as well as nonsocial stimuli and that the greater the impairment, the greater the cerebellar anatomical abnormality as measured by MRI. fMRI and ERP studies also show that the cerebellum plays a role in the rapidly shifting attention between different sources of sensory information and that, like patients with acquired cerebellar lesions from stroke or tumor, autistic children and adults are slow to shift attention and miss information as a consequence. Moreover, autistic patients, as well as patients with acquired cerebellar lesions, are missing at least two neurophysiological responses associated with redirecting attention—one that signals frontal cortex to orient (Fig. 2) and another that may signal posterior cortical structures to disengage and redirect attention to a new spatial locus or sensory modality.

An important caveat to both current and future fMRI research on social abnormalities in autism is that individuals with autism have less social experience than their normal peers, thus making claims about the functioning of neural regions difficult to interpret. Furthermore, tests of social intelligence frequently have complex attentional demands, yet another area of considerable difficulty for individuals with autism. Nonetheless, because social functions are markedly maldeveloped in autism, brain–behavior studies of this

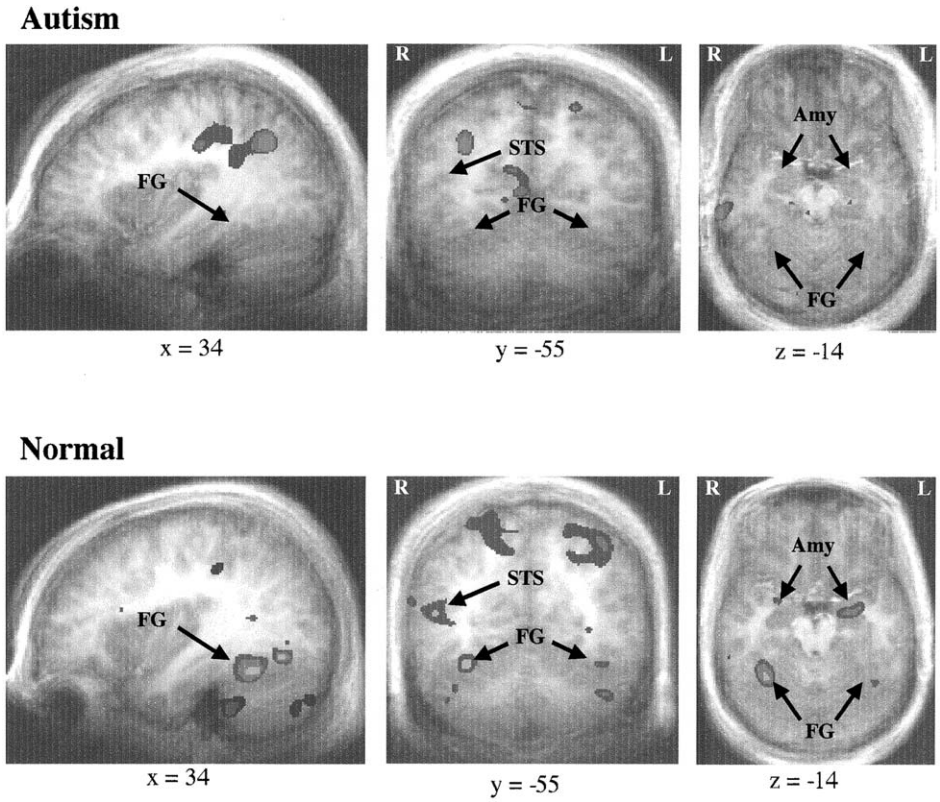

Figure 1 Within group t-maps for both autism and normal groups showing significant regions of activation. Note fusiform, superior temporal sulcus and amygdala activation in normals, in comparison to a lack of positive activation in the autism group. Decreased functional activity in the autism group is likely due to the inconsistent patterns of activation noted across individual autism subjects, which would fail to be seen when results are averaged (from Pierce *et al.*, 2001). (See color insert).

disorder promise to provide special insights into the neural systems underlying human social development.

B. Language and Speech Abnormalities

1. Characteristics

It is the delay or regression of language, usually at approximately age 2, that first prompts parents to seek professional help. Although such delays are significant indicators of problems in child development, they are not specific to autism and are commonly found in many other childhood disorders (e.g., general language delay). By itself, language delay does not account for most of the features of the disorder but can be used as a metric for predicting developmental outcome. For example, several studies have shown that autistic children without speech by age 5 are much less likely to live independently later in life than children with functional speech. Also, the presence or absence of language has often been used to distinguish "high" from "low" functioning autism. The understanding of language abnormalities in autism, however, is critical for the development of appropriate treatment approaches, offers insights into the relationship between various symptoms in the disorder (e.g., between play and language skills), and is an excellent domain for fMRI studies investigating neurofunctional organization in autism.

It is commonly noted that 50% of individuals with autism fail to develop functional speech. For those that do, speech is often characterized as rigid and stereotyped, in which a word or phrase is used in limited contexts and verbal routines may be used to serve the individual's communicative needs. More specific aspects of language, such as syntax, have been examined by investigating the presence of grammatical morphemes during continuous speech. Comparing children with autism to those of similar ages, syntax is

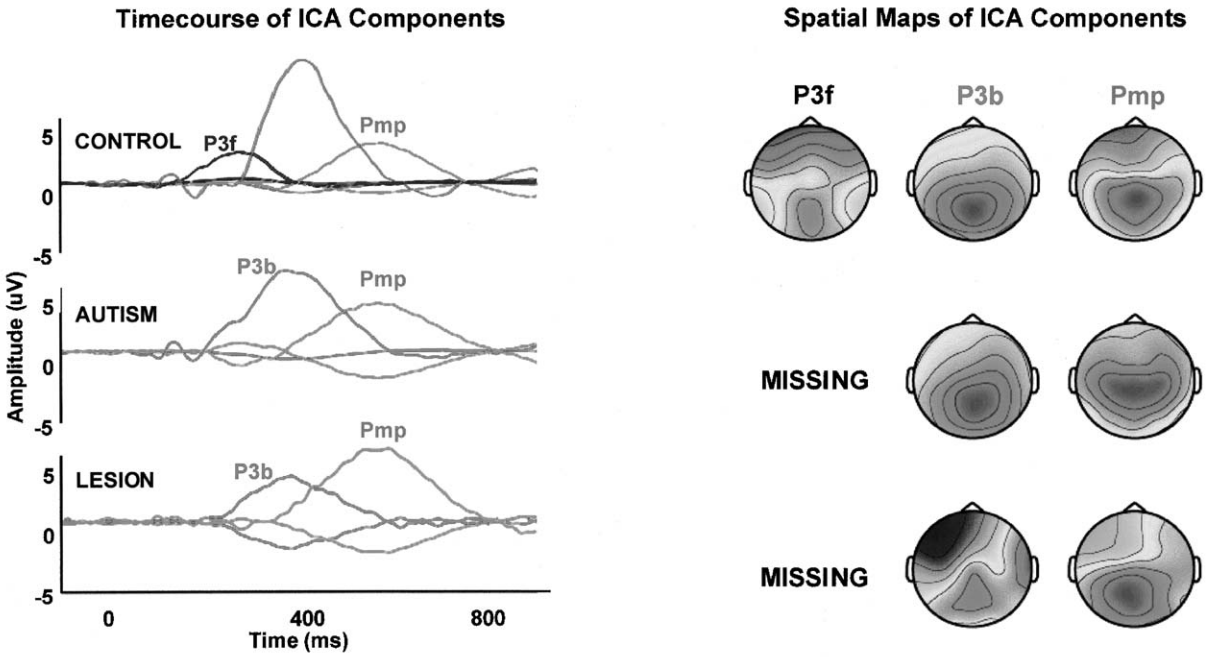

Figure 2 ICA decomposition waveforms and source maps for control, autistic, and cerebellar groups. ICA analyses were performed on grand average ERPs during a spatial attention task. ICA identified the P3f (P3 frontal) occurring at approximately 300 msec, the P3b occurring at approximately 400 msec, and the Pmp (postmotor potenential) occurring at approximately 500 msec for the normal control subjects, but it identified the absence of the P3f for autistic and cerebellar groups (from Westerfield, M., Townsend, J., and Courchesne, E., unpublished data).

severely deviant. Comparisons with mental age matches, however, suggest minimal differences between groups.

Autism is also characterized by several unusual applications of language, such as the repetition of words previously heard (either immediate or delayed) —a characteristic known as "echolalia." For example, an autistic child might repeat a phrase heard earlier on television, such as "You are the next contestant on the Price is Right!" several times throughout the day. Research has suggested that this unique form of communication may in fact serve very specific functions, such as such signifying confusion or requesting clarification. One study found that children with autism were more likely to engage in immediate echolalia in response to questions or commands they did not understand. Once the children learned the correct answer, rates of echolalia dramatically decreased. Other interesting aspects of language use in autism include pronoun reversals (e.g., saying "you want cookies" instead of "I want cookies") and the use of neologisms or nonsensical words. Combined with such unique uses of language are the often noted patterns of odd intonation and tone, usually in the form of monotony.

There is evidence that communication deficits in autism are related to the failure of preverbal mechanisms thought to be important to the development of language pragmatics, such as joint attention described previously. Furthermore, a strong relationship exists between social nonverbal communication and the level of language development in autism. That is, children with autism who display signs of nonverbal communication behaviors during social interactions (e.g., gesture and gaze) develop more receptive language than those that do not. Interestingly, however, the fluid and persistent use of the pragmatics of language persist as an enduring problem, even for autistic individuals who do develop functional speech.

C. Brain–Behavior Findings

There is inconclusive evidence from electrophysiological and PET blood flow studies suggesting that

language deficits in autism may be associated with a lack or reversal of left hemisphere dominance found in most normal adults. However, abnormal asymmetries have been observed in other electroencephalogram, ERP, PET, and SPECT studies that did not involve language tasks. It therefore remains open whether there is any specific link between functional asymmetries and language impairment in autism.

D. Restricted Range of Interests: Repetitive Behaviors and Stereotyped Patterns

1. Characteristics

In addition to salient disturbances in social behavior and language, individuals with autism may also exhibit abnormally intense preoccupations with one subject or activity, exhibit distress over changes in routines, insist on sameness in their environment, and engage in repetitive or ritualistic behaviors. For example, a child may exhibit signs of physical and emotional distress when a new piece of furniture is introduced into the home or if he or she is prevented from taking a traditional route up and down the aisles during grocery shopping. Still another child may center the majority of his or her activities around an obsessional object, such as toilets; he or she may draw pictures of them, talk about them, and flush all toilets in proximity as part of his or her daily life. Finally, others may repetitively bang a spoon or flap their hands for minutes, sometimes hours, during a single day. Such restricted and repetitive behavior may have particularly important developmental consequences for young children with this disorder because it may lead them to miss learning opportunities that fall outside their narrow scope of interest.

2. Brain–Behavior Findings

A novel environment offers an important opportunity for young children to explore and learn. However, when placed in a novel environment, autistic children typically fail to explore or explore only a fraction of available stimuli and this limited exploration is correlated with anatomic abnormality of cerebellar vermis lobules VI and VII (Fig. 3). Additionally, it appears that the more perseverative and stereotyped behavior shown by an autistic child, the greater anatomic abnormality of cerebellar vermis lobules VI and VII.

The correlation between deficits in exploratory behavior and cerebellar anatomic abnormality in autistic children is consistent with a large body of evidence from animal studies. Studies of mice with mutations causing cerebellar anatomic pathology show a reduced tendency to explore novel objects or environments and an increased tendency to move about perseveratively in testing environments. Hypoplasia of vermis lobules VI and VII has been specifically linked to abnormalities in exploratory behavior in two mutant animals, the GS guinea pig and the L1CAM knockout mouse. Potentially, defects in vermis lobules VI and VII may be sufficient to cause deficits in exploratory behavior. Nonetheless, since recent functional neuroimaging studies show that different cerebellar regions have different functional specializations, systematic studies will need to be conducted to learn whether and how various cerebellar regions, in addition to the vermis, play a role in deficits in exploratory behavior in autism. Studies of humans also indicate a role for the cerebellum in exploratory behavior. For instance, humans with acquired cerebellar lesions are inefficient in exploring and learning possible solutions to novel visuospatial puzzles. Interestingly, PET studies show the human cerebellum to be active during mental or ''imagined'' exploration of a spatial configuration.

E. Attention

1. Characteristics

In addition to the severe social abnormalities noted by Kanner, descriptions of attentional disturbances are also prominent features of this first paper on autism. Kanner quotes a father's description of his autistic son: ''He displayed an abstraction of mind which made him perfectly oblivious to everything about him … and to get his attention almost requires one to break down a mental barrier between his inner consciousness and the outside world.'' The first experimental demonstration of overly focused attention or ''stimulus overselectivity'' in the autistic child was by Lovaas, Koegel, and Schreibman in the early 1970s; they showed that autistic children respond to a restricted range of environmental stimuli, suggesting they may miss critical social and nonsocial information. Impairments in attention are now known to be among the most consistently reported type of cognitive deficit in this disorder, whether observations come from parents, teachers, clinicians, or researchers. Also, among cognitive deficits in autism, attention deficits are one

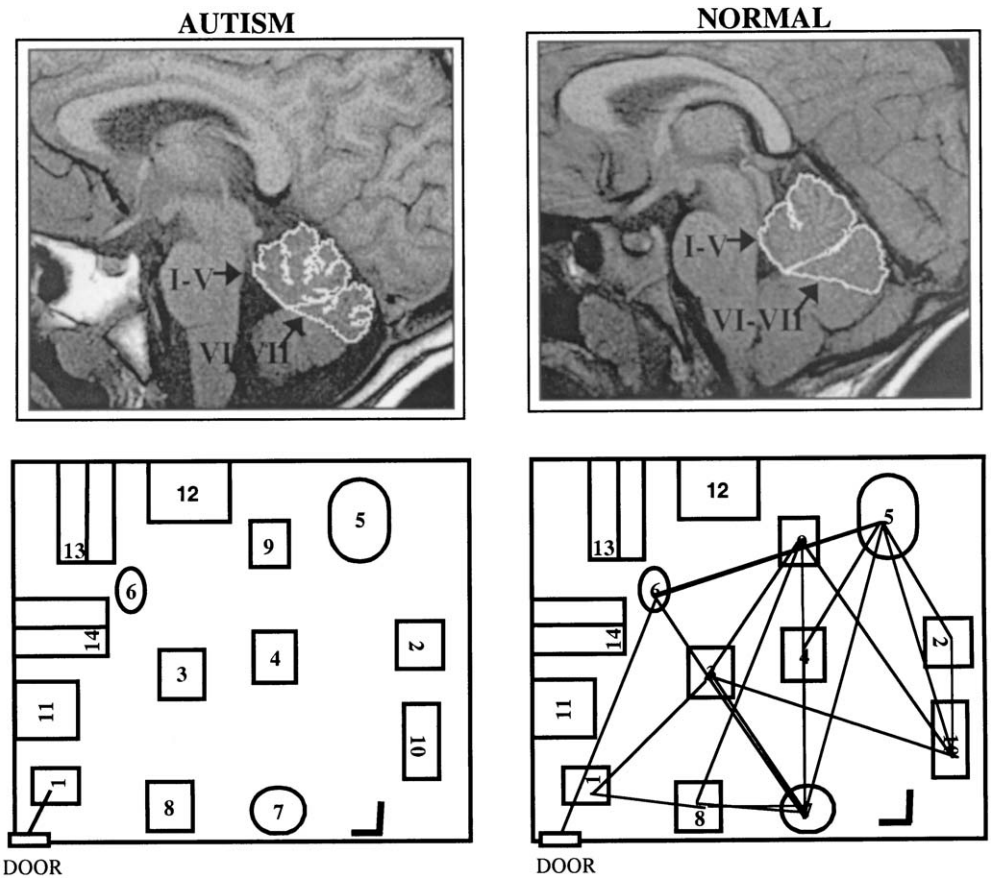

Figure 3 (Top) T1-weighted magnetic resonance image showing midsagittal vermal lobules I–V and VI–VII for a 6-year-old autistic boy and his matched normal control. Note sulcal widening and hypoplasia in the autistic child in comparison to his matched control. (Bottom) Exploration map for the autistic and matched control subject (cerebella for each child shown in the top portion). Lines depict patterns of movement across the entire session. Note the varied exploration pattern of the normal child in comparison to the near absent exploration of the autistic child (reproduced with permission from Pierce and Courchesne, 2001. Evidence for a cerebellar role in reduced exploration and stereotyped behavior in autism. *Biological Psychiatry* **49,** 655–664. Copyright 2001 Society of Biological Psychiatry).

of the most thoroughly examined by anatomical and functional neuroimaging technologies.

Attention abnormalities may contribute to clinical features in autism. As described earlier, a cardinal feature of autism is failure to engage in joint social attention and it is among the first striking deficits noticed in the autistic infant. In normal development, from joint social interactions between infants and mothers spring social knowledge and many higher cognitive, affective, and communicative functions. Tronick writes "successful regulation of joint interchanges … results in normal [cognitive, affective, and social] development. The crucial element is that the infant and mother … share the same focus of attention during the interaction." To do so, an infant must do more than focus his or her attention on a single, captivating aspect of an object or person: The infant must follow the rapid and unpredictable ebb and flow of human social activity, such as words, gestures, touching, postures, facial expressions, and actions on objects. By being able to smoothly, selectively, and rapidly adjust attention, the normal infant is able to combine, as a single entity in memory, the various and separate elements of a social situation. Abnormalities in adjusting attention would place the autistic child at a severe disadvantage in such rapidly changing social situations, and, in conjunction with severe abnormality in social and emotional systems, would add an additional major impediment to engaging effectively in joint social interchanges.

The regulation of attention is likewise important in the adaptive and active exploring of novel environ-

ments, acquiring a wide array of nonsocial knowledge, understanding causal relationships, appreciating the context of discrete events or stimuli, learning multimodality sequential stimulus relationships, and observing relationships among different sensory attributes of objects, people, or spatial arrays. Moreover, the inability to attentionally anticipate or react in a flexible moment-to-moment manner may, in combination with other impairments, increase the autistic child's tendency to remain restricted in interests and activity.

As described next, behavioral performance during tasks requiring rapid and dynamic adjustments in the direction of attention is clearly impaired in autism, but performance during tasks requiring simple sustained or selective attention is often reported to be normal or even supernormal in some autistic patients. One interpretation is that these latter attention functions may be spared, reflecting once again the variability in which brain functions are affected and which are not. Recent knowledge gained from neuroimaging studies, however, has revealed previously unsuspected abnormality in neural functions that mediate these "normal" or "supernormal" attention performances and thereby raises the important issue of neural compensatory reactions in the face of developmental neural defect.

2. Brain–Behavior Findings

Studies of the brain bases of attention functions in autism provide a classic example that normal behavior does not necessarily indicate normal neural function.

a. Sustained and Selective Attention In simple tasks requiring an autistic child to sustain his or her attention to a stream of stimuli (e.g., pictures and shapes) presented one at a time in order to detect a target stimulus, performance can be near normal or normal. More interesting are reports that during some tasks requiring selective attention, such as detecting a specific target stimulus at one of many possible spatial locations, accuracy and speed of pressing a button to the target might even exceed normal. Such behavioral performance, however, belies the presence of underlying abnormal neurophysiological responses to these stimuli.

Thus, although autistic patients seem to be attending and behaviorally performing normally, the stream of stimuli and the targets either fail to elicit attention-related ERP brain responses, such as the Nd, N1, N270, or Nc, or elicit abnormally reduced responses, such as the auditory P3b. Often such brain responses are also atypically located. Moreover, like patients with acquired lesions of the cerebellum, autistic patients performing such attention tasks fail to produce a cerebellar-dependent neural response that may signal frontal cortex (Fig. 2). Also, in cerebellar and autistic patients the attention-related P3b response is abnormal. The P3b is cerebral cortical activity reflecting recognition of task-relevant information and updating of the stimulus context. Unlike the normal brain that produces this response reliably to each single target stimulus, in these patients the P3b response occurs intermittently and with highly variable amplitude and latency to target information. In fact, the challenge has been to find attention-related ERP brain responses that act normally in normally performing autistic patients.

The large disparity between the appearance of normal and intact behavioral performance and the reality of abnormal underlying neural functional activity remains to be experimentally explained. One possibility is that tasks used to date fail to be sufficiently demanding on the neural system supporting it, and properly demanding conditions would reveal behavior deficits consistent with abnormal neural activity. Such a possibility is lent credence by numerous examples of resolution of analogous disparities in studies of other types of patients. Another possibility is that systems mediating these particular attention functions are indeed spared, and the abnormal neural responses recording during such tasks reflect other aberrant operations whose responsibility is to effectively process the information that sustained attention mechanisms "bring in." A third possibility is that the abnormal neural responses reflect the result of successful compensatory brain reorganization in the face of developmental neural damage.

The first possibility is supported by evidence that adds an anatomic twist. Autistic patients with parietal volume loss appear to have a narrow, spotlight-like attention. Therefore, when their task is to detect target stimuli at only one specific location and ignore other nearby stimuli, they behaviorally respond faster to targets than normal, have shorter latency P3b responses to targets than normal, and have larger than normal visual sensory P1 responses to targets. Conversely, when their task is to make a difficult discrimination and they are led to expect it will occur in one location but instead the stimulus occurs in another, they are slower and more inaccurate, missing discrimination opportunities. For other autistic patients who do not have parietal volume loss, the reverse

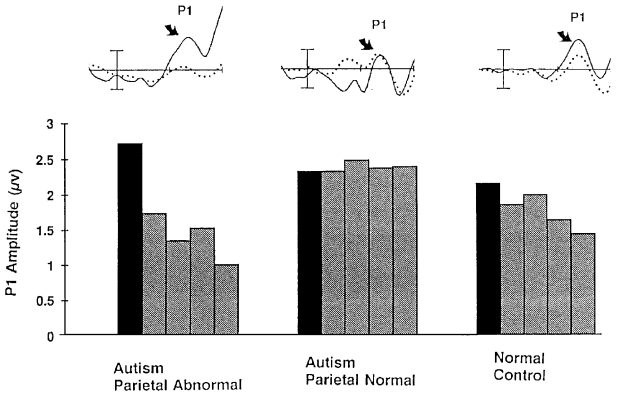

Figure 4 ERP evidence that autistic patients with parietal lobe volume loss have an extremely narrow "spotlight" of visual–spatial attention. Bar graphs are shown for autistic patients with and without parietal abnormalities and normal control subjects. The figure shows the P1 peak amplitude ERP response at occipital scalp sites to visual stimuli at an attended location (dark bar) compared to the P1 ERP responses at that location when attention was focused one, two, three, and four locations away (lighter bars in order left to right). Visual–spatial locations were separated by 2.7° of visual angle. Waveforms at the top show P1 ERP responses at occipital sites to attended locations (solid line) compared to the average of all unattended (dashed line) locations (reproduced with permission from Townsend and Courchesne, 1994; Parietal damage and narrow "spotlight" spatial attention. *J. Cog. Neurosci.* **6,** 220–232, Copyright 1994 by the Society for Neuroscience).

is seen in these tasks with opposite demands for either narrowly or broadly focusing attention (Fig. 4).

Therefore, in autism, it may be that the underlying type and extent of anatomic defect interacts with selective attention demands, such that certain defects may allow or even facilitate successful performance under certain attention conditions but not under others, but entire neural attention functions such as selective or sustained attention are not uniformly spared per se.

b. Dynamic Regulation of Attention: Disengaging, Orienting, and Shifting Even though the autistic child sometimes seems able to sustain attention to something in his or her environment, he or she typically seems impaired in adjusting attention to follow unexpected and rapid changes in the source of information. Especially demanding are the unexpected and quick changes in verbal, gestural, postural, tactile, and facial cues that signal changes regarding where to direct attention in a stream of social information. Much information comes and goes (a momentary facial expression) or moves from place to place (different speakers in a room). Neuroimaging studies of normal subjects show that the rapid, dynamic regulation of attentional resources in demanding attention conditions involves a distributed neural network including the parietal and frontal lobes, thalamus, colliculus, and cerebellum. Multiple operations underlie such regulation utilizing different as well as overlapping neural components.

In autism, three such operations have been thoroughly studied via neuroimaging techniques. First, disengaging attention is a reactive operation implemented when important stimulus information unexpectedly occurs outside the immediate focus of attention. The parietal cortex is an essential neural component in this operation. Autistic patients with parietal cortical volume loss are slow to disengage attention, and the more loss, the slower the implementation of the disengagement so that in patients with the most loss, by the time attention has been disengaged information needed to make critical sensory discriminations has often already disappeared. ERP imaging shows that in patients with parietal cortical loss, there is an abnormally narrow distribution of visual–spatial attention such that neurophysiological responses to stimuli at the center of attention are hypernormal in size while those outside this center are subnormal in size. This suggests that important stimuli unexpectedly occurring outside the immediate focus of attention are less able to rapidly and effectively trigger the disengage mechanisms. Therefore, in autism, parietal structural defects may impair the formation of effective attentional sensory maps of extrapersonal space, impair the operation of mechanisms that implement disengagement of attention, or both.

Second, when attention is not yet engaged and a stimulus occurs that signals the likely location of upcoming important information, attentional resources are normally immediately applied to that location in anticipation of the upcoming information. Successful anticipatory orienting increases the speed and accuracy of information processing of the upcoming information. Patients with cerebellar lesions from stroke or tumor and autistic patients are slow and inaccurate in such cued, anticipatory orienting of attention, and in the autistic child or adult the greater the cerebellar hypoplasia, the slower and more inaccurate the anticipatory orienting (Fig. 5). This effect has also been demonstrated for orienting to social and nonsocial stimuli.

Third, very often a particular stream of information will reach a point when it provides specific information or cues that explicitly direct or signal that attention is

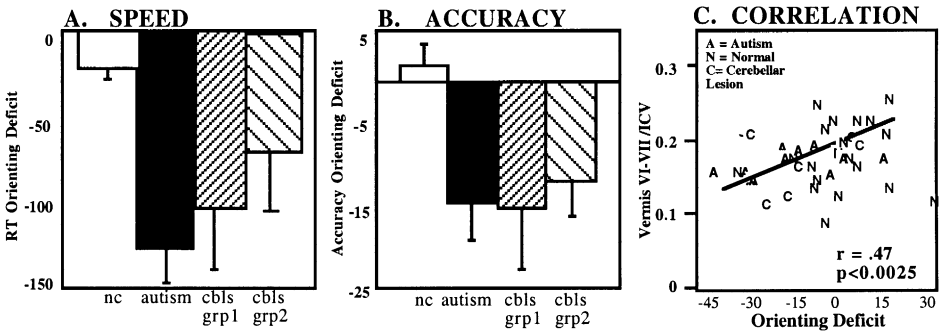

Figure 5 Orienting deficits (RT or accuracy at validly cued location at long cue-to-target delay and at short cue-to-target delay). A more negative orienting deficit indicates slower response or decreased accuracy to targets at cued locations when there is little time between cue and target onset. (A) Autism and cerebellar lesion subjects (cbls groups 1 and 2) showed significantly greater orienting deficits than normal control groups during the spatial detection task. (B) Autism and cerebellar lesion groups displayed significantly greater orienting deficits than normal controls during the spatial discrimination task. (C) Correlation of orienting with vermal lobules VI–VII in 22 normal, 10 autism, and 7 cerebellar lesion subjects. Vermal lobule VI–VII area measures in each subject were divided by that subject's intracranial brain volume (ICV) to control for overall brain size [reproduced with permission from Townsend, J., Courchesne, E., Singer-Harris, N., Covington, J., Westerfield, M., Lyden, P., Lowry, T. P., Press, G. A. (1999) Spatial attention deficits in patients with acquired or developmental cerebellar abnormality. *J. Neuroscience* **19,** 5632–5642.]

now to be shifted to another source of information (e.g., such as when a mother is speaking to her child and then tells the child to look at something). In natural situations, such shifting of attention back and forth between different sources of information occurs often and rapidly, and fMRI studies show that cerebellar and parietal cortex are actively involved in normal people. It is unclear whether operations underlying such moment-to-moment and rapid shifts of attention overlap with the single instance of anticipatory orienting, but this seems likely based on fMRI experiments in normal people. Patients with cerebellar lesions from stroke or tumor and autistic patients are slow and inaccurate in shifting of attention rapidly and frequently back and forth between very disparate (e.g., sights and sounds) sources of information. Therefore, when cerebellar or autistic patients have little time to implement a shift, they often miss detecting important information appearing at the new source of attention and their neurophysiological responses confirm that they failed to mentally register that important information. Stimuli that explicitly signal the need to immediately shift attention elicit an "Sd" brain response, but this is abnormally small or absent in cerebellar or autistic patients.

Although slow and inaccurate in anticipatory orienting and shifting of attention, cerebellar and autistic patients eventually do adjust the direction of their attention if given sufficient time, according to both behavioral and ERP imaging evidence. Thus, it has been a misconception among some researchers that autistic patients are incapable of orienting or shifting attention. Tests requiring conscious and effortful judgments about when to change or shift mental set, such as the Wisconsin Card Sorting Task, are not tests of the cerebellar or parietal involvement in the capacity to make immediate (in the hundreds of milliseconds range) and accurate adjustments in the direction of attention signaled by unexpected stimuli occurring within an attended stream of information. Rather, the successful ability to make such extremely quick and accurate anticipatory attentional adjustments must depend to a large extent on prior learning of associations between the signal to shift and the appearance of subsequent important information. Such automatic and swift neural actions are likely the product of well-known cerebellar association learning mechanisms. Such mechanisms may first learn predictive associations between successive events and then use that information by sending, on a moment-to-moment basis, preparatory signals to appropriate brain systems.

F. Associated Features

1. Mental Retardation

A robust finding is that approximately 75% of individuals with autism also meet *DSM-IV* criteria for mental retardation. For the minority with "normal" intellectual functioning, subtle deficits in social and language behavior clearly set them apart from their typically functioning peers.

There is no consensus regarding the role of mental retardation in autism and scientists have approached the topic in several ways. One thought has been that since mental retardation is not specific to autism (e.g., children with Down's syndrome and cerebral palsy also have mental retardation), attempts to understand its role in the disorder will not elucidate etiological or pathobiological mechanisms. Thus, the role of mental retardation is largely ignored. Another approach has been to investigate only a "pure" form of the disorder and "subtract out" effects due to mental retardation by studying only nonretarded individuals with autism. A further idea has been to control for the presence of mental retardation by comparing autistic individuals with mental age-matched individuals, either normal subjects (usually substantially younger) or subjects from a special population (usually Down's syndrome or general mental retardation). Although each approach has its own unique set of problems (e.g., lack of generalizability of finding when studying only nonretarded individuals), taken together they raise important issues regarding mental retardation and autism. First, autism and mental retardation are inextricably linked and attempts to dissociate the two may not only be impossible but also misleading. Furthermore, it is conceivable that subjects at either end of the mental retardation spectrum—those with profound mental retardation and those without apparent mental retardation—will be important to study because they could potentially represent examples of the extreme forms of biological mechanisms supporting the pathogenesis of the majority of autistic cases. For example, a hypothetical finding of increased brain volume in a severely retarded autistic child could represent the overall phenomenon of excessive brain overgrowth at early ages in autism. It is apparent in this individual because he or she represents the most severe biological version of the disorder. Thus, if such cases of retardation are excluded, important findings may be missed. On the other hand, given the extreme heterogeneity seen in autism, combining subjects with potentially disparate etiologies and courses may also dilute results. Currently, no consistent scientific solutions to the issue of mental retardation in autism have been embraced, but researchers are beginning to analyze data in multiple ways, such as with both group and single subject analyses.

2. Savantism

As is often popularized by the media, a small percentage of people with autism (less than 1%) display a special savant ability. The phenomenon of the savant offers a unique opportunity to study the presence of an extraordinary skill in the background of general cognitive impairment. Savant skills in autism have been reported in artistic talent, musical ability, numeric calculation skills, and "calendar calculation" skills, which involve the generation of the weekday of a given date within seconds. For example, a musical savant might have the extraordinary ability to play any song on the piano after hearing it only once on the radio. Savantism in autism is intriguing because many (although not all) such individuals may not even possess functional communication. Many theories, such as exceptional memories, have been espoused as to why savantism occurs in autism, but none have been definitively supported.

3. Seizures

Approximately one-third of autistic individuals will experience one or more epileptic seizures by adolescence. All types of seizures have been reported in autism, and complex partial seizures with associated centrotemporal spikes are most common, although other spike patterns have been noted. Severity of autism and other phenotypic markers do not seem to be associated with an elevated risk for seizures. Furthermore, the relationship of epileptic activity, if any, in the pathogenesis of autism is unknown.

4. Hyperserotenemia

Approximately one-third of individuals have elevated levels of blood platelet serotonin 5-hydroxy tryptamine (5-HT). This interesting finding has been replicated several times, and scientists have begun to use neuroimaging methods to make inferences regarding serotonergic brain function in autism. One method that has been tried has been the use of a serotonin tracer (α-[^{11}C]methyl-L-tryptophan) in combination with PET. Although a relatively new line of research, reports have indicated asymmetries in serotonin synthesis in autism. For example, decreased serotonin synthesis has been found in frontal cortex, whereas increased synthesis has been noted in the dentate nucleus. As with several other biological systems in autism, inconsistency seems to be a consistent theme. The potential role of the serotonergic system in the etiology of autism is a vigorous line of investigation and points to the serotonin transporter gene as a logical gene candidate. Furthermore, this work has

prompted the use of several pharmacological interventions that specifically target 5-HT systems.

IV. ANATOMICAL BRAIN DEFECTS

A. Multiple Anatomical Abnormalities

Among all types of biological abnormalities in autism, evidence for neuroanatomical abnormality is the strongest. Studies show that in autism, most major brain structures are affected (Fig. 6); these include the cerebellum, cerebrum, limbic system, corpus callosum, basal ganglia, and brain stem. Recent evidence shows that within the cerebellum and cerebrum, there is abnormality in white and gray matter. Such widespread anatomic abnormality explains why autism involves pervasive and persistent neurological and behavioral dysfunction.

Among all anatomic findings, the most consistent is abnormality in the cerebellum. According to MRI data on large numbers of autistic children and adults, there is a reduction in the size of the neocerebellar vermis and the volume of cerebellar cortex. Also in autistic children, there is an inverse relationship between the size of the cerebellar vermis lobules VI and VII and the size of frontal lobes, such that the smaller the vermis, the larger the frontal lobes. In brain autopsy studies, 90% of autistic cases have reduced numbers of Purkinje neurons in the cerebellar vermis and cerebellar hemispheres. The amount of loss typically ranges from about 20 to 60% across different autistic individuals, but in one autistic case Purkinje neuron loss was nearly total throughout the cerebellar hemispheres. Also, Purkinje neuron loss is patchy, and the distribution across the cerebellar hemispheres and vermis differs between individual autistic cases. Autopsy studies have also reported other types of cerebellar anatomic abnormality in other autistic cases. Therefore, cerebellar anatomic abnormality is present in 95% of all autism autopsy cases, making this the most common biological abnormality known for this disorder (Fig. 7).

The limbic system is another common site of anatomic abnormality. In living autistic patients, the amygdala has a reduced volume and the dentate gyrus has a reduced cross-sectional area. In autopsy studies, anatomic abnormality in limbic structures is present in most, but not all, autism cases. When present, limbic system abnormality involves increased density of neurons and reduction in neuron sizes.

Another important site is the cerebrum. A recent MRI study found abnormally increased volume of the

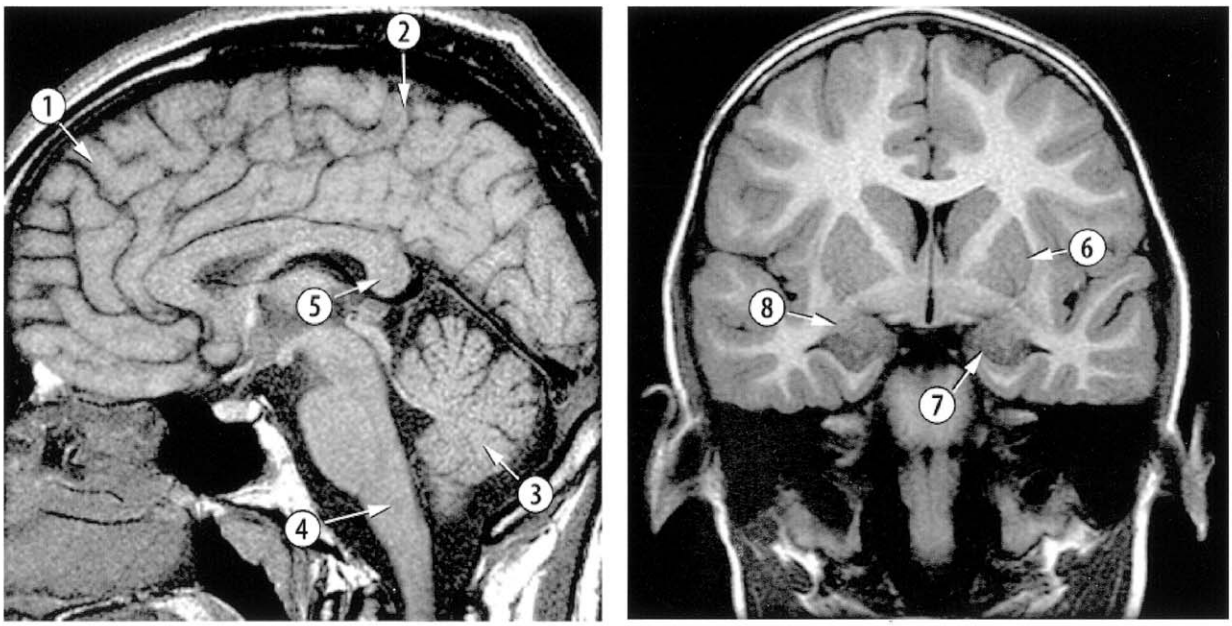

Figure 6 Depiction of cortical and subcortical structures reported as abnormal in autism via autopsy or MRI data from laboratories throughout the United States and Europe. 1, frontal lobes; 2, parietal lobes; 3, cerebellum; 4, brain stem; 5, corpus callosum; 6, basal ganglia; 7, hippocampus; 8, amygdala. (See color insert).

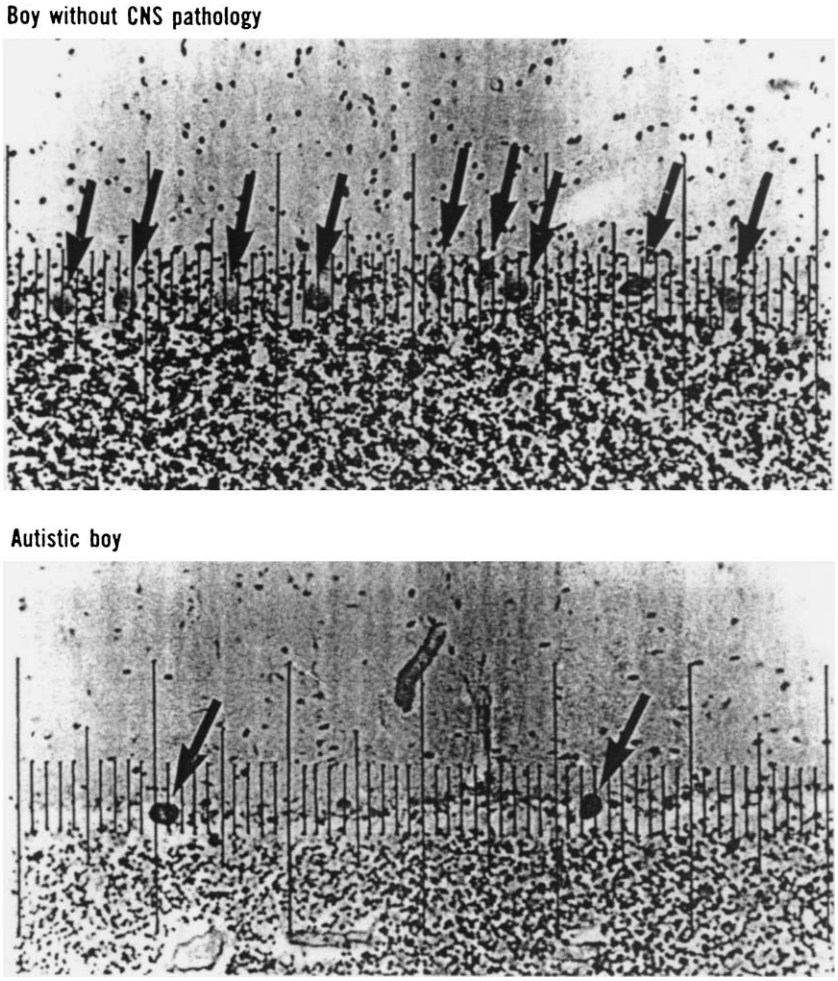

Figure 7 In autism, reduction in cerebellar Purkinje neuron numbers is a common finding across postmortem cases examined to date. (Top) Control case; (Bottom) autism case. Figure shows a comparable span of cerebellar cortex in a control case and in a case with autism. Arrows point to Purkinje cell bodies in these Nissel-stained sections. There also appear to be fewer granule neurons in the case with autism [adapted with permission from Ritvo, E. R., Freeman, B. J., and Scheibel, A. B. (1986). Lower Purkinje cell counts in the cerebella of four autistic subjects: Initial findings of the UCLA–NSAC autopsy research report. *Am. J. Psychiatry* **143,** 862–866.]

cerebrum, but only in 2- to 4-year-old autistic children. A follow-up study found a gradient of abnormality in these very young autistic children, such that abnormal increases in volume were most marked in frontal brain regions and least in posterior regions. In autopsy studies, some autistic patients have abnormally increased thickness of frontal cortical regions; however, other autistic patients have irregular formation of the layers of cortical regions. The corpus callosum is a massive tract of fibers enabling communication between the right and left hemispheres of the cerebrum, and in the posterior portion of it there is a reduction in size.

Anatomic abnormalities in some sites have only been reported from single MRI studies (e.g., parietal lobe and basal ganglia) or in single individuals at postmortem (e.g., superior olive agenesis and facial motor nucleus dysgenesis); how common these sites of abnormality are remains unknown.

In conclusion, anatomical abnormalities in the autistic brain prove that this is a biological disorder, not a psychogenic one. Different brain structures have different types of abnormality (e.g., cerebellum and cerebrum), and even within a particular brain structure (e.g., frontal cortex) more than one type of abnormality can be seen in different autistic patients. Also, among patients with the same type of anatomic defect, there are differences in the amount and exact location of abnormality. Such individual-specific differences in anatomic abnormality in the cerebellum, limbic sys-

tem, cerebrum, and so forth may be the reason for individual differences in initial symptoms and behavioral outcome.

B. Brain Development

Information about what brain abnormalities are present early in development and how they change with age cannot be gained by observations of the brains of older children or adults alone because the older brain is the outcome or end product of developmental transformations. Animal model studies demonstrate that early abnormal perturbations can create complex cascades of structural alterations. Abundant evidence from developmental neurobiology shows that when the developing brain sustains significant neural insult precipitated by environmental or genetic factors, the typical balance of competition that mediates anatomical and functional organization is altered and can result in atypical functional activity and structural growth (reduced or enlarged dendritic arbors, neurons, representational maps, or even whole cytoarchitectonic regions). This neuroplasticity may produce arrangements that successfully compensate for the structural defect but may also produce arrangements that do not (perhaps this partially explains the different degrees of impairment among autistic individuals). If the developing autistic nervous system abides by well-known principles of competition and neuroplasticity in the face of neural defect, then anatomical and functional abnormality at a given site or age will affect growth at other sites or later ages. In other words, under both normal and abnormal conditions, brain development can be thought of as a cascade of events that trigger multiple series of typically nonlinear and interdependent structural and functional transformations from prenatal life through maturity (and even then change continues). Thus, the end product of developmental neuroplasticity will be multiple sites and types of abnormality. To determine the developmental anatomical phenotype in autism, age-related changes in anatomy must be studied directly from the earliest ages possible.

1. MRI Evidence

With *in vivo* MRI, it is possible to study brain development at the time of clinical onset during the first years of life through maturity. Unfortunately, as with postmortem evidence, anatomic evidence from *in vivo* MRI also comes primarily from adults, adolescents, and older children with the disorder. Currently, there is little knowledge regarding what neuroanatomic abnormalities are present at the earliest developmental stages of this disorder (2 or 3 years of age) and what pathological growth trajectories characterize subsequent years of brain development. This is due to the scarcity of studies, small samples reported, and difficulty in both identifying autistic patients at the youngest ages and recruiting normal youngsters. Nonetheless, several important observations about the developmental anatomic phenotype of autism have been made, and, surprisingly, one has to do with neonatal head circumference.

At birth, head circumference in autism is typically normal, which is indicative of normal overall brain volume at that age. By ages 2–4 years, however, a majority of autistic children have a brain volume larger than normal (Fig. 8); in fact, more than one-third of young autistic children have a brain size falling into the definitional zone of developmental macrencephaly. One autistic 3-year-old had a brain volume whose weight we calculated to be 2000 g, which exceeds weights reported on more than 8000 normative child and adult cases in the literature (Fig. 9). One reason for this excessive and premature brain size among autistic 2- to 4-year-olds is premature overgrowth of white matter in both the cerebrum and the cerebellum; the magnitude of this abnormality is the largest for any anatomic defect reported in the autism MRI literature (Fig. 10). Another reason is premature overgrowth of cerebral gray matter. Strangely, after this young age, further growth is retarded in autism, whereas the

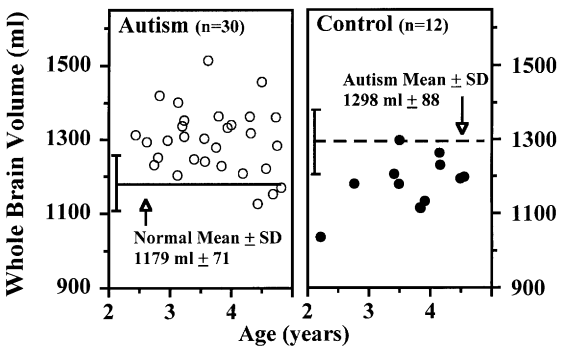

Figure 8 Two- to 4-year-old autistic and normal males (circles) are plotted showing overall whole brain enlargement of the youngest autistic children. As shown, 31 of 36 (86%) of the autistic boys and girls had whole brain volumes larger than the normal mean. In contrast, only 1 of 24 (4%) normal boys and girls in this age range exceeded the autism mean (reproduced with permission from Courchesne *et al.*, 2001).

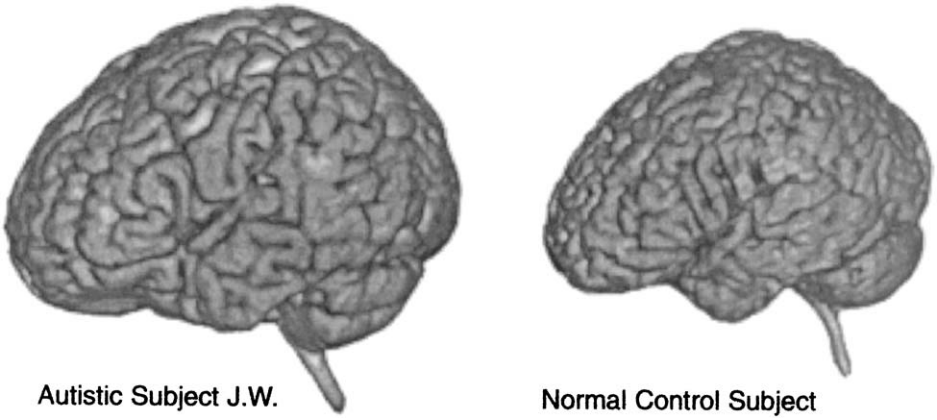

Figure 9 A case of extreme macrencephaly in autism. Three-dimensional image of 3.4-year-old autistic subject, JW (left), compared to that of a normal male child whose brain volume was scaled to equal normal average size (right). The autistic child's brain volume (1816 ml) was more than 6 SDs above the normal average (1162 ml) for his age (from Courchesne *et al.*, unpublished data).

normal child's brain continues to grow at a strong pace. By older childhood and adolescence, the normal child's cerebrum and cerebellum have reached or surpassed sizes achieved at an earlier age by the very young autistic child. This explains why postmortem observations of the weight of the autistic brain show it to be normal in the majority (86%) of older children and adult cases, although a few rare cases of extreme weight at that age do exist.

Apparently, after birth but prior to about 2 or 3 years of age in autism, several cerebral and cerebellar anatomical abnormalities rapidly occur, which means that postnatal, biologically guided intervention prior to the full expression of these abnormalities may be a possibility in the future. These observations suggest autism involves an unusual, perhaps unique, developmental neuroanatomic phenotype.

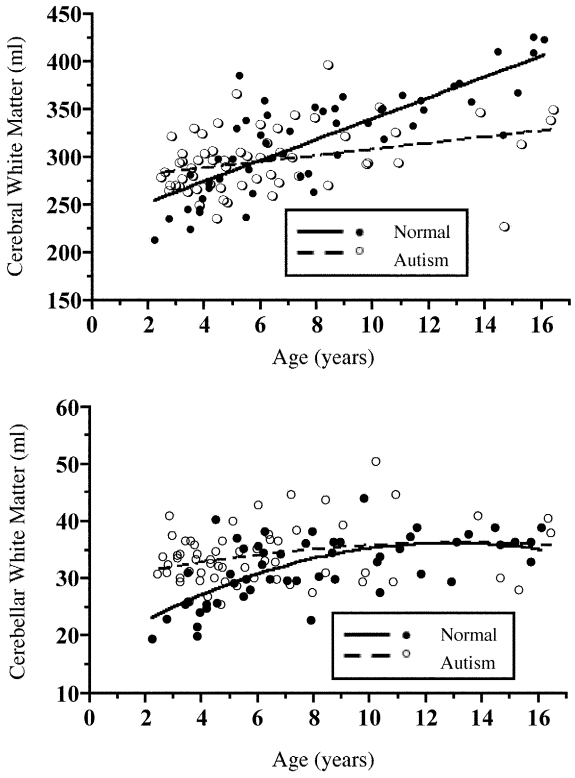

Figure 10 Volumes of cerebral white matter (top) and cerebellar white matter (bottom) are plotted with their best-fit curves for normal and autistic 2- to 16-year-old males. Despite precocious growth by early childhood, in autism, both cerebral and cerebellar white matter growth were smaller than normal by adolescence. (reproduced with permission of Courchesne *et al.*, 2001).

2. Postmortem Evidence

The major strength of postmortem research is that it allows detailed histoanatomical examination unattainable by MRI, and many important observations of the brain of the older child or adult with autism come from such studies. However, currently, there are too few postmortem autism cases in the literature to provide definitive evidence of either age at pathological onset or developmental trajectories for any brain structure. Only six postmortem cases of autism less than 19 years of age have been reported, and only one of these is younger than 9 years of age (i.e., one 4-year-old case). Additionally, postmortem studies of purported "autistic" infants and children under the age of 5 years suffer from one obvious drawback: At that young age, the diagnosis of autism remains uncertain, and obviously no longitudinal observations may be per-

formed to confirm or alter an initial diagnosis of autism suspected at that age.

Nonetheless, some neuropathological features are indicative of early developmental onset. Such features include cells arrested in migration in the inferior cerebellar peduncles, inferior olive malformation, irregular lamina disarray in small focal cerebral regions, reduced numbers of Purkinje neurons in the apparent absence of glial scarring, dysgenesis of facial motor nuclei, and agenesis of the superior olivary nuclei. However, several of these pathologies have only been noted in one or a few cases and not in the majority of postmortem cases, and therefore they do not provide definitive evidence about age of onset of pathology in the majority of autism cases. Interestingly, the different pathological features point to several different prenatal periods of onset.

Other reported pathological features—small cell size, increased cell packing density, and thickened cortices—are not indicative of any particular age of onset, but it is parsimonious to hypothesize onset during early development.

Since cerebellar pathology is ubiquitous among autism cases, knowledge of age of onset would be valuable in seeking causes and effective interventions. Decreased Purkinje neuron number is not accompanied by empty basket cells, which is indicative of early rather than later developmental age at the time of loss. Since the decrease in Purkinje number is evident regardless of history of seizures or seizure medication, the age of onset and cause of cell loss are not explained by seizure onset or seizure treatment. Also, cerebellar folia do not show signs of atrophy (mutant mice with developmental loss of Purkinje cells show cerebellar hypoplasia, not atrophy). In several autism cases, the inferior olives (which are developmentally, structurally, and functionally intimately involved with cerebellar Purkinje neurons) are maldeveloped and neuronal migration errors appear in the inferior cerebellar peduncles. In one postmortem autism case, Purkinje neurons were irregularly aligned, which could not caused by some later postnatal event. The dysplastic olives and migration errors are clear signs of first trimester events but have only been seen in three autism postmortem cases. The developmental ramifications of dysplasia and migration defects are unknown. Despite the reduced number of Purkinje neurons, cerebellar cortex in autism has clearly defined cortical lamina (granule, Purkinje, and molecular layers), even in cases with large distances between single surviving Purkinje neurons. Although Purkinje neuron loss or dysgenesis could occur prenatally along with olivary dysgenesis and the migration errors in the inferior cerebellar peduncle, observations of intact cerebellar lamina seem to argue against a massive dysgenesis or loss of Purkinje neurons before the final phases of granule cell proliferation and migration. Therefore, the possibility cannot be reasonably ruled out that Purkinje neuron loss could occur postnatally, perhaps in the first 1 to 3 years of life.

V. POTENTIAL ETIOLOGIES

Autism is currently thought to be etiologically heterogeneous. Many ideas about the etiology of autism have been presented in the literature; for example, mitochondrial DNA mutation and toxin exposure have been cited as possible causes of autism. Although intriguing, these do not yet account for subsets of persons with autism.

A. Genetic Findings

Autism is among the most heritable of neuropsychiatric disorders. Twin studies report pairwise concordance rates of up to 91% for autism among monozygotic twins and 24% among dizygotic twins, suggesting the disorder is strongly genetic. The increased risk of autism among siblings of autistic probands is 2%, which is about 45 times the rate expected in the general population. For the majority of the autistic population, multiple interacting genes are likely to be etiologically involved. About 5% of autistic patients have abnormalities in one or another of nearly all possible chromosomes; therefore, across autistic individuals with a chromosomal abnormality, the site of abnormality is variable.

Nonetheless, according to many reports, the most common site of chromosomal abnormality is 15q11-13. This abnormality occurs in about 2–4% of all autism cases, and it has been suggested that the autism phenotype occurs with maternal transmission of this particular chromosome defect. Because of the relative frequency of chromosome 15q11-13 abnormalities in autism, several candidate approach studies specifically tested and found significant linkage within the 15q11-13 region; two studies obtained statistically suggestive linkage. One specific location within this 15q11-13 region, the GABRB3 155-CA2 location, was highly significant in linkage with autism in a recent study that used data from all available genetic studies combined.

The first few genomewide searches for potential autism-related effects have only recently been completed. These searches studied families that have multiple affected individuals (which represent 3% of autism cases), and generalizability of their positive as well as negative findings to the larger autism population is uncertain. To date, results have been highly variable and generally not replicable. Some genomewide studies report only weak to modest linkage scores for several different sites; other studies find no significant linkage to any site or weak linkage with a large number of sites from nearly a dozen chromosomes. No reported site has been definitively statistically replicated by other genomewide studies. Genetic studies have been consistent in finding no association between carefully diagnosed autism and the fragile X gene (although autistic features are seen in many fragile X patients).

Because of the link between autism and hyperserotonemia in about one-third of patients studied, candidate gene studies have investigated known serotonin genes. Two such studies found significant linkage with the promotor of the serotonin transporter gene but to opposite alleles of the promotor, whereas another two studies found no linkage.

Despite the fact that autism is likely a complex genetic disorder and modern genetic techniques have only recently been applied to autism, several important observations have been achieved and more success can be expected.

B. Teratogens, Toxins, and Viruses

Specific teratogens, toxins, or viruses have not been shown to account for any substantial subset of the autism population, although clearly in each category there are known members capable of producing developmental brain damage, including damage to regions commonly affected in autism. For example, in humans, prenatal and neonatal exposure to alcohol causes Purkinje cell loss in the cerebellum. Prenatal exposure to the anticonvulsant medication valproic acid has been linked to cases of autism in one family and causes significant reduction of cerebellar Purkinje neuron numbers in rats. Prenatal exposure to sedatives such as thalidomide has been linked to autism in some individuals, and an animal model using rats to study treatment for opiate and cocaine addiction using the indole alkaloids ibogaine and harmaline found degeneration of a subset of Purkinje cells in the vermis.

Cells of the early developing brain are in a state of rapid proliferation and differentiation in the fetus and neonate—conditions ideal for viruses that replicate best in dividing cells. This in turn can lead to severe or lethal birth defects. Lymphocytic choriomeningitis virus infection of 1- to 7-day-old rats interferes with cerebellar development, resulting in cerebellar hypoplasia and permanent ataxia. After developing rats are exposed to Borna virus, affected animals show similar cerebellar pathology as well as abnormal play and other social behavior.

Recent speculation that the measles, mumps, and rubella vaccine may be an etiological factor in autism led to a thorough examination of the evidence by many medical researchers. No scientific support for the speculation was found. Nonetheless, scientists remain open to the possibility that some teratogenic, toxic, or viral exposures might serve as risk factors that add to or compound the etiological effect of genetic factors.

VI. TREATMENT

When the disorder was first described almost 60 years ago, few if any treatment options were available, and parents were left with little hope of cognitive or behavioral advancement for their child. It was common for autistic children of this era to be placed in institutions, largely ignored, grouped together with children with other special needs (e.g., general mental retardation and blindness). Although there is still no cure for autism, modern-day treatment of this disorder affords several possibilities and research has shown that significant advances in cognitive and behavioral domains can be made. In fact, today, most children receive intervention on a daily basis, some as early as age 2. Furthermore, many school-aged children with autism are ''mainstreamed'' or are placed in classrooms with typically developing children for some or all of their school day. The reasons for this dramatic metamorphosis in thinking about the treatment of autism come from several sources. First, the 1940s through the 1970s was a time when autism was thought of as ''psychogenic'' in origin—a disorder resulting primarily from poor parenting, particularly on the part of the mother. The late 1960s and early 1970s, however, brought new scientific information, such as elevated serotonin levels, the presence of seizure activity, and increased rates in monozygotic twins compared to dizygotic twins in autism. Such information presented clear evidence that this disorder was of biological, likely genetic, origin. This belief is still true

today. Increased sophistication of diagnostic tools, heightened media attention of the disorder, federal laws mandating specialized education for children with disorders, and a growing knowledge of biological principles have all contributed to a new understanding of the treatment of autism.

Although intervention in autism is multimodal and typically includes several treatment types (e.g., language therapy and occupational therapy), takes place in several locations (e.g., the home and school), and is implemented by several treatment providers, (e.g., parents, teachers, and speech therapists), by far the most common treatment approach is one that relies on a behavioral model. The behavior analytic view is that autism is a syndrome of behavioral deficits that are amenable to change in response to specific, carefully programmed, constructive interactions with the environment. Within this framework, both global approaches, such as discrete trial training, or specific approaches, such as video modeling, have been used. Behavior analytic treatment focuses on teaching small, measurable units of behavior systematically. Every skill absent in the child's repertoire—beginning from simple responses such as looking at an object to complex ones such as verbally describing an object—is broken down into small steps. Each step is taught to the child by providing consistent prompts or instructions followed by consistent reward for accurate and/or other appropriate behavior. Inappropriate behavior is often ignored or redirected. Teaching trials are repeated many times, often in rapid succession, until the child performs the target behavior in the absence of adult prompting. For example, a child may practice the association between the word "car" and a picture of a car dozens, perhaps even hundreds of times per day. It is this repetition along with gradual increases in demands in skill complexity that characterize behavioral treatment for children with autism.

Based on review of the treatment literature in autism, three general themes emerge: (i) Interventions based on a behavioral model are successful in increasing some functional behaviors (e.g., eye contact or language) as well as decreasing some nonfunctional behaviors (e.g., repetitive motor movements); (ii) the same intervention does not affect all children in the same way, even when factors such as IQ are controlled for; and (iii) the earlier the intervention is provided, the more efficacious for the child. These points raise larger questions regarding the biological mechanisms that may support their conclusions.

First, what are the mechanisms that might support positive behavioral change in autism after treatment? As described previously, in many behavioral approaches the use of repeated contingencies or associations forms the foundation of most teaching interactions. Similarly, repeated environmental stimulation is a common method for initiating plasticity in animals. For example, it is well-known that mice repeatedly exposed to an exercise gym have more motor neurons and increased numbers of synapses than mice without such repeated exposure. The approach of repeatedly pairing a stimulus and response may be particularly effective in autism because it targets associative learning, a function mediated by the cerebellum, a structure consistently cited as abnormal in autism. The importance of the cerebellum in associative learning has been well documented. For example, a traditional cerebellar/association learning experiment might compare cerebellar activity during the presentation of random unpaired tones and air puffs to that during paired conditioning trials. Relative to the unpaired condition, increased glucose metabolism is often found during the paired associative conditions in various cerebellar regions. In autism, perhaps substantial changes in behavioral phenotypes can be more readily achieved when using a method that attempts to remap this potentially deficient function. Another possibility is that during the initial stages of treatment in autism, the environment is typically cleared of all distractions (e.g., the child may receive treatment in a quiet room without the sound of other children in nearby classrooms or potential unexpected sounds, such as the telephone ringing). If it is indeed true that autism involves difficulties in sensory integration and attention, a quiet and distraction-free environment would likely be less stressful for a child than one with ambient noise, etc. Animal studies have in fact shown that neurogenesis in structures implicated in autism, such as the dentate gyrus, is facilitated by an enriched environment and stymied by a stressful one. Therefore, treatments aimed at reducing sensory stress while presenting clear and repetitive learning trials might be the most palatable for the nervous systems of children with autism. It is important to note, however, that as the child progresses in ability and response complexity, the need for long periods of repetition and a distraction-free environment decreases. That is, once the nervous system of the autistic child is able to assimilate basic information, he or she may be more readily able to learn from his or her environment in a way more similar to that of typically developing children.

Second, why does the same treatment fail to initiate the same level of efficacy for each child with autism? In

order to illustrate this point, consider the landmark paper on treatment in autism in which Lovaas reported that 47% of children with autism receiving high-intensity behavioral treatment (i.e., 40 hr per week) were placed in mainstreamed academic environments after treatment, whereas the remaining 53% were not. These differential rates of treatment success cannot be explained by single behavioral phenotypic characteristics (e.g., severity of autistic symptoms, IQ, and language ability) because no significant differences were found between treatment "high responders" and treatment "low responders." The explanation might be found when one takes into account biological substrates that distinguish these two outcome groups. In order to push the child with autism down the most beneficial pathway, treatment efforts must be based on brain–behavior research that provides information regarding the most fruitful starting point from which to intercede *for each particular child*. Although brain-based treatments of this type have yet to be implemented, current evidence supports the conclusion that available experimental and analytic methods can be used to sort patients into biologically distinct groupings on which to test whether different treatment approaches have reliably different efficacies. However, to succeed, it is necessary to first establish direct experimental correlations between specific behavioral and psychological dysfunctions, on the one hand, and specific underlying physiological, anatomical and other biological abnormalities on the other hand. Recent studies have in fact succeeded in doing so. These studies suggest, and new studies may further specify, the distinctly different compensatory mechanisms used by different autistic individuals. Furthermore, such brain–behavior findings will identify specific neurobehavioral operations (e.g., deployment of visual spatial attention, shifting attention, and others) that may be pivotal to the normal development of still more complex, higher cognitive, linguistic, and social functions. The validity of treatment efforts based on epigenetic theories can thus be easily tested: The strength of brain behavior correlations (e.g., overly focused visuospatial attention correlated with parietal abnormalities) should decrease over the course of treatment as compensatory mechanisms are enhanced in the autistic brain.

Third, why does treatment initiated at age 2 seem to have more beneficial effects than treatment initiated at age 6? Again, we turn to well-known principles of neural development provided by animal research. Specifically, animal models of developmental abnormality show the importance of critical periods or "windows of opportunity" for effective treatment. For example, for the kitten, the longer the period of abnormal neural activity caused by monocular deprivation from birth, the more abnormal the neural structural and functional outcome. Abnormality compounds gradually; correspondingly, the possibility for recovery declines gradually. Therefore, the longer one waits before starting treatment, the poorer the recovery, and eventually an age is reached when treatments cease to be effective. Fortunately, the human cerebral cortex has an exceptionally long period of continued growth, providing both the opportunity and vulnerability to change. Therefore, assuming the biological etiologies causing autism begin prenatally or early in infancy, the lesson from developmental biology is to take advantage of these windows of epigenetic opportunity by intervening as early as possible. Early and biologically informed treatments are especially critical when rare human neurodevelopmental disorders are due to mutations of genes with pleiotropic effects. Theoretically, if initiated early enough, a single, biologically precise treatment may prevent the cascade of multiple paths of maldevelopment; if not, multiple types of treatment may be needed to address each of the distinct and unrelated biological and behavioral outcomes that characterize such gene mutations. Not surprisingly, a major goal of autism research is to devise specific biological or behavioral countereffects that avert or significantly mitigate the disorder before they are fully manifested and require multiple, marginally effective treatments. Early intervention research efforts have embraced this notion, with treatment often beginning as early as 14 months of age or as soon as a provisional diagnosis is made. Combined with neuroimaging technique, scientists have for the first time the ability to track potential changes in neurobiology as a result of intensive early intervention in autism.

A. Pharmacological

A wide range of pharmacological agents have been used as viable treatment options for autism, ranging from serotonin uptake inhibitors, such as clomipramine and even the common antidepressant Prozac, to dopamine antagonists such as haloperidol. Overall, drugs have not proven successful at ameliorating the key features of autism but, rather, may have a modest effect on specific features of the disorder for some children. For example, serotonin uptake inhibitors

(known to be effective in the treatment of obsessive–compulsive disorder) have been shown to be effective in reducing repetitive behaviors seen in autism. Side effects common with psychotropic medications (e.g., tardive dyskenisia), however, typically limit the use of such interventions. Most children with autism participate in pharmacological intervention at some point during their treatment course, but it is the minority that maintains drug use across their life span.

B. Other

Behavioral treatment is not the only option for children with autism and it is typically augmented with other approaches, such as occupational therapy and/or sensory integration training, language therapy, play therapy, or pharmacological intervention. Each of these approaches is grounded in a particular theory of autism. For example, sensory integration theory posits that autism is a disorder with impairments in processing sensory information and methods common to this treatment type are aimed at making the absorption and integration of sensory information more palatable for the autistic child. Methods common to this intervention type include "brushing" the child to enhance vestibular awareness and providing controlled tactile stimulation, such as exposure to objects that are extremely course to extremely rough, in an effort to reduce tactile defensiveness. Interestingly, although there is little or no scientific evidence that treatment of this type is effective in autism, it is a very common component of the education of most autistic children, and parents often express that it is both an important and an efficacious aspect of their child's treatment. Finally, it is important to note that not all treatments for children with autism are based on a behavioral model and may be combined with or replaced by treatment approaches based on other models, such as a developmental one. Developmental models have been particularly useful in the treatment of play, language, and social skills in children with autism, although less documentation is available for this approach.

A unique aspect of the treatment of autism throughout the decades has been the presence of "alternative" approaches, such as swimming with dolphins or other animal therapy, holding therapy wherein the child is held tightly for several hours, art therapy, music therapy, facilitated communication, and megavitamin and hormone therapy. Such intervention approaches come and go, and they have yet to make a solid contribution to our understanding of or the treatment of this complex disorder.

VII. CONCLUSIONS

Neuroanatomical, neurofunctional, and neurobehavioral findings in autism all suggest that the disorder cannot be reduced to one primary deficit that underlies the disorder. Thus, there is not just one important neural defect or one important neurobehavioral deficit; there are many. Such neurobehavioral domains include, but are not limited to, deficits in reciprocal social interactions, affective responses, verbal and nonverbal communication, face perception, problem solving, working memory, orienting and shifting attention, spatial attention, sensorimotor learning, auditory processing, and motor coordination. In order to fully appreciate why the autistic child has pervasive and devastating disorder in the development of numerous abilities from social to motor, it is necessary to understand the entire pattern of anatomical and neurobehavioral impairment he or she faces throughout life. This picture of multiple types, times, and sites of neural defect is analogous to that seen in complex genetic neurodevelopmental disorders (e.g., fragile X, Williams' syndrome, CRASH, adenylosuccinate lyase deficiency, and PKU). In such complex genetic disorders, the genetic defects have adverse pleiotropic effects on brain development, such that multiple neural sites and often extraneural systems develop abnormally. Autism is almost certainly a complex genetic disorder, with involvement of one or more genes, and gene defects will likely have pleiotropic effects producing maldevelopment in multiple brain structures and possibly extraneural systems.

The importance of understanding the neural basis of autism cannot be underestimated. It will facilitate, for example, the development of treatment approaches that address individual differences in neural organization, the development of biologically guided measures of the efficacy of treatment approaches that can augment current behavioral measures, and the development of animal models of autism that will be crucial for validating genetic or nongenetic explanations or biological or behavioral treatments. (Note that animal models rely on the availability of brain–behavior linkage data to be modeled.) In fact, the proposed combined behavioral, neurofunctional, and neuroanatomical approach is consistent with the types of approaches currently taken in the study of animal

mutants and knockouts, potentially facilitating the translation of information from these studies to future autism animal model studies.

Moreover, the combination of neuroimaging techniques, such as fMRI, with cognitive and behavioral techniques will help to sharpen diagnostic distinctions not only between autistic and normal individuals but also between biologically different subgroups within the disorder of autism. Finally, as suggested by our preliminary fMRI data, brain–behavior findings on autism may provide insights into specific types of deviant functional organization as well as possible forms of compensatory organization invoked during development in autism.

Autoimmune Diseases

FELIX MOR and IRUN R. COHEN
Weizmann Institute of Science, Rehovot, Israel

GLOSSARY

autoimmune disease A disease process mediated by self-reacting antibodies or T cells.

Behçet's syndrome A multisystem, chronic recurrent disease characterized by ulceration in the mouth and genitalia, iritis, uveitis, arthritis, and thrombophlebitis.

DNA vaccination The use of DNA-encoding proteins to induce immune responses in subjects inoculated with it.

major histocompatibility complex The set of gene loci specifying major histocompatibility antigens (e.g., HLA in man, H 2 in mice, RLA in rabbits, RT 1 in rats, DLA in dogs, and SLA in pigs).

multiple sclerosis A human inflammatory disease affecting the central nervous system causing motor impairment, characterized by the gradual accumulation of focal plaques of demyelination particularly in the periventricular areas of the brain.

oral tolerance Administration of antigens orally to modulate immune responses to the given antigen.

paraneoplastic diseases A group of diseases in cancer patients affecting organ systems at sites remote from the tumor and mediated by secreted factors or immune reaction to tumor antigens cross-reactive to normal tissue antigens.

systemic lupus erythematosus A human disease characterized by multisystem involvement and the presence of anti-nuclear antibodies.

T cell receptor The antigen-recognizing receptor on the surface of T cells. Heterodimeric (disulfide linked), one member of the immunoglobulin superfamily of proteins, binds antigen in association with the major histocompatibility complex, leading to the activation of the cell.

T cell vaccination The use of T cells to treat autoimmune disease by enhancing the regulation over T cells mediating the disease.

I. INTRODUCTION

Most human brain diseases are not causally linked to the immune system; cerebrovascular and degenerative brain diseases, which account for the greatest toll in human life and suffering, do not directly involve the immune system. A minority of brain diseases are thought to be autoimmune—those caused by a mistaken attack of the immune system against various components of brain tissue. Autoimmune brain damage can be part of a generalized autoimmune disease such as systemic lupus erythematosus or Behçet's syndrome, or it can result from a brain-specific disease such as multiple sclerosis. Paraneoplastic diseases are another group of autoimmune neurological diseases; these conditions are triggered by an immune attack on tumor antigens that are cross-reactive with brain antigens.

Learning about human disease is greatly aided by the analysis of disease models in experimental animals. Models help answer questions related to the development of the disease and to the various mechanisms operating in its inception, perpetuation, and recovery. In addition, a model enables the development of novel therapeutic modalities resulting from our enhanced understanding of the disease process. Our understanding of autoimmune disease develops in parallel with our understanding of the immune system in general.

Since the study of self–nonself discrimination is at the core of immunology, the evolution of our understanding of autoimmune diseases has significantly changed in recent years. A comprehensive review of all autoimmune brain diseases is beyond the scope of this article; we will discuss general principles of autoimmunity. We will draw concrete examples, where needed, using multiple sclerosis (MS) as a prototype autoimmune brain disease, based on our understanding of experimental autoimmune encephalomyelitis (EAE), which is an animal model for MS. The general principles outlined for EAE and MS are applicable to other tissue-specific autoimmune diseases, such as rheumatiod arthritis, insulin-dependent diabetes mellitus, or inflammatory bowel diseases. In other diseases, the pathogenic autoantigen and autoreactive T cells are different but the mechanisms of disease regulation and recovery are similar. Thus, the rules developed and the modalities of treatment can be copied from one autoimmune disease to another.

MS is an inflammatory demyelinating disease (causing the destruction of myelin, the insulating coat of axons) affecting the white matter of the central nervous system. In the United States, more than 300,000 patients suffer from MS. Women are more frequently affected (the female to male ratio is 2:1). The disease often begins in the second to the fourth decade of life and results in paralysis, sensory disturbances, incoordination, and visual impairment. EAE will be discussed later.

II. BENIGN AUTOIMMUNITY

The mammalian immune system is composed of two classes of elements: innate and adaptive. The innate arm of the immune system is encoded in the germline of the species and is inherited by the individual from his or her parents. Innate immunity includes the macrophages, neutrophils, and other inflammatory cells and molecules. The adaptive arm of the immune system contains the T cells and the B cells, which express antigen receptors that are somatically generated in each individual. Activated B cells secrete specific antibodies of various isotypes. The adaptive arm of the immune system recognizes antigens and progressively learns from the person's ongoing immune experience; immune memory is an attribute of the adaptive arm of the immune system.

The individual's immune system develops in such a way that the effort to combat foreign invaders (bacteria, viruses, and other parasites) is usually successful, while the self-tissues are not damaged by autoimmune disease. This is achieved by a process of "education" in the thymus, in which most of the self-reacting T cells are purged from the mature immune cell repertoire. The thymus is an organ high in the thorax that serves as a "factory" for the generation of new T cells. This process of "negative selection" (killing of self-reactive T cells by contact with self-antigens) in the thymus is thought to be important for the prevention of autoimmunity. However, one can easily detect self-reacting antibodies and T cells in both humans and experimental animals. Analysis of normal human serum reveals a multitude of antibodies that bind normal tissue components. Immunization of experimental animals with self-antigens (proteins or peptides) results in the generation of self-reacting T cells that can induce autoimmune disease. Thus, the process of purging the immune repertoire from self-reactivity is far from complete, and there exist effective mechanisms that act to regulate the autoimmune repertoire in most individuals. Therefore, if the individual manages to live at peace with his or her autoimmune lymphocytes, what causes an autoimmune disease?

III. TRANSITION FROM BENIGN TO PERNICIOUS AUTOIMMUNITY

Fortunately, the process of transition from immune recognition of self to the full blown antiself attack is relatively uncommon; autoimmune disease affects about 5% of the population. For a disease to develop, several conditions must be met. The individual must have certain predisposing genetic features, including human leukocyte antigens (HLAs). HLA molecules are a set of surface proteins expressed on immune cells that are important in forming a complex with peptides to be recognized by T cells. In addition to HLA, hormonal factors, tissue susceptibilities, and others, along with an inciting event, trigger the development of the disease. This trigger is often an infection. The infectious agent (viral or bacterial) may have antigenic epitopes that activate T cells capable of attacking the self; the immune attack against a foreign invader starts an immune reaction that spills over and results in mistaken antiself attack. Alternatively, an emotional stress may result in loss of regulation over anti-self-reactivity that may evolve into pernicious autoimmunity. During emotional stress various hormones are secreted, including corticotropin-releasing factor, ACTH, and adrenal steroids, which can induce

apoptosis of both immature and memory lymphoid cells including regulatory cells. In many individuals, this early autoimmune attack activates regulatory immune mechanisms that will prevent future attacks of the disease. Thus, some patients with MS will have a single attack of optic neuritis (inflammation of the optic nerve causing transient blindness) with complete recovery and no further evidence of MS. However, in other patients, probably lacking efficient antidisease regulation, the disease runs a course of recurrent attacks leading to progressive damage. In contrast to pathogenic (disease-causing) T cells, which are well characterized, the regulatory cell population is less clearly defined. This population of cells is probably heterogeneous and contains (i) antiidiotypic T cells, which specifically recognize the T cell receptor (TCR)—the molecule used by T cells to recognize antigenic peptide in the MHC binding groove—of the pathogenic cells and have the ability to suppress them; (ii) antiergotypic T cells, which respond to activated T cells irrespective of their TCR; (iii) antigen-specific Th2 cells, which react to the pathogenic peptide but produce inhibitory cytokines that suppress the pathogenic cells; and (iv) natural regulatory T cells that are characterized by the expression of the α chain of the interleukin-2 (IL-2) receptor (CD25). In addition to regulation mediated by other cells in the pathogenic population, the disease-causing cells may undergo activation-induced apoptosis (cell death) following contact in the brain or other organs with death-inducing molecules, such as tumor necrosis factor and FAS.

IV. EXPERIMENTAL AUTOIMMUNE ENCEPHALOMYELITIS

EAE is a model in experimental animals that, due to similarities in the clinical and pathological features, is considered by many investigators to reflect human MS. EAE is probably the most intensively studied autoimmune disease model. The experimental animal (mouse, rat, guinea pig, or monkey) is injected with a protein from the central nervous system (CNS) myelin (myelin basic protein, proteolipid protein, or myelin oligodendrocyte glycoprotein) in a suitable adjuvant —a material added to the antigen to enhance the immune response (containing oil and bacterial products). Ten to 14 days after the injection, the animal shows signs of neurological damage, including paralysis of the tail and posterior and anterior paws and loss of urinary sphincter control. This neurological disease lasts from several days to several months (depending on the animal strain); in some animals there are repeated attacks of paralysis (similar to the remitting relapsing form of human MS). An identical form of EAE can be induced by injecting a T cell clone reactive to a myelin protein antigen. A T cell clone is composed of a homogeneous population of T cells with identical T cell receptors: All cells in a clone emerge from a single parental cell. This form of adoptive EAE usually starts earlier than actively induced EAE (within 3–5 days after T cell inoculation), and the animal shows identical symptoms to the actively induced disease. Animals that have recovered from EAE are usually resistant to another attempt to induce the disease. Postrecovery resistance to EAE is probably related to induction of efficient regulatory T cells since resistance can be transferred to other animals with T cells. In some studies, anti-MBP antibodies could also transfer resistance.

What have we learned from EAE? First, as in humans, there is a genetic predisposition to the disease; some mouse and rat strains are susceptible to the disease, whereas others are resistant. The cell causing the disease is a T helper type 1 (secreting IL-2 and γ-interferon and mediating tissue damage) reactive to myelin antigens. Upon activation, the pathogenic T cells acquire the capacity to migrate to the CNS and cause inflammation resulting in demyelination and paralysis. Some of the pathogenic T cells then undergo apoptosis (programmed cell death). In some animal models, there is spreading of the autoimmune reaction to other epitopes in the same myelin antigen or to other antigens. This molecular immune spreading may be a reason for additional attacks of the disease. Thus, the crucial elements of the autoimmune reaction in EAE are the trimolecular complex of the TCR reactive to the pathogenic peptide within the appropriate major histocompatibility complex (MHC) class II antigen (molecules, which include HLA in the human, are expressed on the surface of immune cells that in association with peptides form the trigger of TCRs). Following the activation of the T cell, it migrates to the target tissue and produces cytokines and other molecules that cause damage. Equally important is a lack or a failure of the regulator cells that normally operate to prevent autoimmune activation.

In other autoimmune reactions (such as paraneoplastic cerebellar degeneration, a disease of the cerebellum manifested by gait and movement abnormalities in patients with tumors in other tissues), the major players may be antibodies reacting against CNS antigens rather than T cells.

V. THERAPEUTIC INTERVENTIONS

The understanding that the autoimmune disease is caused by an immune response directed against self points to possible modes of therapeutic interventions. Following this understanding, it was possible to prevent or treat EAE by

1. Blocking MHC class II molecules
   - By antibodies that are specific to the MHC or to the complex of particular MHC molecules with the pathogenic peptide embedded in its binding groove.
   - Using peptides that bind the MHC and do not activate the pathogenic T cells; thus, the peptides block the interaction between the pathogenic T cells and the MHC.
   - Using peptides that bind both the MHC and the pathogenic TCR, but the effect of this interaction is silencing of the T cells. Such peptides are termed TCR antagonists. A related group of peptides, called altered peptide ligands, also bind the MHC and TCR, but the result of stimulation modifies or changes the effector function of the T cell, inducing the secretion of different cytokines or the creation of T cells incapable of mediating disease.
2. In addition to the TCR contacting its appropriate peptide in the MHC, efficient T cell activation needs an interaction called "the second signal" or T cell costimulation. In other words, the signal delivered to the T cell by the interaction of its TCR with the peptide–MHC complex is not sufficient to cause activation, and another trigger to a simultaneously bound surface molecule on the T cell is needed to enable the stimulation to proceed. This second signal is termed a costimulatory signal. Blocking this interaction by decoy molecules prevents T cell costimulation. Such interventions in animal models of autoimmune disease result in prevention or cure of the disease.
3. Blocking the TCR, using anti-TCR antibodies, either against a specific disease-causing TCR or against a family of TCRs known to be involved in the disease.
4. Tolerance induction by administering the pathogenic antigen in a form that will abort the immune response to it. An example is administering the antigen orally or intravenously.
5. Recently, several researchers have examined the possibility of using DNA instead of protein or peptides to induce forms of tolerance. Using DNA encoding the TCR V β 8.2, EAE was prevented and the anti-MBP T cell response was shifted from Th1 (secreting interferon γ and IL-2) to Th2 (secreting IL-4 and -5). Others have used DNA-encoding myelin antigens to prevent EAE.
6. After pathogenic T cells have been activated in the periphery, they have to cross the blood-brain barrier to enter the site of the disease. The adhesion of activated T-cells to endothelial cells is mediated by the T cell molecule very late antigen type-4 (VLA-4; a protein expressed on the surface of T cells late after activation) interacting with the vascular cell adhesion molecule (a member of intercellular adhesion molecules) on endothelial cells. Blocking this interaction by monoclonal antibodies can prevent EAE. Clinical studies with a humanized version of anti-VLA-4 are now in phase II clinical trials in MS. The migration of T cells across the extra cellular matrix involves the secretion of enzymes such as matrix metalloproteinases. Inhibition of these enzymes is another way of treating EAE.
7. Once the pathogenic T cells have reached the target tissue, the damage is inflicted in part by cytokines secreted by these cells. Thus, one way to treat autoimmune diseases involves the neutralization of cytokine effects (e.g., anti-tumor necrosis factor antibodies or IL-1 antagonists). These treatments were found to be successful in patients with rheumatoid arthritis.
8. An additional mode of immunointervention is to enhance the immune regulation over the pathogenic T cells by procedures such as T cell vaccination and TCR peptide vaccination or by injection of anti-idiotypic T cell lines (T cells that are specific for the TCR of the pathogenic cell and have the functional capacity to suppress the disease causing-cell).

VI. TREATING THE HUMAN DISEASE

Current treatments for many human autoimmune diseases are largely based on immunosuppression, usually by giving medications such as corticosteroids, cyclophosphamide, azathioprine, or cyclosporin A, which inactivate or kill all classes of lymphocytes. In many patients these medications are effective in the short term only; their administration does not usually alter the natural history of the disease, and the toxicity of these drugs is considerable. This toxicity is related to nonselective immunosuppression, which results in susceptibility of the patient to infections and malignancies. In addition, these medications have considerable side effects (such as in the case of corticosteroid

drugs: elevated glucose levels, hypertension, obesity, osteoporosis, and psychiatric disturbances). Thus, the ideal therapy for autoimmune disease should affect the pathogenic clone or clones specifically without suppressing the entire immune system; it should be devoid of toxicity; and it should be easily administered. Although considerable efforts have been made to improve the treatment of autoimmune disease, none of the current immunosuppressive therapies are satisfactory.

Many of the procedures found to be successful in experimental animals have raised hopes (often unfulfilled) in the scientific community; many successful experimental procedures are being translated to the clinical scene and have undergone clinical trials in patients with MS and other autoimmune disorders.

Oral tolerance to myelin antigens, anti-CD4–T cell monoclonal antibodies, T cell receptor vaccination, T cell vaccination, stem cell replacement, intravenous pooled immunoglobulins, and copaxone have all been developed in EAE and attempted in human MS. Currently, of these novel treatments, the most widely used in MS patients are β-interferon and copaxone. In general, the treatment modalities developed as a result of experimental studies have proven to be safe and show beneficial effects in treated patients. However, since many of the patients enrolled in such studies have failed other treatments and are in an advanced stage of disease, it is difficult to show complete recovery because some of the damage inflicted is not reversible.

VII. FUTURE DIRECTIONS

The major force in the introduction of new and effective treatment for autoimmune diseases is our enhanced understanding of immunology in general and control of immune cell activation in particular. As we discover the key players in T cell activation and the molecular tools to abort an immune response in its early stages without adversely affecting the millions of other beneficial immune cells, we will be able to introduce novel and more effective treatments. Since these diseases cause considerable suffering and loss of life, the sense of urgency has shortened the time in which clinical applications of inventions in the laboratory are carried out.

Axon

KATHLEEN S. ROCKLAND
Brain Science Institute, RIKEN, Saitama, Japan

GLOSSARY

anterograde tracers Substances taken up by and transported from the cell body toward the distal portion of an axon. After appropriate processing, these reveal which target structures receive connections from the injected region.

arbor The distal terminal portion of an axon, which carries the synaptic specializations.

axon a single process, usually emitted from the cell body, with membrane specializations adapted to the conduction of the nerve impulse.

bouton (French "button") General term that refers to the light microscopic appearance (swellings, beads, or stalked endings) of what are usually synapses. Some swellings, however, may be just accumulations of mitochondria, without synaptic vesicles. Boutons can also be called terminal specializations.

dendrites Extensions, usually multiple, of the cell body. Dendrites receive synaptic inputs and are usually much shorter than axons. For some neurons, such as local circuit neurons, dendrites and axons occupy about the same volume.

feedback A type of cortical connection that originates mainly from neurons in layer 6, terminates in layer 1, and has an elongated arbor (>1.0 mm long).

feedforward A type of cortical connection that originates mainly from neurons in layer 3, terminates in layer 4, and has one to four small arbors (≤ 0.2 mm in diameter).

retrograde tracers Substances taken up by synaptic endings and transported back to the cell body. After appropriate processing, these reveal which areas send projections to the injected region.

synapse (Greek "to fasten together") Intercellular junctions that are specialized for the transmission of nerve impulses. Neurotransmitter substances are packaged within synaptic vesicles, as seen by electron microscopy.

Almost all nerve cells, and only nerve cells, have an axon. This structure can be several microns (50–200) to several centimeters in length, and is specialized for conduction of the nerve impulse This article begins with a brief historical survey, followed by a discussion of the cell biology of axons and network properties. Because much of the experimental research on axons employs invasive techniques, this article emphasizes work carried out in animal models. The current understanding, supported by selective verifications, is that the results in most cases will extrapolate to humans, at least from closely related mammalian phyla.

I. INTRODUCTION

Nerve cells consist of three components: the cell soma, dendrites, and axon (Fig. 1). There are usually multiple dendrites and a single axon (there are instances of neurons with no axon and, rarely, of neurons with multiple axons). Dendrites are frequently viewed as extensions of the cell body and are the primary target for synaptic inputs to the neuron. Unlike the dendrites or cell body, the axon does not contain ribosomes, the apparatus of protein manufacture. Via the excitable plasmalemma and other specializations, it is mainly

concerned with conduction and transmission of the nerve impulse and other signals.

Modern investigations of the axon are proceeding on several fronts, namely, the cell and molecular biology of the axon, especially concerning the mechanisms of axoplasmic transport; the specializations and mechanisms of the plasmalemma as an excitable membrane; and the network properties of the axon as a constituent of neural architectures. These issues are of major importance for further understanding of the basic science of neural function and bear directly on pathological conditions, such as peripheral neuropathies, demyelinating diseases, and diffuse axon injury subsequent to trauma. Recent progress has been rapid in all these areas owing to dramatic technical advances. The technical armament includes physiological techniques such as nodal voltage clamping and optical methods for studying electrical activity, sophisticated immunocytochemical and ultrastructural methods, and an array of fine molecular tools.

II. HISTORICAL SURVEY

The early morphological description of nerve fibers has been credited to Antoine van Leeuwenhoek (1718), who studied nerve bundles from cow or sheep spinal cord under the microscope. In his report, however, the individual fibers are described as hollow tubes. In cross section, given the suboptimal preservation of the specimens, the dark core of axoplasm would be shrinken, and myelinated axons would therefore appear hollow.

Further characterization of the axon, through the second half of the 19th century, was hindered by technical limitations as well as by the controversies surrounding the basic organization of nerve cells. One of the most important contributions during this period was made by O. F. K. Deiters. By microdissection of individual nerve cells from histologically treated specimens of spinal cord, Deiters successfully established the continuity of the soma and its processes and distinguished between the protoplasmic processes (''dendrites'') and what he called the more slender axis cylinder. He correctly concluded that the nerve cell is a cell that bears on its soma one axon and several dendrites.

The advent of the Golgi silver stain (1883), which demonstrates a small number of neurons, often in their complete or near complete entirety, stimulated a highly creative period in cellular neuroanatomy, culminating in the Nobel prize awards in 1906 to Camillo Golgi and

Ramon y Cajal. These morphological studies, especially those of Cajal, firmly established the neuron as the basic cellular unit of the brain, as opposed to the "reticularist" position promulgated by Golgi. They also clarified the dynamic polarization of the neuron, as a cell with receiving and transmitting elements (respectively, the multiple dendrites and single axon).

With this work, the investigation of axons rapidly expanded to their functional anatomy and their connectivity and network properties. Axons were defined as two major subtypes, those with local ramifications and those with extensive ramifications (Fig. 2). These became known as Golgi type II and type I, respectively (or local circuit and projection neurons). These two types were later found to correspond generally to inhibitory and excitatory connections, each using different neurotransmitters. In the same period, many of the specific sensory, motor, and associational pathways interconnecting subcortical nuclei and cortical areas were successfully mapped.

III. CELL BIOLOGY OF THE AXON

The fine structural organization of axons has been extensively investigated since the mid-1950s using various forms of electron microscopy (EM), such as standard transmission, high voltage, and EM combined with freeze etching. From such studies, we know that the axon cytoplasm contains many of the same components as the neuronal soma and dendrites; that is, mitochondria, multivescicular bodies, agranular endoplasmic reticulum (ER), neurofilaments, and microtubules. Axons, however, do not have free ribosomes or granular ER and therefore do not engage in protein synthesis (Fig. 3; Table I).

A. Subdivisions

Axon structure can be analyzed in several ways. One way is to distinguish between cytoskeletal and membranous components. The cytoskeleton is considered to comprise three domains linked in a microtrabecular meshwork: the microtubules, neurofilaments, and, adjoining the peripheral membrane, the actin microfilaments. Neurofilaments are a type of intermediate filament, about 10 nm in diameter, which consist of a species-specific ratio of three proteins (68, 150, and 200 kDa). Microtubules are somewhat larger (20–26 nm in diameter), and consist of two globular polypeptides, α and β tubulin, 50 kDa each. Microtubules have

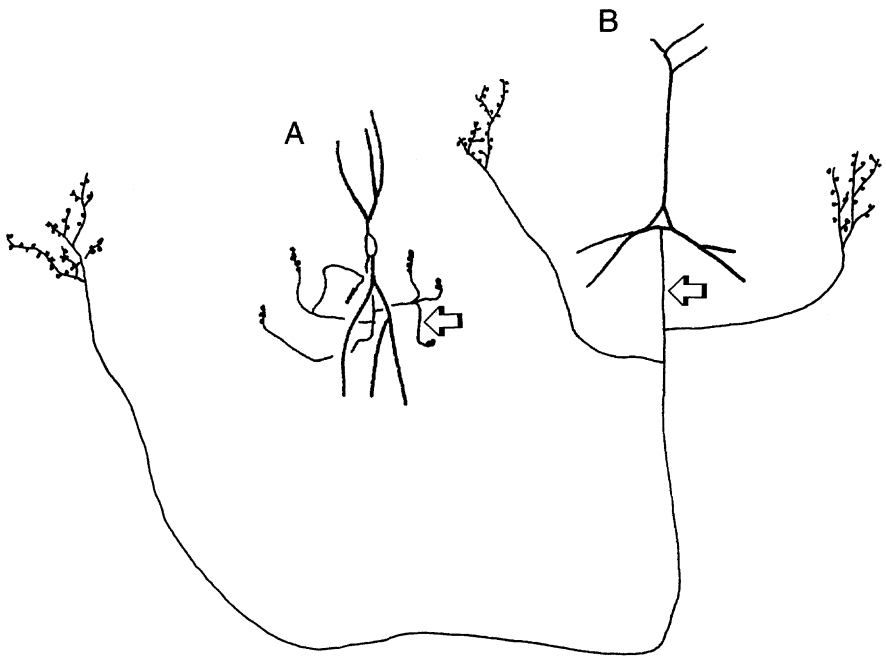

Figure 2 Schematic illustration of (A) local circuit neurons, whose axons arborize in the immediate vicinity of the cell body, and (B) a cortical projection neuron, whose axon typically projects to distant targets, several millimeters or centimeters away. Open arrows point to axons. The caliber of the dendrites has been exaggerated to distinguish these from the axon.

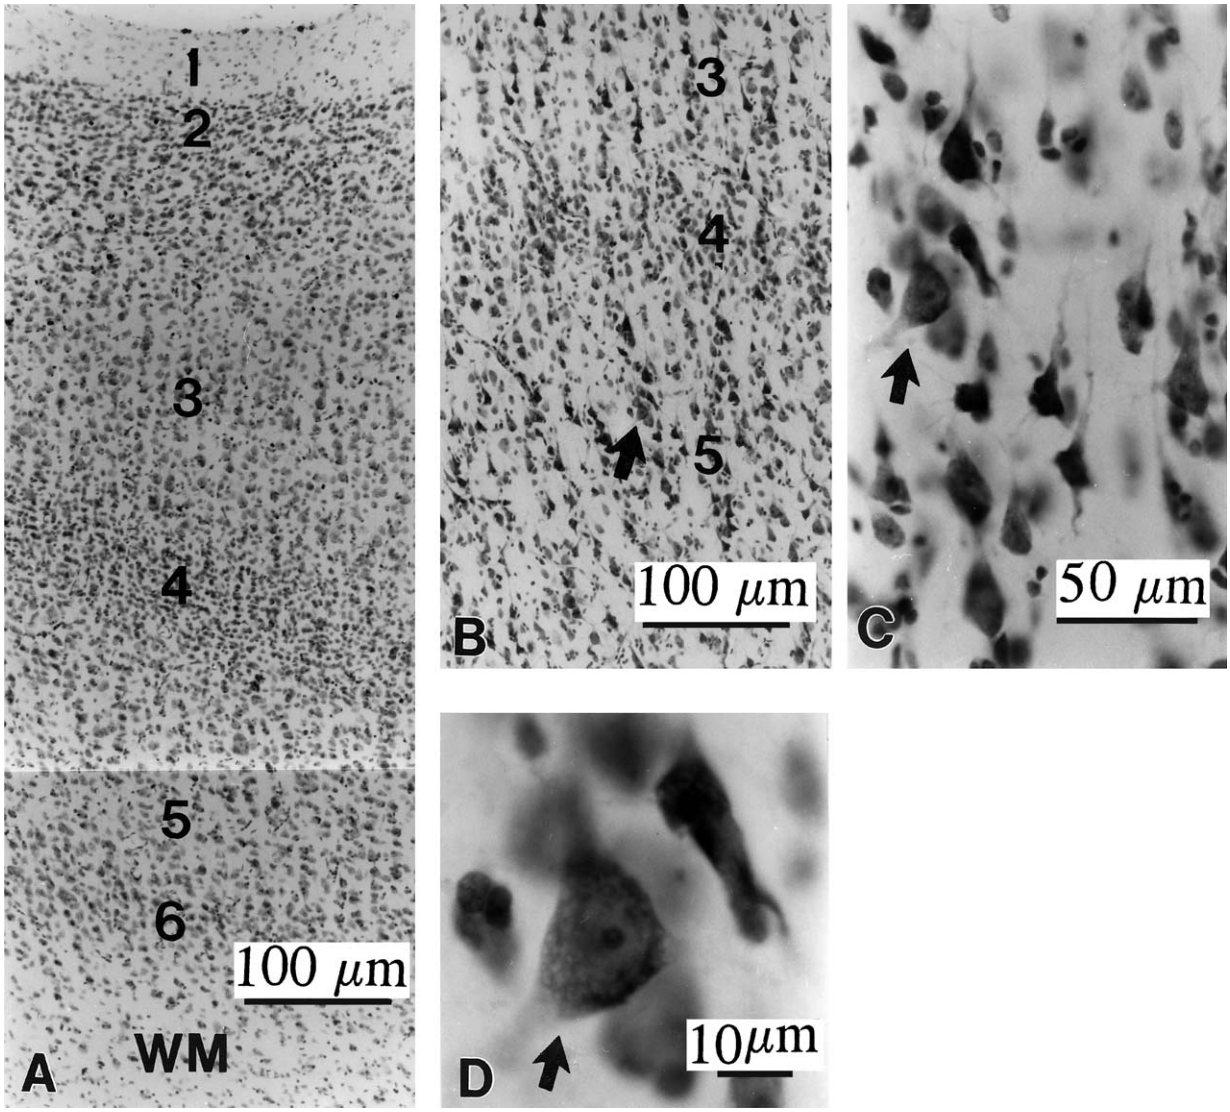

Figure 3 (A) Overview of the six cortical layers in monkey (from visual association cortex). (B) Portion through the middle cortical layers of human temporal cortex from a surgical specimen. (C, D) Progressively higher magnification from the arrow in B. In D, clumps of rER are visible in the cell body. Numbers denote the conventional cortical layers 1–6. WM, white matter.

polarity, by conventional designated as "+" or "−" (respectively nearest the distal or proximal cell body region). Head-to-tail polymerization occurs, with subunits added to the plus end and released from the minus end ("treadmilling"). There are several microtubule-associated proteins (MAPS) that protrude as side arms and contribute to the microtrabecular meshwork.

Neurofilaments predominate in large axons, but microtubules predominate in small axons, and the total number of both structures is proportional to the caliber of the axon (Fig. 4). These structures play a role in skeletal support as well as in intracellular transport of ions, metabolites, and vesicles.

A major membranous component of the axon is the agranular ER, which is thought to consist of two subsystems: (i) clusters of tubules and flattened sacs at the outer wall of the axons and (ii) a complex of narrow tubules and sacs oriented parallel to the long axis of the axon, which is believed to extend the full length of the axon. The agranular ER has been thought to contribute to axonal transport, and it possibly contributes to the sequestration of Ca^{2+} ions and the provision of membrane for forming synaptic vesicles.

Table I
Characteristics of Axons and Dendrites[a]

Axon	Dendrite
1. Extends from either cell body or dendrite	1. Extends from cell body
2. Begins with a specialized initial segment (except dorsal root ganglion cell and autonomic ganglion cell)	2. At least in proximal portions, continues cytoplasmic characteristics of cell body
3. May be absent as in amacrine cells of retina	3. May be absent as in dorsal root ganglion cell
4. Unique in most cells, but there are some examples of multiple origin	4. Usually multiple
5. May be myelinated or unmyelinated	5. Rarely myelinated (and if so, only thinly)
6. Almost never contains ribosomes (Except in initial segment)	6. Contains granular endoplasmic reticulum or ribosomes, diminishing with distance from origin
7. Usually has smooth contours and cylindrical shape	7. Usually has irregular contours and specialized appendages
8. Usually is the thinnest process of the cell at site of origin	8. Usually originates as a thick tapering process
9. Ramifies by branching at obtuse angles	9. Ramifies by branching at acute angles
10. Usually gives rise to branches of the same diameter as parent stem	10. Usually subdivides into branches smaller than parent stem
11. Ramification can be close to cell body or at great distances; may extend long distances away from cell body, even into peripheral nervous system	11. Ramification usually confined to the vicinity of the cell body; if cell body lies in central nervous system, dendrites remain entirely within central nervous system
12. Neurofilaments predominate in larger axons	12. Microtubules predominate in larger stems and branches
13. Capable of generating action potentials, propagating them, and synaptic transmission	13. Conducts in a decremental fashion, but may be capable of generating action potentials
14. Primarily concerned with conduction and transmission	14. Primarily concerned with receiving synapses.

[a]From *The Fine Structure of the Nervous System: Neurons and Their Supporting Cells, Third Edition* by Alan Peters, S. L. Palay, and H. Webster, Copyright © 1990 by Alan Peters, Used by permission of Oxford University Press, Inc.

Many long, type I axons have an associated specialization, the myelin sheath of the plasmalemma, which is elaborated by glial processes. The myelin wrapping is interrupted by nodes of Ranvier, which are involved in the process of saltatory impulse conduction.

Axons can also be subdivided into several specialized portions along their proximal to distal length. The proximal portion, at the juncture with the cell body, is termed the axon hillock (Fig. 1). This region is characterized by fascicles of microtubules and a high density of sodium-dependent channels. The high density of channels accords with the importance of this region as a "trigger zone" for the initiation of axon impulses.

Adjoining the axon hillock distally is the initial segment (20–50 nm in length). This portion has clusters of microtubules and an undercoating of dense material below the plasmalemma. The initial segment leads into the body of the axon. This can range from <0.5 mm in the case of type II, local circuit axons to several centimeters or even meters in the case of axons projecting from motor cortex to the lower spinal cord of larger animals. Axons in some systems can send branches ("collaterals") to different target structures. Finally, at the distalmost portion, axons form terminal arbors (Fig. 5). Arbors consist of preterminal and terminal portions. The preterminal portions are where the axon begins to branch repeatedly, and, if myelinated, loses the myelin sheath. Terminal portions are thin-caliber branches, decorated with synaptic terminal specializations.

B. Axoplasmic Transport

The axoplasm is not static but, rather, participates in a state of dynamic flow. There are at least two reasons for this. One is the necessity for maintenance of the

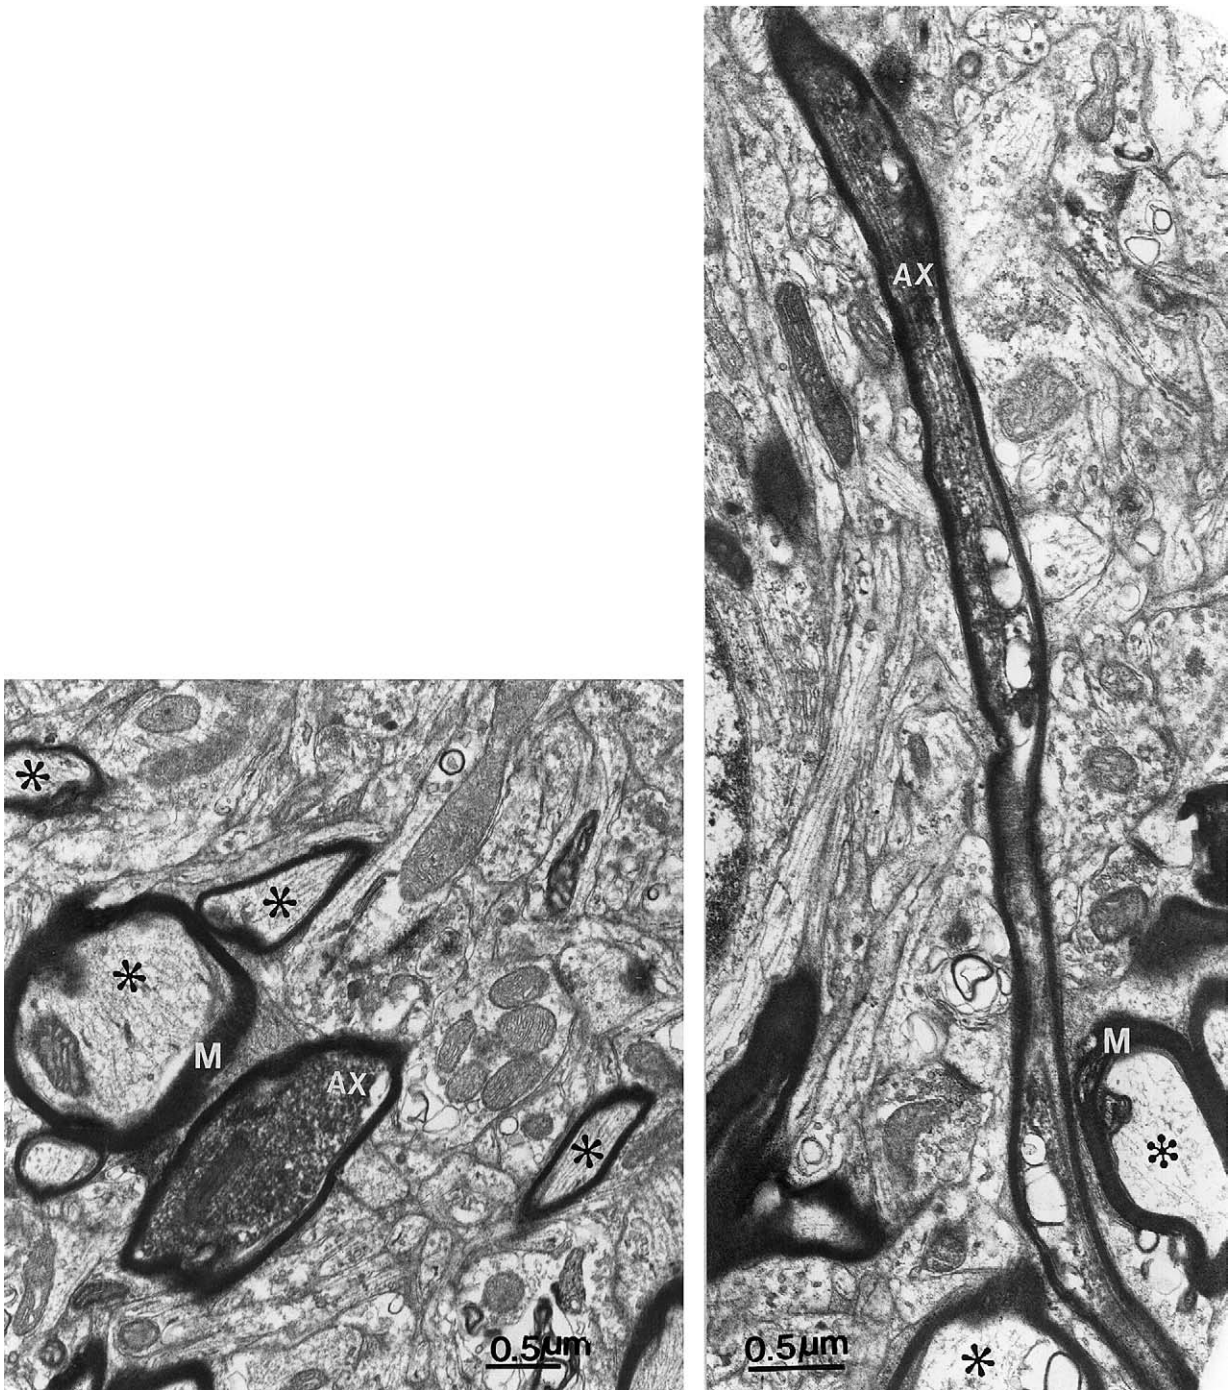

Figure 4 Electron micrographs of monkey cortical tissue. Two axons (AX) have been anterogradely filled with tracer transported from a distant injection site. Several other unlabeled axons occur in the same field (asterisks). M, myelin.

cytoskeleton, plasmalemma, synaptic apparatus, and other organelle components. Since little or no protein synthesis takes place within the axon proper, materials synthesized within the cell body must be transported along the full length of the axon. A second, less understood requirement relates to the encoding and regulatory functions of the axon, whereby conditions at its distal end are signaled back to the cell body.

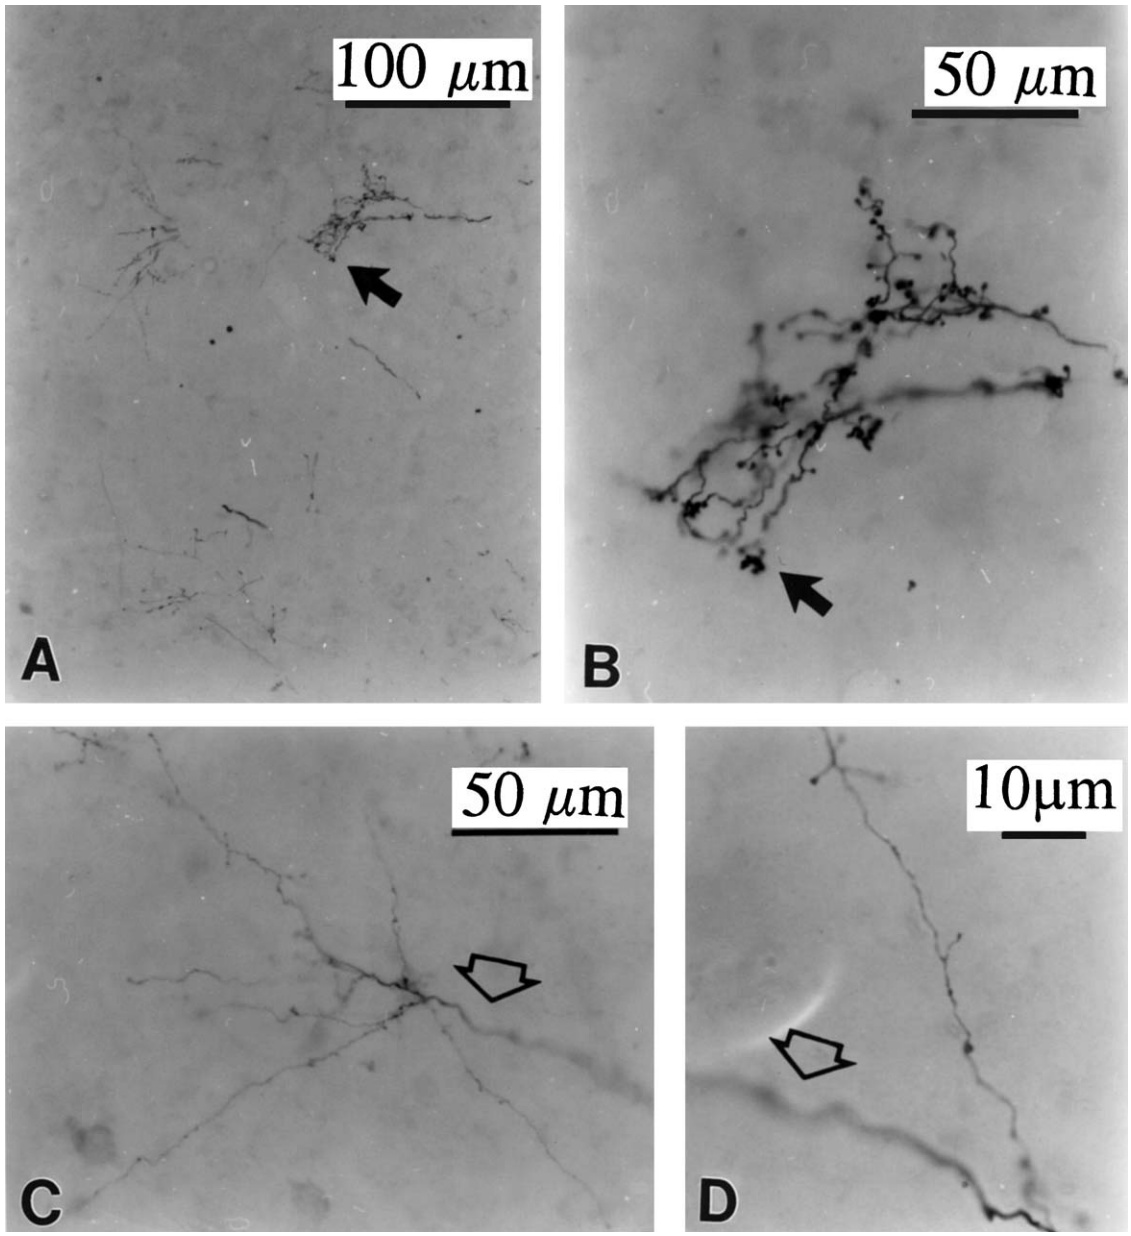

Figure 5 Photomicrographs of two corticocortical axon arbors anterogradely filled with tracer (BDA) transported from a distant injection site. Both arbors are about the same size. One (A, B) has very large terminal specializations. The other (C, D) has delicate beaded and stalked endings and is more typical. B is higher magnification of A. D is higher magnification of C. Arrows point to corresponding features.

Axon transport is a complex process that operates in both the anterograde (toward the distal end with terminal arbors) and retrograde (toward the cell body) directions (Fig. 6). There are several subcomponents that require many different mechanisms. The main distinction is between fast and slow transport. Fast transport operates in both the anterograde and retrograde directions and comprises several rate classes. These may reflect differences in transport mechanisms and/or the sieving action of the cytoskeletal meshwork on organelles of different sizes. Small vesicles and neurotransmitter molecules are conveyed at the fastest velocity (200–400 mm/day), mitochondria at 50–100 mm/day, and various metabolic enzymes at

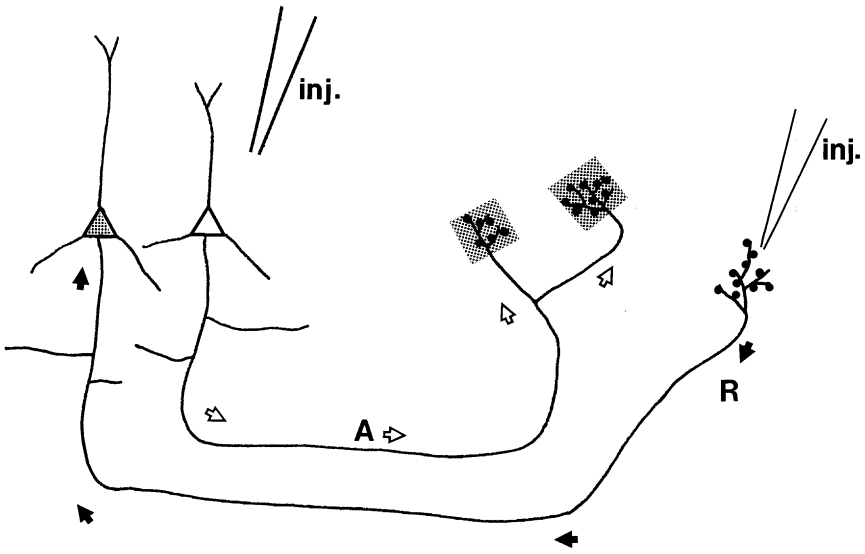

Figure 6 Schematic representation of axonal transport in the anterograde (A) and retrograde (R) directions.

28 mm/day. Microtubules and neurofilaments migrate by slow transport, which proceeds at less than 5 mm/day.

1. Fast Transport

Early work on axon transport took place in the 1940s, in part motivated by interest in axon regeneration during World War II. The phenomenon was simply but convincingly demonstrated by the accumulation of an irregular bulge of material proximal to a ligature placed around a single axon. When the constriction was removed, the accumulated material continued down the axon at a rate of about 1.0 mm/day. Fast transport (i.e., at rates of 50–400 mm/day) was demonstrated several decades later by the uptake of radioactively labeled amino acids by the cell soma. The label is incorporated into proteins and transported down the axon, where the pulse of radioactive material is then sampled by either autoradiography or scintillation counting.

Recently, investigations of axon transport have shifted from elucidation of what materials are transported and at what rate to unraveling the underlying mechanisms. Indirect evidence had already suggested the importance of microtubules. For example, agents such as colchicine that disrupt microtubules, also interfere with transport. More direct evidence of the role of microtubules in fast transport was provided by studies using the compound β, β_1-iminodiproprionitrile, which causes microtubules to segregate from neurofilaments and form several bundles in the center of the axon. Electron microscopy and autoradiography show a clear association of mitochondria and other rapidly transported elements with the central clusters of microtubules. Finally, enhanced videomicroscopy of microtubules extruded from axoplasm indicates that these can transport organelles and vesicles.

In the transport process, microtubules operate in concert with several "molecular motors" (Fig. 7). The energy-transducing protein, kinesin transports organelles anterogradely along microtubules. Dynein, another microtuble-associated ATPase, is implicated in retrograde transport. The role of kinesin has been established experimentally. Injection of antisense oligonucleotides suppresses kinesin heavy-chain expression and concurrently results in abnormal accumulation of protein within the cell body. Additionally, kinesin heavy-chain mutations produce various disruptions in action potential propagation and neurotransmitter release.

Recent studies have identified additional carboxy-terminal-type proteins within the kinesin superfamily that participate in the transport of specific organelles at specific velocities. Most of these putative motors have been characterized by molecular cell biological approaches, such as cloning and sequencing of the genes encoding these proteins, expression and purification of the proteins using the baculovirus Sf9 cell system, observation of molecular structures by EM,

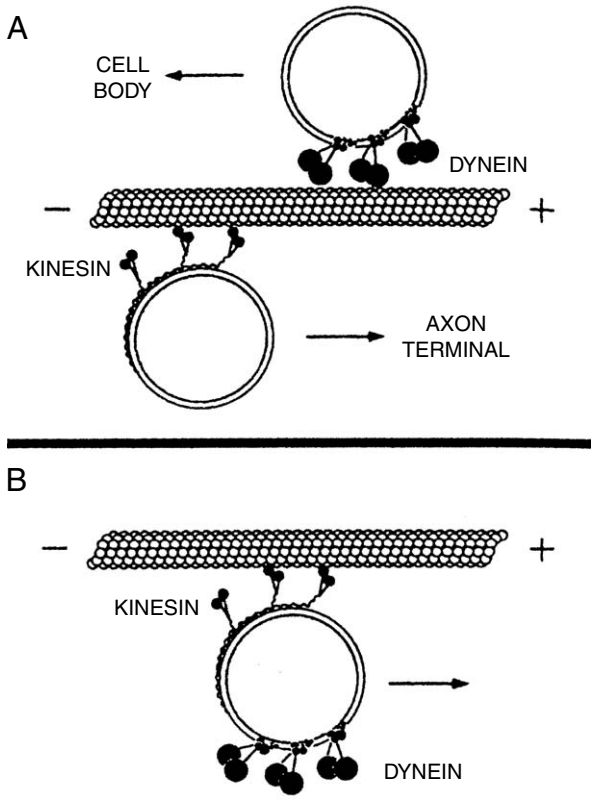

Figure 7 Alternative models for the function of molecular motors in fast axonal transport. (From *The Axon: Structure, Function and Pathophysiology* by S. G. Waxman, J. D. Kocsis, and P. K. Stys. Copyright © 1995. Used by permission of Oxford University Press, Inc.).

in vitro motility assays, immunocytochemistry, and identification of particular cargoes by subcellular fractionation and immunoprecipitation.

2. Slow Transport

Less is known about the mechanisms of slow transport. The polymer sliding model proposes that cytoskeletal proteins, assembled in the cell body, travel down the axon in the form of individual microtubule and neurofilament polymers. Several recent experiments, however, suggest that cytoskeletal proteins are transported as small oligomers along microtubules. For example, in a modern variant of classical metabolic labeling studies, a recombinant adenoviral vector, encoding epitope-tagged neurofilament-M protein, was used to infect neurons of a transgenic mouse line in which axons normally lack neurofilaments. The viral-encoded subunits do not form polymers, but confocal and electron microscopy demonstrated that these nevertheless were transported (at a slow rate of 5 mm/day) and that transport occurred in the close vicinity of microtubules.

IV. METHODS FOR INVESTIGATING CONNECTIVITY

The excitable axonal membrane is specialized for the propagation and conduction of the nerve impulse. Via synaptic connections with dendrites and, to a lesser extent, neuronal somata and other axons, axons are the chief means of "information transfer" within neural networks.

The organization of connectional systems has been investigated by a variety of experimental techniques, mostly in animal models. A large body of work has been devoted to simply mapping the complex interconnections of different structures. Much of this work has utilized extracellular injections tracer substances, which typically cover a tissue volume of 0.1–2.0 mm in diameter.

A. Anterograde Tracers

Anterograde tracers, such as ^{3}H amino acids or WGA-horseradish peroxidase (HRP), are taken up by the thousands of cell bodies within the injection site, transported anterogradely in different compartments through the axon, and accumulated along the axonal membrane and/or at the terminal specializations. Histological processing reveals label in structures that receive connections from the injected region (Fig. 6). Recently, a new generation of glycoconjugate anterograde tracers (biocytin, biotinylated dextran amine, and kidney bean lectin) have been introduced that bind to the plasmalemma and, after appropriate histological processing, result in morphologically detailed images of axon structure, including branch points and fine terminal specializations.

B. Retrograde Tracers

Retrograde tracers such as the enzyme HRP and several fluorescent dyes (including a kind of latex paint) are taken up by synaptic terminations within the injection site. They are transported retrogradely through the axon process to the cell body. Thus, labeled neurons are visualized in those structures that send projections to the injected region.

C. Electrophysiology

Electrophysiological investigations define receptive field and other functional properties. These are carried out by intra- or extracellular recordings, usually from the soma but also from axon processes. Axonal conduction velocity is another important parameter. This is analyzed by measuring the latencies of spikes evoked by antidromic activation of axons by electrical stimulation. Temporal relationships between the firing times of two neurons can also be assessed by cross-correlation techniques, although these are more often used for inferring whether two neurons are connected.

A particularly elegant approach is intracellular or intraaxonal microelectrode recording combined with intracellular microinjections of tracers such as HRP or biocytin. In this way, physiological characteristics can frequently be correlated with morphological specializations. For example, thalamocortical connections to primary visual cortex are subdivided into several functionally distinct categories concerned with form or motion vision. Axons conveying "information" related to form (from the parvocellular layers of the lateral geniculate nucleus) have properties consistent with achieving fine spatial resolution. Among other specialized features, their terminal arbors are smaller than those of axons concerned with motion vision (from the magnocellular layers).

D. Techniques Used in Humans

1. Microstructure

In humans, methods for direct investigation of axon connectivity are restricted to noninvasive approaches. At the microlevel of individual axons, morphological techniques are limited to a small number of methods that can be applied in postmortem tissue or surgical biopsies. First, the classical Golgi stain can demonstrate aspects of axon structure, especially in young tissue, although the identity and full conformation of long axons are difficult to establish. Second, degeneration methods can be used with moderate success. In these methods (the precursors to the more physiological modern methods, which utilize axon transport of injected tracers), tissue is treated in a series of solutions that stain fragments of axons degenerating as a result of damage related to stroke or some other traumatic process. Third, some labeling can be achieved by intracellular fills of neurons or axons in tissue slices *in vitro*, but this technique is necessarily restricted to shorter connections or only incomplete portions of longer connections. Fourth, one class of tracers, lipophilic carbocyanine dyes (DiI and DiO), has been found to bind to the plasmalemma, even in postmortem tissue, and transport by diffusion. These tracers produce high-resolution, Golgi-like labeling, but only within a distance of 2–5 mm of the injection spot. Thus, although evidence supports the applicability of animal data to the human brain, there is a serious need for new techniques that might allow direct investigation of fine axon connectivity in human tissue. Finally, there is an increasing number of antibodies available for immunohistological investigation of neural structures. Many of these (e.g., antibodies against peptides, calcium binding proteins, transmitters, receptors, or cytoskeletal elements such as neurofilaments) can successfully be used in human biopsy or postmortem tissue. Most of these markers, however, are for cellular or subcellular components and not long-distance axons.

2. Macrostructure

In humans, long-distance cortical connections have been easier to investigate at the macrolevel of axon bundles or tracts. Major tracts include cortical commissural fibers crossing in the corpus callosum to the contralateral hemisphere, projection fibers to and from subcortical nuclei (such as the thalamus, basal ganglia, and colliculi), and ipsilateral cortical association fibers.

The various white matter tracts were grossly identified more than 100 years ago by methods such as blunt dissection or myelin staining subsequent to localized lesions. These techniques were successfully used in identifying pathways such as the uncinate or arcuate fasciculi (respectively linking temporofrontal or occipito- and parietofrontal fields) or the cingulum (frontoparahippocampal) bundle.

Recently, specific pathways or tracts have been visualized in their stem portion by diffusion-weighted magnetic resonance (dwMR; "stem" refers to the compact coherent middle portion of an axon bundle, contrasted with its more fanned-out proximal or distal extremes). This technique detects the diffusivity of water molecules in three dimensions. For oriented tissue, such as fiber bundles, this diffusivity tends to be anisotrophic. Images of the location, size, and trajectory of major white matter bundles acquired by dwMR accord well with earlier postmortem studies based on histological myelin stains.

Visualization of white mater bundles in humans is important for issues of both clinical and basic science. In clinical neurology, there are many conditions, such as stroke, multiple sclerosis, amyotrophic lateral sclerosis, and traumatic head injury, that lead to pathological alterations in white matter tracts. Imaging techniques allow improved *in vivo* diagnosis and analysis of these conditions. These techniques also offer immense promise as a probe of normal connectivity in the human brain.

3. Electrophysiology

Electrophysiological studies of axon organization in humans are also highly constrained by the need for noninvasiveness. Considerable information, however, is available from methods such as evoked potentials, which can record populational responses through the skull. Evoked potential recordings can be in response to presented stimuli or, recently, to transcranial magnetic stimulation. Electroencephalogram coherence analysis is another method for studying connectivity in both the human brain and the animal brain.

The need for precise localization during neurosurgical procedures provides another source of data. Surface electrodes are routinely used to map regions involved in cortical language processing, and in certain conditions depth electrodes may be placed in structures such as the amygdala, hippocampus, or substantia nigra.

V. NETWORK PROPERTIES OF AXONS

Long axons form connections between structures. Connections are often schematized by arrows (e.g., 'area A $\rightarrow$ area B'), but this is really a shorthand notation for complex processes, such as convergence (how many axons converge on a given postsynaptic target), divergence (how many postsynaptic neurons are contacted by a single axon), and combinations and integration of multiple inputs.

Network properties are difficult to investigate, even in animal models. To some extent, we know what is connected to what, but only partial and incomplete data exist concerning biophysical parameters and dynamic properties. A recent, powerful approach is the combination of intracellular labeling and EM analyses with dual or triple intracellular recordings *in vitro*. This combined anatomical–physiological approach provides highly precise data regarding the number and location of synapses between interconnected neurons and also regarding the functional dynamics of the identified synapses. For example, in pyramidal-to-interneuron but not pyramidal-to-pyramidal connections, higher presynaptic firing rates result in frequency-dependent, incremental facilitation.

For long-distance connections, network properties have been more difficult to address. This is partially because of their spatial dispersion. It is difficult to trace a single axon along its complete trajectory and through multiple spatially separate arbors. Moreover, there is only a relatively small EM database, especially for human and subhuman primates, and this leaves many unanswered questions: Are there changes in caliber along the course of an axon? What are the postsynaptic targets? How do multiple inputs interact at a given postsynaptic target?

A. Thalamocortical Connections

Such data as are available pertain mainly to thalamocortical systems terminating in primary sensory areas since these can often be identified by physiological and/or structural criteria. For example, the two main groups of geniculocortical axons terminating in the primary visual cortex have been physiologically characterized, labeled by intraaxonal injection of tracers, and then morphologically analyzed by histological reconstructions. Such studies demonstrate that parvocellular axons have a small diameter, small arbors ($\sim$0.2 mm in diameter), and a moderate number of terminal specializations ($<$1500), consistent with their functional specialization for form and color vision. Magnocellular axons, which are associated with motion vision (requiring low spatial but high temporal resolution), have a larger diameter, larger arbors, and a large number of terminal specializations ($>$3000). Since each termination makes on average two synapses, if there is one synapse per postsynaptic neuron, then a reasonable estimate is that a single parvocellular axon diverges to about 3000 postsynaptic elements and a single magnocellular axon to at least 6000. The degree of convergence of parvocellular axons has been estimated to be at least 20–40. These numbers are important for further understanding of neuronal transformations, which are considerably more complicated than simple "relays."

EM studies suggest that both parvo- and magnocellular pathways have similar postsynaptic pools,

which suggests that other aspects of circuitry, such as recombinations with local and other extrinsic connections, contribute to the physiological differences associated with the cortical stages of these two pathways. Further analysis of network properties, at the resolution described previously for dual or triple intracellular recordings, will depend on new technical advances.

B. Feedforward and Feedback Cortical Connections

Beyond the primary sensory areas, axon properties are more difficult to characterize both physiologically and structurally. On the basis of structural evidence, interareal corticocortical connections have been subdivided into two broad categories: feedforward and feedback (Fig. 8). The terms reflect an assumption of serial organization, whereby feedforward connections progress from primary sensory through higher order areas. They are reciprocated in the "reverse" directions by feedback connections. Feedforward axons originate from neurons mainly in layer 3, terminate mainly in layer 4, and have one to four spatially separated arbors, each about 0.2 mm in diameter. Serial section reconstruction of axons labeled with the newer anterograde tracers demonstrates that individual arbors carry 50–400 terminal specializations, for a total number per axon of 400–1000 boutons. Feedback axons originate from neurons mainly in layer 6, terminate heavily in layer 1, and tend to have a single, rod-like axon at least 1.0 mm long, also with 400–1000 terminal specializations. On the basis of these data, if each bouton corresponds to one synapse, and if no more than one synapse is made with any postsynaptic neuron, a divergence factor of 1:400–1000 is suggested. No estimates are available for convergence in these pathways, and there are only sparse data available concerning postsynaptic populations. In primates, feedback inputs to layer 1 are commonly thought to target predominantly apical dendrites since these are a major constituent of layer 1, but the actual mix and identity of the postsynaptic targets are unknown. Similarly, the actual postsynaptic targets of feedforward connections, while probably including apical dendrites of deeper neurons that pass through layer 4 and the basal dendrites of overlying neurons in layer 3, are not known. Confocal microscopy may be an improved means of approaching these questions because it offers the necessary resolution of EM—to verify that boutons close to a structure are actually contacting that structure—without impractically slow EM processing and analysis.

In contrast to thalamocortical connections to primary sensory cortices, the functional properties of feedforward and feedback axons are not known. A convenient assumption is that feedforward axons are relays from early to higher order cortical areas and are

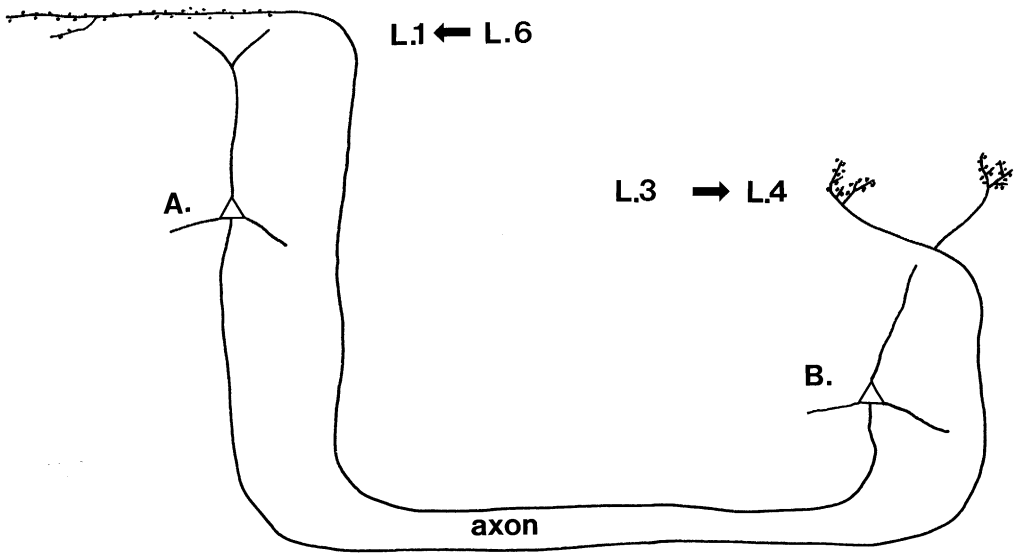

Figure 8 Schematic representation of two distinguishable types of cortical axons: feedforward (A) and feedback (B).

involved in progressive elaborations, whereas feedback axons exert a return, "modulatory" influence. This is clearly an oversimplification, however, in several respects. First, neither of these systems operate in isolation but, rather, are part of a broader network of thalamocortical, callosal, and intrinsic connections, among others. Second, the efficacy of feedback connections, despite their location on distal dendrites in layer 1, may actually be considerable since recent work has identified mechanisms for active boosting of synaptic inputs at dendritic locations distant from the axon hillock. Third, both feedforward and feedback axons, rather than operating as complementary pairs, likely comprise many functionally significant subdivisions.

C. Subtypes of Connections

1. Morphological Evidence

The current evidence for subdivisions within the main connectional groups derives mainly from the characteristics of the cells of origin. Neurons belonging to one projection class (e.g., corticoclaustral vs corticogeniculate projection neurons in layer 6 of primary visual cortex) frequently have a distinctive laminar pattern of their local axon collaterals. Other experiments suggest that projection systems can be distinguished by the distribution of neurofilament protein in the cell bodies. That is, some feedback projections in the visual pathway are reported to exhibit a higher proportion of neurofilament protein-containing neurons that the feedforward projections (70–80 vs 25–36% for projections to area V4). Additional criteria, such as specificity of surface molecules on the cell body, have been more difficult to establish, although it seems likely that this is due to technical limitations rather than any basic uniformity.

There are a few known examples of strikingly distinct structural specialization of axons. For example, corticothalamic projections to association thalamic nuclei (subdivisions of the pulvinar and the mediodorsal thalamus) originate from two groups of neurons: large pyramidal neurons in cortical layer 5 and smaller neurons in layers 5 and/or 6. This has been known since the late 1970s from the results of retrograde tracers injected into the thalamus and transported to cortical areas. Recently, studies using high-resolution anterograde tracers combined with serial section reconstruction have shown that the axons of these two groups differ dramatically (Fig. 9). Axons differ in caliber, being respectively greater than and less than 1.0 μm, and in the configurations of their terminal arbors. The larger axons terminate in small, round arbors with a small number of large terminal specializations. The smaller axons have elongated fields bearing a larger number of slender specializations. The physiological characteristics of these two types are not known, although it seems likely that the larger axons would be faster because of their larger diameter and larger terminations.

Another recognizable axon type is the connections originating from the giant Meynert cells in the deeper layers of primary visual cortex (Fig. 10). The axons of these cells are thick (2 or 3 μm in diameter) and have distinctively large terminal specializations. Both features are suggestive of a fast conduction velocity, although the functional properties of Meynert cells are not known. Some but not all of these axons can branch to multiple targets, including the pulvinar, cortical area MT/V5, and superior colliculus. The latter two structures are known to have a role in motion processing.

2. Physiological Evidence

Other evidence of axonal subtypes comes from physiological investigations of conduction velocity. Conduction velocity depends on several factors: axon caliber (larger axons are faster), myelination (myelinated axons are faster), the existence of branching, synaptic dynamics, and integration delay at the postsynaptic target. Axon length is less important. Conduction velocity is analyzed by measuring the latencies of spikes evoked by antidromic activation of axons by electrical stimulation or by calculating the temporal relationships between the firing times of two impaled neurons in cross-correlograms.

Long-distance projecting axons typically exhibit a spectrum of conduction velocities and caliber (Fig. 11). Projections from cortical motor areas to the spinal cord (corticospinal tract) are subdivided into slow and fast components. Slow fibers, comprising the majority, have an antidromic latency of about 2.6 msec from the brainstem pyramid, whereas for fast fibers the equivalent latency is 0.9 msec. These latencies respectively correspond to conduction velocities greater than or less than 30 $msec^{-1}$, and axon calibers <4 μm or >6 μm (in man). Curiously, in this system there does not seem to be any correlation of fiber size with either phylogenetic status or digital dexterity. From comparative studies, the largest fibers (25 μm) have been reported in the seal.

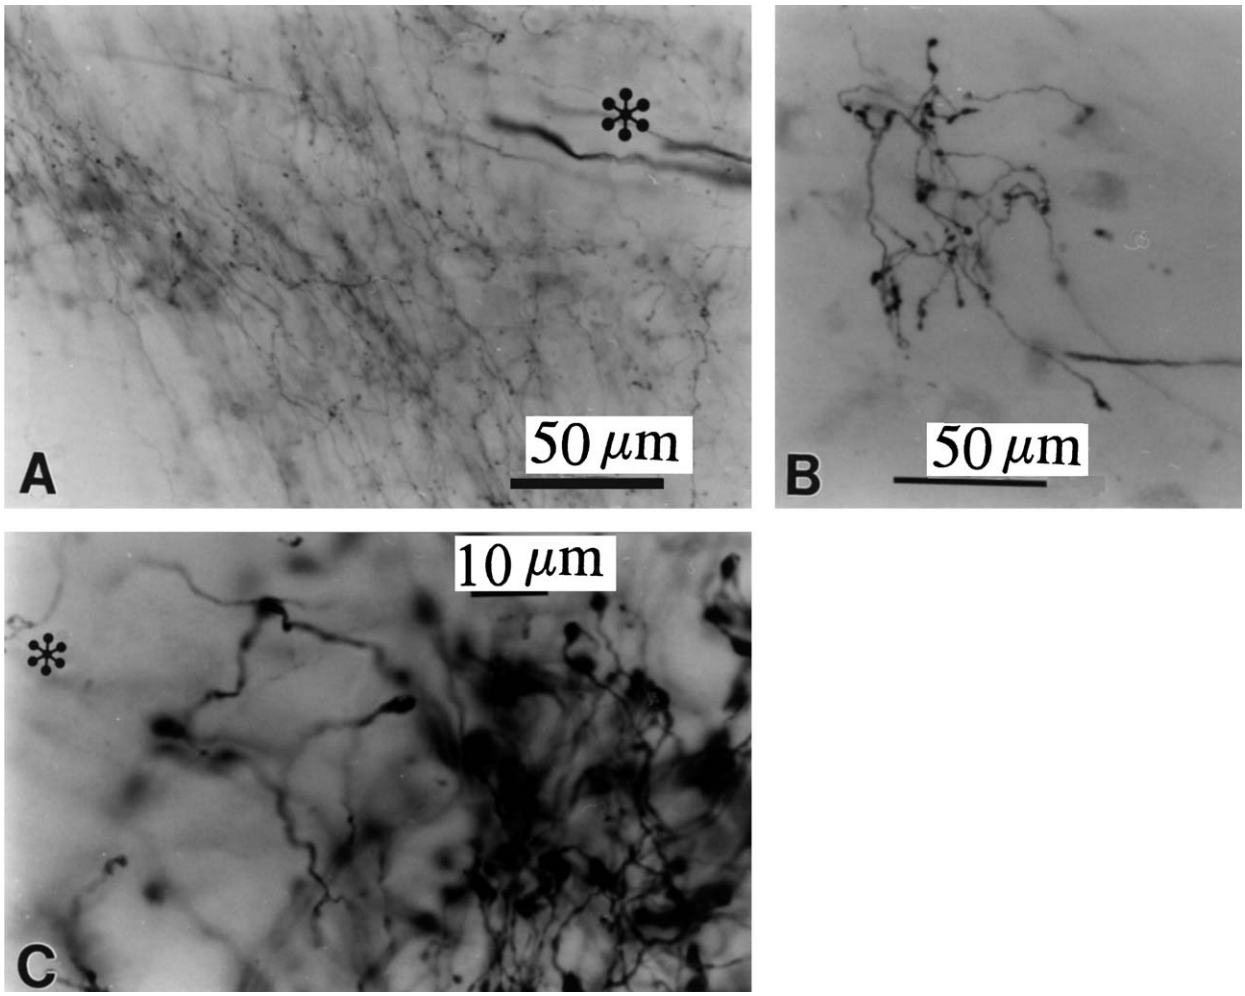

Figure 9 Photomicrographs of two morphologically distinct types of corticopulvinar axons. (A) A field of thin axons with slender, spine-like terminations. Portions of two thicker axons pass in the vicinity (asterisk). (B) A single, round arbor bearing a small number of larger boutons. (C) Higher magnification of a field of large boutons, mixed with a small group (asterisk) of the thinner terminations.

Several studies have investigated the distribution of latencies to visual stimulation in different areas of the visual system of macaque monkeys. These suggest an average latency difference of 10 msec between neurons in successive areas. All areas, however, exhibit a range in latencies, and it has been noted that short-latency neurons in higher order areas in inferotemporal cortex can respond to a given stimulus before long-latency neurons in area V1. The range in conduction velocity may correlate with axon caliber, which for most interareal cortical connections ranges from about 0.5 to 2.0 μm in diameter. How these timing differences contribute to cortical processing is the subject of ongoing investigations.

The temporal–computational characteristics of individual axons have been analyzed by simulating the propagation of an action potential in arbors traced with histological techniques. Simulated results on latencies and conduction velocities are in good agreement with those found electrophysiologically, and this technique may provide an effective tool for probing issues such as how the velocity of spike propagation is affected by changes in axon diameter at branching points or at boutons, the delay in activation latencies between boutons, and how conduction velocity might be modified by the previous occurrence of an action potential. An interesting general result from this work is that different axon geometries can lead to similar patterns of spatiotemporal activation. This raises the issue of how close a correspondence there is between the morphology and computational properties of an axon. A larger sample of different axons and more

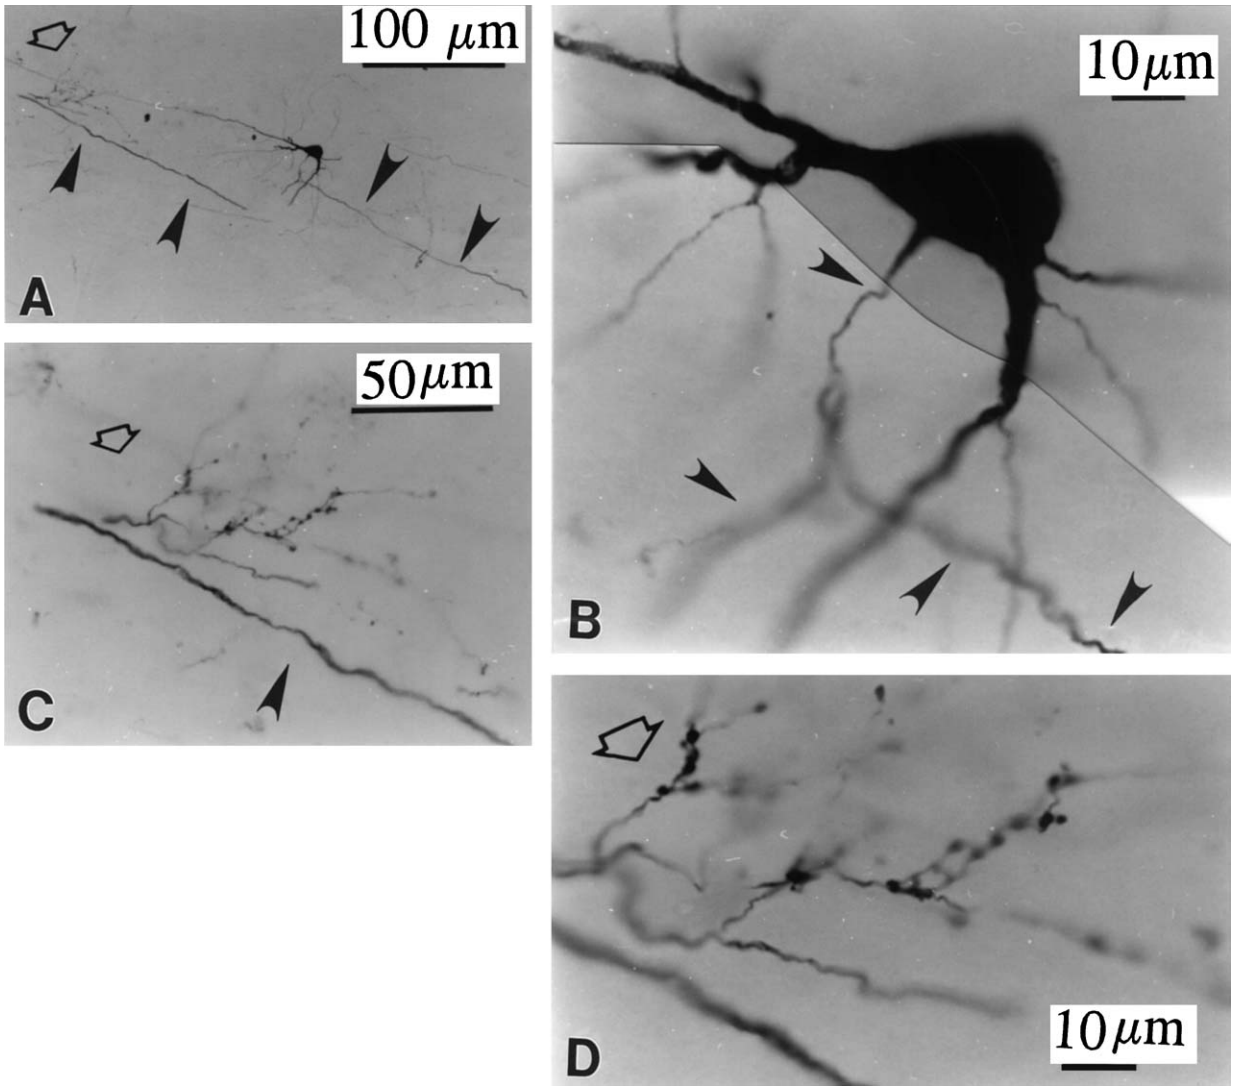

Figure 10 Photomicrographs of axons originating from large Meynert cells of primary visual cortex. These are large caliber and terminate in arborizations with large boutons. [A and (higher magnification) B] Cell body, dendrites, and axon (arrowheads) filled with BDA. [C and (higher magnification) D] One of several terminal arbors. Open arrows point to corresponding features in A, C, and D. (Portions in the deeper planes of the histological section are out of focus.)

precise data on the biophysical properties of the terminal arbor are necessary to extend this line of research.

VI. HOW AXONS RELATE TO CORTICAL LAYERS AND COLUMNS

Two key elements of cortical architecture are layers and modules (''columns,'' ''assemblages,'' or cell groups). Both layers and columns are complicated structures. Layers can be distinguished on the basis of cell sizes and density, and in many cases enzyme concentrations and other markers also show orderly laminar patterns.

As described previously, feedforward systems terminate heavily at the level of layer 4, and feedback systems preferentially target layer 1. Intrinsic collaterals of pyramidal neurons tend to arborize mostly in layers 3 and 5. It is not clear, however, whether laminar specificity implies, as it does in the hippocampal formation, dendritic stratification of inputs. Available evidence suggests, to the contrary, that extrinsic axons

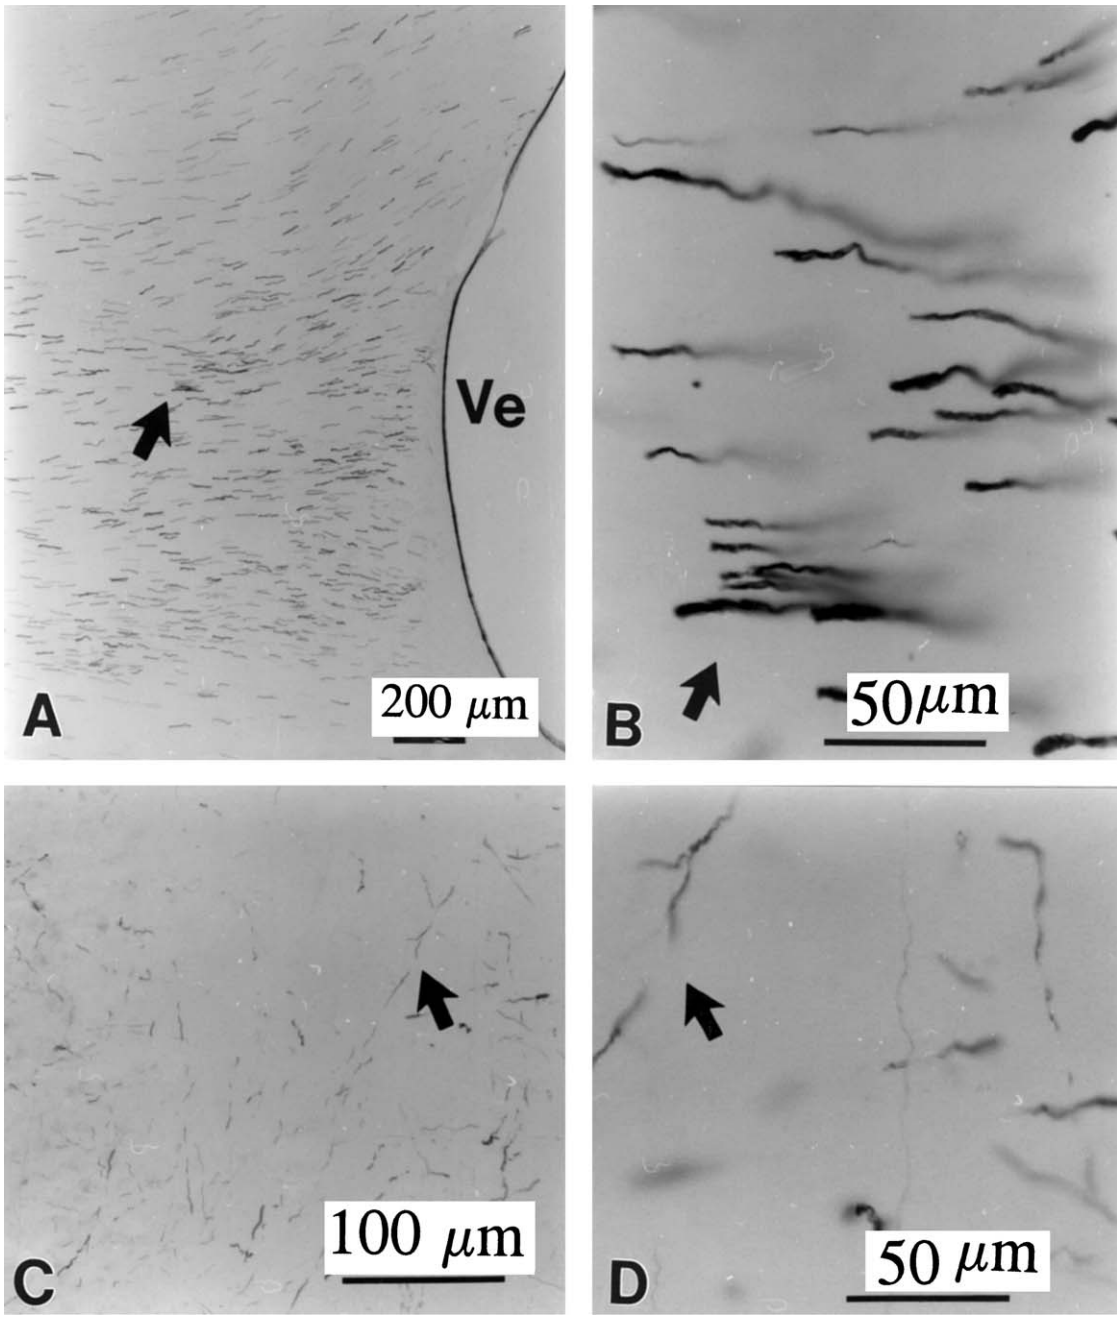

Figure 11 Photomicrographs of axons labeled by BDA anterogradely transported from an injection site. [A and (higher magnification from arrow) B] A field of axons crossing in the corpus callosum. The histological sectioning results in axon fragments that can be identified and traced in sequential sections. Note the range of different fiber diameters. [C and (higher magnification from arrow) D] Field of corticocortical axons subjacent to their target region. Branched profile is evident at the arrows.

synapse on many of the structures within their terminal domain.

The relationship between axon systems and cortical columns is likewise complex. For example, in visual cortex geniculocortical axons derived from the left or right eye segregate into alternating ocular dominance columns. These constitute the primary anatomical substrate for the functional columns that can be demonstrated by microelectrode recordings or by activity-driven imaging (with the metabolic tracer

2-deoxyglucose in animals or position emission tomography or functional magnetic resonance imaging in humans). It is important to remember, however, that the functional columns, that are visualized as extending from pia to white matter through the cortical depth, are actually a combination of direct thalamocortical connections to layer 4 and local, short interlaminar relays from layer 4 to the upper and lower layers.

In nonprimary cortices, the anatomical substrates of columnar architecture are still under investigation. Apparently different from the primary areas, in the association areas many connectional systems directly terminate in an extended column involving several layers. These projection columns, which can range from 0.2 to 0.5 mm in diameter, result from the convergence of hundreds (thousands?) of axons. The individual arbors vary in size and laminar distribution but are usually smaller in diameter than the parent column.

Thus, although cortical architecture is commonly compared to a brickwork of repetitive modules (''ice-cube'' model of the cortex), surprisingly few data are available about columnar microorganization, and the actual structure may be considerably more elaborate.

VII. AXONS AND CONSCIOUSNESS

Several contemporary theories of consciousness give a prominent place to axons. At a large-scale global level, the theory of neuronal group selection proposes that selectionist (as opposed to instructionist) mechanisms govern the formation, adaptation, and interactions of local collections of neuronal groups. Group activity is cojoined or correlated in what is viewed as a dynamic process brought about by reentrant connections. Reentry implies reciprocal feedforward–feedback networks, but the concept is also compatible with the axonal networks in aggregate. A key component is the sheer density of the connectional plexus, where vast numbers of combinations can be effectuated by the massively parallel organization in space and time.

Basal Ganglia

BRUCE CROSSON,*,† LEEZA MARON,* ANNA B. MOORE,*,† and LAURA GRANDE*

University of Florida Health Science Center and †VA Medical Center, Gainesville

GLOSSARY

basal ganglia A group of phylogenetically old structures, including the caudate nucleus, putamen, globus pallidus, archistriatum, and ventral pallidum, that are thought to play a role not only in motor functions but also in more complex cognitive operations, such as language, learning, and working memory.

caudate nucleus The nucleus of the basal ganglia that follows the inner curvature of the lateral ventricle from the head of the caudate nucleus (embedded in the frontal horn of the lateral ventricle deep to the frontal lobe) to the body of the caudate nucleus (inferior and adjacent to the body of the lateral ventricle deep to the parietal lobe) and to the tail of the caudate nucleus (adjacent to the temporal horn of the lateral ventricle deep within the temporal lobe). In terms of its histological features and connectivity, it is homologous to the putamen; collectively, the two structures are referred to as the neostriatum.

cortico-striato-pallido-thalamo-cortico loops In 1986, Alexander and colleagues discovered five parallel and segregated loops through the basal ganglia; motor, occulomotor, anterior cingulate, dorsolateral frontal, and orbitofrontal loops. These loops involve glutamatergic input from the cortex to the striatum and GABAergic projections from both the striatum to the globus pallidus and from the globus pallidus to the thalamus. Reciprocal projections between the thalamus and the cortex are glutamatergic and, therefore, excitatory in nature.

executive functions Complex cognitive functions that involve the use or modification of more basic information or the control of other cognitive processes. Examples of executive functions are reasoning, organization and planning, and selection of actions appropriate to an external context.

globus pallidus A cone-shaped structure situated medial to the putamen that consists of an external (lateral) and internal (medial) segment. The globus pallidus is separated from the thalamus by the posterior limb of the internal capsule and from the head of the caudate nucleus by the anterior limb of the internal capsule. Collectively, the globus pallidus and the putamen are referred to as the lentiform nucleus, but the internal structure of the globus pallidus is distinct from that of the putamen. From a standpoint of connectivity, the medial segment of the globus pallidus and the substantia nigra pars reticulata are homologous structures.

Huntington's disease An autosomal-dominant genetic disorder characterized by choreiform movements and later dementia. In the early stages of the disease cell loss can be observed primarily in the head of the caudate nucleus; however, as the disease progresses, cell loss involves other parts of the basal ganglia and cortex, particularly the frontal lobe.

nucleus accumbens The nucleus inferior to the head of the caudate nucleus and putamen. The nucleus accumbens consists of core and shell divisions. The core division is considered part of the archistriatum (or old striatum). Its pattern of connections is similar to that of the neostriatum, except that its input is primarily from limbic cortex instead of the neocortex and its projections are primarily to the ventral pallidum instead of the globus pallidus.

Parkinson's disease A syndrome caused by loss of midbrain dopaminergic neurons in the substantia nigra pars compacta and ventral tegmental area. Parkinson's disease produces disturbances of movement such as tremor, rigidity in movement, difficulty initiating movement, and disturbance of gait.

putamen A basal ganglia structure situated lateral to the globus pallidus and deep to the insula, separated from the insula by the external capsule, the claustrum, and the extreme capsule. Although it is histologically dissimilar from the globus pallidus, the two are often grouped together due to their spatial proximity and are labeled as the lentiform nucleus. Because of their similar internal structures and patterns of connectivity, the putamen and the caudate nucleus are collectively referred to as the neostriatum.

substantia nigra The midbrain nucleus lying dorsal to the cerebral peduncles. Pars compacta is the dorsal portion of this nucleus and contains dopaminergic neurons that project to the caudate nucleus

and putamen. Pars reticulata is the ventral portion of this nucleus and is considered a homologous structure to the medial globus pallidus because of its similar connections.

thalamus An oblong group of nuclei bordering on the third ventricle medially and separated laterally from the lentiform nucleus by the posterior limb of the internal capsule. Thalamic nuclei have extensive, mostly reciprocal connections, with specific cortical regions. Some thalamic nuclei act as relays between lower centers and visual, auditory, and somatosensory information. Other thalamic nuclei receive projections from the globus pallidus and substantia nigra pars reticulata, acting as a part of cortico-striato-pallido-thalamo-cortical loops.

Deep within the cerebral hemispheres lie phylogenetically old structures collectively known as the basal ganglia. These structures are prominent in the reptile brain. When compromised in the human brain, devastating effects on behavior and cognition can result. In some instances, disruption of the basal ganglia produces disturbances of movement characteristic of Parkinson's disease. Symptoms of Parkinson's disease include tremor, rigidity in movement, difficulty initiating movement, and disturbance of gait. In severe cases, patients suffering from this disorder can be almost frozen, barely able to initiate any movement. They require complete care. In the autosomal-dominant disorder of Huntington's disease, cell loss occurs in the basal ganglia (specifically in the neostriatum), producing involuntary movements that resemble portions of volitional movements. The disorder progresses to the point where the patient is totally incapacitated. Both Parkinson's and Huntington's disease patients commonly have changes in mental status. Sometimes in Huntington's disease, cognitive symptoms can precede the movement disorder, and patients may even be psychotic. Given these phenomena, the reader might be surprised to learn the function of the basal ganglia is a matter of debate.

I. MACROSTRUCTURE AND CONNECTIONS OF THE BASAL GANGLIA

Classically, the basal ganglia consist of the globus pallidus, the putamen, and the caudate nucleus. Because of their wedge-shaped appearance in coronal (Fig. 1) and axial (Fig. 2) sections, the putamen and the globus pallidus are sometimes collectively referred to as the lentiform nucleus. The putamen is the more lateral structure of the two, and the globus pallidus is the medial, tapered end of the wedge. The globus pallidus can be divided into a lateral (or external) and a medial (or internal) segment. Despite the fact that they share the same name, the medial and lateral globus pallidus differ in terms of connectivity and function. The medial globus pallidus is in fact frequently considered a homologous structure to the substantia nigra pars reticulata. Even though the putamen and globus pallidus are adjacent and can be referred to with a collective label, they are neither structurally nor functionally homologous. The internal structures of the caudate nucleus and the putamen are quite similar. Although their connectivity is not overlapping, it can be considered to be parallel; this parallelism of connections will become evident when we discuss the connectivity of the basal ganglia. Collectively, the caudate nucleus and the putamen are referred to as the neostriatum or, often, as just the striatum.

When viewed in sagittal section (Fig. 3), the caudate nucleus forms a structure that arches over the lentiform nucleus and the internal capsule. The head of the caudate nucleus is comparatively bulky and is embedded in the frontal horn of the lateral ventricle, lying posterolaterally to this portion of the ventricular system. The caudate nucleus follows the inner curvature of the lateral ventricle posteriorly, from the head (deep to the frontal lobe) to the body (deep to the parietal lobe) to the tail (deep within the temporal lobe), with the tail ending adjacent to the amygdala. The caudate nucleus tapers considerably as it moves posteriorly from the head through the body to the tail, until the tail becomes difficult to discern.

The internal capsule is a band of white matter that molds itself around the lentiform nucleus and the lateral portions of the caudate nucleus. The anterior limb of the internal capsule separates the caudate nucleus from the putamen and globus pallidus, although at points thin bands of gray matter traverse the internal capsule to connect the caudate nucleus and putamen. The posterior limb of the internal capsule separates the putamen and globus pallidus from the thalamus. The posterior and anterior limbs meet at the genu (or knee) of the internal capsule. The internal capsule contains fibers from the frontal cortex to the brain stem and spinal cord (e.g., corticopontine and corticospinal tracts). The internal capsule also contains reciprocal fibers between the cortex and the thalamus (i.e., corticothalamic and thalamocortical fibers). Pallidothalamic fibers compose a portion of the inferior thalamic peduncle and, therefore, traverse an inferior portion of the internal capsule.

Phylogenetically older structures bearing some similarity to the neostriatum, especially from the standpoint of connectivity, are referred to as the

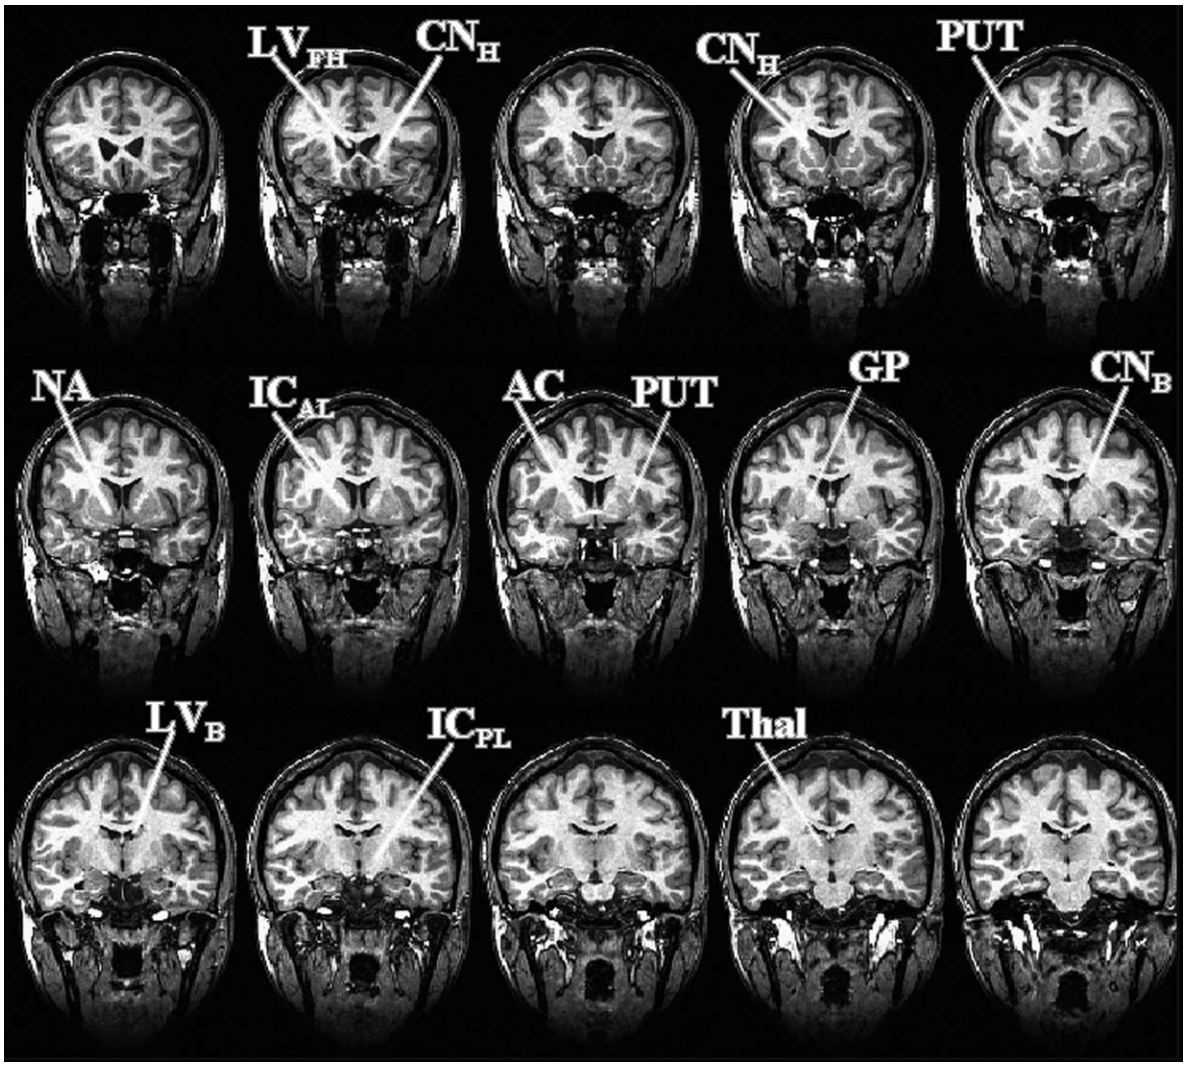

Figure 1 T1-weighted coronal MRI images showing the basal ganglia. Basal ganglia structures can be traced from the more anterior sections (upper left) to the more posterior sections (lower right). The slices are 1 mm thick, with one slice every 3 mm. The frontal horn of the lateral ventricle (LV_{FH}) is already apparent in the first slice of the top row and can be traced through consecutive slices until it becomes the body of the lateral ventricle (LV_B) around the fifth slice of the second row. The head of the caudate nucleus (CN_H) is embedded in the frontal horn of the lateral ventricle; it appears in the second slice of the top row and can be traced through consecutive slices until it tapers into the body of the caudate nucleus (CN_B) around the fourth and fifth slices of the second row. The putamen (PUT) can be seen as early as the third slice of the first row (lateral to CN_H and separated from it by the internal capsule), and remnants of it are visible in the fifth slice of the third row. The nucleus accumbens (NA) is best seen in the first slice of the second row; it occupies a position ventral to CN_H and PUT and seems to join the two. The anterior limb of the internal capsule (IC_{AL}) is the band of white matter between CN_H and PUT; it is labeled in the second slice of the second row but runs from the third slice of the first row through the third slice of the second row. The globus pallidus (GP) first appears in the third slice of the second row and can be seen until the third slice of the third row. The thalamus (Thal) can first be seen clearly on the first slice of the third row. The thalamus is separated from PUT and GP by the posterior limb of the internal capsule (IC_{PL}). The anterior commissure (AC), which connects the left and right temporal lobes, can be seen in the third slice of the second row.

archistriatum, or sometimes as the limbic striatum, because of their connection to the limbic system. The structures that comprise the archistriatum include the olfactory tubercle and the core portion of the nucleus accumbens (Fig. 1). Likewise, a portion of the basal forebrain region inferior to the anterior commissure is designated as the ventral pallidum and has connectivity similar to that of the globus pallidus except with

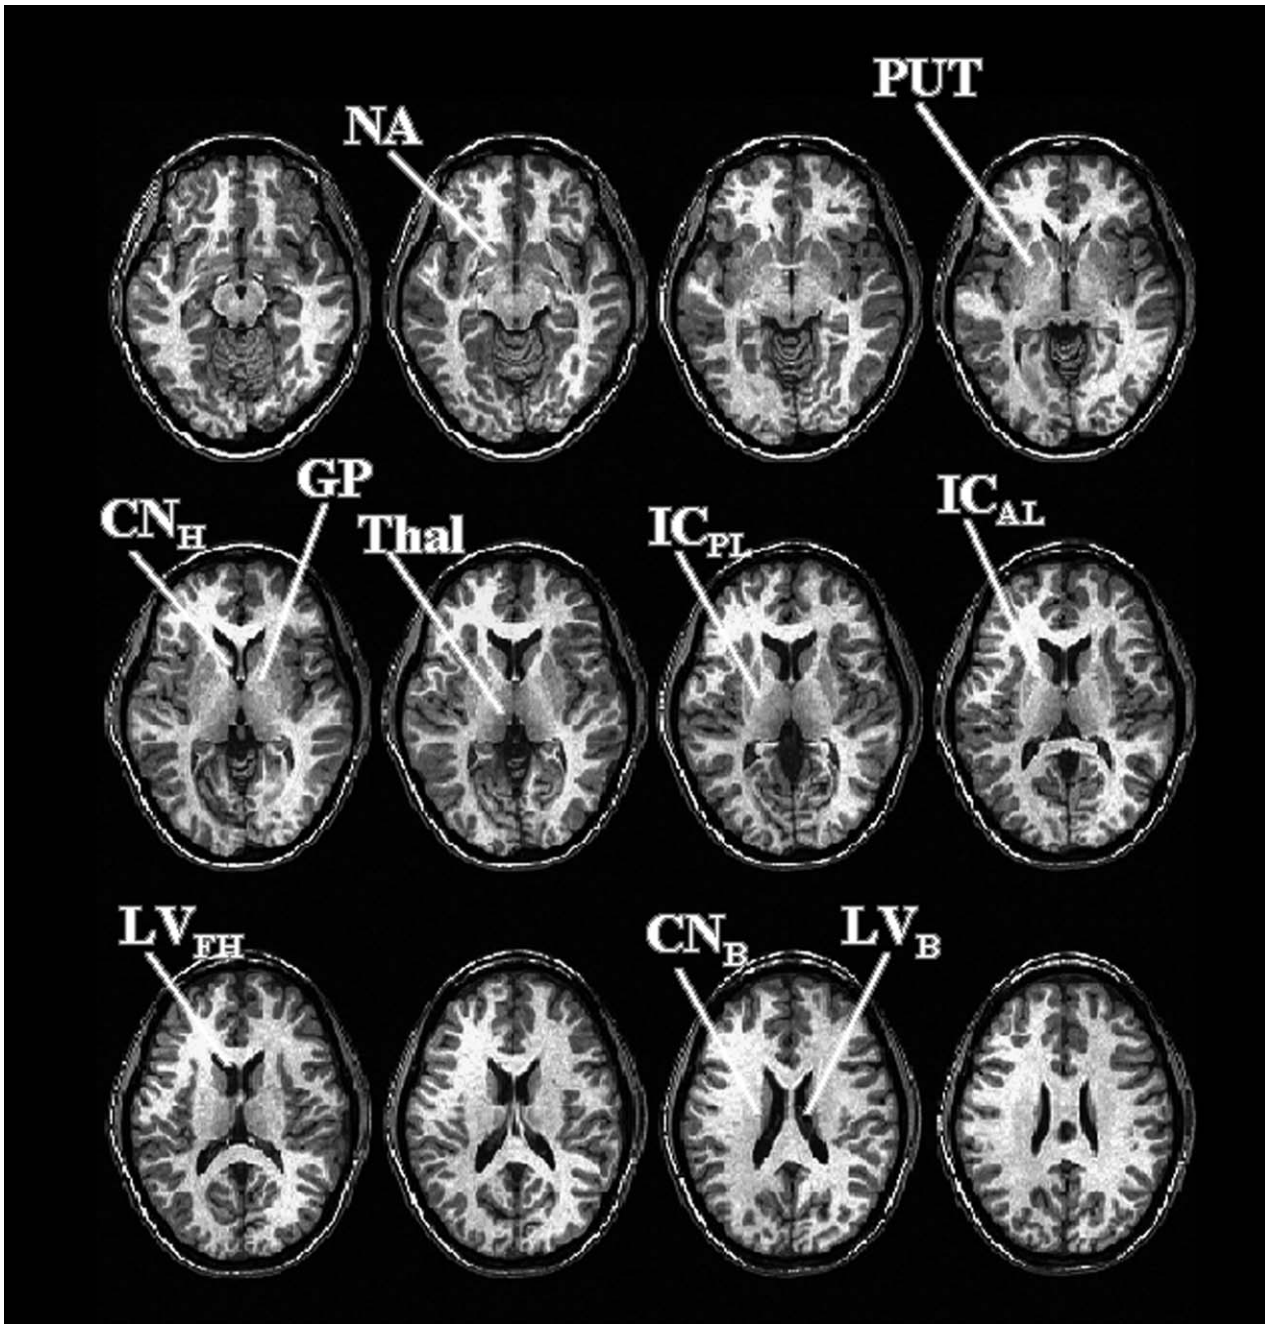

Figure 2 T1-weighted axial MRI images showing the basal ganglia. The basal ganglia can be traced from the more inferior sections (upper left) to the more superior sections (lower right). The slices are 1 mm thick, with one slice every 3 mm. The nucleus accumbens (NA) is best seen on the second slice of the first row; it occupies a position ventral to the head of the caudate nucleus (CN_H) and the putamen (PUT). The PUT, CN_H, frontal horn of the lateral ventricle (LV_{FH}), and globus pallidus (GP) all can be seen beginning on the fourth slice of the first row. The thalamus (Thal) can first be seen clearly on the second slice of the second row and is visible for four or five slices. As the caudate nucleus and lateral ventricle arch over the thalamus, they become the body of the caudate nucleus (CN_B) and the body of the lateral ventricle (LV_B), respectively. Again, the anterior limb of the internal capsule (IC_{AL}) separates CN_H and PUT, and the posterior limb of the internal capsule separates Thal from PUT and GP.

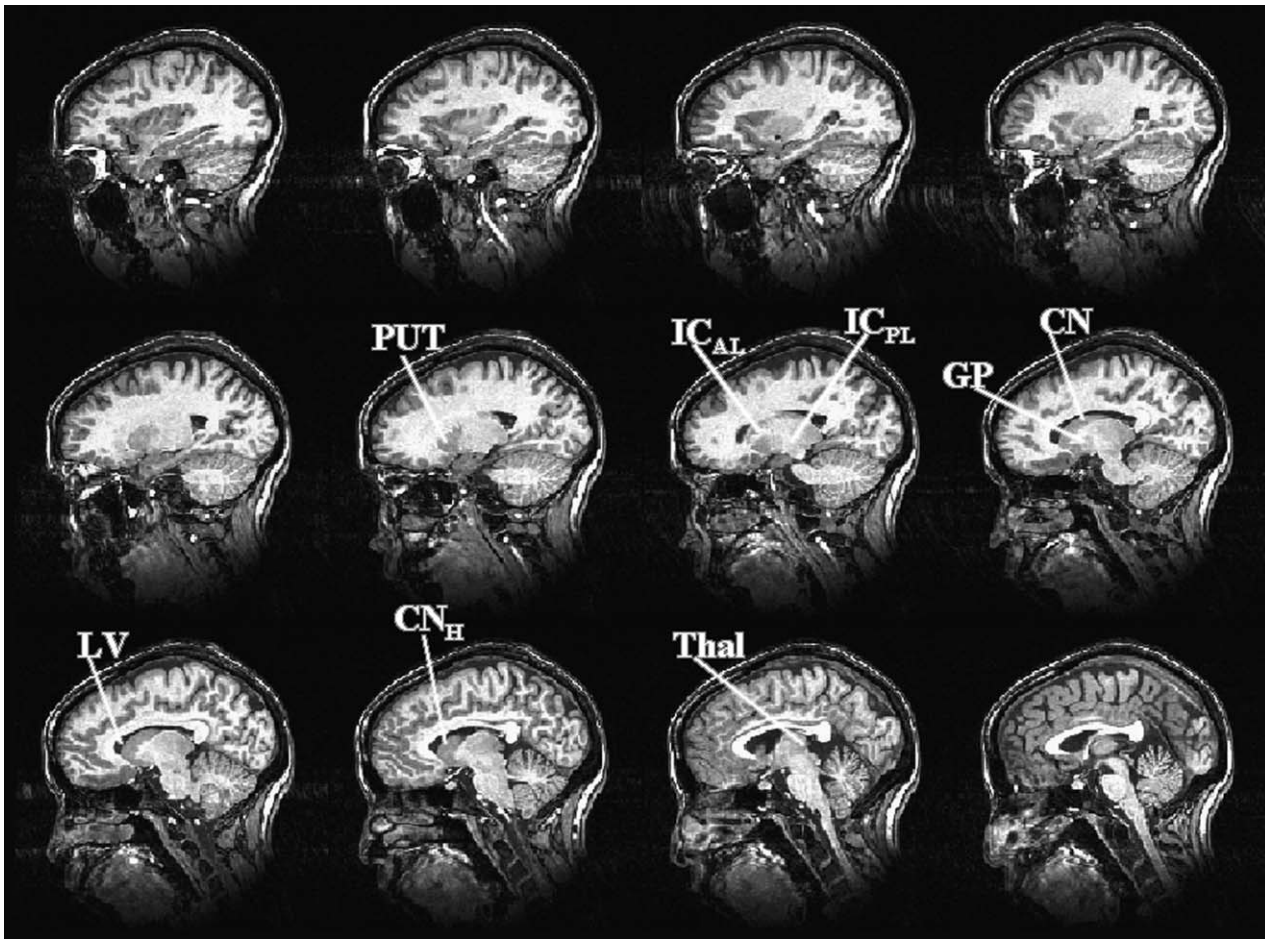

Figure 3 T1-weighted sagittal MRI images showing the basal ganglia. The basal ganglia can be traced from the more lateral sections (upper left) to the more medial sections (lower right). The slices are 1 mm thick, with one slice every 3 mm. The putamen (PUT) is first clearly visible on the first slice of the second row. The caudate nucleus (CN) is first seen on the third slice of the second row, as it follows the lateral ventricle (LV). The globus pallidus (GP) can be seen in the third and fourth slices of the second row. The thalamus (Thal) can seen in the second slice of the second row and runs through the most medial slice of the series. Again, the anterior limb of the internal capsule (IC_{AL}) separates CN_H and PUT, and the posterior limb of the internal capsule (IC_{PL}) separates Thal from PUT and GP.

limbic structures. Although the amygdala and the claustrum are sometimes referred to as part of the basal ganglia, we will not follow this convention here.

The organization of the basal ganglia into circuits with the cortex was described in the late 1980s by Alexander, Delong, and Strick. From the standpoint of connectivity, the basal ganglia are closely related to specific thalamic nuclei and cortical structures. As noted previously, the connectivity of the basal ganglia to these structures follows a predictable pattern that generally involves projections from the cortex to the striatum, from the striatum to the pallidum, from the pallidum to the thalamus, and from the thalamus back to the cortex (Fig. 4). Different portions of the frontal lobe project to different segments of the striatum. Grossly, anterior cingulate cortex projects to the archistriatum, premotor and motor cortex project more heavily to the putamen, and lateral prefrontal cortex projects to the caudate nucleus. The striatum projects to the lateral and medial segments of the globus pallidus. Various segments of the medial globus pallidus project to locations within the ventral lateral, ventral anterior, and dorsomedial thalamic nuclei. These loops involving projections from the cortex to the striatum, from the striatum to the globus pallidus, and from the globus pallidus to the thalamus are

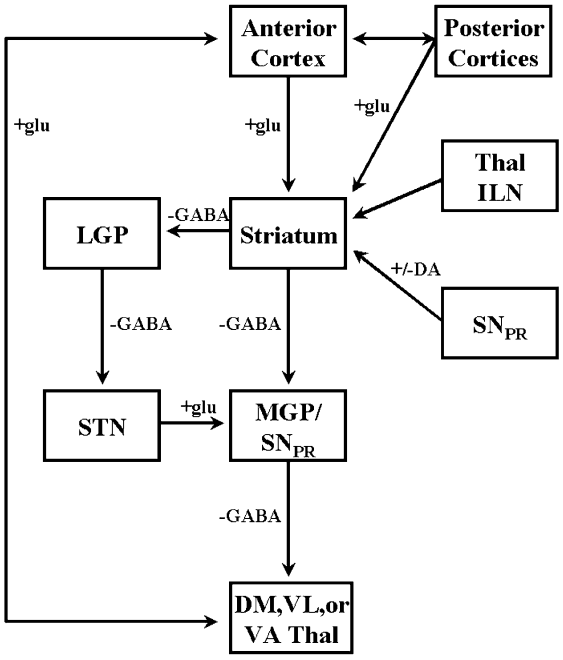

Figure 4 Diagram showing the relationship between components of basal ganglia loops. As conceptualized by Alexander *et al.*, both anterior and posterior cortical areas contributed input to the loops, as shown. More recent conceptualizations of these loops (e.g., Middleton and Strick, 2000) are that they are primarily closed, i.e., they involve a single cortical input that is also the target of the loop. DM, dorsal medial nucleus of the thalamus; ILN, intralaminar nuclei; LGP, lateral globus pallidus; MGP, medial globus pallidus; SN_{PC}, substantia nigra pars compacta; SN_{PR}, substantia nigra pars reticulata; STN, subthalamic nucleus; Thal, thalamus; VA, ventral anterior nucleus of thalamus; VL, ventral lateral nucleus of thalamus; +glu, the excitatory neurotransmitter glutamate; −GABA, the inhibitory neurotransmitter gamma amino butyric acid, +/−DA, dopamine that can have an inhibitory or excitatory impact depending on which output neurons it affects.

considered closed due to the thalamic projections to frontal cortex. It is worth noting that these thalamocortical projections are reciprocated by direct corticothalamic connections. These cortico-striato-pallido-thalamo-cortico loops appear to be separated from one another at all levels. Although the loops were eloquently examined by Alexander *et al.* it is worth noting that the influence of the motor loop on motor disorders was explored at least as far back as 1942 with Bucy's paper. The seminal work of Alexander and colleagues described five cortico-striato-pallido-thalamo-cortical loops: a motor loop, an occulomotor loop, an anterior cingulate loop, a dorsolateral frontal loop, and an orbitofrontal loop. They also predicted that other parallel basal ganglia loops would be discovered. Indeed, Strick and colleagues described supplementary motor area, ventral premotor, and primary motor cortex loops within the motor domain.

Several other aspects of basal ganglia connectivity should be mentioned. First are the midbrain dopaminergic projections to the striatum. Neurons in pars compacta of the substantia nigra project to the caudate nucleus and the putamen. It is the loss of the dopaminergic neurons projecting to the putamen that is responsible for the motor symptoms of Parkinson's disease. Projections from the ventral tegmental area provide dopaminergic input to the archistriatum. Second, the lateral globus pallidus projects to the subthalamic nucleus that lies below the thalamus, separated from it by an inferior portion of the internal capsule. The subthalamic nucleus, in turn, projects to the medial globus pallidus, creating a kind of subloop in the cortico-striato-pallido-thalamo-cortical loops. Third, the intralaminar nuclei of the thalamus project heavily to the striatum, constituting another source of input to this structure.

As noted previously, cortico-striato-pallido-thalamo-cortical loops maintain separation at all levels, including the level of the thalamus. The motor loops include portions of the ventrolateral thalamus. The anterior cingulate loop passes through a portion of the dorsomedial thalamus; the oculomotor, dorsolateral prefrontal, and lateral orbitofrontal loops pass through different portions of the ventral anterior and dorsomedial thalamic nuclei.

To summarize, the basal ganglia are structures deep within the cerebral hemispheres that collectively consist of the putamen, the caudate nucleus, the archistriatum, the globus pallidus, and the ventral pallidum. Organization of the basal ganglia is dominated by multiple parallel but segregated loops that start in the cortex and project to the striatum. The striatum, in turn, projects to the medial globus pallidus and the substantia nigra pars reticulata. The latter two structures project to thalamic nuclei that project back to the cerebral cortex. Recent work suggests that the loops can best be considered as closed because the cortical target of the loops is the same as their cortical input. Multiple frontal loops exist, but temporal and parietal loops recently have been discovered. In a subloop, or indirect pathway, fibers from the lateral globus pallidus project to the subthalamic nucleus, which in turn sends fibers to the medial globus pallidus. This anatomic connectivity helps to determine the role of the basal ganglia in behavior and cognition. The nature of the neurotransmitters between these structures provides another clue to how the loops function.

II. MICROSTRUCTURE AND NEUROTRANSMITTERS OF THE BASAL GANGLIA

Several aspects of the microstructure of the basal ganglia as described by Wilson, Groves, and others are worth specific mention. The vast majority of striatal neurons (90–95%) are medium-sized spiny neurons characterized by the proliferation of spines on the dendrites. These spiny neurons are the output neurons of the striatum. They use gamma aminobutyric acid (GABA) as their primary neurotransmitter and have an inhibitory influence on targets in the medial and lateral globus pallidus and in the substantia nigra pars reticulata, although these neurons also contain neuropeptides such as enkephalin, substance P, and dynorphin. The axons of these medium spiny neurons also give off short collaterals within the striatum that appear to terminate on neighboring neurons forming a network of collateral inhibition. In the past, it was assumed that this network of collateral inhibition accounted for the relatively low basal firing rates of the medium spiny neurons. However, Wilson recently reviewed evidence suggesting that it is not collateral inhibition that keeps the basal firing rates low. Rather, it takes coherent excitatory input distributed over a large portion of the dendritic tree of the spiny neuron to overcome the effects of potassium currents that act to shunt less coherent inputs.

Corticostriatal inputs use glutamate as the neurotransmitter and have an excitatory influence on the vast majority of the target neurons in the striatum. Perhaps half of the input to medium spiny neurons of the striatum derives from corticostriatal projections. Another major input to the striatum derives from the thalamic intralaminar nuclei. Besides medium-sized spiny neurons, neurons in the striatum include large spiny neurons and cholinergic aspiny neurons. The classification of these neurons has been refined since early reports.

The pioneering work of Gerfen, Graybiel, and others in the 1980s indicated that compartmentalization is an important aspect of striatal organization. Early work on striatal compartmentalization indicated that the internal structure of the striatum could be divided into striosomes (or patch compartments) and a matrix compartment. An early discovery about these compartments was that they could be distinguished by the presence of markers for acetylcholine in the matrix compartment and a relative absence of these markers in the striosomes.

Connections of these compartments were also found to vary, with the striosomes projecting to pars compacta of the substantia nigra and the matrix compartment projecting to both segments of the globus pallidus and pars reticulata of the substantia nigra. Since this seminal work, other complexities have been noted. It has been discovered that limbic cortex projects more heavily to striosomes, whereas neocortex projects more heavily to the matrix compartment. Gerfen and others have related this feature to the dorsal–ventral organization of corticostriatal projections; that is, limbic connections predominate in the ventral portions of the striatum (nucleus accumbens), whereas neocortical projections predominate in dorsal portions of the striatum (caudate nucleus). Other characteristics of striosomal compartmentalization include increased μ-opiate receptor binding and increased staining for the neuropeptides enkephalin and substance P. However, inhomogeneities in enkephalin and substance P distribution within the striosomal compartments suggests additional levels of organization within the neostriatum.

In the 1980s, Yelnik, Percheron, and Francois described important aspects of the microstructure of the globus pallidus. Pallidal neurons have sparsely branched dendritic arborizations distributed in disc-shaped fields that are parallel to the lateral border of their respective pallidal segment. Thus, these dendritic fields appear to be oriented in a direction perpendicular to incoming striatopallidal axonal fibers. It can be speculated that this organization leaves pallidal neurons in a position to provide spatial and temporal summation of inhibitory inputs from different striatal inputs. Neurons in the globus pallidus and those within pars reticulata of the substantia nigra that are a part of the basal ganglia loops are primarily GABAergic and, as noted previously, project to specific thalamic nuclei.

Other aspects of neurotransmitter function in the basal ganglia should be briefly mentioned. First, in the subloop from the lateral globus pallidus through the subthalamic nucleus and back to the medial globus pallidus, the pallidal efferents are GABAergic, as are other pallidal projection neurons. The neurotransmitter from the subthalamic nucleus to the medial globus pallidus is excitatory and thought to be glutamate. Second, the thalamocortical neurotransmitter appears to be excitatory and is also thought to be glutamate. Finally, dopaminergic input to the striatum from pars compacta of the substantia nigra seems to have a different impact on striatal neurons projecting to the lateral globus pallidus, which in turn projects to the subthalamic nucleus, than it does on striatal neurons projecting

directly to the medial globus pallidus and pars reticulata of the substantia nigra. Gerfen and others have noted that in striatal neurons projecting to the lateral globus pallidus, D_2 receptors predominate, and dopaminergic activity appears to have an inhibitory impact on these striatial neurons. In those striatal neurons projecting to the medial globus pallidus, D_1 receptors predominate, and dopaminergic activity appears to have an excitatory impact on these striatal neurons.

In summary, the striatum can be divided into striosomal and matrix compartments. Striosomes are dominated by projections from limbic cortex, whereas the matrix compartment is dominated by connections from neocortex. This distinction may be related to the ventral–dorsal division of the striatum. More ventral portions of the striatum, the archistriatum (olfactory tubercle and nucleus accumbens), receive input primarily from limbic cortex, whereas more dorsal portions of the striatum, the caudate nucleus and putamen, receive connections primarily from neocortex, with limbic input primarily reserved for striosomes. Striosomal projections are primarily to the dopamine-rich portion of the substantia nigra, pars compacta, whereas matrix projections go to the lateral and medial globus pallidus and pars reticulata of the substantia nigra. Corticostriatal fibers use glutamate, which has an excitatory influence on striatal projection neurons. Striatal projections are dominated by GABA, an inhibitory neurotransmitter. Striatal neurons project to the medial and lateral globus pallidus and pars reticulata of the substantia nigra; projection neurons in the latter structures appear to integrate input from different striatal areas and are also GABAergic. Fibers from the medial globus pallidus and substantia nigra pars reticulata project to various thalamic nuclei, which then send excitatory (glutamatergic) fibers to the cortical component originally projecting into the loop. An indirect pathway sends inhibitory GABAergic fibers from the lateral globus pallidus to the subthalamic nucleus, which in turn sends excitatory fibers to the medial globus pallidus/pars reticulata of the substantial nigra. Finally, dopamine input to the striatum seems to have an inhibitory impact on striatal fibers projecting to the lateral globus pallidus and an excitatory impact on fibers projecting directly to the medial globus pallidus. These aspects of neural transmission are shown in Fig. 4. Understanding of the basal ganglia loops and their neurotransmitters provides a basis for exploring functions of the basal ganglia.

III. FUNCTIONS OF THE BASAL GANGLIA

Despite all that is known about the macrostructure and microstructure of basal ganglia and about neurotransmitters in these structures, the functions of the basal ganglia in cognition and behavior are not definitively understood. Many theoretical descriptions of basal ganglia functions are based on the knowledge discussed previously. Such theories were devised to explain various aspects of cognition and behavior. A review of such theories could occupy a sizable volume on its own and, therefore, is well beyond the scope of this article. Here, we present brief descriptions of some theoretical propositions about basal ganglia, referring the reader to the suggested readings at the end of the article for greater detail. However, before undertaking these descriptions, a couple of preliminary matters must be addressed. The first is the means of studying basal ganglia functions; the second is general operational characteristics of the basal ganglia.

In addressing basal ganglia functions, we focus primarily on our understanding of human basal ganglia function. Much of the information discussed previously has been obtained from animal models. This method of exploring such issues as anatomical connectivity, neurotransmitter systems, and physiological responses has been long accepted. Although there can be substantial differences between humans' and other animals' brain systems, investigations across species can give us greater confidence in applying findings to humans. However, animal models can have limitations. Nowhere are such limitations more obvious than in the study of complex cognition. In particular, there are no good animal models for complex human language, for which the differences in human and animal brain systems are most important.

To specifically address basal ganglia functions in humans, many methods have been used. One such method is the lesion method. Modern X-ray computed tomography (CT) scanning and magnetic resonance imaging (MRI) have afforded a fair degree of accuracy in locating lesions caused by stroke, tumor, and other pathologies. Extensive behavioral and cognitive paradigms can be applied to patients with such lesions to describe how the lesions have disrupted behavior. However, naturally occurring lesions in humans are rarely limited to the structure of interest. Additional phenomena such as ischemic neuronal dropout and hypoperfusion are not well visualized on structural imaging techniques such as CT and MRI scanning.

This issue is particularly relevant to studies of basal ganglia lesions.

A related method is to study degenerative diseases of the basal ganglia such as Parkinson's and Huntington's diseases. Although the study of both diseases has provided important insights regarding probable basal ganglia functions, both diseases involve structures outside of the basal ganglia, including those of the cerebral cortex. This phenomenon makes it difficult to isolate basal ganglia functions. Another method of increasing importance in the study of human brain functions is functional neuroimaging, such as positron emission tomography or functional MRI. Functional neuroimaging has the potential to enhance our knowledge of brain systems but also has many drawbacks, including difficulty imaging some types of changes, an inability to readily distinguish inhibitory from excitatory neuronal activity, and the ambiguities almost always present in behavioral designs. Techniques such as surface evoked potentials have been of little value in studying basal ganglia function because of their inability to localize to deep structures.

A flurry of studies exploring basal ganglia function resulted from the increasing use of CT scanning in the 1970s and structural MRI scanning in the 1980s. The use of the lesion method is worth discussing in greater detail because of the specific problems related to exploration of basal ganglia function. In this regard, the most common lesions affecting behavioral and cognitive functions have been vascular. In particular, problems have been detailed that arise when striatocapsular infarctions are used to model basal ganglia functions. In the 1990s, Nadeau, Weiller, and others addressed these critical issues for human basal ganglia research. Striatocapsular infarctions are comma-shaped lesions that include portions of the caudate nucleus and putamen, the anterior limb of the internal capsule between them, and often portions of the globus pallidus. Although this region deep within the cerebral hemispheres is supplied by the lenticulostriate arteries, which branch from the initial segment of the middle cerebral artery, the cause of the infarction is often blockage of the middle cerebral artery just after it branches from the internal carotid artery or sometimes even blockage of the internal carotid artery itself. The reason that the whole territory of the middle cerebral artery in these cases does not show cystic infarction, which can be identified on structural imaging (CT or MRI), is that end-to-end anastomotic circulation from other arterial distributions supplies regions in the middle cerebral artery distribution outside the area of cystic infarction in the basal ganglia. The lack of cystic infarction does not mean that these areas are functioning normally, however. It has been demonstrated that patients who show significant and lasting cognitive deficits demonstrate poor anastomotic circulation and later recanalization of the middle cerebral artery after stroke, whereas patients without such deficits tend to have more adequate anastomotic circulation and/or early recanalization. Lasting cognitive deficits could be due to ischemic neuronal dropout or otherwise inadequate function in the territory of the middle cerebral artery outside the region of cystic infarction. The latter problems might be caused by circulation that is inadequate to support normal tissue function but not so inadequate as to cause cystic infarction that can be identified on a CT or MRI scan. Similar problems occur with hemorrhagic lesions where intracerebral hematomas under dynamic tension tend to cause pressure ischemia around the hematomas. In summary, large vascular lesions of the basal ganglia may be accompanied by damage or dysfunction in surrounding areas of cortex that are difficult to identify on structural imaging. In some instances, smaller lacunar infarctions may provide a better model for the study of basal ganglia function because they are not subject to the same vascular dynamics as larger lesions.

The second matter is the operational characteristics of the basal ganglia. In a seminal work in the late 1980s, Divac, Oberg, and Rosenkilde divided neural activity into quantitative and patterned neural activity. Quantitative activity affects the activity level of target structures and involves the number and rate of firing of neurons in the relevant structure; it does not code specific information. Patterned activity involves the temporal firing patterns of neurons and the temporal relationship between the firing of active neurons; such patterns are used to code specific information. Lesions will interrupt both quantitative and patterned neural activity; however, stimulation with implanted electrodes will cause firing of neurons in the stimulated structure that will mimic quantitative neural firing but interrupt specific temporal–spatial patterns of activity characteristic of patterned activity. It is critical to understand the neuronal activity of the basal ganglia if we are to understand its function. If the basal ganglia are limited to quantitative output, it is likely their function will be primarily of a regulatory nature, either on a tonic or phasic basis. However, if the basal ganglia are capable of processing patterned neural activity, then they are likely to be involved in complex information processing functions. As noted later, both positions have been represented by scientists working in the area.

In the following sections, functional considerations of the basal ganglia are addressed. How the basal ganglia operate is still a matter of study, and it may be years before generally agreed on models are developed. In other words, theories of basal ganglia function are still being developed and debated. In the discussion that follows, emphasis is placed on general theoretical considerations. The various functions that are considered include motor functions and movement programs, language, learning, and reward.

A. Motor Functions and Movement Programs

Given the motor symptoms of Huntington's and Parkinson's diseases and the major involvement of the basal ganglia in these disorders, the involvement of the basal ganglia in movement has been taken for granted. Huntington's disease is an autosomal-dominant genetic disorder characterized by choreiform movements (i.e., involuntary movements that resemble segments of voluntary movements). In the early stages of Huntington's disease, cell loss is obvious in the head of the caudate nucleus, but as the disease progresses cell loss becomes obvious in other parts of the basal ganglia and in the cerebral cortex, most conspicuously in the frontal lobe. Dopamine antagonists have been used to treat symptoms of Huntington's disease. Hemiballismus is also a disorder in which abnormal involuntary movements occur on one side of the body. Ballism represents the more forceful, or violent, form of involuntary movement. Discrete lesions of the subthalamic nucleus cause hemiballismus. Parkinson's disease is characterized by resting tremors, difficulty or slowness in initiating voluntary movements (bradykinesia), rigidity, and gait disturbance. Parkinson's disease is caused by loss of midbrain dopamine neurons (the pars compacta of the substantia nigra and the ventral tegmental area), particularly those projecting to the motor portions of the striatum. Theoretical explanations of the involvement of the basal ganglia in movement as far back as Bucy's (1942) paper attempt to explain the symptoms of one or more of these disorders by involvement of the basal ganglia motor loops.

Because of the involvement of the striatum and the subthalamic nucleus in disorders exhibiting involuntary movements (Huntington's disease and hemiballismus, respectively), the indirect basal ganglia loop involving projections from the striatum to the lateral globus pallidus, from the lateral globus pallidus to the subthalamic nucleus, and from the subthalamic nucleus to the medial globus pallidus has frequently been assigned the function of suppressing unwanted movements. One interesting facet of Huntington's versus Parkinson's disease is that the effects of the former can be mitigated with dopamine antagonists, whereas the effects of the latter can be mitigated with a dopamine precursor. These differences in response to dopaminergic agents, as well as the differences in motor symptoms (involuntary movements in Huntington's disease and bradykinesia in Parkinson's disease), have been related to the different phenomena affecting the indirect loop. The loss of striatal neurons influencing the indirect loop in the case of Huntington's disease prevents this loop from suppressing unwanted movements. The loss of inhibitory effects of dopamine on striatal neurons projecting into the indirect loop is purported to cause so much suppression of movement in the case of Parkinson's disease that it is difficult to switch to new movements. Rigidity in both Huntington's and Parkinson's diseases has been related to effects on the direct loop (loss of striatal neurons projecting to the medial globus pallidus in Huntington's disease and loss of dopaminergic excitation of these same neurons in Parkinson's disease). In their seminal 1986 work, Penny and Young gave detailed treatment to these differences.

In a recent review, Jueptner and Weiller described their work regarding functional neuroimaging of the basal ganglia and cerebellum. They concluded that the basal ganglia are involved in the selection of movements, whereas the cerebellum processes sensory information and integrates it with movement. The concept of movement selection is consistent with the suggestion that the basal ganglia enhance desired movements while suppressing unwanted movements.

B. Language

Nowhere has the function of the basal ganglia been more enigmatic than in the area of language. Formulations regarding the involvement of the basal ganglia in language have represented the entire range of possibilities from no involvement to a central role in selection of the words used to express oneself. One reason for skepticism about a role for the basal ganglia in language concerns the vascular lesion cases that have been used as evidence for such a role. As discussed previously, cortical dysfunction that is unseen on

structural CT or MRI images often accompanies basal ganglia infarction or hemorrhage. The variability of symptoms in cases with anatomically similar lesions suggests dysfunction of different cortical regions between such cases. Such cortical dysfunction may account for many of the more obvious language symptoms. A 1997 review by Nadeau and Crosson gave extensive treatment to this topic.

However, it appears likely that the presence of more obvious cortical symptoms masks more subtle deficits that may be due to basal ganglia dysfunction, and some investigators have suggested that core language symptoms can be found with lesions of the dominant neostriatum and internal capsule. In their 1994 work, Mega and Alexander indicated that these core elements include impairment of generative aspects of language (verbal fluency, sentence generation, and extended discourse). Based on evidence that stimulation of the dominant caudate nucleus can evoke language fragments, others have suggested that the basal ganglia may be involved in releasing cortically formulated segments for speech. This evidence was extensively discussed in works by Crosson and colleagues. It is worth noting that such hypotheses essentially propose regulatory functions for the basal ganglia which could be based on quantitative rather than patterned neuronal activity.

Perhaps the most comprehensive work on nonthalamic subcortical language functions was Copland's (2000) doctoral dissertation, which described a series of well-designed studies using cases of nonthalamic subcortical lesion of the left hemisphere as well as cases of Parkinson's disease. Among cases of nonthalamic subcortical lesion, basal ganglia damage was prominent. Various publications by Copland and colleagues are beginning to describe aspects of these studies. Copland's work indicated that patients with nonthalamic subcortical lesion have difficulty with higher level language processes (e.g., providing multiple meanings for semantically ambiguous sentences). A series of priming studies suggested that these patients have difficulty with resolution of lexical–semantic ambiguities under conditions involving controlled cognitive processing, with automatic processing less affected by the lesions. In the context of previous literature, the studies of Copland implied a role for the basal ganglia in executive language functions. His work also indicated that lesion of the basal ganglia and Parkinson's disease, which deprives the basal ganglia of its midbrain dopaminergic input, do not result in the same pattern of language-related deficits.

C. Learning and Memory

For some time, a division between the anatomical structures involved in declarative memory and those involved in procedural memory has been proposed. Declarative memory involves the ability to learn facts or items that can be deliberately recalled; procedural learning involves the ability to master a set of procedures to perform a specific task. Procedural memory has been explored primarily in patients with degenerative diseases of the basal ganglia (i.e., Huntington's and Parkinson's diseases). Although results in the cognitive realm of procedural learning have been mixed, findings have been more consistent with motor skill learning being impaired in patients with these diseases. Nonetheless, even within the realm of motor skill learning, evidence suggests that the basal ganglia are needed more for some skills than for others.

If one reviews the literature on memory deficits in Huntington's and Parkinson's diseases, problems with declarative memory are also evident. A relatively consistent pattern emerges: Patients with these disorders demonstrate maximum deficits on memory tasks requiring recall of information, but they demonstrate normal or near normal memory performance when only recognition of information is required. Some have interpreted better recognition than recall as an indication of difficulty in retrieving information that is actually stored in long-term memory. Problems with retrieval have been linked to the influence of basal ganglia circuits on frontal functions; however, cortical deterioration cannot be entirely ruled out as a cause of these difficulties.

Activity in prefrontal cortex has been associated with working memory functions. Working memory refers to the ability to hold information on line in order to use it for some impending activity. Because of its connectivity to the prefrontal cortex, it has been suggested that the basal ganglia are involved in working memory. However, support for the role of the basal ganglia in working memory is equivocal and the issue deserves further attention. Gabrieli reviewed many of these issues in 1995.

D. Reward

Studies have shown that dopaminergic neurons in the substantia nigra pars compacta and ventral tegmental area respond to administration of rewards and

guidance of behaviors to obtain rewards. In a seminal 1995 work, Houk and colleagues set forth a theory that explains how animals might learn that certain events tend to predict reward. The theory is quite complex and should be read in its entirety. Briefly, this theory suggests that cortical activity associated with events that might predict reinforcement creates a receptivity to dopamine in striatal spiny neurons residing within striosomal units. When reinforcement occurs, dopamine is released and instantiates a change in synaptic strength. This change at the synaptic level is posited to make firing of the striosomal spiny neuron more likely the next time the predictive event occurs. The hypothesis that synapses related to specific events are strengthened in striosomal neurons implies that patterned neuronal activity is required for this basal ganglia function. Continued study of the relationship between reward and dopaminergic activity in the basal ganglia promises not only to shed light on mechanisms involved in motor skill learning but also to reveal underlying motivational mechanisms for a variety of behaviors.

IV. CONCLUSIONS

The basal ganglia are phylogenetically older structures deep within the cerebral hemispheres. Connectivity between basal ganglia structures, the cortex, and the thalamus are organized in parallel but separate cortico-striato-pallido-thalamo-cortical loops. The loops project only back to the cortical region that projects to their striatal component. Although these loops are thought to be critical to understanding basal ganglia functioning, the precise role of the basal ganglia in behavior and cognition is not well understood. Without a doubt, the glutamatergic connections between the cortex and the striatum and between the thalamus and the cortex, and the GABAergic connections between the striatum and the globus pallidus and between the globus pallidus and the thalamus, play a significant role in basal ganglia functions. The inputs from the intralaminar nuclei to the striatum may also play a significant role in basal ganglia functions.

Consensus indicates that the basal ganglia play an important role in motor behavior and learning. Many of the devastating effects of Huntington's disease and Parkinson's disease on movement appear to be due to changes within the neostriatum and closely related structures. The basal ganglia are also thought to play significant roles in various cognitive processes related to executive functions. These roles probably involve selection and initiation of responses that are simultaneously tied to external circumstances and internal motivations. The basal ganglia may also play some role in complex language processes, working memory, motor procedural memory, and reward. Continuing research will provide increasing definition to these roles.

GLOSSARY

allele Alternative form of a specific gene, sometimes leading to the production of different proteins or RNA products.

chromosome One of the DNA–protein structures that contains part of the nuclear genome of a eukaryote.

epistasis Alteration of phenotypic effects of one gene by the specific alleles of another gene.

gene A stretch of DNA coding for a specific protein or RNA product.

genetic correlation Correlation between the effects of one single gene or a set of genes on two different phenotypes; indicative of pleiotropy.

genome The entire genetic complement of a living organism.

genotype Genetic constitution (set of alleles present in each cell of a particular individual), as contrasted to phenotype.

heritability The proportion of phenotypic variation for a given character that can be associated with genetic variation in a given population. Heritability, commonly denoted h^2, is therefore character and population specific.

homologous recombination A process by which one DNA segment can replace another DNA segment with a similar sequence.

inbreeding Reproduction by the mating of closely related individuals resulting in an increased frequency of homozygotes.

knockout mice A mouse that has been engineered so that it carries an inactivated gene.

locus A location on a specific chromosome defining the position of a specific DNA sequence.

phenotype A measurable characteristic manifested by an organism. Phenotypes can be defined at many levels, ranging from the isoform of a protein to a complex trait such as neuroticism. Two organisms may have the same genotypes but different phenotypes (owing to environmentally induced variation). Also, two organisms may have the same phenotypes but different genotypes (e.g., heterozygotes and homozygotes in the case of dominance).

pleiotropy A single gene affects two or more different phenotypes.

quantitative trait locus (QTL) A chromosomal locus correlated with individual differences in a given trait. Such a locus is believed to contain a gene in which differences in the coding DNA cause quantitative individual differences in that trait. A QTL generally explains only part of the total genetic variation.

recombination The process during germ cell formation that generates sperm or eggs with allele combinations different from those of the individual's own chromosomes.

selective breeding Also called artificial selection. Animals that score high (or low) on a desired trait are artificially selected and mated to produce offspring.

transgenic mice Mice that have a foreign gene inserted into their genome.

wild type The most frequent allelic form of a gene found in natural (or laboratory) populations.

zygosity Twins may be dizygotic (stemming from two eggs), in which case they share on average half of their parental genes identical by descent. Twins may also be monozygotic (stemming from one egg), in which case they share all their genes identical by descent (so-called "identical" twins).

Behavioral neurogenetics is the study of the way in which genes, directly or in interaction with the environment, influence the structure, chemical composition, and/or function of the central nervous system and, through this, cause individual differences in behavior. This article presents a brief overview of the field, providing some examples from human and animal studies.

I. HISTORICAL BACKGROUND

Plato, in *The Republic*, speculated that behavioral and personality characteristics might be heritable, but only in more recent times have such phenotypes become amenable to genetic analysis. In the 19th century, Francis Galton (1822–1911) started the scientific study of human behavioral phenotypes and, in the second half of the 20th century, the field of behavior genetics was born with the publication of John Fuller and Robert Thompson's classic book *Behavior Genetics* in 1960. By 1960, it was quite clear that behavior is influenced by genetic factors, as shown by a wealth of studies on inbred strains and crosses between them, by the generation of artificially selected lines, and by the results of twin studies. However, with the exception of some neurological mutations with rather severe phenotypical effects, the genes remained elusive. Questions concerning where the genes were located on the chromosomes, what proteins they encoded, and where in the nervous system they were expressed remained a mystery. All this changed in the 1970s when a new technology, recombinant DNA, was born that allowed scientists to study the molecular mechanisms underlying neural function. At the same time, a few scientists, such as Benson Ginsburg and Dick and Cynthia Wimer in the United States and Hans van Abeelen in Europe, began to integrate behavioral, neurobiological, and genetic aspects of their research, and this integration has continued in both animal and human studies. This led to the emergence of the new and budding field of behavioral neurogenetics, which is rapidly coming of age with its own specialist society (the International Behavioural and Neural Genetics Society; *http://www.ibngs.org*).

The new genetic technologies that have become available in recent years have created very high expectations for progress in the near future. Although it is doubtful that single gene analyses will help us to elucidate complex cognitive functions, the manifold advantages offered by modern behavioral–neurogenetic analysis should help us unravel the cellular basis of brain–behavior relationships. This creates great potential for the development of new therapeutic tools.

II. FROM TRAIT TO GENE AND BACK: A GENERAL OUTLINE

The fundamental goal in behavior neurogenetics is to understand the genetic basis of the neuronal processes underlying individual differences in behavior. At the outset, the relative contribution of genetic factors to a trait needs to be established. In humans, the similarities in a trait are examined in subjects of different degrees of genetic relatedness. Comparison of monozygotic and dizygotic twins in the classical twin method, for instance, allows a reasonable estimate of the heritability of a trait. In animals, for instance, the ability to selectively breed lines that score either extremely low or extremely high on a trait is a good indication of the amount of genetic influence on that trait. If substantial heritability has been demonstrated for a trait, it becomes feasible to search for the building stones, i.e., the differences in coding DNA sequences underlying the genetic part of the individual differences in that trait.

Finding the actual genes is a formidable task for several reasons. Many of the targeted behaviors (aggression, cognitive ability, and depression) are very complex and can usually be quantified on more than one aspect (often with more than one measure per aspect). As a first step the trait under study is refined by using a combination of multiple measures of the trait that best capture a common underlying genetic factor. A subsequent problem is the vast amount of genes involved. Candidate gene studies can be used when previous studies have identified a specific gene that codes for a protein involved in a pathway known to be relevant to the variation of the trait under study. This applies only to genes with known location and function and to pathways

that are already partially understood. All other situations need a different approach. Whole genomic searches are used to establish the most likely location on the entire DNA of genes that influence the trait under study. These may be genes that were identified but had not been suspected to be linked to the trait, or they may be new genes. Because there is a large degree of homology between animal DNA and human DNA, animal studies can be very helpful to focus genomic searches on only a part of the human DNA (a single chromosome or even a part thereof). Also, after a putative location has been found, animal studies may help to fine map that region to find the actual gene. Gene finding in animals is generally easier because various types of controlled crosses, such as repeatedly backcrossing or intercrossing, can be made at will.

Once the gene has been found, many studies can be performed to elucidate the exact biological pathway by which the allelic variation in the gene influences variation in the neurophysiological or behavioral trait. In animals, genes can be deleted (knockout models) or inserted (transgenic animals) to investigate the scope of the gene's effects and how it operates. By selecting either animals with a known genetic background or humans with known allelic variants for the gene under study, it is possible to do gene-by-environment studies in which the differential effects of manipulations of the environment on different genotypes can be directly tested. Most important, once animals/humans can be characterized by their genetic predisposition for a trait, structural (e.g., size of hippocampal cell population) and functional aspects of the brain (e.g., electrophysiological response to a stimulus) can be compared to lay bare the actual biological pathways connecting gene and behavior.

In the following sections, the most commonly applied research paradigms in behavioral neurogenetics will be discussed and illustrated on the basis of a specific trait. The methods to determine the actual presence of genetic factors—selective breeding and/or comparing inbred strains in animal studies and the classical twin method in human studies—are discussed in Sections III and IV, respectively. The search for genes is discussed in Sections V (linkage, association studies in humans) and VI (intercrosses and backcrosses in animals). Recently developed techniques, such as knockout and transgenic methods in animals, are discussed in Section VII, while interactions between genes and the environment are discussed in Section VIII. Finally, in Section IX we focus on the intermediate brain structures.

In our discussion of the various research paradigms, we use aggression as the main example of a behavioral trait. Aggression is exemplary for complex traits such as depression or cognition, with their multiple aspects and multiple levels of measurement. One of the first problems encountered is the definition and the consequent way of measuring the trait under investigation. In humans, we can use the outcomes of questionnaires as a measure of aggression, but we can also use registered criminal acts or convictions for violence. All three variables might very well yield different results. Aggressive behavior in animals appears to be easier to measure than in humans: We can stage an actual fight between two animals. However, there are many different ways to influence the results of a test—for example, by varying the opponent to be attacked, the environment in which the encounter takes place, or the duration of the test. Also, many different aggression parameters are used, ranging from simple ones such as attack latency, which is the time it takes for the animal under investigation to attack its opponent, to more complex measures that combine different aspects of offensive behavior over time and calculate an overall aggression score. This has created an abundance of aggression tests and measures that are sometimes difficult to compare.

Different measures of aggression may be under distinct genetic control mechanisms. Thus, the way aggression is measured will strongly influence results of behavioral neurogenetic testing. This is not only true for aggression but also for all other complex traits. This cautionary note must be kept in mind.

III. STRATEGIES IN ANIMALS: INBRED LINES AND SELECTIVE BREEDING

In animal studies there are two fundamental strategies to determine whether a trait is under the influence of genetic variation. The first one is the comparison of inbred strains. An inbred strain is generated by repeatedly mating close relatives. Since these relatives (usually brothers and sisters) are approximately 50% genetically alike (counting only those genes for which their parents had different genotypes), individuals of the same sex will be almost genetically identical after 20 generations of inbreeding. Within an inbred strain, nearly all trait variability will be caused by the

environment, whereas differences among strains will be virtually genetic in origin. Therefore, when in a controlled testing environment multiple strains are compared for a specific behavior, the extent to which inter-strain differences exceed the pooled within-strain variability provides a test of the existence of genetic influence. A good illustration of the variation in inbred strains is the data collected on aggressive behavior in the laboratory of Pierre Roubertoux in Orléans, France (Table I). As can be observed in the table, levels of aggressiveness vary enormously among strains. NZB mice always attack (20 of 20 animals; 100%), whereas C57BL/6J males almost never attack (1 of 20; 5%).

Inbred strains are generally stable over time and across laboratories. For instance, NZB mice have been demonstrated to be aggressive in several laboratories on different continents since they were first tested. However, certainly the most important advantage of inbred strains is that they are the conditio sine qua non for the recently developed high-tech molecular–genetic techniques, such as the creation of knockouts and transgenics. A disadvantage of the use of inbred strains is that they do not represent natural populations in which heterozygosity is the rule rather than an exception.

Another useful technique to show that a specific trait is genetically influenced is selective breeding or artificial selection. This method has been used throughout recorded history, even long before people understood how it actually worked, and is currently still being applied extensively. It is based on the fact that the offspring of animals with a desired quality are more likely to demonstrate that quality than the progeny of random individuals. For centuries, farm animals and pets have been bred for desired characteristics, some of them behavioral (e.g., in dogs: hunting dogs, shepherd dogs, etc.). Similarly, mice and rats can be bred for various behaviors, such as learning performances or aggression. Usually, animals are selected for the opposite of the desired behavior (directional selection).

Table I
Proportion of Attacking Males in Seven Inbred Mouse Strains

Strain	% attacking males (*N=20*)
BA	20
BALB/c	40
CBA/H	20
C57BL/6	5
CPB-K	50
DBA/2	50
NZB	100

For aggressive behavior, various pairs of selection lines exist. One of the more conspicuous ones originated from animals from a feral population caught in The Netherlands that were subsequently selectively bred for behavior in a test cage developed by Geert van Oortmerssen. Different chambers of the cage were connected through slide doors such that home territories and a border area were created. Since in the wild most agonistic encounters occur at the border of the territories, this design takes the natural settings of the test animals into account. Moreover, the aggression test takes 3 days, with one encounter every day. This procedure not only reduces the effects of chance but also creates the opportunity to investigate the development of aggression over time. Using the previously mentioned paradigm, van Oortmerssen selected two lines for attack latency (Fig. 1): one highly aggressive line, characterized by short attack latencies (SALs), and one low to nonaggressive line, characterized by long attack latencies (LALs).

Although it is beyond the scope of this article to discuss the theory and practice of selected lines in detail, the following strict conditions must be met in order to reliably reveal the genetic underpinnings of behavior. First, one has to bear in mind the obvious. Behavior without genetic variation underlying it cannot be selected for or against. Therefore, if no differences for the desired trait are observed in a panel of inbred strains, it is theoretically impossible to selectively breed for that characteristic. Second, the simpler the phenotype, the better the experiment generally works. Third, if possible, a genetically defined, replicable founding population should be used. In this case, one can always use the parental population if needed. These conditions can be met relatively easily and without great financial resources. However, a last theoretical requirement results in almost prohibitive costs. Since selection depends on genetic variation, inbreeding is its natural enemy. Inbreeding often leads to mortality or loss of fertility, but it also conflicts with the desired result of selection: to increase the frequency of only those alleles that favor the trait under selection. Inbreeding is not desired for the vast majority of genes that need to be kept segregated. To this end, one would have to maintain an unrealistically large number of animals. In practice, selective breeding leads to the subsequent loss of alleles (genetic drift). However, it is possible to

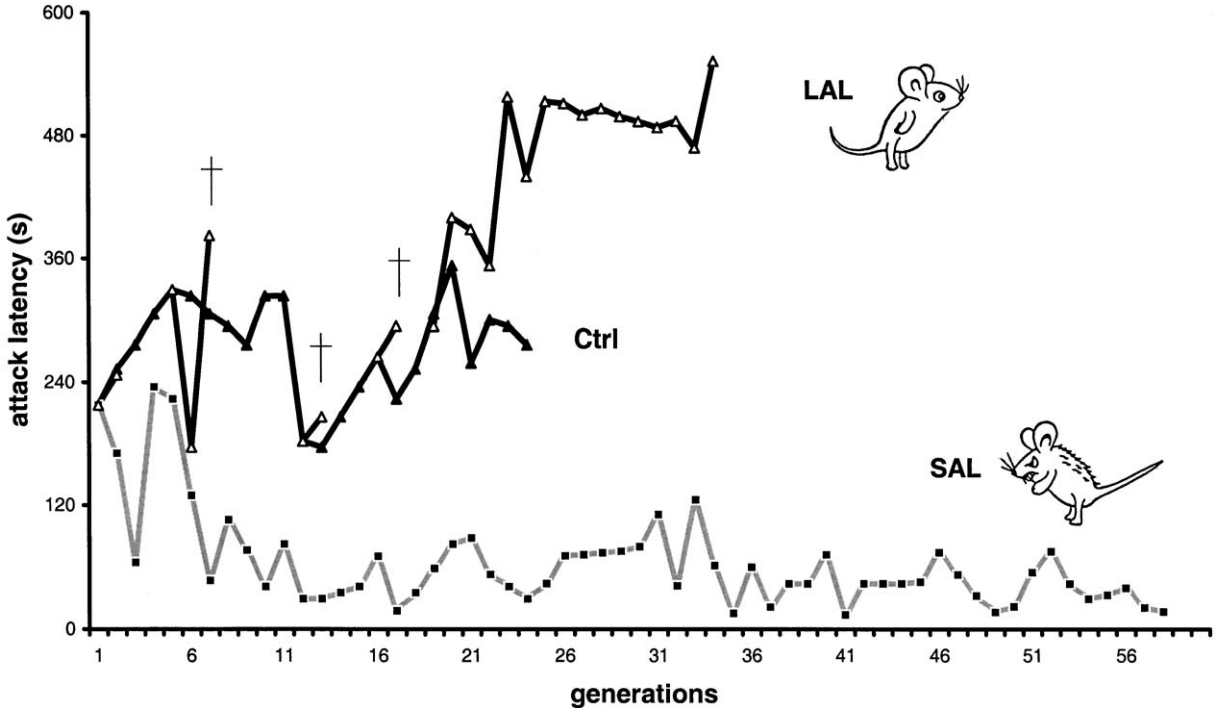

Figure 1 Artificial bidirectional selection for attack latency in male wild house mice. Three lines have been established: one control line (Ctrl) and two selection lines—one highly aggressive line, characterized by short attack latencies (SAL), and one low to nonaggressive line, characterized by long attack latencies (LAL). Differences in the number of generations between SAL and LAL mice originated from difficulties in developing the LAL line per se (†, unsuccessful attempts) and in unequal rates of reproduction, with the SAL females producing both earlier and larger litters.

control to a certain extent for genetic drift through the establishment of separate, replicated lines.

IV. STRATEGIES IN HUMANS: THE TWIN METHOD

The twin method is one of the most powerful and frequently used tools to determine genetic and environmental influences on variation in traits. It compares the resemblance between genetically identical, monozygotic (MZ) twins to the resemblance between fraternal or dizygotic (DZ) twins. MZ twins have the same allelic combinations at all their genes, whereas DZ twins share, on average, 50% of allele combinations (counting only those genes for which their parents had different genotypes). The shared environment for both is very comparable. Hence, the demonstration that MZ twins are more similar than DZ twins for a certain trait points to a genetic contribution to the variation in this trait. Efficient use of the information available in the variances and covariances of genetically related subjects (e.g., twins) can be done with a statistical technique called structural equation modeling. Basically, the total variance in a trait is decomposed into several contributing factors: (i) additive genetic variance, which results from the additive effects of the two alleles of all contributing genes; (ii) dominance genetic variance, which results from the nonadditive effects of the two alleles for all genes showing a dominance effect; (iii) shared environmental variance, which results from environmental events shared by both members of the twin pair (e.g., school and diet); and (iv) unique environmental variance, which results from nonshared environmental effects and also includes measurement error. The influence of confounding variables such as age or socioeconomic status can be incorporated in the model. In addition, a further refinement from univariate to multivariate models allows exploration of the question of whether any covariance between different variables is genetically and/or environmentally determined.

There are some pitfalls in the twin method that need to be avoided. First, there is the matter of zygosity. An underestimation of the number of MZs will lower

estimates of genetic effects because they will raise the fraternal twin correlation and lower the correlation of identical twins. Conversely, underestimation of DZs will raise estimates of genetic influences. Correct zygosity has become even more important with the increasing use of DZ twins for the location of quantitative trait loci (QTL). An accurate zygosity diagnosis is now easier than ever. Usually, six to eight highly polymorphic DNA markers are adequate to discriminate between MZ and DZ twins. The second pitfall is the so-called equal environments assumption, which holds that the degree of environmental similarity is comparable in MZ and DZ twins. At first, this assumption seems quite justified. Both types of twins share the same womb and are reared in the same family, all at the same time. However, the two types of twins may be treated differentially. For instance, MZ twins may be treated more similarly than fraternal twins. If this is true and MZ twins would experience more similar environmental influences than DZ twins, the genetic contribution to the variation of the trait under investigation would be overestimated. Although there is evidence that the equal environment assumption is violated, studies on a range of traits suggest that the violations do not seriously compromise the validity of the twin method. Finally, like any other study, twin studies make sense only when statistical power is adequate. In earlier studies samples were often too small because experimenters thought they could use the same sample size required to compare means. Power studies have demonstrated that large samples are necessary for an accurate estimate of the presence and size of genetic influences, especially if heritability is low.

The use of the twin method in the genetic analysis of human aggression has been demonstrated in a recent study. Using three types of questionnaires, nine different aspects of aggression were measured: physical assault, indirect hostility, irritability, negativism, resentment, suspicion and verbal hostility, trait anger, and type A behavior. All these aspects showed moderate to fair heritabilities, varying from 23% for indirect hostility to 53% for resentment and suspicion. A multivariate analysis revealed two common additive genetic and two common environmental factors. Hence, two sets of genes and two sets of unique environmental factors give an adequate description of the pattern of associations between the nine measured aspects of human aggression. Of course, the nine measures are also individually influenced by specific additive and/or environmental factors. This replicates an extensive literature on twins and aggression or related concepts such as antisocial behavior and hostility (thoroughly reviewed elsewhere). The correlation between MZs is not perfect, showing that unique environmental factors play a role in these types of aggression. In all studies, however, MZs are more similar than DZs, indicating a genetic contribution to the variation in aggressive behavior. Finally, results from a related design, the adoption method, further corroborate the existence of a significant genetic contribution to aggression.

The obvious question remains, which genes are responsible for the variation in aggression? Also, where are they located on the chromosomes? What proteins do they encode? Where are they expressed in the brain? Are they always expressed or only during a certain time period? Actually, there is a gene that is specifically associated with a behavioral phenotype that includes disturbed regulation of impulsive aggression. However, before we discuss this gene, we review the techniques to find "behavioral" genes.

V. CANDIDATE GENE STUDIES AND GENOMIC SEARCHES

The major problem facing gene hunters is not the sheer number of possible genes that need to be examined, of which—despite the recent completion of the Human Genome Project—the majority are unidentified, but the relatively small contribution each gene may make to the relevant trait. As a rule, genes will be found more easily if they explain more of the variance in a trait. Therefore, gene finding is relatively easy if only a single gene affects the trait. In these instances, a simple Mendelian segregation of a limited number of phenotypes is observed for all possible genotypes at a specific locus. Many rare diseases or disorders (but also Huntington's disease) are Mendelian in nature. As a general strategy to find such Mendelian genes, many DNA markers of known location, evenly dispersed throughout the entire genome, are measured in individuals from multiple generations. DNA markers can be mutations in a single base pair [single nucleotide polymorphisms (SNPs)] or a variable number of repeats of two or more base pairs (microsatellites) and need not be part of a functional gene: They are just landmarks in the genome. As with genes, all individuals have the same markers (in this sense the term "marker" may be misleading); it is the allelic variant of the marker that may differ between individuals. When a given marker is situated near the gene influencing the

trait of interest, allelic variants of the marker and the gene will be more likely to be transmitted together to the next generation than if they are distant or on different chromosomes. This so-called cosegregation, however, is not perfect. Sometimes, the marker and the gene may be separated by recombination events during meiosis. The extent to which marker and gene cosegregate is referred to as "linkage," and (this is a crucial assumption) the chance of linkage increases if the marker and the gene are close physically (although not necessarily linearly—not all chromosomal locations have equal chance for recombination). For each marker, evidence for linkage is derived using statistical procedures that trace the cosegregation of the trait (and thus in many instances the gene) and a specific variant of the DNA marker along familial lineages in extended pedigrees. Simply stated, if two children resemble each other for a certain trait and they both received exactly the same variant of a DNA marker from the same parent, that marker might be close to the gene influencing the trait.

Linkage analysis assigns a probability value (LOD score) to all markers, and a LOD score profile is obtained for each chromosome. Evidence for linkage is said to be present when the maximal LOD score exceeds a predefined threshold, which depends on the size of the genome and the number of genotyped markers. The chromosomal region surrounding a marker with a significantly high LOD score will be selected for fine mapping, which is essentially a repetition of the same procedure but now with all markers concentrated in the area of interest on a single chromosome. If the region containing the putative gene is sufficiently small, the DNA in the entire region is sequenced in full for a few persons or animals. Because genes have a specific structure, this identifies all genes in the region. By comparing all base pairs in these genes in many different persons/animals, the sites of allelic variation, also called polymorphisms, within these genes can be identified (mutational analysis). If the trait is a disease or disorder, comparison of the polymorphisms between patients and controls without the disease will ultimately reveal which allelic variant is responsible for the disease. The entire process from significant LOD scores to the actual allelic variants is usually called "positional cloning."

In 1993, using classical linkage in pedigrees, Han Brunner and colleagues discovered a point mutation associated with a behavioral phenotype that includes disturbed regulation of impulsive aggression. This mutation affected a gene that codes for one of the two isozymes [monoamine oxidase A (MAOA)] that are responsible for the breakdown of several neurotransmitters, including dopamine, noradrenaline, and serotonin. Since the MAOA gene is located on the X chromosome and the mutation is recessive, only males that possess the mutant allele show behavioral changes. One should nonetheless be extremely cautious in calling this gene an "aggression gene." The phenotype is not limited to impulsive aggressive behavior but also extends to borderline mental retardation, arson, attempted rape, and exhibitionism. Aggression is therefore merely one of the impulsive behaviors by which these individuals differ from "normal" people.

Because of its power to localize classical Mendelian genes, linkage analysis has been the workhorse for mapping genes for simple monogenic traits/diseases. Unfortunately, most complex traits (depression, intelligence, and aggression) are polygenic, i.e., they are influenced by many different genes, environmental factors, and their possible interactions. These interactions involve gene–gene interactions (epistasis), gene–environment interactions, and environment–environment interactions. Also, the same trait may be brought about by different subsets of genes in different individuals (genetic heterogeneity). Traits that are influenced by many genes and environmental factors are usually quantitative traits, and each of the genes that influence them is called a polygene. The locus where such a polygene can be found is called a quantitative trait locus (QTL). The contribution of a single polygene to the population variance in most complex behaviors is likely to be very small. Statistical power for the detection of such a QTL remains a major concern for the simple reason that only one gene (explaining 30% of the variation in fruit size in tomatoes) has been identified using these methods. Among the various solutions to boost power are the use of isolated populations to reduce genetic heterogeneity, the use of more DNA markers, and the use of selected family members (e.g., sibling pairs with either very high or very low values for the trait).

Two general alternative approaches to find genes for complex traits can be distinguished.

A. Candidate Genes

In some cases, there may be good theoretical reasons to focus on a single candidate gene. For instance, because neurotransmission is crucial to virtually every behavior, all known genes for receptors, transporters, or

synthesis elements for neurotransmitters are usable as candidate genes. The ideal candidate gene has been shown to be functional: It influences the concentration of the (iso)form of a protein, its functionality or efficiency, or, perhaps most important, its responsiveness to environmental factors triggering the expression of the gene. All candidate gene studies are association studies and are similar in design to classic case-control studies in epidemiology. DNA is collected from all participants and the trait is compared across the various allelic variants of the candidate gene. Also, frequencies of the various allelic variants may be compared in subjects with a particular disease to detect an association between a particular allele and the occurrence of the disease.

The main problem of association studies is false positives that arise due to population stratification. The famous example is the "chopstick" gene. Suppose that the genome of random San Francisco inhabitants was used in a study on the complex trait of "using chopsticks to eat" without stratification for Chinese or Anglo-Saxon background. There would be many genes associated with chopstick eating simply because frequencies differ between Chinese and Anglo-Saxon populations for a multitude of genes.

B. Genomic Searches

In most cases, no a priori information is available on the nature or location of the gene in question. A random search of the genome for QTL is then the most viable strategy employed. A first strategy is sib pair analysis. As in classical pedigree studies, several hundred DNA markers are obtained from siblings and (optimally) their parents. Siblings in a sib pair study, however, come from different families rather than from a few single pedigrees. By definition, the differences between two siblings for a trait will be smaller if they share the same variant of a QTL for that trait. Linkage of a marker to a QTL implies that the differences in the trait between the siblings will also be smaller if they share the same variant of the marker, obtained from the same parent. In a regression procedure originally derived by Haseman and Elston, the likelihood that a marker is in linkage with the trait is obtained by regressing the trait difference between siblings on the proportion of marker alleles shared identical by descent (IBD). QTL for complex common diseases can also be mapped by affected sib pair analysis. The probability that siblings share zero, one, or two alleles IBD for any gene is 0.25, 0.5, and 0.25, respectively. However, if a marker locus is close to the QTL this will be detectable as increased allele sharing IBD at the marker by two affected sibs. A major drawback of this method is that it requires large numbers of sibs to detect significant evidence for linkage.

With recent advances in genetic molecular technology, several thousand SNPs can be assessed on a microarray or DNA chip. This allows a second strategy for genomic searches: allelic association to detect linkage disequilibrium. This method is akin to the association approach in candidate gene studies. However, it is not the variation in a known functional gene that is associated to the trait but, rather, the variation in a series of DNA markers (which may but need not be in any functional gene). Linkage disequilibrium occurs when a marker allele and the QTL are so close on the chromosome that they remain linked over many generations of meiotic recombination. The advantage over sib pair analysis is that linkage disequilibrium mapping can detect the region of a QTL with only very small effects on the trait. The disadvantage is that linkage disequilibrium is found only when the marker and QTL are very close. A complete genomic search may require thousands of markers. However, technological barriers have been removed with much more ease than logistical barriers (i.e., the sampling of very large numbers of siblings).

VI. FROM ANONYMOUS QTL TO IDENTIFIED GENE IN ANIMALS

Increasingly, the laborious steps of positional cloning have become easier due to the ongoing sequencing of the entire human genome. A rapidly increasing database on all polymorphic DNA is now available as are appropriate data mining algorithms to combine this wealth of genetic data with existing protein and mRNA databases. Homology searches in DNA, mRNA, or protein databases for possible genes in the region identified by linkage analysis can aid in identification of the candidate genes. Although this will speed up gene hunting immensely, the need to first identify the region of interest in a genomic search and to narrow that region by (repeated steps of) fine mapping remains. Only after the region is sufficiently small (e.g., <100 genes) does the positional candidate gene approach becomes feasible. Repeated fine mapping is expensive and laborious, particularly when the

low statistical power of each repeated search step is taken into account. Not surprisingly, most QTL mapping has been conducted in animals. Animal QTL studies have the clear advantage that the environment can be controlled, and that a sufficient number of progeny and types of crosses can be performed. The latter advantage is of great importance if the chromosomal region containing a QTL is still very large. Various strategies are available, including constructing congenic strains. They are produced by repeatedly backcrossing the strain with the mapped QTL (donor) to another strain (recipient) while checking each backcross for the presence of the QTL using flanking DNA markers. After a number of predefined backcrosses, a strain is developed that is genetically almost identical to the recipient strain except for the QTL area. Phenotypic comparisons between congenic and recipient strains might verify the existence of the QTL, its impact, and possible interactions with other QTLs. Once the existence of the QTL has been proven by means of congenic lines, the actual fine mapping can commence. This is done by phenotyping substrains that are recombinant at various places in the QTL area.

Other strategies to fine map QTLs are the production of recombinant congenic strains, advanced intercross lines, or interval-specific congenic strains.

Also, exclusively in animals, transcript mapping techniques such as reverse transcriptase polymerase chain reaction and exon trapping can be used to locate genes. For a detailed review of these strategies, the reader is referred to the suggested reading.

VII. KNOCKOUT AND TRANSGENIC STRATEGIES

The development of targeted gene disruption has been one of the more important breakthroughs in unraveling the molecular underpinnings of behavior. The aim is to selectively inactivate a gene of interest (i.e., disrupt a targeted gene) and to compare this so-called knockout animal (usually a mouse) with a control or wild-type animal that has all its genes intact. Observed differences can then be attributed to the gene in question. Hence, by comparing the behavior and underlying neuronal processes of knockouts and wild types, one can deduce the function of the gene and determine its effects on complex traits.

It is beyond the scope of this article to discuss the technical details of this technique. Briefly, this technique relies on the fact that embryonic stem cells can be grown *in vitro* and modified by transfection. By homologous recombination the wild-type (or normal) gene in question can be replaced by a disrupted form of the gene that for example, codes for an antibiotic. The latter is used to select for recombined embryonic stem cells. These engineered cells are then injected into a recipient embryo to form chimeric mice (mice that have both cells with the normal gene and cells with the disrupted gene). Next, only those mice that have transmitted the mutation in their germline are used to generate nonchimeric mice carrying this artificial mutation.

To date more than 30 genes that influence male offensive behavior have been identified using the knockout technique (Table II). Interestingly, the involvement of the MAOA gene in abnormal social behavior (including aggression) was confirmed by a knockout study. Mice having a disrupted MAOA gene show more aggressive behavior than control mice. Also, the relatively nonspecific consequences of this gene defect were confirmed: MAOA-deficient mice tremble, have difficulty in righting themselves, and are fearful and blind. Other knockout lines show a more specific aggressive behavioral profile. For instance, mutant mice lacking the 5-HT1B receptor do not exhibit any obvious developmental or behavioral defects but do show enhanced aggressive behavior. In this respect, it is notable that about half of all studies on gene knockouts and aggression indicate that there is either a direct or an indirect relation between aggression and serotonin. Although the exact mechanisms through which serotonin exercises its influence on aggressive behavior is far from clear, data suggest that a low serotoninergic transmission is associated with increased aggressive behavior.

At this point, some comments on knockout studies must be made. First, there is always the possibility that the knockout and the wild type differ in more than one gene. This so-called "flanking gene" problem results from the technical procedure per se and may lead to false positives. A second problem is the genetic background of the knockout, which is either randomized or, at best, homogeneous. In the latter case, the obtained knockout is repeatedly crossed back to mice from the same inbred strain. After many predefined backcrosses, usually 10 or more, in which the presence of the mutated allele is checked every generation, the background is said to be homogeneous. A comparison between the knockout and the inbred strain will then yield information on the effect of the knocked out gene on a specific genetic background. However, it is certainly possible that an inactivated gene

[a] +, knockout increases aggression; –, knockout decreases aggression; +(=), increase but depending on background/paradigm/test day; –?, possible decrease; +/–, increase/decrease depending on design/type of aggression

dramatically affects a trait on one background, whereas it has no or a different effect on another background. This phenomenon, in which gene(s) influences the effect of another (i.e., the background genes interact with the knockout gene), is called epistasis and has been found in aggression research. For instance, the effect of the Y chromosome on aggressive behavior depends on the genetic background to which it has been backcrossed. Third, traditional knockouts are constitutive: They lack the gene in every cell and tissue from conception on. This means that in practice one cannot study the effects of genes that affect complex traits that are also essential for normal development. Such knockouts simply die at or before birth.

Joe Tsien at Princeton University developed a method to overcome these problems. He encountered this problem when he knocked out various subunits of the NMDA receptor. This receptor is thought to increase the synaptic strength between two nerve cells, a process called long-term potentiation (LTP), which is fundamental for learning and memory. By coincidence, he engineered NMDA knockout mice that lacked the subunit in a specific section of their hippocampus termed the CA1 region, which appears to be essential for memory. Hence, these so-called conditional, regionally restricted knockouts lack an essential "memory" gene, but only in a specific part of the brain and nowhere else in the body. As expected, it appeared that these animals demonstrated not only decreased LTP but also poor spatial memory.

Genetic engineering can be used not only to knock out genes but also to insert extra copies of a gene. This method is called transgenic integration. One of the more convincing behavioral examples comes from the same laboratory that developed the conditional NMDA knockouts. Instead of inactivating a gene, they inserted an extra copy of another memory gene. This gene codes for an NMDA subunit called NR2B, which is more strongly expressed in young people and stays open longer than the "old people's" NR2A, a phenomenon that might explain the age-related differences in learning and memory. Indeed, transgenic mice that had an extra copy of the gene for this receptor learned certain tasks better than did normal mice.

The development of both knockout and transgenic integration techniques has certainly deepened our knowledge about the effects of specific genes on complex traits. However, in addition to the previously mentioned, more pragmatic problems (flanking gene effects, genetic background, and temporal and spatial limits), there is another, more theoretical pitfall. Fundamentally, two types of genes coexist in nature: polymorphic and monomorphic genes. When studying genes that in nature are monomorphic, we generally deal with underlying mechanisms common to most or even all members of a species. In contrast, when studying natural genetic variation, we investigate mechanisms underlying spontaneous individual differences (i.e., polymorphic genes). Analysis of this natural genetic variation may thus enable us to identify genes that modify behavioral and neural function to a degree that is not grossly disadvantageous to the individual that carries such alleles. In short, whereas one type of question addresses, for example, how animals store information, the other type of question asks why some individuals perform better in a given task than others. Artificially induced mutations (e.g., knockouts and transgenes) can be used to study both types of genes, but it should be realized that the results of knockout or transgenesis studies do not contribute to the explanation of naturally occurring interindividual variation in cases in which the genes investigated are monomorphic in nature. In fact, most null mutations are not found to occur spontaneously in natural populations.

VIII. GENE–ENVIRONMENT INTERACTIONS

In the previous sections, we have shown that individual differences in behavior can be partly explained by genetic variation. Obviously, genetic variation is not the only source of variation; differences in the environment also play an important role. This section focuses on the border of both sources of variation—the so-called gene–environment interaction. Generally, the term refers to the phenomenon that the behavioral expression of the genotype depends on the environment.

A recent example of a gene–environment interaction in aggression research is a study that compared the behavior of male mice in which the brain-specific isoform of the creatine kinase gene was knocked out with animals that did not lack the gene (wild types). Both knockouts and wild types were tested for their aggressive behavior in the neutral cage paradigm. In this test the encounters took place on neutral grounds;

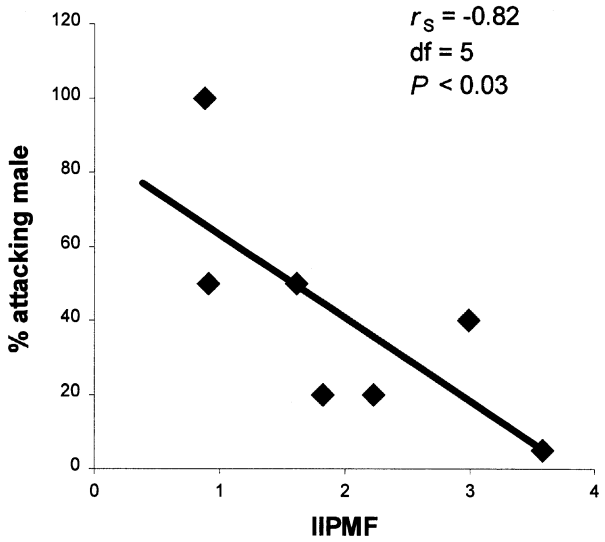

Figure 2 Relationship between the sizes of the hippocampal intra- and infrapyramidal mossy fiber (IIPMF) projections and attack behavior in seven inbred mouse strains. Data from Guillot *et al.* (1994).

that is, neither the animal under investigation nor its opponent were familiar with the test cage. Moreover, each mouse was tested twice on consecutive days against genetically different standard opponents. At first, knockouts did not seem to differ from wild types: Both were similarly aggressive against whichever opponent. A more detailed analysis, however, revealed that knockouts were more prone to attack one of the two opponents, whereas wild types showed no preferences.

Another example showing that the behavioral expression of the genotype depends on the environment comes from mice that lack a specific part of the NMDA receptor in a specific section of their hippocampus. As mentioned previously, when raised under normal laboratory conditions, they perform relatively poorly in learning and memory tasks. However, when they are exposed to an enriched environment each day for an extended period, they improve markedly and do as well as normal mice in various tasks. This behavioral enhancement is reflected anatomically: The number of connections between hippocampal cells actually increases. Hence, in these mice the enriched environment counterbalances a genetically engineered memory defect.

IX. GENETIC ANALYSIS OF BRAIN–BEHAVIOR RELATIONSHIPS

So far, we have not dealt with the intermediate neuronal structures through which genes modulate aggressive behavior. Results from knockout studies have certainly identified a wealth of brain receptors that might be involved in aggressive behavior. However, do they also represent naturally occurring variation in behavior and underlying neuronal structures?

One of the more eye-catching products of genetic analyses of brain and behavior comes from studies on the hippocampal intra- and infrapyramidal mossy fiber (IIPMF) terminal fields. Also, this research clearly demonstrates the importance and strength of classic behavioral genetical techniques.

The hippocampus has been shown by means of lesion studies to be involved in learning and memory. Subsequently, it was shown that the performance of mice in learning tasks dependent on hippocampal integrity is correlated with heritable variations in the size of the IIPMF. Animals with larger IIPMF projections perform better on spatial learning tasks. However, several mossy fiber studies also indicate hippocampal involvement in the regulation of intermale aggression.

The first indication for the involvement of genetics and the IIPMF sizes in the development of aggression came from the two selection lines previously mentioned. (Aggressive) SAL males had shorter IIPMF terminal fields than (nonaggressive) LAL males. Soon after, a study that compared multiple inbred strains for both the sizes of the IIPMF terminal fields and aggressive behavior clearly demonstrated that the SAL–LAL difference was no coincidence. In fact, a strong negative genetic correlation was observed between these two variables: The shorter the IIPMF sizes, the more aggressive the behavior (Fig. 2). These findings strongly suggest that hereditary neuroanatomical variations in a defined brain structure, the hippocampus, may influence intermale attack behavior.

Behavioral Neuroimmunology

DOUGLAS L. DELAHANTY and JULIE K. CREMEANS-SMITH
Kent State University

GLOSSARY

cytokines Protein messenger molecules secreted by cells of the immune system that serve to communicate between immune cells and signal the presence of foreign material within the body.

lymphocyte proliferation assay An assay conducted to examine the ability of lymphocytes to mount a response against one of a number of standard mitogens.

mitogen A plant-like substance that elicits a cascade of immune responses, including the division of lymphocytes.

stress A negative experience elicited by threat, harm, or demand.

Research in behavioral neuroimmunology examines the interaction of central nervous system-mediated behavior and the immune system, two areas that were once thought to operate relatively independently. However, recent interdisciplinary research has revealed that these components can affect and be affected by each other. Specifically, the primary focus of behavioral neuroimmunology research is on the bidirectional relationship between behavior and immunity, examining the impact of health-risk behaviors on the immune system, and the relatively newly discovered impact of immune activation on subsequent behavior.

I. OVERVIEW OF THE IMMUNE SYSTEM

Although a more detailed description of the immune system is provided in other articles of this encyclopedia, it is necessary to briefly review the basics of immunology. This is not meant to be a comprehensive review but, rather, is meant to provide the reader with sufficient background to interpret research in the field of behavioral neuroimmunology.

The general purpose of the immune system is to defend the body against infection and disease by identifying and eliminating foreign "nonself" pathogens and mutated "self" cells. This is accomplished through the activity of two general categories of immunity: innate (also called nonspecific or natural) and acquired (also called specific) immunity. Natural killer (NK) cells, macrophages, and neutrophils are agents of innate immunity. These cells serve a surveillance function and will attack pathogens or cancerous cells without specificity and without requiring prior exposure to the invader. In contrast, acquired immunity involves a specific cascade of reactions to a particular antigen, and the magnitude of response to this pathogen increases with each successive exposure. Acquired immune responses can be classified into two types: cell-mediated and humoral immunity. Cell-mediated immunity is carried out by T lymphocytes (which mature in the thymus), whereas humoral immunity is mediated by antibodies that are produced by B lymphocytes (which mature in the bone marrow in humans).

Perhaps the most efficient way of reviewing the acquired immune response is to trace how the immune system would respond to a given pathogen (Fig. 1). Upon initial infection, a macrophage or other antigen-presenting cell (APC) encounters the pathogen, engulfs it, and digests it. The macrophage then displays

the foreign antigen on its surface so that it can be recognized by antigen-specific T cells. In addition, the macrophage secretes cytokines or chemical messengers such as interleukin-1 (IL-1) that stimulate helper T ($CD4^+$) cells to begin proliferating. Upon encountering the APC, helper T cells secrete IL-2 and interferon (IFN), which stimulate cytotoxic T cells ($CD8^+$) to destroy infected cells. In addition, helper T cells secrete IL-4, which activates the humoral branch of the immune response. IL-4 stimulates B cells either to mature into plasma cells or to become B memory cells. Plasma cells produce large quantities of antibody specific to the antigen that serve to destroy it. B memory cells "remember" the particular antigen so that, upon subsequent reexposure, the speed and magnitude of the immune response will be increased.

II. CONDITIONED IMMUNOSUPPRESSION

Although early research suggested that allergic reactions could be provoked with artificial roses, and hay fever attacks could similarly be stimulated by exposure to pictures of hay fields, Ader and Cohen's (1975) demonstration that immunosuppression could be conditioned to a novel stimulus provided the first empirical investigation of the relationship between behavior and the immune system. In their landmark study, Ader and Cohen paired the novel taste of saccharin with the immunosuppressive agent cyclophosphamide in a taste aversion paradigm. Subsequent presentation of saccharin resulted in an attenuated immune response to sheep red blood cells. These results suggested that the immune system should be viewed as an integrated physiological system subject to the influence of psychosocial and environmental factors and not, as previously thought, an autonomous system operating relatively independently of other physiological processes. These findings were replicated and extended in both human and animal studies and led to the development of the field of psychoneuroimmunology. Subsequent research has provided extensive evidence for the relationship between stress and immune alterations and has examined possible mechanisms through which psychosocial factors could lead to altered immune activity. In addition, moderators of the stress–immune system relationship and the role of stress-induced immunosuppression in various disease processes have been studied.

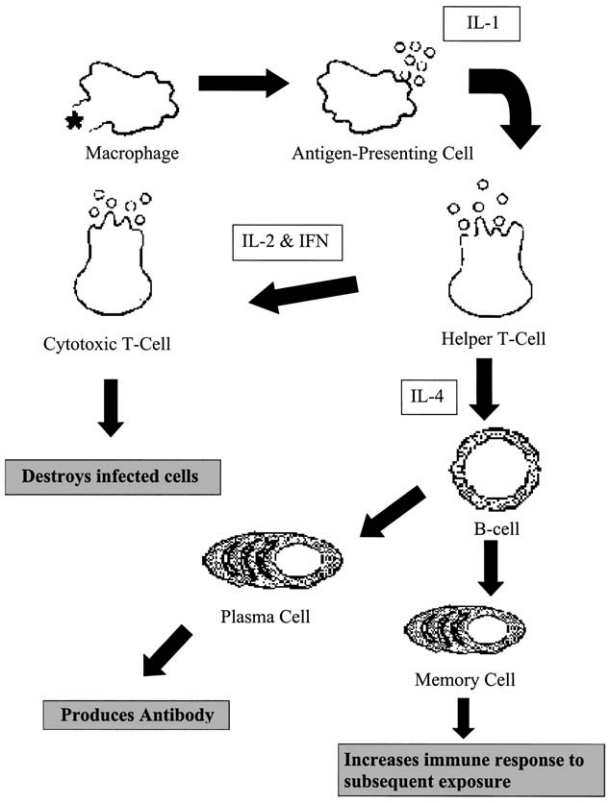

Figure 1 The cascade of responses by the acquired immune system to stimulation by a pathogen. IFN, interferon; IL, interleukin.

III. STRESS AND IMMUNITY

The demonstration of links between the brain and immune system suggested that emotional states such as stress could affect immunity, leading to hundreds of studies that have measured the effects of stress on humans and animals. Most of these studies have examined the impact of acute laboratory or more chronic naturalistic stress on various enumerative and functional indices of immune activity.

A. Acute Laboratory Stressors

1. Animal Research

Animal researchers have typically defined acute stressors as being relatively short in duration or consisting of relatively few exposures to a stressful stimulus. This general definition allows for numerous types of stressors differing in intensity, duration, and effects. Examples of stimuli that have been used to study the effects of acute stress on animals include aggressive confrontations, noise or bright light exposure, passive avoidance tasks, and tail shocks. Early animal studies reported decreased T cell proliferation during and following acute stress exposures concomitant with increases in levels of circulating corticosterone. Subsequent research determined that stress-related

increases in corticosterone provided a mechanism through which stress could lead to suppressed immunity. However, recent research has clouded these conclusions by demonstrating that acute stressors do not always result in immunosuppression. By varying the type, severity, and duration of exposure as well as the time at which immune measures are sampled, acute stressors can result in suppressed, unaltered, or even enhanced immune system activity.

2. Human Research

Acute stress in the human literature is often defined as transient exposure to a variety of distressing or challenging laboratory tasks (e.g., mental arithmetic, speech tasks, and distressing films) or as a short-duration naturalistic event (e.g., first-time tandem parachute jumping). Despite differences in type and duration of stressors used and sampling time during or following stress exposure, research examining the immunomodulatory effects of acute stressors suggests that numbers of peripheral lymphocytes increase during and following acute stress, whereas lymphocyte proliferation to assorted mitogens is typically suppressed. Increased numbers of lymphocytes are thought to be due to a redistribution of cells from lymphoid organs into the peripheral blood. However, these cells are often immature and not fully capable of combating pathogens, thus leading to suppressed proliferation. In addition, acute stress may lead to decreased immune activity by downregulating the activity of existing cells.

Whereas lymphocyte proliferation consistently appears to be suppressed during stress, research examining the effects of acute stress on NK cell activity has yielded more inconsistent results. Some researchers have reported increased activity of NK cells during and following acute stress, whereas others have found decreased activity. Closer examination of the timing of blood samples in these studies suggests that those examining NK activity during or immediately after stress exposure found increases in activity, whereas those examining later time points found decreases in activity. In other words, NK activity may follow a biphasic pattern in response to acute stress, with initial increases in activity being followed by a subsequent decrease to levels below baseline. Increased innate immunity during acute stress may allow an individual to fight off opportunistic agents without having to mobilize the entire cascade of the acquired immune response. Simple opponent processes have been hypothesized to account for the subsequent decrease below baseline.

In summary, results of studies examining the impact of acute laboratory stressors on immunity suggest that acute stress is associated with increases in number but decreases in the functional efficacy of circulating lymphocytes. In addition, NK cell activity may follow a biphasic pattern of initial increases in activity followed by a decrease to below baseline levels upon stressor termination.

B. Naturalistic Examination Stress

Laboratory studies of stress, while providing standardized sampling times and controlling for numerous extraneous factors, suffer from questions of generalizability. Whether responses to laboratory stressors parallel those to naturally occurring acute stressors is questionable, and the extent to which transient changes in immune activity observed in the lab are clinically relevant is unknown and thought to be minimal.

To improve upon some of these shortcomings, Kiecolt-Glaser and Glaser conducted a comprehensive series of studies in which they examined the immunomodulatory effects of a commonplace, everyday stressor: academic examinations. In their standard protocol, medical students were examined at two time points during their first 2 years of medical school; first during a lower stress baseline period in which exams were not being given and then a month later during examinations. Results revealed that exam stress was associated with decreased NK activity, decreased lymphocyte proliferation to mitogens, and decreased production of various cytokines. In addition, exam periods were associated with greater self-reports of illness (primarily upper respiratory infections) suggesting that the observed immune changes may have health consequences. Students' levels of plasma albumin and transferrin fell within normal ranges during the exams, suggesting that immune changes were not due to poor nutrition during the examination period. Subsequent studies revealed that the immunosuppressive effects of exam stress altered the competence of the cellular immune system to control latent herpesviruses and influenced students' responses to a series of hepatitis B inoculations. Less stressed students were more likely than more stressed students to seroconvert after the first inoculation, providing more evidence for health consequences of exam-related immune alterations. Because examination stress was shown to reliably decrease immune efficacy, an intervention was conducted to determine if decreasing stress through hypnosis and relaxation could attenuate these immunosuppressive effects. Although NK activity and

the percentage of T lymphocytes decreased during exam time in both the intervention and the control groups, more frequent practice of the relaxation exercise was associated with higher T cell percentages within the intervention group. This suggested that a stress-reducing intervention could, in part, moderate the immunosuppressive effects of exam stress.

In summary, the studies of Kiecolt-Glaser and Glaser demonstrated that relatively mild, everyday stressors have consistent immunosuppressive effects. It is important to note that the participants in these studies were medical students who had been taking (and typically excelling on) examinations for the majority of their lives, so this stress was not beyond the realm of their normal experience. Furthermore, these studies suggested that the transient changes in immunity exhibited during exam periods could have possible health implications.

C. Chronic Stress and Depression

1. Animal Research

One of the major criticisms of research conducted on the effects of chronic stress on animals is that the stressor is not qualitatively different from that used in acute conditions. That is, acute stress is often differentiated from chronic stress only quantitatively, by the number or duration of exposures to the stimulus. Despite these problems in operationalizing chronic stress, animal research has suggested that the immune system may be differentially affected by acute and chronic stress situations. Studies have shown that exposures to sessions of acute noise stress for less than 1 week are associated with increased NK activity, whereas exposure for 3 weeks or more is associated with decreased NK activity.

Animal studies have also examined the effects of chronic social stress on immunity. In these studies, subjects were exposed to numerous changes of social environment, resulting in struggles to establish dominance. This stressor paradigm is thought to more readily approximate the human chronic stress experience. Results of studies using social hierarchy disruption as a stressor in rats demonstrate that submissive animals have lower immune responses on some immune measures but not others. Studies of social stress in nonhuman primates may more adequately examine the processes underlying human chronic stress, but these studies have also produced mixed results. Some have reported suppressed T cell function in response to chronic social stress, whereas others have found no significant immunological effects. This may be due, in part, to the small sample size examined in primate research and the consequent lack of power to detect significant results. Despite some exceptions, for the most part animal research suggests that prolonged exposure to stressful stimuli or situations results in immunosuppression.

2. Human Research

The results of studies examining immune consequences of chronic stress in humans largely parallel the findings in animals. Research across a range of chronic stress situations, including bereavement, caregiving for a relative with dementia, unemployment, and diagnosis with a life-threatening illness, reveals that stressed individuals have altered immune function in comparison with controls. In contrast to the acute stress literature, chronic stress is typically, although not always, associated with lower numbers of immune cells and weaker immune functioning. In particular, chronic stress associated with the loss or disruption of personal relationships has been shown to reliably alter immune activity. For instance, women who have been separated or divorced for less than 1 year have demonstrated poorer immune function than married women, and both men and women who reported poor marital quality had lower immune function than more happily married individuals. Research has also suggested that recently widowed women whose husbands died of lung cancer had more impaired immune function than women whose husbands were dying of lung cancer and women with healthy husbands.

The effects of losing a loved one on immunity have also been examined prospectively. Men whose wives died of breast cancer had significantly lower lymphocyte proliferation after the death of their spouse than prior to bereavement. Alterations of immune activity in chronically stressed individuals may also have important health consequences. For example, Alzheimer's caregivers have exhibited significantly impaired antibody and T cell responses to an influenza virus vaccine, and poor response to the vaccine has been associated with increased risk of influenza infection and higher rates of clinical illness. Similarly, caregivers have also been shown to take significantly longer to heal from a cutaneous punch biopsy wound than a matched control group.

Chronically stressed individuals exhibit a greatly increased incidence of depression, and the relationship between depression and immunity has also been examined. However, results have been mixed, perhaps due to differing diagnoses and medical treatment protocols among patient samples and to different immune measures being assayed. Depression does not

appear to be consistently associated with alterations in particular lymphocyte subsets, although overall a higher number of leukocytes have been reported in depressed patients compared to controls. Studies of lymphocyte proliferation to mitogens in depressed patients have been particularly mixed, resulting in findings of higher, lower, or no differences in activity between depressed and age- and gender-matched nondepressed patients. Decreased NK activity appears to be the most consistent immunological change linked with depression. In addition, depressed individuals taking selective serotonin reuptake inhibitors demonstrate significant increases in NK activity (NK activity had been significantly lower than that of controls at the start of the experiment) which coincide with alleviation of the depressive symptoms. Although depression appears to be linked with suppression of some immune indices, many variables have been shown to affect the relationship between immune and depression, including age of the patient, severity of symptomatology, hospitalization status, and gender. Therefore, the complex nature of the relationship between depression and immunity makes it inappropriate to conclude that depression, in general, is associated with specific immune consequences without examining the effects of these moderating variables.

D. Traumatic Stress and Posttraumatic Stress Disorder

Although many studies have examined the effects of acute, laboratory stress and chronic, naturalistic stress on immunity, relatively few have studied immune alterations in response to severe, traumatic stressors. Stressors can vary along many dimensions, including the duration of the event, the duration of threat experienced, and the duration of responding to the stressor. Therefore, distinguishing between acute and chronic stressors may be too simplistic and may not encompass the full range of stressful experiences. Sudden traumatic stressors involving life threat and direct bodily harm may be qualitatively different from other types of stress. Often, the traumatic event is acute in duration, but in some individuals distress may persist long after the event is over. A small but significant percentage of victims may develop posttraumatic stress disorder (PTSD), which is characterized by persistent reliving of the event, avoidance of situations that remind one of the event, and hyperarousal in response to reminiscent stimuli.

Evidence suggests that acute-phase responding to naturalistic and human-caused disasters is associated with increases in some immune measures, but the lack of published studies examining immune levels immediately after traumatic events necessitates viewing this conclusion with caution. Longer term follow-up of victims indicates that stress stemming from both human-caused and natural disasters appears to be associated with fewer cells and decreased functional efficacy of a wide range of immune measures. Immune system changes associated with human-caused disasters appear to be particularly persistent. Altered immune activity was found as many as 6 years after a nuclear accident in residents of Three Mile Island. Residents had greater numbers of neutrophils, but fewer B lymphocytes, cytotoxic T lymphocytes, and NK cells than did controls. In addition, residents displayed higher antibody titers to herpes simplex virus than controls, suggesting downregulation of cellular immunocompetence. The longest follow-up of a naturalistic disaster indicated that hurricane victims had significantly lower NK activity than laboratory controls 2 years after the hurricane, but that NK activity did not differ between the two groups 4 years post-hurricane.

Although traumatic stress appears to be immunosuppressive in the majority of trauma victims, findings concerning immune system activity in victims who meet criteria for PTSD are more mixed. Despite equivocal findings, research suggests that war veterans with PTSD may exhibit greater immune activity than similarly exposed veterans who do not meet PTSD criteria. However, these findings must be interpreted cautiously due to several characteristics of the patient sample. For instance, the length of time that has passed between the traumatic event and sampling for immune measures in these studies is often great. PTSD patients in these studies have typically suffered from chronic PTSD, often presenting with symptoms for more than 20 years. This chronicity of symptomatology is unusual and may account for some of the findings. These patients also often suffer from comorbid drug and alcohol abuse, making conclusions regarding immune alterations in PTSD difficult.

One mechanism through which PTSD could lead to increases in immune activity has been examined and provides suggestive results. The majority of studies have found lower 24-h urinary cortisol excretion in patients with PTSD compared to patients without PTSD and normal controls. Cortisol exerts immunosuppressive effects, so persistently low levels could be associated with increased immune activity. However, future research examining immune levels in less chronic PTSD without comorbid diagnoses is necessary before conclusions can be drawn with any certainty about the relationship between PTSD and immunity.

E. Summary

In general, research has produced mixed results with regard to the effects of stress on immune activity. This may be due, in large part, to differences in methodology, subject samples, and especially immune components being examined. The immune system is an extremely complex physiological system with numerous cellular and chemical components that may respond differently to stressful stimuli. Therefore, it is necessary in future research to examine multiple measures of immunity rather than focusing on one particular cell or cytokine. Overall, acute and chronic stressors appear to be associated with immunosuppression, although acute stress has been linked to increases in the number of circulating lymphocytes and increases in NK activity. With regard to traumatic stress, very little research has been conducted examining immune changes during acute phases of responding to a traumatic event. Long-term immune changes appear to parallel the immunosuppression seen in chronic stress and depression; however, research has suggested that chronic PTSD may be associated with immunoenhancement.

IV. MECHANISMS OF STRESS-RELATED IMMUNE ALTERATIONS

The finding that psychosocial stressors can evoke consistent changes in immune measures led researchers to begin searching for the mechanisms through which emotional states could impact immune levels. Results of these studies suggested that stress has both direct and indirect effects on immunity. Direct effects stem from the activation of the two primary stress pathways: the sympathetic nervous system (SNS) and the hypothalamic–pituitary–adrenal (HPA) axis. SNS activation is accompanied by increases in levels of catecholamines in the bloodstream, whereas HPA activation results in increased release of glucocorticoids. These hormones appear to participate in regulating the immune system both through direct neural innervation of lymphoid tissue and through their activity at relevant receptors on lymphocytes. As mentioned previously, cortisol often acts as an immunosuppressive agent, and animal research has suggested that genetically low glucocorticoid responders are more susceptible to autoimmune disorders, whereas high glucocorticoid responders appear to be at increased risk for infectious disease. On the other hand, catecholamine increases are associated with a transient lymphocytosis or an increase in the number of circulating lymphocytes, especially NK cells. This increase in the number of circulating cells appears to be accompanied by a reduction in immunological functional capabilities. Therefore, activation of stress-related endocrine pathways provides a direct route by which stress may induce immunosuppression.

Stress can also affect immunity indirectly by leading to negative health behaviors that can contribute to alterations in immune functioning. Stress is typically associated with riskier health behaviors, including increased drug/alcohol use, increased smoking, poorer sleep, and poorer nutrition. These behaviors can also negatively affect the immune system, although the relationship between individual health risk behaviors and immunity is often not clear. Partial sleep deprivation has been shown to decrease immune functioning in humans and rats, and poor sleep has been hypothesized as one mechanism through which repeated, intrusive thoughts may impact immunity. The immunological effects of cigarette smoking, on the other hand, have been particularly mixed, with research reporting decreases, increases, and no change in immune functioning. Some of this variability may be due to differences in the amount of smoking, acute versus chronic effects of smoking, and the timing of sampling in relation to when the participant last smoked. Many other factors can affect the relationship between smoking and immunity, and recent evidence suggests that cigarette smoking may interact with depressed mood such that depressed smokers exhibit the greatest alterations in immunity.

Use of alcohol also increases during periods of stress, and results of studies examining the immunological effects of chronic alcoholism suggest that immune activity is suppressed while individuals are using alcohol but recovers within months after participants stop drinking. These results must be interpreted cautiously because alcoholism is associated with many other factors that may affect immunity (poor diet, less exercise, etc.). Recent research suggests that minimal intake (one or two drinks per day) may provide some protection against certain chronic diseases. However, chronic and moderate acute alcohol use can increase susceptibility to bacterial and viral infections, although the effects of alcohol on immunity appear to be differentially affected by alcohol dose, extent of alcohol use, and time since use.

V. MODERATORS OF THE STRESS–IMMUNE LINK

Although many situational and personal variables have been shown to affect the relationship between stress and immunity in individual studies, only a few

have been shown to have consistent effects across studies and research groups. These include perceived control over the stressor, the presence of or perceived social support, and personality variables such as optimism.

A. Perceived Control

Perceived control over illness has been shown to be positively associated with better psychological adjustment in many studies of different chronic illnesses, with the strongest relationships being found in patients with more severe disease. In addition, the effects of stressor controllability have been widely researched in animal models. Animals exposed to uncontrollable stress typically demonstrate decreased immune responses and faster disease progression than yoked animals exposed to controllable stress. Human studies of immune alterations to uncontrollable stress have produced mixed results. Whereas some have found reduced lymphocyte proliferation to mitogens in participants exposed to controllable versus uncontrollable stress, the majority have found the opposite. It appears that objective control (actually having control over the stressful stimulus) is not as important as *perceived* control in modulating immune responses. Research examining the impact of perceived controllability over both acute and chronic stressors has found decreased functional and enumerative immune measures in participants perceiving less control over the stressor. These findings persist whether the stressor is actually controllable or not.

B. Social Support

As mentioned earlier, research examining the relationship between quality of personal relationships and immune function has demonstrated consistent immunosuppressive effects in individuals who reported low marital satisfaction or who recently lost a spouse. Similarly, social support has been linked with physiological processes associated with risk for cardiovascular disease and cancer, and less social integration is associated with higher mortality rates from all causes. Individuals with high levels of social support have lower baseline blood pressures than those with lower levels of support, and the presence of a supportive individual has been shown to decrease cardiovascular reactivity during an acute laboratory stressor.

Individuals reporting greater diversity of social support also appear less likely to develop the common cold upon exposure to a virus than those with a less diverse social support network. Consistent with these findings, social support has been shown to moderate the effects of stress on immunity. For the most part, greater social support is related to stronger immune responses. High levels of social support in spouses of cancer patients were associated with greater NK cytotoxicity and lymphocyte proliferation responses. Similarly, levels of social support have been positively related to NK cell activity, and NK activity has been linked to measures of disease progression in breast cancer patients. These results suggest that social support may buffer the immunosuppressive effects of stress, and that the attenuation of these effects may have relevant health consequences.

C. Optimism

Personality variables also appear to moderate the relationship between stress and immunity. Research has suggested that optimism, or the generalized tendency to "look on the bright side of things," affects the way in which individuals perceive stressful situations and is associated with better health and positive health outcomes. Optimism has been linked to better physical health, better quality of life following coronary artery surgery, decreased stress in breast cancer patients, and later symptom onset and longer survival time in AIDS patients. An optimistic outlook has also been shown to buffer the immunosuppressive effects of stress.

Situational optimism has been associated with higher immune activity in first-year law students, although many factors can affect this relationship because optimism has been shown to interact with mood and perceived stress to account for immune changes. Characteristics of the stressor may also determine the efficacy of optimism in attenuating stress-related immune changes. Optimism has been shown to buffer the effects of acute stress on immunity, but in response to high levels of persistent distress, optimists have demonstrated more immunosuppression than pessimists. Although optimism may be beneficial for dealing with transient stressors, persistence of distress is inconsistent with the expectations of an optimistic individual and optimists may therefore face difficulties in coping with persistent distress.

D. Summary

As demonstrated in the previous sections, the relationship between stress and immune changes is complex. It is difficult to interpret mixed or contradictory findings

due to the use of different types of stressors and different immune measures. Overall, stress appears to have an immunosuppressive effect. However, many personal and situational variables have been shown to moderate the relationship between stress and immunity, further complicating interpretation of the research. Perceived control, optimism, and social support all appear to be associated with buffering the effects of stress on immunity, although these variables can interact with each other and other variables to affect this relationship. In addition, although stress has consistently been associated with alterations in immunity, observed immune levels often remained in the normal range, leading many researchers to question the meaningfulness and impact of stress-related immune changes.

VI. STRESS-INDUCED IMMUNOSUPPRESSION AND HEALTH

Stress has repeatedly been linked to poorer health, greater incidence of the common cold and upper respiratory infections, faster progression of chronic diseases such as cancer and AIDS, and exacerbation of autoimmune disorders. Despite these consistent findings of stress-related impairments in health, relatively few studies have demonstrated that stress-related immunosuppression could serve as a mechanism through which stress could lead to disease. Although the extent to which stress-related immunosuppression is clinically relevant is debated, recent research has attempted to prospectively show relationships among stress, immunity, and health.

A. Cancer

Research on the psychoimmunology of cancer presumes that stress may alter the immune system, leading to faster growth and progression of neoplastic disease. However, this presumption is very controversial and the extent to which stress-related changes in immunity result in clinically significant development or growth of malignant tissue is unknown and often considered minimal. The literature is further complicated by contradictory findings in animal models of stress and cancer. In animals, stress has been shown to result in both exacerbation and inhibition of tumor growth and metastases, with differences in results due to timing of tumor induction, type of stressor examined, type of tumor, and species and prior experience of animals examined.

Human research examining the relationship between stress and cancer has also produced mixed results. For example, although initial studies suggested that stress could lead to the development of cancer, contradictory findings also exist. Furthermore, due to methodological limitations and questions concerning the events and timing of initial tumor development, many researchers have concluded that there is no demonstrable relation between stress and cancer onset. However, research examining the effects of stress on progression of cancer is more suggestive, and the immune system has been examined as a mediator of the relationship between stress and cancer progression. Current knowledge regarding the role of the immune system in surveillance against tumors is limited, but the majority of studies have focused on NK cells due to their antitumor properties. As mentioned earlier, NK cells also appear to be very responsive to psychosocial stress, and stress-related alterations in NK activity have been widely reported. Examination of levels of NK activity in breast cancer patients has revealed that measures of distress in patients recently diagnosed with cancer predict current and subsequent NK activity. In addition, NK activity appears to be an important predictor of disease status in breast cancer patients.

Another way to examine the relationship between stress, immunity, and cancer is to reduce stress in some cancer patients and determine any consequent effects on immunity or disease progression. Stress-reducing interventions have been shown to increase vigor and the use of more effective coping strategies in malignant melanoma patients. In addition, at a 6-month follow-up, intervention patients had higher percentages of NK cells and greater NK activity than patients who did not receive the intervention. Six years after the intervention, intervention participants were more likely to have survived than control participants, although NK activity levels were not related to survival.

B. Wound Healing

Perhaps the strongest, albeit indirect, evidence for clinical health consequences of stress-induced immunosuppression derives from studies examining differences in stressed and nonstressed individuals in length of time to heal from standardized wounds. In these studies, women who were caring for relatives with dementia and age- and income-matched controls received a standard 3.5-mm punch biopsy wound resulting in identical tissue damage to all participants. Results revealed that the chronically stressed care-

givers took significantly longer to heal than controls. In addition, stimulated peripheral leukocytes from caregivers produced significantly less IL-1β (a cytokine involved in the initial stages of wound healing) than did leukocytes from controls. Therefore, chronic stress appears to slow wound healing and affect a cytokine that serves multiple functions in early stage wound repair. Subsequent research examined a less chronically stressed sample and found that it took 3 days longer on average for dental students to heal from an oral biopsy wound during examinations than during summer vacation. In addition, IL-1β production was significantly lower during the exam period. These results demonstrate that relatively mild, everyday stressors can also have effects on immune activity and healing. However, neither study examined the relationship between IL-1β levels and healing, making conclusions concerning the role of stress-induced immunosuppression in slowed healing difficult.

C. Summary

Overall, the inability to demonstrate clinical effects of stress-induced alterations in immune activity on health appears to be the major limitation of research in behavioral neuroimmunology. Research has consistently demonstrated stress effects on health and stress effects on immunity; however, immune changes have not been shown to mediate the effects of stress on health. This may be due to methodological difficulties. As mentioned previously, the immune system is very complex and its components may respond differently to stress. Perhaps measuring activity or the number of one or a few immune cells is not a realistic representation of *in vivo* immune responses to stress or illness. Recent results showing stress-induced immune alterations and poorer health are suggestive, but research examining multiple immune indices and testing mediational models is necessary before we can conclude with any certainty that immune changes in response to stress play a role in disease progression.

VII. IMMUNE ACTIVATION AND SICKNESS BEHAVIOR

Although the majority of research in behavioral neuroimmunology has examined the impact of stress and central nervous system (CNS) activation on immune activity, it has become apparent that the immune system can also directly communicate with the CNS and thus alter behavior. Therefore, it is necessary to consider the relationship between the immune system and the brain as bidirectional. Furthermore, recent research has suggested that the immune system might often initiate this bidirectional communication by acting as a sensory organ, informing the brain of infection, and triggering behaviors designed to combat the infection (Fig. 2).

A. Sickness Behavior

The primary illustration of the immune system's, influence on the CNS involves a collection of responses to infection termed sickness behavior. In the early 1960s, researchers examining the activity of various mitogens determined that simple activation of the immune system resulted in a collection of behaviors

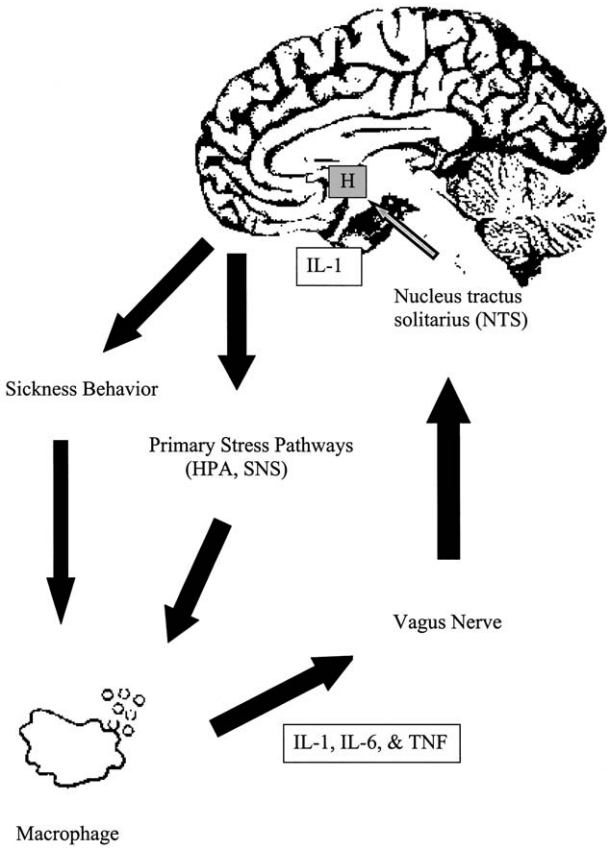

Figure 2 Bidirectional communication between the immune system and the brain begins with the activation of macrophages by foreign particles. Activated macrophages secrete various cytokines that stimulate the vagus nerve. The vagus then sends a neural signal to several brain regions, including the nucleus tractus solitarius (NTS) and hypothalamus (H), whose activation leads to symptoms of illness such as fever and loss of appetite. In addition, the activated immune system also triggers activation of the hypothalamo–pituitary–adrenal (HPA) axis and the sympathetic nervous system (SNS), which results in immunosuppression. IL, interleukin; TNF, tumor necrosis factor.

normally seen in sick animals. In these studies, animals were typically injected with lipopolysaccharide (LPS), a fragment of the cell wall of gram-negative bacteria such as *Escherichia coli* bacteria. LPS does not cause infection in the animal but, rather, triggers the typical cascade of immune responses to infection. Although the animals were not injected with any disease-causing agent, they still exhibited reduced food consumption and decreased levels of general activity, suggesting that these sickness behaviors were triggered solely in response to immune system activation. However, the mechanism through which an exogenously administered mitogen could trigger this type of response was unknown.

A hint of a possible mechanism was provided by early attempts to treat cancer patients with various cytokine therapies. Cancer researchers searching for therapeutic agents that could elevate immune responses and help to combat the disease examined the efficacy of a variety of cytokines [including IL-1, IL-4, IL-6, IL-12, and tumor necrosis factor (TNF)] in slowing cancer progression. Clinical trials conducted with both healthy and ill individuals demonstrated serious side effects of cytokine administration, such as fever, anorexia, general malaise or depression, irritability, and delirium. Again, these symptoms parallel those seen in illness and suggest that cytokine activation may serve a primary role in initiating these sickness behaviors.

Subsequent research supported this hypothesis and demonstrated that sickness behavior results from an initial cytokine cascade triggered largely by the activation of macrophages. As mentioned earlier, macrophages are cells of the innate immune system which engulf foreign particles that have entered the body and release cytokines upon activation. Cytokines relay the message of immune system activation to the CNS, which evokes a number of changes in behavior designed to mobilize the body's resources to combat infection. These behavioral changes are typically referred to as sickness behavior and consist of depressed levels of general activity, decreased bodily care, reduced consumption of food and water, temperature change (usually fever), and increased sleeping.

The symptoms of sickness behavior are the result of the acute-phase immune response to bacteria, viruses, or other stimuli and thus remain constant despite differences in the particular invading pathogen. The primary function of sickness behavior is to conserve energy by limiting expenditure so that energy reserves may be put into generating fever. Fever is an adaptive symptom because it slows the growth of many pathogens and increases the activity of both nonspecifc and specific immune system processes. Because fever is the result of an increase in the hypothalamic set point for body temperature, the organism is motivated to seek out warm places. Other symptoms of sickness behavior, such as increased sleep and decreased levels of general activity, are designed to conserve energy. In addition, a sick individual also experiences anorexia and adipsia, which may appear counterintuitive, because the individual should be motivated to consume in an effort to increase energy reserves that may be used for fever generation. However, an organism that is foraging for food and water is exposed to predation and is exposing body surfaces to the elements, resulting in a loss of heat that has already been generated. The reduction of foraging efforts during sickness allows the organism to conserve energy by reducing activity and complements other symptoms, such as increased amounts of sleep. Anorexia is also beneficial by reducing iron levels in the blood, which can slow pathogen replication. Although sickness behavior is an unpleasant state for an organism, this pattern of behavior allows for more efficient destruction of pathogens and more speedy recovery. Therefore, sickness behavior represents an evolved strategy designed to limit infection, conserve energy, and promote recovery of the organism.

The primary cytokines that have been implicated in the production of sickness behavior are IL-1α/β and TNF-α. Many other cytokines have been shown to play a role in sickness behavior, but IL-1 has been the most studied due to its discovery as the first endogenous pyrogen. In addition to stimulating fever, IL-1 appears to be primarily involved in producing the reduction in social activities that occur during sickness. However, although individual cytokines appear to serve specific roles in sickness behavior, there is much overlap in their activities, and cytokines have been shown to compensate for each other in triggering certain behaviors. For instance, research has demonstrated that intracerebroventricular injection of an IL-1 receptor antagonist did not alleviate the effects of intraperitoneal (ip) LPS on social behavior. This suggests that other cytokines may have compensated for the absence of IL-1 effects by producing a reduction in social behavior, demonstrating the complex nature of cytokine involvement in triggering sickness behavior following immune system activation.

B. The Immune System as a Sensory Organ

The phenomenon of sickness behavior illustrates that the immune system may be considered as another

sensory organ of the body. Following this definition, the immune system's function is to detect "noncognitive stimuli," such as bacteria, viruses, and tumors, and to alert the CNS of their presence. The immune system has particular receptors (or, in this case, different types of cells) that detect specific stimuli, produce signals that can be understood by the CNS, and transmit messages to the brain. As a result of receiving this specific sensory input, the CNS is able to respond by inducing physiological and psychological changes in behavior designed to combat infection.

C. Evidence for Bidirectionality

Despite the fact that research has only recently begun to focus on the sensory capabilities of the immune system, much evidence has been collected that supports the existence of bidirectional communication. First, the immune system and the CNS make use of the same messenger molecules. There is a commonality in their production of and sensitivity to hormones and neurotransmitters. For example, although traditionally research has examined the impact of stress on levels of cytokines, IL-1 has been found to act directly on the HPA axis resulting in the production of corticotropin-releasing hormone (CRH), adrenocorticotropic hormone, and glucocorticoids. Therefore, although we have principally reviewed studies indicating that stress hormones can impact immunity, it appears that the immune system can also directly affect levels of stress hormones.

For the immune system to communicate directly with the CNS and lead to sickness behavior, neural connections must exist through which peripheral immune activity can signal the brain and inform it of infection. However, the pathway through which this is accomplished is still under debate. Although initially it was thought that cytokines merely traveled through the circulatory system into the brain, they are large hydrophilic proteins that are unlikely to be able to penetrate the blood–brain barrier (BBB). Rather, researchers favor the theory that peripheral cytokines stimulate the vagus nerve, which then sends a neural signal to several brain regions involved in producing symptoms of sickness behavior. Attention has focused on the vagus nerve as the primary pathway through which the immune system could stimulate the CNS because it serves as the main afferent route from the abdominal cavity to the brain and because it innervates tissue that plays an important role in immune activation, such as the liver, thymus, and gastrointestinal tract. Afferent vagal fibers have also been shown to terminate in the nucleus tractus solitarius (NTS), a brain region that is highly activated following peripheral immune system activation.

Further evidence for the role of the vagus nerve in relaying the message of immune activation to the brain has been provided by studies of subdiaphragmatic vagotomy. Animals that have had their vagus nerves severed display reduced sickness behavior symptoms in response to peripheral injections of LPS and IL-1 than do animals with intact vagus nerves. The reduction of sickness behavior following vagotomy has been found in several different animal models (including guinea pig, mouse, and rat), but only in response to peripheral immune activation triggered by ip injections of IL-1β or LPS. Vagotomy has no effect on sickness behavior triggered through central immune activation or from intravenous (iv) injections of immunostimulants. Because severing the vagus has no effect on iv injections of immunostimulants, cytokines must be able to relay the message of immune activation to the CNS through some pathway in addition to the vagus nerve. As mentioned previously, vagotomy decreases but does not eliminate the effects of peripheral immune activation on sickness behaviors. Therefore, investigators have examined possible secondary pathways through which the immune system could signal the brain. Research suggests that this secondary pathway may involve the direct passage of cytokines through areas in which the BBB is modified to allow greater contact with substances in the blood. The organum vasculosum laminae terminalis (OVLT) has been indicated as a possible site for this type of signaling. Future research will continue to investigate these and other pathways through which the immune system may communicate with the CNS to affect behavior.

Additional evidence supporting the role of the vagus as a major pathway between the peripheral immune system and the CNS stems from the fact that the brain regions in which the vagus terminates have been found to play an important role in the various symptoms of sickness behavior. The primary area of termination for the vagus nerve is within the NTS. The NTS and the area postrema are activated in response to ip injections of IL-1 and appear to be very sensitive to low levels of this cytokine. Areas within the NTS project to the paraventricular nucleus of the hypothalamus, which controls production and secretion of CRH, one of the hormones found to be produced in response to immune activation. The hypothalamus has been found to play a major role in the production of symptoms such as anorexia and fever. In terms of the specific symptom of reduced consumption, it has been demonstrated that IL-1β suppresses the neural activity of glucose-sensitive neurons in the lateral hypothalamus

and induces excitation in the ventromedial nucleus of the hypothalamus. These areas have been studied extensively in terms of the role that they play in initiating and terminating eating behavior, respectively. Therefore, the pattern of inhibition and excitation produced by IL-1β induces anorexia and fits the profile of sickness behavior. Fever, on the other hand, is thought to be the result of projections from the NTS to the preoptic area of the hypothalamus, where catecholamines trigger the synthesis and release of prostaglandins that act on temperature-sensitive neurons. As a result, the hypothalamic set point for temperature is raised, triggering the activation of other mechanisms, such as shivering and increasing metabolism, that are designed to defend the new set point. To date, the majority of research has focused only on the brain mechanisms involved in the production of anorexia and fever and has not addressed the other symptoms involved in sickness behavior.

D. Summary

Research has demonstrated that the connection between the CNS and the immune system is not unidirectional, as once thought. Rather, evidence suggests that the immune system is able to directly affect the CNS, perhaps most directly shown through the effects of immune activation on sickness behavior. Upon infection, the immune system sends a neural signal of activation to regions of the brain (particularly the hypothalamus) that govern the production of symptoms such as fever and anorexia. The vagus nerve is the most likely pathway through which peripheral immune system activation is relayed to the brain. However, studies of vagotomized animals suggest that secondary pathways exist through which cytokines can affect behavior. Most research has focused on weaker areas of the BBB, such as the OVLT, as the secondary pathway. Research examining the impact of immune activation on behavior is in its infancy and future studies will undoubtedly provide more information concerning the relationship between immunity and sickness behavior and the health implications of immune-mediated behavior change.

VIII. CONCLUSION

The research reviewed in this article indicates that much progress has been made in the field of behavioral neuroimmunology. However, although we currently have a greatly increased understanding of the bidirectional relationship between the CNS and the immune system, the implications of this association for health and disease have not been fully realized. Although many studies have demonstrated that the experience of stress is related to decreased immune functioning, the resulting health consequences of stress-induced immunosuppression have yet to be determined. Also, research on the effects of immune activation on the CNS and subsequent behavior has not fully examined potential health consequences. Therefore, although findings have begun to change the way we think about health and disease, the applied aspects of behavioral neuroimmunology are merely in their infancy. We are only now beginning to translate the meanings of bidirectional communication into investigations of the onset, progression, and outcomes of disease. Future research will continue to provide basic knowledge concerning the relationships between behavior and immunity, and applications of these findings will further our understanding of the vast and complicated interrelationships of health, immunity, and disease.

Behavioral Pharmacology

PETER B. DEWS
New England Regional Primate Research Center

GLOSSARY

behavior The activities of a reasonably intact subject that affect its environment. "Reasonable" is not a precise specification, but activities of a few cells or even a length of intestine removed from the body would not be considered behavior of a subject. Activities of a subject from whom a length of intestine has been removed would be considered behavior of the subject.

drug A comprehensive term for chemical agents that affect physiological functions of a subject. The term is used most often for effects in animals, especially "higher" animals, including vertebrates, mammals, and humans. Because enough of any agent, even water, can perturb physiological function, it is useful to refer to an agent as a drug only if it has effects at a reasonable dose. ("Reasonable" is not a precise specification, but if more than a few grams per kilogram body weight of an agent is required for an effect it would probably not be called a drug.) Vitamins and other trace elements of the diet cause physiological effects, as do hormones such as epinephrine, insulin, and cortisol. It is simpler to accept them as drugs and to recognize their physiological role than to contrive a definition that excludes them. The term drug should not suggest only substances of abuse such as heroin and cocaine.

operant response (or often just "response") An item of behavior that, when related to a reinforcer, is increased or maintained in frequency in similar circumstances in the future.

receptor Receptors are the special part of a cell that binds a particular drug, with consequences to the function of the cell. Many receptors are molecular patches on the surface of cells. The existence of specialized receptors each selective for a limited class of drugs has been recognized by pharmacologists for more than 100 years, but it is only in the past few decades that the molecular structure of individual receptors has been able to be determined. Now, for increasingly more receptors, not only is their structure becoming known but also it is becoming known how they are changed when molecules of drug bind to them and how these changes initiate a cascade that modifies the function of the cell.

reinforcer An event occurring in relation to an operant response that increases or maintains the frequency of occurrence of the response in similar circumstances in the future.

Behavioral pharmacology is an experimental laboratory science measuring the effects of drugs on specific interchanges of a subject with its environment—that is, the effects of the drugs on aspects of the behavior of the subject. Behavioral pharmacology deals with physical as opposed to subjective phenomena and requires the same standards of evidence for conclusions as the rest of pharmacology. By usage, psychopharmacology has come to mean a largely clinical science, studying the effects of drugs in psychiatry. It seeks to determine the optimum regimes for drugs to maximize clinical benefits and minimize toxicity and side effects. New drugs are evaluated and psychopharmacology helps in the development of new agents and their introduction into clinical use. As with other primarily clinical subjects, including medicine and surgery, extension into experimental laboratory experiments is integral to progress in the subject. Other than anatomy, more has been learned about the human brain from studies in laboratory animals, and certainly more about its workings, than by studies in humans. The following discussion concerns mostly

results from laboratory studies in nonhumans, but the history of validation in humans, where possible, is excellent. Behavioral pharmacology and psychopharmacology are complementary and have a relationship to one another similar to that of other fields of basic pharmacology and their corresponding pharmacotherapies. Well-established principles of behavioral pharmacology will be illustrated by examples in this article; no attempt to be topical will be made.

I. WHAT IS BEHAVIORAL PHARMACOLOGY?

Subjects commonly studied in behavioral pharmacology are people, monkeys, rats, and mice, with rats probably the most studied, but the study of mice is increasing. Larger animals may be required when surgical interventions or electrode implantation in brain are part of the study; otherwise, smaller animals such as mice are easier to house and work with, cheaper, can be studied in larger numbers, and are genetically more homogeneous.

The methods of behavioral pharmacology are numerous and varied. It is usually easy to devise a means of recording objectively a type of behavior of interest, and scores, perhaps hundreds, of methods have been described in the literature. Further, it is the rule rather than the exception for workers in a laboratory to modify published methods to suit their own needs. It is obviously impossible to describe all these methods and variants. Instead, a description of a generic class of methods that have been particularly influential in the development of behavioral pharmacology will be presented. Typically, in such a behavioral pharmacology laboratory, several subjects will be studied each working day, both simultaneously and serially at each of several separate study stations. Each study station has one or more key devices, various means of presenting signals to the subject, and ways of presenting a measured quantity of food or water or other ''reinforcer'' in relation to operations of the key. The key device may be a bar, lever, chain, or string to pull; treadle, switch, or other mechanical device; or even a light beam to a photocell to be interrupted or other nonmechanical detector. They will be referred to generically as ''keys.'' Operation of the key by the subject constitutes a response that generates an electrical signal. In principle, responses could be related to delivery of the reinforcer by mechanical or pneumatic means. Today, almost no one would consider using a nonelectrical system any more than they would consider using smoke signals or semaphore flags to communicate. Examples of signals presented to subjects are colored lights, sounds, and television displays. Occurrences of the signals, recording of the operations of the key, and presentations of the reinforcer are effected by a microcomputer through an interface. The events of the experiment are displayed, tabulated, and stored for later scrutiny, analysis, and summarizing. Sessions for individual subjects may last from a few minutes to many hours, often on a daily basis.

Each subject will work under a consistent program for weeks or months or longer. While a subject is involved in an ongoing experiment, times of feeding, watering, room lights on and off, and other features of the subject's environment during and between the sessions are kept constant. It goes without saying that subjects must be in good health and disposition because a sick or miserable subject must be assumed to have a different behavioral performance and different susceptibility to drug effects. If included, such subjects would bias results; therefore, they are not studied (unless determining the effects on a subject with a particular disease is the object of the study). Repeated sessions allow the range and variability of the control performance, the performance in sessions when no drug or only a drug vehicle such as saline has been given, to be measured with required precision. Effects of drugs are measured as changes from control in the number and pattern in time of responses. Repeated sessions also allow a complete dose–effect curve to be determined in each subject because a series of doses are given over time. The doses are usually given some days apart so the effect of each dose is not influenced by previous doses (not always possible). Cumulative dosing is sometimes employed when incremental amounts of a long-acting drug are given at intervals in a single session. Information on dose–effect relations is an almost universal requirement for interpretable results in pharmacology. Each dose is usually evaluated at least twice. Having dose–effect information on each subject allows both session-to-session variability and subject-to-subject variability to be measured directly. Thus, both sampling errors and systematic and experimental errors are included in the error estimate and not just the theoretical sampling error, which underestimates the actual error, sometimes greatly. At the same time, the shape and position of the dose–effect curve is determined more precisely because the different doses are given to the same subject. Repeated observations on the same subject are quite usual in behavioral pharmacology. Behavioral experiments are generally harmless to the subject.

Repeated use of the same subject is not usual in many fields of pharmacology because measurement of drug effects often requires irreversibly invasive methods (although increasingly more measurements can be made noninvasively or with minimal invasion, e.g., by insertion of a probe).

Much of the previous discussion has to be modified when the subjects are humans. It is rarely possible to make humans work daily for long periods on what are, in the context of human life, usually trivial tasks, so investigators have to be content with much more limited periods of observation than are possible for laboratory animals. Also, it is usually not permissible to give a human subject more than a limited number of drug doses. Further, the environment of human subjects outside the experimental sessions is not able to be controlled as well as the laboratory environment of experimental subjects can be controlled. Therefore, it is more difficult to obtain precise results in humans, but, of course, study them we must. Results obtained in human subjects often require less extrapolation to be applied in the clinic.

The drugs that are studied by behavioral pharmacologists naturally depend on the environment, interests, and purposes of the particular investigators. In academic laboratories, well-established drugs that have been extensively studied pharmacologically and behaviorally continue to be studied in the search for coherent principles of behavioral pharmacology. In recent years, however, more new drugs have been studied that were created to have affinity for particular known receptors or for selected mechanism. Such studies enrich aspects of both neuroscience and behavioral pharmacology. Academic investigators also study new drugs begining clinical use to establish how their behavioral effects fit into the context of what is known about the behavioral pharmacology of previously studied drugs. Finally, there is currently a great effort to understand the behavioral pharmacology of drugs that are important socially because they are abused: cocaine, amphetamines, heroin, and the other street drugs.

In the laboratories of pharmaceutical companies there will usually exist an up-to-date library of the effects of many standard drugs that have been studied in that laboratory in the past to provide reference standards for effects of new chemical entities. New agents that have shown promise in an initial screening procedure are studied further. The behavioral pharmacologist will try to help the discovery team choose the most promising compounds and will provide information about what to expect regarding behavioral effects of the agent if, as all hope, the agent progresses to a clinical trial. As mentioned previously, the behavior that is measured is often simply the pattern in time of objectively recorded responses. It may seem that such a trival sample of behavior—and indeed the key operations are usually deliberately made trivial in terms of effort—is a small basis on which to attempt to understand any significant part of the rich complexity of the behavior of mammals, including humans. It is amazing, however, what a rich variety of behavioral phenomena can be formulated in such a way that they can be illuminated by scrutiny and measurement of patterns in time of responses on keys. In this article, I will only be able to hint at the possibilities. It is well to remember that other sciences have prospered on what seems a trivial sample of their subject matter. All that is known about the universe beyond the solar system is derived from analysis of minute amounts of electromagnetic radiation, and much that is known about subatomic phenomena comes from examination of paths of condensation in bubble chambers and similarly trivial samples. Students of behavior are fortunate in that their subject matter is accessible for experimental probes and repetitions and the information that can be collected is not limited by ineluctable physical constraints, as in astronomy.

II. ORIGINS

The effects of some drugs affecting behavior have been described as far back as there is written record and there are many more agents with an ancient pedigree. Opium, for instance, has been lauded by physicians for millenia. Some have been incorporated into religious rituals (e.g., mescaline for some Amerindians). Until recently, however, knowledge of behavior-affecting drugs was limited to descriptions of what could be seen in people under the influence of the drugs, supplemented by what the subjects told observers. Even when pharmacology developed into a flourishing scientific field, by the end of the 19th century, behavioral pharmacology languished and it was not until the 1950s that behavioral pharmacology became established as a recognized field. Even later, a respected textbook of pharmacology cited Shakespeare on the pharmacology of alcohol. Scientists do not generally cite artistic descriptions as their authority.

As is usual when a new field of science emerges, it is easy to identify prior work that presaged it. For example, the work of Russian Pavlovian physiologists

in the early 20th century was aimed explicitly at developing a science of behavior and extended to studying effects of drugs on behavior. Working primarily on dogs, interesting and influential results were obtained, but the line of work did not lead to a recognized field of pharmacology. The failure was likely due to the rigidity of the framework: All behavior had to be identified as reflexive: unconditioned or conditioned reflexes. That is, behavior consists only of responses to stimuli. Such a view not only is contrary to common experience but also frustrated scientific progress.

Another example is work in Baltimore from 1915 onwards. The vision was clear. A pharmacologist wrote: "The effect of drugs on psychological functions has been the subject of remarkably little investigation on the part of either psychologists or pharmacologists ··· so that the field of 'psychopharmacology' is virgin soil, full of opportunities." Studies on movement capabilities of rats led to methods that were applied to pharmacology. Rats climbed a rope to reach a platform with food and the effects of the drugs on climbing time were measured. Although, again, the field of behavioral pharmacology did not develop in the short run, it is interesting to trace the subsequent history of the methods. After being largely ignored for a couple of decades, they were revived by their originator (and modified, of course) in the 1940s and then applied by scientists at a drug company United States. They were then adapted (and modified) by scientists at a drug company in France. There, they helped in the discovery of the drug chlorpromazine, which in turn was important in the rapid development of behavioral pharmacology in the 1950s.

In retrospect, a paper published by B.F. Skinner and colleague in the psychological literature in 1937 presaged much of the behavioral pharmacology of the 1950s. It passed unnoticed by pharmacologists.

Why was behavioral pharmacology late to develop? Automatic programming was used extensively in behavioral pharmacology from the first. Automatic programming had been in use in industry since at least the 1920s and had been applied to behavioral research in the 1930s, so what eventually started in the 1950s could have started in the 1930s. However, it seemed self-evident to researchers interested in the behavioral effects of drugs that the drugs must affect primarily the "higher" functions of the brain, especially functions that came to be loosely called "cognitive." Learning, in particular, was assumed to be a frequent target of drugs. Higher functions were vaguely associated with higher organisms, particularly humans. (Paradoxically, what we know about learning as a biological phenomenon is compatible with learning being a primitive function with a long evolutionary history: It is not a peculiarly human phenomenon.) However, when researchers tried to measure such effects on higher functions, results were ambiguous, difficult or impossible to interpret, and did not seem to lead anywhere. Therefore, researchers were discouraged and abandoned the line of work, so the field did not develop. The truth is that it is usually bad to approach a scientific field with some of its basics accepted as self-evident because they are quite likely wrong. For example, it was considered self-evident that the earth was flat and stationary at the center of the universe, but approaching the study of the earth and the universe with this conviction was not hopeful. What may seem to be self-evident about behavioral phenomena may be equally false. It was not until behavioral phenomena were approached without prejudice and respected as the appropriate subject matter to be studied for drug effects on behavior that behavioral pharmacology could begin. Preconceptions had diverted attention from the actual subject matter.

It is not clear why behavioral pharmacology started just when it did. It has been suggested that the quantitative graphic method of displaying behavioral phenomena in real time, the cumulative record—the type of display given by a kymograph and as such familiar to pharmacologists of the time—was seminal. Displays of this kind are compelling and informative and do seem to facilitate the development of a field, since physiology was stimulated by the introduction of the kymograph in the mid-19th century. Such displays had been present in behavioral research for a decade and a half. They doubtless facilitated behavioral pharmacology. Whatever the reasons for behavioral pharmacology starting in earnest when it did, it is clear that the effort was launched before chlorpromazine came on the scene. It is equally clear that the great growth of behavioral pharmacology in the next few years was helped by the impact of the introduction of chlorpromazine and one or two other drugs.

III. EXAMPLES AND DISCUSSION OF BEHAVIORAL PHARMACOLOGY STUDIES

A. Example

A method that contributed to the discovery of chlorpromazine was a descendant of the rat rope

climbing studies. A rat cage had a grid floor. A rope hung from the roof of the cage. A rat was put in the cage. A single ring of a bell was sounded and a few seconds later a small AC current was applied across the grid. The current was sufficient to prompt escape by the rat but not, of course, sufficiently strong to cause any harm. If the rat climbed the rope, it removed itself from the current. After a few experiences the rat began climbing the rope promptly when the bell sounded. The effects of drugs on consistency and speed of climbing were studied.

It was known in the 1940s that clinically available antihistamine drugs caused a side effect of "drowsiness" even though the various drugs belonged to many different chemical classes. Sometime before the end of 1950, a group at a French drug company had the insight to consider that perhaps the drowsiness is indicative of interesting new pharmacology. Therefore, starting with an antihistamine, 3277RP (promethazine) marketed by the company, the group helped guide the synthetic program of chemists in the team toward compounds with potent behavioral effects using, inter alia, the method just described as one of their tests. They selected a compound designated 4560RP, which became chlorpromazine. They found many effects of the drug but in particular the following: In the rope (or pole) climbing test, with increasing dose, the latency from the sound to the rat climbing increased progressively until the rat sometimes remained on the grid until onset of the current, whereupon the rat promptly climbed the rope. As dosage was further increased, the rat increasingly did not climb the rope after the sound but continued to do so at onset of the current. The climbing at onset of the current showed that the lack of climbing during the sound was not due to motor incapacity to climb. A barbiturate at increasing dose caused increased latency, but at dose levels at which the rat failed to climb after the sound, it also failed to climb at onset of current. The investigators thought that the dissociation produced by chlorpromazine was indicative of a new and interesting pharmacology. Indeed they were right.

After an inauspicious beginning, chlorpromazine found its way into psychiatric wards in Paris as Largactil. Within a few years it was in use worldwide (as Thorazine in the United States) and had produced the most profound therapeutic revolution that psychiatry has experienced, certainly since the cessation of the punitive treatment of the insane. Chlorpromazine has beneficial effects in psychoses such as schizophrenia and manic-depressive psychoses that previously had no effective treatment. Chlorpromazine is said to have "antipsychotic" properties. What it does particularly well is quieten agitated, disoriented, difficult to handle psychotics. As a result, the large, custodial psychiatric hospitals run by states and cities became quieter and more manageable places. In a relatively short amount of time, a large fraction of the population of hospitals was able to be discharged for care in the community. The hospitals were consolidated and many closed. There have been problems, of course, because many families and communities lack the knowledge, resources, or willingness to continue the level of care that the ex-hospitalized psychotics still require since chlorpromazine is not curative. Still, anyone who remembers the bleak and dreadful hopelessness of the large public so-called mental hospitals can only regard the problem as an acceptable price to pay for the great emancipation.

Chlorpromazine had a major impact on attitude in psychiatry. Hitherto, the mission of psychiatry was to help patients cope with their disorders and be more comfortable. Chlorpromazine came without warning and showed that it was possible to help psychotics with drugs not just by "sedating" them but by moving them toward normality. The question now asked was, if chlorpromazine can do this, for what other beneficial effects can agents be discovered? An optimism about future therapies permeated psychiatry, even though a minority of psychiatrists, most with doctrinaire affiliations with old "schools," resented the advent of pharmacotherapies and regarded help from drugs as failure to persist with persuasion. Because a chemical agent could be antipsychotic, there was new faith that biological bases of psychoses could be discovered and there was increased research activity and funding. The drug companies were galvanized into developing new research and development programs, and many new phenothiazine and other chemical classes of antipsychotic agents were introduced.

B. Methods of Wider Applicability

Operant behavior is defined in *Webster's New Collegiate Dictionary* (1974) as "behavior or responses (as bar pressing by a rat to obtain food) that operate on the environment to produce rewarding and reinforcing effects." Most people have some familiarity with the basic situation but not with its ramifications. It is the type of behavior described in Section I as commonly used in behavioral pharmacology.

In the present context, the word "response" is not used in its dictionary sense but to mean an operant response. According to common usage, a response is a reactionary behavior "to" something. An operant response, however, is simply an elementary unit of behavior that (i) has a selected detectable effect on the environment (e.g., operation of a key) and (ii) can have its frequency of occurrence in similar circumstances in the future increased or maintained by an event called a reinforcer. A reinforcer is recognized because when it occurs in relation to an operant response the frequency of occurrence of the response in similar circumstances is first increased. Then, with repetition of a consistent relationship between responding and reinforcer, a consistent pattern of rates of responding develops and is maintained. Because rates of responding are commonly the focus of interest, a response usually calls for only brief operation of the key, but this is not necessarily so. For example, a response requirement could call for a minimum force to be exerted for many minutes or longer. Obviously, the definitions of operant response and reinforcer are circular, like the definitions of mass and force in Newtonian physics. This means that they have to be dealt with together. The implication in *Webster's* definition that a reinforcer must be rewarding is now known not to be true. There are reinforcers that no one would consider rewarding but that will maintain responding, as will be described later.

Of great importance was the discovery that responding can be maintained with only rare occurrences of the reinforcer, for example, after the elapse of hours with hundreds or even thousands of responses between occurrences. Indeed, the ability to maintain certain types of behavior over long periods depends critically on infrequent occurrences of reinforcers. For many reinforcers, e.g., food or water, frequent presentations lead to temporary loss of efficacy as reinforcers. The program that specifies when the reinforcer will occur is called the schedule of reinforcement. Two basic requirements that can be imposed by schedules are numbers of responses and elapsed time. In its simplest form, the former could specify that the reinforcer would occur when some number of responses has been made since a starting event, usually the last occurrence of the reinforcer (e.g., 30, 100, 300 responses—so-called FR schedules). In the second type, the reinforcer occurs in relation to a response when a certain amount of time has elapsed (e.g., 100, 1000, or 10,000 sec—so-called FI schedules). Under a FI 1000-sec schedule, the reinforcer occurs when a response occurs after the lapse of 1000 sec since the start of timing of the interval. Schedules can have both number and time requirements (e.g., 10 responses with at least 10-sec elapsed time between responses) and sequential requirements. More than one schedule can be programmed in a session either with unique signals (usually lights or tones) paired with each schedule or with no distinctive signals associated with each schedule. More than one schedule can operate simultaneously. It is evident that by combining number and time and sequences and adding second and third keys, adding concurrent schedules and so on, an almost limitless variety of schedules can be devised; in fact, a great many have been studied. Typically, a subject is first exposed to an easy, undemanding preliminary schedule such as the reinforcer occurring immediately when a response occurs. Then parameters are changed incrementally toward the desired schedule parameters. The final schedule is then presented consistently until a similar performance is seen session after session. How long it takes to reach steady state depends on many factors, one being, not surprisingly, the complexity of the schedule. With standard, relatively simple schedules and signals, steady state may be reached in 10–30 sessions and pharmacological interventions can start. The computer programming the schedule can also perform analyses in real time that can be used to modulate schedule parameters within single sessions. The long and detailed description of schedules of intermittent reinforcement has been given because studies on such schedule-controlled patterns of responding have been prominent, even dominant, in the development of behavioral pharmacology. The following example is from work published in the mid-1950s.

C. Example

Steady-state performance of a subject under a schedule was developed and is shown in Fig. 1. The schedule was mult FR30 FI300s, which is technical shorthand for the following schedule: A stimulus, A, starts: When the subject has made 30 responses, a reinforcer is presented (FR30). Then, a stimulus starts again. If it is A, then FR30 is in effect again. If, however, it is a different stimulus, B, then the first response after 300 sec has elapsed leads to the reinforcer. FR and FI components continue in an irregular sequence (Fig. 1), with each component accompanied by its distinctive stimulus. In Fig. 1, each of the four upward-sloping continuous lines shows a complete session. The sessions are spaced some days apart. The record is

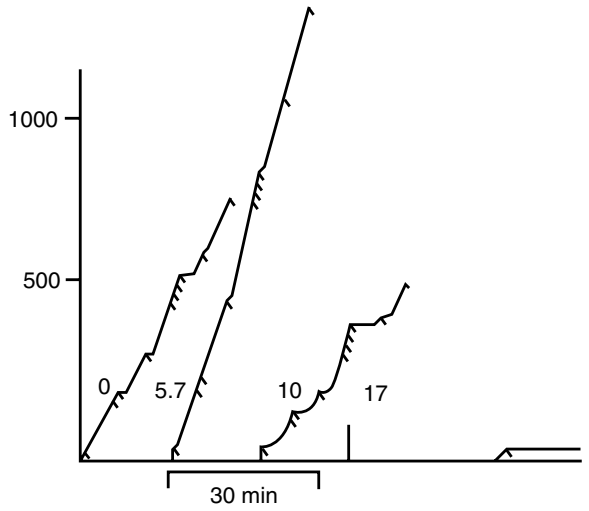

Figure 1 Effects of three different doses of phenobarbital in the same subject. Ordinate is cumulative number of responses in session. For description see text (reproduced with permission from *Annals of the New York Academy of Sciences* **65,** p. 272, Fig. 5, 1956).

made by an ink pen on paper moving from left to right. Each response moves the pen one step up the paper. Results today are not obtained, of course, by measuring a record with a ruler, any more than astronomers hand measure star positions on a photograph. The computer presents results as desired. But graphic displays are still useful in communicating information, and some workers still find the cumulative record a useful real-time monitor.

The leftmost line in Fig. 1 shows the control performance. The remaining three records show the performance of the same subject after doses of 5.7, 10, and 17 mg of phenobarbital, from left to right. (Phenobarbital was widely prescribed in low doses during the first half of the 20th century for its calming effect).

The subject was a pigeon, a frequently studied subject at the time, on a restricted diet; during the session, operation of a key led intermittently to brief food deliveries, the reinforcer. Each session comprised five FR30 segments and five FI 300s segments, each concluded by food delivery. The two distinctive stimuli were visual, different colored lights, consistently accompanying the FR components and the FI components. The sequence of components was the same in all sessions: FR30, FI300 sec, FR30, FI300 sec, FI300 sec, FR30, FR30, FR30, FI300 sec, and FI300 sec. The sessions thus lasted about 30 min. In the first record, labeled "O" (a control session), the FR components appear as two horizontally (i.e., timewise) closely spaced hatch marks with a high constant rate of responding (steep slope). The FI components, in contrast, show low or absent responding at the beginning of the interval, followed by a period of acceleration (short here) to a rate less than that under FR that is then sustained until the interval ends and the reinforcer ensues.

The effects of phenobarbital are major and obvious. Following 5.7 mg, the total number of responses in the session increased to about 1500 (averaging more than 1 per second) compared to about 750 in the control session. Responding under FR is not visibly changed, although the rate is actually somewhat increased. The initial pause in the intervals is markedly attenuated by the phenobarbital so that responding approaches a constant rate through the interval. It should be noted that the 5.7-mg dose is already higher than the usual daily dosage that was given to ambulant patients: The effects, however, are also greater than were sought therapeutically.

Following 10 mg of phenobarbital, FR responding is still not visibly affected, but responding under FI is reduced and almost abolished in the fourth interval. Following 17 mg, responding under FI is abolished, but one FR is completed, albeit at an abnormally low rate of responding.

D. Discussion

A general lesson illustrated by this simple series of experiments is that the effect of a given dose of a drug in a given subject in a single session can be strongly modified by the pattern of responding engendered by the schedule in effect. Specifically, in this example, after an appropriate dose of phenobarbital the rate of responding under FR was slightly increased, while rate of responding under FI was decreased. Responding in a FR component persisted following a dose that abolished responding under FI. As noted, researchers have often approached behavioral research with preconceptions as to what influences on behavior are important (e.g., motivations, emotions, phenomena of learning, and "cognition"). The preconceptions extended to the study of drugs and much ingenuity and effort have been expended in seeking experimental situations that had plausibility as reflecting the influence of interest. For example, if a drug has a different effect on responding in the presence and absence of an influence (e.g., the influence of a putative "emotion" such as "fear"), there was a tendency to immediately attribute the effect to an attenuation (or enhancement) of the influence (e.g., attenuation of fear). The

conclusion was not warranted. It relied on two assumptions: That the change in rate of responding was the effect of fear and that the change due to the drug was due to a selective effect on fear. Either or both assumptions may be incorrect. In any case, it is a basic finding of behavioral pharmacology, illustrated already, that different rates of responding can be differently affected by a dose of drug. If the putative effect of fear was to slow the rate of responding and the drug increased the slowed rate of responding more than the rate in the absence of fear, the parsimonious explanation is that the difference in the rates of responding produces the difference in the effects of the drug. It is not surprising that different rates of responding should be differently affected by a dose of drug. It is commonplace in pharmacology for the effect of drug to be influenced by the physiological state of the system that is affected by the drug. The effect of epinephrine on the smooth muscle of the gastrointestinal tract is to cause relaxation if the tone is already high but contraction if the tone is low. The relationship between effect on drug and the control rate of responding has been extensively investigated. It is surprising, however, that there are many instances in which the effect of the drug, expressed as a ratio to control, is related to the control rate by a simple relationship: Namely, the log of the effect is a descending linear function of the log of the control rate. High control rates may be lowered by a dose of a drug, whereas low control rates are increased. The slopes and intercepts of the relationship vary widely with different drugs and different doses, and the direction of the slope can even be reversed as in the example of phenobarbital.

IV. REINFORCERS

The ability of an event to function as a reinforcer is not an inherent, constant quality of particular stimuli. The ability to function as a reinforcer depends on circumstances. For example, food delivery does not ordinarily function as a reinforcer in a sated subject. Similarly, the ability of fluids, heat, light, sex, and so on to function as reinforcers is dependent on circumstances.

Behavior may also be maintained by schedules that program that responses will postpone, avoid, or turn off a stimulus. The ability of a stimulus to function in this capacity parallels the ability of the reinforcer discussed previously in depending on circumstances. Such stimuli are commonly called aversive stimuli and there are many. Some stimuli can suppress responding, depending on circumstances. A puff of air in the face of a squirrel monkey following a response may suppress responding for food. The same stimulus may (but may not) maintain responding that avoids and suppresses responding that produces it in similar circumstances. None of these findings with so-called positive reinforcers or aversive stimuli that have been described so far are counterintuitive.

In the early days of behavioral pharmacology there was some expectation that the effects of drugs would be different on behavior maintained by positive reinforcement such as food or fluid from that maintained by aversive stimuli. There are instances in which similar behaviors are clearly differently affected by a particular dose of a drug depending on the nature of the reinforcer. In general, however, similar behaviors have been found to be similarly affected, without regard to the maintaining stimuli, which is interesting and somewhat surprising. Amphetamine, for example, may increase response rate both under schedules that program food delivery and under schedules that program termination of lights associated with the occurrence of an aversive stimulus. What is more surprising, however, is that the clear distinction between positive reinforcers and aversive stimuli has broken down. It has been emphasized that the ability of an event to function as a positive reinforcer or as an aversive stimulus depends on circumstances: history, experience, deprivation, ambient influences, and so on. It also depends on the schedule under which the reinforcer is delivered. The same is true of aversive-type stimuli: Their ability to maintain or suppress responding also depends on circumstances and the schedule under which they are delivered. The dependence is not only quantitative but also qualitative.

Monkeys will continue responding when the reinforcer is the delivery of nicotine under, for example, the FI300-sec schedule. Monkeys will also respond to postpone injections of nicotine that would otherwise have occurred. The rate of responding of squirrel monkeys working under FR30 for food was greatly suppressed when the first response in the FR delivered nicotine. The first of these results shows that an injection of nicotine can function as a positive reinforcer, but the second and third show the injection of nicotine to have aversive-type actions. Subjects can be trained to respond regularly to postpone a brief current that would otherwise recur regularly. After the experience of pressing a lever to avoid current, squirrel monkeys were exposed to the following schedule: A

light appeared and remained on for 10 min. The monkey continued to respond, although as for FI 10 min for food, there were no programmed consequences to responses during this time. At the end of 10 min a response produced the same brief current that the subject had previously avoided by responding. The light thereupon went out for 30 sec and then the cycle repeated. The pattern of responding during the 10-min interval came to be similar to that shown in Fig. 1 of the subject responding for food. The aversive-type stimulus was thus functioning as a positive reinforcer. The phenomenon has been independently confirmed in another species and with other types of aversive-type stimuli as well as with drugs such as nicotine.

Thus, an identical physical event, depending on circumstances and schedule, may maintain responding that avoids or postpones the event, may maintain responding that produces the event, or the event may suppress responding maintained by another reinforcer. The schedule and training are the prime determinants of how an aversive-type stimulus will function, and the devil is in the details.

Two caveats are required. First, the phenomena of transmutation of reinforcing function is not a unique peculiarity of application of a particular stimulus. Therefore, seemingly irrational behavior may be maintained by events that would seem to have aversive properties and would not intuitively be expected to be positive reinforcers. When faced with seemingly irrational or self-destructive behavior, this possibility must be considered. The second caveat, however, is that it must not be assumed that any positive reinforcer can be transmuted into an aversive-type stimulus and vice versa according to a standard formula. At the least, the schedule parameters, the environment, and the course of training and experience will be different from agency to agency for it to function, on the one hand, as a positive reinforcer and, on the other hand, as an aversive-type event. At the most, it may simply be impossible to devise means to transmute the reinforcing or aversive function of some stimuli. Insufficient systematic results have been published for it to be possible to delineate what could or could not be accomplished.

V. BEHAVIORAL PHARMACOLOGY OF DRUG ABUSE

Behavioral pharmacology is one of the fields (along with neuroscience, neurochemistry, sociology, psychiatry, epidemiology, etc.) that are pursued in the hope of greater understanding of the phenomena of abuse of drugs. The present discussion will attempt to relate behavioral pharmacological matters to phenomena of drug abuse in society.

It seems self-evident that in the abuse of drugs, such as intravenous injection of heroin or sniffing of cocaine base, the drug represents the reinforcer that maintains the behavior of obtaining the drug. Nevertheless, it was not until it was arranged in the laboratory for an injection of certain drugs to occur occasionally on a response, according to an appropriate schedule, that it was established scientifically that some drugs could function as reinforcers. Responding can be maintained much as with similar presentation of food, fluid, etc. These drugs include most of those that are abused on the streets—notably heroin, cocaine, and amphetamines—but not most of the drugs that are not abused. So-called self-administration has proved to be a useful technique for studying many phenomena relevant to drug abuse, notably circumstances and other drugs that modulate the intake of the drug being self-administered. Combined with "drug discrimination," the study of self-administration can provide laboratory information to help predict abuse liability of agents early in development of a new drug. The following is an example of a drug discrimination situation. A subject responds on two levers. When under the influence of a particular dose of a drug, food is delivered on a schedule of reinforcement of responding on one of the levers, whereas responding on the other lever is without programmed consequences. After saline injection, the consequences of responding on the two levers are reversed: Responses on the second lever are reinforced on the schedule, whereas responses on the first lever are without programmed consequences. A subject may be trained so that while under the influence of the drug almost all responding is on the first lever, whereas when not under the influence of the drug almost all responding is on the second lever. Specifically, a subject can be trained to respond on the first lever when under the influence of heroin. If a new drug in development leads to robust self-administration and to a trained subject under its influence responding on the heroin lever rather than the saline lever, such findings suggest the new agent possesses heroin-like attributes and increase the likelihood that further development of the new agent will be abandoned.

Although self-administration may be an approximate qualitative guide to possible abuse liability, the avidity of self-administration (e.g., the amount of

responding that administration of the agent will maintain and its robustness) is affected by many factors. First, the speed with which the agent can cross the blood–brain barrier and cause its pharmacological effect influences its efficacy as a reinforcer. Generally, rapidity enhances reinforcing effectiveness. Second, agents have pharmacological effects beyond those related to reinforcing effects. For example, on the one hand, cocaine has the ability to increase responding maintained under a variety of schedules of, e.g., food delivery. On the other hand, heroin tends to reduce responding under a variety of schedules and circumstances. Such direct pharmacological effects will inevitably modulate behavior related to self-administration. Such modulations make quantitative comparisons of reinforcing effectiveness difficult, even impossible, without extensive additional investigations. Third, the relative contribution of pharmacological effects to other attributes of abused agents varies widely so that even if the reinforcing effectiveness of the agent were known, it would not generally provide sufficient information to predict abuse liability. This seemingly paradoxical statement can be clarified by examples. For cocaine and heroin, the pharmacology is important for maintenance of their use. In both people and laboratory animals, cocaine or heroin will lead to sustained self-administration with a range of preparations by a variety of routes of administration and under a variety of schedules. Even with heroin and cocaine, however, social context is important in prompting self-administration in a former use; for example, ''hanging out'' with the old gang who are ''doing drugs'' in an environment in which the drug has been taken in the past. There are also reports of people continuing to maintain a habit in a supportive group when the drug they were taking was so diluted as to be essentially without pharmacological effect. With alcohol, the pharmacological aspects are less dominant. The form in which the alcohol comes, the beverage, is more important than is the vehicle for cocaine or heroin. It has been said that a clue as to whether an individual is an alcoholic can be gained by asking ''What do you drink?'' An alcoholic is more likely to name a specific brand than to say whisky or gin. The flavor and bouquet of the beverage are reinforcing, and the appearance of the label and the pouring and mixing are conditioned reinforcers. That is not to say that a Chivas Regal consumer will not drink vodka if nothing else is available, but it will lack some conditioned associations that enhance consumption. With cigarette smoking, the drug nicotine may be even less important in maintaining habitual use. In laboratory animals, self-administration of nicotine could not at first be demonstrated. As the right conditions for maintenance of self-administration were worked out and published, self-administration of nicotine became more reliable across laboratories. It is true that nicotine-free cigarettes do not generally maintain smoking well, but nicotine gum and nicotine patches are easily available but are not appreciably abused. For example, they do not seem to be used by smokers on long nonsmoking flights, when the delay in onset after gum or patch would not be expected to be important. Cigarette smokers generally get little satisfaction from smoking a pipe, although they can readily get as much nicotine from the pipe as from cigarettes. The fragrance and flavor of tobacco smoke and the pleasurable stimulation of the respiratory mucosa in cigarette smoking may be of similar importance to the specific pharmacology of nicotine in maintaining smoking. Cigarette smoking has been dubbed ''nicotine addiction,'' thus associating it with heroin and cocaine, which produce habits that most people have been led to believe are so strong that they cannot be discontinued by the victims' own efforts. Because they have been taught that they are ''addicted'' to nicotine, many cigarette smokers approach the task of discontinuing smoking without confidence that they will be able to do so, which is a good prescription for failure. The role of caffeine in maintaining coffee or tea drinking is even more marginal than nicotine in cigarette smoking. Decaffeinated coffee and tea do maintain their intake, so the fragrance and flavor and fluid intake and, for some, sweetness and ritual are sufficient to maintain consumption.

Drug abuse is not simply a matter of the ability of certain insidious substances to produce a ''euphoria'' so sublime that individuals experiencing it cannot resist the temptation to repeat. Indeed, euphoria was a hypothetical intervening variable whose only postulated properties were to ''explain'' the abuse of the drug. How can the abuse of LSD, MDMA, and other psychedelic intoxicants that produce hallucinations, disorientation, and ''bad trips'' be explained? There may be homology to the laboratory animal with behavior maintained by an aversive-type stimulus. Some habits seem to self-maintain themselves as a quirk of how behavior has evolved to be controlled by historical, contextual, and schedule effects that in most normal circumstances have survival value but can malfunction. The analogy is the immune system, which makes it possible for us to survive in a hostile microbial environment but can produce disease by autoimmune and hypersensitivity reactions.

VI. STATUS OF BEHAVIORAL PHARMACOLOGY

The terms behavioral pharmacology and psychopharmacology both came into common usage in the 1950s. There has never been any doubt about what behavioral pharmacology stood for: rigorous objective assessment of behavioral effects of drugs. Psychopharmacology was more loosely defined at first. In the early days, a session called "psychopharmacology" at a national meeting, such as the Federation of American Societies for Experimental Biology (now Experimental Biology) could have contributions from chemists studying metabolism of catecholamines, behavioral pharmacology studies, and clinical studies. Usage has led to clarification, and as noted psychopharmacology has come to be reserved for primarily clinical science studies.

Early communications in behavioral pharmacology appeared in the *Journal of Pharmacology and Experimental Therapeutics* (JPET) and other pharmacological journals. JPET established specific field editors in 1959 (Vol. 125) to oversee publications in the various fields of pharmacology, one of which was called psychopharmacology. However, it was really behavioral pharmacology, and the name was changed to behavioral pharmacology in 1960 (Vol. 129) and remained until 1998 (Vol. 284), when the system of specific field editors was discontinued. Papers on behavioral pharmacology appear in leading journals of pharmacology throughout the world, including the description of the pharmacology of chlorpromazine in *Archives Internationales de Pharmacodynamie* in 1953. In the early years, there were many behavioral pharmacology papers in the psychological literature, especially in the *Journal of the Experimental Analysis of Behavior*, but fewer behavioral pharmacology publications seem to be following that route today. The Behavioral Pharmacology Society was established in 1957 following a few years of informal meetings, and there is now a European Behavioral Pharmacology Society. In 1999, the American Society for Pharmacology and Experimental Therapeutics established a division for behavioral pharmacology to parallel its division for cardiovascular pharmacology, division for drug metabolism, and several other divisions. In summary, behavioral pharmacology is now a well-recognized scientific discipline with prestigious outlets for its communications.

Psychopharmacology is also well established. Its early development (and also that of behavioral pharmacology) was facilitated by the establishment in 1955 of a Psychopharmacology Service center in the USPH National Institute of Mental Health to foster psychopharmacology (and behavioral pharmacology) and to help collaboration between industry, academic laboratories, and the federal government in developing new agents for psychiatric disorders. It was a manifestation of the wave of optimism for developments in psychiatry that followed the introduction of chlorpromazine. An organization called the Collegium Internationale Neuro-Psychopharmacologicum was founded in 1962 and shortly thereafter established a journal called *Psychopharmacologia* (now *Psychopharmacology*) that has served both behavioral pharmacology and psychopharmacology well. The American College of Neuropsychopharmacology (ACNP) was established in 1961 and started a journal sometime later. The developments in North America followed the pioneering in Europe that gave us chlorpromazine and were paralleled worldwide. ACNP now has approximately 20 sister organizations throughout most of the world. Due partly to the initiatives of such organizations since the 1950s, psychiatric pharmacotherapy, and evaluation of agents both old and new, has changed from being rudimentary in 1950 to as well-developed as any field of pharmacotherapy. It is true that the measuring instruments available in psychiatric pharmacotherapy, mostly scales, inventories, checklists, and the like, are enumerative rather than measurements physically derived in units. However, the care in the design of studies and the means to minimize bias are now of the same standard as prevails in clinical pharmacology of other systems.

Although behavioral pharmacology has been a legitimate science for almost 50 years, it is only in recent decades that it has been able to go beyond concern with behavior and effects of drugs thereon and to establish meaningful relationships with other branches of science. A science is enriched and empowered when it can be related to other scientific disciplines in both reductionist and emergent directions. For example, integrative physiology has been enriched by reductionist analyses. The physiology of Starling's law of the heart, relating the rate of return of blood to the heart to the size and force of the heartbeat, was a legitimate science. However, it becomes much more powerful when the law can be related to the known mechanisms of the molecules that power contraction in the heart cells and how they do it. Physics has been enriched by the feedback from its emergent permeation of astronomy and its reduction to mathematical strings. Attempts of behavioral pharmacology to relate to the effects of drugs on the central nervous system initially had limited success. Not so many years

ago people attempted to relate particular behavioral effects of a drug to the effects of the drug on a particular anatomical part of the brain, e.g., certain drugs that produce behavioral alerting effects were said to be (cerebral) "cortical stimulants." However, neuropharmacologists have not confirmed that their effects are confined to or even predominantly exerted through a discrete gross anatomical part of the brain.

Drugs are chemicals: There is no reason to expect them to respect the gross anatomical contrivances of evolution. However, the chemical anatomy of the brain is another story. Chemicals must do what they do chemically. Although the idea of neurons communicating by extruding chemicals has been mooted by pharmacologists for 100 years, only recently have methods become widely available to analyze the chemical details of how the neurons of the central nervous system communicate. Not surprisingly, it is exceedingly complex. There are many transmitters and modulators and many more receptors as targets so that although the methods for studying them are powerful, the task has only just begun. The ancient Egyptians knew how to survey, but the survey of the world was not completed for several millennia. A powerful tool has even more recently become widely available. It is now possible to selectively delete all the chemicals consequent on the actions of a particular gene by deleting that gene. This approach, so to speak, is orthogonal to traditional methods and such independent flows of information have been valuable historically in the evolution of sciences. Because the ability to modify genetic makeup is more advanced for mice than for other species, it is likely that mice will increasingly become subjects for behavioral pharmacologists. Thus emergent extensions of behavioral pharmacology are also occurring. Funding agencies support behavioral pharmacology for its contributions to mental health research and the problems of drug abuse. Unsentimental drug companies support behavioral pharmacology for its contributions to understanding psychoses and neuroses and to discovery of remedies for their treatment. The future prospects for behavioral pharmacology are bright indeed.

Bilingualism

JYOTSNA VAID
Texas A&M University

GLOSSARY

aphasia Deficits in language comprehension or production arising usually after left unilateral damage to the brain following stroke, degenerative disease, or trauma.

bilingual An individual who has knowledge of and regularly uses two languages, although the two languages need not be used in the same contexts or known to the same degree.

cerebral lateralization of function The extent to which particular cognitive skills (such as those underlying language) are functionally mediated more by the left or the right cerebral hemisphere.

crossed aphasia The occurrence of aphasic deficits following injury to the right hemisphere in right-handed individuals.

polyglot aphasia The occurrence of aphasic deficits in one or more languages of individuals who knew two or more languages prior to the brain injury.

Bilingualism has been the focus of a rapidly growing body of research in cognitive neuroscience. This overview summarizes conceptual, methodological, and interpretive issues relevant to understanding the literature on "the bilingual brain" that spans more than 100 years, from early case reports of aphasia in bilinguals and polyglots to recent brain imaging studies of patterns of cortical activation in brain-intact bilinguals. An underlying issue in both the clinical and the experimental research has been to determine whether, or in what circumstances, there are distinct intra- and/or interhemispheric neuropsychological correlates of acquiring and using two or more languages. Four potential sources of evidence on this issue are critically reviewed: (i) language recovery patterns in bilingual or polyglot aphasia, (ii) the incidence of crossed aphasia in bilinguals/polyglots vs monolinguals, (iii) the extent of right hemisphere involvement in language functioning in brain-intact bilinguals vs monolinguals, and (iv) findings from brain imaging studies of bilinguals regarding whether neural regions activated when processing each language are spatially overlapping or distinct. Evidence from each source is discussed in terms of how well it provides a test of the question of whether differential brain localization and/or lateralization can be attributed to knowing and using two languages.

I. WHY BILINGUALS?

Viewed globally, far more individuals understand and use two, if not more, languages in their daily life than those who understand and use only a single language. However, psycholinguistic theorizing has, until recently, held monolingualism as the canonical form of language use to be problematized.

A repercussion of this monolingual-as-norm assumption has been that research on bilingualism has either been neglected or marginalized. To the extent

that bilinguals are viewed as being qualitatively different from monolinguals, they are not seen as being relevant to models addressing the monolingual-as-norm. When included in mainstream research, bilinguals are cast as differing only quantitatively from monolinguals, and they are regarded as valuable for cross-linguistic comparisons (addressing how a particular variable is manifest in one language vs another). There is little room in this view for asking how language processing may be affected by exposure to and coordination of two linguistic systems. Indeed, phenomena that would appear to mark bilinguals as distinct from monolinguals, such as their ability to move from one language to another, have been argued to have counterparts in monolingual usage, such as when a speaker shifts from a formal to an informal speech register. The suggestion that bilinguals are basically the sum of two monolinguals and that there is thus no reason to view them as being qualitatively different from monolinguals may have contributed to the underinclusion of bilingualism in psycholinguistic research.

The view that bilinguals are nothing but the sum of two monolinguals has not gone unchallenged, however. One challenge has taken the form of disputing the monolingual-as-norm assumption on numerical grounds, in view of the fact that bilingualism is globally a more prevalent mode of language experience. As a consequence, to be representative, research and theory would need to address the bilingual situation directly; monolinguals, in this view, would be considered a deviant variety of language use. Adoption of this view would shift what is considered to be interesting in monolingual language use to those phenomena that have clear counterparts in bilingual language use.

Another challenge to the monolingual-as-norm position has been one that privileges neither bilinguals nor monolinguals. Rather, it holds that a truly comprehensive understanding of language functioning depends on enlarging the scope of language experience typically studied to include the full spectrum of language acquisition contexts and language use, rather than the arbitrary designation of only one form of use as appropriate or sufficient for study. Such a view encourages inquiry into the influence of such parameters as the structural properties of the language or linguistic subsystem; when the language was acquired (at birth, before the onset of puberty, or later); what level and type of proficiency was achieved in the language; and how the language was learned and used (formally or informally, primarily in a written mode or in naturalistic discourse, etc.); on how language is perceived, processed, or represented. With the exception of language structural variables, most of these parameters have simply not been examined when only monolinguals have been the subject of study, given that monolinguals tend to be relatively uniform regarding when, how well, and in what circumstances they acquire their language. Bilinguals, however, are quite heterogeneous on these dimensions and thus more readily lend themselves for such study. Insights derived by considering bilingual subgroups varying on these dimensions can thus enrich models of language processing and representation.

Considering the full spectrum of language experience may thus be a more judicious approach to the study of language functioning because it encourages a broader range of questions for study. One fundamental question that has been the subject of much debate and research concerns the cognitive repercussions of exposure to two languages. Vygotsky maintained that the ability to express the same thought in different languages enables a child to view his or her language as one particular system among many and to view its phenomena under more general categories; this leads to awareness of the child's linguistic operations. In his pioneering empirical studies of bilingual memory, Wallace E. Lambert similarly concluded that early exposure to two languages enhances metalinguistic awareness and promotes cognitive flexibility. Lambert further suggested that simultaneous versus consecutive exposure to two languages may have differential consequences, with early, simultaneous exposure having more pronounced cognitive enhancement effects. A vast body of psychological research addressing cognitive concomitants of bilingualism in turn led to questions about neural correlates of variations in language experience.

II. WHY THE BILINGUAL BRAIN?

For a long time, the topic of neurological substrates of bilingualism was simply not addressed in the neuropsychological literature, or it was raised only in obscure outlets. As already noted, a comprehensive account of brain–behavior relations can no longer afford to ignore bilingualism, which represents a particularly prevalent and varied form of language experience. The inclusion of bilinguals broadens the scope of research questions, permitting a fuller examination of how language functioning is influenced both by biological parameters (such as the state of brain

maturation at birth versus at puberty, with obvious implications for differences in the processing of languages acquired early versus late in life) and by cultural parameters (such as how a language is taught and in what context it is primarily used).

The earliest empirical research on the bilingual brain took the form of case reports of selective language loss or recovery following aphasia in speakers of two or more languages. This literature on polyglot aphasia, as it was called, sparked many questions and subsequent investigations of brain involvement in the language functioning of brain-injured and brain-intact bilinguals using a diverse array of methods. Questions raised in the context of the polyglot aphasia literature (and subsequently tested using normative samples) include the following: What factors influence which language is recovered following brain injury in polyglots? To what extent is language impairment parallel or differential across languages? Does brain damage impair the ability to translate or code-switch between languages? Does it produce novel forms of language mixing? How are the different regions of the left hemisphere organized for language in bilinguals? What is the role of the right hemisphere in bilingual versus monolingual language functioning? How does the modality in which the language is learned or other factors in the context of language acquisition influence the pattern of brain involvement in language functioning?

Although there are now several hundred clinical reports of aphasia in polyglots and bilinguals and more than 160 experimental studies on cerebral lateralization of language in brain-intact bilinguals, generalizations from this literature are fraught with difficulty. A major source of this difficulty is the fact that although theorizing about the bilingual brain has been shaped by prevailing conceptions about language, bilingualism, and the brain, each of these domains has undergone considerable changes in conceptualization. Thus, some of the earlier hypotheses examined in the bilingual neuropsychological literature are untenable because they rely on assumptions about the brain, language, or bilingualism that have not been supported. Similarly, some evidence acknowledged to be relevant to testing existing hypotheses has turned out to be inadequate, whether in the sense of being insufficient or unsystematic or in the sense of not providing a true test of the hypothesis under study. Moreover, some phenomena that have been interpreted predominantly in bilingual-specific, neuroanatomical terms (e.g., translation or switching) may alternatively be interpreted in terms of more general cognitive attentional phenomena. Finally, it has become apparent that despite the size of the existing neuropsychological literature on bilingualism, many questions remain understudied.

In light of the complexity of the literature, this review uses a combination of a sociohistorical and a methodological approach, in which the aim is to situate the questions in terms of the prevailing zeitgeist and methodologies available at different points in the research enterprise.

III. HISTORICAL CONTEXT

The association between aphasia and damage to a particular region of the left cerebral hemisphere in the vast majority of right-handed individuals (and, to a lesser extent, among left-handers) has, since it was first noted by the neurologist Paul Broca in the late 1800s, generated an explosion of research into neural bases of language organization and functioning. Much of the early research took the form of clinical case reports of aphasia following various kinds of brain injury. Other clinical research, such as that carried out in the 1950s by the Montreal-based neurosurgeon Wilder Penfield, studied patients scheduled to undergo neurosurgery for treatment of severe cases of epilepsy. These patients first underwent cortical electrical stimulation to map sites responsible for language production. Another technique used with these patients, the Wada technique named after its founder, involves injection of sodium amytal into the left or right cerebral artery, which has the effect of rendering the patient temporarily aphasic, but only when the language-dominant hemisphere has been injected. In contrast to these invasive techniques, which are restricted to patient populations, many noninvasive methods emerged in the 1960s that allowed questions about brain organization of language to be addressed in neurologically healthy individuals. Laterality techniques were used to draw inferences about brain functional asymmetry from performance asymmetries in judgments on dichotic listening or tachistoscopic half-field viewing tasks. These behavioral measures have been supplemented in the past two decades by electrophysiological and neurobehavioral measures based on brain imaging technologies that provide snapshots of cortical and subcortical functioning while participants are engaged in some cognitive task.

The vast majority of clinical reports described aphasic deficits in only a single language. However, as early as 1919, the neurologist Bychowski noted that

"it seems quite improbable that the many aphasics whose extensive case histories have been published should have spoken and understood only the one language of the researcher." What was not known until fairly recently is that many cases were indeed being published documenting aphasia in speakers of two or more languages. Although by no means as numerous as reports of aphasia in (ostensibly) monolingual speakers, reports of aphasia in polyglots have appeared as far back as the 1860s. The fact that as many as 70% of the first 250 cases culled from largely European journals appeared in languages other than English (mostly German or French) made this body of research largely inaccessible to a North American audience until recently, when certain investigators, such as Martin Albert, Loraine Obler, and Michel Paradis, began to make this literature more widely known within the United States through comprehensive monographs and anthologies of this research in English translation.

IV. NEUROANATOMICAL HYPOTHESES ABOUT THE BILINGUAL BRAIN

From the early neurological literature one can extract at least eight different neuroanatomical hypotheses of bilingual language organization proposed during the past century, primarily as explanations for the diverse patterns of language recovery observed in clinical populations.

A. Available Space

According to the available space view, brain damage affects multiple language use by limiting the total brain space available for language functions. Thus, the more extensive the damage, the greater the overall aphasic deficit, regardless of the language. There is no claim as to the deficit being greater for a particular language compared to another.

B. Modality Performance

The modality performance view is often attributed to the neurologist Alexander Luria, who argued that the type of language deficit observed will vary as a function of whether each language was acquired and used primarily in a written or a spoken mode and whether the injury involved areas that selectively disrupted visual or auditory functioning, respectively. Thus, languages used primarily for reading and writing should recover better if the damage spared posterior, occipital cortical areas, whereas languages used primarily in speech should experience more disruption following damage to more anterior, temporal areas.

C. Context/Age of Language Acquisition

According to the context of language acquisition view, proposed by Wallace E. Lambert in the late 1950s, bilinguals who acquired their languages consecutively and in separate contexts (coordinate bilinguals) should be more likely to have differential disturbances in their languages than those who acquired the two languages simultaneously and in similar contexts (compound bilinguals). The assumption is that the earlier a second language is acquired, the more likely it is that it will share the neural substrate with the first language. No claim is made about the locus of the neural substrate. A recent study of 50 Catalan–Spanish bilingual aphasics classified as compound or coordinate did not find a different pattern of language recovery in the two groups; however, as Hamers and Blanc suggest, the criteria used to classify subjects in this study were not the same as those used in the original study by Lambert, and other psychosocial differences between the groups could have been operative.

D. Differential Localization

The differential localization view holds that the different languages of the polyglot are localized in spatially distinct regions of the language-dominant left hemisphere. This view was first articulated by R. Scoresby Jackson in 1867, who, anecdotally describing the case of an Englishman who had lost his knowledge of Greek following head injury, asked, "Where was that gentleman's Greek deposited that it could be blotted out by a single stroke whilst his native language and all else remained?" Scoresby Jackson proposed that since the foot of the third frontal convolution harbors one's native language, any successively learned language might be represented in the rest of that convolution.

E. Selective Inhibition

Pitres, who authored the first monograph devoted to polyglot aphasia in 1895, dismissed speculations of

differential neuroanatomical localization of the languages of polyglots. He argued that it was unnecessary to propose the existence of new centers for each new language learned by polyglots. Instead, he proposed a functional account of language recovery in which the apparent selectivity in language loss and recovery following aphasia reflects inhibitory processes rather than actual neurological destruction of language areas.

F. Differential Intrahemispheric Localization of Proficient vs Nonproficient Languages

On the basis of evidence from naming deficits following cortical stimulation of different sites within the language-dominant hemisphere of bilingual epileptic individuals, H. A. Whitaker suggested that a smaller cortical region is needed to subserve automatized functions (and presumably the language in which one is more proficient) than that needed to subserve functions that are more labored.

G. Differential Lateralization

The notion that the right hemisphere might be more involved in bilingual language use was first proposed by an early neurologist, Gorlitzer von Mundy, based on a single case study. In their monograph on the bilingual brain, Albert and Obler argued for the plausibility of this notion after surveying a vast body of neuropsychological and behavioral research on bilingualism. Much recent laterality work with brain-intact bilinguals (reviewed later) has sought to uncover support for greater right hemisphere involvement in bilingual language functioning.

H. Differential Lateralization of Early vs Late Bilinguals

Chernigovskaya, Balonov, and Deglin presented a theoretical framework based on evidence of language recovery patterns in a Turkmen–Russian schizophrenic undergoing shock therapy. In their proposed framework, semantic representations and surface structures in a second language learned later are held to be localized in the left hemisphere, whereas those in a first language and in a second language acquired in childhood are held to be located in the right hemisphere.

The neuroanatomical hypotheses outlined previously are included here largely for their heuristic value. Many remain to be systematically tested.

V. RELEVANT SOURCES OF EVIDENCE

In the remaining sections, actual clinical and experimental evidence bearing on brain organization of language in bilinguals is reviewed and evaluated. The evidence is examined with respect to the notion of whether bilinguals show differential intrahemispheric localization and/or differential interhemispheric organization of language, either in one of their languages relative to the other or in either language relative to monolingual users or other bilingual users.

There exist many potentially informative sources of evidence. For example, there are four studies of cortical electrical stimulation in a total of 11 polyglot patients, five studies representing a total of 9 bilingual epileptic patients who were administered sodium amytal, two studies of electroconvulsive shock therapy administered to a single bilingual psychiatric patient, and one study of the effects of anesthesia on language recovery in a bilingual patient. While clearly relevant to the present discussion, inferences drawn from these largely clinical studies to language organization in brain-intact bilinguals may be problematic given the very likely possibility that early damage to the brain in many of these patients may have led to functional reorganization of language.

We focus instead on four sources of evidence on which there is much more information. Two of these involve clinical populations and two involve normative samples. The sources to be reviewed include (i) clinical reports of language recovery patterns in polyglot aphasia, (ii) studies of the incidence of crossed aphasia in bilinguals versus monolinguals, (iii) studies of cerebral lateralization of language in brain-intact bilinguals, and (iv) studies of functional neuroimaging in brain-intact bilinguals. For each source, criteria that ideal studies of each type would need to meet to provide a better test of the question are outlined. The extent to which each of these four sources provides an adequate test of the question of differential intra- and/or interhemispheric involvement of language in bilinguals is then addressed.

VI. LANGUAGE RECOVERY FROM APHASIA

The polyglot aphasia literature, consisting in large part of case reports (approximately 400), documents a rich

variety of patterns of language impairment and recovery following unilateral brain injury due to a stroke, tumor, trauma, etc. What is particularly intriguing about many of these reports is that aphasic patients who spoke two or more languages fluently before injury do not necessarily recover their languages at the same rate or to the same degree.

A. Patterns of Recovery Observed in Polyglot Aphasia

Paradis documented six basic patterns of recovery in bilingual or polyglot aphasia: parallel (when both or all languages are similarly impaired and restored at the same rate), differential (when the languages are impaired to a different degree relative to their premorbid proficency), successive (when one language recovers only after another has been maximally restored), antagonistic (when one language regresses as the other improves), selective (when one or more languages do not recover), and blended (when elements of the various languages are mixed or blended inappropriately). These patterns are not mutually exclusive either over time or between languages. Three additional patterns have recently been observed: alternate antagonism (a variant of antagonistic recovery, in which patients alternate in having access to only one of their languages), differential aphasia (where patients present with different types of aphasia in their different languages), and selective aphasia (where there are clear impairments in one language without any measurable deficit in the others).

The existence of these different patterns allows one to infer possible functional models of language organization or functioning in bilinguals. Paradis argues, for example, that cases of parallel recovery indicate that the language faculty as a whole can be affected and thus that it forms a neurofunctional macrosystem. In differential, selective, successive, and antagonistic recovery, one language is clearly selectively impaired, allowing one to presume that each language constitutes a subsystem of the larger language macrosystem.

B. Factors Accounting for Nonparallel Language Recovery

Many factors related to the patients' premorbid language use have been proposed to explain the particular patterns of recovery observed in individual cases. These include familiarity or proficiency (Pitres' rule); primacy (the so-called rule of Ribot); context of use, whereby the language used in the patient's recovery environment was thought to be more likely to return; and affective factors, whereby the language associated with more pleasant experiences in the patient's life was thought to recover better. These factors provide plausible accounts for many observed patterns even though no one principle accounts for the majority of the patterns observed.

The existence of nonparallel recovery in polyglot aphasics, particularly selective or differential aphasia, has also been interpreted to mean that each language is located in a different part of the cortex, whether in the left hemisphere per se or also in the right hemisphere. However, an alternative account first proposed by Pitres is also plausible, according to which each language could be independently inhibited rather than differentially localized. Indeed, antagonistic recovery, and alternating antagonism in particular, cannot easily be explained in terms of differential localization. Pitres' account is particularly pertinent in explaining such cases of temporary inaccessibility. Data from patterns of recovery from polyglot aphasia, in their present form, are equally compatible with a differential localization account as with a functional inhibition account of nonparallel recovery.

C. Limitations of Applicability of Existing Aphasia Evidence

Many limitations of the aphasia literature weaken attempts to argue in favor of differential localization of language in polyglots. First, the accounts of polyglot aphasia are highly varied in level of detail provided both about the nature of the neurological damage and about the language deficits. Indeed, many of the early reports were anecdotal or second-hand accounts. Second, only scattered information is available on the extent of patients' premorbid skills and usage in each of their languages. Third, because of the overrepresentation of single, selected cases in this literature, one does not have an accurate estimate of the relative incidence of the different patterns. The few studies of unselected cases seem to indicate that parallel recovery is the norm. The absence of accurate and meaningful estimates of the probabilities of occurrence of the different patterns of recovery, and their correlation with factors in the bilinguals' language acquisition use prior to insult, makes attempts

to test the various models of brain organization proposed conjectural at best.

During the past two decades, more systematic assessment instruments such as Paradis' Bilingual Aphasia Test, have been developed. The BAT is now available in over 60 languages and 150 specific language pairs. It is hoped that wider use of these instruments will result in more systematic and thorough assessment of unselected cases of aphasia in bilinguals and polyglots.

D. Criteria for Further Evidence Based on Language Recovery from Aphasia

A more direct test of neurological interpretations of differential language recovery patterns in polyglot aphasia would require a more detailed and systematic mapping of aphasic deficits in each of the patients' languages following damage to specific regions of the left hemisphere. One would want to search for consistent patterns of deficits or recovery associated with specific neurological parameters (e.g., the location, size, and etiology of the damage). This approach would require access to comparative data from a large body of unselected cases, diagnosed using a comparable test instrument, with detailed premorbid language use information preserved.

VII. INCIDENCE OF CROSSED APHASIA

Although the predominant focus of investigations of polyglot aphasia has been to document and seek to explain the patterns of language recovery and loss, one aspect of this literature is thought to be particularly relevant to the question of whether there is greater right hemisphere (RH) participation (premorbidly) in bilinguals. Before discussing this evidence, it is instructive to consider what is meant by greater participation in language.

A. Role of the Right Hemisphere in Language Functioning

1. Redundant Role

It is generally acknowledged that the left hemisphere (LH) is the dominant hemisphere for language. Thus, when one talks about greater RH participation in language in bilinguals, it is important to specify what exactly one is hypothesizing because there are at least two senses in which the RH could be said to be more involved in language in bilinguals. The RH could serve as a redundant, additional processor of language available for bilinguals but the LH might still be the predominant hemisphere for language, even in bilinguals. In this view, damage to the RH should not be expected to have differential consequences for bilinguals and monolinguals since the LH would still be intact.

2. Complementary Role

If the RH is instead viewed as being complementary to the LH, mediating functions essential to language processing but that constitute affective and/or pragmatic (rather than phonological or syntactic aspects of language, which may be subserved by the LH), then one would expect that right-sided damage could indeed result in certain kinds of linguistic deficits (i.e., those involving pragmatic or affective components). To the extent that bilinguals rely more than monolinguals on these components in language processing, one would expect bilinguals to be more disrupted than monolinguals by right-sided damage. In this view, it would make sense to compare the relative incidence of aphasia following lesions to the RH in bilinguals and monolinguals. Most research has tended to adopt this latter position in searching for a differential incidence of crossed aphasia in bilinguals and monolinguals.

B. Early Studies of Crossed Aphasia in Polyglots

Crossed aphasia, or aphasia following right-sided lesions in right-handed individuals, is estimated to be very rare, ranging from 2 to 4% of the general population. Three initial studies sought to compare the low estimate of crossed aphasia in monolinguals with that in polyglots, drawing on cases of aphasia in polyglots reported in the published literature in which information about handedness and side of lesion could be extracted. The samples studied ranged in size from 15 to 102. All three studies indicated an incidence of crossed aphasia in right-handed polyglots of 12–15%, nearly three times the estimate for monolinguals.

1. Problems with Early Studies

a. Sampling Bias However provocative the percentages of a higher incidence of crossed aphasia in

polyglots, their reliability has been questioned since the samples on which they are based have an overrepresentation of single or selected cases. Given the rarity of crossed aphasia in the general population, reported accounts of crossed aphasia in bilinguals or polyglots may well have been published because they were unusual. Any conclusions derived from statistical tallies of this literature are therefore open to the criticism of a sampling bias.

b. Variation in Neurolinguistic Assessment Another problem that affects estimates of crossed aphasia obtained by tallying cases drawn from the published literature is that different studies may have used different diagnostic criteria to assess aphasia. Given that neurologists since the mid-19th century have regarded the LH as the "language-dominant" hemisphere (the RH being literally called "mute" or silent), it is entirely likely that the assessment of aphasia due to RH damage may have been less than rigorous in the past, with certain language deficits associated with RH lesions going undetected. In the absence of uniform or comprehensive assessment instruments, variations in diagnostic criteria are likely to add noise to any compilations of data from different laboratories.

C. Criteria for Evaluating the Claim of Greater RH Involvement Based on Crossed Aphasia Evidence

In order to have confidence in the accuracy of the estimates of crossed aphasia in bilinguals, one would want the study to meet the following criteria: (i) The sample should consist of a large number of randomly obtained, unselected cases of monolinguals and bilinguals; (ii) testing should be undertaken at a single location, using a comprehensive testing instrument, with the severity and type of deficit noted along with the occurrence of any language-related deficit; and (iii) cases of left- and right-sided lesions in both aphasic and nonaphasic persons should be included. Comparing bilinguals and monolinguals already diagnosed as aphasic does not provide a true test of the actual incidence of aphasia subsequent to right-sided injury in each group.

D. Recent Studies of Crossed Aphasia in Bilinguals

Three studies meet at least the first two of these criteria. The first study, by Nair and Virmani, examined the incidence of aphasia following right- and left-sided lesions in a large group sample of hemiplegics, many of whom were polyglot, presenting at the researchers' clinic. Although a rather high incidence of aphasia following right-sided lesions was noted (12/24 right handers), a separate breakdown of the relative incidence of crossed aphasia in the polyglots versus the monolinguals in their sample was not provided. Two additional studies have since been published that do provide the requisite breakdown by language status. Both report data from large samples of unselected cases of monolingual and polyglot patients seen at the researchers' clinics in south India.

In a study by Chary, a total of 100 consecutive patients presenting with speech disorders at the author's clinic in Madras, India, were examined (excluding patients with known histories of psychiatric disorders). An aphasia assessment battery administered to the patients revealed that 88 were aphasic. Of these, 31 were polyglot and the remainder monolingual. Of critical interest is the relative incidence of aphasia following injury to the right side. Like that noted in the earlier studies drawn from selected cases, the incidence of crossed aphasia noted by Chary was high for the polyglots (13.6%); however, crossed aphasia was found to be nearly as high in the monolinguals (12.9%).

In the other study of crossed aphasia in bilinguals, by Karanth and Rangamani, two samples were described. One consisted of 48 patients (all right-handed) diagnosed with aphasia at the All India Institute of Speech and Hearing in Mysore in 1984 and 1985. Thirty-two were polyglot and 16 were monolinguals. Four of the patients had crossed aphasia: Two were monolinguals (12.5%) and 2 were polyglot (6.3%).

Note that this sample, as well as that reported by Chary, does not meet criterion (iii) noted previously, inasmuch as patients in these samples already presented with speech disorders. Another sample collected by Karanth and Rangamani that does meet all three criteria is therefore of particular interest. In this sample, all cases of patients treated for stroke at the National Institute of Mental Health and Neurosciences in Bangalore, India, in 1984 were examined. There were 205 cases in all. Of these, 9 were omitted because they had thalamic lesions or dementia. Furthermore, only those patients on whom clear records were available of handedness, side of lesion, and the presence or absence of aphasia (with patients with dysarthria constituting the nonaphasic group) were retained. There were 94 such cases. Of these,

information on language background was available only on 78 patients. Sixty-one of these were polyglots (including only 1 left-hander); the remaining 17 were monolingual (all right-handed). The finding of interest was that the incidence of crossed aphasia was 25% (6/24 patients) among the polyglots; in contrast, none of the 7 monolinguals who had right-sided lesions showed crossed aphasia.

Given the extremely low incidence of reported left-handedness in their samples, Karanth and Rangamani suggest that the higher incidence of crossed aphasia noted in Indian samples as a whole may reflect an overrepresentation of forced right handers, given the strong cultural pressure against use of the left hand. However, even acknowledging that the estimate of crossed aphasia could be influenced by handedness classification, the fact that a higher incidence of crossed aphasia was nevertheless found among the polyglots relative to the monolinguals in the Bangalore sample (which included both aphasic and nonaphasic unselected cases) is intriguing. It remains for further research to determine if this effect is replicable. It would also be helpful for future evidence of this type to provide a more detailed account of the severity of the aphasic impairment in each language following RH damage. Finally, it should be noted that the effort to test the hypothesis of greater RH participation in bilinguals solely by considering the incidence of crossed aphasia may serve to exclude cases of bilateral participation in language, consistent with the other view of RH involvement stated earlier.

E. Overall Assessment of the Generalizability of Clinical Data

Although suggestive, clinical data are not ideal when one wants to extrapolate to healthy populations. In some cases, early onset of brain damage could have resulted in functional reorganization of language functions. Second, assessment of language deficits drawn from studies of aphasics and also from studies of epileptics (e.g., cortical stimulation and amytal data) has tended to weight language production more heavily than comprehension, no doubt because production deficits are easier to observe. Third, interpretation of severity of loss of language functions following aphasia is complicated by the fact that patients may compensate for their deficits by drawing on resources from the nondamaged areas. As a result, it becomes difficult to disentangle premorbid from postmorbid mobilization of brain resources (particularly, RH resources). In light of these problems, if one wants to extrapolate to brain organization of language in healthy individuals, it would be best to study them directly.

Approximately three decades ago it became possible to do just that, due to the refinement of techniques in experimental psychology enabling lateralized presentation of sensory input (whether auditory, visual, tactile, or even olfactory). Most of the techniques available to study brain lateralization in healthy individuals have been applied to bilingual populations.

VIII. CEREBRAL HEMISPHERIC FUNCTIONAL ASYMMETRY

In this section, we consider the available evidence on the question of differential cerebral lateralization of language in brain-intact bilinguals.

A. Overview of the Bilingual Laterality Literature

To date, there are more than 160 studies of brain organization of language in neurologically healthy bilinguals. Nearly one-fourth of these are unpublished studies, including 18 theses and/or doctoral dissertations. The studies may be classified as focusing primarily either on language-specific parameters or on language acquisitional parameters. Studies examining language-specific variables seek to establish whether specific attributes of a language (e.g., a tonal language) are associated with distinct patterns of hemispheric processing compared to a language in which that attribute is absent. In studies of this type, the bilingualism of the participants has been secondary to the goal of examining language-specific differences. Studies examining language acquisitional parameters in turn may be subdivided into those simply trying to establish whether bilinguals as a group differ from monolinguals and those in which specific bilingual subgroups are compared with other bilingual subgroups. In the latter case, the questions of interest center around differences in the context of acquisition of the two languages, i.e., in comparisons between early vs late bilinguals, between formal vs informal learners, between beginning vs advanced second language users, etc.

In an attempt to integrate the various hypothesized outcomes, in 1980 Jyotsna Vaid and Fred Genesee proposed a model according to which,

> *right hemisphere involvement will be more likely the later the second language is learned relative to the first, the more informal the exposure to the second language, and possibly, the earlier the stage of language acquisition. Left hemisphere involvement is more likely the earlier the second language is learned relative to the first, the more formal the exposure to the second language, and the more advanced the stage of acquisition.*

In general, the model posited that the more similar the conditions of first and second language acquisition, all other things being equal, the greater the likelihood that bilinguals will show comparable patterns of hemispheric involvement in processing their two languages, whereas the less similar the language acquisitional conditions, the greater the likelihood of dissimilar patterns of hemispheric involvement in each language, with the specific nature of the pattern reflecting a complex interaction of the effects of the acquisitional variables operative.

1. Languages Studied

The vast majority of bilingual lateralization studies used bilinguals who spoke English as one of their languages. Only 15 studies did not include English as either of the languages studied. Four studies tested speakers from differing languages and 3 studies specifically examined trilinguals. Where English was one of the languages spoken, the five most commonly studied languages paired with it were French (22 studies), Spanish (18 studies), Chinese (15), Hebrew (12), and Japanese (8). Other languages studied with English include (in decreasing frequency), American Sign Language, German, Hindi, Navajo, Portuguese, Crow, Italian, Russian, Yiddish, Arabic, Dutch, Hopi, Korean, Malay, Kannada, Tok Pisin, and Vietnamese.

2. Range of Stimuli and Tasks Used

Stimuli and tasks used have ranged widely from consonant vowel syllables to common single words, word pairs, sentences, and text, presented visually or auditorily. Although many early studies simply measured word recall accuracy, other studies have varied the kinds of judgments to be made on the stimuli, including rhyme, synonym, or semantic and syntactic category judgments. Still other studies have examined shadowing, translation and interpretation accuracy, and Stroop interference.

3. Range of Paradigms Used

The two most commonly used methods have been dichotic listening and tachistoscopic viewing; both of these methods were particularly popular during the 1980s. The next two most commonly used procedures have been the dual-task methodology and electrophysiological measures (which include eletroencephalograph studies, magnetocephalographic studies, and event-related brain potential studies).

4. Range of Outcomes

Studies of lateralization in bilinguals have yielded varied and occasionally contradictory findings: Although some have found group and/or language differences in cerebral lateralization among bilinguals in either or both of their languages, others have reported no differences and still others have found differences that reflect task demands rather than subject variables. However, variability of outcomes should not be surprising to those familiar with laterality studies in general since it is not uncommon to find that even subtle variations in method, task, and stimulus parameters can alter patterns of asymmetries. Adding a set of subject variables related to bilingual language acquisition clearly complicates the situation.

By the early 1980s several reviews of the laterality literature appeared, including methodologically oriented analyses. Aside from variation in methodological parameters, the literature has also been fairly diverse in terms of the particular theoretical rationale underlying the studies. Thus, some researchers have consistently included monolingual and bilingual comparison groups in their design, whereas others have focused on cross-language comparisons within a single bilingual group, and still others have compared the performance of one bilingual group with that of another varying in language acquisition context. These differences make the task of comparing studies more difficult.

B. Vaid and Hall Meta-Analysis, 1991

In an attempt to make sense of this complex literature, in 1991 J. Vaid and D. G. Hall undertook a meta-analytic review of all the bilingual laterality studies on

which the relevant data were available and amenable for analysis at that time. These included a total of 59 studies, one-fourth of which were unpublished. Five hypotheses about presumed effects of bilingualism on brain lateralization as articulated in the laterality literature were tested. The analysis examined comparisons by language, group, and hemisphere; each comparison was further coded on such dimensions as paradigm and response measure, age, sex, handedness, and second language acquisition context (in particular, the relative age, stage, and manner of second language acquisition). Two dependent measures were examined in testing whether a given comparison supported or refuted any of the five hypotheses: an overall hemisphere main effect, indicating the direction and extent of difference between the two hemispheres on the task, and a hemisphere by group or hemisphere by language interaction. Effect size estimates used were Pearson product-moment correlations, which indicated the direction in which and the degree to which scores on a laterality task correlated with involvement of a particular hemisphere or a particular combination of hemisphere by language or group.

1. Hypotheses Tested and their Outcomes

a. The Balanced Bilingual Hypothesis The first hypothesis examined was the most general, comparing bilinguals as a group to monolinguals to test whether bilinguality per se (and the presumed cognitive restructuring it entails) has differential neuropsychological repercussions, reflected perhaps in a greater reliance on RH processing in language, relative to that noted in monolinguals.

A total of 17 studies in the corpus included monolingual controls (English users in the majority of cases). Six of these studies used consonant vowel (CV) syllables as stimuli and were thus analyzed separately, leaving 11 studies. The analysis showed that on their first language bilinguals were not significantly different from monolinguals in laterality patterns. In 8 of the studies for which bilinguals tested in their second language only were compared to monolingual users of that language, bilinguals' performance was found to be significantly more RH lateralized. In the separate analysis undertaken on the CV syllables based on 6 additional studies, all involving speakers of Native American languages (typically Navajo–English users) and English-speaking monolinguals, bilinguals were again found to be significantly more RH lateralized.

b. The Second Language Hypothesis According to this hypothesis, bilinguals should be less lateralized in their second language relative to their first language. This hypothesis was examined in 45 comparisons from 39 studies. The results indicated no significant support for greater RH involvement in the second language. However, several variables moderated the size of the effect: The hypothesis was more likely to be supported under conditions in which subjects received a visual task (tachistoscopic presentation) rather than an auditory task (typically, dichotic presentation) and when response latency rather than accuracy was the dependent measure. Another relevant moderating variable was directionality of the second language: Readers of second languages that are read from right to left (e.g., Hebrew) were more likely to show less lateralized outcomes, reflecting a presumed influence of scanning biases.

c. The Stage of L2 Acquisition Hypothesis According to the stage hypothesis, greater RH involvement should occur in the early stages of second language acquisition than in more advanced stages. Twenty-comparisons drawn from 17 studies formed the basis of this analysis. No support was obtained for the notion that LH involvement increases with greater proficiency.

d. The Manner of L2 Acquisition Hypothesis This hypothesis tested the prediction that a second language acquired in a more informal mode would be more likely to engage RH processing mechanisms than a language learned primarily in a formal context. Only six comparisons drawn from five studies addressed this variable. Although no reliable difference was noted, the effect sizes in five of the six comparisons, though small, were in the direction predicted by the hypothesis. It is possible that a larger set of comparisons may have yielded a significant outcome.

e. The Age of L2 Acquisition Hypothesis Deriving from prior psychological research on the effects of language acquisition context on language processing, this hypothesis proposed that RH participation would differ in early versus late proficient bilinguals (the latter classified as having acquired their second language after the age of 10 years, whereas the former were defined as acquiring both languages before the age of 6 years). The nature of the difference was thought to be such that late bilinguals would show greater RH involvement than early bilinguals.

A total of 16 comparisons drawn from 12 studies (a majority involving French–English bilinguals) tested this hypothesis. Although no early/late bilingual difference was obtained on the first language (L1) comparison, for the second language (L2) and the combined L1/L2 comparisons, the two groups were significantly different. Interestingly, the direction of the difference was that early bilinguals were the less lateralized group.

2. Interpretation of the Meta-Analytic Findings

Viewed as a whole, the meta-analytic results present a mixed picture, not unlike the literature as a whole. Although two hypotheses (e.g., the stage hypothesis and the manner hypothesis) received no support at all, two others received qualified support (e.g., the second language hypothesis and the balanced bilingual hypothesis), and one receiving clear support (the age hypothesis) was supported in an unexpected manner.

It must be noted that the number of comparisons available to test these differing hypotheses ranged widely from a low of 6 (in the case of the manner hypothesis) to a high of 45 (in the case of the second language hypothesis). Moreover, there were surprisingly few studies that included monolingual controls in the corpus at large (and at least 5 that could not be included in the meta-analysis owing to the form in which the data were available).

The lack of support for the stage hypothesis need not be taken at face value if one recognizes that the predominant paradigm used to test this hypothesis (in 11/17 cases) was dichotic listening accuracy. This method is the least sensitive for detecting group differences. According to the stage hypothesis, beginning second language learners are thought to be more attuned to semantic and pragmatic aspects of language input, which is why they are thought to rely more on RH processing. A direct test of this idea would require presentation of tasks that test for differential reliance on these different components of language, which a standard dichotic listening procedure (which more readily taps phonetic components) is not suited to do. It could well be the case that the stage hypothesis has not been appropriately operationalized to date.

a. Task Matters Perhaps the most interesting outcome of the meta-analysis is the one that was not anticipated, namely, that early bilinguals were less lateralized compared to late bilinguals. The age hypothesis arose out of empirical observations that early and late bilinguals differ in what aspects of verbal input they process more readily. Early bilinguals were found to be more inclined to process for meaning, whereas late bilinguals were found to be more adept at processing surface characteristics of words. We now know that tasks requiring semantic processing (relative to those requiring phonetic or syntactic processing) show the most bilateral involvement. Hence, it is not surprising that early bilinguals are the less lateralized subgroup.

In general, the meta-analyis suggests that brain lateralization for one or both languages of certain subgroups of bilinguals may indeed differ from that in other subgroups and monolinguals. A close examination of individual studies in which differences were obtained suggests that differences arise when the task can be performed in more than one way and as such may reflect strategy differences. The importance of including appropriate task measures to directly tap into presumed strategy differences thus becomes evident. Many of the early studies represented in the meta-analysis were not designed to tease out the relative components of language processing or to systematically examine task-related processing demands interacting with individual differences in task performance.

C. Evaluating the Functional Asymmetry Evidence

1. The Validity Issue: When Can One Infer Hemispheric Asymmetry?

Performance asymmetries are intended to signal differences between the hemispheres in underlying specialization of function. Unfortunately, there is not always a direct or simple correspondence between behavioral asymmetries and hemispheric asymmetry: Many artifactual, nonhemispheric factors have been shown to affect the size and even the direction of behavioral asymmetries. In their initial enthusiasm with the availability of noninvasive methods to infer hemispheric lateralization, researchers neglected to search for and rule out noncerebrally based explanations, tending to ascribe any observed asymmetry to a neural source or to interpret any lack of behavioral asymmetry in terms of bilateral hemispheric involvement. The danger in this kind of reasoning is magnified when one is additionally claiming group differences in degree of lateralization. A standard criticism of many bilingual laterality studies has been that in the absence of objectively assessed, systematic criteria for subject

selection, such as language and task proficiency, group differences could simply reflect floor or ceiling effects mistakenly attributed to bilateral hemispheric involvement.

2. The Conceptualization Issue: What Aspects of Language Are Lateralized in Each Hemisphere?

It is now known that language is not uniformly subserved by the LH. When applied to bilinguals, the question of differential lateralization of language becomes one of interpreting what a greater RH effect in bilinguals might mean. Does it mean that aspects of language normally subserved in the LH in monolinguals are bilaterally mediated in bilinguals? Or does it mean that in both monolinguals and bilinguals language lateralization is the same; what differs is the relative reliance of the groups on those aspects of language thought to be under RH control. Although the latter view would appear to be more parsimonious, the research to date is still not at a point where these possibilities can be separated and tested. One can try and disentangle these possibilities by designing studies with processing components presumably mediated by one or the other hemisphere to determine if hemispheric differences will differ by task. In some work that attempted to do this, Vaid found that when a task calls for phonetic processing, a LH superiority was found in both languages of bilinguals, whether early or late bilinguals, as well as in monolinguals. Similarly, when the task called for syntactic processing, a LH superiority was again observed in all groups. On semantic tasks, group differences emerged, with monolinguals and late bilinguals showing a LH superiority and early bilinguals showing either no hemisphere differences or a RH superiority in both their languages.

D. Vaid and Hull Meta-Analysis, 2001

Since the 1991 meta-analysis of Vaid and Hall, the literature on behavioral functional asymmetry in bilinguals has more than doubled. Many of the newer studies do not suffer from at least the more obvious methodological limitations that plagued the earlier studies, although it has also become clear that continued use of standard dichotic listening procedures may not be particularly informative. Many recent studies have begun to consider task-related processing differences in interaction with language and group differences. In view of the expanded literature and its greater sensitivity to task-related variables, a new meta-analysis was undertaken by Vaid and Hull in 2001. This meta-analysis focused only on those studies, whether published or unpublished, in which monolinguals were compared with late bilinguals on their first language or with early bilingual speakers.

In all, 28 studies met the above inclusion criteria. Three findings from Vaid and Hull are of particular relevance to the present discussion. First, there were significant effects attributable to paradigm: dichotic-listening was the most strongly left lateralized, whereas the tachistoscopic and dual task methods were both bilateral. Task was also a significant moderator: Tasks involving surface auditory processing were the most left lateralized, whereas those involving global or semantic processing were the least. Second, there was a clear bilingual/monolingual difference: Monolinguals were significantly more left lateralized than bilinguals, who showed no overall asymmetry as a group. Third, early bilinguals were less lateralized than monolinguals or than late, fluent bilinguals. This group difference was more pronounced among men than women. Additional meta-analyses are planned for those laterality studies in which bilinguals were compared with other bilinguals (i.e., in the absence of monolingual comparison groups). For now, the results of Vaid and Hull corroborate Vaid and Hall's 1991 finding of less pronounced functional asymmetry associated with bilinguality, particularly early bilinguality, relative to monolinguality.

What remains is to consider studies that have used neuroimaging techniques to address the question of differential intra- or interhemispheric activation in bilinguals' language processing.

IX. NEUROIMAGING DATA

Our focus here is on studies using positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) techniques to examine patterns of language activation. These techniques are being increasingly extended to bilingual populations and have been the focus of a recent review by Vaid and Hull. Although PET studies provide good temporal resolution, the results from individual participants are usually not available because group averages are typically reported. fMRI studies, in turn, offer better spatial resolution and permit visualization of data of

individual participants. Studies using each methodology with monolinguals have already uncovered strong evidence for greater LH activation in the so-called classic language areas. However, bilateral activation has also been reported more than might have been expected on the basis of the lesion data.

A. An Overview of Bilingual Neuroimaging Studies

Within the past decade, several studies using PET and fMRI techniques to assess patterns of neural activation in healthy bilingual adults have been performed, including 13 studies using PET and 25 using fMRI.

1. Participant Characteristics

Two of the neuroimaging studies tested bilinguals from diverse languages and two tested trilinguals in all three languages. The predominant language pairs studied to date have beeen Chinese–English (over 10 studies), followed by French–English, Spanish–English, and Sign language–English. Other language pairs studied include German–English, Italian–English, Polish–English, Russian–English, Spanish–Catalan, Russian–German, Japanese–English, and Finnish–English. The majority of the studies used bilinguals who had acquired their second language, on average, after the age of 7 years. The proficiency of these bilinguals varied from moderate to high, although the criteria for assessment of proficiency, when stated, also varied.

2. Tasks

The studies differ in the types of tasks employed and in the modality of the input or output. The range of tasks employed included sentence-level comprehension, listening to stories, thinking about the events of the previous day in one language or another, silent word generation including repetition, word stem completion and generating words beginning with a specified letter ture, cued picture naming, translation, rhyme vs synonym generation, and semantic vs nonsemantic judgments. Only two of the studies kept the stimuli constant, with only the task varying. In one of these, subjects were to make abstract/concrete judgments, as an example of a semantic task, or upper-lowercase judgments based on the same stimuli, as an example of a nonsemantic task. The baseline tasks used (necessary to do the analyses, which are based on a subtractive logic) ranged from silent rest periods (during which subjects were asked not to think at all) to silent word repetition tasks and reading tasks.

B. Patterns of Activation across L1 and L2: Distinct or Overlapping?

The question explicitly addressed in the studies to date that have examined bilingual participants has been whether the two languages of bilinguals activate nonoverlapping, spatially distinct brain regions (cortically or subcortically, in the left or right side) or whether the regions of activation overlap.

With respect to this question, three sets of outcomes have been reported: (i) a language-specific effect, as, for example, noted in the studies comparing users of signed versus spoken languages, whereby the two languages of the bilinguals show overlapping LH regions of activation but where only one language (the signed language), whether in hearing or deaf users, shows greater RH activation; (ii) a pattern of consistent and overlapping activation in, but not restricted to, the classic language areas in the LH and (iii) a pattern of greater variability of activation of the two languages in the L2, both cortically and subcortically, in the left and right sides.

The predominant outcome has been a pattern of overlapping activation for both languages of bilinguals in the classic language areas on the left side and in the pattern of bilateral activation in homologous sites. However, exceptions to this pattern have been reported in a few fMRI studies.

1. Patterns of Nonoverlapping Activation in fMRI Studies

One fMRI study, based on five bilinguals who had studied a third language and were tested in all three on a silent word-generation task, reported that the amount of activation in the three language areas studied was greatest in the least proficient language. Another study found that while early bilinguals showed overlapping activation for L1 and L2 in the left inferior frontal gyrus (Brodman's area 44), late bilingual speakers of different languages showed differential activation within this region for their two languages. A third study reported that activation in the left and right frontal and temporal regions was more widespread in the second than in the first

language of French–English late bilinguals of moderate proficiency.

2. Patterns of Nonoverlapping Activation in PET Studies

An interpretation of a unitary cortical representation of the bilinguals' two languages based on findings of no differences between the languages noted in many of the PET studies has been countered by suggestions that the PET studies, since they rely on averaged data, may not be as sensitive in detecting actual differences as fMRI studies, particularly when these may involve adjacent regions. However, even PET studies have occasionally reported some differences across the languages in patterns of activation.

In two PET studies, both with English–French bilinguals, greater left putaminal activation was observed in the participants' second than first language on word-generation tasks; this effect was interpreted to reflect greater articulatory effort in the second language. However, two subsequent PET studies (one with Chinese–English and one German–English speakers) have not replicated this finding, suggesting that other parameters may also be at play. Variation in activation patterns by language in still other regions has also been reported. In one PET study, greater activation was found for the supramarginal gyrus in German–English late bilinguals perceiving words in their second language; the other study reported greater right middle temporal gyrus activation for L1 and greater right hippocampal and superior parietal lobule activation for L2 in Spanish–Catalan early bilinguals.

C. Summary of Outcomes of Imaging Studies

The predominant outcome from these studies is that of a robust pattern of overlapping activation in users of even highly diverse languages such as Chinese and English, particularly among late bilinguals. However, although most studies stress a strong overlap in patterns of neural activation for L1 and L2, slightly more than half document some variability in activation patterns across the two languages. For example, users of sign languages vs spoken languages appear to show differences in interhemispheric activation. Moreover, studies of Catalan vs Spanish, despite being highly similar languages, have nevertheless shown differences (in the RH) even among early bilinguals. Studies of Chinese–English speakers have tended not to show differential activation. In some cases, the overlap in activation has been attributed to carry-over effects from L1 to L2 processing.

D. Interpretation of Imaging Study Outcomes

1. Nonproficient Bilinguals

Although there has been no direct test of the role of proficiency as a determinant of variability in sites activated in the second language relative to the first, many of the studies propose proficiency (rather than age of onset of bilingualism) as a post hoc explanation of the discrepant results noted in the literature. However, only one study, by Perani *et al.* in 1998, actually compared two groups of late bilinguals varying in second language proficiency. In referring to their finding, Perani *et al.* echo the stage hypothesis:

> *A possible interpretation of what brain imaging is telling us is that, in the case of low proficiency individuals, multiple and variable brain regions are recruited to handle as far as possible the dimensions of L2 which are different from L1. As proficiency increases, the highly proficient bilinguals use the same neural machinery to deal with L1 and L2.*

2. Proficient Bilinguals

The predominant observation of overlapping activation in the two languages of bilinguals raises a question of its own. In the words of Perani *et al.*,

> *How do we reconcile the discrepancy we observe between the imaging data (largely similar activations with L1 and L2 in highly proficient individuals, regardless of age of acquisition) with … behavioral findings [of L1–L1 differences even in early bilinguals]? … We wish to raise the possibility that spatially overlapping networks to process L1 and L2 should not immediately be equated with competence, or performance identity.*

So just how are we to interpret these results? The question resists easy answers, for as Perani *et al.* point out,

> *What our results show is that for the happy few late bilinguals that reach high proficiency, the (macroscopic) brain activation is similar to that of native learners of the language. What we do not know, however, is whether the similarity in brain*

activation is the consequence or cause of learning L2 successfully. Further research is needed to clarify this point.

E. Methodological Concerns

For many reasons, the neuroimaging data in their present form do not provide satisfactory or conclusive answers to the question of whether there is differential hemispheric activation in bilinguals and what overlapping patterns of activation might mean. As already noted, the studies have varied widely in their tasks (including overt and covert production vs comprehension tasks, with the unit of language varying from single words to sentences or discourse); however, task parameters have not specifically been addressed in most of the studies. Although proficiency and age of onset of bilingualism have been proposed to explain discrepancies across studies, only two studies specifically compared early versus late proficient bilingual users (controlling for language used), and only one directly compared proficient and nonproficient late bilinguals.

More important, since only 3 of the 38 imaging studies employed monolinguals and only 4 controlled for whether a particular language was the first or the second language, it is not clear to what extent the patterns of activation observed (whether differential or overlapping) simply reflect language-specific effects (e.g., characteristics of the languages' orthographies, phonologies, or grammar). Another problem in interpreting the studies is that task performance was not consistently monitored behaviorally. It is important to do so both to ensure that subjects were complying with instructions and to determine subjects' level of performance on each language. In some cases, where subjects were reported to be slower in performing the task in the second language, their pattern of brain activation showed no difference across languages. In other studies subjects were pretested to be equivalent in their task performance in the two languages and overlapping patterns of brain activation were again observed.

As Paradis cautions, PET and fMRI data may tell us that some cerebral area is activated during the performance of a particular task, but they do not tell us what function is activated in this area, nor is it possible to determine if the areas that are activated in a particular study are crucial or incidental to language. Furthermore, failure to detect activation in a specific area is not evidence that this area is not active—only that it is not revealed by the procedure that is used. The likelihood of observing a change in activation is influenced by both the study design and the image analysis technique employed. That is, areas found to be significantly activated are activated only with reference to the particular task chosen as a baseline (whether this be attentive silence, periods of rest, random noise, word repetition, or backward speech) and with reference to the statistical tools (and cutoff thresholds for significance) and rationale used, regarding what is to be subtracted from what. Indeed, the appropriateness of the practice of using a subtractive logic to study functional activation of language in general has been questioned.

F. Criteria for Evaluating Bilingual Neuroimaging Studies

Given improvements in the availability and use of neuroimaging technologies, one should expect to see many more studies being conducted with a variety of populations, including bilinguals. However, caution should be exercised in interpreting these studies because they are still at a preliminary stage with regard to researchers' sensitivity to possible artifacts. At the very least, the following set of considerations should be applied when designing or evaluating future neural imaging studies of bilinguals.

1. Adequate assessment of the bilinguals on proficiency and other language acquisition and use parameters,
2. Use of a homogenous language sample rather than speakers of various different language pairs
3. Inclusion of early and late bilinguals, with each group subdivided according to degree of L1 and L2 proficiency
4. Inclusion of monolingual comparison groups for each of the languages under study
5. Monitoring of participants' behavioral responses during the scanning to provide additional evidence regarding task performance and to ensure that participants complied with instructions
6. Inclusion of a measure of stimulus complexity (e.g., word frequency or other measures)
7. Inclusion of some task parameters, ideally in such a way that the stimuli are kept constant, leaving only the task to vary (e.g., by varying the instructional demands)
8. Inclusion of more than one baseline measure for purposes of comparison

9. Examination of all sites where either significant increases or decreases in activation were noted, not just sites in the so-called classic language areas
10. Statistical testing for relative activation in left and right hemisphere sites, both cortical and subcortical, to the extent possible
11. Use of converging measures (e.g., testing the same subjects on different paradigms)
12. Use of statistical analyses that search for interaction effects of language or by group by task or site direction
13. Use of hypotheses that are grounded in prior theory and research in bilingualism.

Despite the rapid proliferation of neuroimaging studies using bilingual participants, the image of the bilingual brain that has emerged to date is neither uniform nor easily interpreted.

X. CONCLUSION: WHAT IS RIGHT? WHAT IS LEFT?

After examining four different sources of evidence bearing on the question of differential intra- or interhemispheric organization of language in bilinguals, one is left with an appreciation of the danger of taking findings at face value. In many cases, the evidence has not been "clean" enough to permit a direct test of the question of interest, allowing for alternative explanations of the phenomena observed. In other cases, the patterns observed appear to be influenced by a myriad of variables, including those specific to the population used (i.e., bilinguals), those specific to the methodologies, and interactions between the two. No one method appears to be ideally suited to address the overall question because each frames the question according to its own assumptions. For example, the laterality data ultimately do not permit examination of nonlateralized differences (e.g., cortical vs subcortical influences or interhemispheric cooperation vs competition effects). The crossed aphasia data do not permit examination of bilateral mediation of language in either bilinguals or monolinguals since they focus on patients with unilateral lesions. The neuroimaging data are constrained by the use of a subtractive logic and by inconsistencies in subject selection and comparison.

At a more subtle level, how one chooses to interpret the patterns observed, or even how one chooses to frame particular questions, may reflect ideological differences regarding bilingualism such as those outlined at the outset. An implicit adoption of the prevailing view of bilinguals as being the sum of two monolinguals may in part account for why many of the behavioral functional asymmetry studies and nearly all the functional neuroimaging ones sought to compare lateralization for L1 versus L2, as though the two languages of bilinguals are indeed separable and independent systems (in some cases, this has meant arbitrarily designating the languages as L1 or L2 as when classifying early bilinguals or trilinguals). In contrast, if one takes the view that the process of acquiring and mastering two or more languages alters how language is processed, one might be led to a different sort of comparison (e.g., not between the two languages so much as between bilinguals and monolinguals or between certain bilinguals and other bilinguals on different tasks).

Yet another variable that has influenced the interpretation of the evidence has been ideological orientations regarding language. For some researchers, language continues to be viewed as a stable, monolithic system, with grammar as its defining core, localized in the LH. However, recent evidence from research with monolinguals suggests a more sophisticated, dynamic, and multidimensional view of language as a system that calls on a number of other processes, some of which may be bilaterally mediated and some subserved by the RH. Clearly, advances in our understanding of language will have distinct implications for how one regards questions about how language is processed in bilinguals, both behaviorally and neurobehaviorally. Similarly, advances in our understanding of bilingualism and in our understanding of the brain will alter the way in which questions about language processing will be framed and interpreted in future research.

Despite the number and perhaps because of the sheer diversity of neuropsychological studies with bilinguals now available, generalizations are difficult to formulate. Progress in this field will depend on attention to reliability and validity of the measures used to infer functional asymmetry, more appropriate and converging methodologies for testing the hypotheses advanced, and a more theoretical grounding of the research undertaken. Further studies need to be tuned to current developments in cognitive and linguistic research on bilingualism and on L2 learning as well as to developments in neuroscience. Only through a joint consideration of cognitive and neuropsychological parameters and assiduous design of experiments can one begin to make sense of the complex and often seemingly contradictory evidence brought to bear on

long-standing questions about language and brain organization in bilinguals and monolinguals alike.

Biofeedback

RICHARD GEVIRTZ
CSPP Alliant International University, California

GLOSSARY

autonomic nervous system (ANS) A branch of the peripheral nervous system that controls any vital functions in the body, especially those involved in adaptation to environmental demands.

biofeedback The process of using information from one's own biological signals to regulate a physiological and/or psychological process.

electroencephalogram (EEG) Electrical activity from the brain is summarized on a graphic display that separates frequency components.

electromyogram (EMG) Electrical activity emitted from the nerves enervating muscle displayed as a raw signal or an integrated average (in microvolts).

neurofeedback Brain wave information is shown and used to achieve a change in function.

parasympathetic nervous system (PNS) One of two branches of the autonomic nervous system usually associated with the restoration of steady states or homeostasis.

respiratory sinus arrhythmia (RSA) The fluctuation of heart rate with normal respiration (heat rate increases with inspiration and decreases with expiration).

sympathetic nervous system (SNS) A branch of the autonomic nervous system usually associated with readiness for fight, flight, or a freeze response.

Biofeedback, the process of using one's own biological signals to achieve a change in physiological functioning, has become increasingly popular for disorders that do not respond well to standard medical treatment, for performance enhancement, and as an adjunct to various meditative or relaxation techniques. This article describes the different ways biofeedback is used in current contexts and briefly summarizes the scientific basis for its efficacy.

I. INTRODUCTION

Humans have demonstrated fascination with the connections between mind and body from our earliest records to the present. As conscious and self-conscious creatures, we have always wondered how our emotions, thoughts, or ideas affect our bodily processes. Scientific progress on this topic had been slow, however, until the latter half of the twentieth century because we were unable to measure physiological processes easily and efficiently. At the same time, the psychological side of the equation was not well-conceptualized until modern psychology abandoned spiritualistic models for cognitive and evolutionary biological ones. In the 1950s, scientists working to delineate the mind–body connection created the term psychophysiology to distinguish themselves from physiological psychology or other early neuroscience subspecialties. As the technology and conceptual

development progressed, psychophysiology also prospered. Typically, early psychophysiological studies manipulated social–psychological variables while measuring physical parameters. For example, early leading researchers (the Lacys, Paul Obrist, or Peter Lang) began to interpret heart rate in light of various cognitive–emotional states. In this way, progress has slowly been made in psychophysiology. At the same time, some psychophysiologists and others asked a different question. If the subject could be made aware of their own physiology, could they actually change it? This "mind over body" idea has always had adherents in religious traditions, eastern meditative traditions, and even medicine (physician as healer). At this point there was a scientific paradigm with the potential to elucidate this concept. Early successes in the laboratory led to an emerging clinical cohort who have tried to use biofeedback to correct problems, enhance performance, or modify experience. Biofeedback is the term coined to indicate the influence of information or feedback of various physiological parameters on the regulation of the same. For example, it was demonstrated that, if a person was given a meter of his or her heart rate and asked to slow or speed it, he or she could in fact accomplish this, at least statistically.

By the 1990s, growing public dissatisfaction with traditional western medical paradigms pushed health providers to offer complementary–alternative medicine services, and biofeedback is often included in this category. Greater sophistication in the neurosciences, together with less expensive instrumentation, has also led to a resurgence of interest in EEG biofeedback, often called neurofeedback. The revolutionary idea that a person could modify his or her own brain wave activity and thereby modify arousal, attention, or seizures has tweaked the imagination of the public.

From these various roots, the field of biofeedback or applied psychophysiology has grown to be a health profession with an international following, professional organizations, and a certification process.

II. BIOFEEDBACK DIRECTED AT MODIFICATION OF A SPECIFIC PHYSIOLOGICAL SYSTEM

There is considerable evidence that subjects or patients can regulate some physiological systems. For systems that fall under the regulation of the voluntary or somatosensory nervous system, the models are not all that revolutionary. For example, feedback from striate muscle with an electromyograph can be used to relax or contract muscles that may have slipped from voluntary control. This kind of work has been done in at least three settings.

A. Rehabilitation

Neuromuscular rehabilitation centers have used EMG biofeedback to successfully aid physical therapy and occupational therapy procedures with stroke, spinal cord, head injury, and various neuromuscular disorder patients. Typically, the feedback is used with stimulation and exercises to recruit neuromuscular pathways that are not up to par. It is hard to pin down the components in this protocol. It may improve patient motivation, reopen neural pathways, help regulate motor homeostasis, or all of the above. John Basmajian, in a pioneering work called *Muscles Alive*, has described this work including the demonstration of conditioning a single motor unit. The feedback appears to potentiate an afferent pathway in a way not possible without it. Within this context, physical and occupational therapists use biofeedback in conjunction with physical hands-on training and stretching techniques (see Fig. 1).

B. Pelvic Floor Muscle Feedback for Incontinence and Vulvodynia

A similar application has strong scientific support: the retraining of pelvic floor muscles using a vaginal or anal EMG sensor. Feedback from the pelvic floor muscles can help the physical therapist and physician diagnose problems such as muscle weakness, spasticity, or poor motor control. Then exercises using visual displays of muscle activity are designed and practiced until mastered. This is another rehabilitation model use of biofeedback, but it appears that the feedback-assisted exercises improve motor control and this leads to a series of positive gains for urinary incontinence or painful intercourse (vulvodynia). A similar application can be used for fecal incontinence. The patient can often regain control of his or her bowel function in a few sessions using an anal probe pressure device with instructions to normalize the pattern of contraction and relaxation of the anal sphincters.

C. Jaw Pain and Dysfunction (Temporomandibular Dysfunction)

Numerous studies have shown that feedback of neuromuscular activity from the masticatory muscles

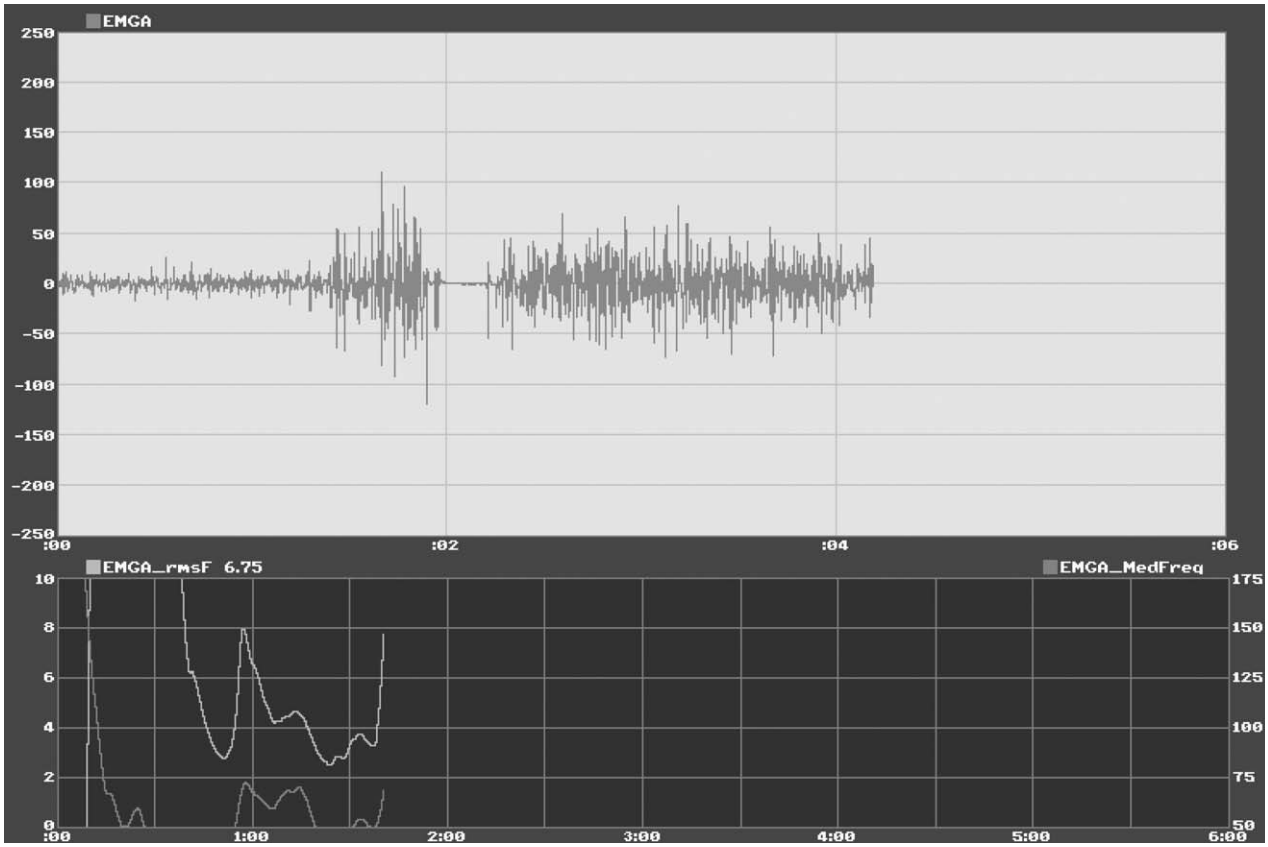

Figure 1 A typical electromyographic (EMG) display with raw activity shown above and RMS integrated levels below (dotted line is a threshold target line).

(jaw, pterygoids, etc.) reduces activity, tension, and pain from these muscles. It is not clear whether the muscle feedback helps reduce muscle activity or simply relaxes the whole muscle system, but the end result is positive. EMG sensors are placed on the jaw muscles and the patient is rewarded for reductions in activity. This is usually accomplished by setting a goal (called a threshold) and supplying feedback (auditory or visual) when the activity in the jaw muscles is reduced below the threshold.

D. Other Muscular Pain Conditions

Biofeedback from other tense muscle sites (low back, head, shoulders, neck) has also been shown to be clinically useful. Typically patients use relaxation techniques in conjunction with EMG feedback to reduce the sensations of pain or tension.

Work by David Hubbard and the author has shown that this is probably due to a reduction in sympathetic flow to muscle spindles rather than to a reduction of voluntary muscle action potentials, but more needs to be done to elucidate the exact mechanism or ''active ingredient'' in the success of EMG biofeedback.

III. AUTONOMIC NERVOUS SYSTEM REGULATION

Perhaps the most paradigm-shifting example of biofeedback comes from the applications to modify autonomic parameters. Until the 1960s it was widely believed that the autonomic nervous system, with its sympathetic branch supporting fight–flight and its parasympathetic branch supporting restoration and homeostasis, perhaps could be modified by Pavlovian or classical conditioning, but not by operant conditioning. It was thought that one might be able to condition a ''reflex'' to a neutral stimulus (bell–meat for a dog) but that the system could not be brought under voluntary control.

In 1969, Neil Miller at Rockefeller University published the results of several studies that showed definitive regulation of autonomic processes such as heart speeding and slowing, urine formation, peripheral blood flow, and blood pressure in lower mammals. The studies were notable because the animals were paralyzed with curare, ruling out any voluntary mediation of the regulation. Miller later showed that quadriplegics suffering from hypotension could raise their blood pressure with a biofeedback protocol in a similar manner. Although the original results have failed to be replicated, the publication of the work produced a shift in paradigm with respect to the autonomic nervous system. Several demonstrations of regulation have been published.

A. Vasodilation and Constriction

It appears that humans (and animals) can regulate vasodilatation and vasoconstriction. Robert Freeman and his colleagues have carefully worked out the mechanisms in finger blood regulation using biofeedback training procedures. First, they demonstrated that volunteers could warm or cool their hands upon command. Then they used a series of pharmacological blockades to show that the ability to cool one's fingers is mediated by the sympathetic nerve, but warming above baseline temperature is blocked by a β-andrenergic blocker in the blood supply. Thus, autonomic voluntary control was demonstrated. Finger warming is a commonly used biofeedback modality.

One particular application of finger warming has a solid scientific basis: Reynauds phenomenon is a multifaceted disorder that produces symptoms of vasospasm in the extremities. Hand warming against a cold challenge appears to be a viable treatment for this serious and sometimes severe problem.

B. Other Autonomic Biofeedback Methods

A few other types of feedback have been reported that seem to indicate learned regulation of the ANS. Some reports of control of sweat gland activity at the extremities appear credible. Hyperhydrosis is a disorder of excessive sweating. Biofeedback is used, with the signal usually taken from the palms of the hands, to reduce excessive activity. Whether the reduction is an example of direct autonomic control or is secondary to learning to dampen the sympathetic response is not known.

Biofeedback of the oculomotor response to improve accommodation has been reported. Special visual devices are used to improve the muscular component of the visual accommodation for improved acuity.

IV. BIOFEEDBACK-ASSISTED CULTIVATED LOW AROUSAL (RELAXATION) PROCEDURES

Biofeedback or applied psychophysiology (AP) has been most frequently used to assist in the attainment of a relaxed physiological and psychological state. Schwartz has labeled the many procedures aimed at accomplishing this task as "cultivated low arousal." The paradigm driving these applications is based on the assumption that many disorders (often called functional disorders) in modern medicine are the result of the sympathetic nervous system and the hypothalamic–pituitary–adrenaline (HPA) system being driven to excessive levels over a long period of time. Disorders included in this list are many: hypertension, headache, irritable bowel syndrome, back pain, asthma, noncardiac chest pain, fibromyalgia, chronic fatigue syndrome, temporomandibular disorder, and perhaps the somatic symptoms of anxiety disorders. Whereas the evidence related to etiology is mixed with regard to most of these disorders, the treatment protocols described next have been fairly successful in reducing or eliminating symptoms.

The biofeedback modalities that have been used include finger temperature warming, muscle activity reductions (usually from the forehead muscles, but also from the trapezii and lower back muscles), respiration training from an abdominal and thoracic strain gauge, skin conductance reduction, and sometimes heart rate reduction. All of these have in common the presumed mechanism of reduction in activity in the SNS with the assumption that the HPA axis will follow. Patients usually report subjective states of low arousal as well. Because these functional or stress-related disorders constitute a large portion of primary medical patients and are accompanied by heavy utilization of medical services, this type of biofeedback application is the most commonly practiced. Most practitioners report good results in 6–10, 1-hr sessions spread out over a few months. The patient is instructed to try to achieve a certain physiological state based on either visual or auditory feedback. Currently, this is delivered on computerized

systems with colorful displays and a variety of available auditory signals. The patient might be instructed to "find a way to warm your hands," or "slow your breath," or "relax your muscles," etc., based on the signals presented.

Because sympathetic activity is not elevated reliably in many of these patients, researchers have been looking for other mediators of symptoms. Respiration has been examined as another alternative to SNS elevation. This work is based on modern knowledge of the respiratory system. Breathing is unique in that it is the one organ system that can be regulated voluntarily but will operate automatically when the organism attends elsewhere. This is probably the reason that meditative traditions throughout human history have incorporated breathing techniques. It appears that humans under threat or stress modify their breathing to a more shallow and rapid style. This depletes the body of CO_2. It turns out that CO_2 regulates the association between the hemoglobin molecule and the oxygen needed by target organs. With prolonged overbreathing and CO_2 depletion, the oxygen is "overbound" to the hemoglobin and therefore unable to adequately fuel the target organ. The resulting anoxia can produce many of the symptoms typical of the disorders listed earlier. For this reason, biofeedback of respiratory parameters is often used to reregulate the gas exchange between oxygen and CO_2. Capnometers that measure expired CO_2 are often used as a feedback device along with indications of breath rate and pattern. Breathing patterns that emphasize slow, diaphragmatic breathing are learned in this way.

V. THE PARASYMPATHETIC BRANCH OF THE AUTONOMIC NERVOUS SYSTEM

Until relatively recently, little attention in biofeedback has been given to the other branch of the ANS, the parasympathetic branch (PNS). Activity from this system is difficult to measure, and it was thought that the sympathetic system was the dominant contributor to stress. However, the evidence to support this idea has not been found. It is difficult to verify sympathetic "overdrive" in the disorders listed earlier. In fact, most patients with functional disorders do not appear to be in obviously stressful circumstances for a sufficient period of time to produce symptoms. This has led some scientists such as Steve Porges at the University of Illinois-Chicago to theorize the importance of the PNS in everyday, nonemergency stress situations. Porges points out that a branch of the Xth cranial nerve (vagus nerve) in the PNS has a distinct anatomy that has evolved in mammals more recently than the more vegatative tracts in the vagal system. This tract seems to be involved in subtle, socially based, heart and lung regulation on an ongoing basis. When a true emergency is perceived, this system moves to the background and allows sympathetic recruitment to occur to meet the challenge. During ordinary experiences when we are negotiating complex social situations, the vagal system is dominant. In biofeedback this can be seen by analyzing the rhythms occurring in the time periods between heart beats. There is a characteristic speeding and slowing of the heart rate with inspiration and expiration called respiratory sinus arrhythmia (RSA). The vagus nerve systematically brakes the heart pacemaker during inspiration and releases the brake during expiration. Biofeedback is based on the attainment of a normal smooth RSA during slow breathing. Patients appear able to learn to produce this pattern by watching their heart rate and respiration on a computer graphic, breathing slowly and effortlessly and finding a "mindful" or blank mental state free of future or past concern, and free of rumination or worry (see Fig. 2). In fact, one group of researchers (Paul Lehrer, Evgeny Vaschillo, and colleagues) has found that 20 min of practice each day at this specific "resonant frequency" improves homeostatic reflexes in the body.

Feedback techniques such as these, which take advantage of newer technologies, may prove to be an important new tool in helping us understand and treat disorders that have puzzled modern medicine.

VI. FEEDBACK FROM BRAIN WAVES

One of the first applications of biofeedback occurred in the 1960s when a great deal of interest in altered states of consciousness arose. A number of researchers in California used newly acquired knowledge from sleep research to study the encephalographic (EEG) aspects of meditative states. It was observed that calm, transcendent states were accompanied by a predominance of α rhythm (8–12 Hz or cycles per second) activity. Biofeedback of this activity was accomplished by providing a tone or other sound when the subject produced a certain amount of the α activity. With shaping, it appeared possible to, in fact, dramatically increase EEG in this band. Many subjects reported meditative types of experiences, and EEG biofeedback

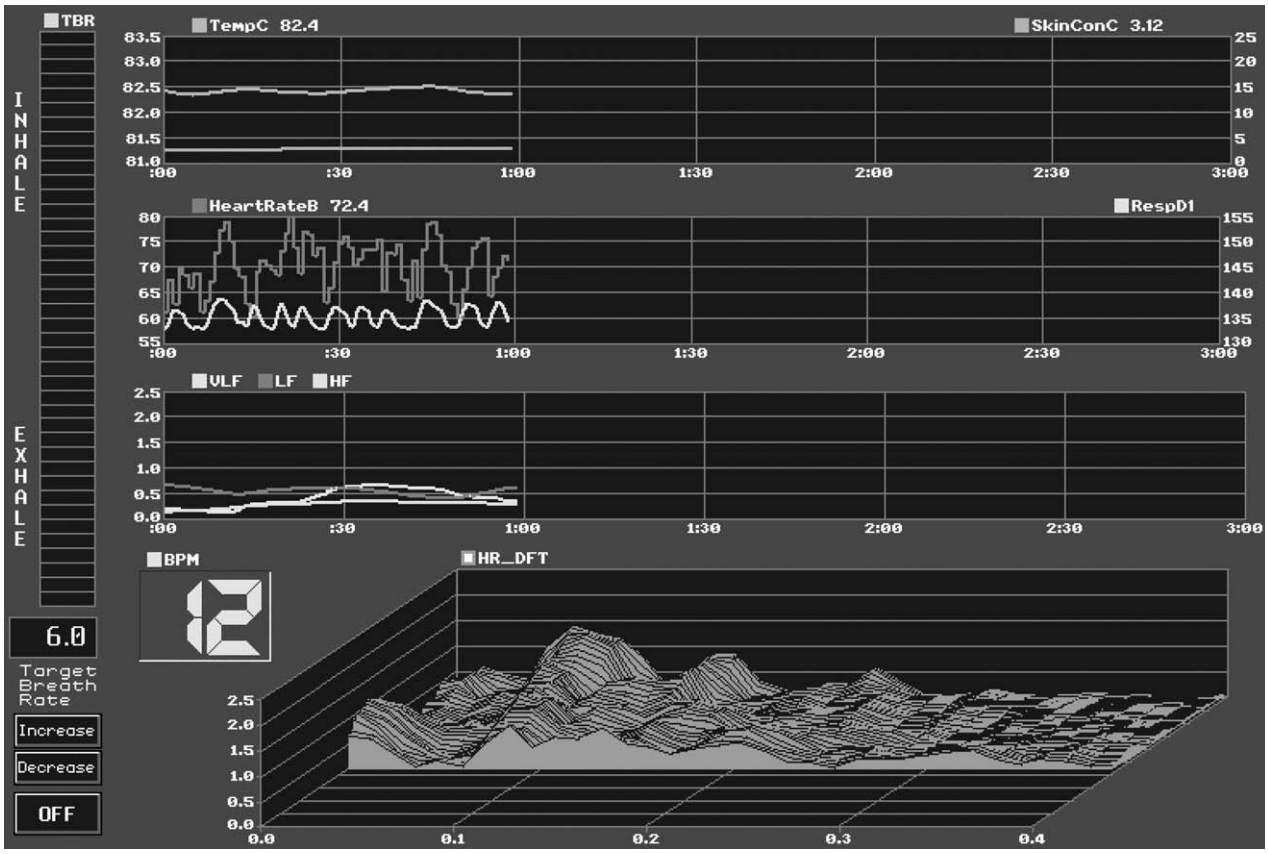

Figure 2 A computerized trace showing (from top to bottom) skin temperature, skin conductance, heart rate, respiration, and spectral derivations of heat rate.

was launched as a number of commercial ventures began producing "Alpha Trainers," promising wondrous results without the time needed to master meditation. Though this trend turned out to be transitory, it did trigger an interest in the use of one's own brain wave information as a way of achieving desired changes. Since then, two applications have established themselves within the field of brain wave biofeedback, often called neurofeedback.

A. Regulation of Brain Activity to Control Siezures

Barry Sterman in Los Angeles and then later Neils Birbaumer in Germany have shown that epileptics whose seizures have not been well-controlled with medication can reduce the frequency and amplitude of their seizures by learning to increase a certain rhythm of EEG over the motor–sensory cortex or by learning to produce a shift in the direct current of part of the brain. As a matter of fact, Birbaumer has convincingly shown that patients who have lost all motor function, including respiration and eye blinks, can learn to communicate by producing a DC shift in brain activity (one patient actually wrote a book this way).

We do not know exactly what mechanisms are involved, but the demonstration of operant control of these rhythms is undeniable.

B. Using Neurofeedback to Change Attentional States

Following the early work on seizures, Joel Lubar and others began to work on a neurofeedback application to help improve the attentional abilities of children and adults with attention deficit disorder (ADD or ADHD). A great deal of research has indicated that ADD is often accompanied by an excess of slow brain waves, especially during less compelling tasks such as

might be found in school. The predominance of θ (4–7 Hz) activity versus β (13–22 Hz) activity at the central vertex of the cranium has been the most common marker. On this basis, θ–β activity is fed back to the ADD participant with rewards for boosting β relative to θ. This is often done using games or other novel stimuli to motivate the learner. Early results indicate that the participants gain attentional abilities that translate into school performance gains. However, the lack of well-controlled trials with placebo or false feedback limits our confidence in these results.

Neurofeedback has become quite popular over the last 5 years and now plays an important role in the field of biofeedback. If research corroborates the impressions of many clinical trials, it could become a common treatment for many prevalent problems.

Body Perception Disorders

GEORG GOLDENBERG
Krankenhaus München Bogenhausen, Germany

GLOSSARY

apraxia A disorder of action planning that affects object use, performance of meaningful gestures on command, and imitation of gestures.

autotopagnosia Inability to designate body parts on command.

finger agnosia Inability to designate single fingers on command.

heautoscopy Seeing a double of oneself.

hemineglect A failure to attend to one side of space.

optic ataxie Inaccurate reaching for visually presented targets contrasting with accurate reaching for targets from other modalities.

phantom The persistence of proprioceptive sensation from missing or deafferented body parts.

proprioception Somatosensory "selfperception" of configuration and movements of one's body.

The importance of perceiving one's body and of knowing about it appears intuitively evident. This intuition and clinical observations of disturbed body perception following local brain damage led to the proposal that there are brain mechanisms specifically dedicated to body perception and body knowledge. "Body schema" and "body image" have become popular terms for designating mental representations of the spatial structure of our body that have a distinct cerebral substrate and can hence be subject to selective damage. Two kinds of criticism have been raised against this idea: Apparently selective deficits of body perception and knowledge have been criticized as being artificially isolated aspects of more general disorders of perception and knowledge, and a unique mental representation of body has been said to be unable to account for clinical dissociations between different kinds of disturbances of body perception and body knowledge. Whereas the first criticism calls into question the existence of any dedicated mental representation of body, the second posits that there must be more than one of them.

I. INTRODUCTION

In this article, I analyze disorders of human body perception to determine whether perception and knowledge of the spatial structure of one's body have a different neural basis than perception and knowledge of other objects, and whether the neural basis of body perception and knowledge includes a comprehensive "master map" corresponding to the intuitive unity of our body. I first consider the sensory sources, modes, and purposes of body perception.

A. Sensory Sources of Body Perception

Information about the spatial structure and configuration of one's body is provided by vision, somatosensory afferences, and monitoring of motor commands. Vision of one's body enters the brain by the same pathways as vision of any other object. Direct

sight of one's own body is limited to the limbs and the front of the trunk but does not basically differ from vision of other person's bodies. Mirrors, photography, and electronic recording provide ample opportunity for seeing one's own body as completely as it can be seen by anyone else. Vision provides a view of one's own body that is very similar to how it can be seen by external observers.

Somatosensory afferences from cutaneous surface receptors subserve primarily the reaction to and recognition of external stimuli, but tactile sensations can also be analyzed with respect to their localization on the body. One can also touch oneself. Tactual exploration of one's own body differs from exploration of external objects by the coincidence of tactile sensations from touching and touched body parts. This coincidence can serve as a clue for recognizing one's own body as being the object of touch.

In contrast to surface receptors, afferences from mechanoreceptors in deep skin layers, joint capsules, Golgi tendon organs, and muscle spindles are predominantly used for proprioception. Proprioception comes from the interior of the body and differs fundamentally from the way in which one's body can be perceived by another person.

Data from the physiology of motor control and perception strongly suggest that "efference copies" of motor commands can be monitored and compared with proprioceptive feedback from motor execution. In routine behavior we are not aware of motor commands as being different from motor execution, but motor commands may rise to consciousness when there is discrepancy between the command and its execution.

B. Modes of Body Perception and Knowledge

One can walk and at the same time have an intellectually demanding discussion. The motor acts of walking and speaking result in changes in the spatial relationships between body parts. These changes have to be constantly monitored in order to enable adequate chaining of motor acts but should not distract attention from the arguments of the discussion. In other situations—for example, when learning a new dancing step—one may pay attention to the relationships between involved body parts and monitor them consciously, presumably being unable to deal with any intellectual problems simultaneously. There are thus two modes of perceiving and knowing one's own body: One functions in the background of attention and is implicitly used in action control, whereas the other one demands focused attention and gives rise to explicit knowledge about body configurations.

C. Purposes of Body Perception and Knowledge

Intuitively, one may discern three significant purposes of knowledge about one's body. First, it is needed for motor control. Second, it can give rise to conscious awareness and evaluation of the integrity and configuration of one's own body. Third, it can serve social communication and learning. The ability to compare the configuration of one's own body with those of other persons and to adapt one's movements to those shown by other persons is important for skill learning and social communication.

The classification of purposes of body perception will serve as a guideline for the structure of this article. I discuss how disturbed perception or knowledge of one's body can affect each of them, considering experimentally induced disturbances in normal persons and disturbances caused by brain lesions.

II. MOTOR CONTROL

In order to plan the muscular actions for bringing a body part into an intended position, the brain has to be informed about its starting position. Afferent information about the body part's final position is needed to control whether the intended position has been accurately reached.

Demands on information about configuration and position of one's body increase when movements are aimed at external targets. Reaching with the hand for a visually presented object requires a transformation of the target location from retinotopic to body-centered coordinates. This transformation has to take into account the position of the eyes relative to the head and of the head relative to the trunk. Hence, information is needed about the actual position of eyes and head in addition to the initial limb position.

A. Prism Adaptation

In normal subjects, flexibility of transformation from retinotopic to body-centered coordinates has been demonstrated by prism adaptation. When subjects view objects through laterally shifting prisms and try to reach for them, their hands will move toward the shifted location and miss the actual object. Subjects

will see their hand deviating from the object's apparent location even further to the side of prism shift. After some trials, however, the direction of movement will adapt to the visual distortion. Subjects will reach the actual object while seeing their hand reaching its apparently shifted location. The actual movement path of the hand thus deviates from its visually perceived movement path in the opposite direction of prism shift. Consequently, when prisms are removed subjects will initially misreach in this direction. Prism adaptation and aftereffects are restricted to the hand that performed the movements. This means that rescaling affects the transformation from a retinal to a one-limb-centered rather than globally body-centered reference frame.

Prism shift creates several conflicts. First, the visual location of the hand deviates from its proprioceptive location. Second, the visual path of the reaching hand deviates from the intended path. Third, after misreaching the visual location of the hand deviates from the visual location of the object. The motor system could use either of these discrepancies for computing the reaching error and rescaling visuomotor transformation. Subjects' introspections, however, accuse a nonexistent discrepancy between intended movement and proprioceptively signaled movement path of the hand as being the source of errors. They report that their movements aimed at the visually perceived target but were mysteriously pulled to the side of prism shift. At the end of the movement they believed their hands were where they saw them—that is, shifted to the prism-distorted locations. In fact, the hand had faithfully followed the intended path, but vision was distorted. I discuss the phenomenon of visual capture later, but retain now that subjects entertain false beliefs about the perceptual basis of coordinate tranformation rescaling. The brain mechanisms of coordinate transformation seem to work outside the realm of conscious body perception.

B. Somatosensory Deafferentiation

An impressive illustration of the importance of somatosensory proprioception for motor control was provided by two patients who lost all proprioceptive afferences from the body up to the neck as a sequel of peripheral nerve diseases. The most dramatic symptom of complete sensory loss was an inability to make purposeful movements. Lacking somatosensory information about the actual position of moving limbs, the patients produced ill-oriented and ineffective movements of inappropriate strength. Eventually, they learned to replace proprioceptive afferences by visual control of moving body parts. One of them even succeeded in learning to walk again, whereas the other patient remained wheelchair bound. However, movement control remained highly abnormal in both patients. Coordinated movements afforded constant visual monitoring and allocation of attention. Even the ambitious patient who had remastered walking could not entertain a discussion nor admire the beauties of the landscape while walking.

Replacing somatosensory by visual perception of limb position thus seems to be associated with changing the mode of body perception and motor control from one working implicitly in the background of attention to one demanding focalized attention and explicit knowledge about body configurations.

C. Blindtouch

Jaques Paillard proposed to name the ability to point to the location of touch without consciously perceiving that touch "blindtouch." It has been explored in two patients suffering from complete anaesthesia of one half of the body. They were blindfolded and asked to point with their intact hand to the location of touch on their anesthetic hand. The accuracy of pointing was reduced but was definitely above chance, even for discriminations between proximal and distal portions of single fingers. One patient commented, "But I don't understand that! You put something here. I don't feel anything and yet I go there with my finger. How does that happen?" Localization was restricted to direct pointing and did not differ from chance when a patient was asked to indicate the localization of touch by pointing to a picture of a hand or by a selection between verbally proposed localizations. When verbal responses were given simultaneously with direct pointing, the verbal errors captured the motor response and pointing accuracy decreased to chance.

Blindtouch can be considered as being the opposite of movement control in deafferented patients. In blindtouch, the implicit processing of somatosensory information about locations on the body seems to be preserved in the absence of any explicit representation of the same information, whereas in deafferented patients the explicit representation of the body is used for compensating the absence of implicitly processed somatosensory afferences.

D. Optic Ataxia

Patients with optic ataxia cannot accurately reach for visually presented targets. They move their hand to the vicinity of the target and then start searching movements until they hit the target. Visual misreaching contrasts with fast and accurate pointing to parts of own body and to auditorily presented targets. Many patients also have difficulties when asked to explore, compare, and estimate spatial positions without reaching for them, but there is no correlation between the severity of this general visuospatial disorder and the severity of visual misreaching. Single patients with optic ataxia pass all tests of visuospatial estimation and exploration perfectly, and many patients with severe visuospatial problems can accurately reach for visually presented targets.

A plausible interpretation of optic ataxia is that it affects the transformation of retinotopic locations into body-centered reference frames necessary for movement planning, leaving intact motor control not requiring visual input as well as visuospatial processing not requiring transformation from visual to body-centered coordinates.

Optic ataxia can be restricted to one hand or one hemifield or even to a specific hand–hemifield combination, and manual misreaching may contrast with accurate fixation by saccades. These dissociations indicate that transformations from retinotopic to body-centered coordinates are made by mechanisms dedicated to single body parts or sectors of the visual field.

E. Physiology and Anatomy

The majority of fibers carrying information from deep mechanoreceptors end in spinal reflex loops or motor control centers in brain stem and cerebellum. Only a minor portion joins the leminiscal pathway and reaches primary sensory cortex via the ventrolateral thalamus. Both patients who completely lost the ability to exploit somatosensory afferences for motor control had peripheral nerve diseaeses that blocked somatosensory input before it reached even the spinal cord. Of the two patients with blindtouch, one had an extensive contralateral parietal lesion that in all probability destroyed the primary sensory cortex, whereas the other one had a thalamic lesion interrupting all sensory input to primary sensory cortex. Taken together, these observations indicate the extent and importance of sensory motor coordination below the level of cortical processing. The preservation of touch localization in the absence of cortical processing suggests that lower-level topographical body representations suffice for distinguishing locations on the body with above chance accuracy. Conversely, the dramatic effects of peripheral deafferentiation may be due to the deprivation of not only cortical but also lower-level representations of body configuration from proprioceptive afferences.

From primary sensory cortex in the postcentral gyrus proprioceptive input is transmitted rostrally to primary motor cortex and caudally to parietal areas. In the parietal lobe, somatosensory infomation meets visual input that is forwarded from secondary visual cortex along the "dorsal" route of visual processing.

Single-cell recordings in monkey have provided evidence that neuronal networks in parietal areas 5 and 7 are capable of transcoding visual locations from retinotopic to body-centered reference frames. These networks are centered within the intraparietal sulcus, which separates areas 5 and 7. Evidence for a similar function of the human intraparietal sulcus is provided by functional imaging of brain activity in prism adapatation as well as by analysis of lesions in optic ataxia: A positron emission tomography study of normal subjects who were exposed to prism adaptation of one hand demonstrated activation in the contralateral intraparietal sulcus. The lesions causing optic ataxia are also centered around the intraparietal sulcus. Unilateral lesions may cause optic ataxia of the contralateral hand, the contralateral visual field, or both.

The accordance of monkey and human data on the importance of the intraparietal sulcus for visuomotor coordination should not diverge attention from a fundamental difference in the anatomical layout of monkey and human parietal lobes. Human areas 5 and 7 are shifted dorsally to the superior parietal lobe and the intraparietal sulcus separates both of them from the inferior parietal areas 40 on the supramarginal and 39 on the angular gyrus. Lesions causing optic ataxia differ from lesions causing general visuospatial disorders by largely sparing the inferior parietal lobule. I discuss the role of the inferior parietal lobe for body perception later.

F. Representation of One's Body for Motor Control

Perception of body configuration for motor control strongly relies on somatosensory input and predomi-

nantly works outside of attention. It can dissociate from or even contradict the conscious perception of one's body. The central nervous system uses information about body configuration for motor control at multiple levels from spinal cord up to the parietal lobe. Presumably, there are representations of the spatial configuration of body parts at each of them. Evidence from visuomotor coordination suggests that even at the highest level there are multiple task- and body part-specific representations rather than one master map of the entire body.

III. AWARENESS OF ONE'S OWN BODY

Human subjects have a body image depicting both the permanent features and the dynamic configuration of their bodies. They can tell whether any of their body parts are mutilated or even absent, and they can perceive and deliberately control the configuration of moveable body parts.

A. Illusive Body Perceptions

Even in normal subjects the integration of visual perception, somatosensory input, and monitoring of motor intentions into a coherent body image may go astray when there is conflict between the senses.

1. Illusions of Impossible Body Configuration

External vibration of a muscle stimulates deep receptors in much the same way as extension of that muscle does. It therefore gives rise to an illusive feeling of limb movement stretching that muscle. This feeling is strong enough to create a strange sensation of impossible body configurations. For example, vibration of the biceps brachii while the fingers are holding the nose leads to a "Pinocchio effect" of apparent lengthening of one's nose. Conversely, vibrating the triceps brachii creates a sensation of the head being pushed backwards and downwards into the body beyond all limits of anatomical possiblity. Ramachandran and Hirstein produced a Pinnochio effect by seating blindfolded subjects behind another person facing the same direction. The experimenter stood behind the blindfolded subject. With his left hand, he took the blindfolded subject's left index finger and used it to repeatedly tap and stroke the other person's nose while his right hand tapped and stroked the subject's nose in synchrony. After a few seconds, the subjects developed the illusion that their own noses has either been dislocated or stretched out.

Illusions of impossible body configurations demonstrate that conscious body perception will sacrifice the permanence of body shape if it is in conflict with the temporal dynamics of ongoing sensations. The synchrony between holding the nose and stretching the arm or between touching a nose and feeling touch on the nose is most parsimonously accounted for by lengthening of the nose. Finding parsimonious accounts for current events seems to have higher value than fidelity to lifelong experience.

2. Visual Capture

The previous examples concerned conflicts between components of somatosensory afference while visual feedback was excluded. When somatosensory afferences is in conflict with visual perception, vision generally wins. This effect, one example of which is prism adaptation, has been termed "visual capture." Visual capture is not merely due to subjects believing their eyes more than their feeling; if distorts somatic sensations to make them correspond with the visual image. Subjects feel their hand to be as they see it. The subordination of feeling to seeing is even more remarkable because visual perception of one's own body is not very discriminative. It can be deceived by replacing the own hand with a mirror image of the other hand, a gloved hand of another person, a hand made of plaster or rubber, or even a shoe. In 1937, Tastevin reported that subjects who held a 5-cm-wide box beneath a cloth with one hand while they were shown a plaster hand holding a 2-cm-wide box up to 30 cm away from their real hand gradually adapted their proprioception to the artificial display so that they could feel their hand holding the small box in the plaster hand's place. Recently, the credibility of this astonishing report has been endorsed by more rigorously controlled experiments. Botvinick and Cohen simultaneously touched a visible rubber hand and the subjects' hand, which was hidden behind a screen. Subjects developed the illusion that the rubber hand was their own hand, provided that there was strict synchrony between seen and felt touch. Ramachandran seated subjects in front of a table on which a shoe was placed. Subjects saw the experimenter repeatedly and randomly stroke the shoe while their own hand was stroked synchronuously behind a screen. Subjects developed the illusion that their tactile sensations were coming from the shoe, which had become part of their own body.

Monitoring of motor commands shows better resistence against visual capture than somatosensory afferences. This leads to the illusive conflict between motor intention and motor execution, which was discussed previously. The conditions for conflicts between motor intention and visual feedback can be further explored by means of a simple mirror. If the mirror is placed sagitally at body midline and one looks into it from one side, vision of the opposite hand is replaced by the reflected image of the hand on that side. Looking from the left side, one sees a mirror image of the left hand replacing the right hand. If the left hand is moved, a symmetrical movement of the right hand will be shown regardless of what the right hand is actually doing. A compelling feeling of moving the right hand in accordance with its pretended image can occur when the right hand rests immobile, particularly when both hands hold moveable objects of the same shape (e.g., rings pending on a horizontal stick). If, however, the hidden right hand performs active movements incompatible with the mirror image, one feels a conflict between intention and execution similar to the conflict described for prism adaptation rather than an uncontradicted feeling of moving the hand in accordance with its visual appearance.

B. Body Part Phantoms

The occurrence of body part phantoms was among the first and continues to be among the most impressive arguments for the contention that a predetermined body image underlies and modifies the way we experience our own bodies.

The basic experience of body part phantoms is somatosensory: A body part is felt to exist, although it is either absent or cut off from the cerebral cortex by peripheral, spinal, or subcortical interruption of somatosensory afferences. Phantoms have been reported for nearly every part of the body but are most frequent and best explored for limbs and female breasts.

1. Somatosensory Influences on Phantom Sensation

It has long been established that touch of the stump can evoke referred sensations in phantoms of amputated limbs, but only recently it has been shown that referred sensations can originate in body parts that have no anatomical proximity to the amputated body part. In patients with upper limb amputations referred sensations have been evoked from both sides of the chest, both sides of the face, and the contralateral arm. Sensations in phantoms of amputated breasts have been evoked by touch of both sides of the back and the ipsilateral pinna. The presence, extent, and localization of referred sensations vary greatly between patients. In some of them, an exact and reproducible topographical remapping from stimulated to referred locations has been demonstrated that remained stable for up to several weeks. Reexaminations after longer delays, however, have documented radical changes or even complete breakdown of topographical referral without accompanying changes of the phantom's size and shape.

2. Visual Influences on Phantom Experience

Phantoms of amputated body parts clearly contradict the visual perception of their absence and thus challenge the dominance of vision for awareness of one's body, but evidence for an influence of vision on phantom experience derives from patients with spinal cord transsection. Their limbs are anesthetic and plegic but visibly present. Virtually all these patients have phantom experience of the disconnected limbs. During the first days many patients feel the phantom limbs to be flexed although their plegic real limbs are extended, but within a few weeks the phantom position joins the real position. Because the patients' brains have no somatosensory information about the real limb position, they must use vision of the real limbs for adapting the phantoms.

Further evidence for a visual influence on phantom experience may be deduced from adaptation to prostheses. In patients fitted with prostheses, phantoms frequently adapt to their shape. Similar to normal persons who were induced to feel a distant shoe as being part of their bodies, some amputated patients integrate the prosthesis into their bodies and identify it with the phantom. They feel touch directly at the surface of the prosthesis rather than deducing it from the prosthesis' pressure on the stump. Apparently, vision of the prosthesis entertains and shapes the phantom experience and makes possible a meaningful and functionally advantageous stabilization and refinement of sensory remapping from stump to phantom.

Upper limb prostheses seem to have less influence on shape and size of phantoms than do lower limb prostheses, but visual capture of upper limb phantoms has been convincingly demonstrated in a series of elegant experiments by Ramachandran and

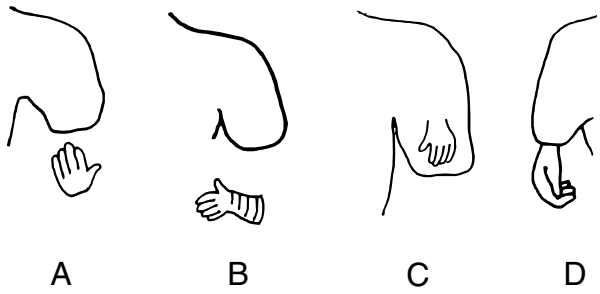

Figure 1 Samples of anatomically impossible or abnormal phantoms after upper elbow amputation. (A and B) The hand is disconnected from the stump. (C) The hand is located within the stump. (D) The extreme shortening of the arm is anatomically possible but corresponds to a deformation that had not been present before amputation (redrawn with permission from sketches made by the affected patients, published in W. E. Haber, Observations on phantom limb phenomena. *Arch. Neurol. Psychiatr.* **75,** 624–636, © 1956, American Medical Asociation).

coworkers. They ''resurrected'' vision of the amputated arm by means of a mirror reflecting the patient's opposite arm or the gloved arm of another person. Movement of the mirror image induced a feeling of phantom movement regardless of whether the patient's or the experimenter's arm had induced the illusion. When the patient's intact arm was touched, patients felt touch at the mirror location on the phantom. This illusion was contingent on the actual application of touch to the intact arm. Seeing touch of the experimenter's hand reflected to the resurrected phantom did not induce a feeling of touch on the phantom. A synchrony between any feeling of touch and vision of phantom touch was necessary for inducing a feeling of touch on the phantom.

3. Phantoms in Congenital Absence of Limbs

The possibility of phantom limbs in persons with congenital absence or very early amputation of limbs has been reliably established, but their frequency is substantially lower than that after later amputation. Permanent phantoms are reported by approximately 10% of persons with congenital absence or very early amputation of limbs compared to approximately 90% of persons amputated after the age of 10 years. The incidence increases to approximately 20% when temporary phantom sensations are considered. Some persons report having had phantoms as long as they can remember, but in the majority phantoms occur only after a delay. The mean time to phantom onset has been calculated to be 9 years in congenital absence and 2.3 years in early amputation. The emergence of the phantom may be triggered by minor trauma to the stump.

Because the affected children had no or only rudimentary opportunity to experience the presence of the now missing limb, the phantom has been said to represent a genetical prefiguration of the mental representation of body shape. However, there is evidence that pre- and postamputation experience can shape phantoms in children. In children with early amputation of congenitally deformed limbs the phantom may replicate the initial deformation rather than restituting a normal limb. This shaping by early experience may contrast with an inability to consciously remember the deformation. Like phantoms of adult patients, those of children can be triggered and shaped by prostheses: Phantoms of congenitally absent or early lost limbs are more frequent in children who have been fitted with prostheses than in those without, and they usually adapt their size and shape to the prosthesis.

4. Anatomically Impossible Phantoms

Over time, the proximal portion of limb phantoms tends to fade. This can lead to the strange sensation of the distal limb being disconnected from but still belonging to the body or to telescoping of the limb (Fig. 1). Telescoping causes a severe deformation of size and shape of phantoms and may result in the anatomically impossible location of fingers inside the stump. Full-sized phantoms may be in unnatural positions violating anatomical constraints. For example, the hand of a phantom arm may penetrate into the chest. There is a report of one girl who, after amputation of her congenitally deformed right leg, developed one phantom adapted to the prosthesis, one reproducing the original deformation, and one consisting of toes fixed to the stump, thus experiencing an anatomically impossible coexistence of three right legs.

5. The Body Representation Underlying Phantoms

The mental representation of one's body underlying the phantom experience seems to be a moldable and fleeting construction aimed at integrating pre- and postmorbid experience, functional affordances, and discrepant sensory afferences. It cannot be reduced to being a replication of a genetically prefigured body image or of the premorbidly intact body shape. It seems doubtful that a genetically predetermined mental representation of normal body shape plays a

role in the genesis of phantoms at all. It is difficult to imagine how a predetermined mental representation can force completion of the body image by phantoms of missing parts but cannot prevent deformation of that image by anatomically impossible phantoms.

C. Personal Hemineglect

Patients with hemineglect fail to direct attention and action toward the hemispace opposite their cerebral lesion. Neglect can affect either side, but it is more frequent, more severe, and more durable after right brain lesions. Hemineglect can disturb attention and action to the left side of extrapersonal space and external objects as well as to the left side of the patient's own body. Patients may fail to wash, comb, shave, and dress the left half of their bodies. They may forget about their frequently plegic left limbs and let them slip into uncomfortable and dangerous positions. When asked to touch their left arm, the reaching movement of the intact right hand may stop at the body midline or at the left shoulder.

It has been suggested that the basic disorder in hemineglect concerns the mental representation of space rather than either perceptual input or motor output. This line of thought leads to the prediction that if there exists a distinct mental represenation of one's own body, hemineglect can be restricted to the patient's own body. Empirical findings on this issue are inconsistent: One study found personal hemineglect without extrapersonal hemineglect in only 1 of 97 right brain-damaged patients, whereas the reverse dissociation occurred in 9 patients. Another study with a smaller sample of patients and using different tests of neglect found that one-third each of patients had predominantly extrapersonal, predominantly personal, and combined hemineglect. These studies were concerned with only relative differences of severity between personal and extrapersonal neglect, but there is one report of a patient showing severe personal hemineglect in testing as well as in spontaneous behavior but no extrapersonal hemineglect.

Although the previous studies invite the conclusion that personal and extrapersonal hemineglect are independent sequels of brain damage that happen to cooccur because of anatomical contiguity of causal lesions, functional interactions between them were demonstrated by varying the relationships between personal and extrapersonal definitions of left and right. In patients with left hemineglect blindfolded detection of touch of the left hand improves when the hand is placed across the body midline into the right hemispace. When the ulnar and radial edge of the left hand are touched simultaneously, neglect will affect the edge that happens to lie on the left side. Ulnar touch will be neglected when the hand is pronated and radial touch is neglected when the hand is supinated. Within a somatotopic representation of one's body, the left hand and its left side would be expected to be coded as being left regardless of their momentary position. The dependence of tactile sensation on hand position suggests an influence of position in peripersonal space on proprioceptive awareness.

In summary, studies of personal hemineglect lend support to the idea that the mental representation of one's own body is distinct from the mental representation of external space but demonstrate close proximity and functional relationships between them.

D. Denial of Ownership of Limbs and Supernumerary Limbs

These delusions are typically though not exclusively observed in patients with left-sided hemiplegia and neglect. Patients may deny ownership of their left arm, claiming instead that the arm to their left belongs to another person or to a dead body. Conversely, they may insist that they have a supernumerary, nonplegic left arm in addition to a plegic one.

Denial of ownership is sometimes embedded in bizarre speculations concerning the origin and purpose of the strange body parts. The basic phenomenon, however, may be traced back to contradictory tactile, proprioceptive, and visual information about the left side of the body. I illustrate this with an example.

I had a conversation with a woman suffering from left-sided hemiplegia, hemianesthesia, and partly recovered hemineglect. During the conversation she recognized her plegic left arm perfectly, but she related an unusual procedure happening to her each night. When preparing her for the night, the nurses would place a strange and lifeless left arm into her bed and ask her to take good care of it. She presumed this to be some new kind of therapy for strengthening her lesioned brain. When asked where her own left arm remained during the night, she guessed that it had always been placed "as it should be." She then described a weird experience that she had the very last night: When grasping the strange arm with her right hand, she felt tension in her left shoulder. She concluded that during that night the nurses must have

fixed the strange arm to her shoulder, perhaps to augment its therapeutic effect. Her bizarre account can be interpreted as an attempt to resolve conflicts between different sources of information about her body: Because of left-sided anesthesia the right-sided sensation of touching an arm was not accompanied by the simultaneous left-sided sensation of being touched and the patient lacked the somatosensory clue to self-touch. When awake in daylight she visually detected the continuity of the touched arm with her own body, but in the dark and with lowered vigilance hemineglect prevented exploration of the strange arm up to its origin at the shoulder. The idea that the strange arm was placed there for therapeutic purposes may have been reinforced by the nurses who probably did not mention that they referred to the patient's own arm when advising her to take good care of the left arm during night. Recovery of proprioception in the left shoulder restituted synchrony between manipulation of the arm and a feeling of being manipulated, but at that stage she preferred to accommodate this isolated piece of counterevidence to the already established belief.

Illusions of supernumerary limbs are regularly associated with a loss of proprioception from the duplicated limb and frequently with the belief that in contrast to the first, plegic limb, the supernumerary limb can actively move. Monitoring of motor commands may play a pivotal role in creating the illusion of having a moving limb supplementing the plegic one. In routine behavior we are not aware of motor commands being different from motor execution. It is only when swift motor execution is prevented that we become aware of the discrepancy between intention and execution by noting a "sense of effort." In hemiplegia, alertness to the discrepancy between command and execution may be affected when sensory disturbances prevent proprioceptive feedback about movement execution from reaching awareness. The patients may react to the lack of an error signal in either of two ways: They may adjust intention to execution and experience a complete inability even to initiate any movement of the affected limb, or they may adjust execution to intention and experience successful execution of the intended movements.

Transient feelings of active movements of a plegic arm are sometimes reported by patients who are perfectly aware of the uniqueness and immobility of their arm. Conversely, some patients experience immobile supernumerary limbs. Illusive movements are not the only factor contributing to supernumerary limbs.

A further contributing factor may be a general incapability to compare and estimate spatial locations. Supernumerary limbs following brain lesions are regularly associated with disturbed localization of stimuli on the body and in external space and may be grossly mislocalized originating, for example, from the middle of the chest or, like a bird's wing, from the back. Reduplication and mislocalization of a part of the patient's body is a manifestation of visuospatial confusion that parallels the patients' distorted copies of complex drawings or three-dimensional constructions. The association between mislocalization of limbs and general visuospatial disturbances is similar to the association between personal and extrapersonal hemineglect and raises the question whether there might be cases in whom mislocalizations are restricted to body parts without affecting stimuli in extrapersonal space.

In summary, I have tried to make the case that the bizarre illusions of having body parts replaced by those of a stranger or of having supernumerary body parts can be traced to failed attempts at reconciling conflicting sensory information about the hemiplegic half of the body. The peculiarity of the resulting beliefs may be due to the sudden occurrence and unfamiliarity of hemiplegia, the distorted nature of incoming information, the absence of adequate exploration of the affected half of the body, the general inability to estimate and integrate spatial relationship, and the adverse influence of brain damage on problem-solving and plausibility control. The observation that these severe disturbances of the body image occur exclusively in combination with disorders of visual exploration or visuospatial processing emphasizes the importance of vision for the perception of one's own body.

E. Heautoscopy

Heautoscopy refers to the strange experience of seeing a double of oneself. The double may attract the person's identity, leading to the weird illusion of being changed into the double and seeing one's left and lifeless former body from outside. The self may vacillate between the two instantations of the same person, possessing each of them in turn. Heautoscopic experiences are often associated with fear and suicidal ideations.

The view of the double may be incomplete, but in most instances it includes the face. The double usually wears clothes that are frequently the same as those that

the person wears when seeing the double. In patients with repeated heautoscopic experiences the dress of the double may thus change clothes between appearances.

Heautoscopic phenomena demonstrate that persons can produce mental images of their own visual appearance. It seems doubtful whether the mental representations underlying these images have much in common with the mental representations involved in phantom experiences and personal neglect. Their emphasis is on clothes and the face much more than on the spatial structure and configuration of the body. In any event, they reflect day-to-day changes of one's visual appearance in addition to permanent knowledge about one's body.

F. Physiology and Anatomy

1. Plasticity of Primary Sensory Cortex after Amputation

Plasticity of somatotopic organization of primary sensory cortex (S1) in patients with phantoms after amputation of the lower arm and hand has been demonstrated by functional imaging with magnetoencephalography. The receptive fields of adjacent regions, devoted to the face on one side and to the upper arm on the other, invade the receptive field originally devoted to the hand. The parallel of remapping of sensations from face and stump to the phantom is striking, but a longitudinal study found that the topography of referred sensations can change without correlated changes in cortical remapping. This finding suggests that a factor besides cortical remapping must contribute to remapping of sensation. Possibly this factor is involved in an interpretative activity of higher brain centers that integrate information from sensory cortex with other sensory afferences to produce a coherent body image.

Cortical remapping in S1 may pose difficulties for the construction of a coherent body image because higher brain centers cannot easily localize the source of sensations signaled from reorganized sensory cortex. Referring them to the phantom is one possibility. Alternatively, they could be correctly assigned to those body parts from which they actually derive. Correct somatotopic assignment of signals from invaded cortex might be used to increase the sensitivity of the stimulated body parts. The reality of such an exploitation of cortical remapping is suggested by observations of increased two-point discrimination on the skin of amputation stumps. Consistency and synchrony with input from other sensory channels as well as possible functional advantages may determine how higher brain centers treat the aberrant signals. Presumably, they will retain and stabilize referral to the phantoms only for sensations from body parts that move in close spatial proximity and temporal synchrony with the phantom. The proximity of face and hand in S1 does not correspond to proximity on the body, whereas the proximity of arm and hand does. Referred sensations from face to hand phantoms are indeed less stable than referred sensations from the amputation stump.

The contention that the sensory homunculus is a source of input to, but not the site of, the neural substrate of a body image is not incompatible with effects of direct stimulation of sensory cortex. In patients in whom phantoms had vanished several years after arm amputation, transcranial magnetic or direct stimulation of primary sensory cortex evoked a resurrection of phantoms. The temporary resurrections of a phantoms in these cases may indicate a rapid reaction of higher brain centers to abnormal signals from primary sensory cortex rather than revealing the cerebral site of the phantom.

2. Parietal Lobe Representations of One's Own Body

The parietal lobes receive afferences from somatosensory and visual cortex, and their close reciprocal connections with premotor cortex enable transmission of information about motor commands. Parietal lobe areas are thus in an optimal position for integrating information from vision, somatosensory afferences, and the motor commands into a coherent image of the body. Clinical evidence confirms this expectation.

There are a few cases in which a cerebral lesion abolished a phantom limb. In all of them, clinical evidence pointed to lesion in the parietal lobe of the opposite hemisphere, and in one of them autopsy confirmed a metastasis in the supramarginal gyrus. In a further case clinical evidence strongly suggestsed sparing of primary sensory cortex. A functional magnetic resonance imaging study found activations in inferior parietal and premotor but not in primary motor or sensory cortex of a patient with phantoms of congenitally absent limbs when she moved her phantom arms.

Lesions at different locations within the right hemisphere can cause hemineglect and visuospatial impairment, but lesions causing severe and permanent neglect and visuospatial impairment usually involve the inferior parietal lobe. A group study found that lesions

that cause personal and extrapersonal neglect are larger than lesions that cause only extrapersonal neglect, but they are equally centered on the inferior parietal lobe, and the patient in whom isolated personal neglect was diagnosed also had a parietal lesion.

In contrast to body perception for visuomotor coordination, perception for awareness seems to depend on integrity of inferior parietal areas 40 and 39 rather than areas 5 and 7. Areas 40 and 39 are linked to the ventral stream of visual processing dedicated to object recognition, and it has been suggested that they build an explicit allocentric representation of space rather than coding egocentric spatial locations for motor control.

3. Laterality of Body Representations

Abolishment of phantoms after parietal lesions was observed with right-sided and left-sided phantoms and was always caused by lesions in the opposite hemisphere. There are no significant differences between the frequencies of left- and right-sided limb or breast phantoms. It can be concluded that each parietal lobe constructs a representation of its opposite hemibody and that both have a similar propensity to replace lost body parts by phantoms. The restriction of disturbed body perception to the opposite half of the body also applies to hemineglect, denial of ownership, and supernumerary limbs, but the distribution of these symptoms is asymmetric. They are mainly caused by right parietal lesions and affect the left half of the body. A possible explanation for the asymmetry is that these symptoms result from an interaction between general visuospatial disorders and disturbed body perception, and that general visuospatial impairment is more severe after right brain damage.

4. The Neural Substrate of Heautoscopic Hallucinations

Heautoscopic hallucinations are associated with temporooccipital rather than parietal lesions. Their brief duration and their occurrence in patients with epileptic seizures suggest that heautoscopic hallucinations are manifestations of partial complex seizures originating from the temporal lobes. Their association with fear and suicidal ideation might be related to involvement of limbic structures in the anterior and mesial temporal lobe. A further clue to the temporal lobe origin of heautoscopy is provided by the frequent inclusion of the face into the heautoscopic hallucination. There is ample evidence that recognition of faces is bound to temporal rather than parietal lobe function.

Heautoscopic hallucinations can be restricted to the visual hemifield opposite the lesion without a clear-cut difference between the right and left sides, but the lateralized hallucinations always include both sides. Either each temporal lobe can produce the visual image of a symmetric body or both collaborate in creating lateralized heautoscopic hallucinations.

G. The Conscious Representation of One's Own Body

The conscious image of one's own body is not necessarily a faithful replication of its actual structure and configuration, nor can deviations from reality be explained as resurrections of a prefigured image of one's body as it should be. It is rather like a fleeting reconstruction aimed at integrating afferences from vision, proprioception, and monitoring of motor commands into a coherent spatial structure. Temporal coherence seems to be a major clue for inferring spatial coherence, and synchronous sensations are assumed to stem from the same location. If synchronous sensations carry different spatial information, the brain uses heuristics for weighting them. Generally, proprioception is assimilated to vision. The subordination of proprioception to vision contrasts with the dominant role of proprioception in body perception for motor control. Monitoring of motor commands resists visual capture but cannot liberate proprioception from being subdued. The conflict between motor commands and vision is therefore experienced as opposing motor commands to proprioception of motor execution.

The construction of a conscious representation of one's own body seems to depend on integrity of the inferior parietal lobes, thus clearly differing from the neural basis of body perception for motor control. Each parietal lobe entertains an image of only the opposite half of the body. The splitting of the neural basis of conscious body representation contrasts with the feeling of a seamless corporal unity.

IV. IMITATION OF BODY CONFIGURATIONS

Imitation is the motor replication of a visually perceived action. The translation of a perceived action into an executed action requires more than a translation from visual percepts to motor commands. It

requires that an action performed by someone else be translated into an equivalent action by oneself. To do this, one must create equivalence between another person's and one's own actions and hence between another person's and one's own body. The need to recognize the communality between another person's and one's own body becomes particularly salient when imitation is examined for pointing to body parts or for meaningless gestures. Because these gestures have neither a conventional shape nor an external referent, they are defined solely as a particular configuration of the body.

In this section, I discuss autotopagnosia, finger agnosia, and defective imitation of meaningless gestures in apraxia. Autotopagnosia and finger agnosia affect the ability to select single body parts corresponding to those shown on a model. Imitation of meaningless gestures tests the ability to translate a configuration of several body parts from a model to one's own body. Although caused by unilateral brain damage, all these disorders affect both sides of the body equally.

A. Autotopagnosia

In 1922, Alois Pick reported on a demented patient who could not point to body parts on command. She searched for her eyes sometimes around her head and at other times on her hands, on the examiner's head, under the bedclothes, or on the ceiling. She also grossly misreached when trying to grasp external objects. Pick nonetheless concluded that this patient had a specific inability to locate parts of her own body and proposed the term ''autotopagnosia'' to designate this disorder.

Modern neuropsychology has retained the idea and the name but has identified it with a much more restricted clinical disturbance: Patients with autotopagnosia commit errors when asked to point to body parts on themselves, on another person, or on a model of the human body. The majority of these errors are contiguity errors in which the patient searches for the body part in its vicinity (e.g., for the wrist on the lower arm). Less frequent is confusion of body parts with similar functions (e.g., wrist and ankle). The error types may combine to lead the patient's pointing response to the most proximate body part with similar function (e.g., to elbow for wrist). Errors affect mainly body parts with ill-defined and inconspicuous borders (e.g., the cheek) and body parts that share many functional properties with similar body parts (e.g., the articulations of the limbs). Localization of individual fingers was repeatedly found to be preserved in autotopagnos ia.

Errors occur not only when the body parts are designated by verbal command but also when they are shown on pictures or when the examiner demonstrates correct pointing and the patient tries to imitate. In contrast, patients are able to name the same body parts when they are pointed to either on their own body or on a model, and they may be able to select a named body part when given an array of drawings of isolated body parts. Nor is there a general inability to point to the parts of their own body: They identify them accurately when asked to indicate the typical location of accessories (e.g., a wristwatch) or the location of objects that had been temporarily fixed to a body part. Some patients were asked to verbally describe body parts. They could describe their functions and the visual appearance but could not relate their location.

In summary, autotopagnosia selectively affects the ability to locate parts of the human body in response to a request that explicitly asks for the locations of the body parts. It has been argued that the disorder is not confined to the human body but also affects pointing to single parts of other multipart objects such as bicycles; however, since this proposal was published several reports have documented patients with autotopagnosia who could locate parts of other multipart objects. The conclusion that the disturbance is restricted to the topography of only the human body is not straightforward. It is questionable whether the structure of bicycles involves a similar amount of subtle distinctions between easily confusable and adjacent parts of the structure of the human body. If such distinctions exist, their cognizance is reserved to experts and is outside the scope of neuropsychological examination. In contrast, subtle distinctions between easily confusable parts of the human body are tested in autotopagnosia and account for the majority of errors. Knowledge about the structure of the human body may be more vulnerable to brain damage because it is more fine-grained and diversified than knowledge about other multipart objects. Few persons have expert knowledge about bicycles, but all have expert knowledge about the human body.

B. Finger Agnosia

In 1924, Joseph Gerstmann reported on a patient in whom an inability to select fingers of either the patient's own hand or the examiner's hand on verbal

command contrasted with otherwise normal language comprehension and with correct pointing to other body parts. Gerstmann noted that the difficulties were most marked for discrimination between the second, third, and fourth fingers. He named the disturbance "finger agnosia," which he considered to be a partial form of autotopagnosia restricted to only the fingers. Gerstmann's patient also had difficulties with writing, calculation, and right–left discrimination. Having observed the same combination repeatedly, Gerstmann speculated that calculation was affected because children learn arithmetic by counting their fingers, writing was affected because it demands differential finger movements, and right–left discrimination was affected because it is made with reference to the hands. None of these speculations are very convincing, and later group studies indeed showed that the correlations of finger agnosia to disorders of writing, calculation, and right–left discrimination were lower than or equal to those of other neuropsychological symptoms that had not been considered as being part of the Gerstmann syndrome.

Like autotopagnosia, finger agnosia is not restricted to verbal testing. Patients also confuse fingers when asked to show on a diagram which of their fingers has been touched or to move a finger as shown on a diagram. Finger agnosia can occur in combination with autotopagnosia but also without it. Because there are cases of autotopagnosia without finger agnosia, it appears that autotopagnosia and finger agnosia represent independent disorders of body part localization. Another association has hitherto been examined only in a few patients and may turn out to be more typical: These patients had similar difficulties with selection of toes as with selection of fingers.

C. Imitation of Meaningless Gestures

Defective imitation of meaningless gestures has traditionally been considered a symptom of apraxia. Other symptoms of apraxia are disturbed production and imitation of meaningful gestures, such as waving goodbye or miming the use of a hammer, and disturbed use of real objects. However, there are, patients with pure "visuoimitative apraxia" in whom defective imitation of meaningless gestures contrasts with preserved production and imitation of meaningful gestures and object use. It thus seems justified to discuss defective imitation of meaningless gestures as a separate disorder.

Defective imitation of meaningless gestures affects not only the translation of gestures from a model to the patient's own body but also translation to other human bodies. Patients who commit errors when imitating gestures also commit errors when asked to replicate a gesture on a mannikin or to select a gesture from an array of photographs showing gestures performed by different persons and shown at different angles.

Similar to the dissociation between autotopagnosia and finger agnosia, defective imitation of meaningless gestures can affect imitation of gestures defined by proximal body parts differently from finger

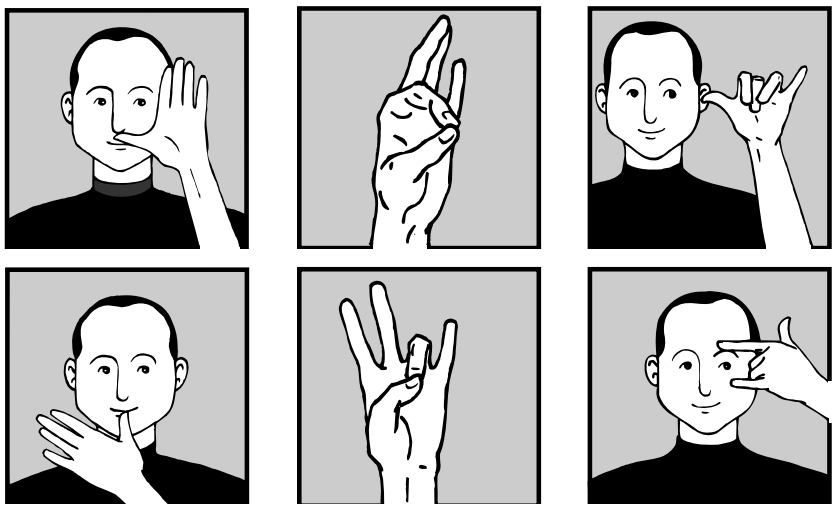

Figure 2 Examples of hand postures, finger postures, and combined gestures (reproduced with permission from G. Goldenberg, Defective imitation of gestures in patients with damage in the left or right hemisphere. *J. Neurol. Neurosurg. Psychiatr.* **61,** 176–180, 1996).

configurations. Figure 2 shows three types of meaningless gestures that have been used to explore these differences: Hand postures specify a position of the hand relative to face and head whereas the internal configuration of the hand remains invariant. Finger postures specify different configurations of the fingers, whereas the position of the hand is not considered for scoring. Combined gestures specify the position of the hand relative to the body as well as the configuration of the fingers. Patients with apraxia have problems with all three kinds of gestures, but the impairment is more severe for hand than for finger postures and more frequently concerns the hand position rather than the finger configuration of combined gestures. There are even single apraxic patients in whom defective imitation of hand postures contrasts with normal imitation of finger configurations. In contrast, patients with visuospatial impairment following right brain damage have problems only with finger configurations.

D. Physiology and Anatomy

''Mirror'' neurons in premotor cortex of the macaque monkey become active when the monkey performs an action and when it observes a similar action performed by the experimenter. The triggering of mirror neurons requires interaction between the agent and the object of an action. When the same movements are performed without the appropriate object or when the object is displayed without an action, the neurons do not react. Mirror neurons may subserve recognition of biologically significant actions. Their existence indicates that the monkey appreciates the communality between actions executed by another subject and by itself and thus possesses an essential prerequisite for imitation, but imitation is not within the behavioral repertoire of these monkeys. It would be a bold speculation to consider mirror neurons as correlates to the neural substrate of human imitation of body-centered gestures.

Lesion data from patients with autotopagnosia, finger agnosia, and defective imitation of meaningless gestures tell a rather straightforward story about the cerebral basis of body perception for imitation. The lesions in cases of pure autotopagnosia are remarkably uniform. They always affect the left inferior parietal lobe. That pointing to proximal body parts depends on integrity of the left hemisphere was confirmed by group studies of patients with left or right brain lesions. Regardless of whether the body parts were designated verbally or nonverbally, only patients with left brain damage committed errrors in pointing to them. In contrast, errors in selecting fingers have been found with about equal frequency in patients with left or right brain damage.

Patients with pure visuoimitative apraxia had either parietal lobe degeneration or vascular lesions in the left inferior parietal lobe. The combination of autotopagnosia and visuoimitative apraxia following left parietal lesions has been documented. The difference between the cerebral substrates of autotopagnosia and finger agnosia is paralleled by a difference between the cerebral substrates of disturbed imitation of hand and finger postures. Imitation of hand postures is disturbed exclusively in patients with left brain damage, whereas imitation of finger postures can be impaired in left and in right brain-damaged patients.

Previously, I identified the inferior parietal lobes as the neural substrate of conscious perception of the opposite half of one's own body. I now ascribe to the left inferior parietal lobe a central role for imitation on both sides of the body. It will be an interesting question for further research whether there is a difference in location between both kinds of body representations within the left inferior parietal lobe.

E. Creating Equivalence between Bodies

The observation that patients with autotopagnosia, finger agnosia, and defective imitation of meaningless gestures commit errors when trying to replicate the demonstrated body configuration on an external model indicates that their difficulties concern the perception and representation of human bodies in general rather than of only their own bodies. This generality is not surprising if one considers that imitation *per se* requires recognition of equivalence between one's own body and that of another person. It would be surprising if a representation of body that applies to two arbitrarily paired persons will not be valid for any other instances of human bodies as well.

A feasible way to create equivalence between human bodies would be to code their configurations with reference to conceptual knowledge classifying significant body parts and specifying the boundaries that define them. Application of this knowledge reduces the multiple visual features of a demonstrated gesture to simple relationships between a limited number of significant body parts. Coding a gesture's visual appearance by classification of body parts produces an equivalence between demonstration and imitation that is independent of the particular angle of view under

which the demonstration is perceived and also independent of accidental minor differences of the exact shapes of demonstrated and imitated body configurations.

The requirements for body part coding of the demonstrated gesture may be different for proximal body parts and the fingers. There are a considerable number and large diversity of proximal body parts, such as forehead, eyebrows, eyes, nose, cheeks, lips, and chin on the face, or shoulder, upper arm, elbow, lower arm, wrist, back, and palm of the hand on the upper extremity. Knowledge about the classification and boundaries of many of these parts is needed for conceptual mediation of proximally defined body configurations. In contrast, the fingers are a uniform set of only five body parts, and the conceptual distinction between them can be reduced to an appreciation of their serial position. Discrimination of proximal body parts may therefore tax conceptual knowledge about the structure of the human body more than discrimination of fingers. Selection of fingers may pose particular difficulties for visuospatial analysis preceding body part coding. The shapes of fingers two, three, and four are nearly identical, and their identity is mainly determined by their spatial position with respect to the other fingers. A careful analysis of their spatial position is necessary for discrimination. A distinction between the index and the middle finger is likely to put higher demand on visuospatial exploration than a distinction between the lips and the chin.

Left and right brain damage may interfere with imitation at different levels: Right brain damage impairs visual exploration and visual analysis of spatial relationships. It affects the discrimination of the spatial position of fingers but not the recognition of perceptually salient proximal body parts. Left inferior parietal damage abolishes body part coding. Selection of fingers can be spared because it puts lower demands on knowledge about body parts and because a direct mapping between the visuospatial configurations of the model's and one's own fingers can partially circumvent body part coding.

Imitation of body configurations is thus subserved by representations that apply equally to one's own and to other persons' bodies and that are not restricted to only one half of the body. Nonetheless, there is no unique neural substrate for all aspects of body configurations. Although the left hemisphere affords classification of body parts, a right hemisphere contribution is needed for spatial discrimination of perceptually similar body parts. A complete representation of the configuration of all parts of the human body requires both aspects and hence involves at least two anatomically separated parts of the brain.

V. CONCLUSIONS

I began this article by postulating three different purposes of body perception and representation: motor control, awareness of the configuration of one's own body, and imitation of the configuration of other persons' bodies. The data support the validity of this classification by showing that the nervous system employs different sensory channels and different central representations for each of these purposes. Perception of one and the same body state can yield different and even contradictory results in representations at different levels of the central nervous system.

There is no such thing as a master map of one's body in the brain. Not only do the neural mechanisms subserving each of the purposes of body perception differ but also there is more than one representation of the body involved in each of them. Most, if not all, of these representations are incomplete and devoted to only limited portions or limited aspects of the body. Some of them seem to be specific to body perception, but others are shared with perception. and representation of other objects. The intuitively given unity and uniqueness of our bodies does not seem to correspond with the neural substrates of body perception.

Borna Disease Virus

W. IAN LIPKIN, THOMAS BRIESE, and MADY HORNIG
University of California, Irvine

GLOSSARY

dopamine A neurotransmitter important in modulation of movement and behavior.

major histocompatability complex Antigen presenting proteins expressed on the surface of most cells; specific immunity to viruses is dependent on recognition of non self (viral) peptide fragments presented in the context of these proteins.

negative-strand RNA virus A virus with a genome composed of ribonucleic acid that serves as a template for transcription of messenger RNA-encoding viral proteins. Its minimal infectious unit is composed of the viral genome, nucleoprotein, phosphoprotein, and polymerase.

reverse transcription polymerase chain reaction A method for logarithmically amplifying ribonucleic acid sequences to facilitate cloning and/or detection of targets present only at low frequency.

Borna disease virus (BDV) is a novel neurotropic RNA virus that infects a wide variety of warm-blooded animal species. Infection may be asymptomatic or result in a broad spectrum of behavioral disorders, dependent on the age of the host and its immune response. Although the question of human BDV infection remains to be resolved, burgeoning interest in this unique pathogen has provided tools for exploring the pharmacology and neurochemistry of neuropsychiatric disorders potentially linked to infection. Analysis of rodent models of infection has yielded insights into mechanisms by which neurotropic agents and/or immune factors may impact developing or mature central nervous system circuitry to effect complex disturbances in movement and behavior.

I. INTRODUCTION

Borna disease virus (BDV) is the prototype genus (bornavirus) of the family *Bornaviridae*, within the nonsegmented, negative-strand (−strand) RNA viruses (order *Mononegavirales*). The name Borna is derived from its association with the city of Borna, Germany, where an equine epidemic in the late 1800s crippled the Prussian cavalry. This neurotropic virus appears to be distributed worldwide and has potential to infect most, if not all, warm-blooded hosts. BDV is similar in genomic organization to other nonsegmented, (-) RNA viruses; however, its approximately 9-kb genome is smaller than those of *Rhabdoviridae* (about 11–15 kb), *Paramyxoviridae* (about 16 kb), or *Filoviridae* (about 19 kb). The BDV genome is remarkably compact and encodes six major open reading frames (ORFs) in three transcription units (Fig. 1). BDV is distinctive in its nuclear localization of replication and transcription. Although this feature is shared with the plant nucleorhabdoviruses, it is unique among nonsegmented, negative-strand animal RNA viruses. The first transcription unit reveals a simple pattern with only one coded protein [nucleoprotein (N), p40]. The second transcription unit encodes the proteins X (p10) and P (phosphoprotein, p23) in overlapping ORFs. The third unit contains coding sequences for the putative matrix protein (M), type I membrane

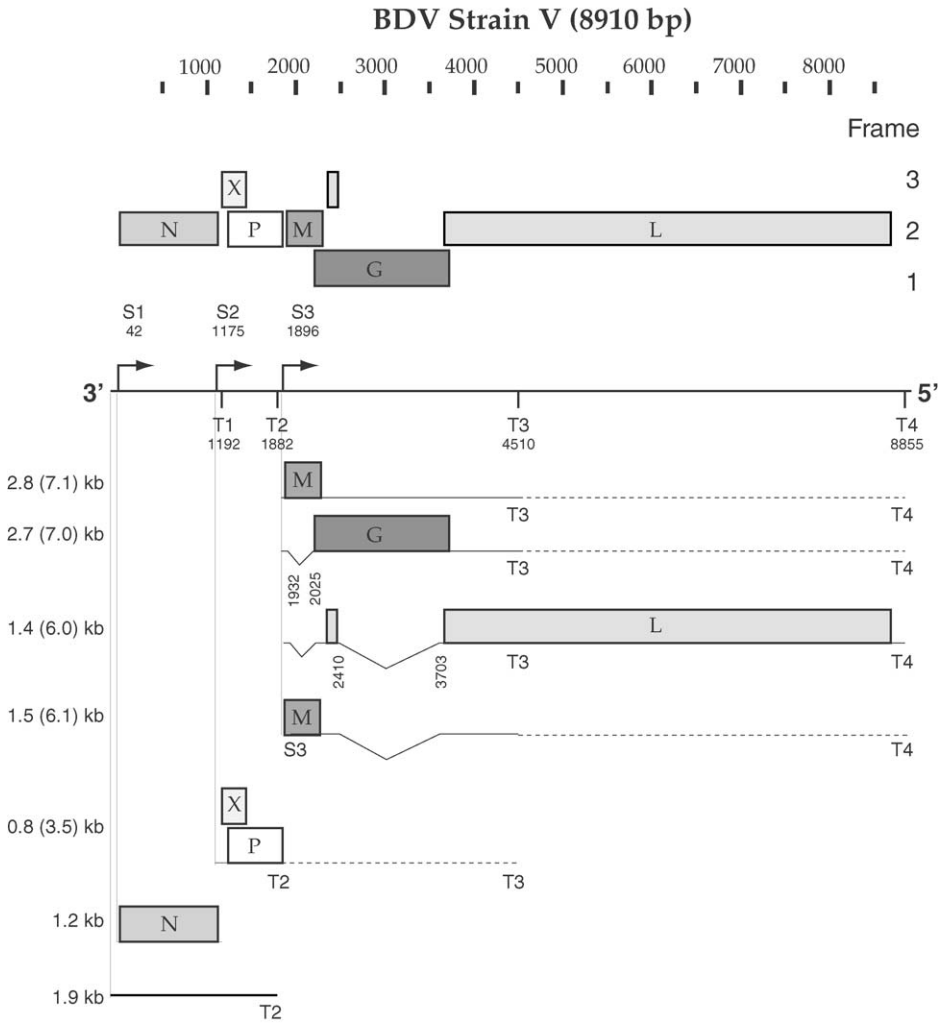

Figure 1 BDV genomic map and transcripts. S1–S3, initiation sites of transcription; T1–T4, termination sites of transcription. Readthrough at termination signals T2 and T3 is indicated by dashed lines.

glycoprotein (G, p57, gp94), and polymerase (L, p190). Elaboration of these proteins is dependent on a variety of mechanisms for transcriptional, posttranscriptional, and translational control of expression, including alternative transcriptional initiation, readthrough of termination signals, alternative splicing, and leaky ribosomal scanning. Although splicing is also found in *Orthomyxoviridae* (segmented, negative-strand RNA viruses), it is unprecedented in *Mononegavirales*.

Virions are stable at 37°C and lose only minimal infectivity after 24 hr of incubation in the presence of serum. Virus infectivity is rapidly lost by heat treatment at 56°C and exposure to pH 5.0, organic solvents, detergents, chlorine, formaldehyde, or UV radiation.

II. EPIDEMIOLOGY OF BDV

A syndrome of progressive meningoencephalitis of horses and sheep consistent with BDV infection was recognized 100 years before the disease received its name from the equine outbreak in Borna, Germany. This syndrome is still considered to represent classical Borna disease; however, infection may also result in asymptomatic carrier status or subtle disturbances in learning and memory, movement, and behavior. Emerging epidemiologic data, including reports of asymptomatic, naturally infected animals, suggest that the host range and geographic distribution of BDV are larger than previously appreciated (Table I). Natural infection has been reported in a wide variety of hosts,

Table I
Animal Species Reported to Be Infected with BDV[a]

Host and country	Seropositive	Viral protein/RNA	Seropositive and viral protein/RNA	Reference
Horse normal USA	3–6% (8–18/295)			Kao *et al*. (1993). *Vet. Rec*. **132,** 241

[a]Tissue examined for protein/RNA. PBMC, peripheral blood mononuclear cells; B, brain tissue; CNS, central nervous system.

including horses, donkeys, sheep, cattle, dogs, cats, rabbits, and birds. Experimental infection has been achieved in many of these species and also in rodents and primates. Whether BDV naturally infects humans remains controversial; however, there is consensus that all warm-blooded animals are likely to be susceptible to infection. Although central Europe has the highest reported prevalence of Borna disease, natural infection without disease has been described throughout Europe, Asia, and North America. It is unclear whether the apparent increase in host and geographic range of BDV is due to the spread of the virus or enhanced case ascertainment.

Neither the reservoir nor the mode of transmission of natural infection are known. Although experimental animals are most frequently infected by either intracranial or intranasal inoculation, infection can be achieved by virtually any method of parenteral inoculation. Natural infection of horses and sheep is typically sporadic and peaks in spring months; epidemics of disease are infrequent. An olfactory route for natural transmission has been proposed because intranasal infection is efficient and the olfactory bulbs of naturally infected horses show inflammation and edema early in the course of disease. One outbreak in a zoo has been attributed to inadvertent inoculation of BDV. Experimental infection of neonatal rats results in virus persistence and is associated with the presence of viral gene products in saliva, urine, and feces. Such secreta/excreta are known to be important in aerosol

transmission of other pathogenic viruses (e.g., lymphocytic choriomeningitis virus and hantaviruses). Normal adult rats housed in cages separate but adjacent to those of neonatally infected rats can become infected, suggesting that aerosol transmission of BDV is plausible. The observations that rodents can be persistently infected with BDV and excrete virus suggest that they have the potential to serve as both natural reservoirs and vectors for virus dissemination. However, the significance of rodents for transmission of BDV to domesticated animals and humans is unknown. Reports of BDV nucleic acids and proteins in peripheral blood mononuclear cells (PBMCs) also indicate a potential for hematogenous transmission. Vertical transmission of BDV has been reported in horses; this appears to be an infrequent event.

III. NATURAL INFECTIONS

Although infection may be asymptomatic, symptomatic disease typically follows a predictable course. Clinical signs at the onset of disease in horses and sheep are nonspecific: excited or depressed behavior, hyperthermia, anorexia, jaundice, constipation, and colic. Classical disease becomes apparent within 1 or 2 weeks. Animals maintain an upright, wide-based stance with their heads extended. Repetitive behaviors are common and may include vacuous chewing, circular ambulation, and running into obstacles. Horses become paretic in the terminal phases of disease. A distinctive decubitus posture associated with paddling movements of the legs has been described. Frequently, in late disease, the virus migrates centrifugally along the optic nerve to cause retinopathy and visual impairment. Acute mortality may be as high as 80–100% in horses and 50% in sheep. Sheep that survive may have permanent neurologic deficits. Recurrence of acute disease has been described in sheep. Natural symptomatic infection with fatal outcome has also been reported in cattle, cats (including a free-ranging lynx), rabbits, and one dog. Epidemics of paresis in ostriches were attributed to BDV infection; however, these data have not been confirmed.

Viral persistence without apparent disease has been described in naturally infected horses, sheep, and cats in Europe and Asia. There is one report indicating subclinical infection of horses in North America.

IV. EXPERIMENTAL MODELS OF BORNAVIRUS INFECTION

A wide range of animal species have been experimentally infected with BDV. Rats, mice, hamsters, rabbits, guinea pigs, tree shrews, rhesus monkeys, and chickens are all susceptible to classical disease; however, the incubation period, mortality, and severity of disease vary considerably between species and immune status of the host. Whereas in adult immunocompetent hosts infection results in dramatic, immune-mediated meningoencephalitis consistent with the classical syndrome observed in naturally infected horses and sheep, animals tolerant of infection due to immature or compromised immune systems have a more subtle course.

A. Adult Rat Model

Susceptibility to disease varies with host rat strain. Wistar and black-hooded rats can be productively infected but have less severe disease than Lewis rats, a strain with a lesion in the hypothalamic–pituitary adrenal axis associated with enhanced susceptibility to immune-mediated disorders, such as experimental allergic encephalomyelitis and adjuvant-induced arthritis. Resistance to BD is reported to be inherited as a dominant trait in Lewis and black-hooded hybrids in a manner independent of major histocompatibility complex genes. Virulence of viral strains for rats may be enhanced by serial passages of virus in rat brain.

Infection is most rapidly achieved with intracranial and intranasal inoculations. Nonetheless, any route of inoculation that allows virus access to nerve terminals (e.g., intramuscular, intraperitoneal, or footpad injection) ultimately results in central nervous system (CNS) infection and classical disease. Viremia is unlikely to play a significant role in BDV dissemination and pathogenesis. Although viral gene products may be detected in PBMCs of infected animals, intravascular inoculation only infrequently results in productive infection. Several observations indicate that BDV disseminates primarily via neural networks: (i) viral proteins and nucleic acids can be traced centripetally and transsynaptically after olfactory, ophthalmic, or intraperitoneal inoculation; (ii) the onset of disease is delayed with distance of the inoculation site to the central nervous system; and (iii) migration of virus to the CNS after footpad infection can be prevented by sciatic nerve transection.

Irrespective of the route of inoculation, initiation of clinical disease coincides with the appearance of viral proteins in hippocampal neurons and onset of meningitis. It has been proposed that BDV, like rabies virus, spreads as a ribonucleoprotein complex (RNP) within neural networks. Structures consistent with RNPs are described in neurons of experimentally infected animals; nonetheless, the form of disseminating virus is unknown.

In adult-infected rats, disease presents clinically as hyperactivity and exaggerated startle responses 10–14 days after intracerebral infection. The acute phase coincides with infiltration of monocytes into the brain, particularly in areas of high viral burden, including the hippocampus, amygdala, and other limbic structures. Two or 3 weeks later, rats have stereotyped motor behaviors, dyskinesias, dystonia, and flexed seated postures. Five to 10% of animals become obese, reaching body weights up to 300% of normal rats. Some investigators have reported isolation of a BDV strain that causes obesity in more than 50% of infected adult rats.

Disorders of movement and behavior are linked to distinct changes in CNS dopamine (DA) systems. Adult-infected BD animals are more sensitive to DA agonists and antagonists than are normal rats. Administration of the indirect DA agonist dextroamphetamine to infected animals results in increased locomotor and stereotypic behaviors. Similarly, cocaine-mediated inhibition of DA reuptake potentiates DA neurotransmission, resulting in enhanced locomotion and stereotypic behaviors. The movement and behavior disorder is improved following treatment with selective DA antagonists; whereas D2-selective antagonists (e.g., raclopride) do not affect locomotor responses in BD rats, high doses of selective D1 antagonists (e.g., SCH23390) and atypical DA blocking agents with mixed D1 and D2 antagonist activity (such as clozapine) selectively reduce locomotor activity in BD rats but not in controls.

The basis for these functional disturbances appears to be partial DA deafferentation with compensatory metabolic hyperactivity in nigrostriatal and mesolimbic DA systems. At the receptor level, both pre- and postsynaptic sites of the DA transmitter system appear to be damaged in striatum (caudate-putamen and nucleus accumbens). DA reuptake sites are reduced in nucleus accumbens and caudate-putamen. D2 (but not D1) receptor binding is markedly reduced in caudate-putamen; D2 and D3 receptor binding is reduced in nucleus accumbens. It is possible that the differential effects of infection on DA receptors in nucleus accumbens and caudate-putamen may reflect BDV-mediated interference with the cellular transcription and/or splicing machinery. Whereas binding to receptors expressed from spliced messages, D2 and D3, is reduced, binding to D1, a receptor expressed from an unspliced message, is not.

Although the increased locomotor activity, stereotypic behaviors, and dyskinesias of the adult BD model are linked to distinct disturbances in DA pathways, additional neuromodulator abnormalities have also been noted. The expression of genes for neuromodulatory substances and their associated synthesizing enzymes, including somatostatin, cholecystokinin, and glutamic acid decarboxylase, is greatly reduced during the acute phase and recovers toward normal in the chronic phase of adult BD. The cholinergic system, a major component in sensorimotor processing, learning, and memory, also appears to be affected in adult BDV infection. A progressive decrease in the number of choline acetyltransferase-positive fibers in hippocampus and neocortex has been observed to begin as early as day 6 postinfection. Preliminary work on dysregulation of the serotonin (5-HT) and norepinephrine (NE) systems suggests metabolic hyperactivity of 5-HT. There is a modest increase in the 5-HT metabolite, 5-hydroxyindoleacetic acid, in striatum and of the NE metabolite, 3-methoxy-4-hydroxyphenethyleneglycol, in prefrontal and anterior cingulate cortex. These changes may reflect compensatory upregulation following partial loss of DA afferents to these brain regions. Selective effects of BDV on 5-HT and NE pre- or postsynaptic receptors have not yet been investigated. The mechanism by which adult BD rats are rendered hypersensitive to the hyperkinetic and convulsant effects of the opiate antagonist, naloxone, is also unclear. In addition, because adult infected rats have marked CNS inflammation, it has not been possible to determine whether monoaminergic, cholinergic, and opiatergic dysfunction in BD results from direct effects of the virus, virus effects on resident cells of the CNS, or a cellular immune response to viral gene products.

In late disease, BDV disseminates throughout the autonomic and peripheral nervous systems and can be readily detected in autonomic plexi in the lungs and gastrointestinal tract and at the neuromuscular junction. It is also present at lower levels in nonneural tissues, including bone marrow, thymus, and PBMCs. Although numbers of mononuclear inflammatory cells in the CNS are markedly reduced during the chronic phase of disease, there is an elevation in titers of antibodies directed against all BDV proteins (N, X, P, M, G, and L). Antibodies specific for M and G have

neutralizing activity *in vitro*. Although virus is not cleared from the brain, neutralizing antibodies may modulate viral gene expression and limit the infection to the CNS, preventing further dissemination to nonneural organs. The blood–brain barrier remains functional in various assays. Animals may have a normal life expectancy despite loss of up to 50% of brain mass.

B. Neonatal Rat Model

Neonatally infected rats may have a wide range of physiologic and neurobehavioral disturbances. They are smaller than uninfected littermates, display a heightened taste preference for salt solutions, and have altered sleep–wake cycles. There is no apparent alteration of glucose, growth hormone, or insulin-like growth factor-1 or amount of food ingested; thus, the cause of runting remains obscure. Behavioral disturbances are less dramatic in neonatally infected animals than in their adult-infected counterparts. A study of behavioral and cognitive changes in Wistar rats infected in the neonatal period found spatial and aversive learning deficits, increased motor activity, and decreased anxiety responses. Similar deficits in spatial learning and memory were found by Carbone and colleagues in neonatally infected Lewis rats. Play behavior is also abnormal in the neonatally infected rats, with decrease in both initiation of nondominance-related play interactions and response to initiation of play by noninfected, age-matched control animals or infected littermates.

The neonatal infection model has not been studied as extensively as the adult infection model. CNS dysfunction in neonatally infected animals has been proposed to be linked to viral effects on morphogenesis of the hippocampus and cerebellum, two structures in rodents that continue to develop after birth. Carbone and colleagues found a quantitative relationship of hippocampal pathology to behavioral abnormalities in the neonatal infection model; the extent of neuronal loss in dentate gyrus appeared to be correlated with the severity of spatial learning and memory deficiencies in neonatally infected Lewis rats.

Humoral immune responses to BDV in neonatally infected animals are significantly lower than in adult infected animals. There is a transient cellular immune response that peaks approximately 4 weeks postintracerebral infection and dissipates within 10–14 days. This period coincides with the presence of high levels of mRNAs for cytokine products of CNS macrophages/microglia (IL-1α, IL-1β, IL-6, and tumor necrosis factor-α) in hippocampus, amygdala, cerebellum, prefrontal cortex, and nucleus accumbens. The extent to which cellular inflammatory infiltrates contribute to neuropathogenesis is uncertain given that thymectomized animals do not have these infiltrates but have the same behavioral disturbances and histopathology.

Marked astrocytosis has been noted in dentate gyrus and cerebellum. Upregulation of tissue factor (TF)—a member of the class II cytokine receptor family primarily produced by astrocytes that plays important roles in cellular signal transduction, brain function, and neural development through its effects on coagulation protease cascades—has been identified as one mechanism by which BDV may alter CNS development. Additionally, levels of two molecules implicated in brain development and plasticity, growth-associated protein 43 (a presynaptic membrane phosphoprotein found in neuronal growth cones) and synaptophysin (a calcium-binding protein associated with presynaptic vesicles), are reduced in cortex and hippocampus prior to neuronal losses in those structures. However, cerebellar changes cannot be explained by this mechanism because neither TF upregulation nor decrease in levels of growth-associated protein 43 or synaptophysin are observed in cerebellum. Furthermore, BDV infection of astrocytes appears to be required for TF upregulation, and cerebellar astrocytes are reported to be spared from BDV infection, at least for 30 days following neonatal infection. Whether BDV infection influences expression in cerebellum of molecules similar in function to growth-associated protein 43, synaptophysin, or TF is unknown.

Although the highest concentration of virus in neonatally infected rats is found in the CNS, it is readily detected in a wide variety of organs and body fluids (urine, saliva, and feces). Neonatally infected rats can transmit virus to adult animals without direct contact (presumably through aerosols), suggesting the possibility that neonatally infected rats may serve as reservoirs and vectors for transmission of BDV in nature.

C. Mouse Models

Mice are readily infected and have high titers of virus in brain. Disease can be induced by adaptation of virus through multiple passages in mice or infection of

specific host strains during the neonatal period. As in rats, severe clinical disease is mediated by MHC class I restricted cytotoxic T cells. A model of subtle behavioral disease has been reported in mutant mice that lack functional CD8 cells (C57BL/10J mice) wherein maze performance was correlated with IP-10 expression independent of frank histopathology.

D. Tree Shrews

Little is known about BDV pathogenesis in phylogenetically higher species such as nonhuman primates and the prosimian tree shrews (*Tupaia glis*). Intracerebral inoculation of tree shrews leads to persistent infections and a disorder characterized primarily by hyperactivity and alterations in sociosexual behavior rather than motor dysfunction. Disturbances in breeding and social behavior were most profound in animals caged in mating pairs. Females rather than males initiated mating, and infected animals failed to reproduce despite increased sexual activity. Although detailed neuroanatomic studies were not performed, the syndrome was interpreted to be due to neuropathological changes in the limbic system.

E. Nonhuman Primates

The only reported studies of experimentally infected primates employed adult rhesus macaques (*Macaca mulatta*). These animals were initially hyperactive and subsequently became apathetic and hypokinetic. Pathology was remarkable for meningoencephalitis and retinopathy. Recent preliminary data suggest that a subtle or subclinical infection can be achieved in monkeys by neonatal intranasal infection.

V. BDV AND HUMAN DISEASE

Recognition of BDV's broad experimental host range, and the observation that disturbances in behaviors in experimentally infected animals are reminiscent of some aspects of human neuropsychiatric diseases, including major depressive disorder, bipolar disorder, schizophrenia, and autism, led to the proposal that BDV might be implicated in their pathogenesis. Although there is consensus that humans are likely to be susceptible to BDV infection, the epidemiology and clinical consequences of human infection remain controversial. There have been no large, controlled prevalence studies. Furthermore, methods for diagnosis of human infection are not standardized; thus, it is difficult to pursue meta-analysis. Most reports suggesting an association between BDV and human disease have focused on neuropsychiatric disorders, including unipolar depression, bipolar disorder, or schizophrenia; however, BDV has also been linked to chronic fatigue syndrome, AIDS encephalopathy, multiple sclerosis, motor neuron disease, and brain tumors (glioblastoma multiforme) (Tables II and III). The improbably broad spectrum of candidate disorders has led some investigators to propose that infection is ubiquitous, and, that in some disorders, elevation of serum antibody titers or the presence of viral transcripts in peripheral blood mononuclear cells or neural tissues reflects generalized (AIDS) or localized (glioblastoma multiforme) immunosuppression.

There are only infrequent reports of isolation of infectious virus from humans, or detection of BDV gene products in human brain by *in situ* hybridization and immunohistochemistry: a group of four North American subjects with temporal sclerosis and a single Japanese subject with schizophrenia. Methods used most commonly for serologic diagnosis of infection include indirect immunofluorescence with infected cells and Western immunoblot or enzyme-linked immunosorbent assays with extracts of infected cells or recombinant proteins. Infection has also been diagnosed through demonstration of BDV transcripts and proteins in tissues or peripheral blood mononuclear cells. Frequently, detection of viral RNA has been achieved through nested reverse transcription polymerase chain reaction (nRT-PCR), a sensitive method that is prone to artifacts due to inadvertent introduction of template from laboratory isolates or cross contamination of samples. Amplification products representing bona fide isolates and those due to nRT-PCR amplification of low-level contaminants cannot be readily distinguished by sequence analysis because, unlike some other NNS RNA viruses, in which the inherent low fidelity of viral RNA-dependent RNA polymerases results in sequence divergence of 10^3 or 10^4 per site per round of replication, BDV is characterized by extraordinary sequence conservation. Although one report from western Austria described a horse with encephalitis, wherein N and P gene nucleotide sequences differed from other isolates by up to 15%, most studies of BDV isolates revealed variability of up to only 4.1% at the nucleotide level and 3% at the predicted amino acid level. Thus, similarities in sequence between putative new isolates

and confirmed isolates cannot be used to exclude the former as artifacts.

A blinded international multicenter study composed of more than 2000 subjects recruited at sites in North America, Europe, and Asia using standardized diagnostic clinical instruments is under way to determine the prevalence of BDV infection in individuals with affective disorders or schizophrenia. Results of serology (antibodies to BDV N, P, and M proteins) and real-time polymerase chain reaction analyses (BDV genetic sequences in white blood cells) are anticipated in late 2002.

No specific vaccine or antiviral therapy is established for BDV. Although there is one report in which BDV was found to be sensitive to amantadine *in vitro* and *in vivo*, three other reports found no antiviral activity *in vitro* or *in vivo*. The nucleoside analog ribavirin inhibits viral replication *in vitro*. Whether it has an impact on viral replication *in vivo* or on severity of disease is unknown.

Brain Anatomy and Networks

M.-MARSEL MESULAM
Northwestern University Medical School

GLOSSARY

cerebral cortex The surface of the forebrain.

heteromodal cortex Neocortical area that is interconnected with association areas serving different sensory modalities.

large-scale network A set of interconnected areas that mediates a specific mental function.

paralimbic areas Cytoarchitectonically transitional areas that are interconnected with the amygdala and hippocampus.

transmodal areas Collective term for all heteromodal, paralimbic, and limbic cortices.

unimodal cortex Neocortical area devoted to the processing of a single sensory modality.

The cerebral cortex of the human brain contains approximately 20 billion neurons spread over nearly 2000 square centimeters of surface area. There is no universal agreement on terminology, no distinct boundaries that demarcate one region from another, and, in most instances, no clear correspondence among lobar designations, traditional topographic landmarks, cytoarchitectonic boundaries, and behavioral specializations. One part of the brain can have more than one descriptive name, and cytoarchitectonic (striate cortex), functional (primary visual cortex), topographic (calcarine cortex), and eponymic (Brodmann area 17) terms can be used interchangeably to designate the same area. The purpose of this article is to provide an introductory guide for navigating the human cerebral cortex from the vantage point of functional specializations.

This article is adapted from Chapter 1 of *Principles of Behavioral and Cognitive Neurology* (M.-M. Mesulam, Ed), pp. 1–120. Oxford Univ. Press, New York, 2000.

I. PARTS OF THE CEREBRAL CORTEX

The absence of clear anatomical boundaries has encouraged the development of numerous approaches to the subdivision of the cerebral cortex. The most commonly used map is based on Korbinian Brodmann's parcellation of the cerebral hemispheres into more than 50 areas, each characterized by a specific pattern of neuronal density and lamination (Fig. 1). These cytoarchitectonic areas can be divided into five major functional zones: *limbic, paralimbic, heteromodal association, unimodal association, and primary sensory–motor*. The principal factual base for this functional categorization is derived from experiments in macaque monkeys. The homologies to the human brain have been inferred from comparative cytoarchitectonics, electrophysiological recordings, functional imaging, and the behavioral effects of focal lesions.

A. The Limbic Zone (Corticoid and Allocortical Formations)

The basal forebrain is usually considered a subcortical structure. However, some of its constituents are

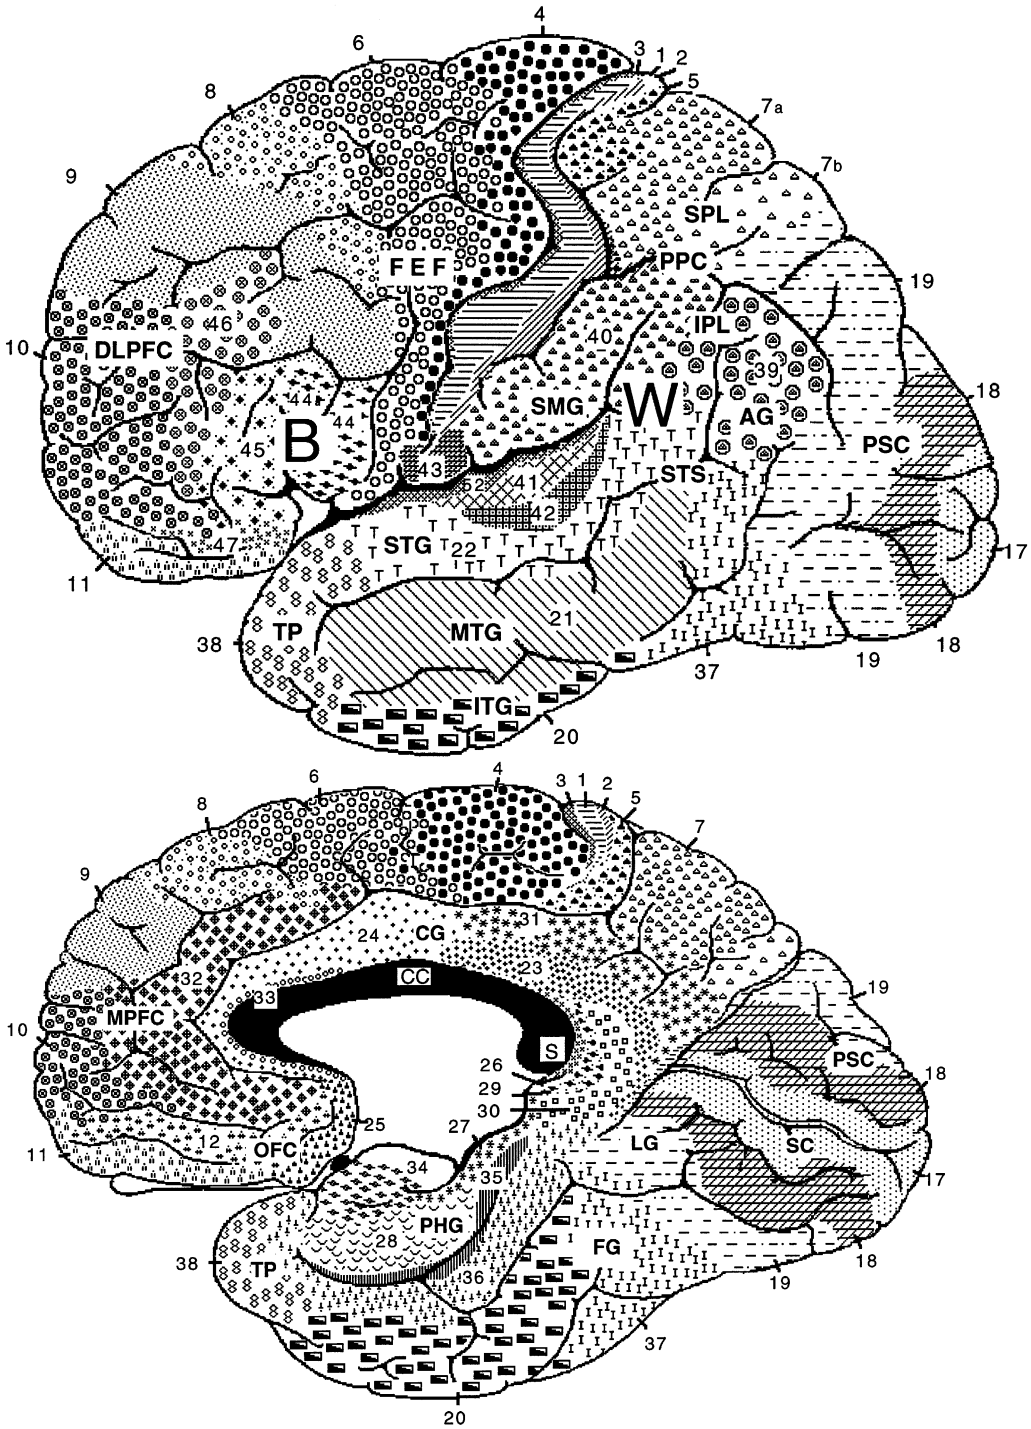

Figure 1 Lateral (*top*) and medial (*bottom*) views of the cerebral hemispheres. The numbers refer to the Brodmann cytoarchitectonic designations. Area 17 corresponds to primary visual cortex, 41 and 42 to primary auditory cortex, 1–3 to primary somatosensory cortex, and 4 to primary motor cortex. The rest of the cerebral cortex contains association areas. AG, angular gyrus; B, Broca's area; CC, corpus callosum; CG, cingulate cortex; DLPFC, dorsolateral prefrontal cortex; FEF, frontal eye fields (premotor cortex); FG, fusiform gyrus; IPL, inferior parietal lobule; ITG, inferior temporal gyrus; LG, lingual gyrus; MPFC, medial prefrontal cortex; MTG, middle temporal gyrus; OFC, orbitofrontal cortex; PHG, parahippocampal gyrus; PPC, posterior parietal cortex; PSC, peristriate cortex; SC, striate cortex; SMG, supramarginal gyrus; SPL, superior parietal lobule; STG, superior temporal gyrus; STS, superior temporal sulcus; TP, temporopolar cortex; W, Wernicke's area. The insula is hidden from view.

situated directly on the ventral and medial surfaces of the cerebral hemispheres and are therefore part of the cerebral cortex. These basal forebrain structures include the septal region, the substantia innominata, the amygdaloid complex, and the anterior olfactory nucleus. Because of their simplified cytoarchitecture, these structures can be designated "corticoid," or cortex-like. In some corticoid areas, such as the septal region and the substantia innominata, the organization of neurons is so rudimentary that no consistent lamination can be discerned and the orientation of dendrites is haphazard. All corticoid areas have architectonic features that are in part cortical and in part nuclear. This duality is particularly conspicuous in the amygdala.

The next stage of cortical organization carries the designation of allocortex. This type of cortex contains one or two bands of neurons arranged into moderately well-differentiated layers. The apical dendrites of the constituent neurons are well developed and display orderly patterns of orientation. There are two allocortical formations in the mammalian brain: (i) the hippocampal complex (i.e., the dentate gyrus, the CA1-4 fields, and the subicular areas), which also carries the designation of *archicortex*, and (ii) the piriform or primary olfactory cortex which is also known as *paleocortex*. The corticoid and allocortical formations collectively make up the limbic zone of the cerebral cortex.

B. The Paralimbic Zone (Mesocortex)

The next level of structural complexity is encountered in the paralimbic regions of the brain, also known as *mesocortex*. These areas are located between allocortex and isocortex so as to provide a gradual transition from one to the other. Allocortical cell layers often extend into paralimbic areas. The sectors of paralimbic areas that abut allocortex are also known as periallocortical or juxtaallocortical, whereas the sectors that abut isocortex can be designated proisocortical or periisocortical. In most paralimbic areas, the transitional changes from periallocortex to periisocortex include

1. Progressively greater accumulation of small granular neurons (star pyramids) first in layer IV and then in layer II
2. Sublamination and columnarization of layer III
3. Differentiation of layer V from layer VI and of layer VI from the underlying white matter
4. An increase of intracortical myelin, especially along the outer layer of Baillarger (layer IV)

In general, the emergence of relatively well-differentiated granular cell bands in layers IV and II, the sublamination of layer III, and the differentiation of layer V from layer VI mark the end of the paralimbic zone and the onset of six-layered homotypical isocortex.

There are five major paralimbic formations in the human brain: the orbitofrontal cortex [posterior parts of Brodmann's area (BA) 11 and 12 and all of BA 13]; the insula (BA 14–16); the temporal pole (BA 38); the parahippocampal cortices, including the pre- and parasubiculum, the entorhinal area, the prorhinal area, and the perirhinal (transentorhinal) area, corresponding to BA 27–28 and 35; and the cingulate complex, including the retrosplenial, ventral cingulate, and subcallosal parolfactory areas, corresponding at least in part to BA 23–26, 29–33.

These five paralimbic regions form an uninterrupted girdle surrounding the medial and basal aspects of the cerebral hemispheres. The olfactory piriform cortex provides the allocortical nidus for the orbitofrontal, insular, and temporopolar paralimbic areas. These are designated olfactocentric paralimbic formations. The hippocampus and its supracallosal rudiment (known as the induseum griseum) provide the allocortical nidus for the cingulate and parahippocampal areas. These are designated hippocampocentric paralimbic formations. The olfactocentric and hippocampocentric sectors of the paralimbic belt merge into each other within the subcallosal, medial orbitofrontal and anterior parahippocampal cortices.

C. Homotypical Association Isocortex (the Heteromodal and Unimodal Zones)

By far the greatest area of the cerebral cortex in the human brain is devoted to six-layered homotypical isocortex (or neocortex), also known as association isocortex. Association isocortex can be subdivided into two major zones: modality-specific (unimodal) and high-order (heteromodal). Unimodal sensory association areas are further divided into *upstream* and *downstream* components: Upstream areas are only one synapse away from the relevant primary sensory area, whereas downstream areas are at a distance of two or more synapses from the corresponding primary area. Unimodal sensory association isocortex is defined by three essential characteristics:

1. The constituent neurons respond predominantly, if not exclusively, to stimulation in only a single sensory modality.
2. The predominant sensory information comes from the primary sensory cortex and other unimodal regions of that same modality.
3. Lesions yield deficits only in tasks guided by that modality.

Unimodal visual association cortex can be divided into an upstream peristriate component that includes areas BA 18 and 19 and a downstream temporal component that includes inferotemporal cortex (BA 20 and 21) in the monkey and the fusiform, inferior temporal, and probably parts of the middle temporal gyri in the human. *Unimodal auditory association cortex* covers the superior temporal gyrus (BA 22) and perhaps also parts of the middle temporal gyrus (BA 21) in the human. The connectivity of the monkey brain suggests that the posterior part of the superior temporal cortex (BA 22) displays the properties of upstream auditory association cortex, whereas the more anterior part of this gyrus and the dorsal banks of the superior temporal sulcus may fit the designation of downstream auditory association cortex.

In the monkey brain, BA 5 in the superior parietal lobule represents an upstream component of *somatosensory unimodal association cortex*, whereas parts of BA 7b in the inferior parietal lobule and the posterior insula may represent its downstream components. In the human, unimodal somatosensory association cortex may include parts of BA 5 and BA 7 in the superior parietal lobule and perhaps parts of BA 40 in the anterior parts of the inferior parietal lobule. The subdivision of unimodal auditory and somatosensory association cortices into upstream and downstream areas in the human remains to be elucidated. Unimodal association areas for olfaction, taste, and vestibular sensation have not been fully characterized. Premotor regions (BA 6, the frontal eye fields, and BA 44) fulfill the role of motor ''association'' areas because they provide the principal cortical input into primary motor cortex.

The heteromodal component of association isocortex is identified by the following characteristics:

1. Neuronal responses are not confined to any single sensory modality.
2. The predominant sensory inputs come from unimodal areas in multiple modalities and from other heteromodal areas.
3. Deficits resulting from lesions in these areas are always multimodal and never confined to tasks under the guidance of a single modality.

Some neurons in heteromodal association areas respond to stimulation in more than one modality, indicating the presence of direct multimodal convergence. More commonly, however, there is an admixture of neurons with different preferred modalities. Many neurons have sensory as well as motor contingencies; others change firing in ways that are responsive to motivational relevance. Defined in this fashion, heteromodal cortex includes the types of regions that have been designated as high-order association cortex, polymodal cortex, multimodal cortex, polysensory areas, and supramodal cortex. The monkey brain contains heteromodal areas in prefrontal cortex (BA 9, 10, 45, 46, anterior BA 8, and anterior BA 11 and 12), the inferior parietal lobule (parts of BA 7), lateral temporal cortex within the banks of the superior temporal sulcus (junction of BA 22 with BA 21), and the parahippocampal region. In the human brain, it is reasonable to assume that the analogous zones of heteromodal cortex are located in prefrontal cortex (BA 9 and 10 and 45–47, anterior 11 and 12, and anterior 8), posterior parietal cortex (posterior BA 7 and 39 and 40), lateral temporal cortex (including parts of BA 37 and BA 21 in the middle temporal gyrus), and portions of the parahippocampal gyrus (parts of BA 36 and 37).

Unimodal and heteromodal areas are characterized by a six-layered homotypical architecture. There are some relatively subtle architectonic differences between unimodal and heteromodal areas. In general, the unimodal areas have a more differentiated organization, especially with respect to sublamination in layers III and V, columnarization in layer III, and more extensive granularization in layers IV and II. On these architectonic grounds, it appears that heteromodal cortex is closer in structure to paralimbic cortex and that it provides a stage of cytoarchitectonic differentiation intercalated between paralimbic and unimodal areas.

D. Idiotypic Cortex (the Primary Sensory–Motor Zones)

Primary visual, auditory, somatosensory, and motor cortices are easily delineated on cytoarchitectonic and functional grounds. Primary visual cortex (also

known as V1, striate cortex, calcarine cortex, or BA 17) covers the banks of the calcarine fissure, primary auditory cortex (also known as A1 or BA 41 and 42) covers Heschl's gyrus on the floor of the Sylvian cistern, primary somatosensory cortex (also known as S1, usually meant to include BA 3a, 3b, 1, and 2) is located in the postcentral gyrus, and primary motor cortex (also known as M1) includes BA 4 and probably also a posterior rim of BA 6 in the precentral gyrus.

There are two divergent opinions about these primary areas. One is to consider them as the most elementary (even rudimentary) component of the cerebral cortex; the other is to consider them as its most advanced and highly differentiated component. The latter point of view is supported from the standpoint of cytoarchitectonics. Thus, the primary visual, somatosensory, and auditory cortices display a "koniocortical" architecture representing the highest level of development with respect to granularization, lamination, and columnarization, whereas primary motor cortex displays a unique "macropyramidal" architecture characterized by highly specialized giant pyramidal neurons known as Betz cells.

The visual, auditory, and somatosensory systems provide the major channels of communication with the extrapersonal world. The information transmitted by these channels plays a critical role in shaping the contents of cognition and consciousness. The primary and unimodal areas related to these modalities are cytoarchitectonically highly differentiated and quite large. The vestibular, gustatory, and olfactory sensations do not have the same type of prominence in the primate brain. The corresponding primary areas are cytoarchitectonically less differentiated, smaller, and closer to limbic structures. In the monkey, primary gustatory cortex is located in the frontoinsular junction in BA 43; the primary vestibular area lies within the Sylvian fissure, where the temporal lobe joins the insula and parietal lobe; and the primary olfactory cortex is a core limbic region located at the confluence of the insular, orbitofrontal, and temporopolar areas. The equivalent areas of the human brain have not been fully identified.

II. CORTICAL ORGANIZATION, CONNECTIVITY, AND TRANSMODAL AREAS

The constituents of the limbic zone have the most extensive hypothalamic interconnections. Through neural and also humoral mechanisms, the hypothalamus is in a position to control electrolyte balance, glucose levels, basal temperature, metabolic rate, autonomic tone, hormonal state, sexual phase, circadian oscillations, and immunoregulation and also to modulate the experience and expression of hunger, aggression, fear, flight, thirst, and libido. In keeping with these functions of the hypothalamus, the constituents of the limbic zone (septal nuclei, substantia innominata, amygdala, olfactory complex, and hippocampus) assume pivotal roles in the regulation of memory, emotion, motivation, hormonal balance, and autonomic function. Many of these behavioral affiliations are related to the upkeep of the internal milieu (homeostasis) and the regulation of genetically programmed basic drives.

At the opposite end of this spectrum of cytoarchitectonic differentiation are the highly specialized primary sensory and motor areas. These parts of the cerebral cortex are most closely related to the extrapersonal space: Primary sensory cortex provides an obligatory portal for the entry of information from the environment into cortical circuitry, and primary motor cortex provides a final common pathway for coordinating the motor acts that allow us to manipulate the environment and alter our position within it. Unimodal, heteromodal, and paralimbic cortices are inserted between these two extremes. They provide neural bridges that mediate between the internal and the external worlds so that the needs of the internal milieu are discharged according to the opportunities and restrictions that prevail in the extrapersonal environment. These three intercalated zones enable the associative elaboration of sensory information, its linkage to motor strategies, and the integration of experience with drive, emotion, and autonomic states. The unimodal and heteromodal zones are most closely involved in perceptual elaboration and motor planning, whereas the paralimbic zone plays a critical role in integrating emotion and motivation with action, perception, and learning.

A. Connectivity of the Cerebral Cortex

Components of each functional zone have *extramural* connections with components of other functional zones and *intramural* connections within the same zone. Experimental evidence, obtained mostly from the monkey, shows that the most intense extramural connectivity of an individual cortical area occurs with components of immediately adjacent functional zones as shown in Fig. 2. For example, although all types of

cortical areas, including association isocortex, receive direct hypothalamic projections, such connections reach their highest intensity within components of the limbic zone such as the septal area, the nucleus basalis of the substantia innominata, the amygdaloid complex, piriform cortex, and the hippocampus. In keeping with this organization, a second major source of connections for limbic structures originates in the paralimbic zone. Thus, the amygdala receives one of its most extensive extramural cortical inputs from the insula, the hippocampus from the entorhinal sector of the parahippocampal region, and the piriform cortex as well as the nucleus basalis from the group of olfactocentric paralimbic areas.

An analogous analysis can be extended to the other zones. Paralimbic areas, for example, have the most extensive extramural connections with limbic and heteromodal areas. Furthermore, the most extensive extramural interconnections of heteromodal areas are with components of the paralimbic zone, on the one hand, and with those of the unimodal zone, on the other hand. Finally, the major extramural connections of unimodal areas occur with primary areas, on the one hand, and heteromodal areas, on the other hand, whereas primary areas derive their major inputs from unimodal areas and the external world. Although some connections cross functional levels, they are not as prominent as those that link two immediately adjacent levels. Thus, the amygdala is known to have monosynaptic connections with unimodal association isocortex and even primary visual cortex, but these are not nearly as substantial as its connections with the hypothalamus and paralimbic regions.

Many cortical areas also have intramural cortical connections within their own functional zones. These are extremely well developed within the limbic, paralimbic and heteromodal zones. In contrast, the intramural connections of primary sensorimotor and upstream unimodal sensory association areas have a particularly restricted distribution. Upstream unimodal association areas in different modalities, for example, have no interconnections with each other. Except for the connection from primary somatosensory to primary motor cortex, there are also no neural projections interconnecting primary areas in different modalities. It therefore appears that there is a premium on channel width within the limbic, paralimbic, and heteromodal regions of the cerebral cortex, whereas the emphasis is on fidelity within the upstream unimodal and primary sensorimotor areas.

B. Intermediary Processing and Transmodal Areas

A fundamental characteristic of the primate brain is the insertion of obligatory synaptic relays between sensation and action and also between the representation of the internal milieu (at the level of the hypothalamus) and that of the external world (at the level of primary sensorimotor cortex). These intercalated synaptic relays collectively provide the substrates for "intermediary" or "integrative" processing. The psychological outcomes of intermediary processing are known as "cognition," "consciousness," and "comportment" and include the diverse manifestations of memory, emotion, attention, language, planning, judgment, insight, and thought. Intermediary processing has a dual purpose. First, it protects channels of sensory input and motor output from being dominated by the emotional and motivational imperatives of the internal milieu. Second, it enables identical stimuli to trigger different responses depending on situational context, past experience, present needs, and contemplated consequences. The neurons that support intermediary processing are located within the unimodal, heteromodal, paralimbic, and limbic zones of the cerebral cortex.

The synaptic architecture of intermediary processing shapes the nature of cognition, comportment, and consciousness. In species with simpler brains, intermediary processing is shallow and does not allow much of a distinction to be made between appearance and significance. The automatic linkage between stimulus and response in such species leads to the many manifestations of instinctual behaviors. A major role of intermediary processing is to transcend inflexible stimulus–response linkages and to enable behavior to be guided by contextual significance rather than appearance.

Unimodal areas contain the initial synaptic relays for the intermediary processing of information emanating from the extrapersonal space. These areas are extremely well developed in the human brain. The absence of interconnections linking a unimodal area in one sensory modality with another in a different modality protects the sensory fidelity of experience and delays cross-modal contamination until further encoding has been accomplished. Unimodal areas are in a position to register the most accurate representation of sensory experience. These areas can encode the perceptual characteristics of specific sensory events, determine if the sensory features of complex entities such as words or faces are identical or not, and even

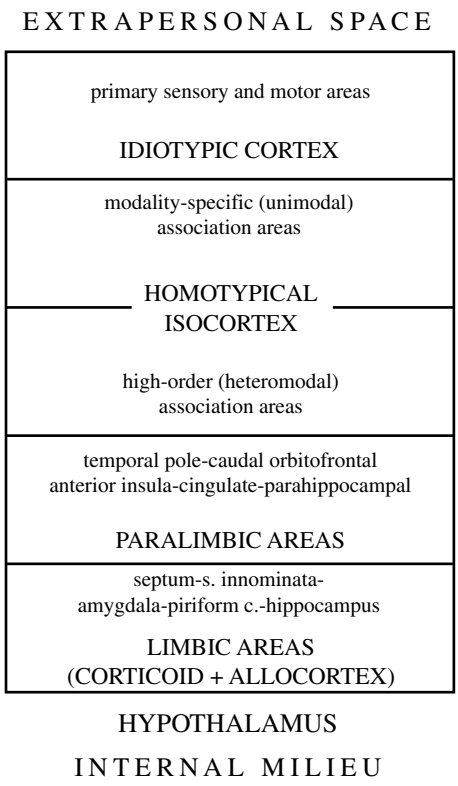

Figure 2 Functional zones of the cerebral cortex.

store all the necessary information in stable memory traces. However, in the absence of access to information in other modalities, unimodal areas do not have the ability to lead from word to meaning, from physiognomy to facial recognition, or from isolated sensory events to coherent experiences. Such integration of sensation into cognition necessitates the participation of *transmodal* areas.

The defining feature of a transmodal area is the ability to support cross-modal integration and, thus, a lack of specificity for any single modality of sensory processing. All components of heteromodal, paralimbic, and limbic zones are therefore also transmodal. A precise localization of transmodal areas became possible initially through the tracing of corticocortical connections in the monkey brain with the use of axonal degeneration methods. Experiments based on this methodology revealed hierarchically organized sets of pathways for linking sensory cortices to primary, secondary, and sometimes even tertiary modality-specific association areas, which in turn sent convergent projections to heteromodal sensory association zones.

The field of neuroscience had been primed to anticipate such a sequential organization through the work of David Hubel and Torsten Wiesel, who had demonstrated a hierarchy of simple, complex, and hypercomplex neurons in primary visual cortex, each successive level encoding a more composite aspect of visual information. The pattern of corticocortical connections in association cortex seemed to be extending this serial and convergent organization from the realms of sensation to those of cognition. A great deal of emphasis was placed on the pivotal role of multimodal convergence in all aspects of mental function, including the storage of memories, the formation of concepts, and the acquisition of language.

Although the importance of serial processing and multimodal convergence to cognitive function was widely accepted, some potentially serious computational limitations of such an arrangement were also acknowledged. Two of these objections are particularly relevant. First, if knowledge of α is to be encoded in convergent form by a small number of neurons, the brain would have to resolve the cumbersome problem of conveying α-related information in all relevant modalities to the one highly specific address where this convergent synthesis is located. Second, the modality-specific attributes of α would succumb to cross-modal contamination during the process of convergence and the sensory fidelity of the experience would be lost. This second circumstance can be likened to the mixing of yellow and blue to obtain green, a process that precludes the subsequent extraction of the original hues from the resultant mixture.

The surfacing of these concerns coincided with the development of newer and more powerful neuroanatomical methods based on the intraaxonal transport of horseradish peroxidase and tritiated amino acids. Experiments based on these methods started to show that the sensory-fugal flow of information was more complicated than previously surmised: There was a central thread of serial processing from one synaptic level to another, but there were also multiple parallel pathways, feedforward and feedback connections, and multiple sites for divergence and convergence. The synaptic templates based on this type of connectivity appeared to have much greater computational power. The objections to the convergent encoding of knowledge, for example, could be addressed by assuming that the principal role of transmodal areas is to create directories for linking (rather than mixing) modality-specific fragments of information into coherent experiences, memories, and thoughts. This alternative

process can be likened to obtaining green by superimposing a blue lens and a yellow lens that can then be separated from each other to yield the original uncontaminated colors. Transmodal areas appeared to fulfill two functions: (i) the establishment of limited cross-modal associations related to the target event, and (ii) the formation of a directory indicating the distributed components of the related information. Transmodal areas could thus enable the binding of modality-specific information into multimodal representations that protect the fidelity of the initial encoding.

Transmodal areas are not centers for storing convergent knowledge but, rather, critical gateways for integrating and accessing the relevant distributed information. They also provide "neural bottlenecks" in the sense that they constitute regions of maximum vulnerability for lesion-induced deficits in the pertinent cognitive domain. Each transmodal area displays a distinctive profile of behavioral specializations that is determined by its overall pattern of neural connections and physiological characteristics. For example, midtemporal cortex plays the role of a pivotal transmodal gateway for face and object recognition, Wernicke's area for lexical labeling, the hippocampoentorhinal complex for explicit memory, prefrontal cortex for working memory, the amygdala for emotion, and dorsal parietal cortex for spatial attention.

III. CHANNEL FUNCTIONS AND STATE FUNCTIONS

Many axonal pathways that interconnect one cortical area with another (or with specific sectors of the basal ganglia and thalamus) are organized in the form of reciprocal point-to-point *channels* where the principal sites of origin and the major fields of termination are of approximately equivalent size. This point-to-point connectivity provides the basic anatomical substrate of specific *channel functions*. Damage to channels such as the splenium of the corpus callosum, the frontotemporal uncinate fasciculus, or the insuloamygdaloid pathway leads to specific impairments such as pure alexia, amnesia, and asymbolia for pain. In addition to these point-to-point channels, each cortical area also receives diffuse modulatory connections. These pathways employ small amines as transmitters and determine the overall *state* of information processing rather than the contents of the information that is being transmitted along the point-to-point channels. These modulatory pathways play important roles in coordinating behavioral states related to arousal, attention, mood, and motivation. At least six such pathways can be identified in the primate brain. Five of these reach the cerebral cortex directly without a thalamic relay, whereas the sixth is relayed through the thalamus:

1. Cholinergic and GABAergic projections from the basal forebrain to the cerebral cortex
2. Histaminergic projections from the lateral and medial hypothalamus to the cerebral cortex
3. Serotonergic projections from the brain stem raphe nuclei to the cerebral cortex
4. Noradrenergic projections from the nucleus locus coeruleus to the cerebral cortex
5. Dopaminergic projections from the substantia nigra and the ventral tegmental area of Tsai to the cerebral cortex
6. Cholinergic projections from the brain stem reticular formation to the thalamus

Each of these modulatory pathways is organized in such a way that a relatively small group of neurons can induce rapid modulations in the information processing state of the entire cerebral cortex. The cholinergic projection from the brain stem to the thalamus, for example, promotes arousal by facilitating the transthalamic passage of sensory information toward the cerebral cortex. The other five modulatory pathways have direct access to the cerebral cortex without any thalamic relay. Each of these pathways displays a slightly different pattern of cortical distribution and physiological specialization.

The cholinergic innervation of the cerebral cortex arises predominantly from the nucleus basalis of the substantia innominata. The neurons of this nucleus are particularly responsive to novel and motivationally relevant sensory events. The major effect of acetylcholine on neurons of the cerebral cortex is mediated through the m1 subtype of muscarinic receptors and causes a prolonged reduction of potassium conductance so as to make cortical neurons more receptive to other excitatory inputs. Cortical cholinergic pathways also promote electroencephalograph desynchronization, long-term potentiation, and experience-induced synaptic remodeling. The ascending cholinergic pathway from the basal forebrain is therefore in a position to enhance the immediate neural impact and long-term memorability of motivationally relevant events. The nucleus basalis also gives rise to a GABAergic projection directed to the cerebral cortex. At least in

the rat, this pathway innervates inhibitory cortical interneurons but its functional specializations remain poorly understood.

The noradrenergic innervation of the cerebral cortex arises from the nucleus locus coeruleus. The neurons of this nucleus are particularly responsive to the motivational relevance of a stimulus. Neocortical norepinephrine increases the signal-to-noise ratio and timing precision of cortical neurons in a way that enhances the specificity of neural responses to significant sensory events.

The dopaminergic projections of the cerebral cortex arise from the substantia nigra and ventral tegmental area of Tsai. These dopaminergic cells are selectively responsive to motivationally relevant stimuli and to cues that signal their existence. In keeping with these characteristics, the dopaminergic projections from the ventral tegmental area to the cerebral cortex and nucleus accumbens appear to play an important role in mediating the neural processes related to substance addiction. Furthermore, both dopamine and acetylcholine promote cortical responses related to working memory.

The serotonergic projection to the cerebral cortex arises from the brain stem raphe nuclei. The electrical stimulation of these neurons can induce an arousal-related pattern of low-voltage fast activity in the cerebral cortex. Serotonin also appears to modulate the sensory gating of behaviorally relevant cues in the environment. The hypothalamus is the source of histaminergic projections to the cerebral cortex. Histamine receptors are widely distributed throughout the cerebral cortex and have been implicated in the regulation of cortical arousal, energy metabolism, autonomic function, and sensitivity to pain.

One anatomical feature common to all of these modulatory corticopetal projections is the absence of equally well-developed reciprocal projections from the cerebral cortex. The nucleus basalis, for example, projects to all parts of the cerebral cortex but receives cortical projections from only a handful of limbic and paralimbic areas. The other cortically projecting cell groups also receive sparse cortical projections, most of which come from limbic and paralimbic areas. This asymmetry of corticofugal versus corticopetal connections allows the neurons of the basal forebrain, substantia nigra–ventral tegmental area, brain stem raphe, and nucleus locus coeruleus to rapidly shift information processing states throughout the cerebral cortex in a way that is responsive primarily to the demands of the limbic system and internal milieu, with relatively little intervention from feedback loops emanating from heteromodal, unimodal, and primary cortices.

Many psychiatric diseases, including mania, depression, paranoia, obsessive–compulsive disorders, and chronic anxiety, are characterized by pathological biases in the interpretation of events and experiences. When compared to control subjects, for example, patients with generalized anxiety disorder show greater metabolic activation of temporal and frontal cortex during the passive viewing of neutral stimuli. Such altered responses, even to neutral stimuli, may indicate the existence of a fundamental processing state abnormality that biases the impact of experience. Indirect evidence based on the pharmacological treatment of depression and anxiety with noradrenergic and serotonergic agents and of paranoia with dopamine blockers suggests that the modulatory pathways of the cerebral cortex may play important roles in setting such fixed attitudinal biases in the processing of sensory experience.

It is unlikely that there will be a one-to-one relationship between any of these modulatory pathways and specific cognitive or comportmental domains. In general, however, the activation of these modulatory pathways provides a mechanism for augmenting the neural responses to novel and motivationally relevant events, facilitating their storage in memory, enhancing their access to on-line processing resources, sharpening the attentional focusing they elicit, and increasing their impact on consciousness. These projections are in a position to alter the tone, coloring, and interpretation of experience rather than its content. In addition to cholinergic and monoaminergic receptors, many areas of the cerebral cortex, especially components of the limbic system, also contain receptors for estrogen, testosterone, and other steroids. Alterations in the circulating level of these hormones, as in puberty or menopause, could influence behavioral states in a manner analogous to the effect of the modulatory projection systems.

The modulatory projections reviewed here are part of the ascending reticular activating system. These pathways highlight the multiple factors that contribute to the neural control of cognition, comportment, and consciousness. Language, spatial orientation, attention, memory, and emotion are all subserved by large-scale networks that contain multiple point-to-point channels. These pathways encode the perceptual, motor, visceral, and affective components of the relevant behavior and the way in which these components are interlinked. The modulatory pathways influence the processing states within which these

domain-specific channels function. In the course of remembering, for example, the content of what is recalled is determined primarily by the information that flows along the point-to-point sensory–limbic interconnections. On the other hand, the speed and efficiency of the recall, and perhaps the perspective from which the information is interpreted, may be regulated by the activity of the modulatory pathways that innervate the relevant regions of limbic and association cortex. In the realm of emotion, the linkage of a specific thought or event with a specific feeling and visceral state is determined by the point-to-point projections of the amygdala and related limbic structures, whereas the intensity of the emotion and its influence on other aspects of mental activity may be determined by the modulatory pathways. Among all the complex factors involved in the neural control of comportment and cognition, those that represent the contributions of these modulatory pathways are the most accessible to therapeutic manipulation by existing pharmacological agents.

IV. DISTRIBUTED LARGE-SCALE NETWORKS AND THEIR EPICENTERS

Transmodal nodes in midtemporal cortex, Wernicke's area, posterior parietal cortex, prefrontal cortex, amygdala, and the hippocampoentorhinal complex link distributed information into coherent multimodal assemblies necessary for face and object recognition, naming, working memory, spatial attention, emotional channeling, and explicit memory. These transmodal areas provide the cortical epicenters of large-scale distributed networks.

The pattern of connectivity summarized in Fig. 3 is based on anatomical experiments related to the network for spatial attention in the monkey and may reflect an organization that is common to all large-scale networks. In Fig. 3, A and B represent two interconnected epicenters of any large-scale neural network. They could represent the frontal eye fields and posterior parietal cortex in the network for spatial attention, midtemporal and temporopolar cortices in the network for face and object recognition, the amygdala and the hippocampoentorhinal complex in the emotion/memory network, Wernicke's area and Broca's area in the language network, and prefrontal cortex and posterior parietal cortex in the working memory/executive function network. Axonal transport experiments in the spatial attention network of the monkey indicate that if one member of such a pair, for example, A, is interconnected with additional cortical areas such as 1–3, then B is also interconnected with the same three cortical areas. Consequently, if A transmits a message, B will receive it directly but also through the alternative vantage points provided by areas 1–3. This arrangement enables parallel processing and contains multiple nodes where transitions

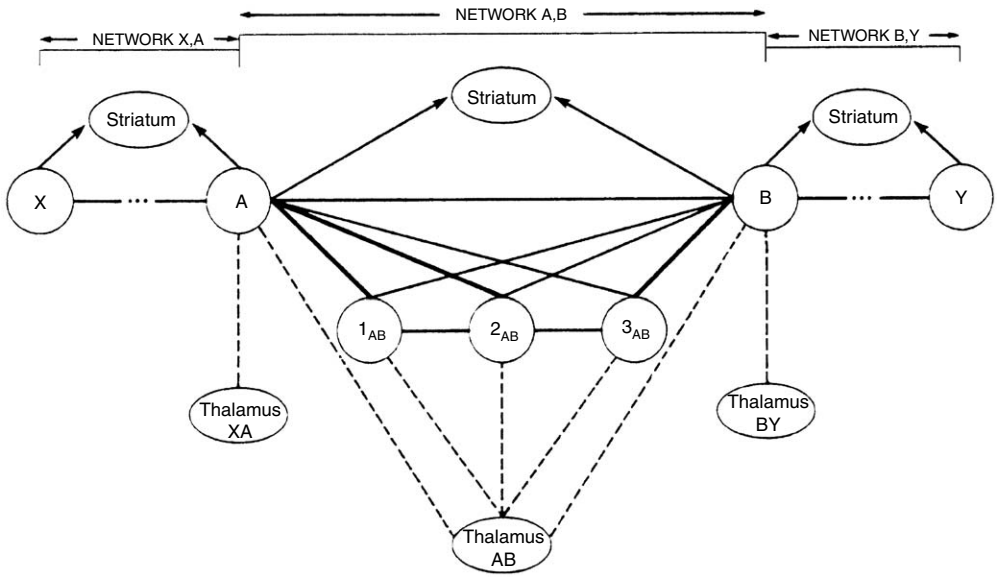

Figure 3 General organizational principles of large-scale neurocognitive networks.

between parallel and serial processing can occur. In resolving a complex cognitive problem such as reconstructing a past memory, selecting words to express a thought, or figuring out the identity of a face, a set of cortical areas interconnected in this fashion can execute an extremely rapid survey of a vast informational landscape while considering numerous goals, constraints, scenarios, and hypotheses until the entire system settles into a state of least conflict that becomes identified as the solution to the cognitive problem.

Because cortical areas tend to have very extensive corticocortical projections, individual sectors of association cortex are likely to belong to multiple intersecting networks. With rare exceptions, however, thalamic subnuclei have almost no connections among each other and some thalamic subnuclei can project to both epicenters of an individual large-scale neural network. Thalamic subnuclei can thus fulfill the very important role of setting coactivation boundaries for individual networks. Neuroanatomical experiments have shown that interconnected cortical areas are likely to send interdigitating projections to the striatum. Since the striatum receives cortical inputs but does not project back to the cerebral cortex, it could serve the role of an efference synchronizer (or filter) for coordinating the outputs of cortical areas in a given network. The human brain contains at least the following five large-scale neurocognitive networks that follow these principles of organization:

1. Dorsal parietofrontal network for spatial orientation: The cortices around the intraparietal sulcus and the frontal eye fields constitute the two major interconnected epicenters. The parietal component displays a relative specialization for the perceptual representation of salient events and their transformation into targets for attentional behaviors, and the frontal component displays a relative specialization for choosing and sequencing exploratory and orienting movements. Additional critical components are located in the cingulate gyrus, striatum, and thalamus. Damage to this network yields deficits of spatial attention and exploration such as contralesional hemispatial neglect, simultanagnosia, and other manifestations of spatial disorientation. Contralesional neglect occurs almost exclusively after right-sided damage to this network, whereas simultanagnosia tends to arise after bilateral lesions.

2. Limbic network for memory and emotion: The hippocampoentorhinal complex and the amygdala constitute the two interconnected epicenters. The former displays a relative specialization for memory and learning and the latter for drive, emotion, and visceral tone. Additional critical components are located in the paralimbic cortices, the hypothalamus, the limbic thalamus, and the limbic striatum. Damage to this network yields deficits of memory, emotion, affiliative behaviors, and autonomic regulation. Severe deficits usually occur only after bilateral lesions. Occasionally, unilateral left-sided lesions give rise to a multimodal amnesia but this is transient. Frequently, unilateral lesions in the left give rise to prominent deficits of verbal memory, whereas unilateral lesions on the right give rise to nonverbal memory deficits that are usually quite mild.

3. Perisylvian network for language: The two epicenters of this network are known as Broca's area and Wernicke's area. Broca's area includes the premotor region BA 44 and the adjacent heteromodal fields of BA 45–47; Wernicke's area includes the posterior part of auditory association cortex in BA 22 and also adjacent heteromodal fields in BA 39–40 and BA 21. Broca's area displays a relative specialization for the articulatory, syntactic, and grammatical aspects of language, whereas Wernicke's area displays a specialization for the lexical and semantic aspects. Additional components of this network are located in the striatum, thalamus, and the association areas of the frontal, temporal, and parietal lobes. Damage to this network yields aphasia, alexia, and agraphia. Such deficits are seen only after damage to the left hemisphere in the majority of the population.

4. Ventral occipitotemporal network for object recognition: The middle temporal gyrus and the temporal pole appear to contain the transmodal epicenters for this network. Additional critical components are located in the fusiform gyrus and inferior temporal gyrus. Damage to this network yields recognition deficits such as object agnosia and prosopagnosia. The lesions that cause such deficits are almost always bilateral. The fusiform gyrus is the most common site of lesions, probably because it is the only part of this network with a vascular supply that makes bilateral damage likely. Occasionally, unilateral left-sided lesions can lead to object agnosia and unilateral right-sided lesions to prosopagnosia.

5. Prefrontal network for executive function and comportment: Prefrontal heteromodal cortex and orbitofrontal cortex are the major cortical epicenters involved in the coordination of comportment, working memory, and related executive functions. The head of the caudate nucleus and the mediodorsal nucleus of the thalamus constitute additional critical components. Deficits of comportment are frequently associated

with lesions of orbitofrontal and adjacent medial frontal cortex, whereas deficits of executive function and working memory are frequently associated with damage to dorsolateral prefrontal cortex. Clinically significant deficits are usually seen only after bilateral lesions. Occasionally, unilateral left-sided lesions give rise to a syndrome of abulia, whereas unilateral right-sided lesions give rise to behavioral disinhibition.

Neuroanatomical experiments in the homologous regions of the monkey brain have shown that the components of these five networks are interconnected according to the pattern shown in Fig. 3. As noted previously, each of these networks receives its sensory information from a common set of unimodal cortical areas. The differences in the resultant cognitive functions are determined by the anatomical location and specializations of the relevant transmodal epicenters. The large-scale network approach predicts that many, if not all, network components will be activated in concert during the performance of any task in a given cognitive domain. In keeping with this prediction, tasks related to spatial awareness, language, working memory, explicit memory, and object identification in human subjects have led to the collective activation of the relevant epicenters noted previously. Functional imaging experiments cannot yet determine whether all network components are activated simultaneously or if the temporal sequence of activation varies according to the nature of the task. Such questions can be addressed by combining functional imaging with event-related potentials.

Large-scale neural networks are organized according to the principles of selectively distributed processing. For example, Wernicke's area occupies the lexical/semantic pole of the language network but also participates in articulation and syntax, whereas Broca's area occupies the articulatory/syntactic pole of the network but also participates in phonological discrimination and lexical access. In the case of spatial attention, the frontal eye fields occupy the motor/exploratory pole of the relevant network but also participate in the compilation of perceptual representations, whereas posterior parietal cortex occupies the sensory/representational pole but also participates in the programming of exploratory movements. In the limbic network, the hippocampal complex is most closely related to explicit memory but also plays a role in emotional modulation, whereas the amygdaloid complex is most closely related to emotional modulation but also participates in the encoding of emotionally salient memories. This organization promotes flexibility without sacrificing regional functional segregation.

At least two levels of connectivity contribute to the functional organization of neurocognitive networks. At one level, genetically encoded and relatively fixed axonal connections specify the type of information that a given region will process. These connections determine the location and functional specialization of network components. At a second level, experience-induced modifications of synaptic strengths enable the gradual accumulation of an experiential base that is unique for each individual. This process is known as neuroplasticity. Although we tend to think of plasticity as a phenomenon confined to early development, dendritic and axonal remodeling occurs throughout life and allows each individual brain to establish new associations, adapt to new situations, and compensate for biological attrition. A deeper understanding of these more dynamic aspects of brain structure is a major goal of behavioral neuroscience.

Brain Damage, Recovery from

PAUL BACH-Y-RITA
University of Wisconsin, Madison

GLOSSARY

brain plasticity The adaptive capacities of the brain; its ability to modify its own structure, e.g., organization and functioning.

nonsynaptic diffusion neurotransmission The diffusion through the extracellular fluid of neurotransmitters released at points that may be remote from the target cells, with the resulting activation of extrasynaptic receptors.

late brain reorganization Changes in sensory and motor representation, as well as other cerebral functions, that occur 2 or more years after damage to the brain.

functional rehabilitation Rehabilitation programs for persons with brain damage that are based on motivating activities relating to real-life activities.

receptor plasticity The up- and downregulation of synaptic and/or nonsynaptic neurotransmitter receptors, such as those on the neuron or glia surface.

There is generally at least some recovery after the brain is damaged. Various mechanisms contribute to early and late reorganization of the brain. Much of the recovery, which is maximized by appropriate rehabilitation, occurs within months of the damage, but functional gains can be obtained even many years after the damage has occurred. The degree of recovery depends on many factors, including age, the brain area and amount of tissue damaged, the rapidity of the damage, the brain's mechanisms of functional reorganization, and environmental and psychosocial factors. If recovery is not expected or sought with the active participation of the disabled person, little recovery is obtained.

I. BRAIN REORGANIZATION

The brain can reorganize on the basis of the structures that remain after brain damage, possibly mobilizing mechanisms such as unmasking of previously present but relatively "weak" neural paths, neuronal sprouting, and the up- and downregulation of receptors at synaptic and nonsynaptic sites. Both human and animal studies have demonstrated mechanisms of brain plasticity and the reorganization of function following brain damage. A *Science* Research News article noted that "a striking body of recent work suggests that the adult brain can reorganize itself in areas that were long thought to be completely 'hardwired.'"

The neurosciences have in general been descriptive and have been influenced primarily by concepts of strict localization of function in the brain, the synapse as the only important means of cell-to-cell communication, and the irreversibility (beyond a certain period of time) of functional deficits produced by brain damage. Until recently, evidence supporting plasticity was generally ignored, and plasticity concepts had little effect on the development of clinical procedures. The functional results of ablating some area of cortex, or of eliminating some sensory input, have been interpreted as meaning that that particular part of the cortex is essential for a particular function, or that particular sensory input is required during a particular

developmental stage for a particular function to develop.

Although such studies are necessary for an understanding of the baseline functions of the central nervous system, the following is the critical plasticity-related question: What is the reorganization capacity of the central nervous system (or some particular subset of it)? When faced with the evidence that a particular type of brain injury ''permanently'' eliminates some function, a brain plasticity-influenced approach is to ask the following: What can be done to reorganize the remainder of the brain to enable that function to be regained? Examples of this include the bilateral motor control that can be developed following hemispherctomy and the recovery from facial paralysis that can be obtained with appropriate rehabilitation even many years after the causative event. In the absence of a particular sensory input (e.g., vision through the eyes), what can be done to enable the brain to interpret comparable information (e.g., vision through a tactile vision substitution system using nonvisual pathways to the brain and nonvisual cortex structures to receive the sensory projection)? Not only experimental evidence but also clinical observations can be interpreted within the framework of brain plasticity only when plasticity is part of the conceptual substance of the neurosciences.

Although brain plasticity is generally positive for recovery, some negative effects, such as the development of spasticity and kindling causing epilepsy, can occur. Furthermore, the presence of mechanisms for plasticity does not automatically lead to recovery of function; appropriate rehabilitation and the appropriate physical and psychosocial environments can play decisive roles in the reorganization.

Rehabilitation and the developmental learning process have some aspects in common. Both include important elements of inhibition in regard to selective function and precisely coordinated movements. For example, a child learning to write initially demonstrates electromyographic activity in virtually all the muscles related to the hand. As ability increases, muscle activity decreases progressively until there is a minimum of activity, which is coordinated precisely to produce just the muscle action necessary for writing. It then becomes virtually fatigue-free. Following brain damage, coordinated movements are often disturbed. Patients become fatigued when attempting controlled movements; rehabilitation is then oriented toward the restoration of precise, fatigue-free movements. Comparably, reflexes that are normal shortly after birth (e.g., Babinski's) are inhibited during maturation and can reappear following brain damage. Studies on unmasking may relate to the balance of excitation and inhibition and may involve increased excitability of surviving neural connections following the loss of some inputs due to neural damage.

Most brain-damaged patients receive rehabilitation during a stage in which they would have demonstrated some spontaneous recovery even in the absence of specific rehabilitation, especially if some of the complications had been prevented (e.g., passive movements to prevent contractures, which may have been an important factor in the remarkable recovery in a series of monkey decortication experiments). Therefore, in addition to the difficulties caused by the absence of accurate and reliable functional assessment methodologies, it is difficult to accurately quantify the effect of an early rehabilitation program since its results are achieved simultaneously with the spontaneous recovery. Brain reorganization associated with rehabilitation can be demonstrated with models of late rehabilitation. Both animal and human models have been developed to evaluate functional recovery.

A. Postulated Mechanisms of Reorganization of Function

Undoubtedly, many mechanisms intervene in the reorganization following damage to the brain. In the first stages, it is likely that surviving cells that have been totally or partially denervated may have one or more of three responses: (i) the ''strengthening'' of synapses from secondary connections (unmasking); (ii) the development of extrasynaptic receptors on the membrane of the surviving cells, which respond by means of nonsynaptic diffusion neurotransmission (NDN) mechanisms; and (iii) receptor development related to the new synapses formed by the sprouting of processes from surviving cells. The contributions of stem cells and neurogenesis have yet to be evaluated, but exciting recent findings open the possibility that they may contribute to functional recovery.

Some mechanisms of brain reorganization are briefly discussed in the following sections. Some may be active in both early and late reorganization.

1. Multiplexing and Unmasking

Multiplexing in the brain consists of the multiple uses of neurons and fibers so that they participate in various functions. Many studies have demonstrated multiple sensory and motor representations of a single brain

region and overlap of representation. This may provide the neural substrates for plastic changes with training. Individual neurons in the brain, such as in the nucleus pontis oralis, can respond to many types of sensory stimuli, and there is evidence that activity produced by one input affects the responses to the other potential inputs. It may be a mechanism for minimizing the number of cells needed and may relate to a proposed law of the conservation of space and energy in the brain. Individual somatosensory neurons in the cortex also have the potential to respond to a wide array of inputs from widespread surfaces on the skin. The rapidly occurring changes in the functional topography of the cortex have been proposed to be mediated by the unmasking of the latent excitatory connections via inhibition of local inhibitory synapses. It has been proposed that injury initiates rapid, concurrent, consistent, and reiterative changes in brain stem and cortical maps, and that changes in thalamic maps may also occur.

The role of unmasking may be of considerable importance in functional reorganization. A series of studies have demonstrated the unmasking of normally ineffective connections that may become active if the dominant inputs are put out of action. In one study, peripheral nerves were cut, removing the normal sensory input to a population of spinal cord cells, without anatomical evidence of degeneration or vacated synaptic sites. Large numbers of cells in a region of the cord that were normally dominated by afferents from the foot and toes began to respond to other areas of the leg days or weeks after section of the peripheral axons that previously supplied their excitatory drive. Comparable changes have been demonstrated in monkey somatosensory cortex following restricted deafferentation. Specific finger exploratory training of monkeys produces a marked increase in the cortical sensory representation of the fingers used for the haptic exploration, which appears to indicate the unmasking of previously existing connectivity. That study also reinforces the concept of overlapping representation; other studies have shown that in monkeys the territories controlling different fingers overlap. Control of any finger movement appears to utilize a population of neurons distributed throughout the M1 hand area rather than a somatotopically segregated population. Human functional magnetic resonance imaging studies have strongly suggested that in the primary hand region around the central sulcus, the same neuronal population is active in the three tasks studied (active finger apposition, texture on fingers, and haptic exploration).

The unmasking-related reorganization can be practically instantaneous. During temporary altered sensory input, the injection of local anesthetic into the receptive fields of neurons of the dorsal column neurons uncovered new receptor fields that emerged within minutes, probably due to the unmasking of previously ineffective inputs. Another of the important studies of unmasking demonstrated cortical plasticity related to training: Both blind and sighted persons reading Braille had expanded sensorimotor cortical representation of the reading finger, and cortical representation is affected by learning to play the piano. One of the most dramatic examples showed that after limited sensory deafferentation in adult primates, somatosensory cortical maps reorganize, over a period of years, over distances previously thought to be impossible (more than 1 cm).

Interesting direct evidence for the unmasking of pathways in monkeys has been provided by a study of monkeys that had spent the first year of life with the eyelids sutured. Microelectrode studies of cells in area 19 revealed that 20% of the cells responded to somesthetic stimuli, whereas in the normal monkey no somesthetic responses are recorded. It had previously been shown that almost half of the visual cortical cells that responded to visual stimuli also responded to auditory and/or pinprick stimuli, but these nonvisual responses had considerably longer latencies and were easily blocked. In blind persons, the visual cortex is metabolically very active in response to auditory and tactile stimuli: Such activity may represent the unmasking of nonvisual inputs to the visual cortex. The pathways related to those responses may be similar to those unmasked by the lid suture.

Comparable changes may occur following brain damage. A specific human case of recovered function has been interpreted in the context of unmasking: Following brain damage, the unmasking activated previously existent pathways that (previous to the injury) had not had the same relationship to the function. The extensive damage included the destruction of a pyramidal tract that, at autopsy 7 years after the stroke, was composed of scar tissue except for approximately 3% of normal appearing fibers scattered through the scar tissue. The recovery was interpreted in terms of the possible unmasking of pathways to the dendrites of the cells with long pyramidal tract fibers and their axonal ramifications. It is possible that connections to large numbers of motoneurons that had previously been relatively inactive were rendered active, possibly in part due to postinjury receptor plasticity in those motoneurons.

Unmasking can be produced by some pharmacological agents: In cats anesthetized with chloralose, pyramidal stimulation not only increased the size of the cutaneous receptor fields of the recorded cortical neurons but also revealed responsiveness to sensory modalities that did not produce responses in the absence of the pyramidal stimulation. Chloralose increased the size of cortical evoked potentials in zones of sensory convergence, and in primary visual cortex, the activity of cells before, during, and after the administration of thiopental anesthesia increased the receptive fields and types of stimuli to which cells respond. Furthermore, thiopental made previously unreceptive cells respond to visual stimuli. In all these cases, apparently the drugs unmasked pathways that already existed but were either inhibited or were not sufficiently active to elicit responses before drug administration.

2. Nonsynaptic Diffusion Neurotransmission and Receptor Plasticity

A postulated example of this class of responses is the dopamine receptor upregulation that had been demonstrated in human stroke patients following the destruction of dopamine pathways (and the synaptic and nonsynaptic dopamine release sites). Upregulation of receptors may have occurred on the extrasynaptic membrane (comparable to the response noted on denervated muscle fibers) following the loss of those dopamine release sites. This may have led to supersensitivity to the neurotransmitters in the extracellular fluid, with activation by nonsynaptic transmission.

Information in the brain appears to be transmitted both by synaptic connectivity and by NDN. NDN includes the diffusion through the extracellular fluid of neurotransmitters released at points that may be remote from the target cells, with the resulting activation of extrasynaptic receptors. The existence of many receptor subtypes offers the possibility of selective neurotransmission at a distance by NDN.

Individual movements or functions, such as playing the piano or watching a tennis game, require great selectivity, rapid initiation, and rapid ending; for such functions, synaptic action is essential. However, for mass sustained functions (e.g., sleep, mood, and hunger), sustained, widespread activity (rather than speed and selectivity) is required, which may be largely mediated by NDN. Many functions may be produced by combinations of both types of neurotransmission. For example regarding piano playing, in addition to the relevant synaptic mechanisms, the finger movements can be more precise in the presence of adequate preparation including changes in brain tone (probably mediated by noradrenaline). Also, the visual perception of the tennis game may require neuronal receptivity to be set at a high level, probably involving several neurotransmitters, including nitric oxide and dopamine in the retina, serotonin and histamine in the lateral geniculate nucleus, and noradrenaline in the visual cortex. These effects appear to be primarily nonsynaptically mediated. Some of them have been called modulation; the modulation of synaptic activity by diffusion outside the synaptic gap is also a nonsynaptic, diffusion-mediated activity.

NDN can be modeled by students in a university classroom, who can be equated to neurotransmitter molecules in a vesicle. Upon release, they must go to specific other classrooms throughout the campus (receptor sites). They flow out into the halls and the grounds between buildings (extracellular fluid), where they mix with other students (neurotransmitter molecules) from other classrooms (vesicles) going to other target classrooms. They walk (diffuse) to their specific classrooms (receptors), which they enter (bind). In contrast, "synaptic transmission" students would be propelled along enclosed walkways connecting the point-of-origin classroom with each target classroom.

This conceptual model of information transmission in the brain, involving both synaptic transmission and NDN, may have considerable relevance to the functional reorganization following brain damage. Receptor plasticity, both at synapses and on the cell membrane away from synapses (reached by nonsynaptic diffusion neurotransmission), may play a major role in the reorganization of function following brain damage.

NDN may be the principal means of neurotransmission in the noradrenergic system, which is involved in many activities related to recovery from brain damage. Both acetylcholine and norepinephrine can provide a state of excitability consistent with cognition, which is consistent with inhibition of the locus ceruleus activity during lack of vigilance. These findings may directly relate to the results of rehabilitation programs: When vigilance is high and the patient is actively involved in the rehabilitation program, good results are more likely to be obtained. There may also be a relationship to functional rehabilitation programs that are based on the interests of the individual patient and to the positive results obtained with some home programs. In all these cases, the increased vigilance and participation may lead to greater locus ceruleus production of

noradrenaline. This and other neurotransmitter changes may also be mechanisms by which psychosocial factors influence recovery.

In 1949, Hebb developed the concept of brain "cell assembly," which continues to be a major model of brain function. He considered that any frequently repeated particular stimulation will lead to the slow development of a cell assembly, a diffuse structure capable of acting as a closed system. Hebbian cell assemblies consist of enormous numbers of individual cells, with every cell connected to every other cell. With such an architecture, however, the length of the links among cells and the resulting volume of the assembly would easily exceed space constraints. In contrast, a "wireless" mechanism, such as NDN, might be consistent with volume limitations. However, the space and energy considerations in synaptic and nonsynaptic neurotransmission have been calculated, and it has been shown that synaptic connectivity in cell assemblies would be too costly in terms of the metabolic energy and the space required, thus suggesting NDN to be a less expensive means for intercellular communication.

3. Extracellular Space Volume Fraction

The extracellular space in the brain plays a role in many functions, including nonsynaptic diffusion neurotransmission. In an assembly of cells in the brain, the distance between neurons can be reduced by 50% with neuron activity that causes them to swell. This has an effect on the excitability and metabolism of the cells by means of changes in the distance between the neurons, which produces changes in ionic concentrations and dynamics.

Changes in the size of the extracellular compartment [volume fraction (VF)] may play a role in membrane excitability in pathological brain states such as epilepsy, brain damage, and in the survival of partially denervated neurons during the postinjury period of receptor upregulation that can lead to reorganization of brain function by unmasking and other mechanisms. Under pathological conditions such as anoxia, the extracellular VF is reduced; it is also reduced (by up to 50%) in hyperexcitability, by changes in the concentration of potassium, and with epileptiform discharges. However, it is also possible that hyperexcitability due to a VF decrease, either independently or in combination with excitotoxic activity, may increase secondary cell death following brain damage.

4. Reactive Synaptogenesis

The third class of responses to damage, is usually called "sprouting." However, a case can be made for calling this "reactive synaptogenesis" when considering recovery of function. Although reactive synaptogenesis may participate in the recovery of function in some cases, it may also compete with the process of restoration by introducing aberrant connections.

It has been proposed that the takeover of muscle fibers when motor neuron loss occurs, such as in polio, may occur through vestigial pathways since in the embryonic stage the muscle fibers are polyneuronally innervated. Although all connections except those from one motor neuron disappear shortly after birth, vestigial remains of the polyneuronal pathways could conceivably serve as tracks for the growth of pathways from surviving motoneurons to the muscle fibers denervated by the motoneuron loss. If such pathways could be demonstrated in the nerve–muscle fiber preparation (which has served very well as a model of central nervous system nerve–cell connectivity), it would be interesting to consider the implications for central nervous system repair mechanisms. In particular, reactive synaptogenesis would have to be considered in the context of the reestablishment of connections that had existed during an early stage of brain development.

Strong evidence for reactive synaptogenesis associated (with appropriate rehabilitation) with functional recovery has emerged from a series of studies on hemispherectomized cats. Hemishperectomy has also been a model for recovery of function for other animal and human studies since remarkable recoveries have been recorded both in experimental animals and in young and adult humans. The outstanding feature of neonatally and adult lesioned cats was the presence of terminal fields in the nucleus ruber (RN) of both sides. The terminals in the RN contralateral to the cortical injection of radioactive material (leucine–proline) for autoradiographic labeling of pericruciate cortical projections to the RN revealed a normal pattern of new innervation for the RN partially deafferented by the hemispherectomy. Thus, an extensive reorganization of the brain may account for the remarkable recovery of function.

5. Diaschisis

Diaschisis relates recovery of function to the recovery from the neural depression of sites remote from, but connected to, the site of injury. Changes in

neurotransmitter function following injury have been suggested as a mechanism by which diachisis could operate. Following a unilateral sensorimotor cortex injury in rats, a depression in norepinephrine function occurs in the cerebellum contralateral to the lesion at 1 day postinjury. The norepinephrine depression, and the hemiplegia, can be resolved by infusions of norepinephrine into the contralateral, but not the ipsilateral, cerebellum. The recovery is maintained permanently. The anatomical mechanism may be via the simultaneous projection of individual locus coeruleus cells to both the contralateral cerebellum and the ipsilateral sensorimotor cortex. Damage to the sensorimotor cortex also damages fibers to the locus coeruleus, which may shift the body's energy from neurotransmitter production to protein synthesis for repair of the damaged terminal. While the body attempts repair, the undamaged terminals elsewhere (e.g., in cerebellum) may not be not functioning normally. However, long-term mechanisms are also probably involved since crossed-cerebellar inhibition has also been demonstrated in humans several years after brain lesion by positron emission tomography studies.

6. Trophic Factors

Trophic factors such as nerve growth factor have also been shown to be related to cell survival and recovery after brain damage. Transmembrane glycoproteins (e.g., integrins), gangliosides, and putrecine have been suggested to have roles in recovery of function.

7. Synapsins

Changes in synapsins may provide a mechanism for brain plasticity, based on regulation of neurotransmitter release. Synapsins are neuronal phosphoproteins that coat synaptic vesicles and bind to the cytoskeleton. Membrane depolarization and neurotransmitter release have been correlated with phosphorylation of the synapsins. The synapsins, a novel class of actin-binding proteins, are located in the presynaptic nerve terminal and contribute a significant portion of the total synaptic vesicle protein. They may connect synaptic vesicles to each other, to the cytoskeletal, or both, and they may play a role in positioning synaptic vesicles in the nerve terminal, thus regulating transmitter release. Studies on synapsins may form a framework for understanding how these molecules function in organizing presynaptic intracellular space, and they could provide a mechanism for reorganizing function.

8. Parallel and Adjoining Cortical Representation Areas

Parallel motor areas could substitute for lost function in brain-injured persons. In a study of the anatomy of motor recovery assessing motor function in 23 patients following capsular or striatocapsular stroke, small capsular lesions, which can disrupt the output of functionally and anatomically distinct motor areas selectively, were considered to reveal the capability of the different motor pathways to substitute each other functionally in the process of recovery from hemiparesis. Contribution of the undamaged hemisphere to the process of recovery was suggested by both electrophysiological and metabolic studies, mediated by either bilateral pathways or uncrossed or recrossing pyramidal tract fibers, which may also play an important role. The reorganization of parallel-acting multiple motor areas ipsilateral to the lesion site was considered to be the central mechanism in motor recovery.

Motor and sensory cortical representation can expand into adjoining cortical areas either following a lesion (e.g., limb amputation) or following specific training, such as in monkeys highly trained in tactile tasks. The cortical representational plasticity may play a role in functional recovery following brain damage.

9. Emergent Mechanisms

Recent findings that may increase our understanding of the mechanisms of brain reorganization include the isolation of stem cells, which are the primordial cells from which all others evolve. They can potentially be made into neural cells that can migrate through the brain to where they are needed after a lesion or that can be implanted in the brain. Neural cells grown in labs have been implanted in the brains of persons who have had a stroke, with resulting improved function. It has been shown in both adult and senescent animals, and adult humans, that neurogenesis can occur (at least in the hippocampus). Adult neural stem cells have been shown to have very broad developmental capacities that may potentially be used to generate a variety of cell types for transplantation. Regeneration has been shown to be possible in some brain regions

We are currently at a stage in which, although much new evidence is accumulating regarding these

emerging research areas, conclusions as to their roles in recovery from brain damage cannot be drawn.

B. Psychosocial and Environmental Factors in Recovery of Function

Family support, mood, the environment, resistance to change, the attitudes of the rehabilitation professionals, and hope and expectations for recovery are some of the factors related to recovery. These factors appear to be intimately related to neurotransmitters and to the effectiveness of rehabilitation programs. The type of physical environment in which the brain-damaged person is placed may be closely related to the recovery.

The most important functional gains in the animal model of traumatic brain injury were obtained with an enriched environment. Most animal studies are undertaken with environmentally deprived laboratory animals, which may distort the experimental results. For example, in beam-walking studies, laboratory rats had difficulty crossing a gap on a 2-cm-wide strip of wood, whereas rats in the wild can scamper across much narrower strips. In addition to the physical environment for rehabilitation, and the content and timing of the rehabilitation programs, psychosocial factors and fitness level can affect outcome of rehabilitation programs. Fitness also affects many functional measures: Physically active men have been shown to have shorter event-related cortical potentials, stronger central inhibition, better neurocognitive performance, and better visual sensitivity.

The excellent functional recovery noted in some unusual cases of recovery from brain damage with home rehabilitation programs may be related not only to neuroplasticity factors but also to psychosocial and environmental considerations and to the functionality of the rehabilitation program.

C. Temporal Factors

Lesions of the brain early in life have effects that differ from those that occur in adulthood. Functional results can be either better or worse, depending on the age at injury and on the area injured. Furthermore, the age at which the lesion occurs may influence motor as well as behavior lesion effects. Damage in infancy yields more profound socioemotional effects than does damage in adulthood. Compensatory mechanisms do not always operate to ensure recovery of functions after early brain damage.

Early lesions (such as in persons with congenital hemispherectomy), resulting in acquisition of language in the right hemisphere, may interfere with right hemisphere nonverbal functions due to the "crowding effect"; this may be a case of functional plasticity being of limited advantage to individuals with regard to total cognitive capacities.

Tactile stimulation with premature babies leads to faster growth. Similarly, tactile stimulation of brain-lesioned laboratory rats led to unexpectedly large attenuation of the behavioral deficits, correlated with reversal of atrophy of cortical neurons normally associated with these lesions. Both premature infants and laboratory rats have in common that both are in impoverished environments. Thus, the positive responses with tactile stimulation can be considered to be related to an improvement in the direction of a normal environment.

Reorganization and recovery of function does not cease at any arbitrary time, such as 6 months; the potential can exist for many years after injury. It is becoming an important area in the field of neurologic rehabilitation since it appears that, in humans, specific late (postacute) rehabilitation programs are necessary to exploit that potential.

D. Neuroplasticity in the Aging Brain

Neurotransmitter levels and mechanisms in the aged brain appear to vary from those in young and adult brains in many ways. Implants of young tissue into aged hosts, and those of aged tissue into young hosts, have been studied in order to determine the relative importance of intrinsic versus extrinsic influences in such factors as age-related adrenergic defecits. Receptor plasticity, the up- or downregulation of receptors for specific neuroactive substances, is an important mechanism of neuroplasticity. Many changes in brain function lead to receptor changes since they must result in changes in neurotransmitters and other neuroactive substances. One study of receptor plasticity of the aged human brain demonstrated upregulation of dopamine D1 receptors in the brains of three persons, 80, 81, and 87 years of age who had died respectively 9, 19, and 27 days following a unilateral infarct of the ventral midbrain, producing a relative dopamine depletion on the lesioned side. In the autopsy material, an increase of between 27 and 37%

of dopamine receptors was demonstrated on the lesioned side. The receptor plasticity demonstrated in stroke patients has been discussed in regard to the possible role of NDN in the functional results of that plasticity. The D1 receptor upregulation may occur on the nonsynaptic cell membrane following the loss of synapses due to the partial denervation. That and comparable up- and downregulation may result in adaptive or maladaptive responses to the brain damage: Many neurotransmitter substances have been demonstrated by microdialysis in the extra cellular fluid, and some of these may produce responses in cells hypersensitive due to receptor plasticity following denervation. A possible maladaptive response is convulsive activity; it has been reported that 10–15% of stroke patients have convulsions.

Recovery of function following brain damage in the aged is also evidence for neuroplasticity; unusual cases of recovery stimulate investigators to explore the mechanisms of such recovery and the means of mobilizing those mechanisms to obtain the maximum possible recovery of function following brain damage. Several unusual cases have been described in the literature that reveal plasticity in the aged brain. Among these is the recovery of function in a patient who, at 65 years of age, had major brain damage (demonstrated on autopsy 7 years later) but who made a good recovery with a home-based rehabilitation program during the 5 years following the stroke. Aged patients with facial paralysis showed significant improvement with a rehabilitation program started years after the damage.

II. NEUROLOGIC REHABILITATION

Clinical rehabilitation has developed in an ad hoc fashion. The first formal stroke rehabilitation method, published by Frenkel in the mid- 19th century, emerged from a program that a nonprofessional wife had developed to successfully rehabilitate her husband. Rehabilitation clinicians still rely on nontheory-related methodologies. Little has been written about the fact that rehabilitation as currently practiced has such meager carryover to real-life activities, and even little carryover from one session to another. This has had the effect of reinforcing the widespread view in the physical rehabilitation field that once a patient reaches a plateau, usually 6–12 months after a stroke, further administration of rehabilitation therapy does not have useful results. With standard rehabilitation, a study showed that there was a difference in what the stroke patients could do in the hospital stroke unit and what the patients did at home. Each activity of daily living was less well performed in the home situation in 25–45% of the cases, and in 52% of the cases the chief caretaker claimed that the patient did not do two or more activities at home that the patient was capable of performing in the day hospital.

Ideally, therapy should be based on experimental findings. Carryover to real-life activities requires programs specifically developed to do so. Issues such as the nature of the interaction between behavioral and neural plasticity and the nature of rehabilitation programs that produce functional carryover should be evaluated. Programs based on conditioned responses have no carryover, whereas those based on shaping and on constraint-induced facilitation have been shown to have excellent carryover to real-life tasks.

A cat hemispherectomy model has provided some of the most reliable information on mechanisms underlying recovery of function in adult cats as well as the functional compensation in the developing animal following neonatal lesion. Forced exercise of the impaired limb was effective in reversing paw preference bias in all cases; however, the adult lesioned cats required more trials and extensive food deprivation. All cats continued improved performance indefinitely in their home cages. Thus, an impressive potential for recovery of directed purposeful movements remains after hemispherectomy, and recovery of function can be enhanced by forced exercise. Although 1 month of recovery time was needed in the adult hemispherectomy cases, recovery time for directed self-feeding movements could be reduced with passive mobilization and treadmill walking and running immediately after the experimental surgery. This provides animal experimental evidence that supports clinical rehabilitation applications of passive movements (which prevent contractures that lead to limited limb range of motion) in the early stages following brain damage.

Another productive, widely used model is the differential effect of serial lesions versus the one-stage lesion of the same amount of tissue, from the same brain area, as the total of all the serial lesions. Many studies have shown that the functional recovery is far greater in the animals that have had serial lesions than in those that have had one-step lesions. Reorganization of function, including reorganization in brain tissue different from the eventually removed tissue, must occur between lesions. This provides firm evidence for brain plasticity and recovery of function, even in the adult animal.

In addition to motor recovery with appropriate rehabilitation, animal models have also demonstrated sensory recovery, such as cat visual recovery from ambliopia with training and the ability to regain all fine sensory functions with rehabilitation following primary somatosensory projection cortex ablations in monkeys trained in tactile discriminations prelesion. An incidental finding is that postlesion it is necessary to inhibit negative cues, and that lesion of the ipsilateral cortex can produce bilateral deficits

There are many excellent recent studies on the scientific basis of recovery of function with rehabilitation. The following are some conclusions drawn by the experimenters of these studies. Rehabilitation must be varied and must not be repetitive. Changes in the motor cortex are driven by the acquisition of new motor skills and not simply by motor use, which may indicate that the repetitive, boring activities of standard rehabilitation are virtually useless. Functional plasticity is accompanied by structural plasticity. Unmasking, multiplexing, synaptic plasticity, sprouting, and inhibition are mechanisms of functional reorganization following brain damage. Functional plasticity in intact cortex is initiated immediately after injury. Activity (rehabilitation) results in an increase in the neuropil, in dendritic arborization, in the number of synapses, and in the separation between neurons, resulting in the reduction of the number of neurons per cubic millimeter. Spontaneous motor recovery cannot be explained by substitution of function in the spared motor cortex immediately adjacent to the lesion. The retention of functional representation in tissue adjacent to the lesion requires motor training (rehabilitation), which appears to have a modulatory effect on plasticity in the surrounding tissue. Blocking the NMDA receptors may be neuroprotective in the early postinjury stage, but blocking them later may reinstate deficits. Immobilizing the good limb too soon after brain damage in a rat model can have extremely deleterious effects, both in behavioral responses and in causing a dramatic expansion of the original lesion, which suggests that either too much or too little activity can have profound negative consequences. In rats, forced disuse for 1 week has many measurable negative effects; thus, studies of the negative effect of forced bed rest in brain-damaged humans are necessary. Mild rehabilitation may improve functional outcome, whereas early moderate rehabilitation can have negative effects, including the exaggeration of infarct size. Human stroke patients had worse outcome with forced speech therapy for several weeks than with brief (15-min) conversations.

Many of these conclusions challenge several dogmas of rehabilitation; however, especially since they are based on experimental findings, they should lead to further studies and, undoubtedly, to changes in the practice of clinical rehabilitation. Clinical studies have rarely used prospective randomized methods. One such study, carried out at the Karolinska Institutet in Huddinge (Stockholm), revealed that for patients for whom early stroke rehabilitation was possible, home rehabilitation was effective. However, well-documented individual case studies demonstrating unusual recovery are valuable, especially since they indicate what is possible and they may suggest effective rehabilitation approaches. In one such study, an elderly stroke patient with extensive brain damage (that was documented on autopsy 7 years later) followed a home rehabilitation program and recovered an extrodinary degree of function and returned to full-time work.

Little emphasis has been placed on late rehabilitation programs, possibly because late recovery has not generally been expected. However, reports of late recovery are not new; it was discussed in an article in the *Journal of the American Medical Association* in 1915, and many such reports have emerged from the treatment of war injuries. A case report of late recovery in a quadriplegic patient noted that since most quadriplegic patients are discharged 4 or 5 months postinjury, many patients have not achieved full motor recovery at discharge. It is possible that in many other cases of central nervous system damage the late recovery of function goes unnoticed since the patients have been discharged.

In addition to neural factors, learned nonuse has been demonstrated in human stroke patients. Although both lower extremities are almost always used as soon as possible in the recovery phase following the stroke since both are necessary for gait, the affected upper extremity is often not used, possibly because many tasks can be performed with one hand, leading to the development of learned nonuse. Behavioral training provided even years after the lesion that could involve as few as 3 days of restraint of the normal limb, thus forcing the use of the affected limb, can reverse the learned nonuse, converting a useless limb into a limb capable of extensive movement. It had previously been shown that forced use of the paretic upper extremity of monkeys with experimentally produced hemiplegia (unilateral cortical area 4 ablation) produced significant recovery of function.

A sensory substitution model of late brain rehabilitation has been developed based on the consideration

that a major sensory loss, such as blindness, removes a large part of the input to the brain and, similar to an actual lesion, induces a major reorganization of the brain. Tactile vision substitution systems (TVSS's) have been developed to deliver visual information from a TV camera to arrays of stimulators in contact with the skin of one of several parts of the body, including the abdomen, back, thigh, forehead, fingertip, and tongue. Mediated by the tactile receptors, images transduced from the camera are encoded as neural pulse trains. In this manner, the brain is able to recreate "visual" images that originate in a TV camera. Indeed, after sufficient training with the TVSS, subjects who were blind since early infancy reported experiencing the images in space instead of on the skin. They learned to make perceptual judgments using visual means of analysis, such as perspective, parallax, looming, and zooming, and to make depth judgments. They have been able to perform complex perception and "eye"–hand coordination tasks, including facial recognition, accurate judgment of speed and direction of a rolling ball with more than 95% accuracy in batting the ball as it rolls over a table edge, and complex inspection–assembly tasks. The results have been interpreted as demonstrating the capacity of the brain to reorganize even when the training (rehabilitation) of congenitally blind persons is initiated in adulthood.

Another post-acute program was developed for persons with long-standing facial paralysis due to facial nerve damage during the removal of an acoustic neuroma who had undergone a VII–XII cranial nerve anastomosis (connecting part of the tongue nerve to innervate the facial muscles). In this model, it is clear that the facial muscles are innervated by nerve fibers from structures genetically programmed to move tongue muscles. However, with appropriate rehabilitation, persons recover spontaneous and voluntary bilateral facial symmetrical movements, and they learn to inhibit dyskinetic movements, even many years after the causitive event. The study was designed to evaluate brain plasticity in a human model in which the extent of the lesion is definitely known and in which, due to the complete loss of connectivity from the brain regions genetically programmed to control facial movements, another system (in this case, the brain regions that had previously controlled tongue movements) could be demonstrated to have reorganized to obtain the functional recovery.

Motivating therapy is effective. An example is the ingenious approach taken by a research group in France to obtain eye movement control in children with cerebral palsy who had eye coordination deficits. They noted, as had others before them, that watching a pendulum aided in the training, but they found that the children refused to watch because they found it too boring. They developed a fascinating functional pendulum by projecting children's movies (*Snow White* and *Lassie*) at a galvanometer–controlled mirror, which reflected the image to the back side of a projection screen. The children sat in front of the screen with their heads fixed so that to follow the pendular movements of the image they had to use eye movements. They underwent 6 hr a week of intense therapy (three movies) and within 1 month improved to the point that they could learn to read.

A comparable approach was taken in the early 1970s with the early electronic pong games, which could be connected to home TV sets. One of the joystick controls was replaced with a device used in the clinic for hemiparetic persons to train arm movements. Instead of meaningless exercise, the arm could control a paddle (paddle size and ball speed were varied according to the capabilities of individual patients) allowing participation in a highly motivating game.

III. IMPLANTED AND ATTACHED INSTRUMENTATION

Miniaturized electronics and device technology (e.g., nanotechnology) offer the promise of overcoming some of the deficits produced by brain damage. Sensors and stimulators have been implanted in the brains of blind and paralyzed persons to interface with computers. An array of electrotactile stimulators built into a false palate (similar to an orthodontic retainer) may allow the tongue to act as a human–machine interface for information from many proposed artificial receptors, such as a TV camera for blind persons, a pitch-and-roll sensor for persons who have lost vestibular function, or a robotic hand with position and touch sensors for paralyzed brain and spinal cord-injured persons. These are examples of the application of emerging technologies to compensate for functional loses.

IV. CONCLUSION

The brain is capable of reorganization during the organism's entire lifetime. Functional improvement after brain damage depends on many biological and psychosocial factors.

GLOSSARY

action potential A sudden overshoot of membrane potential of excitable cells caused by a stimulus that is chemical, electrical, or mechanical in nature.

development Increase in weight of the organ due to an increase in size of the cells through synthesis and deposition of cell constituents such as protein, lipid, and RNA (hypertrophy).

gliogenesis Emergence of glial cells from a specific section of the neuroepithelium from where no other cells (neurons) originate.

gray matter Outer layer of cerebrum (cerebral cortex) or cerebellum (cerebellar cortex) where the majority of the neurons (about 75%) reside. The cerebral cortex is thought to be the center of all higher mental functions.

growth Increase in weight of an organ due to an increase in the number of cells through cell multiplication (hyperplasia).

growth spurt The period when the growth of a tissue is at its peak. This is the period when the tissue is most vulnerable to internal as well as external inhibiting agents.

neurogenesis Birth of neurons from the stem cells (neuroblasts) of the neuroepithelium, with each neuroblast generating a specific family of neurons.

neurotransmitter Specialized substances that mediate the transmission of nerve impulse from the presynaptic to the postsynaptic membrane and produce a postsynaptic effect (excitatory or inhibitory) by interacting with specific receptors.

The brain is the most complex of all biological tissues in nature. The complexity lies in the fact that the brain is an extremely heterogeneous tissue, composed of many constituent parts. Each part not only has its own structural organization, cellular makeup, chemical composition, and functional activity but also has a unique developmental characteristic. However, the different parts develop and maintain among themselves a highly organized coordinated system that contributes ultimately to the functioning of the brain seemingly as a single organ. It is estimated that the human central nervous system contains 11–12 billion nerve cells, each of which is capable of making up to 10,000 synaptic interconnections. According to one estimate, the number of intercellular interactions that could possibly occur within a single human brain may be greater than the total number of particles in the whole universe. It is the development of a network of this vast number of interactions that forms the basis of the functioning of the brain. Understanding the complex developmental processes of the brain and brain functions has indeed been one of the greatest challenges for man. This article explores and unveils some aspects of the complex processes of brain development in man and other animals.

I. BASIC STRUCTURE OF THE BRAIN

The brain has undergone a long process of evolution, taking millions of years for it to take the shape and organization currently found in man. During this evolution, the brain has increased not only in size but also in its level of organization, sophistication, and

complexity. The increased size of the brain, however, is not necessarily an indication of increased intelligence. Larger animals, such as the elephant or the whale, have much larger brains than that of man. Also, the basic chemical and metabolic setup of the brain of even the lower mammals and that of man are, in a broader perspective, difficult to distinguish. However, the human brain is very special in relation to culture, consciousness, language, memory, and especially intelligence. It distinguishes itself from even the most highly developed brains of other animals.

The morphology and cytology of the brain tissue are now well understood. A large variety of cell types occur in the brain that can be classified into two major groups according to their general morphology and function: the neuronal cells and the glial cells.

A. Neurons

Neurons are the excitable nerve cells of the brain. They are involved in the initiation and conduction of nerve impulses. Because of this unique property, neurons are considered the functional, computing elements of the nervous system. Two kinds of processes are formed from extensions of the neuronal plasma membrane—the axons and the dendrites (Fig. 1).

In vertebrates, the function of the axon is to conduct the nerve impulse in one direction only, usually away from the neuronal cell body (efferent) to another neuron or another part of the system through intercellular junctions called the synapses. On the other hand, dendrites carry information from the synapse to the cell body (afferent).

B. Glia

Unlike neurons, glial cells are not excitable and do not have any signaling apparatus (axons or synapses). Therefore, these cells do not participate in initiating the nerve impulse or in mediating activities of the nervous system. Their main function is to form myelin (which facilitates nerve conduction) and to support growth and differentiation of neurons. Glial cells, in relation to neurons, become increasingly numerous along the phylogenetic scale, and in mammals they constitute almost half the volume of the brain and greatly outnumber neurons by a ratio of approximately 10 to 1. Thus, as many as 100 billion glial cells are found in the human central nervous system (CNS).

C. The Synapse

In the nervous systems of both vertebrates and invertebrates, the neurons are in close apposition with each other and they relay information from one to another. The junctions at which the cells are interconnected and through which the impulses are propagated are called synapses, first named by Sherrington in 1906 from the Greek word *synapto* meaning tight

clasping. The membranes that participate in the formation of synapses are those of the axons, dendrites, and the main cell body.

D. Basic Principle of Nerve Action

The basic principle of all nerve impulses and nerve functions is the production of an action potential across neuronal membrane. The action potential is a sudden and transient overshoot of membrane potential of neuronal membrane from the resting value of −60 to −70 to 20 mV or more, caused by an electrical, chemical, or mechanical agent. The action potential is conducted along the axon and then transmitted to the next neuron and finally to the target tissue. The response of the target tissue is specific to the chemical substances that mediate this transmission (the neurotransmitters).

II. HYPERPLASTIC GROWTH OF THE BRAIN

The weight gain of a given organ with time is a measure of growth of that organ. Weight gain is indeed the simplest and the easiest criterion of growth, provided that the presence of an unusual amount of water in edematous condition does not affect the actual situation. However, the weight curve of tissues including the brain, like that of the body, is not linear with time but follows a sigmoidal pattern (Fig. 2), meaning that there is a period of more rapid growth compared with that occurring before or after that period. This period of rapid growth is known as the growth spurt and is a determinant for the so-called "critical" or "vulnerable" period because at this time even a slight disturbance in the growth-supporting environment may have a profound effect on the overall growth and development of the tissue.

The anatomical heterogeneity of the brain makes the developmental study of the tissue particularly difficult because it is almost impossible to dissect its hundreds of tiny functioning parts and study them. However, valuable information has been obtained from the study of the major regions of the brain—the forebrain, cerebellum, and brain stem (Fig. 2)—although such studies are of limited value with regard to the growth spurts of the composite structures in each of these regions.

Generally, the growth process of the brain, like that of any other organ, encompasses two major processes—*growth and development*. The growth process consists of an increase in the number of cells until the

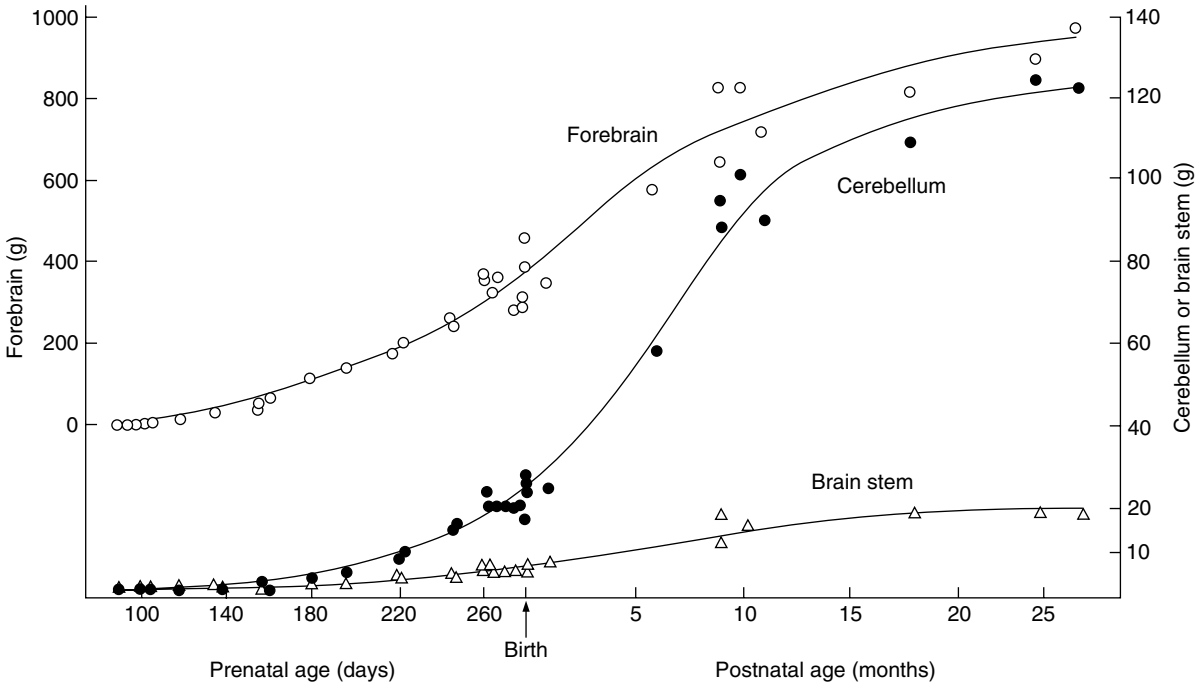

Figure 2 Growth curves of human forebrain, cerebellum, and brain stem.

adult cellular population is achieved in the tissue. This process of growth by cell multiplication is known as *hyperplasia* and is determined by the genetic makeup of the individual organs. The process of development, on the other hand, is one in which the cells obtained through hyperplasia are developed into mature functioning units as a result of deposition of different cellular constituents (e.g., protein and lipid). This process is termed *hypertrophy*. Therefore, mature cells differ from immature ones in both size and chemical composition. For the brain, the major events in hypertrophy are myelination and synaptogenesis.

Brain cells are mostly diploid, and the amount of DNA in all diploid cells of a given species is constant, with the value being slightly different in different species. For example, the value is 6.2 pg for the rat diploid cells and 6.0 pg in humans. Therefore, the total number of cells in a brain can be determined by dividing its total content of DNA by the value per cell.

Once the number of cells of an organ is known, the weight per cell and the protein content, RNA content, or lipid content per cell can be determined from the total weight of the tissue and the total content of protein, RNA, and so on. These values are used as an approximate measure of the size of the cells of that tissue. An increase in these values indicates an increase in cell size (i.e., hypertrophy). However, the general problem associated with this assumption for the brain tissue lies in the different cell types: One cell type is likely to have an amount of protein or lipid very different from that of another cell type.

Within these limitations, the neurochemical approach has made an important contribution toward our understanding of the general pattern of growth and development of tissues including the brain. Based on these principles, Myron Winick proposed that organs grow and develop in three consecutive phases (Fig. 3). During the first phase, growth proceeds entirely by cell multiplication (hyperplasia alone), with a proportional increase in weight and in protein, RNA, or lipid content, so that the cell size, as measured by weight/DNA or protein/DNA, remains constant. At the end of this phase, the rate of DNA accretion gradually slows, but the accumulation of other constituents continues. This constitutes the second phase of mixed hyperplasia and hypertrophy, in which there is an increase in cell size and a smaller increase in cell number. In the third phase, DNA growth stops altogether and the cells develop by increasing in size by continued synthesis and accumulation of proteins and lipids. This is the phase of hypertrophy. Finally, when net protein or lipid synthesis, and therefore the weight of the cells, is established, the tissue attains the state of maturity.

The scheme proposed for the brain by Davison and Dobbing in terms of growth and development of

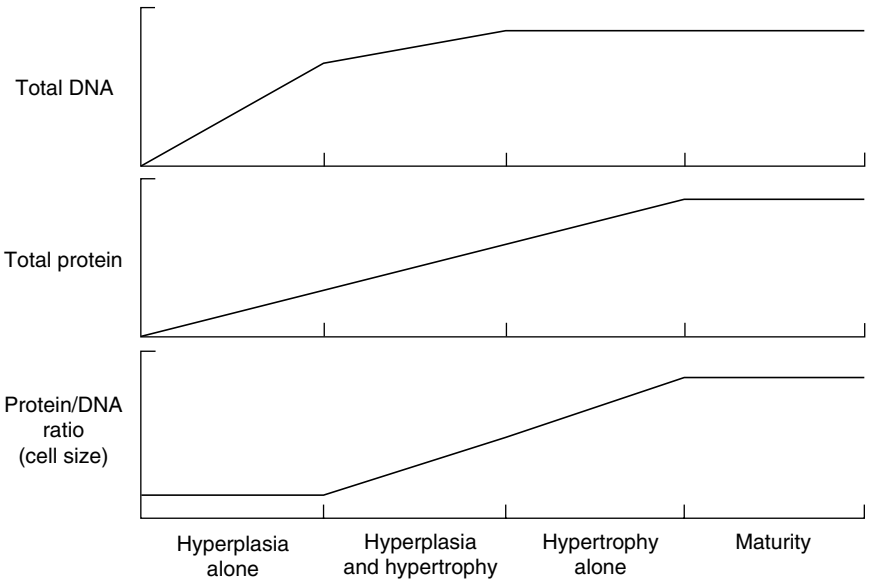

Figure 3 Relationship between DNA, protein, and protein/DNA ratio during the three phases of tissue growth (reproduced with permission of Oxford University Press).

different types of cells and their associated structures fits well with the general scheme of Winick:

Stage I: Organogenesis and neuronal multiplication (hyperplasia alone?)
Stage II: The brain growth spurt, including
II(a). A maturation period of axonal and dendritic growth, glial multiplication, and myelination (hyperplasia plus hypertrophy)
II(b). a later period of growth in size (hypertrophy alone)
Stage III: The mature, adult state (maturity)
