According to this scheme, organogenesis, followed by neuronal multiplication, takes place in the first stage. The brain growth spurt occurs in the second stage. It includes maturation of the axons and dendrites, multiplication of cells, and myelination. The third stage consists almost entirely of continued myelination and increase in tissue size, at the end of which the brain is thought to attain structural maturity.

A. Species Differences

The developmental stages outlined previously for the brain proceed in a sequential manner in all species studied. Regarding the physical development of the mammalian brain, one major difference between species is the timing of birth in relation to the time of brain growth spurt. In some animals, brain growth spurt occurs prenatally (guinea pig, sheep, and monkey), in some it occurs perinatally (human and pig), and in others it occurs postnatally (rat and mouse) (Fig. 4). Accordingly, these animals are called prenatal, perinatal, and postnatal brain developers, respectively. Thus, the event of birth in mammals, although representing a major physiological milestone in the development of the respiratory and cardiovascular structures and functions, is apparently of little significance to the development of the brain and behavior.

B. Structural Differences

Studies of the gross anatomical regions of the brain have revealed an extraordinary rapid rate of growth of the cerebellum compared to that of the rest of the brain in all mammalian species examined (Fig. 2). In the race of growth and development, the cerebellum starts slightly later but finishes earlier. This makes this part of the brain especially vulnerable to internal or external influencing agents.

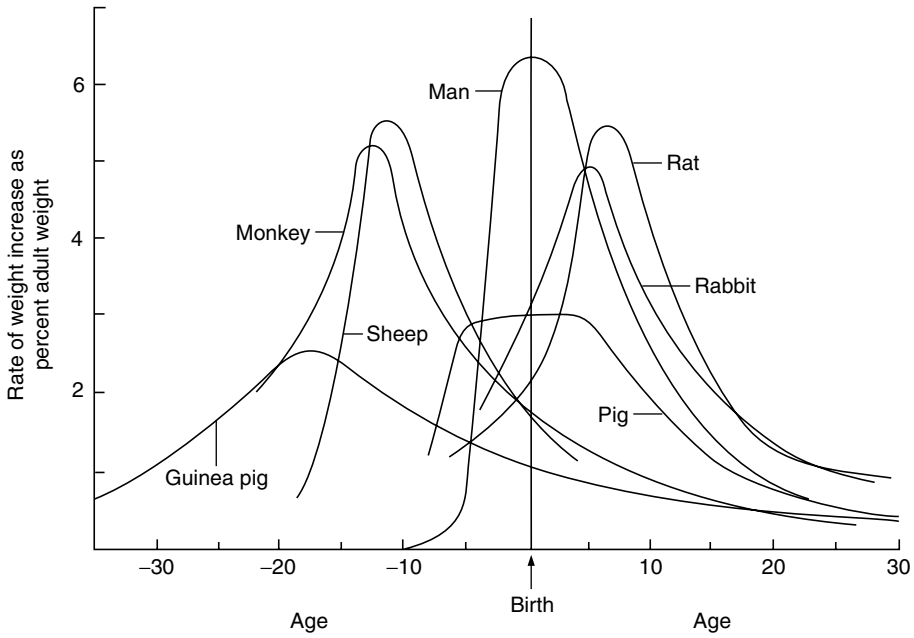

Figure 4 The timing of brain growth spurts in various mammalian species in relation to the timing of birth. The units of age for the different species are as follows: guinea pig, days; sheep, × 5 days; monkey, × 4 days; man, months; rat, days; rabbit, × 2 days; pig, weeks (reproduced with permission from authors and Elsevier Science).

C. Gray and White Matter of the Developing Brain

Marked changes occur in the relative proportions of the gray and white matter of the brain during development. During early developmental stages, the proportion of gray matter increases, and then, when myelination begins, the proportion of the white matter increases. For example, biochemical studies showed that at 2 weeks of age (i.e., at the time when active myelination has just begun), the rat brain is composed mainly of gray matter (85%). During the following 4 weeks of growth, the gray matter proportion decreases rapidly to approximately 70%, whereas the proportion of the white matter increases from the initial value of 15% to approximately 30%. Later, this change in percentage proportions is gradual, and at 52 weeks of age the two matters share the total mass of the brain almost equally (Fig. 5).

However, when the absolute amounts of gray and white matter in the developing brain are considered, the amount of gray matter is found to increase (by approximately 12%) only up to 3 weeks of age and remain almost constant thereafter (up to the age of 9 weeks), whereas the absolute amount of white matter increases steadily throughout this growth period (Fig. 5).

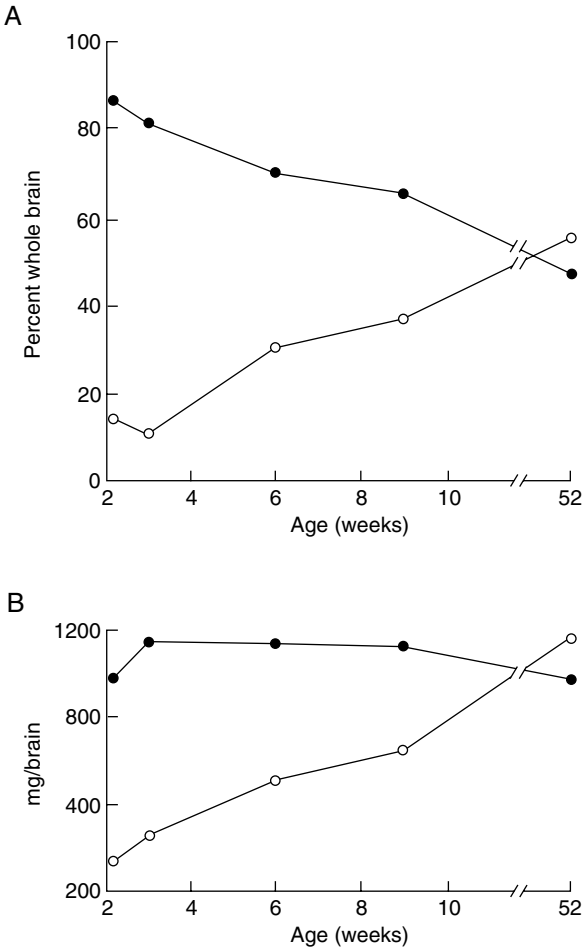

Figure 5 Changes in the (A) proportions and (B) total amounts of gray (●) and white (○) matter of the developing rat brain (reproduced with permission of International Society for Developmental Neuroscience).

D. Growth of Different Cell Types

Not only do the different parts of the brain grow at different times and at different rates but also there are differences in the timing of multiplication of different cell types within a particular brain region. It has been known for a long time that multiplications of the neurons and of the glia are two consecutive processes, the former being followed by the latter.

While studying the cellular growth of the human brain, Dobbing and Sands observed two distinct peaks of DNA accumulation in the forebrain, the first occurring at 18 weeks of gestation and the second at approximately birth (Fig. 6). The first peak was interpreted as corresponding to the peak of neuronal multiplication and the second to that of glial multiplication. However, it is likely that the adult neuronal population is not achieved at 18 weeks of fetal life; some neurons continue to divide beyond this time, but their number is not significant compared to the number achieved by 18 weeks of gestation. Man is thus a fortuitous species in that his brain neuronal population is established as early as mid-fetal life and thus saved from the deleterious effects of even severe nutritional insufficiency in the mother.

E. Neurogenesis

Neurons originate from the stem cells (neuroblasts) of the neuroepithelium. Understanding of the process of neurogenesis was enhanced by studies on relatively simple nervous systems, such as those of the nematode, leech, and insects. During embryonic development of the CNS, an enormous diversity of cellular types are arranged and interconnected in a remarkably precise pattern. For example, within the neuroepithelium in each segment of the grasshopper embryo, 61 neuronal precursor cells (neuroblasts) are arranged in two

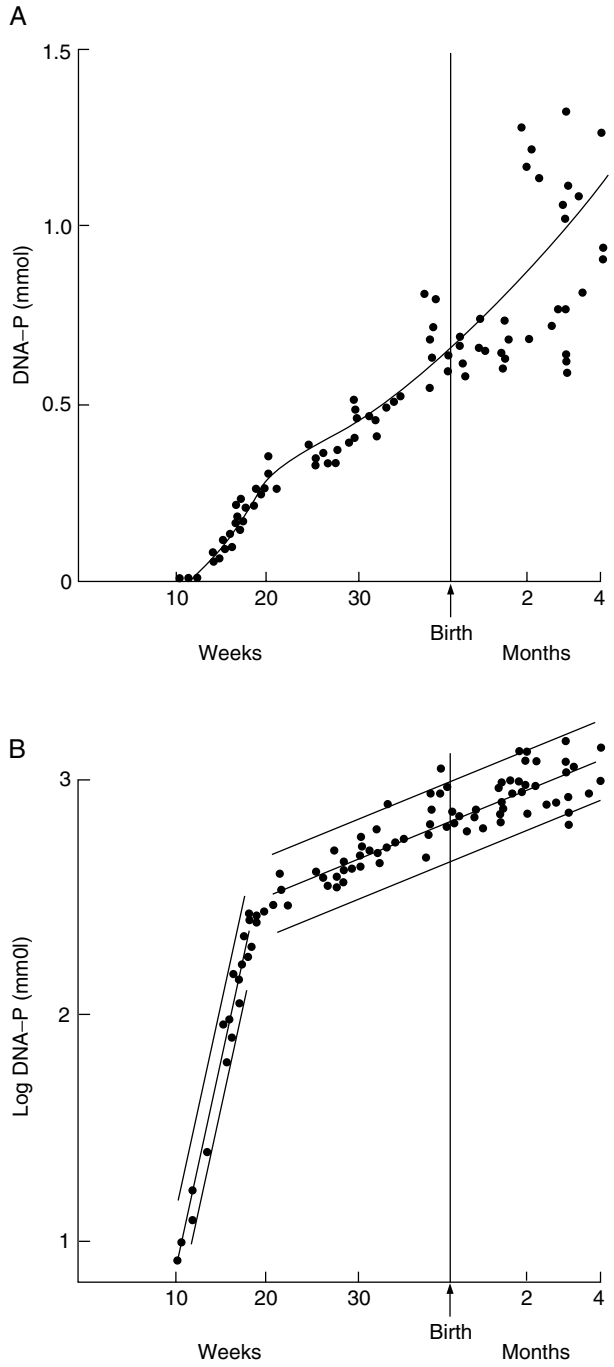

Figure 6 (A) Changes with age in total DNA–phosphate, equivalent to total cell number in the human fetal and infant forebrain. (B) A semilogarithmic plot of the same data as in (A). Regression lines with 95% confidence are drawn in B (reproduced with permission of British Medical Journal).

symmetric plates of 30 neuroblasts each and one median neuroblast (Fig. 7). Each neuroblast can be identified by its position within the neuroepithelium and also from the highly stereotyped family of neurons it produces.

As a neuroblast appears in the neuroepithelium, it divides repeatedly to generate a chain of ganglion mother cells. Each ganglion mother cell then divides once more to produce two ganglion cells in a chain of cell doublets, which then differentiate into a family of neurons. The families of neurons originating from different precursor neuroblast cells differ by their unique morphology, physiology, biochemistry, and function.

Thus, each neuroblast appears to generate a specific family of neurons, and a neuroblast's position in the epithelium is so specific that no other cell, including the ectodermal cell adjacent to it, can take its place, nor can the progeny of one neuroblast be replaced by the progeny of the neighboring neuroblasts. The final differentiation of the individual neurons depends on their mitotic ancestry and their later cell-specific interactions with other neurons in the environment.

F. Gliogenesis

In the vertebrate CNS, the neuroepithelium gives rise to most of the neuronal as well as the macroglial cells found in mature tissue. The mechanism by which the neuroepithelial cells first differentiate and follow the different cell lineages is largely unknown, nor is it clear when the decision for differentiation is made.

As with neurogenesis, most of the current understanding of the process of gliogenesis derives from the study of a relatively simple nervous system, such as the optic nerve. The optic nerve develops from the optic stalk, which is an extension of the original neuroepithelium (Fig. 8). The neuroepithelial cells that form this optic stalk give rise only to glial cells (astrocytes and oligodendroglia) and not to neurons. Neurobiologists have used this characteristic of the cell lineage systems of the optic stalk to study the pattern of gliogenesis.

G. Neuronal Death and Nervous System Development

Neuronal death is a major phenomenon in the normal development of the vertebrate as well as the

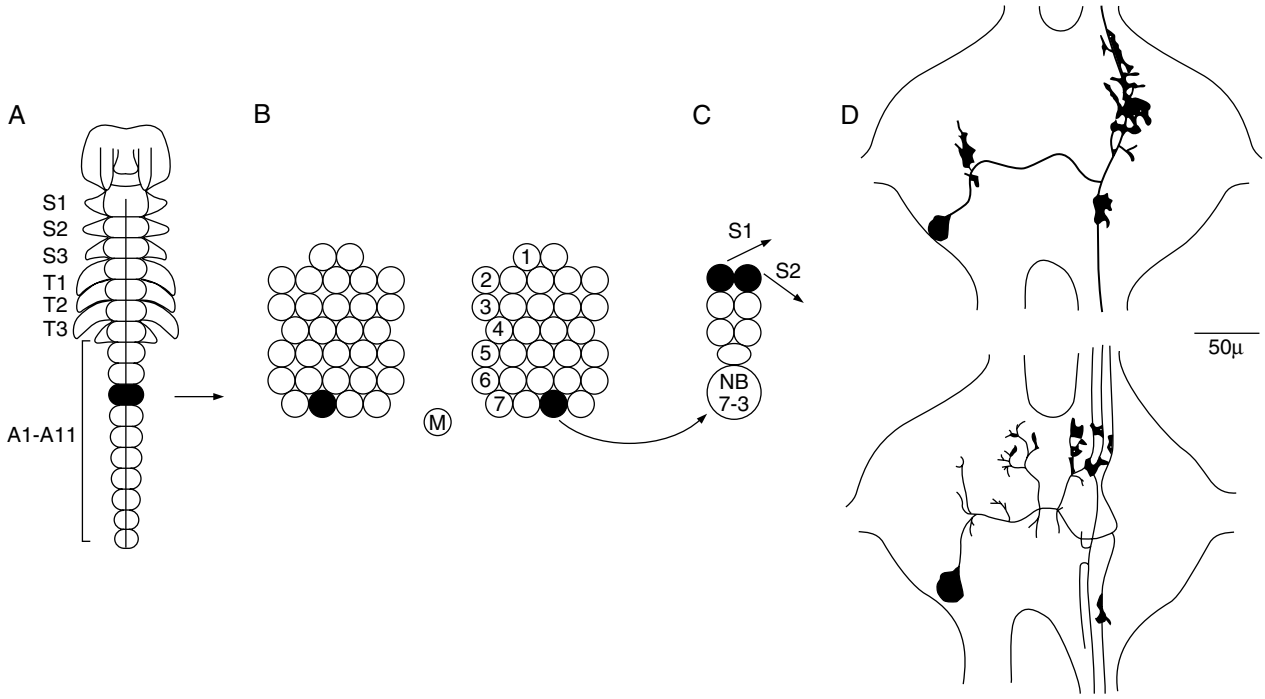

Figure 7 Neurogenesis in the grasshopper central nervous system (CNS). (A) Schematic diagram of a 30% grasshopper embryo (hatching occurs at 100%) showing the segmental structure of the ectoderm. The middle of the ectoderm is a longitudinal strip of neuroepithelium that gives rise to the CNS. The location of the neuronal precursor cells for a single segment (A4) are drawn in black. (B) Pattern of neuroblastomas (NBs) for a single segment (A4) includes two plates of 30 NBs arranged in a precise pattern of seven rows and one median neuroblastoma (MNB), for a total of 61 NBs. (C) Cell lineage of two identified serotonin immunoreactive neurones, S_1 and S_2, from NBs 7–3. NBs generate neuronal progeny by a series of asymmetric cell divisions that produce small, ganglion mother cells. Ganglion mothers cells then each divide once more symmetrically to produce two cells that will both differentiate into neurons. The cell lineage is represented with a ganglion mother cell closest to the NB and older neuronal progeny lying progressively farther away from the NB. (D) The cell-specific morphologies of neurons S_1 (top) and S_2 (bottom) in the A4 ganglion at 70% embryonic development, as revealed by intracellular injection of Lucifer Yellow followed by HRP immunocytochemistry with an anti-Lucifer Yellow antibody (reproduced with permission from Macmillan Journals Ltd).

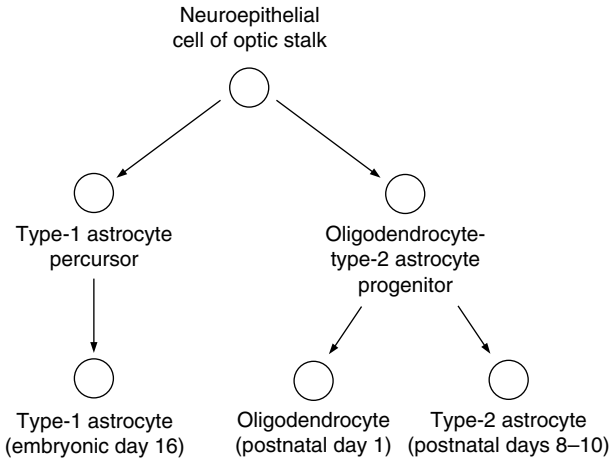

Figure 8 Postulated glial cell lineages in rat optic nerve.

invertebrate nervous systems. The first systematic report in this context was that of Hamburger and Levi-Montalcini, who observed massive cell losses by death in dorsal root ganglia of the growing chick at the upper cervical and thoracic levels. Subsequent studies showed similar neuronal degeneration in other nerve structures to the extent of 25–75% occurring during a well-defined period of days or weeks. For example, 30% of the cells of mouse cerebral cortex or lateral geniculate nucleus are lost between Postnatal Days 5 and 30, and chick trigeminal mesencephalic nucleus loses as much as 75% of the cells between Embryonic Days 11 and 13.

There are many reasons for the natural death of the neurons in the developing nervous system, but the best understood and most documented is the lack of maintenance from the target tissue. The target cells are known to secrete one or more trophic factors, the

so-called neurotrophic factors, of which the nerve growth factor is the best characterized. These trophic factors are essential for the survival of the neurons and are made available to the neurons by retrogradic transport.

Many observations have clearly indicated the phenomenon of "competition" among neurons to gain access to the target tissue and obtain the necessary trophic factors. More active neurons have been shown to win and survive, whereas less active ones make fewer synapses, receive less trophic factors, and eventually degenerate. This is in agreement with the suggestion made more than 100 years ago by Roux that cells, including neurons, follow the Darwinian "struggle for existence—survival of the fittest" theory.

During early periods of development, many diffuse, inaccurate, and aberrant synaptic interconnections are formed in the nervous tissue that have to be removed for a precise and topographically ordered synaptic network characteristic of the nerve tissues to be established. Death of the neurons with such aberrant connections would be a way to achieve this. However, cell death is not the only means by which neuronal connections are eliminated. In many cases, this is achieved by pruning the axons of aberrant neurons without the death of the cells.

H. Regeneration of Brain Cells

One important difference between the nervous systems and most other tissues of the body is that in the nervous tissues, neuronal cell division has "once-and-for-all" characteristics. Once adulthood is reached, neurons stop multiplying in any appreciable number. However, studies of the incorporation of labeled thymidine into DNA show that the glial cells divide even in the normal, mature brain but with negligible rate of turnover. These rates are found to increase in response to traumatic injury of the brain.

III. HYPERTROPHIC DEVELOPMENT OF THE BRAIN

The cellular growth of the brain described in the preceding section is followed by *hypertrophic* development. During this phase, cells are developed by a process whereby the size of the main cell body and the length and size of the cell's different processes increase. This increase in size is accomplished by synthesis and quantitative deposition of proteins and lipids in various cellular membranes, particularly the deposition of lipids around the axons in the form of myelin.

A. Brain Lipids during Development

The brain is the tissue of the body that is most abundant in lipids. With the exception of a small proportion of lipids concerned with cellular dynamic processes such as signal transduction, the bulk of the lipid material is located in structural components of various membranes, especially the myelin. Therefore, the rate of lipid accretion in the brain during development governs the rate of synthesis of the whole component structure of the membranes. From the knowledge of membrane specificity of different lipid substances, it is possible to understand the developmental profile of a particular membranous structure by monitoring the developmental profile of the lipid specific to that membrane. For example, cholesterol is widely used as a marker of myelination; however, cerebrosides and sulfatides are more specific myelin lipids. Gangliosides are generally accepted as a marker of dendritic arborizatin and synaptic development.

The lipid content and composition of the brain at early stages of growth are very similar to those of other tissues. However, due to a rapid synthesis of lipids in the brain during development, lipid content as well as composition of the mature nervous tissue become markedly different from those of tissues in the rest of the body. The brain also differs from other tissues in that it is rich in more complex and polar lipids. On the other hand, the adult brain contains negligible quantities of esterified cholesterol and almost none of the triglycerides that are abundant in almost all other tissues.

It should be noted that the sequence of lipid deposition in the brain at various stages of development does not differ substantially between species. However, within the brain, not all lipids are synthesized and deposited at the same rate. For example, myelination, as evidenced by deposition of cholesterol, proceeds at different times and at different rates in different tracts even within the same region of the brain.

In mammals, the peak rate of cholesterol synthesis, and therefore myelin formation and deposition, occurs sometime after the peak period of glial cell multiplication. Thus, the peak rate of myelin accumulation occurs at approximately 15–18 days of age in the rat brain, at the time of birth in the guinea pig brain, a few

days after birth in the pig brain, and during the first 8 or 9 months after birth in the human brain (Fig. 4). Moreover, the cells that multiply just before the peak cholesterol synthesis are almost all oligodendroglia, the cells that form myelin around the central neuronal axons. The same sequence of cell (oligodendroglial) multiplication and peak cholesterol accumulation is also seen in the brain of nonmammalian species such as the catfish.

Gangliosides, a group of sialoglycosphingolipids, are present in the plasma membrane of all animal cells. Their hydrophobic ceramide portion is embedded in the lipid matrix of the membrane, whereas their hypdrophilic sialoglycosyl chain is oriented toward the extracellular medium. These sugar chains, which are different from one kind of cell to another, are believed to contribute to the cell adhesion and cell–cell recognition properties of living cells.

Gangliosides are most concentrated in the brain compared to the rest of the body. Within the brain, the concentration in the gray matter is several times higher than that in white matter. Within the gray matter, these lipids are most concentrated in the axon terminals and dendrites, the structures that constitute most of the synaptic interconnections. As mentioned previously, gangliosides are thus considered label lipids for synaptogenesis. Based on ganglioside measurement, it has been shown that the period of most rapid synaptogenesis in the human brain is the first 8–12 months after birth.

B. Lipids of Gray and White Matter

The general view of lipid distribution in the brain is that lipids such as cholesterol, cerebrosides, and sulfatides are more concentrated in the white matter than in the gray matter, whereas the gangliosides are gray matter-specific constituents. The phospholipids as a whole are specific neither for the gray nor for the white matter, although ethanolamine phosphoglycerides and sphingomyelin are found more in the white than in the gray matter.

C. Myelin Composition in Developing Brain

Myelin accounts for more than 25% of the weight of the mature brain. Myelination is thus a major event in brain development. Myelin is composed mainly of lipids, proteins, and water, with small amounts of inorganic salts. About 40% of the wet weight of myelin is water. Of the material, 75–80% is lipids, and most of the remainder is proteins. The most extensive studies on myelin composition have been confined to lipids, although attention is now being given to proteins.

1. Myelin Lipids and Proteins

The most prominent changes that take place in the lipid composition of the CNS myelin during development are in relative mole proportions of cholesterol, phospholipids, and galactolipids, which attain a final value of approximately 2:2:1 as opposed to about 8:10:1 in the whole brain.

The content of protein in myelin is much less than that usually found in typical cell-surface membranes. The protein composition of myelin is unique. Most typical membranes contain many different kinds of proteins, none of which supercede the others in quantitative terms. On the other hand, myelin, not only contains less protein than other membranes but also has fewer (four or five) types of proteins. These four or five proteins have been separated by polyacrylamide gel electrophoresis. Of these, three are found to be highly specific for myelin: myelin basic protein (so named because of its relative richness in basic amino acids), proteolipid protein (so named because it is soluble in neutral organic solvents), and the so-called intermediate protein (lies intermediate between basic and proteolipid protein in an electric field). The relative proportions of these and other minor proteins change during myelin maturation.

2. Lipid–Protein Associations in Developing Myelin

At the beginning of myelination, as the flattened surface membrane of the myelin-forming glial cell wraps the axon for the first time, a double-membrane structure, the mesaxon, is produced. This double-membrane mesaxon, in the course of its differentiation into myelin, seems to serve as a "template" (protomyelin lattice) for the accumulation of myelin-specific lipids and proteins leading to the assembly of the myelin structure. The synthesis and deposition of the basic proteins and the lipids is thought to represent an early step in the differentiation process, which is advanced further by the accumulation of large amounts of more lipids and the proteolipid protein. Myelin basic proteins are synthesized on free polysomes in glial processes, whereas the proteolipid protein is synthesized on bound polysomes

(endoplasmic reticulum) in the glial cell body. The basic proteins are more rapidly incorporated into the developing CNS myelin sheath (within 2 min after synthesis), whereas the proteolipid protein appears in the myelin sheath after about 30 min. This assembly of myelin (incorporation of finished products into myelin sheath) is thought to be regulated by axonal signals.

D. Synaptic Development

1. Increases in Dendritic Arborization and Axon Density

One major process in brain development is the establishment of synaptic interconnection between individual neurons or between a neuron and its target cell. After the neuroblasts have divided and been transformed into neurons, the neurons, in order to serve as functional units of the nervous tissue, develop by increasing in size. This increase in cell size manifests itself in an increase in the size of the main cell body as well as in the size and length of the cellular processes—the axons and the dendrites. This in turn results in increases in dendritic arborizaion and axon density. The axons continue to grow in length until they find and form synapses with their target membranes. A target membrane may be the cell soma, dendrite, or the axon of another neuron (the axosomatic, axodendritic, and axoaxonal synapses) within the CNS, or it may be the plasma membrane of an excitable cell such as muscle cell (neuromuscular junction) in the peripheral nervous system. Thus, an increase in axon density is immediately followed by an increase in synaptic number (Fig. 9).

Synaptic activity begins when the presynapic neuron acquires the ability to secrete its neurotransmitter upon stimulation and the neurotransmitter thus released produces an effect, excitatory or inhibitory, on the postsynaptic membrane. The brain and other nervous regions become increasingly active when the number of synapses and their activities increase during development. Concomitant with this increase in synaptic number and synaptic activity is an increase in the content of the neurotransmitters and in the activities of the enzymes involved in their metabolism. In the simple nervous system of the leech, it has been shown that by the time of body closure, the neurons show characteristic action potentials and are therefore connected to functioning synapses. At this time, the synthetic activity for acetylcholine and other neurotransmitters is achieved, but at very low levels. The synthetic activity then increases enormously, 25 times the initial value, when the axons reach the connective and segmental nerves.

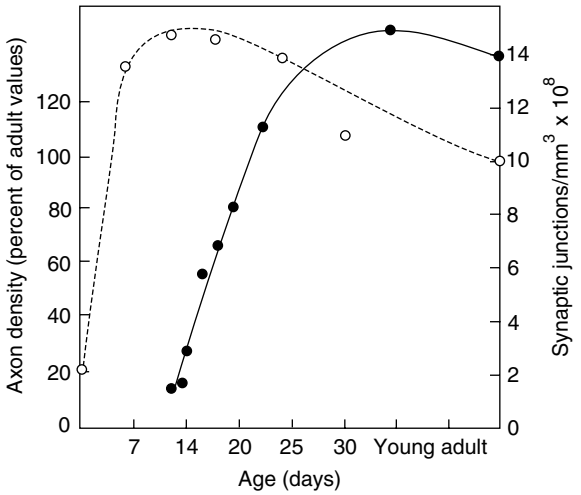

Figure 9 Increases in axon density and in synaptic number in layer 1 of the developing rat cerebral cortex. ●, synaptic number, parietal cortex; ○, axon density, sensorimotor cortex (reproduced with permission of Elsevier Science and Cambridge University Press).

In the vertebrate CNS, the monoaminergic neurons develop very early during ontogeny and are among the first to differentiate, synthesize, store, and release their transmitter substances (dopamine, noradrenaline, or serotonin) long before the maturation of the brain region they innervate. These neurons are therefore thought to play important roles in neurotrophy and plasticity in the developing nervous system.

2. Mechanism of Synaptogenesis

Most of the structural synapses in the brain are formed within the early stage of life, e.g., during the first month after birth in rats and 1 or 2 years after birth in humans. However, determining the exact mechanism whereby the neurons in the developing nervous system form synapses remains a central challenge in neurobiology. Some neurons, such as those in the brain, do not project their axons very long before finding their appropriate synaptic partners. In other neurons, such as the motoneurons of the spinal cord, the axons traverse long distances to find and form synapses with the desired postsynaptic target membrane, bypassing all "inappropriate" membranes along the migration pathway. The question thus arises how the neurons distinguish appropriate from inappropriate

postsynaptic membranes. Questions also arise regarding how the growth of the axons is regulated, what makes them stop growing when they reach their target cells, and what brings about the changes in the ultrastructural organization of the cytoskeleton that results in metamorphosis of the growth cone (axon tip) into the normal nerve terminal. Much research during the past decade has attempted to answer these and other questions relating to the process of synaptogenesis. Today, we have some insight into the mechanism, but we do not know all the details of the mysterious method whereby neurons establish their synaptic interconnections.

Many suggestions have been put forward to explain neuronal specificity in synaptogenesis. Sperry first proposed a chemoaffinity hypothesis that postulates that the specificity of neuronal connections is conferred by specific interactions between molecular addresses in the presynaptic membrane and the complementary molecules residing in the postsynaptic target membrane. This hypothesis is based on studies of presynaptic retinal neurons and the postsynaptic target neurons in the tectum. Hoffman and Edelman discovered a sialic acid-rich neuronal glycoprotein, termed N-CAM (neural cell adhesion molecule), that mediates intercellular adhesion in the absence of Ca^{2+}. This glycoprotein might be a part of the molecular address (mentioned previously) on neuronal membranes that is recognized by specific receptor sites on target neurons, and it may be important in the development of the nervous system by maintaining the topographical relationships between individual neurons and/or their axons in a set of neurons.

During the formation of a synapse, a complex series of ultrastructural changes occur, notably in the synapsing axon and its tip. The net result is that the axon stops growing in length and its tip (the growth cone) takes the shape of a typical nerve terminal.

3. Orchestration at the Synapse

Another important aspect of synaptogenesis is the molecular and structural reorganization in the postsynaptic membrane upon formation of a synapse with a prospective presynaptic nerve terminal. It is conceivable that the receptor proteins in the postsynaptic membrane must be aligned exactly opposite to the sites in the presynaptic membrane where the transmitters are released. Such alignment is maintained as long as the membrane participates in synaptic activity. Indeed, during early periods of development when synapses have not yet formed, the transmitter receptor proteins are distributed throughout the membrane surface of the postsynaptic cell. Also, during nerve degeneration, the receptor proteins disperse and the whole orchestration at the synapse breaks down. On the other hand, during synapse formation as well as during nerve regeneration, the receptor proteins aggregate themselves again to form clusters at the point of synaptic junctions. Thus, some signal mechanism must exist that regulates the behavior of the postsynaptic membrane during synaptogenesis and synaptic degeneration.

IV. ENERGY METABOLISM OF THE DEVELOPING BRAIN

Much like the changes in lipid and protein compositions described earlier, energy metabolism of the brain also undergoes an interesting shift during development. The most dramatic of these changes are changes in blood flow and oxygen consumption and the utilization of glucose as the source of energy. It is well-known from both *in vitro* and *in vivo* studies that oxygen consumption by the cerebrum remains at a low level at birth, although oxygen supply to the tissue may be high. Investigations show that relative to the amount of oxygen consumed, the amount of oxygen delivered to the cerebrum during fetal life exceeds that in the newborn and adult by as much as 70%. This may protect the fetus from the stress of labor and delivery, or it may simply be an obligatory adaptation to the low arterial oxygen pressure in the intrauterine environment. After birth, both oxygen supply and oxygen consumption increase rapidly and reach maximum levels at the time of peak development. Oxygen consumption then slowly decreases to the adult level at maturity.

The primary fuel that fulfills the high demand by the brain for metabolic energy is glucose. However, utilization of glucose and the efficiency of the process are not uniform throughout the developmental program. Early immature brain is less aerobic than the mature adult brain and oxidative processes (mitochondrial metabolism and respiration) are not fully developed in the immature brain. Many years ago, it was shown that newborn rats can withstand anaerobic conditions for as long as 1 hr, but this resistance to hypoxia disappears when the animals are administered iodoacetate, an inhibitor of the glycolytic pathway. This led to the understanding that early in development (before or at birth in rats or humans),

glycolytic breakdown of glucose to pyruvate or lactate is a major mode of glucose utilization. However, as is known, comparatively little energy is produced in this pathway (only 2 net moles of ATP are synthesized per mole of glucose utilized compared with 36 mol in the oxidative pathway). After birth, as development proceeds, respiration becomes increasingly important, and the oxidative pathway (complete oxidation of glucose to CO_2 and H_2O) plays a dominant role in glucose metabolism.

This shift in the metabolic pattern of the brain is understood from the changes in the activities during postnatal development of the enzymes of the glycolytic, TCA cycle, and the electron transport systems, with the latter two representing oxidative mechanisms of glucose utilization. For example, it has been found in the rat that the glycolytic enzymes in the brain, (e.g., glyceraldehyde-3-phosphate dehydrogenase, hexokinase, aldolase, and lactate dehydrogenase) already are considerably active after birth and show relatively small increases during the entire postnatal life, whereas the activities of the enzymes of the other two systems show marked variations. In the case of the rat brain, the latter enzymes generally remain at very low levels during the first 10 days after birth, following which their activities rapidly increase and reach maximum levels at about 40 days of age. Figure 10 shows examples with glyceraldehyde-3-phosphate dehydrogenase (glycolytic) and succinate dehydrogenase (TCA cycle), and Fig. 11 shows an example with cytochrome oxidase (electron transport chain). Activities of many other enzymes of oxidative metabolism (e.g., pyruvate dehydrogenase, citrate synthase, isocitrate dehydrogenase, and fumarase) also change markedly during this period.

The activities of the enzymes of both glycolytic and oxidative pathways develop first in the spinal cord and medulla, then in the hypothalamus, striatum, midbrain, and the cerebral white matter, and finally in the cerebral cortex and cerebellum (i.e., development is in the caudocephalic direction). This is consistent with the embryological and neurophylogenetic development of the brain regions, which is known to proceed from the medulla to the telencephalon (the end brain), and strongly indicates that the development of morphological and neurological maturity in the various regions of the brain is correlated with the development of their aerobic potential. Particularly interesting in this context is the development of the pyruvate dehydrogenase complex since this enzyme has a key regulatory role in controlling the flux of glucose carbon via pyruvate into the TCA cycle for energy metabolism in all tissues including the brain. Indeed, in the brain of species born neurologically mature (the prenatal brain developers such as guinea pig), pyruvate dehydrogenase activity is fully developed at birth, whereas in the brain of the purely postnatal brain developers such as the rat (which are born

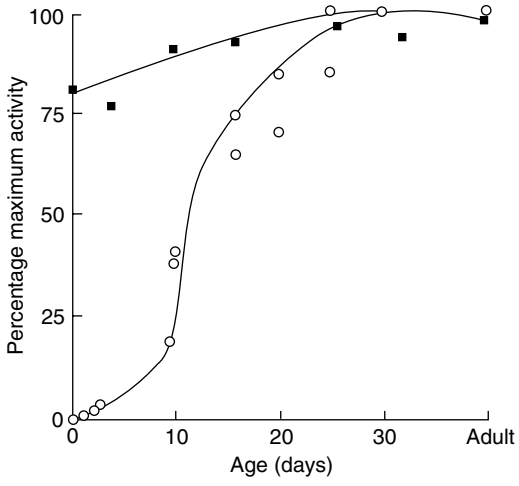

Figure 10 Changes in the activities of glyceraldehyde-3-phosphate dehydrogenase (●, moles substrate/kg protein of forebrain/hr) and succinate dehydrogenase (○, moles substrate/g whole brain/hr) in the developing rat brain. Values are plotted as percentages of maximal activities (reproduced with permission from Pergamon Press).

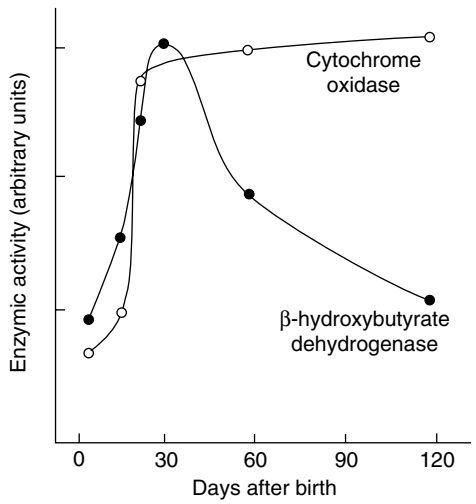

Figure 11 Changes in activities of cytochrome oxidase (○) and β-hydroxybutyrate dehydogenase (●) in the developing rat brain (reproduced with permission of the American Society of Biological Chemists).

neurologically immature), the activity of the enzyme is low. The subsequent neurological development of the latter species is correlated with the development of the pyruvate dehydrogenase activity in their brains.

An important aspect of energy metabolism in the neonatal brain concerns the utilization of ketone bodies, β-hydroxybutyrate and acetoacetate, as an additional source of energy. Probably because of an underdeveloped blood–brain barrier, the neonatal brain can take up ketone bodies and utilize them for the production of energy. During the early postnatal period, the ketone bodies are preferred to glucose as substrates for synthesis of phospholipids and sphingolipids to meet the requirements for growth and myelination. The ketone bodies thus form an important fuel metabolite for the rat brain during early periods after birth.

The pattern of cerebral metabolism of glucose also changes during development. Thus, in the adult brain of most mammalian species, the rate of glucose utilization ranges between 0.3 and 1.0 mmol/kg tissue/min, and most of this metabolism ($>90\%$) is carried through the glycolysis $\rightarrow$ TCA cycle $\rightarrow$ electron transport pathway. In contrast, in neonates, the hexose monophosphate (HMP) shunt represents a significant mechanism for the metabolism of a portion of total glucose. It has been estimated that the HMP shunt is responsible for as much as 50% of total brain glucose utilization during the first 4 weeks of life in the rat. Since production of ribose and NADPH is characteristic of the shunt, it is very likely that this pathway is utilized by the developing brain to meet its own demand for rapid synthesis of nucleic acids and large amounts of lipids, respectively. As the brain matures, the activity of the shunt gradually decreases, as reflected by a decrease with age in the activity of glucose-6-phosphate dehydrogenase, the first enzyme of the shunt, relative to the activities of the glycolytic and the TCA cycle enzymes.

V. INFLUENCE OF ADVERSE FACTORS ON BRAIN DEVELOPMENT

The process of brain development is accomplished by a series of continuous and sometimes overlapping events. These events of chemical and structural significance—organogenesis followed by cellular proliferation and later by synaptogenesis and myelination—proceed for a long time in a unidirectional manner until the mature adult tissue has emerged. These events, all occurring in early periods of life, must therefore be allowed to proceed in the genetically programmed fashion relative to age if a normally functioning tissue is to be formed. Any adverse extrinsic (environmental) or intrinsic (genetic) interference with the program would likely have deleterious effects on the ultimate makeup of the tissue. Because of the once-and-for-all characteristics of most developmental events and because the brain constituents are metabolically relatively inert, some effects are likely to persist throughout life.

During growth and development, the brain is especially vulnerable. Any derangement might have a profound effect on the functioning of the brain and, subsequently, on the behavior of the affected individual. If derangements caused in early life are permanent, the individual would be permanently deficient in behavior and mental functions. It is this apprehension that has aroused keen interest among neuroscientists in their search for teratogenic agents and their effects on brain development. Extrinsic agents include viruses, drugs, various forms of irradiation, nutritional insufficiency (including mineral and vitamin deficiencies), and probably also an inadequate environment. Intrinsic agents, such as defects in the genetic makeup of the brain, cause serious malformation of the brain as well as serious defects in brain function and metabolism. They are commonly referred to as inborn errors of metabolism.

Of the extrinsic factors, only viral infection and exposure to drugs and irradiation can affect organognesis and therefore also the later phases of brain growth and development. On the other hand, numerous studies have shown that nutritional inadequacy in early life can affect only the later processes of brain growth and development. The effects are not as profound and obvious as those found with defects in organogenesis. These studies have thus added a new dimension to the subject of teratology, with the increasing belief that important aspects of brain growth and development, such as cell multiplication, myelination, and synaptogenesis (which occur long after organogenesis is complete), are vulnerable to influences such as nutrition. The subject of nutrition and brain development has therefore become a widely studied field of research during the past few decades. This is not surprising in view of the fact that undernutrition and hunger are a part of life for at least one-third of the world's population. Children are the worst victims.

Indeed, protein-energy malnutrition is prevalent in varying degrees among children and mothers of almost all developing countries. It is also quite common for

poverty, hunger and malnutrition, concomitant with a high infant mortality rate, to also exist among the indigent communities of developed and industrialized countries also. Apart from high mortality rates among these children, particularly those less than 5 years old, there is increasing concern about the possible effects of nutritional insufficiency in early life on the later development of the survivors. The smaller stature, smaller brain, and more important, the apparent lower mental capabilities found in adolescents and adults of poor communities have often been correlated with restricted growth in early life.

VI. CONCLUSION

This article on brain development provides a simplified version of the subject. The process of brain development is much more complex and complicated than depicted, particularly for humans. Familial and social environment has been increasingly implicated in the development of the human brain, both structurally and functionally. Indeed, children raised in an enriched environment do better on intelligence tests than children raised under the same nutritional regime but in a poorer environment. Heredity is another important determinant in brain development.

The whole human situation is extremely complex, compounded by intricate interactions between nutrition, environment, and heredity on the overall development of physical and mental health. The brain stands in the center of this complex milieu, and, as noted by John Eccles, a great pioneer in brain research, we must continue to use our brains to understand how they show plasticity toward these and other possible factors to attain the ultimate potentiality of the development and function of our brains.

GLOSSARY

anoxia A cellular environment that is absent of oxygen.

brain herniation A movement of brain tissue from one compartment of high pressure to another compartment of decreased pressure.

coma A state of unresponsiveness in which the patient remains with eyes closed and is unarousable.

persistent vegetative state A condition following diffuse brain injury that results in the absence of cognitive function but the persistence of sleep–wake cycles.

programmed cell death An active process by an individual cell that requires energy and sometimes new protein synthesis which eventually leads to the directed destruction of the cell.

Organic brain disease is the result of neuronal and vascular injury that can occur as a consequence of several injury paradigms that include anoxia, vascular disease, and metabolic insults. Such insults can then subsequently precipitate both anatomic and cellular neuronal disease. However, it is the downstream cellular and molecular pathways that are increasingly being recognized as vital mechanisms that can both prevent and reverse neuronal injury. This article provides a pathophysiologic approach to the diagnosis and treatment of organic brain disease that incorporates current knowledge from both clinical patient studies and basic science investigations. Further analysis of neuronal injury that relies on a ''bimodal'' clinical and basic approach will foster the development of rationale, efficacious, and safe therapeutic interventions for the treatment of organic brain disease.

I. ANOXIC COMA

A. Historical Background

Initial credit for the recognition of the dependence of the vital organs on the circulatory system can be attributed to Galen in the 2nd century AD. The doctrines of Galenic physiology stated that blood was produced in the liver, flowed to the heart to obtain vital spirits, and subsequently bathed the brain to gain ''animal spirits.'' William Harvey extended this work during the 17th century to illustrate that blood within the human body was under continuous circulation. The vital spirits were later discovered to consist of oxygen.

Oxygen was discovered independently by Schiele in Sweden and by Priestly in England. It was named oxygen (acid-former) by Antoine Lavoisier (1743–1794) of France. Lavoisier made significant medical discoveries concerning oxygen's role in respiration and determined that oxygen makes up only approximately one-fifth of the volume of atmospheric air. In addition, oxygen is the only gas in air that sustains combustion and respiration. In animal experiments, Lavoisier and others discovered that anoxia can rapidly lead to death.

In 1920, Barcroft introduced the terms "anoxic," "anemic," "histotoxic," and "stagnant" to designate the various forms of anoxia. However, clinical (human) anoxia is complex and consists of several components such as decreased oxygen availability, systemic acidosis, hypercapnia, and eventual superimposed ischemia (loss of oxygen and blood flow). The synonymous use of the terms "anoxia" and "ischemia" reflects the fact that hypoxic and ischemic states usually overlap and it is sometimes difficult to determine which predominates.

B. Etiology

Lack of oxygen to the brain can be categorized as anoxic anoxia, anemic anoxia, and ischemia. Anoxic anoxia consists of reduced arterial oxygen content and tension. This may be secondary to decreased oxygen in the environment or an inability for oxygen to enter the circulatory system such as during cardiac arrest or during pulmonary disease. Anemic anoxia consists of low oxygen content in the blood secondary to decreased hemoglobin content. Ischemic anoxia describes a state of insufficient cerebral blood flow. Such decreased flow states may be secondary to cardiovascular collapse or conditions of increased vascular resistance, such as in stroke or migraine.

The brain normally consumes approximately 3.5 ml of oxygen for each 100 g of brain tissue per minute. When this rate declines to 2.5 ml, delirium and subsequent coma can develop. Rates of cerebral oxygen metabolism below 2 ml/100 g per minute are incompatible with a conscious state. The brain cannot store oxygen and survives only for minutes after its oxygen supply is reduced below critical levels. In acute anoxia, consciousness is lost within 15 sec. Pyramidal cells in the CA1 sector of the hippocampus, Purkinje cells of the cerebellum, and pyramidal cells of the third and fifth layers of the cerebral cortex are vulnerable to even moderate degrees of anoxia. Widespread necrosis of the cortex with the brain stem intact produces a vegetative state. More severe anoxia affecting the cortex, basal ganglia, and brain stem results in coma and subsequent death.

Under physiologic conditions, glucose is the brain's only substrate and crosses the blood–brain barrier by facilitated transport. During each minute, the normal brain uses approximately 5.5 mg (31 μmol) of glucose per 100 grams of tissue. If there is hypoglycemia, defined in adults as a blood glucose concentration of less than 40 mg/dl, signs and symptoms of encephalopathy result secondary to cerebral cortex or brain stem dysfunction. The cerebral cortex is more vulnerable to the effects of hypoglycemia, whereas the brain stem and basal ganglia exhibit less histologic damage during periods of reduced serum glucose. Although periods of hypoglycemia may precipitate or confound anoxic coma, serum glucose must be maintained in a closely controlled range to prevent further neurologic disability. Similar to the detrimental effects of hypoglycemia, periods of hyperglycemia (>180 mg/dl) have been shown to worsen neurologic outcome.

C. Clinical Presentation

Coma is a state of unresponsiveness in which the patient remains with eyes closed and is unarousable. During the initial assessment of the patient in coma, the physical examination of the patient becomes vital. Although the etiology of coma may be obvious in cases of diffuse cerebral ischemia following cardiac arrest, the patient should be evaluated for evidence of head trauma, such as scalp laceration, hemotympani, otorrhea, and rhinorrhea. During coma, patients may also suffer from peripheral nerve injuries. Compartment syndromes and compression neuropathies have been described in comatose individuals of duration ranging from 4 to 48 hr.

Although several conditions may precipitate hypoxic–ischemic coma, acute anoxic coma usually is a result of cardiac arrest. Approximately 1.5 million people per year in the United States succumb to a cardiac death. In addition, of the 200,000 attempted cardiac resuscitations, only 70,000 are considered successful. Of those considered successful, only 10% of these survivors return to their former lifestyles. Survival among young adults is also not very promising. In this population of patients, one-fourth of the cases of cardiac arrest are caused by ischemic heart disease and one-fourth are caused by drug overdose with maximum long-term survival estimated at 28%. Following cardiac arrest, individuals admitted to intensive care units in coma suffer a high mortality rate. For example, those in coma for more than 48 hr have a 77% mortality rate. In contrast, individuals not in coma have an 11% mortality rate.

The neurologic examination of an individual in coma consists of an assessment of the level of consciousness as determined by eye opening, verbal responses, and purposive movements in response to noxious stimulation of the face, arms, and legs. Neuroophthalmologic function is assessed by

documenting the pupillary size and response to light, spontaneous eye movements, oculocephalic (doll's eyes), and oculovestibular (ice water caloric) responses. This approach considers the brain in terms of its hierarchical, longitudinal organization into cortical and brain stem functions. Clinical neurologic signs can be correlated with specific anatomic sites to establish the severity and extent of central nervous system dysfunction.

The level of consciousness is determined by the degree of behavioral arousal. Attempts should be made to elicit a behavioral motor response by verbal stimulation alone. If no response follows verbal commands that are known to be clearly audible, noxious stimulation can be applied to the face by digital supraorbital pressure and individually to the arms and legs by gentle compression of distal interphalangeal joints with a nontraumatic object, such as a soft wood tongue blade. Eye opening indicates activity of the reticular activating system, whereas verbal responses indicate cortical hemispheric function.

The fundus of each eye should be examined for signs of increased intracranial pressure that would include papilledema or hemorrhage. Bilateral dilated, fixed pupils indicate enhanced sympathetic nervous system activity due to either an endogenous sympathetic discharge, such as during anoxia–ischemia, or to exogenous catecholamines. Comatose patients may have no spontaneous eye movements. In such cases, doll's eyes responses and an ice water caloric test can be used. Doll's eyes indicate the integrity of proprioceptive fibers from the neck structures, the vestibular nuclei, and the nuclei of the third and sixth cranial nerves. When doll's eyes are absent, it becomes necessary to perform the ice water caloric test. During severe bilateral functional cortical depression that leads to coma, the doll's eyes can disappear before the ice water caloric responses because the latter are produced by a stronger stimulus.

Decorticate or flexor responses occur following damage to the hemispheres or during diffuse metabolic depression of cortical function. Decerebrate or extensor responses correlate with destructive lesions of the midbrain and upper pons but also may be present during anoxic coma. The absence of motor responses, especially if flaccidity and areflexia are present, indicates severe brain stem depression and is frequently found in terminal coma or in severe sedative intoxication. Withdrawal and localizing responses imply purposeful or voluntary behavior. If the individual can follow commands, then this is considered to be a positive response and marks the return of consciousness.

During cerebral anoxia, the brain experiences insufficient delivery of oxygen (Table I). Generalized brain anoxia is usually a consequence of systemic circulatory arrest caused by cardiac arrhythmia. Although other organs, such as the kidney and heart, can tolerate ischemic periods of up to 30 min, the brain can tolerate no more than a few minutes of anoxia. Brief episodes of cerebral anoxia are usually well tolerated, with patients escaping any irreversible deficits. However, an amnestic syndrome may follow transient periods of global ischemia. Patients may experience a severe antegrade amnesia and variable retrograde memory loss with preservation of immediate and remote memory resembling Korsakoff's psychosis. Individuals with anoxic–ischemic coma of more than 6 hr duration, but with unremarkable cranial magnetic resonance imaging (MRI) or cranial computed tomography (CT) imaging, have demonstrated persistent poor learning and recall of paired associations when compared with age- and intelligence quotient-matched controls. During a recovery from the immediate effects of an anoxic insult, a few patients have been known to return to an unconsciousness state. Delayed neurologic deterioration occurs in approximately 1 or 2 individuals per 1000 cardiac arrests and is not predictable by the type of insult, duration of anoxia, or any other identifiable variable.

Severe or prolonged periods of hypotension can result in focal cerebral ischemic lesions that result in coma. Individuals usually remain in coma for at least 12 hr and on awakening experience deficits including partial or complete cortical blindness, bibrachial paresis, and quadriparesis. Cortical blindness is rarely permanent in nature and is a result of ischemia to either occipital pole, which are located in an arterial border zone. Bilateral infarction of the cerebral motor cortex in the border zone between the anterior and middle cerebral arteries appears to be responsible for the syndrome of bibrachial paresis, sparing the face and lower extremities following cardiac arrest.

The spinal cord is considered to be more resistant to ischemic insults than more rostral sections of the central nervous system. However, cases of isolated spinal cord infarction can occur without evidence of cerebral injury. Syndromes of spinal cord ischemia following transient hypotension are characterized by flaccid paralysis of the lower extremities, urinary retention, and a sensory level in the thoracic region with the anterior spinal–thalamic tracts usually more affected than the posterior columns.

Table I
Clinical and Pronostic Correlation Following Cerebral Anoxic Injury

Anoxic insult	Clinical signs	Prognosis
Rapid and less than 5 min	Transient cognitive or memory loss	Complete recovery, rare delayed deterioration
Prolonged and more than 6 hr	*Cerebral hemisphere dysfunction*	Incomplete recovery with deficits
	Cognitive loss	
	Personality changes, depression	
	Brachial paresis or quadriparesis	
	Cortical blindness	
	Seizures	
	Myoclonus	
	Parkinsonism	
	Spinal cord dysfunction	Incomplete recovery with deficits
	Flaccid paralysis of the lower extremities	
	Urinary retention	
	Sensory loss of pain, temperature	
Severe circulatory arrest	Vegetative state	Chronic vegetative state
	Loss of cortical and brain stem function	Brain death

The most devastated group of patients following diffuse anoxic injury suffer widespread destruction of the cerebral cortex and progress to either a persistent vegetative state or death from neurologic complications. Extrapyramidal tract dysfunction following anoxia, such as during cardiac arrest or carbon monoxide poisoning, can produce a clinical syndrome identical to Parkinson's disease. Parkinsonian features may represent only a small part of widespread cerebral injury, but in other instances the clinical presentation of rigidity, akinesia, and tremor may represent the only neurologic disability.

Movement disorders, such as myoclonic jerks and cerebellar ataxia, may also follow episodes of anoxic injury. The "action myoclonus" syndrome can occur following global cerebral ischemia. The myoclonic jerks are frequently stimulus activated by light, sound, or initiation of movement and can incapacitate individuals in their daily living activities. Therapy with various agents, such as serotoninergic agents, clonazepam, and valproic acid, has been used with some success. Cerebellar ataxia, involving the trunk or extremities, is an infrequent postanoxic syndrome and may be secondary to the selective vulnerability of Purkinje cells to anoxia.

D. Clinical Evaluation and Management

Imaging studies such as cranial CT or MRI can assist in determining the presence of complications following an anoxic insult. These studies can differentiate between an ischemic infarct, intracerebral hemorrhage, and a mass lesion involving the cortex or the brain stem. A CT without contrast is helpful in suspected cases of cerebral hemorrhage. Within the first 72 hr of intracerebral hemorrhage onset, a cranial CT usually provides greater resolution than a MRI. In addition, CT and MRI are useful to demonstrate cerebral herniation prior to clinical presentation. Both positron emission tomography (PET) and magnetic resonance spectroscopy have also been used to follow cerebral metabolic function in individuals suffering from cerebral anoxic injury. Recently, MRI with the apparent diffusion coefficient of water has become a sensitive tool of neuronal physiology and may represent a reliable indicator of progressive neuronal injury following cerebral ischemia.

The electroencephalogram (EEG) can be useful in assessing cortical dysfunction and identifying the presence of epileptic activity. The EEG is classified in terms of increasing severity in five categories. Grade I

represents normal alpha with theta–delta activity; grade II is theta–delta activity with some normal alpha activity, grade III is dominant theta–delta activity with no normal alpha activity, grade IV is low-voltage delta activity with alpha coma (nonreactive alpha activity), and grade V represents an isoelectric tracing. In individuals suffering postanoxic coma, grade I is compatible with a good prognosis, grades II and III have no definitive predictive value, and grades IV and V are compatible with a poor prognosis and infrequent recovery.

In addition to the EEG, evoked potentials can provide information regarding the functional state of the cerebral cortex following cerebral anoxia. Somatosensory evoked potentials determine the functional integrity of the spinal cord posterior columns, brain stem medial lemniscus, thalamus, and frontoparietal sensorimotor cortex. During the loss of bilateral cortical responses despite the etiology of the coma, afflicted individuals can experience a high mortality rate. In anoxic coma, patients who maintain normal responses throughout their illness maintain a good prognosis but may have permanent neurologic sequelae. Brain stem auditory evoked potentials correlate with brain stem dysfunction during coma. A simultaneous latency increase of all components is consistent with progressive ischemia of the posterior fossa and a decrease in cerebral perfusion pressure. Although brain stem auditory evoked potentials are rarely modified by exogenous factors, they can be altered by hypothermia, anesthetics, and barbiturates.

Recovery of the comatose patient is dependent on the rapid treatment of the underlying disorder. Prompt attention must be directed to the restoration of respiratory, hemodynamic, and metabolic homeostasis. The respiratory rate and its pattern should be documented prior to therapeutic measures such as intubation and mechanical ventilation. Following initial examination of the respiratory rate, an adequate airway should be obtained. If intubation is required in a comatose patient, one must rule out the existence of a neck fracture prior to hyperextension of the head for endotracheal tube insertion. Arterial blood gases should be obtained to ensure adequate oxygenation (oxygen saturation $>90\%$) and to monitor serum acid/base status.

On the establishment of adequate ventilation, blood should be obtained for determination of serum glucose, routine chemistries, and toxicology. Since patients in coma may have poor nutrition and are susceptible to Wernicke's encephalopathy, initially 100 mg of thiamine should be given intravenously. Bedside stat glucose determinations should be employed to identify hypoglycemia. In such cases, 50 mg of 50% dextrose should be administered. Although administration of one ampule of dextrose is not detrimental in cases of hyperosmolar coma, identification of hyperglycemic states is important since elevated serum glucose may promote ischemic damage in cases of anoxic coma.

The hemodynamics of the patient should be closely controlled. Hypertension may be secondary to Cushing's reflex with increased intracranial pressure or a result of brain stem ischemia. Hypotension may be indicative of myocardial infarction, hemorrhagic shock, sepsis, or sedative–hypnotic drug overdose. Bradycardia associated with elevated blood pressure suggests brain stem compression or increased intracranial pressure. One must note, however, that elevated intracranial pressure does not decrease the heart rate in all instances. Reversible causes of transtentorial herniation, such as subdural hematoma, should be immediately considered before cardiovascular collapse ensues.

Status epilepticus following cardiac arrest can result in progressive anoxic brain damage and requires immediate attention. Following airway stabilization, generalized convulsions can initially be treated with diazepam intravenously in up to a 10-mg total dose. This is to be followed by a phenytoin loading dose of 18 mg/kg (50 mg/min) intravenously. If status epilepticus continues, 20 mg/kg phenobarbital intravenously should be administered. Persistent convulsions at this point require general anesthesia. In the case of generalized convulsions that are not consistent with status epilepticus, phenytoin orally in appropriate daily dose (dependent on body size) should be maintained in individuals with either EEG or CT/MRI evidence of a persistent epileptic focus (hemorrhage, neoplasm, large ischemic infarct, abscess, etc).

Measurement of the patient's rectal temperature is a vital component of the initial evaluation. Hypothermic patients with temperatures below 34°C (93.2°F) should be warmed slowly to a body temperature higher than 36°C (96.8°F). Since hypothermia below 80°F results in coma, resuscitative measures are indicated in all hypothermic patients even if vital signs are absent. Hypothermic patients have recovered following cardiac arrest, presumably because of the protective effects of low body temperature and depressed cerebral oxygen requirements. In addition, hypothermia has been shown to reduce neuronal death in the hippocampus and caudate putamen in animal models with forebrain ischemia and is currently under investigation in the clinical setting.

Some centers advocate aggressive treatment of raised intracranial pressure to significantly reduce mortality. Measurement of intracranial pressure can be performed through the use of epidural monitoring or through intraventricular pressure measurements. Intracranial pressure monitoring can differentiate between active hydrocephalus and mass lesions requiring surgical intervention. Intracranial pressure monitoring has also been linked to prognosis. Most patients with a maximum intracranial pressure increase of less than 30 mmHg experience good recovery, whereas a pressure increase above 25–30 mmHg represents a great risk for brain tamponade.

E. Clinical Prognosis

Several studies have examined the prognosis of individuals who remain in coma for extended periods following cardiac arrest. Patients can suffer memory impairment if coma duration is at least 6 hr. In some groups of patients, a poor prognosis was evident in individuals who lacked a motor response to pain. Poor recovery has also been associated with the presence of generalized myoclonus status, which can be suggestive of diffuse neocortical damage. More comprehensive studies evaluating individuals in coma following diffuse global ischemia have demonstrated that individuals with absent pupillary light reflexes never regain independent daily function. However, following the initial insult, the early onset of incomprehensible speech, orienting spontaneous eye movements, or the ability to follow commands were indicative of a good prognosis. Individuals with the best chance of recovery have preserved brain stem function following the initial insult. The most favorable sign of a good outcome is incomprehensible speech, such as moaning. At Day 1, the following signs are each associated with at least a 50% chance of regaining independent function: any form of speech, orienting spontaneous eye movements, intact oculocephalic or oculovestibular responses, ability to follow commands, and normal skeletal tone.

II. METABOLIC COMA

A. Historical Background

The patient in metabolic coma may be the cause of some of the greatest diagnostic errors ever made. Some historians believe that the description of Jesus resurrecting his friend Lazarus from the dead may represent one of the first reports of an individual in coma that eventually recovered from a metabolic disability. In addition, recent descriptions, documented approximately 150 years ago, discuss the diagnosis of ''apparent death'' as a possible synonym for coma secondary to metabolic illness.

B. Etiology

Although levels of attention and alertness are affected in metabolic coma, each disease process also yields a specific clinical picture. For example, severe anoxic ischemia following cardiac arrest will produce coma, whereas alcohol withdrawal will initially result in an agitated delirium. Metabolic encephalopathy is often reversible if the underlying systemic disorder is corrected promptly.

Under physiologic conditions, glucose is the brain's only substrate and crosses the blood–brain barrier by facilitated transport. Each minute, the normal brain requires 5.5 mg (31 μmol) of glucose per 100 grams of tissue. However, one of the most significant complications of exogenous insulin therapy is hypoglycemic coma. If there is hypoglycemia, defined in adults as a blood glucose concentration of less than 40 mg/dl, loss of cortical function ensues secondary to cerebral cortex and brain stem dysfunction. Neurologic presentation during hypoglycemia can be variable. Some patients will present with focal motor or sensory deficits, whereas others become comatose.

A significant proportion of cases of metabolic coma are a result of drug ingestion, with at least half of the afflicted individuals administering multiple drugs. Proper diagnosis relies heavily on the physical examination since an accurate or complete history may be unobtainable from the patient. Toxic drug screens of blood and urine will assist in the diagnosis. Excessive barbiturate consumption results in hypothermia, hypotension, and possible apnea. An individual's pupils remain small but reactive with intact ciliospinal reflexes.

Alcohol ingestion may be indistinguishable from other metabolic disorders, such as depressant drug intoxication or hypoglycemia. In addition, progressive loss of consciousness may be complicated by underlying cerebral trauma such as a subdural hematoma. Evidence of ''alcohol on the breath'' provides insight into the etiology of the coma but does not distinguish between pure alcohol intoxication or a ''cocktail'' of

alcohol, sedative, and hypnotic drugs. A blood alcohol level and drug screen should be determined in individuals with alcohol and/or multiple drug abuse who present with coma.

Benzodiazepines can result in stupor or coma without respiratory depression. Clinical trials have studied treatment with the benzodiazepine antagonist flumazenil. Flumazenil is also considered to have a diagnostic value in cases of mixed-drug intoxication.

Opiate and heroin overdoses occur by either parenteral injection or sniffing of the agent. Neurologic impairment secondary to opiate abuse is currently on the rise despite a reduction in use during previous years. Systemic complications include hypothermia, hypotension, bradycardia, respiratory slowing, and pulmonary edema. Coma does not require chronic administration and can result following an initial injection of the opiate. Opiate coma is characteristically associated with pinpoint pupils reactive to bright light.

Toxicity from cocaine administration has systemic, psychiatric, and neurologic manifestations. Neurologic complications of cocaine use range from benign headaches to coma. Focal neurologic manifestations include subarachnoid hemorrhage, anterior spinal artery syndrome, lateral medullary syndrome, transient ischemic attacks, and cerebral infarction. Although the exact mechanism of cocaine-related cerebral vascular disease is unknown, adrenergic stimulation and surges in blood pressure may play a significant role.

Overmedication with prescription agents can also lead to coma. The most notable neurologic manifestations of tricyclic antidepressants are seizures and coma. Lithium toxicity can progress to seizures, lethargy, and coma. Treatment consists of supportive care with artificial ventilation, fluid, and electrolyte infusions in conjunction with hemodialysis. Valproate can lead to coma during excessive drug levels or during carnitine insufficiency. Amantadine, an antiviral agent employed in the therapeutic regimes for Parkinson's disease and fatigue syndromes, has been reported to induce coma in the presence of end-stage renal disease. Ibuprofen, a popular over-the-counter analgesic agent, is rarely associated with nervous system toxicity, but abuse of this agent can result in metabolic acidosis and lead to coma.

In addition to drug administration, other metabolic mechanisms that lead to coma should be considered. For example, endocrine dysfunction that occurs with severe hypothyroidism or renal insufficiency can result in coma. Infectious processes, such as cerebral malaria and meningitis, lead to increased intracranial pressure and subsequent coma if allowed to progress without treatment. Less common causes of coma, such as ciguatera food poisoning and hyperammoniemia, should also be considered when the diagnosis appears obscure.

C. Clinical Presentation

Metabolic coma is significant not only in clinical terms but also on economic grounds. For example, individuals admitted in coma with methanol poisoning suffer a significant mortality rate of 64%. The annual cost for this intensive care management of high-mortality patients is more than $40 billion.

The patient in coma as a result of a metabolic disorder requires a detailed physical and neurologic examination. The patient should be evaluated for evidence of head trauma, such as scalp laceration, hemotympani, otorrhea, and rhinorrhea. Blisters of the skin during coma may be suggestive of barbiturate overdose, whereas bullous skin lesions have been associated with antipsychotic drug ingestion. Patients in coma may also succumb to compartment syndromes and compression neuropathies.

Similar to the assessment of individual's suffering from anoxic coma, the neurologic examination consists of an assessment of the level of consciousness as determined by verbal responses, eye opening, and purposive movements. Attempts should be made to elicit a behavioral motor response by verbal stimulation alone. If no response follows even shouted commands, noxious stimulation can be applied to the face by digital supraorbital pressure and individually to the arms and legs by compression of distal interphalangeal joints with a nontraumatic object, such as a soft wood tongue blade. Verbal responses are indicative of dominant hemisphere function, whereas eye opening indicates activity of the reticular activating system.

During the neuroophthalmologic examination, the fundus of each eye should be examined for papilledema or hemorrhage. In coma due to metabolic brain disease, the pupils are generally small but reactive to light. Small, reactive pupils are present in normal individuals during sleep and are a common finding in elderly persons due to degenerative changes in the iris and ciliary muscles. Small, sluggishly reactive pupils that respond to naloxone administration are characteristic of an overdose of opiates. Pinpoint pupils occur in brain stem pontine compression.

Bilateral dilated, fixed pupils may be secondary to endogenous sympathetic discharge following periods of diffuse anoxia or to the release of exogenous catecholamines. Dilated pupils are also seen in glutethimide-induced coma and overdosage with tricyclic antidepressant or other atropine-like agents. In coma due to amphetamine, cocaine, and LSD overdosage, the pupils are large but reactive. Midposition, fixed pupils are indicative of midbrain failure and loss of both sympathetic and parasympathetic pupillary tone, whether caused by structural or metabolic disease. A unilateral, dilated fixed pupil suggests damage to parasympathetic fibers of the external portion of the third cranial nerve.

In comatose patients without spontaneous eye movements, doll's eyes responses and the ice water caloric test can be used to determine the integrity of the eighth, sixth, and third cranial nerves and their interconnecting brain stem pathways. Doll's eyes indicate the integrity of proprioceptive fibers from the neck structures, the vestibular nuclei, and the nuclei of the third and sixth cranial nerves. If the cortical influences are depressed but brain stem gaze mechanisms are intact, the eyes will deviate conjugately to one side when the head is rotated to the opposite side. When doll's eyes are absent, it becomes necessary to perform the ice water caloric test. The caloric response may be absent not only during barbiturate and phenytoin overdosage but also during brain stem lesions and labyrinthine disease.

The motor examination provides insight into the functional integrity of the neuronal networks linking the cortex, brain stem, and pyramidal tracts. Although techniques such as transcranial magnetic evoked potentials are sometimes used to assess the pyramidal tract pathways in comatose patients, the neurologic examination remains the mainstay for assessment of the patient in metabolic coma. The absence of motor response, especially if flaccidity and areflexia are also present, indicates severe brain stem depression and is frequently found in severe sedative intoxication. Decerebrate or extensor responses correlate with destructive lesions of the midbrain and upper pons but may also be present in reversible conditions such as anoxic coma. Decorticate or flexor responses occur after damage to the hemispheres as well as in metabolic depression of brain function. Withdrawal and localizing responses imply purposeful or voluntary behavior. Obeying commands is the best response and marks the return of consciousness. Generalized or focal repetitive movements, not affected by stimuli, usually represent seizure activity.

D. Clinical Evaluation and Management

Imaging with cranial CT or MRI can be useful in metabolic coma to differentiate between an ischemic infarct, an intracerebral hemorrhage, and a mass lesion involving the cortex or the brain stem. However, these imaging studies are often unremarkable during metabolic coma. Patients in coma who present with cranial nerve deficits and posturing likely suffer from a mass lesion involving the cortex or the brain stem. However, patients in coma with unilateral masses may not initially suffer from transtentorial herniation. In this group, CT and MRI demonstrate horizontal displacement at the level of the pineal body.

In some centers, continuous bedside monitoring of regional cerebrocortical blood flow with laser Doppler flowmetry is employed to follow fluctuations in the cerebral microcirculation in comatose individuals. PET and single positron emission computerized tomography (SPECT) provide an alternative method of imaging that also assesses cerebral function. MRI spectroscopy may provide suggestive evidence of neuronal function through *N*-acetylaspartate/creatinine ratios. Blood flow and metabolic studies can also be used as diagnostic aids to differentiate individuals in coma from patients with the "locked-in" syndrome.

Monitoring with EEG is useful in assessing cortical dysfunction since it is sensitive to fluctuations in cerebral blood flow and metabolism. In addition, EEG can detect the presence of occult seizure activity, which reportedly can occur in more than 30% of intensive care patients suffering from metabolic disorders. In patients with overt convulsions, the EEG can also be used to temper anticonvulsant treatment in the comatose patient to prevent or reduce neuronal cell loss. In addition to issues of care, the EEG has been used to assess prognosis. In patients with terminal coma, onset of abnormal EEG changes may sometimes be suggestive of a poor outcome.

Evoked potentials can provide information concerning the functional state of the cerebral cortex and brain stem. Patients with bilateral absence of cortical responses exhibit mortality rates of 73–98%. Others report that motor evoked potentials, although less sensitive than somatosensory evoked potentials during coma, are helpful in directing management. The bilateral absence of motor evoked potentials is suggestive of a poor outcome during metabolic coma. Brain stem auditory evoked potentials correlate with brain stem function and can provide a useful tool for the assessment of brain stem activity. Simultaneous latency increase of all components can be consistent

with progressive ischemia of the posterior fossa and a decrease in cerebral perfusion pressure. Loss of the brain stem auditory evoked potentials is usually suggestive of an incumbent deterioration and death. Although brain stem auditory evoked potentials are not usually modified by exogenous factors, brain stem auditory evoked potentials can be falsely altered by hypothermia, anesthetics, and barbiturates.

Treatment of the comatose patient must be directed toward the restoration of respiratory, hemodynamic, and metabolic function. The respiratory rate and its pattern should be documented prior to therapeutic measures such as intubation and mechanical ventilation. Following initial examination of the respiratory rate, an adequate airway should be obtained. If intubation is required, one must rule out the existence of a neck fracture prior to hyperextension of the head for endotracheal tube insertion. Arterial blood gases should be obtained to ensure adequate oxygenation and to monitor serum acid/base status.

On the establishment of adequate ventilation, blood should be obtained for determination of serum glucose, routine chemistries, and toxicology. Since patients in coma may have poor nutrition and are susceptible to Wernicke's encephalopathy, initially 100 mg thiamine should be given intravenously. Bedside glucose determinations should be employed to identify hypoglycemia. Identification of hyperglycemic states is also important since elevated serum glucose may promote ischemic damage in cases of anoxic coma. Naloxone should be administered intravenously in cases of suspected opiate abuse, and flumazenil should be administered in cases of benzodiazepine-induced coma.

Measurement of the patient's rectal temperature is a vital component of the patient's care. Hypothermia can be due to environmental exposure, near drowning, sedative drug overdose, hypothyroidism, and Wernicke's disease. Hypothermic patients with temperatures below 34°C (93.2°F) should be warmed slowly to a body temperature higher than 36°C (96.8°F). Since hypothermia below 80°F results in coma, resuscitative measures are indicated in all hypothermic patients even if vital signs are absent. The presence of fever in a comatose patient requires investigation for an underlying infection.

Seizure control is also critical to the management of the metabolic comatose patient. Status epilepticus can result in permanent anoxic brain damage and requires immediate attention. Following airway stabilization, generalized convulsions can initially be treated with diazepam intravenously up to 10-mg total dose. This is to be followed by a phenytoin loading dose of 1000 mg (50 mg/min), but may be increased to 1500 mg if required.

E. Clinical Prognosis

In most cases, coma secondary to infection or sedative drug intoxication carries a low mortality rate. If ventilatory and hemodynamic support are supplied without delay, most individuals experience no residual neurologic impairment. However, complications can include cardiovascular collapse secondary to hypothermia, hypotension, dysrhythmias, myocardial infarction, or pulmonary edema.

In cases complicated by cerebral ischemia, patients can suffer permanent neurologic sequelae if coma duration is at least 6 hr. Individuals with absent pupillary light reflexes usually never regain independent daily function, but the early onset of incomprehensible speech, orienting spontaneous eye movements, or the ability to follow commands can be indicative of a good outcome following the initial insult.

Other factors also play a role in the eventual outcome from coma. Metabolic coma complicated by traumatic lesions, such as subdural hematoma, can have less than a 10% recovery rate. Comatose patients with increased plasma glucose, hypokalemia, elevated serum leukocyte counts, or absent P300 event-related potentials also have a poor prognosis.

III. BRAIN HERNIATION

A. Historical Background

In the 17th century, the human body began to be viewed as a system of subunits and independent compartments. This eventually led to the first human anatomical descriptions that mapped the body into different organs and tissues. As a result of this "subunit" or "compartment" theory, the Latin term *herniation* was employed to describe the protrusion of a portion of an organ or tissue through an abnormal passage.

B. Etiology

Brain herniation may result from either supratentorial or subtentorial lesions. Supratentorial masses, such as

those that result from lobar hemorrhage, cause brain shifts that can be termed cingulate, central (transtentorial), or uncal herniation. Cingulate herniation refers to the displacement of the cingulate gyrus under the falx cerebri with subsequent compression of the internal cerebral vein. A mass in the cerebral hemisphere that produces cingulate herniation can compress the ipsilateral anterior cerebral artery, producing subsequent vascular ischemia, edema, and progressive mass effect.

Downward displacement of the hemisphere with compression of the diencephalon and midbrain through the tentorial notch results in central herniation. Lesions of the frontal, parietal, and occipital lobes initially can precipitate cingulate herniation that progresses to central herniation. Displacement of the diencephalon against the midbrain produces hemorrhage in the pretectal region and thalamus. The medial perforating branches of the basilar artery rupture during herniation of the midbrain and pons.

Uncal herniation involves shift of the temporal lobe, uncus, and hippocampal gyrus toward the midline with compression of the adjacent midbrain. During this process, the ipsilateral third cranial nerve and the posterior cerebral artery are compressed by the uncus and edge of the tentorium. Both central and uncal herniation can compress the posterior cerebral artery, resulting in occipital lobe ischemia. Further increased intracranial pressure results from compression of the aqueduct. In this instance, cerebral spinal fluid cannot drain from the supratentorial ventricular system, producing a pressure gradient between structures above and below the obstruction. In addition, expansion of the supratentorial volume can yield pressure necrosis of the parahippocampal gyrus.

Supratentorial herniation results in an orderly progression of neurologic dysfunction from the cerebral hemispheres to the brain stem. Exceptions to this observation exist. Massive cerebral hemorrhage can rapidly flood the ventricular system, compress the fourth ventricle, and result in acute medullary failure. Isolated medullary failure can also occur from withdrawal of cerebral spinal fluid by a lumbar puncture in a patient with incipient central herniation from a supratentorial mass.

C. Clinical Presentation

Untreated or progressive cerebral herniation can result in increased morbidity and mortality rates. For example, in cases of fulminant hepatocellular failure, cerebral herniation is the leading cause of death and disability. Even in controlled environments such as the operating room, cerebral herniation can be the primary cause of death in approximately 15% of patients.

Patients with elevated intracranial pressure resulting in cerebral herniation require a detailed physical and neurologic examination. Similar to patients presenting with coma, individuals should be evaluated for evidence of head trauma, such as scalp laceration, hemotympanum, otorrhea, and rhinorrhea. The neurologic examination consists of an assessment of the level of consciousness as determined by verbal responses, eye opening, and purposeful movements. Attempts should be made to elicit a behavioral motor response by verbal stimulation alone. If no response follows even shouted commands, noxious stimulation can be applied to the face by digital supraorbital pressure and individually to the arms and legs by compression of distal interphalangeal joints with a nontraumatic object, such as a soft wood tongue blade. Verbal responses are indicative of dominant hemisphere function, and eye opening indicates activity of the reticular activating system.

During the neuroophthalmologic examination, the fundus of each eye should be examined for papilledema or hemorrhage. Although episodic anisocoria associated with headaches is usually benign, a unilateral, dilated fixed pupil (sometimes referred to as a "blown pupil") suggests damage to parasympathetic fibers of the external portion of the third cranial nerve as a result of brain herniation. In contrast, pinpoint pupils suggest compression of pontine structures. Midposition, fixed pupils indicate midbrain failure and loss of both sympathetic and parasympathetic pupillary tone, whether caused by structural or metabolic disease.

As previously described for comatose patients without spontaneous eye movements, doll's eyes responses and the ice water caloric test can be used to determine the integrity of the third, sixth, and eighth cranial nerves and their interconnecting brain stem pathways. If the cortical influences are depressed but brain stem gaze mechanisms are intact, the eyes will deviate conjugately to one side when the head is rotated to the opposite side. When the doll's eyes' responses are absent, it is necessary to perform the ice water caloric test.

The motor examination provides insight into the functional integrity of the neuronal networks linking the cortex, brain stem, and pyramidal tracts. Although diminution of brain stem auditory evoked potentials and somatosensory evoked potentials can be sugges-

tive of transtentorial brain herniation, the neurologic examination remains the mainstay for assessment of the patient with increased intracranial pressure. The absence of motor response, especially if flaccidity and areflexia are also present, indicates severe brain stem depression. Decerebrate or extensor responses correlate with destructive lesions of the midbrain and upper pons. Decorticate or flexor responses occur after damage to the hemispheres and in metabolic depression of brain function. Withdrawal and localizing responses imply purposeful or voluntary behavior, but the ability to follow commands is considered to be the best response and marks the return of consciousness.

D. Clinical Evaluation and Management

Supratentorial lesions can be classified as either extracerebral or intracerebral. Extracerebral lesions include neoplasms, infections, and trauma-related injuries such as hematomas. Lesions such as neoplasms or abscesses impair consciousness via the mass effect that they exert. Headaches, seizures, motor sensory deficits, and cranial nerve dysfunction, rather than an altered state of consciousness, are usually the initial symptoms of neoplasms. Occassionally, a progressing frontal lobe lesion can produce behavioral changes prior to brain herniation. Subdural empyema, a process secondary to otorhinologic infection, meningitis, or intracerebral abscess, can present as an extracerebral lesion. Initial presentation includes subdued consciousness, sinusitis, headaches, focal skull tenderness, and fever. Further deterioration can lead to language dysfunction, hemiparesis, seizures, and eventual coma.

Intracerebral disease initially produces focal deficits involving motor, sensation, or language function prior to altering consciousness. As previously described, frontal lobe lesions, as well as intraventricular masses, may present only with changes in personality before progressing to cerebral herniation.

Among supratentorial vascular lesions, hemorrhage into the cerebral parenchyma is the most common cause of altered consciousness. The etiologies of cerebral hemorrhage include rupture of an intracerebral blood vessel or arterial aneurysm rupture, leakage from an arteriovenous malformation, and bleeding into a metastatic tumor. Primary hypertensive cerebral hemorrhages usually involve the putamen, internal capsule, or thalamus. When these structures are involved, patients present with motor sensory deficits, headache, or loss of language function. The size of the hemorrhage usually correlates with the neurologic deficit, but clinical symptoms such as headache intensity may be more dependent on the anatomical location of the hemorrhage. A parenchymal cerebral bleed may extend intraventricularly. Ventricular system hemorrhage alone produces little more than a chemical meningitis. Downward brain herniation can occur when rapid flooding of blood into the ventricles causes a pressure gradient between the anterior and posterior fossae. Large cerebral infarcts can present with obtundation that sometimes results in brain herniation. Cerebral vascular congestion and edema reach a maximum within 4 days following the infarct. At this point, patients are at risk for transtentorial herniation.

Lesions below the tentorium can involve the brain stem reticular activating system directly or impair its function by compression. Coma arises from intrinsic brain stem lesions that destroy the paramedian midbrain or impair its vascular supply. Mass lesions alter consciousness by exerting direct pressure on the midbrain and pons with resultant ischemia and necrosis.

Upward transtentorial herniation of the cerebellum and mesencephalon occurs with enlarging masses of the posterior fossa. During this process, the posterior third ventricle is compressed, obstructing cerebral spinal fluid flow and contributing to increased intracranial pressure. Upward herniation also distorts the vasculature of the mesencephalon, compresses the veins of Galen and Rosenthal, and produces superior cerebellar infarction from occlusion of the superior cerebellar arteries.

Downward herniation of the cerebellar tonsils from a posterior fossa mass or hemorrhage occurs as an isolated process or in conjunction with upward herniation and direct brain stem compression. It is normal for the cerebellar tonsils to extend 2 cm into the cervical canal. Downward compression of the tonsils into the foramen magnum produces ischemia of the cerebellar tonsils, medulla, and upper cervical cord.

Imaging studies, such as cranial CT or MRI, can assist in determining the etiology of cerebral herniation. These studies can differentiate between an ischemic infarct, intracerebral hemorrhage, and a mass lesion involving the cortex or the brain stem. A CT without contrast is helpful in suspected cases of cerebral hemorrhage. As previously noted, CT within the first 72 hr of onset of intracerebral hemorrhage usually provides greater resolution than MRI. Contrast CTs are necessary to visualize the cerebral

vasculature following the exclusion of a cerebral hemorrhage. Patients in coma who present with cranial nerve deficits and posturing are most likely to suffer from a mass lesion involving the cortex or the brain stem. However, patients in coma with unilateral masses may not initially suffer from transtentorial herniation. In this group, CT and MRI may demonstrate early downward displacement of the midbrain. Although the clinical exam remains the gold standard for the initial assessment of cerebral herniation, MRI can be a valuable asset in the early recognition of cerebral herniation.

During the acute management of an individual with suspected brain herniation, the respiratory rate and its pattern should be documented prior to therapeutic measures such as intubation and mechanical ventilation. Following initial examination of the respiratory rate, an adequate airway should be obtained. Alterations in respiration correlate well with brain dysfunction. With supratentorial lesions, Cheyne–Stokes respiration may be evident, with waxing and waning hyperpnea alternating with shorter periods of apnea. Progressive brain herniation involving the midbrain–upper pontine tegmentum yields central neurogenic hyperventilation characterized by an increase in the rate and depth of respiration to the extent that respiratory alkalosis results. Low pontine lesions result in apneustic breathing, which consists of respiratory pauses of approximately 3 sec following full inspiration.

Treatment for elevated intracranial pressure relies on several modalities. The goal is to normalize elevated intracranial pressure by restricting cerebral blood flow or fluid to the brain tissue. Currently used treatments include hyperventilation, diuresis, fluid restriction, blood pressure control, steroids or surgery when indicated, and drug therapy.

Hyperventilation produces hypocapnia, which in turn decreases cerebral blood flow globally through vasoconstriction. Reduction in pCO_2 from 40 to 30 mmHg can reduce intracranial pressure approximately 30%. It is recommended to maintain pCO_2 at 25–30 mmHg since aggressive hypoventilation below 25 mmHg may reduce cerebral blood flow excessively and result in cerebral ischemia.

Fluid restriction and fluid elimination are both employed in the treatment of elevated intracranial pressure. In some cases, hypotensive therapy has been advocated. Normal saline is administered to maintain normal serum osmolality and to prevent systemic intravascular depletion. Restriction of normal saline infusion to one-half maintenance can help reduce intracranial pressure. In addition, osmotic agents can be administered acutely to control intracranial pressure. These drugs do not cross the blood–brain barrier and therefore pull water from cerebral tissue across an osmotic gradient into plasma. Long-term therapy with osmotic agents may not be as efficacious as use on an acute basis. Equilibrium with cerebral tissue is eventually established with these drugs.

Mannitol reduces intracranial pressure and increases cerebral perfusion pressure and cerebral blood flow approximately 10–20 min following infusion. Recommended doses are 0.5–1 g/kg, with higher doses effective for up to 6 hr. Diuretics have also been employed to produce an osmotic diuresis. They function by decreasing formation of cerebrospinal fluid, and through the removal of sodium and water from brain tissue. Renal loop diuretics, such as furosemide and ethacrynic acid, are usually employed in conjunction with osmotic agents when a single agent does not sufficiently reduce intracranial pressure.

There is conflicting evidence concerning the use of steroids to reduce elevated intracranial pressure. Steroids are efficacious in reducing edema from brain neoplasms and in the treatment of such conditions as pseudotumor cerebri. In addition, a relatively small dose should be employed, such as 4 mg dexamethasone per day, since efficacy is not lost but toxicity is minimized. There is no advantage to high-dose dexamethasone in clinical outcome in severe head injury, and corticosteroids have not proved beneficial in the treatment of global brain ischemia. In addition, steroids elevate serum glucose and may worsen the effects of cerebral ischemia.

Barbiturate administration can reduce cerebral blood flow and cerebral metabolic requirements. However, the efficacy of barbiturates in reducing elevated intracranial pressure remains controversial. In addition, prophylactic use of pentobarbital following severe head injury does not decrease the incidence of elevated intracranial pressure or the duration of intracranial pressure hypertension. The most notable complication of barbiturate administration is hypotension. Barbiturates may also yield dysrhythmias, myocardial depression, and impaired uptake or release of glutamate.

Recent clinical studies suggest the use of decompressive craniectomy during brain herniation. Decompressive craniectomy is recommended for the specific indications of increased intracranial pressure such as those following severe head injury. Surgery is not indicated for cases that involve significant primary lesions, cerebral ischemia, or central herniation.

E. Clinical Prognosis

In cases of cerebral herniation complicated by ischemia, patients may suffer permanent neurologic sequelae if coma duration is 6 hr or longer. In addition, individuals with absent pupillary light reflexes never appear to regain independent daily function, but the early onset of incomprehensible speech, orienting spontaneous eye movements, or the ability to follow commands are considered indicative of a good outcome. Recent studies confirm the prognostic value of the neurologic examination that focuses on pupillary and motor function.

Measurement of intracranial pressure has also been linked with prognosis. Most patients with a maximum intracranial pressure increase of less than 30 mmHg experience good recovery. In contrast, a pressure increase more than 30 mmHg, and in some cases an intracranial pressure increase more than 20 mmHg, represents a great risk for the brain. Others have noted that in a limited number of cases aggressive treatment based on intracranial pressure monitoring can reduce mortality when applied to patients in coma secondary to cerebral infarction.

IV. PERSISTENT VEGETATIVE STATE

A. Historical Background

The term ''vegetative'' refers to a passive or involuntary existence with limited cerebral activity. In 1972, Jennet and Plum described the ''vegetative state'' as a chronic condition following diffuse brain injury that resulted in the absence of cognitive function but the persistence of sleep–wake cycles. Individuals could open their eyes to auditory stimuli and were autonomically stable with the maintenance of respiratory and hemodynamic function.

The American Neurological Association Committee on Ethical Affairs and the Quality Standards Subcommittee of the American Academy of Neurology have individually defined the vegetative state as a chronic condition that preserves the ability to maintain blood pressure, respiration, and cardiac function but not cognitive function. Specifically, the individual has no consciousness of self or the environment. The patient does not possess language function and therefore lacks any ability to communicate. Voluntary behavior or movements are absent, but facial expressions such as smiling, frowning, and crying can occur. These are not linked to any external stimulus. Sleep–wake cycles are present but do not necessarily reflect a specific circadian rhythm and are not associated with the environment. Although medullary brain stem functions remain intact to support cardiorespiratory functions, the presence of midbrain or pontine reflexes may be variable. Spinal reflex activity may also be present, but bowel and bladder function are absent.

The diagnosis of vegetative state can be made once the previously mentioned criteria are satisfied. This condition differs from the diagnosis of persistent vegetative state in both clinical and prognostic terms. The persistent vegetative state consists of the vegetative state that continues for a duration of 1 month or longer. Persistent vegetative state does not imply permanent disability since in some cases patients can partially recover from this condition.

B. Etiology

Multiple etiologies may lead to the persistent vegetative state. The end result is severe neuronal loss of the cerebral hemispheres with sparing of at least the lower brain stem. Following an anoxic insult, CT may reveal diffuse cortical swelling and progress to hypodensities in both cerebral hemispheres. In animal models of persistent vegetative state induced by transient global brain ischemia, neurodegeneration of Purkinje cells and the hippocampal CA1 pyramidal cells represents the initial phase of cerebral damage. Postmortem examinations of vegetative patients have demonstrated the loss of forebrain and neocortical structures with an intact brain stem.

Cerebrovascular accidents, such as those secondary to cardiac arrest, or the progressive loss of cortical function, such as dementia, appear to be the most common causes of the persistent vegetative state, accounting for at least 63% of the cases in one study. In younger individuals, cerebral trauma is a common cause of persistent vegetative state. Trauma patients who progress to a vegetative state have been reported to sustain more severe closed-head injury and develop swelling or shift of midline structures. Metabolic disorders such as hypoglycemia can also result in the vegetative state.

C. Clinical Presentation

Limited information on the clinical characteristics of individuals in the persistent vegetative state is available, but it is estimated that approximately 25,000

adults in the United States carry the diagnosis. In one group of nursing home patients, persistent vegetative state was diagnosed in 3% of the individuals. The age of afflicted individuals ranged from 19 to 96 years and the duration of the persistent vegetative state ranged from 1 to 16.8 years. Twenty-five percent of the patients were vegetative for more than 5 years. Other studies have indicated that all vegetative patients require at least one type of functional support, such as respirators, gastrotomy tubes, or intravenous hydration. The average cost of care can be as high as $170,000 per patient.

Individuals in the vegetative state require a multidisciplinary approach to patient care. Their course is frequented by extended hospital stays and multiple complications, such as pneumonia, decubiti, urinary incontinence, and urinary infection. In addition, patients may experience disordered neuroendocrine dysfunction with elevated profiles of growth hormone, prolactin, luteinizing hormone, and cortisol.

As with any neurologic disorder, the patient evaluation should consist of a thorough general physical and neurologic examination. The general physical examination is important for the initial assessment of a patient in the vegetative state. The presence of scalp lacerations, hemotympanum, otorrhea, and rhinorrhea may suggest recent trauma and a treatable condition such as a subdural hematoma. Bedridden patients may also suffer compartment syndromes and compression neuropathies that require decompression. In addition, pressure sores are common in this population of patients.

Eye opening, language function, and purposive movements in response to noxious stimulation should be determined to assess the level of consciousness. The neuroophthalmologic examination evaluates pupillary size and response to light, spontaneous eye movements, and oculocephalic (doll's eyes) and oculovestibular (ice water caloric) responses. In some vegetative patients, spontaneous nystagmus during wakefulness or REM sleep may be present. The respiratory pattern may supply further information concerning the level of the insult. Increased intracranial pressure may be associated with Cheyne–Stokes respiration. In contrast, midbrain pontine lesions may result in central neurogenic hyperventilation, and low pontine lesions can cause apneustic breathing. A common issue concerning the persistent vegetative state focuses on whether patients are able to perceive pain. Careful clinical examination and postmortem studies do not support the concept that these patients experience pain or suffering.

Misdiagnosis of the persistent vegetative state is not uncommon but unfortunately may severely affect patient care. Some individuals initially described as having persistent vegetative state do not meet the strict diagnostic criteria of this syndrome. Patients have been found to be interactive with their environment, to possess alternative diagnoses such as multiple sclerosis, or to be in coma rather than in the persistent vegetative state.

One factor that appears to result in misdiagnosis is the confusion in terminology used to describe vegetative patients. The terms "apallic syndrome," "akinetic mutism," "coma vigil," "alpha coma", and "neocortical death" should not be used to depict individuals in the persistent vegetative state. In addition, the neurologic conditions of coma, locked-in syndrome, and brain death are not synonymous with the persistent vegetative state.

Unlike individuals in the persistent vegetative state, locked-in patients are conscious but lack the ability to communicate with their environment. Loss of motor control of their facial musculature and extremities prevents these individuals from speaking and interacting with their surroundings. Occasionally, even ocular movements may be lost. Usually, these patients are not aphasic and are able to comprehend language. In contrast, patients in the persistent vegetative state are not conscious and cannot communicate with their surroundings.

Brain death is declared when there is loss of function of the entire cortex and brain stem. A brain-dead individual has no response to noxious stimulation. The pupils are fixed to light stimulation. Corneal blink reflex, doll's eyes, and cold water caloric responses are not present. Brain stem reflexes are absent, with loss of spontaneous respiration. The documentation of apnea is vital to the determination of brain death. The diagnosis of brain death requires the death of the brain stem, whereas the persistent vegetative state preserves brain stem function.

D. Clinical Evaluation and Management

Cranial imaging studies, such as CT or MRI, can assist in determining the etiology of the persistent vegetative state. Approximately 48 hr following a prolonged anoxic episode, hypodensities in the cerebral and cerebellar cortices and in the caudate and lenticular nuclei can occur. Days to weeks later, focal infarcts, edema, and atrophy may be evident.

PET and SPECT provide an alternative method of imaging that assesses cerebral function rather than brain anatomy. In vegetative patients, cerebral blood flow and metabolism are globally depressed. These procedures are useful in examining remaining cortical and brain stem function. In some cases, global reduction of cortical blood flow in the persistent vegetative state appears to be a consistent predictor of poor long-term outcome. Blood flow and metabolic studies can also be used as a diagnostic aide in differentiating individuals in the vegetative state from patients with the locked-in syndrome.

In patients with the persistent vegetative state, the EEG is useful in assessing cortical dysfunction and identifying the presence of occult seizure activity. The EEG may show a variety of changes. Some individuals in the persistent vegetative state have an isoelectric EEG or have periodic tracings consistent with REM sleep. If seizures develop and aggressive management is desired for the patient with the persistent vegetative state, then epileptic activity should be treated to reduce further neuronal cell loss in the cortex. Status epilepticus, status myoclonus, and myoclonic status epilepticus are associated with inability to recover consciousness in cardiac arrest survivors. In addition to issues of care, the EEG has been used to assess prognosis. In patients with terminal coma or persistent vegetative state, onset of abnormal EEG changes may be suggestive of a poor outcome.

Evoked potentials can provide information concerning the functional state of the cerebral cortex and brain stem. As previously described, patients with bilateral absence of cortical responses experience mortality rates between 73 and 98%. Brain stem auditory evoked potentials correlate with brain stem function. Simultaneous latency increase of all components can be consistent with progressive ischemia of the posterior fossa and a decrease in cerebral perfusion pressure. Loss of the brain stem auditory evoked potentials is usually suggestive of an incumbent deterioration and death. Although brain stem auditory evoked potentials are not usually modified by exogenous factors, brain stem auditory evoked potentials can be falsely altered by hypothermia, and combined use of anesthetics and barbiturates can induce latency and eventual abolition of brain stem auditory evoked potentials.

Management of the patient in the persistent vegetative state can raise several ethical concerns. The decision to assume an aggressive course or to gradually terminate care must be made after careful consideration of the patient's prior documented wishes. If the patient has not provided advance directive, then the course for further management should be decided between the patient's physician and health care surrogate (guardian, spouse, children, and family members). Decisions for care should focus on the utility of future treatment modalities, quality of life, and possible resource constraints.

Several therapeutic modalities have been proposed for the treatment of patients in persistent vegetative state. Sensory and electrical stimulation is a method that attempts to "increase arousal" in vegetative patients. Deep brain stimulation of the mesencephalic reticular formation increases cerebral evoked potentials and EEG activity, whereas cervical cord spinal stimulation can activate cerebral glucose metabolism and blood flow. Pharmacological manipulation of the central nervous system has also been attempted in several cases of persistent vegetative state. Treatment with amantadine or Sinemet has been reported to improve the level of consciousness in some patients. However, these reports are anecdotal, and prospective, controlled trials with significant numbers of patients are required to determine the true efficacy of these treatment protocols. Nutrition should also be considered a component of the therapeutic regiment. The degree of nutritional support should correlate with the level of care selected.

E. Clinical Prognosis

The ability to predict outcome for individuals in the persistent vegetative state is important for the generation of a reasonable care plan for the patient. Several variables play a role in the prognosis of patients in the persistent vegetative state. One factor that may influence outcome is the etiology of the persistent vegetative state. For example, subarachnoid hemorrhage can have the worst prospects for recovery, whereas insults resulting from hypoxia–ischemia and metabolic causes may have a better outcome.

Duration of coma and the persistent vegetative state following a hypoxic–ischemic event can also influence outcome. Although some case reports document recovery following prolonged periods in the persistent vegetative state, patients can suffer permanent neurologic sequelae if coma duration is at least 6 hr. Most individuals in the persistent vegetative state for a duration of 1 month following a hypoxic–ischemic insult do not recover.

In survivors of cardiac arrest who become vegetative, the prognosis for recovery is not significantly

correlated with age. Younger patients may demonstrate improved ability to recover motor function. However, age is not a factor in the recovery of cognition, behavior, or speech.

Prediction of outcome for traumatic-induced persistent vegetative state usually parallels the criteria used for persistent vegetative state unrelated to trauma. Persistent vegetative state of prolonged duration rarely results in recovery of independent function but does occasionally occur. Features such as young age (less than 40 years old), pupillary reactivity, and eye opening signify a favorable prognosis for individuals in the persistent vegetative state following trauma.

V. CELLULAR AND MOLECULAR MEDIATORS OF NEURONAL DISEASE

A. Pathways That Determine Neuronal Injury

Despite the immediate event, such as cardiac arrest or cerebral trauma, that may ultimately result in organic brain disease, specific cellular signal transduction pathways in the central nervous system ultimately influence the extent of neuronal injury. However, one must remember that it is multiple mechanisms, rather than a single cellular pathway, that determine neuronal survival during organic brain disease. Although neuronal injury associated with several disease entities, such as stroke, Alzheimer's disease, and Parkinson's disease, was initially believed to be irreversible, it has become increasingly evident that either acute or chronic modulation of the cellular and molecular environment within the brain can prevent or even reverse neuronal injury. Pharmacological manipulation of glutamate receptor activity and imidazole receptor binding agents have been shown to reduce the extent of ischemia within the penumbral zone. In addition, muscarinic agonists have been demonstrated to possibly influence neuronal plasticity. In order to develop rational, efficacious, and safe therapy against organic brain disease, it is vital to elucidate the cellular and molecular mechanisms that modulate neuronal injury. Some of these pathways include nitric oxide, programmed cell death, peptide growth factors, and metabotropic glutamate receptors.

B. Free Radical Injury in the Brain

Nitric oxide (NO), a free radical, has been shown to alter neuronal survival. Glutamate release during neuronal injury leads to both calcium influx into neurons and the production of NO. NO is toxic to the neuronal population under certain conditions, such as during glutamate release and during anoxia. As free radical, NO can react with superoxide to produce peroxynitrite, an agent that leads to cell lipid peroxidation. This process may account for the selective vulnerability of neurons in the hippocampus and cortex.

Experimental models have illustrated that ischemic generation of the free radical NO can be a "trigger" for the subsequent induction of neuronal injury in cortical neurons, hippocampal neurons, and mesencephalic neurons. Inhibition of NO production in cell culture systems during anoxia has been shown to be neuroprotective. During a global cerebral insult, production of NO is increased and nitric oxide synthase (NOS), the enzyme responsible for NO generation, is induced in hippocampal astrocytes. Blockade of NO formation by some NOS inhibitors can reduce infarction following middle cerebral artery occlusion and prevent cerebral endothelial cell disease such as atherosclerosis. In addition, inhibition of neuronal NO formation in transgenic animals can reduce infarction following middle cerebral artery occlusion. The cellular pathways generated by NO that result in neuronal injury are varied but include neuronal endonucleases, intracellular acidification, and cysteine proteases. As a result of its close link to the molecular pathways that lead to neuronal injury, NO functions not only as a potential therapeutic target but also as a valuable investigational agent. New clinical treatments, especially for organic brain disease, are now focusing on NO and the subsequent downstream pathways of neurodegeneration.

However, not all studies demonstrate a detrimental role for NO. Some experimental models have argued for the protective effects of NO-induced vasodilatation. Increased production of NO, in some circumstances, has been shown to decrease rather than increase cerebral stroke size in animals. Although these results have been attributed to improved cerebral perfusion to the ischemic penumbra, others have illustrated that improved cerebral perfusion alone to the ischemic zone is insufficient to sustain neuronal survival. It is unclear why certain environmental conditions may predispose NO to function as a neuroprotectant rather than a toxin. Several factors appear to contribute to these divergent observations and involve such parameters as the experimental model, external environmental conditions, duration of the insult, and age of the neuronal system.

C. Programmed Cell Death

Programmed cell death (PCD) is also believed to be one of the contributing factors to neuronal injury and is considered to be an active, directed process that can rapidly lead to the destruction of a cell. In contrast to necrosis, PCD is characterized by the preservation of membrane integrity and internal organellae structure, chromatin condensation with nuclear fragmentation, and the budding of cellular fragments known as "apoptotic bodies." In most cellular systems, the end result of PCD is termed apoptosis. The protein- or gene-mediated mechanisms of PCD form the basis of several organic brain disorders. In some clinical investigations of global cerebral ischemia, the ischemic vulnerability of cerebellar granular cells has been attributed to early apoptotic DNA fragmentation. *In vitro* studies also support a role for PCD during neurodegeneration. Glutamate toxicity in primary neuronal cultures may lead to double-strand DNA breaks and to early single-strand DNA breaks that are consistent with apoptotic neuronal death. The detailed understanding of the cellular mechanisms that modulate PCD may provide the basis for novel therapeutic strategies to prevent or reverse neuronal loss.

Neuronal and vascular PCD is believed to proceed through two dynamic but distinct pathways that involve both DNA fragmentation and the loss of membrane asymmetry with the exposure of membrane phosphatidylserine (PS) residues (Fig. 1). These processes are considered to be functionally independent determinants of neuronal PCD. The internucleosomal cleavage of genomic DNA into fragments may be a late event during PCD and ultimately commit a cell to its demise (Fig. 2). In contrast, the redistribution of membrane PS residues can be an early event during PCD that usually precedes DNA fragmentation and may serve to later "tag" injured cells for phagocytosis (Fig. 3).

However, one of the current central issues surrounding PCD focuses on whether this process, once initiated, is committed in nature to lead to cellular death or is reversible to the extent of preventing further neuronal injury. Experimental studies have illustrated that at least the onset of PCD can be significantly limited during therapeutic modulation, such as during neuronal ischemia, excitotoxicity, and free radical exposure. In addition, these models have demonstrated a prominent link between the generation of the free radical NO and the induction of neuronal PCD during brain injury since NO can result in the rapid induction of PCD.

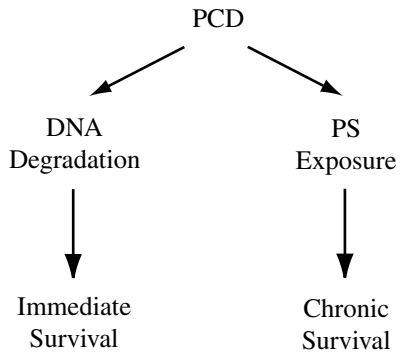

Figure 1 Programmed cell death (PCD) consists of two independent pathways. The potential sequence of events following cellular PCD induction is illustrated. Neuronal and vascular PCD is believed to proceed through two distinct pathways that involve both DNA degradation and the loss of membrane asymmetry with the exposure of membrane phosphatidylserine (PS) residues. The internucleosomal cleavage of genomic DNA into fragments may be a late event during PCD and ultimately commit a cell to its demise. In contrast, the redistribution of membrane PS residues can be an early event during PCD that usually precedes DNA fragmentation and may serve to later identify injured cells for phagocytosis.

Current techniques employed to assess PCD following NO exposure, such as terminal deoxy-UTP nick end labeling (Fig. 2) or transmission electron microscopy, are useful for identifying the extent of PCD induction. However, these procedures lack the ability to assess dynamic changes in PCD in individual cells. As an alternative, a recently developed technique can monitor the induction and change in PCD in individual living cells over a period of time. The method employs the reversible labeling of annexin V to exposed PS residues of cells undergoing PCD, an early primary event during PCD induction (Fig. 3). By exploiting the dependence of annexin V on cellular calcium to bind to exposed membrane PS residues, one can reversibly label individual neurons over time. During the induction of PCD, such as following NO exposure, progressive externalization of membrane PS residues occurs that is independent of the loss of neuronal membrane integrity.

Given the ability to continually monitor changes in the course of PCD, it is now conceivable to assess whether neuronal brain injury during PCD is, in fact, reversible in nature. Studies employing neuroprotective regiments, such as the application of either trophic factors or metabotropic glutamate receptor agonists, have provided evidence supporting the concept of reversible injury during PCD. For example, since cytosolic and nuclear changes associated with PCD are evident within the first hour of NO exposure, the signal

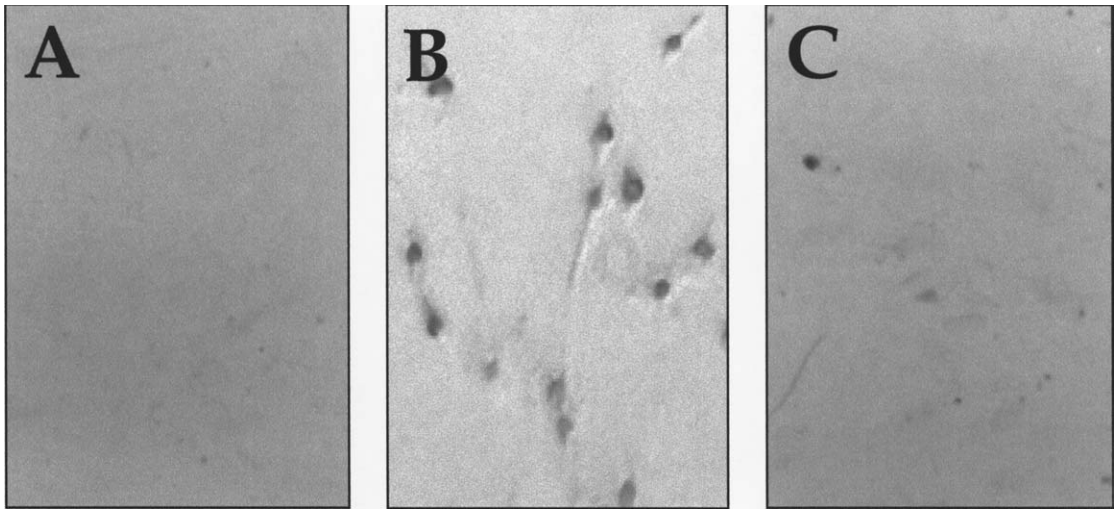

Figure 2 Prevention of neuronal DNA fragmentation following NO exposure. A representative figure is shown of neuronal DNA fragmentation that was assessed using the terminal deoxy-UTP nick end labeling (TUNEL) assay. (A) Untreated neurons (control) are without significant TUNEL labelling. (B) Neurons were exposed to NO and DNA fragmentation was assessed 24 hr later. In the presence of NO, DNA fragmentation was present in approximately 71% of the neurons examined. (C) Treatment with the growth factor, basic fibroblast growth factor, significantly prevented neuronal injury and genomic DNA fragmentation induced by NO exposure.

transduction mechanisms of the metabotropic glutamate system may reverse early steps in PCD.

The ability to prevent genomic DNA degradation and maintain membrane PS asymmetry may be closely linked to the modulation of cysteine protease activity. NO is believed to be one of the signal transduction systems that can elicit cysteine protease activity and can directly stimulate caspase 1- and caspase 3-like activities. Caspase 1 has been linked to the modulation of membrane PS residues through cytoskeletal proteins such as fodrin. Caspase 3 can lead to the direct degradation of DNA through the enhancement of DNase activity. Application of some neuroprotective agents, such as trophic factors or metabotropic glutamate agonists, can directly prevent the activation of caspase 1- and caspase 3-like activities following NO exposure, suggesting that these agents may maintain both genomic DNA integrity and membrane PS asymmetry through the modulation of cysteine protease activity. In addition to directly downregulating cysteine protease activity, specific neuronal enzymes responsible for the destruction of genomic DNA and

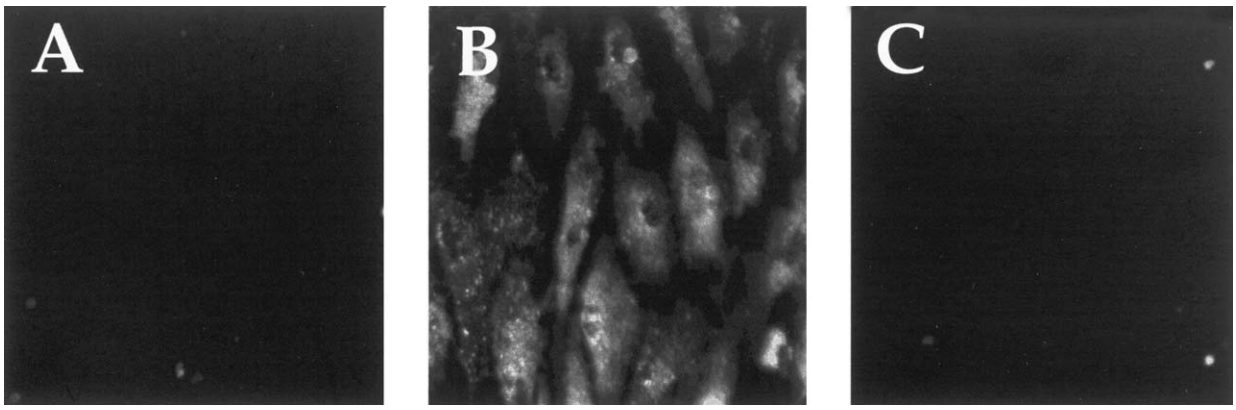

Figure 3 Prevention of endothelial cell NO-induced phosphatidylserine (PS) externalization. A representative figure is shown of cerebral endothelial cells that were identified for PS externalization following exposure to NO with fluorescent microscopy. (A) Untreated endothelial cells (control) are without significant PS exposure. (B) Endothelial cells were exposed to NO and PS exposure was assessed 24 hr later. In the presence of NO, PS was present in approximately 80% of the endothelial cells examined. (C) Treatment with the metabotropic glutamate receptor agonist DHPG significantly prevented endothelial cell injury and cellular membrane PS exposure induced by NO exposure.

their cation modulators have been identified that may contribute to acute neuronal injury. As an alternative mechanism, free radical regulation of intracellular pH can also influence PCD induction. It is hoped that further knowledge of these pathways will assist in the development of therapeutic regiments against organic brain disease.

D. Future Directions for the Treatment of Organic Brain Disease

In terms of preventing or reversing neuronal injury, peptide growth factors are increasingly being investigated as therapeutic regiments. Although currently the most efficacious application of growth factors involves the peripheral nervous system, progress is being made with central nervous system injury during both growth factor application and the generation of neuronal progenitor cells. The mechanisms employed by trophic factors to achieve neuroprotection can be diverse and not well understood. However, peptide growth factors have been shown to prevent neurodegeneration in hippocampal cultures during glutamate toxicity, potassium cyanide administration, hypoglycemia, and NO toxicity. In addition, the neuroprotective effects of peptide growth factors have been intimately linked to the modulation of the signal transduction systems of NO and protein kinase C.

Recently, several cloned metabotropic receptor subtypes have also been linked to the modulation of neuronal survival. They function through signal transduction pathways such as cAMP, protein kinase C, inositol phosphate, ion channel flux, and phospholipase D. Activation of the metabotropic receptors can reduce glutamate toxicity, protect synaptic transmission during periods of hypoxia, and increase neuronal survival during NO exposure. Current investigations have elucidated the role of the metabotropic glutamate system during cysteine protease activation, neuronal endonuclease and pH modulation, and intracellular calcium flux.

With the proper therapeutic intervention, organic brain disease may not only be preventable but also be reversible. The ability to effectively translate therapeutic intervention into the clinical spectrum requires an initial understanding of the predominant cellular mechanisms that may mediate neuronal injury during stroke. In this regard, future work that is directed at investigating the character of the injury, such as necrotic versus apoptotic disease and neuronal versus vascular injury, and the underlying cellular and molecular pathways that can contribute to the injury, such as the activity of specific cysteine proteases, is necessary in order to formulate a better understanding of the ability of a particular neuronal insult to influence both clinical plasticity and functional outcome in the nervous system. Thus, neuroprotective agents should be viewed as possessing two distinct utilities that function not only as agents to prevent or reverse clinical neuronal injury but also as investigational tools to elucidate the cellular pathways that modulate subsequent neuronal function. However, in all aspects, these separate functions for a neuroprotective agent should be considered parallel in nature in order to procure the foundation for the development of more safe and efficacious future neuroprotective strategies for the treatment of organic brain disease.

GLOSSARY

astrocyte Control function of the neuronal environment influencing local electrolyte and neurotransmitter concentrations.

contusion Necrotic cortex and white matter with variable quantities of petechial hemorrhages and edema due to head trauma.

Creutzfeld–Jacob disease Transmissible spongiform encephalopathy leading to a widespread cortical atrophy with the prion (proteinaceous infectious particle) as the responsible agent.

cytotoxic edema Accumulation of excess intracellular water.

encephalitis Brain infection commonly due to bacteria, viruses, fungi, or protozoa.

epidural hematoma Collection of blood between the skull and the dura.

focal ischemia Pattern of damage caused by a stroke resulting from a brain infarct.

head trauma Damage of the brain and/or skull due to a trauma.

morbus Alzheimer Most common degenerative brain disease causing a presenile or senile dementia.

multiple sclerosis Demyelinating disorder affecting the central nervous system with predominant white matter lesions.

oligodendrocyte Myelin-forming cell of the central nervous system.

subdural hematoma Collection of blood between the dura and the underlying brain frequently a result of torn veins draining into the dura or dural sinuses.

A lesion is the structural or functional correlate of a disease or illness to which clinical signs and symptoms can be attributed. Specific lesions are related to distinct groups of diseases or types of injuries. In general, a brain lesion is understood as a structural one. However, a lesion may be purely biochemical or systemic; thus, not all diseases have overtly visible lesions associated with them, despite profound consequences for the patient.

I. INTRODUCTION

In this article, we present an overview of possible brain lesions. We focus on commonly occurring or controversially lesions of clinical relevance (Table I). Emphasis is on the correlation between pathogenic aspects, on the one hand, and clinically as well as obvious and diagnosable lesions, on the other hand. Neuropathological and pathophysiological aspects of brain lesions and relevant repair mechanisms are considered.

II. GENERAL MECHANISMS RELATED TO BRAIN LESIONS

A. Structure, Function, and Reaction of Central Nervous System Cells to Injury

1. Neuron

Neurons and their networks of axons, dendrites, and synaptic contacts are the basic elements for perception, conduction, and processing of information. They vary in shape and size and show different changes in

Table I
Overview of Pathogenetic and Clinical Aspects of Brain Lesions

Inflammatory	Infections	Bacterial
		Viral (HSV, HIV)
		Fungal
		Parasitic
		Prions (CJD)
		Immunosuppressed patients
	Immunologic	Multiple sclerosis
Vascular	Cerebral ischemia	
	Intracerebral haemorrhage	
	Vascular malformations	
	Vaskulitis	
Traumatic	Traumatic hematomas	Epidural, subdural, subarachnoidal hematomas
	Parenchymal lesions	Concussion
		Contusion
		Intracerebral hemorrhages
Degenerative	Cerebral cortex	Alzheimer's disease
		Pick's disease
	Basal ganglia and brain stem	Parkinsonism
		Huntington's disease
	Spinocerebellar	Friedreich's ataxia
		Olivopontocerebellar atrophy
	Motor neurons	Motor neuron disease
Neoplastic	Gliomas	
	Tumors of neuronal origin	
	Tumors of primitive or undifferentiated cells	
	Tumors of meninges	
	Lymphomas	
	Metastatic tumors	
Nutritional/metabolic/toxic	Alcohol-related disorders	Wernicke–Korsakoff syndrome
		Central pontine myelinolysis
		Cerebellar atrophy
		Cortical atrophy
	Vitamin B-group deficiency	Wernicke–Korsakoff syndrome
		Subacute combined degeneration of the spinal cord
	Hepatic encephalopathy	Wilson's disease
		Hepatoportal encephalopathy
	Leukodystrophies	Metachromatic leukodystrophy
		Adrenoleukodystrophy
		Krabbe's disease
	Mitochondrial encephalopathy	MELAS, MERRF syndrome

diseases associated with specific etiologic agents or pathologic processes. A noxious condition that affects the nervous tissue results in biochemical and subsequent morphologic alterations. In most cases, no pathologic process is limited to a single cellular element and the subsequent effects result in a constellation of cellular reactions. For our purposes, however, it is convenient to evaluate seperately the changes in neurons, glia, connective tissue, and vascular structures. Some of the more important or commonly encountered ones are listed in Table II.

2. Glia

Astrocytes mediate between the mesenchymal and the neuronal compartment. They surround the vessels, provide a border to the brain at the meninges, and surround the extracellular space of the brain as a supportive framework for other cells in the central nervous system (CNS). Their main function is the control of the neuronal environment influencing local electrolyte (especially potassium) and neurotransmitter concentrations. Astrocytes show changes in response to almost every type of injury or disease in the CNS. Their reactions may take the form of degeneration, hypertrophy, or hyperplasia, although they are less vulnerable to hypoxia than are neurons. Loss of neurons from any cause, breakdown of myelin, or injury to nerve fibers are followed by an increase in the number of astrocytes and glial fibers; this process is called gliosis, which is composed entirely of cellular processes.

Oligodendrocytes are the myelin-forming cells of the CNS. In white matter they are frequently lined up along the myelinated fibers. In gray matter they tend to cluster around the neurons, where they are called satellite cells. Since they are responsible for synthesis and maintenance of myelin, they are affected in disorders that depend on myelin and myelination, mainly the leukodystrophies and demyelinating diseases (e.g., multiple sclerosis). The reaction to injury is limited: The cell turnover is very slow and the presence of axons is necessary for their proliferation.

Microglial cells, which are brain-intrinsic cells, have phagocytic properties and contribute to the CNS's macrophage response to injury. The conditions under which the microglial reaction is found cover a range from mild proliferation around chromatolytic neurons to the removal of degenerating terminals and the invasion of totally necrotic brain as in an infarct. Since they express major histocompatible antigens, microglial cells also act as antigen presenting cells.

Table II
Categories and Types of Neuronal Reactions to Noxious Conditions

Category	Type
Acute necrosis	Ischemic nerve cell change
	Hypoglycemia
Atrophy and degeneration	In many system degenerations without specific change
Abnormal accumulations	Neurofibrillary tangles (M. Alzheimer)
	Argentophilic inclusion (M. Pick)
	Lewy body (M. Parkinson)
	Inclusion bodies of viral diseases (cytoplasmic/nuclear)
	Lipofuscin excess
	Abnormal accumulation of storage diseases
Chromatolysis	Axonal damage

3. Connective Tissue

Connective tissue encloses the meninges, including the dura, arachnoid, and the pia, covering the complete surface of the brain. The properties of separate compartments (subarachnoidal, subdural, and epidural) result in different effects of lesions, even in cases in which they are also the origin and target of disorders (e.g., infections and tumors). Extradural lesions tend to be localized, whereas subarachnoidal lesions (e.g., subarachnoidal bleeding) can expand widely over the surface of the whole brain. An important function of the mesenchyme is the resorption of the cerebrospinal fluid (CSF) into the venous sinus via arachnoid granulation. Interruption of resorption at these sites due to obliteration after inflammation or hemorrhage leads to an accumulation of CSF with the potential risk of increased intracranial pressure and hydrocephalus.

4. Blood Vessels

The blood vessels in the CNS are similar in structure and function to those elsewhere in the body, with the important exception of the capillaries. The capillaries within the CNS differ from most other capillaries because they are not fenestrated. Tight junctions are

present between adjacent cells and the endothelial cell basement membrane is intimately surrounded by a network of astrocytic processes. These special structural features are important constituents of the blood–brain barrier. In general, an inflammation of the CNS (e.g., encephalitis) and/or the meninges (e.g., meningitis) is associated with a disturbance of the blood–brain barrier. Such malfunction of the blood–brain barrier enables the visualization of brain lesions by contrast enhanced functional imaging. Congenital or acquired malformations of the cerebral blood vessels (e.g., angioma, AV fistula, and cavernoma), inflammation (e.g., viral, bacterial, autoimmunological, radiogenic, granulomatous, sarcoidous, and angiitis), structural anomalies (congophilic angiopathy), venous or arterial obstruction (sinus thrombosis and thrombotic or embolic arterial occlusion), or disturbed autoregulation of the diameter of the small brain vessels (e.g., microangiopathy) can cause a variety of brain lesions, such as lacunar or territorial ischemia, hematoma, edema, or calcifications.

B. Common Pathophysiologic Complications

The enclosure of the brain and its coverings in the rigid box of the skull limit the potential for alterations of its volume. This renders the brain susceptible to interrelated pathophysiologic complications that occur in many different pathologic processes.

Any space-occupying lesion that is able to increase the volume of the intracranial contents is also able to produce increased intracranial pressure—for example, hemorrhage, infarct, tumor, cerebral abscess, cerebral diffuse or focal edema, and hydrocephalus.

The edema is either a correlate of the primary brain lesion, such as diffuse swelling due to cerebral hypoxia or due to severe head trauma, or it develops as a secondary perifocal edema surrounding focal brain lesions (e.g., due to hematoma, tumor, abscess, or filiae). The underlying mechanisms of cerebral edema can be divided into a cytotoxic and a vasogenic component. The most common form is the vasogenic edema. This results in an accumulation of a protein containing filtrate of plasma in the extracellular space that settles either on damaged capillaries that have lost their barrier function (infarcts and contusions) or on newly formed capillaries that have not yet established a barrier (primary or metastatic tumors). Predominantly the white matter is affected.

Cytotoxic edema is the accumulation of excess intracellular water that occurs in processes resulting in a breakdown of cerebral energy metabolism. Since the sodium/potassium pumps are altered in their function, this leads to a passive influx of sodium and water into the cells. This type of edema is more pronounced in the gray matter than in the white matter.

An internal hydrocephalus often occurs as a consequence of a focal brain edema with compression of the aqueduct (e.g., due to a cerebellar swelling caused by a ''malignant'' cerebellar infarction) or as a consequence of a blockage of the foramen of Monroi (e.g., due to compression of the third ventricle caused by a hemispherical swelling with a ''midline shift'').

The interaction among the three processes of primary brain lesions, the (focal or diffuse) edema, and the potential development of a secondary hydrocephalus is one of the most frequently encountered and potentially dangerous complications of CNS afflictions.

Depending on the size of the lesion and the acuity of expansion, there are initially three ways to compensate a potential increase in intracranial pressure. The volumes of CSF are reduced by enlarged resorption and reduced production, and the volumes of blood are reduced by vasoconstriction. These compensatory mechanisms allow the brain to expand without serious effects. Pressure-induced atrophy occurs most commonly with slow-growing extrinsic lesions.

After this phase, a critical period occurs in which a further increase in the intracranial contents will cause an abrupt increase in intracranial pressure. Further expansions lead to a shift of intracranial tissue, evident in the shift of midline structures, which is followed by herniation. Depending on the site of the space-occupying lesion, herniations occur mainly at characteristic sites (transtentorial, cerebellar tonsillar, and below the falx cerebri). Since vital respiratory centers in the medulla are compressed, transtentorial herniations are a frequent cause of death.

The impact of brain lesions varies depending on different degrees of size, site, subcortical extent, and temporal evolution. Apart from the functional deficits within the lesion area, local brain lesions involve corticocortical connections as well as afferent and efferent cortical projections. They also affect functionally connected but structurally intact brain regions (diaschisis).

C. Compensatory Mechanisms of Repair

In this section, we describe the processes involved in the restitution of function (requiring tissue survival) or

of functional reorganization (in permanent brain damage) following brain lesions. These become obvious as the functional recovery mechanisms of relearning, within-system recovery, substitution by related systems, or assumption of new strategies take over.

In several experiments, increased and prolonged field potentials due to an increased NMDA/GABA ratio were found in the surrounding areas and these spread widely throughout areas connected to a focal brain lesion. It has been suggested that this hyperexcitability supports synaptic plasticity and reorganization by facilitating heterosynaptic long-term potentation (LTP), a mechanism also involved in learning.

An increasing number of neurotrophic factors have been found to be able to promote neuronal survival (protection against the late retrograde death of distant neurons) and sprouting, synapse formation (stabilization of LTP), glial proliferation and growth of new blood vessels. Reorganization of synaptic networks due to sprouting of new pre- and postsynaptic endings has been demonstrated in cases of regenerative axonal long-distance extension after injury. Even the possibility of induction of new neurons from precursor cells from the temporal lobe subventricular zone has been shown in *in vitro* experiments.

In studies of motor cortex lesions, a lesion-induced reduced reciprocal inhibition of pyramidal neurons that form interconnected patterns has been considered as a potential mechanism to increase the coupling strength between pyramidal cells in order to modify motor cortical output. Various studies concerning cortical neuronal plasticity demonstrated an enlargement of areas representing specific cortical functions directly adjacent to the lesion site.

D. Relation between the Site of Lesion and Functional Consequences

Even though a local lesion causes neurological symptoms that can be attributed both to the site of lesion and to disturbances of network-encoded functions, there are symptoms that implicate a topical classification of the underlying lesion. In many cases, the etiology plays only a secondary role because the combination of symptoms (e.g., caused by a stroke or a tumor of frontal or central areas) can be quite similar apart from their temporal course. An overview of the correlation between the site of the lesion and the related dysfunctions is provided in Table III.

Table III
Topistic Relation between the Brain Lesion Site and the Correlated Functional Deficit

Site of lesion	Functional deficit
Frontal	Personality change (alteration in drive and affectivity, e.g., disinhibition or decreasing concern of family or business affairs, intellectual impairment, memory defects)
	Broca aphasia (dominant hemisphere)
	Epilepsy (focal motor, adversive, status epilepticus)
	Contralateral weakness/hemiparesis
	Loss of micturition control
	Optic atrophy
	Loss of smell
Parietal	Amnestic aphasia, dyslexia (dominant hemisphere)
	Neglect, geographical confusion, apraxia (nondominant hemisphere)
	Epilepsy (sensory seizures)
	Sensomotory hemiparesis (mainly sensory)
	Hemianopia
Temporal	Personality changes (subtle: depressive, irritable, anxious)
	Epilepsy (temporal lobe epilepsy)
	Upper quadrantic hemianopia
	Wernicke's aphasia
Occipital	Dyslexia, visual agnosia
	Epilepsy (seizures with visual aura)
	Homonymous field defects
Basal ganglia	Lack of drive
	Akinetic Parkinsonism
	Hemiparesis
Cerebellum	Limb ataxia, truncal ataxia, intention tremor, optokinetic symptoms
	Signs of raised intracranial pressure
Brain stem	Signs of cranial nerve disturbances, possibly in combination with sensory loss and/or hemiparesis

III. TYPES OF LESIONS

A. Vascular Lesions

Disturbances of cerebral blood flow are one of the most frequently encountered causes of neurological

Table IV
Etiology, Morphology, and Consequences of Vascular Malformations

Etiology	Morphology	Consequences
Brain stem aneurysms (1–2% of the population)	Abnormal, focal or segmental extension of the brain stem arteries in cases of congenital weakness of the blood vessel walls at section with a high hemodyamic load, resulting in sack- or berry-shaped distensions of the walls, especially in ACA, and exit of ACP from ACI and ACM	Rupture, frequently seen as a potentially letal event resulting in SAB, ICB, vasospasms, and residual bleeding
Arteriovenous angioma	Birth defects with the formation of dysplastic arterial and venous vessels as a result of a lack of differential development of the blood vessel plexus in the embryo into a capillary network with persisting arteriovenous short-cuts. This results in convolutions of the blood vessels of various sizes in the cerebral hemispheres. Regressive changes may be found in the blood vessel walls with fibers, calcification, and signs of thrombosis.	Widespread intracerebral bleeding, bleeding in the ventricles, and infarct as a consequence of steal effect accompanying high shunt volumes
Cavernous angioma	Vessels show sinusoidal convoluted distensions of variable size and a lack of the typical layering of the structure of the walls. Frequently clinically apparent are small sources of bleeding surrounded by gliosis.	Residual small sources of bleeding but frequently free of obvious clinical symptoms

illness. The sudden appearance of paralysis to one side of the body is clinically described as a stroke. This term does not immediately imply that the pathology underlying the symptomatology is pathogenetic due to an ischemic lesion or is directly associated with an intracerebral bleeding. Vascular lesions may occur as a result of an occlusion or stenosis in the branches or network of the arteries leading from the origin of the aorta from the left ventricle to the affected region. They can also reflect a chronic or subacute arterial hypertension (e.g., arteriosclerosis, status lacunaris, and hypertonic encephalopathy) or derive from defects in the development of the blood vessels (basal aneurysms, arteriovenous angioma, and cavernous angioma; Table IV).

B. Cerebral Ischemia

In clinical practice, two general types of acute cerebral ischemia can be distinguished: a focal and a global cerebral ischemia. Global cerebral ischemia is a result of cardiac arrest (i.e., following a collapse of the circulation) and leads to diffuse hypoxic brain damage. This is caused by various mechanisms that will not be discussed here. Disturbances in a supply area of a cerebral artery lead to focal perfusion deficits followed by an abrupt or ictal onset of focal or global neurologic symptoms, which can be permanent or reversible.

Clinically, a variety of symptoms may become overt that can be attributed to particular anatomical areas affected by the disrupted blood flow. The cardinal symptom arising from a stroke is a hemisparesis. In conjunction with additional neuropsychological deficits, the affected hemisphere can be identified; if associated with cranial nerve dysfunction, crossed symptoms, or an initial lack of consciousness, then a vertebrobasilar locus can be diagnosed. Lacunar infarcts often lead to monosymptomatic, minor strokes.

Focal ischemia is the term applied to the pattern of damage caused by a stroke resulting from a brain infarct (Fig. 1). Here, it is important to distinguish between the seriously affected *core* of damage and the less severely damaged *penumbra* on the borders. Even within the core of the affected area, a small degree of blood flow remains (<10 ml/100 g/min). This is not enough to supply the tissue with the necessary minimum of oxygen and glucose. In turn, this means that the cells will become necrotic within 1 hr. The ischemic peripheral penumbra is defined by a rate of

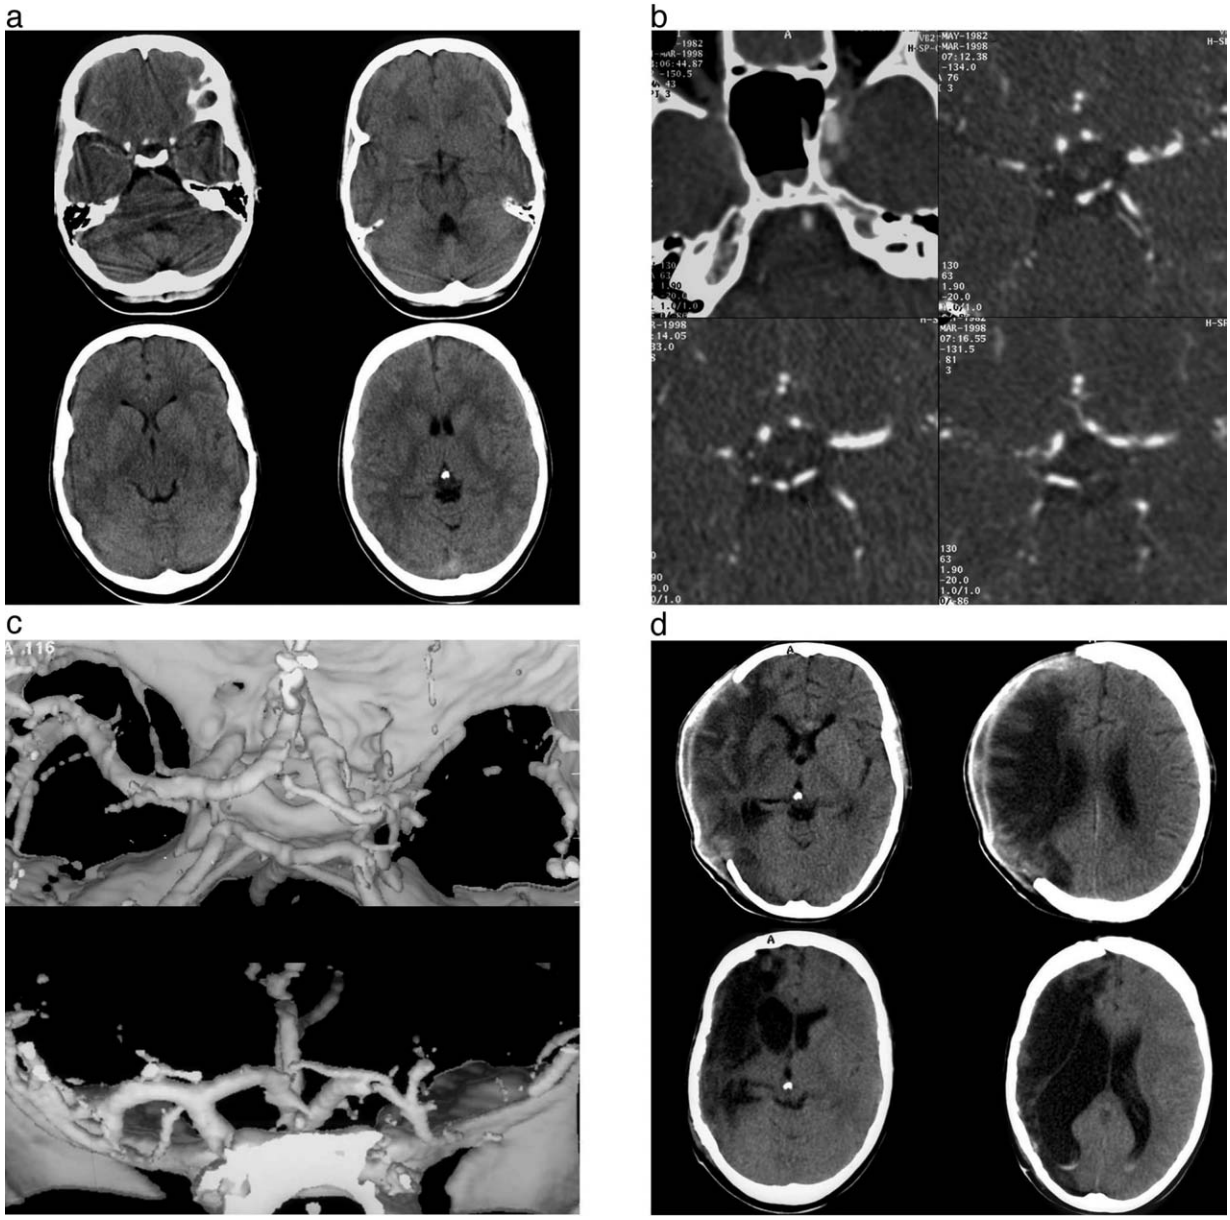

Figure 1 CT scan of a 65-year-old woman with an acute stroke and a left sided hemiparesis: (a) initial CT with (b) contrast-enhanced angio-CT (dense media sign), (c) three-dimensional reconstruction (occlusion of the ACM), and (d) after craniectomy (top) and re-implantation of the bone (bottom).

perfusion of about 10–25 ml/100 g/min. This constitutes more than the minimum required to maintain tissue metabolism in the short term. However, it is not enough to maintain neuronal function in the long term. The period during which the cells will tolerate an ischemia (i.e., those that make up the penumbra) depends on the extent of the ischemia, just as the extent of the ischemia depends on the number of surviving cells. If this critical period becomes too long or the blood flow decreases below the minimum, the consequence is an infarct. The temporal dependence of the infarct gives rise to the concept of a therapeutic window for clinical regimens (thrombolysis and drug treatment).

At the cellular level, the energy deficit abolishes the sodium/calcium exchange at the membrane and thus

leads to an increase in the intracellular sodium levels. Similarly, the energy deficit also impairs glutamate uptake inhibition that naturally leads to excessive levels of extracellular glutamate. Glutamate activates NMDA binding sites, stimulating the flow of calcium into the cell. At the same time, glutamate activates the metabotropic binding sites, leading to the outflow of calcium from intracellular stores. The resultant major increase in intracellular calcium is a central aspect of the cell destruction in ischemia. The high calcium levels activate a series of protein kinases (including protein kinase C) leading to the phosphorylation of cell proteins. Via protease activation (e.g., endonuclease), proteolysis results in the breakup of the DNA and through activation of phospholipases the breakup of lipids. This lipolysis also results in an increase in platelet activating factor and arachidonic acid, which promote the formation of free oxygen radicals. These free radicals interact with a host of related molecules, destroying these and causing more lipolysis. Reperfusion of the tissue brings a supply of oxygen that only serves to increase the formation of more radicals and can cause secondary reperfusion damage.

In the absence of oxygen, glucose is metabolized to lactate. This sets many protons free, leading to a marked acidosis that is neurotoxic and, though inducing vasodilation and reducing the density of NMDA receptors, neuroprotective.

At the level of microcirculation, protective and destructive mechanisms appear. On the one hand, vasodilation results from various neurogenic and metabolic influences. This can improve the remaining blood flow through the ischemic tissue. On the other hand, this increased perfusion is inhibited by a swelling of perivascular cells and endothelia, platelet aggregation, and leukocyte adhesion.

This juxtaposition of factors promoting repair and cell damage provides insight into why one attempts to reduce the damage resulting from a brain infarct by interfering with these circular processes.

Another route to initiate cell death following cerebral ischemia is by so-called "apoptosis." Apoptosis is the genetically regulated form of cell death. It enables the balance between growth and elimination of cells and occurs physiologically during the embryonal development or involution processes. It seems likely that all cells have evolved the capability to undergo apoptosis and that alterations in the environmental conditions can initiate, accelerate, or slow down the process. However, dysregulation of apoptosis can also result in inflammatory, malignant, autoimmune, or neurodegenerative diseases. Furthermore, infectious agents and other cell-damaging circumstances (e.g., traumatic or ischemic conditions) can lead to apoptosis.

Apoptosis takes place in four consecutive stages: stimulation, intracellular response, apoptosis, and phagocytosis. Stimulation is mediated by many different mechanisms that are either receptor mediated or directly act on the cell. Receptor-mediated apoptosis has been demonstrated for several growth factors [transforming growth factor-β and cytokines including tumor necrosis factor (TNF)] acting via a large family of receptors on the surface of target cells (TNF receptor superfamily). Non-receptor-mediated stimuli promoting apoptosis penetrate the cell directly. They include heat shock/stress factors, free radicals, ultraviolet radiation, toxins, numerous drugs, synthetic peptides, and lymphocyte enzymes. Both types of stimuli induce the intracellular response consisting of direct activation of caspases or via the mitochondrial release of cytochrome c, which is also influenced by proapoptotic and antiapoptotic mediators.

Activated caspases are cystein proteinases that form an intracellular proteolytic cascade modulating many cellular events in the apoptotic pathway, including activation of transcription factors and induction of apoptosis-related genes. In the next step of apoptosis, intracellular calcium is released accompanied by a depletion of ATP, degradation of DNA, expression of cell surface phagocyte recognition molecules, and cell dismantling. The last step consists of phagocytic recognition of apoptotic bodies and phagocytosis of the apoptotic cells by phagocytes.

The apoptotic program is not just executed in cases of cell damage; it occurs in cases of missing growth factors and inadequate stimulation of growth. Therefore, apoptosis is also a physiological safety tool eliminating cells with deregulated growth.

In therapeutic approaches the modulation of apoptotic cell death enables new ways to treat disease. Possible mechanisms are induction of apoptosis in malignant cells, prevention of apoptosis in senescence or neurodegenerative disorders, or regulation of tissue regeneration/repair by inducing apoptosis to limit fibroblast activity and scar formation.

Four principles that are important for determining therapy may be derived from the basis of the pathophysiologic precursors described previously: reperfusion, the influence of the blood clotting system, improvement of global cerebral perfusion, and neuroprotection. Substances administered to improve neuroprotection should prolong the tolerance to ischemia in the functionally disturbed neurons and glia.

Alternatively they should protect these cells against toxic metabolites (e.g., free radicals) and excitatory amino acids (excitotoxicity). To date, animal experimentation has provided numerous impressive results that unfortunately cannot be transferred to the clinical situation. Many substances are being tested in clinical trials, whereby the next step must consider the possible combination of these substances with forms of therapy designed to promote revascularization.

C. Traumatic Lesion

1. Head Trauma

The clinical picture of the effects of traumatic head injuries is defined in terms of the morphological damage inflicted on the brain and skull. Either an open or a closed head injury is diagnosed depending on the mechanism that mediated the trauma. An open head injury means that there is an open connection between the subdural and epigaleal space (i.e., between the CSF and the outside world). An open head injury usually results from penetrating brain damage (e.g., from a shooting incident or use of another weapon) but can also arise from a tearing of the dura (e.g., with ventricular fistula following basal skull fractures). An additional categorizatation of the morphology of skull and brain injury indicates the presence or absence of bone damage and whether intracranial lesions are focal or diffuse. The types of head injury are summarized in Table V in terms of the mode of accident, the clinical picture, and the damage as represented by imaging techniques.

Primary brain damage results from the effects of shear, stretch, and pressure on the tissue (including intracranial and intracerebral pressure gradients). Damage is usually a consequence of either extreme pressure on a particular point on the skull (contact injury) or a rapid acceleration/deceleration of the head and the brain mass. Primary damage occurs immediately at the site of the accident and consists of the breaking of the skin and scalp fracture, contusions and crushing of the brain tissue, intracranial bleeding, and/or diffuse damage to the neuronal tissue and axonal network of the brain (Fig. 2).

Secondary brain damage appears with a delay. This manifests itself as a complication of the course and may be based on hypoxia, free radical formation, release of excitatory amino acids, ischemia, a swelling of the brain tissue, increased intracranial pressure, infection, or delayed (subacute) intracranial bleeding.

Table V
Classification of Traumatic Brain Injuries According to Biomechanical and Morphological Aspects[a]

Classification		
	Mechanism of injury	
Closed	High speed (e.g., car accident)	
	Low speed (e.g., a fall with somatic injury)	
Open	Missile injury	
	Other penetrating injuries	
	Morphology of the injury	
Skull fracture	Skull cap	Along the length/cross-sectional with/without impression; open/closed
	Base/basis	With/without CSF fistula; with/without facial paresis
Intracranial lesion	Focal	Epidural
		Subdural
		Intracerebral
	Diffuse	Diffuse axonal injury

[a]Modified from Keidel and Miller (1996).

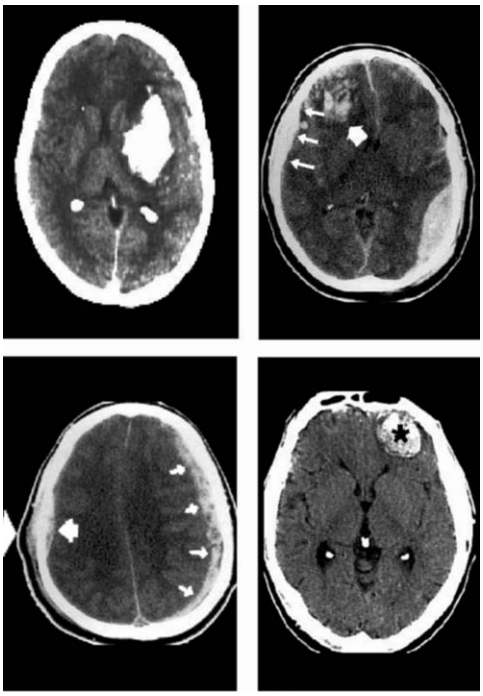

Figure 2 Common types of traumatic brain injuries. (Top, left) Intracerebral hemorrhage. (Top, right) Intracerebral contusion of the right frontal lobe accompanied by an ipsilateral frontotemporal epidural hematoma (coup) and a left-sided temporoparietal epidural hematoma (contre). (Bottom, left) Right-sided temporoparietal epidural hematoma, soft tissue injury, and contralateral subdural hematoma. (Bottom, right) Left frontal traumatic hemorrhagic contusion.

An overview of primary and secondary brain damage is presented in Table VI.

2. Intracerebral Bleeding

Epidural hematoma is a collection of blood between the skull and the dura. It usually results from low-speed head injuries (e.g., from falls or impact with objects). It occurs most commonly in association with linear skull fractures that traverse meningeal vessels and tear them. In about half of the patients, after an initial short period of unconsciousness on impact, a lucid interval can be observed that is followed by a progressive loss of consciousness and contralateral hemiparesis. The underlying mechanism, the expanding mass-producing compression of the corticospinal tract, transtentorial herniation, and diencephalic derangement, is visible in computed tomography (CT) scans as a biconvex structure of the epidural hematoma bounded by dural insertion at cranial sutures (Fig. 2).

Table VI
Type of Lesion and Mechanism of Injury in Posttraumatic Primary and Secondary Cerebral Damage

Lesion	Mechanism
Primary cerebral damage (acute manifestation)	Scalp injury
	Bruising or crushing of the brain
	Intracranial bleeding
	Diffuse axonal brain damage
	Acute intracranial hematoma
Secondary cerebral damage (delayed manifestation)	Hypoxia or ischemia
	Space occupying mass
	Delayed formation of hematomas
	Brain swelling
	Brain edema
	Hyperemia
	Hydrocephalus
	Increased intracranial pressure
	Arterial vasospasm
	Infections
	Cellular mechanisms
	Phospholipid metabolism
	Lipid peroxidation, arachidonic acid
	Prostaglandins, leukotrienes
	Platelet-activating factor
	Free oxygen radicals
	Excitotoxic mechanisms
	Glutmate, acetylcholine
	Neuropeptides
	Endorphines
	Disturbances of Ca^{2+} and Mg^{2+} metabolism
	Lactate acidosis
	Disturbances of axonal transport
Long-lasting sequelae	Focal scar formation
	Secondary degeneration of the neuronal pathways and nuclei
	Posttraumatic Demyelinization
	Brain atrophy
	Hydrocephalus internus

The *subdural hematoma* is a collection of blood between the dura and the underlying brain and frequently the result of torn veins draining into the

dura or dural sinuses. It may be the result of high-speed impacts, such as occur in car accidents. Associated severe brain damage (contusions and edema) is common. In CT scans damaged areas are not bordered by sutures and can cover most of the hemisphere but do not cross the interhemispheric fissure (Fig. 2). The treatment of both types of hematoma is comparable and consists of neurosurgical interventions to reduce the effects of the expanding mass.

The term *contusion* describes necrotic cortex and white matter with variable quantities of petechial hemorrhages and edema. Traumatic contusions show a typical pattern of distribution, covering the poles of the frontal and temporal lobes, the orbital surface of the frontal lobe, and the inferolateral temporal lobes (Fig. 2). Due to the contact of the brain to bony or meningeal structures, several types of contusions can be distinguished: at the site of fracture, at the site of impact (coup), contralateral to the site of impact (contre-coup), or at the site of herniation. All these appear in CT scans as areas of variable densities (increased, decreased, or normal).

Diffuse axon damage commonly occurs in traffic accidents due to shearing injury. Since a strong acceleration or deceleration can elicit these shearing forces and pressure gradients, a direct impact on the skull is not necessary. Often, traumatic hematoma of the corpus callosum and necrotic hemorrhages of the dorsolateral brain stem are associated with diffuse axon damage. Furthermore, it can develop from a trauma-induced sequence of changes of tissue by neurotoxic mediator substances leading to the final breakdown of axonal function. The diagnosis should be considered if, in unconscious patients, no focal lesion is displayed in the CT scan, perhaps merely a small swelling is evident.

D. Inflammatory Lesions

1. Infections

The CNS is protected from the direct spread of infectious agents by bony and meningeal coverings and by the blood–brain barrier. There are four routes of infection in the brain: hematogenous spread, direct implantation, local extension, and the neural route. The most common is the hematogenous route. Most viruses, bacteria, fungi, and protozoa use this route, often after local growth in nonneural tissue (mucous membranes of respiratory or enteric systems) or proliferation in the blood stream. There are several ways to penetrate the blood–brain barrier: Transport in infected reticuloendothelial cells, transport in circulating immune complexes, replication in infected endothelial cells, or passive pinocytotic transfer in the plexus chorioideus have been identified as strategies for viruses.

Direct implantation takes place almost invariably in traumatic lesions, but it is also sometimes iatrogenic (ventriculoperitoneal shunt and lumbar puncture). Furthermore, extensions of local adjacent infections of frontal or mastoid air sinuses or an adjacent osteomyelitis are portals of entry for bacterial infections.

The underlying mechanism of the neural route is bidirectional axonal transport that carries products of axolemmal renewal and the constituents of synapses. Pathologic agents may also use either the centropetal pathway (e.g., herpes simplex virus, rabies virus, or tetanus toxin) or the centrofugal pathway (e.g., reactivated herpes simplex or varizella zoster viruses or rabies virus).

Once an infectious pathogen has crossed the barriers into the nervous system, unique anatomical features are encountered. The brain has no intrinsic system for antibody prduction, no lymphatic system in the usual sense, and few phagocytic cells. The blood–brain area that inhibits invasion also deters clearance and impedes the entry of therapeutic agents. However, since few microorganisms overcome the barriers into the CNS, the invasion of the CNS is still a rare event.

The first responses to invading viruses consist of increased levels of lymphocytes (mostly T cells) and monoytes in the CSF. There may also be a modest increase in protein concentration. The reaction to pyrogenic bacteria is a fast and spectacular increase in polynuclear leukocytes and proteins. Less dramatic changes are seen after more slowly developing and less pyrogenic microorganisms (e.g., tuberculosis or listerial meningitis) invade. The pathological consequences of CNS infection depend on the type of microorganism. Viruses can induce a perivascular infiltration of monocytes and lymphocytes. Indirect inflammatory or direct cytopathic responses can induce neuronal damage until cell lysis along with damage to the myelin and glial cells and small focal hemorrhages. Various associated immunocomplexes also play a role in the response to viral and CNS components. For example, B cells migrate in, producing antibodies against the invading micororganisms, and as a reaction to the microbial antigens, T cells release cytokines that attract and activate other T cells and macrophages. Viruses show different preferences for inflicted cells:

On the one hand, rabies, polio, and herpes simplex and flavin viruses infect neurons, whereas on the other hand, the Jakob–Creutzfeldt virus attacks oligodendrocytes. Pathological changes appear more rapidly after bacterial infection. Here, local responses to bacterial antigens and toxins play an important role.

Brain infections such as encephalitis occur much more rarely than infections of the brain membranes such as meningitis. This means that many other factors must interact to allow relatively common bacteria or viruses to cause CNS infection. Bacterial infections are frequently marked by an inflammatory abscess for which the sources are difficult to differentiate. These arise from the immunological response in the form of fibrin deposits and exudates resulting from inflammation. These take the form of capsules and are mostly surrounded by a large edema. Streptococci and staphylococci can be found along with pneumococci, enterococci, and other anaerobic organisms. These abscesses appear as hyperdense areas in a CT scan: The edema presents itself as a ring of enhanced contrast.

Viruses are a more frequent cause of encephalitis than is bacteria. Indeed, the most frequent cause of severe, sporadic encephalitis is the herpes simplex virus. The virus may originate in the nasal mucus and cross the tractus olfactorius, or it may be reactivated from a persistent cache in the trigeminal ganglion. It may then infect the basal regions of the frontal or temporal lobes of either or both hemispheres. The effect is a dimming of consciousness, aphasia (reflecting a preferred infection of the left hemisphere), moderate hemiparalysis, and perhaps focal if not general epileptic discharges.

The pathological characteristics of herpes simplex encephalitis can be clearly visualized, if somewhat delayed, in radiological images. These consist of the spotty but continuous area of necrotic tissue, reflecting the infiltration of granular lymphocytes, and a marked edema in cases of rapid pressure damage (Fig. 3). Persistent tissue damage with severe signs of a neuropsychological deficit is frequent, despite antiviral therapy.

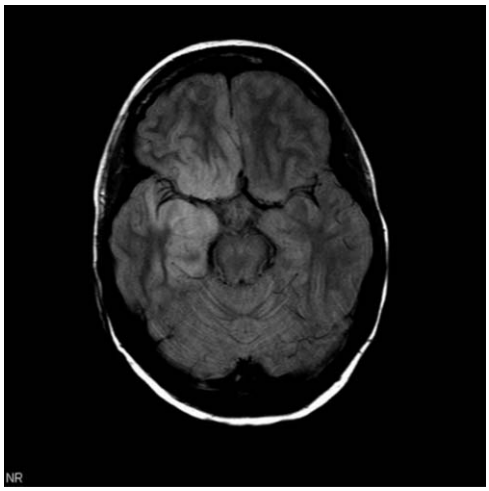

Figure 3 MRI scan of a 32-year-old man suffering from encephalitis caused by herpes simplex virus. Note the typical hyperintense lesion of the right temporal and basal frontal lobe.

2. Creutzfeld–Jakob Disease

Creutzfeld–Jacob disease (CJD) belongs to the group of transmissible spongiform encephalopathies. This group occurs in animals (scrapie in sheep and bovine spongiform encephalopathy) and in man (Kuru; fatal, familial insomnia; Gerstmann–Sträussler–Scheinker disease; and primarily CJD and a new variant nvCJD). They all share the following features: The pathological changes are neuronal degeneration and loss with astroglial proliferation presenting as small cystic (spongiform) areas in gray matter without any inflammatory signs leading to a widespread cortical atrophy. The clinical course includes a prolonged incubation period, possibly a decade or layer, with a subsequent progressive fatal course following the first symptoms. All diseases are transmissible and the responsible agent is the prion (proteinaceous infectious particle). Prions differ from all other microbial agents in that they contain no nucleic acid. This results in no immune response. They are also very resistant to the usual sterilization procedures (heat, radiation, ultraviolet light, and chemical agents). The pathologic prion protein (PrPsc) develops from a physiologic cellular prion protein with the same sequence of amino acids as a result of conformational change with more pronounced beta folding structure. The underlying mechanism of this conformational change is unclear. However, PrPsc is able to induce the same transformation from which it develops.

CJD occurs in sporadic, inherited (several mutations) and iatrogenic forms due to transplants of cornea or dura, insufficiently sterilized neurosurgical instruments, and growth hormone extracted from human hypophyses. The clinical course of all three forms is comparable: progressive dementia often accompanied by myoclonus, visual, cerebellar, or motoric disturbances and finally an akinetic mutism and decerebration. The electroencephalogram shows typical periodic complexes of sharp waves in an underlying decelerated background activity. Since

clinical diagnostic tools are not sufficiently, sensitive, a definite diagnosis depends on postmorteum analysis of cerebral tissue, including neuropathologic, immunhistochemical, and Western blot analysis with antibodies against PrP.

In 1996, a new variant of Creutzfeld–Jakob disease (nvCJD) was described. In contrast to the classical form, it starts at an ealier age (<30 years) with pronounced psychiatric signs. Also, electrophysiological and neuropathologic findings differ from those in sporadic cases. The similarity to experimentally induced CJD analog changes in macaque monkeys infected by transfer of BSE led to the hypothesis that nvCJD is caused by food containing BSE. This hypothesis has not been proven.

3. Multiple Sclerosis

Multiple sclerosis is a demyelinating disorder affecting the CNS. The clinical associations reflect white matter damage: upper motor neuron weakness and paralysis, incoordination, visual disturbances, and paraesthesia. The course is often acute onset followed by a progress of many years with alternating remissions and relapses. Less commonly, there are different variants, such as an acute severe disease that incurs a rapid progress to death, chronic progession without remission, and minimal signs with very long remissions. The typical pathologic findings are so-called ''plaques,'' areas of demyelination characterized inflammatory infiltrates in early stages, profound myelin loss, an almost total absence of oligodendrocytes, and a scattering of astrocytes in the late stages. Although plaques have a predilection for the angles of the cerebral ventricles and the corpus callosum (Fig. 4), they may occur anywhere in the CNS.

Multiple sclerosis is an autoimmune disease in which the patient's immune system reacts against the neuronal myelin sheath. In addition to demyelination, damage in the CNS occurs to the axons and an inflammatory filtrate can be detected. Although numerous aspects of the genetics, histopathology, and other immunological details have been the subject of recent and wide-ranging investigations, the precise pathophysiological course of the illness remains unclear.

Early microscopic studies revealed that the typical periventricular demyelinated foci oriented radially in the blood vessels. There are three recognized histopathological stages of lesion development:

1. Early developing lesions (acute inflammatory reaction of all parts of the myelin system and disrupted blood–brain barrier)

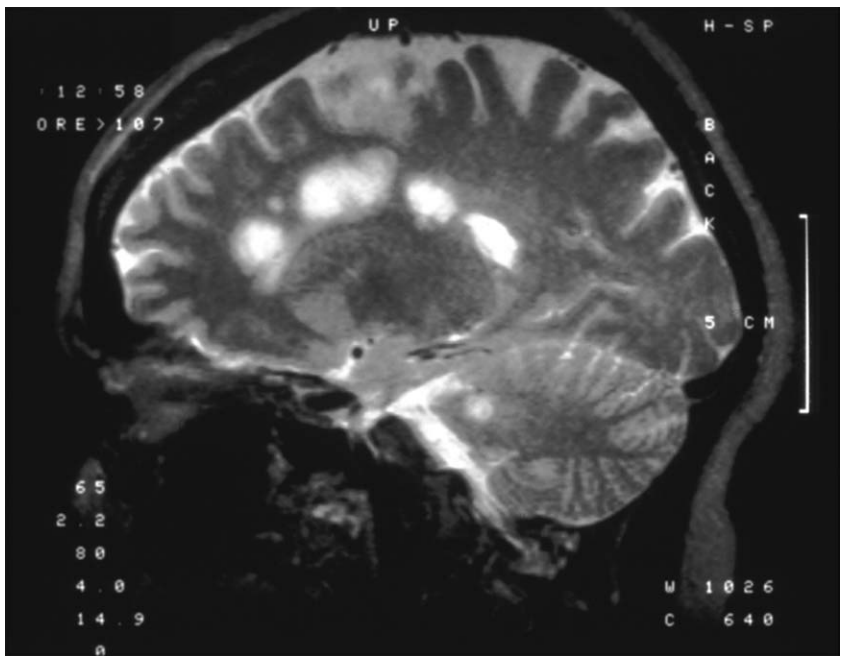

Figure 4 MRI scan of a 25-year-old woman with multiple sclerosis, which was diagnosed at age 22. Note the hyperintense pericallosal white matter lesions.

2. Late developing lesions (marked breakdown of the myelin in the absence of myeline oligodendrocyte glycoproteins or CNPase)
3. Inactive demyelinated lesions

Comparison of histological findings with those from magnetic resonance neuroimaging have shown that due to an impaired blood–brain barrier, the lesions in their early stages can take up much gadolinium. However, surprisingly, T2-weighted images show a remarkably weak signal intensity. Rather, the late developing or old lesions show areas of hyperintensity and a more homogeneous uptake of gadolinium. In contrast, axonal lesions can be shown to be associated more with hypointensities in T1-weighted images.

It is clear that the key immunological role in the development of the illness is played by activated T cells. Activated T helper cells interact with specific proinflammatory cytokines, particularly tumor necrosis factor-α, lymphotoxin, interferon-γ (IFN-γ), and interleukin-2 (IL-2). They can thus activate macrophages and damage the target tissue. Whereas in the peripheral circulation monocytes and macrophages can take up an antigen once detected, T cells are available, and phagocytosis can occur, in the CNS such activities are directed against the microglia, astrocytes, oligodendrocytes, and the myelin they synthesize. The most important target candidates include proteolipid protein (which that makes up about 50% of the protein content of the myelin sheath), basic myeloprotein, myelin-associated glycoprotein, and myelin oligodendrocyte glycoprotein. T2 helper cells destroy the antiinflammatory cytokines such as IL-4 and IL-10 that would otherwise keep the functions of the inflammatory T cells in check. During restitution, this type of cell shows a higher level of activity. Nevertheless, this subtype of helper cell supports antibody synthesis in the β-lymphocytes with the result that the inflammatory process and the underlying mechanisms are perpetuated and the damage becomes chronic.

The course of the inflammatory process may occur as follows: T cells are activated by an unknown antigen in the periphery. This activation is followed by the release of specific cytokines (e.g., the expression of integrins and the intracellular cell adhesion molecule-1 from the superfamily of immunoglobulins) that promote the binding of the activated T cells to the endothelium of the blood vessels. By way of the release of the proinflammatory cytokines, the structure of the blood vessels in the blood–brain barrier disintegrates. This enables the migration of T cells to the structures that would otherwise have been protected. During the course of this migration, mediators of the toxic effect on myelin are released, edemas form, and the constituents of myelin are affected in their function and eventually destroyed. The cytokines of the T2 helper cells (IL-4 and IL-10) are modulators of this process. They help reduce the extent of the inflammation and may even increase in number during the more stable phases of the illness. The extent to which apoptosis (programmed cell death) of the T cells actually influences this process cannot be determined with confidence.

The mainstays of therapy constitute neurophysiologically based practice, ergotherapy, and various measures for support and rehabilitation: the latter include psychotherapy, pharmacotherapy directed toward symptom relief, as well as the putative causes (immunomodulation, inhibition of glial scar formation, and the promotion of remyelination). High-dose corticosteroid therapy in the acute phase can help inhibit inflammation and can stabilize the blood–brain barrier, and it can be directed toward T cell apoptosis. In the form of illness with an episodic course, immunomodulators may also be applied. Thus, recombination IFN-β can antagonize the effects of IFN-γ and the induced suppressor activity, and it can stabilize the blood–brain barrier. Glatirameracetate, a synthetic polypeptide, can promote T cell activation and reintroduction of the disturbed TH1–TH2 balance. Other therapeutic options include the use of mitoxantron, azathioprin, and methotrexate, which can inhibit global proliferation and inflammation.

E. Degenerative Lesions

Use of the rubric of neurodegenerative disease is intended to cover a group of illnesses characterized by a progressive loss of neuronal populations in the CNS. In contrast to the defined metabolic, toxic, hypoxic–ischemic, or infective lesions described previously, the pathogenesis of neurodegenerative illness remains largely unknown. Some of these illnesses belong to the most frequent neurological entities and include Alzheimer's and Parkinson's disease. The affected neuronal populations in some of these illnesses do show a characteristic histologic pattern of damage (e.g., Alzheimer's and Pick's disease). However, in other illnesses there seems to be little more to describe than a general reduction of the number of neurons in

particular parts of the brain. In many cases, the affected brain regions demonstrate a decided atrophy during a long course with an associated pattern of functional disturbance.

Depending on how the degenerating neurons are distributed, one can classify the illnesses according to a diffuse and generalized atrophy (e.g., Alzheimer's disease), or a system (anatomic and function)-specific atrophy (Parkinson's disease). Occasionally a third group of multisystem atrophy is referred to in which several functional systems are affected (olivopontocerebellar atrophy). An overview of degenerative diseases is presented in Table VII.

1. Alzheimer's Disease

Alzheimer's disease is the most common degenerative brain disease and the most common cause of dementia, and it includes a presenile and senile form. Most cases occur sporadically, although a small proportion are familial and inherited. The heritability is distinguished by an autosomal dominant disorder that leads to disease and vulnerable genes that increase the probability of illness. The pathological features of Alzheimer's disease are neuritic plaques that consist of amyloid proteins and neurofibrillary tangles that contain isoforms of the phosphorylized τ-protein. Both are also found in normal aging, although their density and distribution typically differ from those seen in Alzheimer's disease, in which the number of plaques is approximately linearly related to the degree of dementia. On a cellular level, pyramidal cells, the main neuronal component of corticocortical pathways, are the major cortical cell type lost in Alzheimer's disease. In the early stages, the loss is predominantly confined to the amygdala and to the temporal and parietal association cortex. Later, degeneration develops in other mesial temporolimbic structures such as the hippocampus and in cholinergic nuclei in the basal forebrain (nucleus basalis of Meynert and the locus ceruleus). Degeneration here incurs a decrease of activity in transmitter systems (acetylcholine, serotonin, and others). Primary visual and sensorimotor areas remain relatively spared so that sensory perception and movement remain intact, whereas deficits in memory, learning, attention,

Table VII
Etiology, Morphology, and Clinical Correlates of Degenerative Disorders of the Brain

Disorder	Etiological factor	Morphological characteristic	Preferred locus	Clinical association
Alzheimer's disease	A4 amyloid presenilin I/II	Tangles, neuritic plaques congoph; angiopathy	Whole cortex	Progessive loss of higher brain functions: dementia
Pick's disease	Mostly sporadic incidence	Eosinophils, round inclusion bodies (Pick bodies)	Frontal and temporal lobes	Primary frontal lobe syndrome followed by progressive dementia
Chorea Huntington	Autosomal dominant hereditary (4p 16.3) trinucleotide (CAG)-coded protein aggregations	Intranuclear inclusions in interneurons of the n. caudatus with a progressive loss	Atrophy of the n. caudatus, also cortical atrophy in the frontal and temporal lobes	Choreatic motor disturbances with progressive dementia and neuropsychiatric symptoms
Parkinson's disease	Neurotoxin hypothesis: disturbance in the chain of respiratory enzymes in the mitochondria	Loss of pigmented dopaminergic neurons; concentric neuronal inclusion bodies (Lewy bodies of synuclein)	Substantia nigra and to a lesser degree the locus coeruleus	Disturbed extrapyramidal movements (rigor, tremor, hypokinesis)
Olivopontocerebellar atrophy	Autosomal dominant, recessive, sporadic	Degeneration and atrophy of the transverse pontocerebellar pathways, loss of Purkinje and granule cells	Ventral pons, cerebellar stem and cortex, and inferior olive	Progressive cerebellar ataxia

and in the ability to solve complex problems increase. The final state consists morphologically of a generalized atrophy of gray matter and clinically of dementia.

The underlying defect remains unknown. It has been suggested that β-amyloid (β-AP) plays a central role. It is produced by the splitting of a precursor protein, the amyloid precursor protein (APP). It is an integrative membrane glycoprotein that is encoded on chromosome 21 and mainly expressed in the brain and the kidneys. Conversely, APP may be internalized and cleaved by unknown secretases to form β-AP fragments, which aggregate in fibrillar, nonsoluble material to comprise the core of the neuritic plaque. It has also been suggested that amyloid production mediates the pathological phosphorylization of τ-protein, leading to the formation of neurofibrillary tangles. The neurotoxicity results in oxidative stress, with increased intracellular reactive oxygen species, and disruption of structures involved in ion homeostasis. Inflammatory responses with reactive glial cells lead to the production of cytokines and complement.

These pathologic events are the possible pharmacological targets in the treatment of Alzheimer's disease. To date, only a cholinergic enhancement with acetylcholinesterase inhibitors has been shown to provide a symptomatic benefit and may slow disease progression. Antiinflammatory and antioxidant medication and mediation of APP metabolism are also options that are being researched.

Acknowledgments

We thank our collegues M. Forsting, J. Weber, and C. Weihl, who gave consent for publication of the CT and MRI scans. We are indebted to Dr. Oades for editorial work on the manuscript.

Brain Stem

WILLIAM W. BLESSING
Flinders University, Adelaide, Australia

GLOSSARY

chronic vegetative state Condition of a person with bilateral forebrain and/or upper brain stem dysfunction that eliminates thinking, purposive behavior, and self-consciousness but leaves intact the basic homeostatic mechanisms necessary for life.

cranial nerves The 12 sensory and/or motor nerves that connect the brain, especially the brain stem, with the peripheral sensory and motor organs in the region of the face and head.

nucleus of the tractus solitarius Secondary sensory nucleus in the dorsomedial medulla oblongata that receives inputs from taste, respiratory, cardiovascular, visceral, and gastrointestinal primary afferents traveling in cranial nerves VII, IX, and X.

parasympathetic motoneurons in the brain stem Preganglionic motoneurons, with axons leaving the brain in cranial nerves III, VII, IX, and X, that innervate cranial, cervical, thoracic, and abdominal postganglionic neurons responsible for controlling visceral functions such as pupillary diameter, salivation, heart rate, bronchosecretion, and gut motility.

premotor neurons Forebrain or brain stem neurons with axonal projections synapsing on somatic, parasympathetic, or sympathetic motoneurons.

presympathetic motoneurons in the brain stem Neurons with axons that descend to the spinal cord and synapse on sympathetic preganglionic neurons in the thoracic and upper lumbar spinal cord.

primary sensory neurons Sensory (afferent) neurons, with cell bodies in the dorsal root ganglia or in peripheral sensory ganglia located in the upper neck or facial regions, that convey information from the periphery to the spinal cord or the brain.

reticular formation Regions of the brain stem containing neuronal cell bodies (motoneurons, premotor neurons, and interneurons) interspersed between bundles of axons; the cell bodies are not gathered into obvious nuclei and the appearance is net-like. The term is also used to signify a brain stem system for alteration of the level of arousal and consciousness.

secondary sensory neurons Brain and spinal cord neurons receiving direct synaptic inputs from the central processes of the primary sensory neurons.

somatic motoneurons Brain stem and spinal motoneurons with a peripherally directed axon that innervates striated muscle; subdivided into general somatic efferent and special visceral efferent.

The brain stem is the portion of the central nervous system rostral to the spinal cord and caudal to the cerebral hemispheres. This article defines the different collections of nerve cells and axonal pathways that constitute the brain stem and summarizes the manner in which brain stem neuronal circuitry mediates the basic bodily homeostatic "housekeeping" functions necessary for our daily lives.

I. NAMES AND THE BRAIN STEM

The brain is such a complex structure that even now we know only a tiny portion of what is to be known about it. One of our human characteristics is the need to feel familiar with the unknown, and one of the ways we achieve this is to give names to things. Thus, a small group of stars in our Southern Hemisphere night sky is named the Southern Cross and recognition of this familiar star patterns is comforting, guiding us on our journeys even if there are no intrinsic properties

connecting the individual stars and demarcating them from surrounding stars. The same principle applies to many of the named regions of the brain. Often, the names are not scientifically justified, and sometimes they are misleading. In the midbrain, the four "colliculi" are named for their resemblance to four "little hills." These same structures also constitute the "tectum," i.e., the dorsal part or "roof" of the midbrain. There is no functional implication in any of this terminology. Thus, traditional names for different brain regions may be a poor guide to the function or even to the structure of the named region.

Thus, when we ask "What is the brain stem?" we need not be too concerned if the answer is a little ambiguous. The underlying rationale for the use of the term is the division of the brain into the cerebral hemispheres (the presumed "flower" of the brain) and the remainder of the brain (the "stem"). The arbitrary dividing line has been drawn at different levels by different investigators. Sometimes the thalamus and the hypothalamus (grouped together as the diencephalon) have been included with the brain stem, especially by physiologists, who developed the concept of the reticular activating system. However, neuroanatomists commonly confine the term to the midbrain, the pons, and the medulla oblongata, without the cerebellum (the little brain). This is the meaning adopted for the term brain stem in this article. In general, it is best to regard the term brain stem as a conveniently loose way of referring to the candal or inferior half of the brain. There are no sharp demarcations between spinal cord, medulla oblongata, pons, and midbrain. The midbrain (the mesencephalon) is so called because as this brain region develops, it is between rostral and caudal flexures in the developing neural tube. The term pons (bridge) derives from the fibers from each side of the cerebellum which sweep around the ventral aspect of the brain stem.

The term "nucleus" (understood in its "collection of neurons" sense, not in its "part of the cell containing the DNA" sense) requires some explanation when it is used with respect to the brain stem. When brain stem sections are examined after a traditional Nissl stain (a technique for demonstrating the cell body portion of the neuron), particular collections of neurons (e.g., the hypoglossal nucleus and the inferior olivary nucleus) virtually define themselves as nuclei. They stand out quite obviously. Other areas of the brain stem appear as a network arrangement of fiber pathways and cell bodies, without clearly definable nuclei. Traditionally, these regions of the brain stem are referred to collectively as the reticular formation.

The brain stem also contains numerous ascending and descending fiber pathways linking the forebrain and the cerebellum with the spinal cord as well as pathways originating in the brain stem. These axonal pathways, called fibers of passage, often pass right through particular brain stem nuclei, dividing them into apparently different subgroups.

The different parts of the brain stem are indicated in a sagittal section (Fig. 1) and in transverse sections of the brain stem from the caudal medulla to the midbrain (Fig. 2).

II. BRAIN STEM NEURONAL ORGANIZATION, INCLUDING THE RETICULAR FORMATION

Portions of the brain stem function as "the spinal cord for the head." The facial, jaw, tongue, pharynx, larynx, and the neck muscles are innervated by efferent axons of brain stem somatic and "special visceral" lower motoneurons (cranial motoneurons), just as the muscles of the arms or the legs are innervated by spinal somatic lower motoneurons. Axons of these cranial motoneurons emerge from the ventral or ventrolateral surface of the brain stem, leave the cranial cavity via specific holes ("foramina") in the skull, and continue on as part of the various cranial nerves. Similarly, on the sensory side, the skin of the face and head is innervated mostly by afferent/sensory axons of trigeminal and upper cervical sensory neurons. The cell bodies of these afferent neurons are in ganglia outside the cranial cavity (i.e., the cavum trigeminale for the trigeminal nerve) and the central processes enter the brain and synapse with secondary sensory neurons in dorsal portions of the medulla and pons, just as spinal afferents synapse in the dorsal horn of the spinal cord.

The rostral end of the neuraxis also receives sensory input from special sensory organs located at the front end of the individual, the portion that first moves into a new environment. Olfactory receptors are stategically placed at the front end of the respiratory system. Eyes and ears are also positioned at the front end, as is the vestibular apparatus located within the inner ear. Taste receptors and their sensory nerves are at the front end of the digestive system. The central processes of sensory neurons carrying information from hearing, vestibular apparatus, and taste receptors enter the brain at the level of the medulla and pons and synapse with second-order sensory neurons located in dorsally situated sensory nuclei. Special sensory neurons also detect internal bodily states (blood pressure, blood oxygen, and carbon dioxide levels; stomach distention;

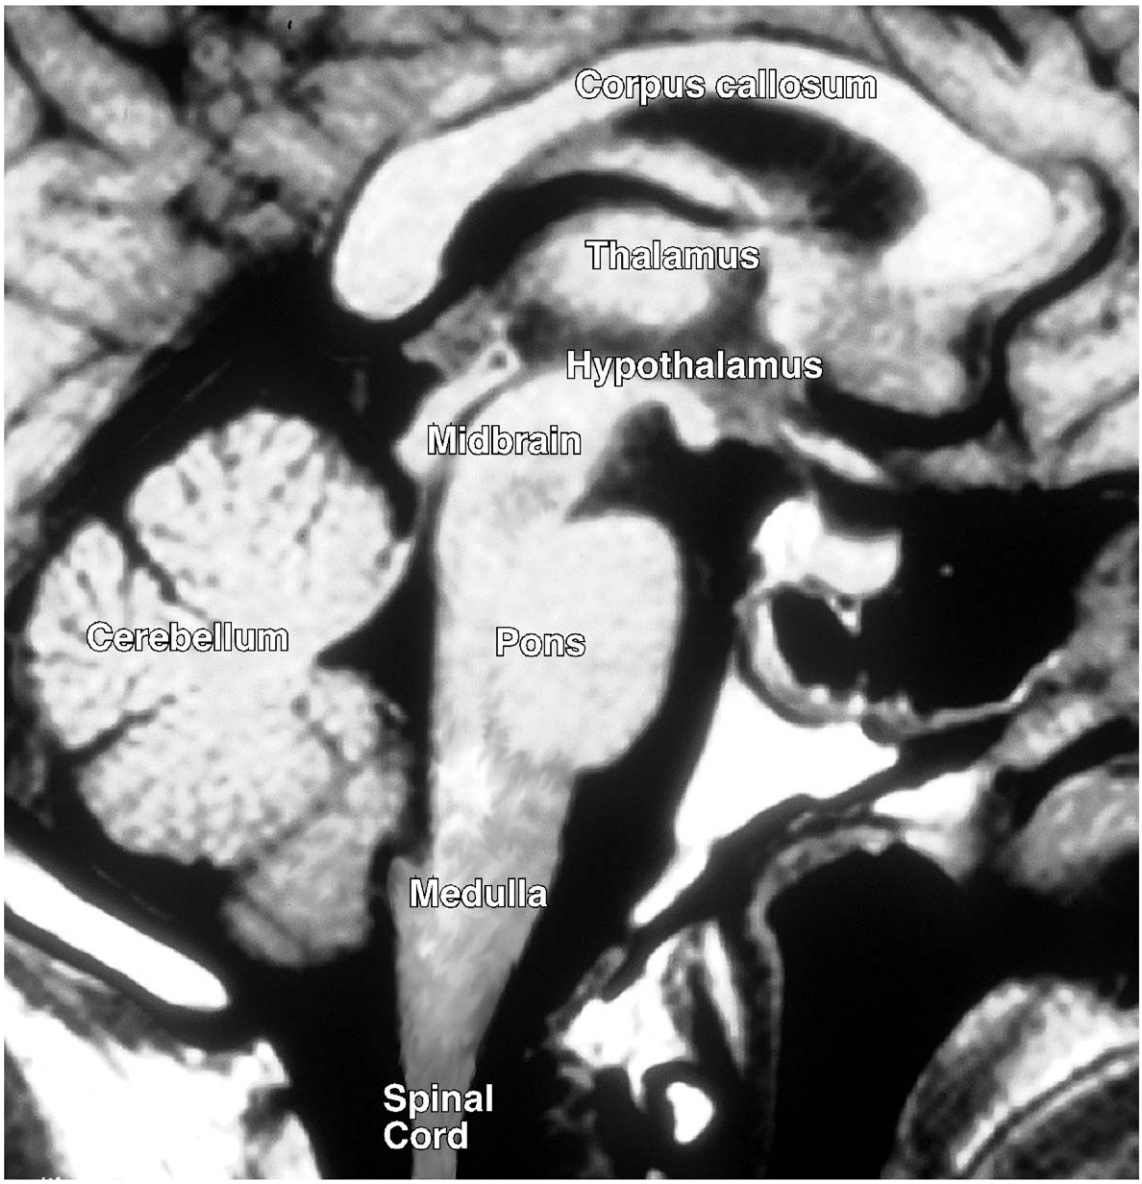

Figure 1 Magnetic resonance image of the sagittal plane of a human brain stem (modified with permission from Blessing, 1997).

and blood sugar level) and the central processes of these cells also reach the brain stem via the lower cranial nerves.

There is no direct communication between different groups of cranial motoneurons, so during, for example, swallowing, coordinated movements of the lips and the tongue are controlled by inputs from integrating premotor neurons with axonal collaterals innervating particular subgroups of lower motoneurons and not by collaterals of the lower motoneurons. Many of the integrative premotor neurons are also located in the brain stem. They help coordinate the behavioral, respiratory, cardiovascular, visceral, gastrointestinal, eliminative, and reproductive events essential for survival of the individual and the species. In turn, the premotor neurons are controlled by interneurons that are controlled by higher order integrative interneurons in the brain stem and in other parts of the brain. These interneurons receive inputs from the afferent side of the nervous system so that their genetically determined patterned output can also reflect the influence of past and present environmental events. Different groups of brain stem premotor neurons and interneurons are described in Table I.

As already noted, in the brain stem not all particular subgroups of neurons are arranged in discrete ''nuclei'' clearly defined with conventional Nissl stains. Certain brain stem neurons (including lower motoneurons, premotor neurons, and interneurons) are arranged diffusely in regions of the medulla, pons, and midbrain, scattered between ascending and descending fiber bundles. The net-like appearance of the regions containing these neurons led to the designation ''reticular formation,'' a term that was originally used in a purely descriptive anatomical sense. However, in the 1950s and 1960s, an additional functional meaning was assigned to the reticular formation so that the name began to refer to a hypothetical anatomical–physiological neuronal entity responsible for regulation of the level of arousal and consciousness as well as the maintenance of bodily posture. Instead of being used in a descriptive anatomical way, the reticular formation was promoted to a functional concept, a brain stem system which, by virtue of its nonspecific connectivity, could act as a kind of volume control for the degree of conscious arousal, among other things. The rostral part of the brain stem reticular formation became the ''ascending reticular activating system'' and loss of consciousness with brain stem injury was attributed to damage to this system. The caudal part of the brain stem reticular formation was seen as a source of descending excitatory or inhibitory inputs to various brain stem centers and to the spinal cord.

The problem was that the very nonspecific and all-inclusive nature of the reticular formation, conceived as a kind of functioning neuronal system, made it difficult to generate specific research hypotheses. This extended use of the term meant that the reticular formation became elevated to a magical entity, an easy shortcut explanation of complex and little understood physiological processes. This was not a helpful strategy. The term reticular formation should be restored to its original neuroanatomical status and emphasis should be placed on specifying the particular group of brain stem lower motoneurons, premotor neurons, and interneurons responsible for the various physiological functions. The cerebral hemispheres and the cerebellum can be viewed as an additional vast collection of interneurons whose coordinated discharge controls less complex sets of interneurons and premotor neurons in the brain stem reticular formation, thereby producing a finely coordinated discharge of brain stem motoneurons. Some axons descending from control neurons in the cerebral cortex synapse directly onto lower motoneurons in the brain stem or in the spinal cord, but a substantial proportion synapse

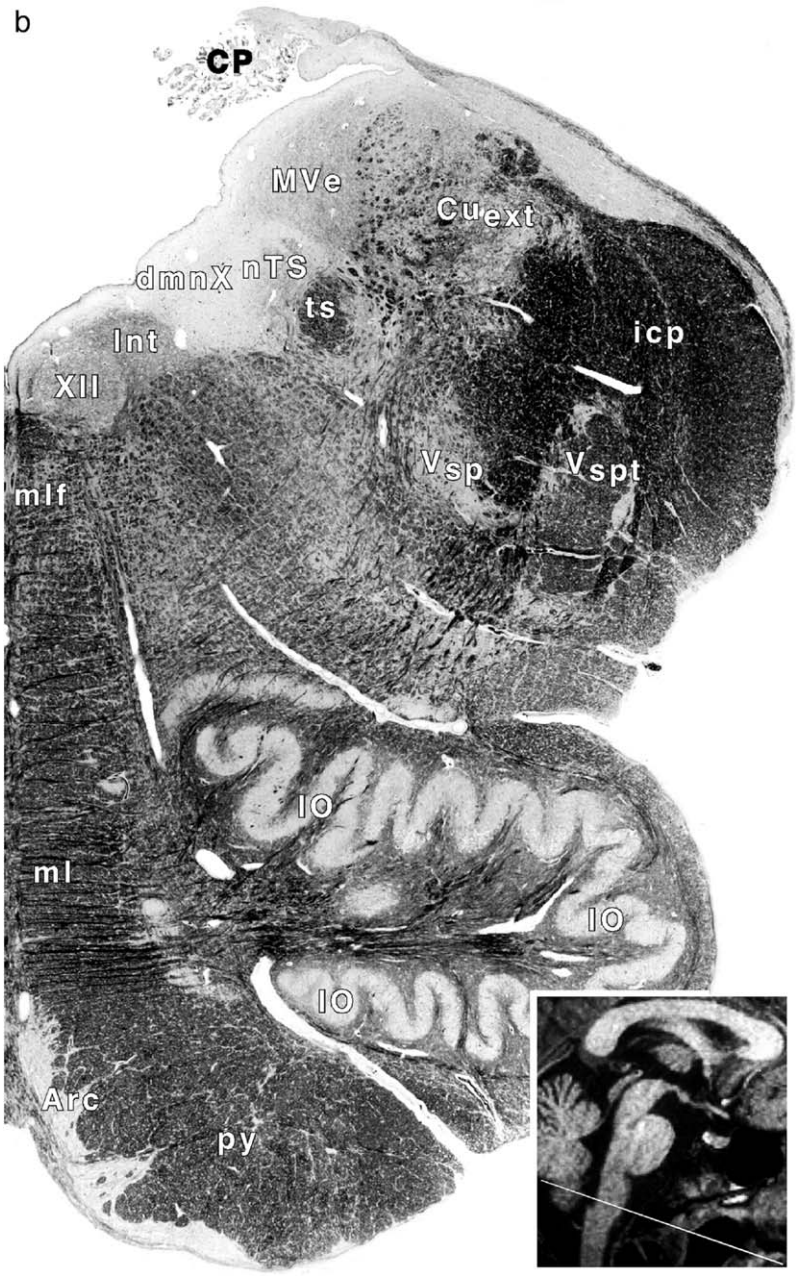

Figure 2 *(continued)*

with relevant brain stem interneurons and premotor neurons.

Much is already known concerning the lower motoneurons and the secondary sensory neurons in the different brain stem regions. Traditionally, these two groups are subclassified into particular categories, as summarized in Table I. Secondary sensory neurons are classified according to whether their peripheral processes terminate in somatic structures (skin and joints), in special sensory structures (hearing, vestibular function, and taste), or from internal receptors in the large arteries (baroreceptors and chemoreceptors) or in the viscera (heart, lungs, stomach, etc). Brain stem lower motoneurons are classed as somatic if their axons innervate striated muscle (e.g., the muscles of the face, jaw, and tongue) and as parasympathetic if their axons

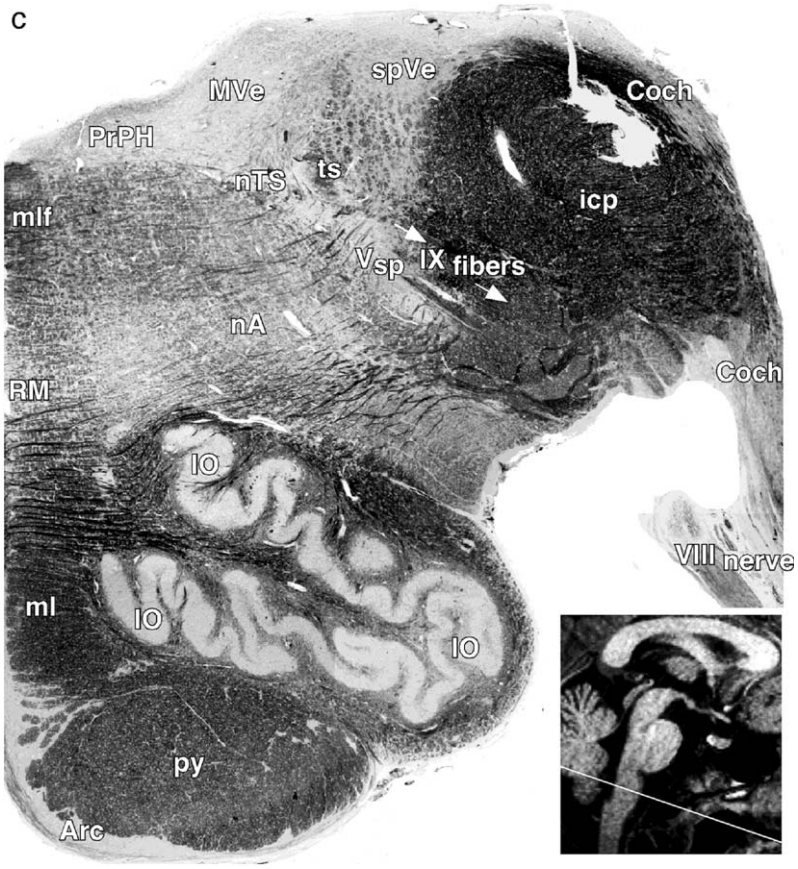

Figure 2 *(continued)*

innervate peripheral ganglionic neurons which, in turn, project to viscera in the head, neck, thorax, or abdomen (e.g., the blood vessels in the head, the salivary glands, the heart, lungs, and the abdominal viscera). Somatic efferents are subdivided (because of embryological considerations) into medially situated general somatic efferent nuclei (innervating extraocular muscles and tongue) and more ventrolaterally situated special visceral efferents, innervating (striated) muscles of chewing, facial expression, and swallowing.

Traditionally, the peripheral parasympathetic cell bodies are designated as "postganglionic" even though they are located within ganglia. It is the axons which are postganglionic. It is best to refer to the parasympathetic cell bodies as final parasympathetic motoneurons. The motoneurons in the brain stem can be referred to as parasympathetic preganglionic motoneurons or, in the appropriate context, simply as brain stem parasympathetic motoneurons. The "preganglionic" terminology is reasonable, but it derives from an earlier period when attention was focused much more on the periphery than on the brain.

Brain stem and forebrain neurons with inputs to parasympathetic motoneurons can be referred to as preparasympathetic motoneurons. The sacral region of the spinal cord also contains parasympathetic preganglionic motoneurons (sacral parasympathetic motoneurons) so that some of the brain stem preparasympathetic motoneurons have long axons descending to the sacral cord from different brain stem groups (e.g., Barrington's nucleus for control of micturition).

A. Cranial Nerves: Associated Motor and Sensory Nuclei

There are 12 paired cranial nerves, numbered in Roman numerals from the most rostral (in the forebrain) to the most caudal (in the lower brain stem). The nerves are named for their particular functions (the "oculomotor" nerves move the eyes) or for some other notable property ("trigeminal," meaning "three twins," is the name given to the fifth cranial nerve; "vagus," meaning "wanderer," is the name for the 10th cranial nerve).

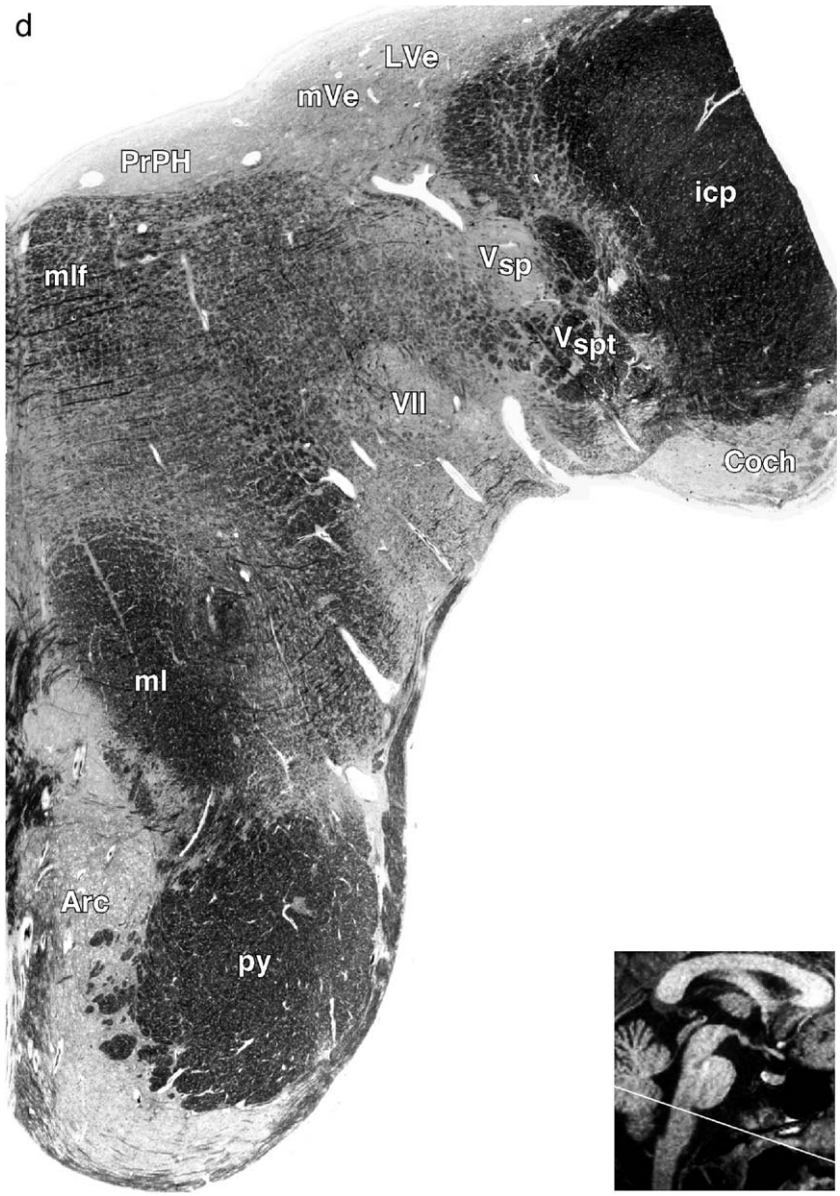

Figure 2 *(continued)*

Some of the cranial nerves are motor, some are sensory, and some are mixed (Table II).

B. Axonal Pathways Traversing the Brain Stem

1. Descending Pathways

The direct motor pathway from the cerebral cortex to the spinal cord comprises myelinated axons of motoneurons in the cerebral cortex. These axons form bilateral thick bundles which traverse midbrain, pons, and medulla. As shown in the different cross sections in Fig. 2, the pathway is often loosely referred to as the pyramidal tract. In the midbrain the anterior region through which the pyramidal tract passes is called the crus cerebri or the basis pedunculi. In the pons the fibers are divided into smaller bundles by bundles of axons which sweep around the front of the brain stem. In the medulla, the corticospinal fibers are again situated medially and anteriorly, and the paired pathways are referred to as the pyramids.

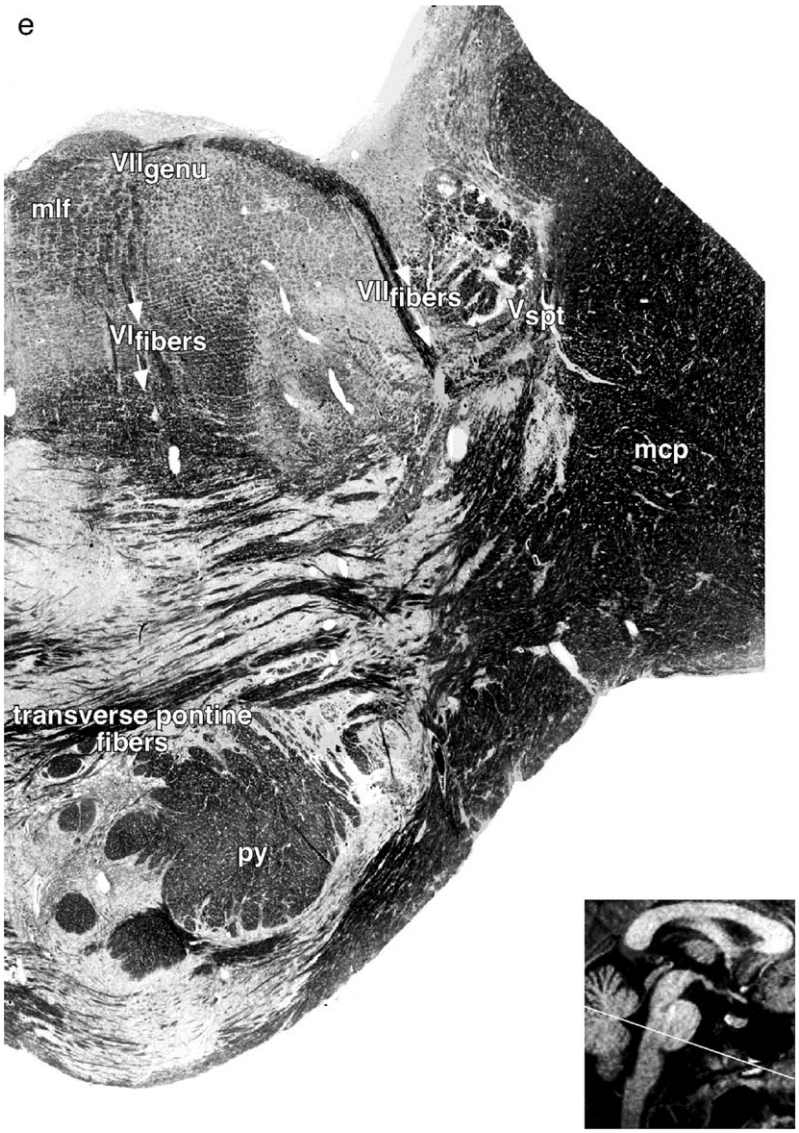

Figure 2 *(continued)*

There are other well-recognized descending pathways whose names provide helpful clues to their neuroanatomy. The rubrospinal tract consists of axons of neuronal cell bodies located in the red nuclei in the midbrain. The vestibulospinal tract consists of axons of neuronal cell bodies located in the vestibular nuclei in the dorsolateral part of the rostral medulla oblongata. Other descending pathways include the so-called ''reticulospinal'' tracts. These axons descend in less well-defined pathways. The hypothalamus and certain regions of the pons and medulla contain neurons (presympathetic neurons) whose axons descend to the spinal cord via the dorsolateral funiculi and innervate sympathetic preganglionic neurons located in the intermediolateral columns of the thoracic and upper lumbar spinal cord.

Other neurons in the medulla and pons function as parasympathetic premotor neurons with axons descending to the sacral portion of the spinal cord to innervate the parasympathetic preganglionic neurons that regulate genital and bowel–bladder function.

2. Ascending Pathways

Cell bodies in the dorsal root ganglia of the spinal cord whose peripheral processes detect light touch,

Figure 2 *(continued)*

vibration, and joint position sense have a centrally directed process that passes into the ipsilateral dorsal column of the spinal cord, ascends to the dorsal region of the medulla oblongata, and synapses on a second-order sensory neuron in the gracile and cuneate nuclei (Figs. 2a and 2b). The axon of the second-order neuron passes ventrally and medially before crossing to the other side and ascending through the medulla, pons, and midbrain in a distinctive pathway known as the medial lemnisus (Figs. 2a–2g). Lemniscal axons synapse in the thalamus.

In contrast, cell bodies in the dorsal root ganglia of the spinal cord whose peripheral processes detect pain and temperature sensation have a centrally directed axon which synapses in the dorsal horn near the level of entry. The axon of the second-order neuron passes ventrally and medially, crossing the midline just ventral to the central canal. The axon then ascends as the spinothalamic tract, through the spinal cord, medulla oblongata, pons, and midbrain, before synapsing in the thalamus.

Other bundles of axons ascend as components of the spinocerebellar pathways, traversing the lateral part of the medulla oblongata and entering the cerebellum via the inferior or superior cerebellar peduncles. In the medulla oblongata, an additional ascending pathway to the cerebellum consists of axons of inferior olivary neurons (Figs. 2b and 2c). These olivocerebellar axons pass medially from the olive, crossing the midline and entering the laterally positioned inferior cerebellar peduncle en route to the cerebellum.

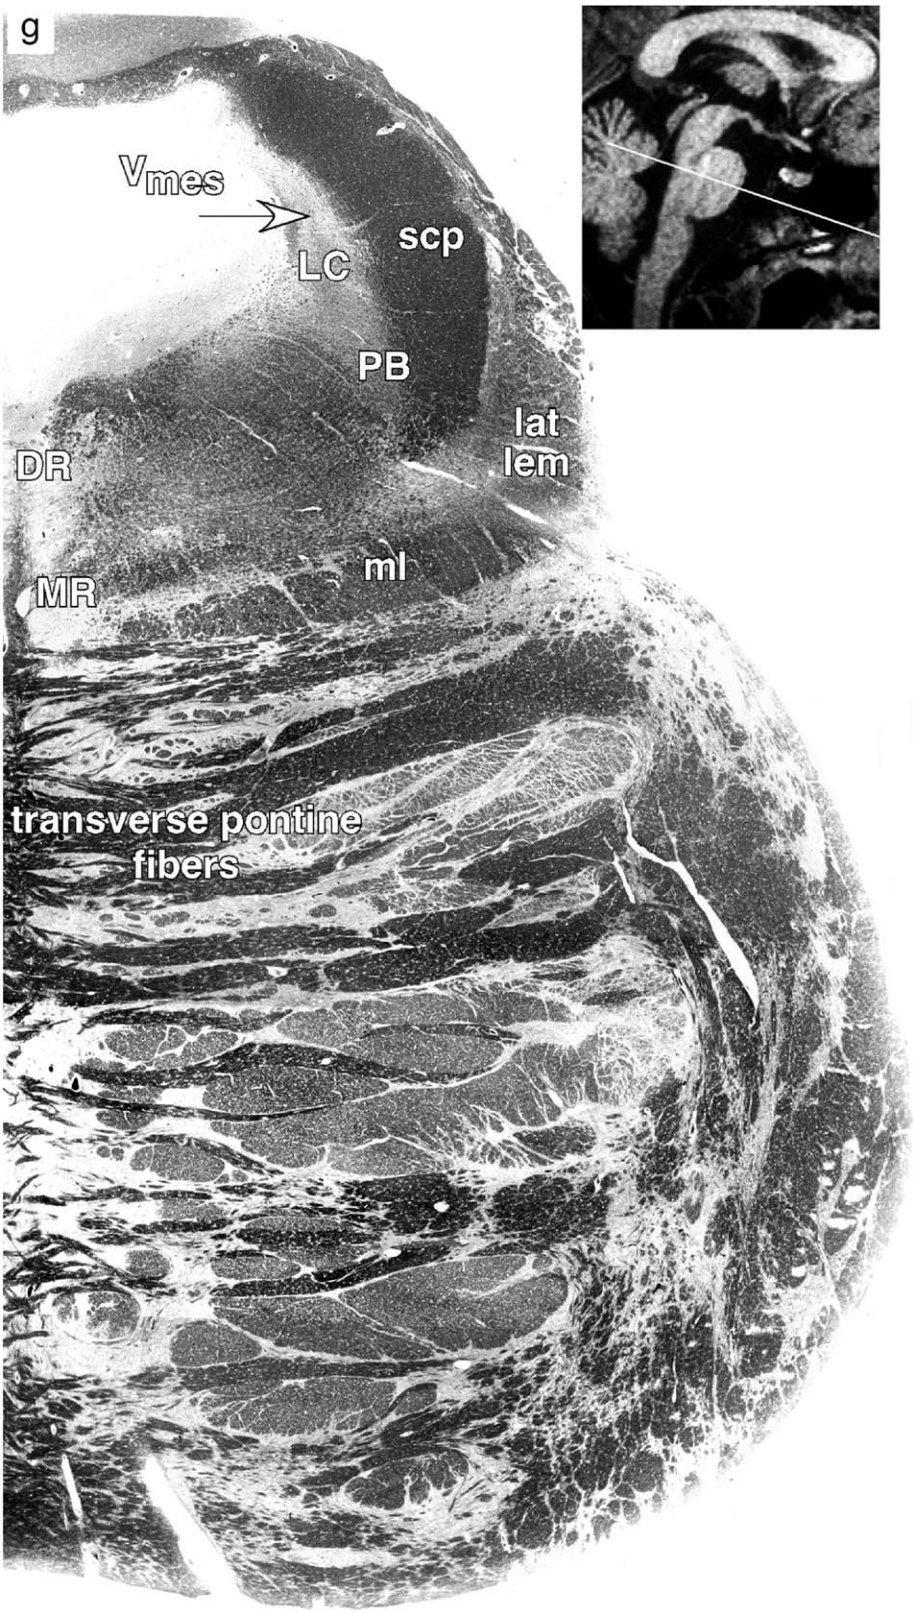

Figure 2 *(continued)*

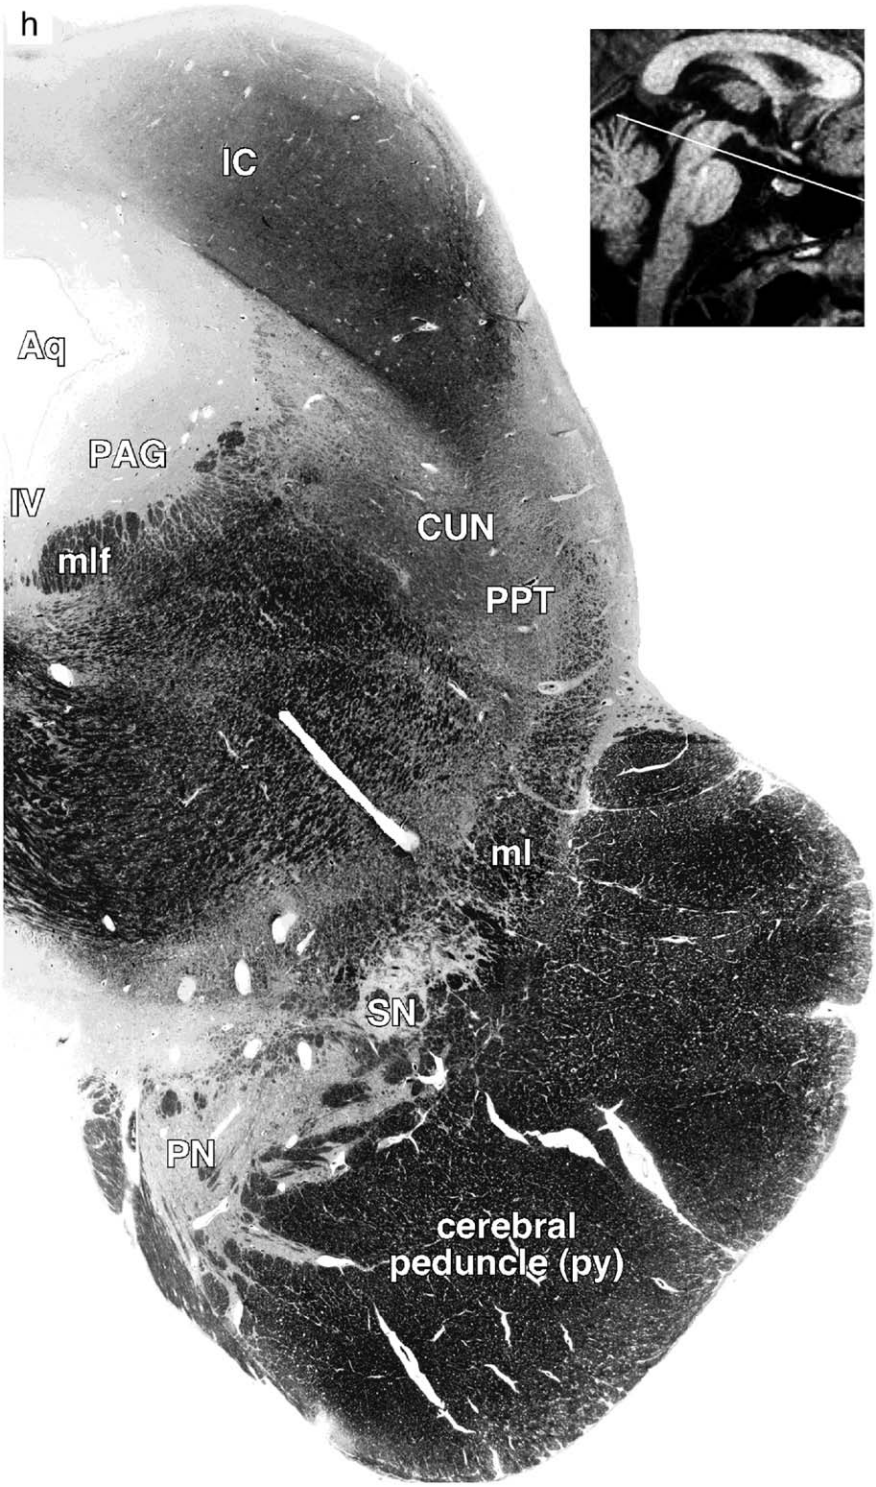

Figure 2 *(continued)*

Table I
Classification of Brain Stem Neurons

Somatic motoneurons

Peripheral striated muscle innervated	Cranial nerve	Brain stem nucleus
Extraocular muscles	III, IV, VI[a]	Edinger–Westphal, trochlear, abducent principal trigeminal motor nucleus
Jaw muscles	V[b]	
Mylohyoid, anterior digastric, tensor tympani, stapedius	V[b]	Accessory trigeminal motor nucleus
Stylohyoid, posterior digastric	VII[b]	Accessory facial nucleus
Facial expression	VII[b]	Main facial nucleus
Swallowing and phonation (muscles of pharynx, larynx, and upper part of esophagus)	IX, X[b]	Nucleus ambiguus (excluding external formation)
Tongue	XII[a]	Hypoglossal
Sternomastoid and trapezius	XI	Accessory

Parasympathetic motoneurons

Peripheral target	Final motoneuron	Cranial nerve	Brain stem nucleus
Ciliary and iris muscles	Ciliary ganglion	III	Edinger–Westphal nucleus
Lacrimal gland	Sphenopalatine ganglion	VII, IX	Neurons dorsal to rostral portion of facial nucleus
Salivary and mucosal glands	Cranial ganglia	VII, IX	Neurons dorsal to rostral portion of facial nucleus
Cranial blood vessels	Cranial ganglia	VII, IX	Probably with salivary and lacrimal preganglionic cells
Lower airways and lung	Ganglia in airways	X	Nucleus ambiguus, dorsal motor nucleus of vagus
Heart	Cardiac ganglia	X	Nucleus ambiguus (external formation)
Abdominal organs	Enteric neurons	X	Dorsal motor nucleus of the vagus

Secondary sensory neurons

Peripheral origin of primary afferent	Location of primary cell body	Cranial nerve	Brain stem nucleus in which primary afferents terminate
General cutaneous from anterior two-thirds of head	Cavum trigeminale	V, IX, X	Principal sensory nucleus of V
Joint position sense	In pons and midbrain	V	Mesencephalic nucleus of V
Nociception, temperature anterior two-thirds of head	Cavum trigeminale	V, IX, X	Spinal nucleus of V, possibly nucleus tractus solitarius
Hearing and vestibular function	Spiral and vestibular ganglia	VIII	Dorsal and ventral cochlear nuclei; medial, lateral, superior, and spinal vestibular nuclei
General cutaneous from posterior one-third of head and rest of body gustation	Dorsal root ganglia	Spinal dorsal roots	Gracile and cuneate nuclei
	Geniculate VII, petrosal IX, nodose X	VII, IX, X	nTS, spinal nucleus of V, and paratrigeminal islands
Baro- and chemoreceptors, receptors in heart, lung, and abdominal organs	Petrosal IX, nodose X	IX, X	nTS, spinal nucleus of V, and paratrigeminal islands

(continues)

Table I *(continued)*

Interneurons, including premotor neurons	
Type of neuron	**Brain stem nucleus**
Interneurons with no primary afferent input and no direct projections to motoneurons	Inferior olive, lateral reticular nucleus, cerebellar nuclei, vestibular nuclei, nuclei pontis, arcuate nuclei, superior olive, nucleus intercalatus, prepositus hypoglossi, locus coeruleus and subcoeruleus, dorsal tegmental nuclei, A7 catecholamine cells, parabrachial, Kölliker–Fuse, pedunculopontine and cuneiform nuclei, PAG
Premotor cells for cranial somatic motoneurons	Ventral pontine nuclei (relay nuclei between cerebral cortex and cerebellum), near various regions of the pons and medulla, many still undefined; neurons loosely scattered between fibers without formation of defined nuclei are referred to as the "reticular formation"
Premotor cells for cervical (phrenic) and thoracic spinal respiratory neurons	Some Kölliker–Fuse and parabrachial neurons, Bötzinger complex neurons, rostral inspiratory and more caudal expiratory neurons in the ventrolateral medulla, some nucleus tractus solitarius; raphe magnus, parapyramidal and more caudal raphe neurons
Presympathetic motoneurons	Paraventricular nucleus of hypothalamus, A5 catecholamine cells, C1 catecholamine cells and other intermingled noncatecholamine cells, raphe magnus, parapyramidal and more caudal raphe neurons
Preparasympathetic motoneurons (cranial outflow)	See details in text
Preparasympathetic motoneurons (sacral spinal outflow)	Raphe and parapyramidal nuclei, rostral ventrolateral medulla, A5 region, Barrington's nucleus, and paraventricular and preoptic nuclei of the hypothalamus
Premotor cells for hypothalamic magnocellular neurons	A1 and A2 catecholamine-synthesizing neurons, and possibly some midbrain raphe neurons

[a]General somatic efferents.
[b]Special visceral efferents.

The medial longitudinal faciculi are paired paramidline tracts containing axons which interconnect cranial nerve nuclei, especially those concerned with horizontal eye movements.

III. BLOOD SUPPLY AND CEREBROSPINAL FLUID CIRCULATION: BLOOD–BRAIN BARRIER, AREA POSTREMA, AND VENTRAL SURFACE OF THE MEDULLA

The brain stem, up to the level of the rostral midbrain, is supplied by the single midline basilar artery, formed by union of the paired vertebral arteries. At its rostral extent, the basilar artery bifurcates into paired posterior cerebral arteries which continue on to supply the medial temporal lobe and the occipital poles of the cerebral hemispheres. This knowledge is very important in clinical practice because patients with brain stem ischemic stroke (vertebrobasilar ischemia) present with a clinical picture (see Section V) quite different from that displayed by patients with ischemia in forebrain territory supplied by the paired internal carotid arteries. The posterior communicating arteries connect the vertebrobasilar arterial supply with the internal carotid supply, forming part of the circle of Willis.

Cerebrospinal fluid (CSF) is filtered from the blood by the choroid plexus in the lateral, third, and fourth ventricles of the brain. Fluid secreted in the forebrain descends through the midbrain aqueduct and enters the large dorsal brain stem pool bounded anteriorly by the dorsal surface of the medulla oblongata and the pons (known as the floor of the fourth ventricle) and posteriorly by the cerebellum and by special folds of the meninges. These folds have openings (formamina of Luschka and Magendie) through which CSF can pass en route to the subarachnoid space surrounding the brain and to the dorsally positioned arachnoid villae which absorb the CSF back into the bloodstream. From the fourth ventricle, the CSF also passes caudally down the central canal of the spinal cord. Occlusion of the aqueduct or of the foramina of Luschka and Magendi obstructs the flow of CSF, causing increased pressure in rostral portions of the system so that the forebrain ventricles enlarge. This condition is known as hydrocephalus and it may be associated with drowsiness or coma.

The "inside" of the brain (the brain parenchyma and the cerebrospinal fluid) is chemically isolated from the "outside" of the brain (the cerebral blood vessels). A particular configuration of the basement membranes in the small cerebal blood vessels results in a blood–brain

Table II
Cranial Nerves

Nerve No.	Nerve name[a]	Site for CNS motoneurons	CNS site for termination of primary sensory axons
I	Olfactory (S)		Forebrain
II	Optic (S)		Forebrain (thalamus)
III	Oculomotor (M)	Dorsomedial midbrain	—
IV	Trochlear (M)	Dorsomedial midbrain	—
V	Trigeminal (S, M)	Pons	Pons, medulla, and upper cervical spinal cord
VI	Abducent (M)	Dorsomedial pons	—
VII	Facial (S, M)	Ventrolateral pons	Nucleus tractus solitarius
VIII	Vestibulocochlear (S)		Vestibular nucleus in dorsolateral medulla
IX	Glossopharyngeal (S, M)	Ventrolateral pons and nucleus ambiguus	Nucleus tractus solitarius
X	Vagus (S, M)	Dorsal motor nucleus of the vagus and nucleus ambiguus	Nucleus tractus solitarius
XI	Accessory (M)	Nucleus ambiguus and upper spinal cord	—
XII	Hypoglossal (M)	Hypoglossal nucleus in dorsomedial medulla	—

[a]M, motor; S, sensory.

barrier that protects the brain from circulating agents which might interfere with normal neurotransmitter action. One particular group of cells on the dorsal aspect of the medulla oblongata forms the area postrema, a specialized circumventricular organ which samples the blood side of the blood–brain barrier and sends action potential messages to the brain, with axons of the area postrema neurons projecting widely within the brain stem, particularly to the parabrachial nuclei.

Cells lining certain portions of the ventral surface of the medulla oblongata, either glial cells or neurons, may be sensitive to different properties of the CSF, especially its hydrogen ion concentration (pH). Some theories of the neuropathological mechanism underlying sudden infant death syndrome (cot death) postulate that the normal sensitivity of these cells is somehow reduced so that when the airway becomes obstructed, affected infants fail to arouse, to turn their head, and to increase their breathing in the normal manner.

IV. FUNCTIONS REGULATED IN THE BRAIN STEM

A. Normal "Vigilant" Consciousness and the Sleep–Wake Cycle

Many lines of evidence point to the importance of the brain stem in maintaining the normal awake state of awareness. Humans with damage to the region of the dorsal pons, midbrain, and thalamus (by trauma, brain tumor, viral or bacterial infection, or ischemic or hemorrhagic stroke) may exhibit an impaired state of alertness, possibly becoming stuporose or comatose. In animals, experimental transection at various levels of the spinal cord and brain stem established that coma ensued after lesions through the level of the colliculi, but not after lesions through the level of the medullospinal junction. In intact anesthetized animals, electrical stimulation in the brain stem caused the neocortical electroencephalogram to change to a pattern normally associated with alertness. This activation probably reflects stimulation of ascending axons arising in noradrenaline neurons in the locus coeruleus, serotonin neurons in the median and dorsal raphe nuclei, and acetylcholine neurons in the pedunculopontine tegmental nuclei (Figs. 2f and 2g).

The locus coeruleus (blue place) consists of a group of pigmented neurons (melanin-containing) located in the dorsolateral portion of the rostral pons. These noradrenaline-synthesizing neurons have extensive efferent connections to the forebrain, including the thalamus and the cerebral cortex, and to the cerebellum and the spinal cord. Activity of neurons in the locus coeruleus is increased when the individual detects a significant, potentially rewarding or threatening stimulus as well as during certain phases of the sleep–wake cycle. It is thought that locus coeruleus inputs to

forebrain neurons increase the efficiency with which the innervated neurons respond to particular environmental stimuli.

B. Control of Pupil Size

Our pupils become larger when we move to a darker environment, and they constrict again when we move back into the light. This light reflex is mediated via contraction and relaxation of the sphincter pupillae muscle, innervated by parasympathetic final motorneurons located in the ciliary ganglia behind the eyeballs. In turn, the final motoneurons are regulated via inputs from brain stem parasympathetic motoneurons in the Edinger–Westfal subdivision of the oculomotor (cranial III) nucleus located in the midbrain, ventral to the aqueduct. The afferent limb of the light reflex involves activity in optic nerve (cranial II) fibers, with a branch to the pretectal nucleus in the superior colliculus of the midbrain and from there to the parasympathetic motorneurons in the Edinger–Westfal nucleus.

The pupils also dilate when strong emotions are experienced, such as when we are surprised, afraid, or sexually aroused. This active dilatation is mediated by sympathetic innervation of the dilator pupillae muscle. The final cell bodies are located in the superior cervical ganglion, near the bifurcation of the common carotid artery. The preganglionic cell bodies are in the upper thoracic spinal cord. The pathway descending from the brain is a principally unilateral direct projection from the paraventricular nucleus of the hypothalamus. Interruption of the pupillodilator pathway in the brain stem, the spinal cord, or in the periphery causes an ipsilateral Horner's syndrome, consisting of a small pupil (meiosis) and slight retraction of the eyeball associated with partial closure of the eyelids. The drooping upper eyelid is referred to as a ptosis.

C. Moving the Eyes

1. Voluntary Movement of the Eyes

The eyeballs move when the extraocular striated muscles contract. Medial movement is mediated by the medial rectus muscle, innervated by somatic motor axons traveling in cranial nerve III (the oculomotor nerve). Lateral movement is mediated by the lateral rectus muscle, innervated by axons which travel in cranial VI (the abducent nerve). Upward movement is mediated by the superior rectus and inferior obliques muscles (both innervated via cranial III) and downward movement is mediated by the inferior rectus muscle (innervated via cranial III) and by the superior oblique muscle (innervated via cranial IV, the trochlear nerve). The brain stem location of the various groups of motoneurons is shown in Fig. 2.

The eyeballs normally move in a mutually coordinated manner. When, for example, the individual voluntarily looks to the right, the lateral rectus muscle of the right eyeball contracts at the same time as the medial rectus muscle of the left eyeball. This horizontal conjugate eye movement depends on coordinated activity in the right abducent nerve (cranial VI) and the relevant fibers in the left oculomotor nerve (cranial III). This coordination is achieved via activity descending from the left cerebral cortex to controlling premotor and interneurons in the brain stem, as outlined in Fig. 3. Vertical eye movements are coordinated by premotor neurons in the upper midbrain.

2. Reflex Movements of the Eyes by the Vestibuloocular Reflex

In a dead person, the eyes stay still in relation to the head so that when the head is held and turned to the left, the eyes move together with the head. In an alive but unconscious person with an intact brain stem, when the examining doctor turns the person's head to the left, the functioning vestibuloocular reflex turns the eyes to the right so that they continue to look straight ahead. This compensatory gyroscope-like adjustment of the eye position is known as a dolls-eye movement. It also occurs in the conscious individual, facilitating fixation of the gaze when the head is moving.

Head movements are detected by the afferent neurons innervating the canal system of the vestibular–labyrinthine apparatus (Fig. 3). For example, if an individual is looking at an object straight in front of him or her and the head is suddenly turned to the left, the left horizontal canal primary sensory neurons will increase their discharge rate. Axons of these neurons enter the brain stem via cranial nerve VIII and excite second-order afferent neurons in the vestibular nuclei of the brain stem (Figs. 2c and 2d). These second-order vestibular neurons project to the contralateral abducens motoneurons (innervation of the right lateral rectus muscle) and to the contralateral abducens interneurons, whose axons cross the midline and ascend in the medial longitudinal fasciculus to the oculomotoneurons (cranial III) that innervate the medial rectus muscle. Thus, turning the head to

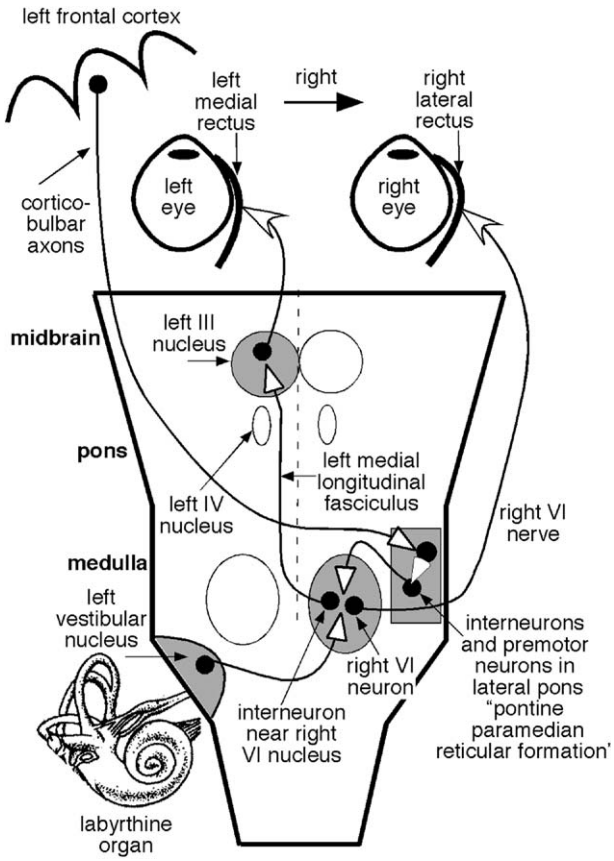

Figure 3 Schematic horizontal section through the human brain stem showing the oculomotor system for voluntary gaze to the right and for movement of the eyes to the right during the vestibuloocular reflex.

the left reflexly leads to contraction of the right lateral rectus and the left medial rectus muscles, turning the eyes to the right.

D. Body Movement and Posture

The expression "running around like a headless chicken" is based on a stark reality. Clearly, many vertebrates can locomote via motor pattern generators intrinsic to the spinal cord. The presence of such segmental and intersegmental spinal circuitry in mammals is evident when a cat with a lower cervical spinal transection is supported and placed on a treadmill. The animal's legs move in a coordinated walking fashion. Control of limb movement is embedded in neural circuitry present at different levels of the neuraxis, with the system operating like embedded procedure loops in a computer program. Each higher level of the nervous system represents a more complex loop, including and controlling the less complex loops. The brain stem, without the forebrain, is capable of coordinating complex movements, including some of the more integrated movements we recognize as behaviors. Decerebrate rats are quite capable of grooming themselves. A decerebrate dog may turn, growl, and bite the fingers holding his hind foot too roughly. Clearly, forebrain neural circuits, including frontal and prefrontal pathways, are necessary if the individual is to accomplish the finely patterned movements of eyes, lips, tongue, and fingers which especially characterize human action. If damage occurs at the midbrain level of the neuraxis (which sometimes occurs with head injury in motor vehicle accidents), the decerebrate individual subjected to a painful stimulus (e.g., a firm pinch on the chest area) may simply increase the breathing rate and internally rotate the extended arms in a purposeless fashion.

Brain stem nuclei with projections to spinal premotor neurons include the red nuclei in the midbrain (rubrospinal), the vestibular nuclei in the rostral medulla and pons (vestibulospinal), the locus coeruleus, and the raphe and parapryamidal nuclei in the pons and medulla. In addition, there are descending motor projections from neurons in various parts of the brain stem reticular formation (collectively named reticulospinal). The brain stem nuclei which innervate spinal motor centers also project to relevant premotor regions in the brain stem, but these pathways are more difficult to delineate and they are usually not referred to by any particular name. The functions of these various brain stem nuclei, and the contribution of each to body posture and movement, are still being defined.

The medulla, pons, and midbrain have numerous interconnections with the cerebellum, a part of the brain intimately involved with coordination of posture and movement. For example, the inferior olivary nucleus in the ventral portion of the medulla oblongata, contains densely packed neurons which project across the midline, enter the inferior cerebellar peduncle, and synapse on neurons in the cerebellar cortex. The information conveyed in these "climbing fibers" derives from various forebrain, brain stem (including the red nucleus in the midbrain), and spinal inputs to the inferior olivary nucleus.

E. Touch, Temperature, and Pain

As noted earlier, the brain stem contains circuitry which subserves "spinal cord functions" for the head

region. General sensation from the face and head region is mediated via trigeminal (cranial V) afferents with perikarya in the trigeminal ganglion. The central process of the trigeminal neuron enters the brain stem at the level of the ventrolateral pons. Myelinated afferents subserving light touch in the face and upper head region synapse in the principal sensory nucleus of V. Light touch and other finely judged senses (vibration and joint position) from the rest of the body are mediated by neurons located in the dorsal root ganglia of the spinal cord. Central processes of these neurons enter the dorsal columns of the spinal cord and ascend to synapse in the gracile and cuneate nuclei in the dorsal medulla oblongata. Axons of the gracile and cuneate cells pass ventrally, cross the midline, and ascend to the thalamus as the bundle constituting the medial lemniscus. Fibers from neurons in the principal sensory nucleus of V also travel to the thalamus as part of the medial lemniscus.

An unusual neuronanatomical arrangement has been described for trigeminal neurons mediating joint position sense for the jaw and the tongue. Perikarya for these primary afferents are located in the brain stem, in the mesencephalic nucleus of V (Fig. 2g).

Pain and temperature sensation is mediated by unmyelinated axons of neurons located in the cavum trigeminale (for the face and head) and in the dorsal root ganglia (for the rest of the body). For the body apart from the face and head, central processes of these neurons synapse in the ipsilateral dorsal horn of the spinal cord. Axons of secondary sensory neurons cross the midline and ascend to the thalamus as the spinothalamic tract. Unmyelinated afferents subserving temperature and pain sensation from the face and head region travel caudally in the spinal tract of V before synapsing in the spinal nucleus of V, sometimes as far caudally as the upper cervical spinal cord. Axons from the secondary sensory axons cross the midline and ascend to the thalamus along with the spinothalamic pathway.

F. Hearing

Sound energy vibrates the tympanic membrane. This movement is amplified by the bones of the middle ear so that vibrations occur in a special fluid-filled organ known as the cochlear. Specialized cochlear receptor cells are innervated by sensory axons of the primary auditory neurons (cranial VIII) located in a peripheral ganglion (spiral ganglion) near the inner ear. Centrally directed afferent axons of these neurons enter the brain stem and synapse with secondary sensory neurons located in the cochlear nuclei on the dorsolateral aspect of the rostral medulla oblongata (Figs. 2c and 2d). The secondary sensory neurons have axonal projections either via the lateral lemniscus directly to the inferior colliculus or via a synapse in the superior olivary nucleus and then via the lateral lemniscus to the inferior colliculus. From the inferior colliculus, ascending axons project to the medial geniculate nucleus of the thalamus and then to the auditory cortex.

G. Sensing Gravity and Movement

The inner ear contains a fluid-filled labyrinth with associated cells sensitive to the orientation and movement of the individual with respect to the outside world. The labyrinthine cells are innervated by sensory axonal processes of nerve cells located in a ganglion near the inner ear (Scarpa's ganglion). Central processes of these afferent neurons reach the brain stem by way of the vestibular branch of cranial nerve VIII and synapse with secondary sensory neurons in the vestibular nuclei located in the dorsolateral portion of the rostral medulla oblongata (Figs. 2c and 2d). In turn, the neurons in the vestibular nuclei project widely to brain stem nuclei (including those regulating eye movements) as well as to the spinal cord motor control regions. The particular vestibular projection which gives rise to the feeling of nausea associated with motion sickness has not been characterized.

H. Lacrimation

The lacrimal (tear) glands and specialized cells in the lining of the nose secrete fluid filtered from the blood, a process regulated by parasympathetic final motoneurons located in the sphenopalatine ganglion. These cells are innervated by axons traveling in the greater petrosal branch of the facial nerve (cranial VII). Brain stem parasympathetic motoneurons are located in the reticular formation, dorsal to the facial nucleus.

I. Tasting

Taste receptor cells in the mouth, tongue, palate, and pharynx are innervated by axons of afferent neurons with cell bodies located in peripheral ganglia

associated with facial, glossopharyngeal, and vagal cranial nerves. Centrally directed axons enter the medulla oblongata and synapse with secondary sensory neurons in the rostral portion of the nucleus of the tractus solitarius (Fig. 2c). Ascending axons of these secondary cells synapse in the parabrachial nucleus (pontine taste center) and also possibly project directly to the thalamus. Neurons in the parabrachial nucleus have extensive rostral connections with forebrain regions, including the amygdala and taste areas of the cortex.

J. Salivation

Saliva is fluid filtered from blood in the various salivary glands and secreted into the mouth via the different salivary ducts. Salivation is initiated by a combination of parasympathetic and sympathetic nerve activity. The parasympathetic final motoneurons are located in ganglia (otic, submandibular, and submaxillary) associated with the facial (cranial VII) and glossopharyngeal (cranial VIII) nerves and along the salivary ducts. The brain stem parasympathetic motoneurons regulating the salivary glands are located in the rostral medulla and caudal pons, diffusely spread in the reticular formation through a region extending dorsally and medially from the facial motor nucleus (cranial VII). Inputs from the forebrain to these parasympathetic neurons presumably mediate the ''conditioned'' salivation that occurs when we catch sight of food or when we think about food. Presumably, there are reasonably direct neural connections between the taste regions of the nucleus of the tractus solitarius and the parasympathetic salivary neurons, but these connections are not yet fully defined.

K. Chewing and Swallowing

Chewing and swallowing of food requires coordinated action of facial, jaw, tongue, soft palate, pharyngeal, and upper esophageal striated muscles. The relevant somatic lower motoneurons are located in a rostrocaudal column of cells, situated in the ventrolateral pons and medulla (VII, IX, and XI), in a more dorsomedial column of cells, just ventral to the central canal and the floor of the fourth ventricle (XII). Details of the premotor neurons and interneurons responsible for coordinating the activity of the different lower motoneurons are sparse. The relevant cells, situated in the reticular formation ventrolateral to the hypoglossal nucleus, presumably have built-in coordinating programs. These neurons must receive input from the forebrain (for voluntary chewing and swallowing) and from the nucleus of the tractus solitarius, the termination site of glossopharyngeal and vagal afferents originating in the pharynx and the esophagus (for reflex swallowing, among many other things).

L. Gastrointestinal Function, Blood Glucose, and Food Intake

Preganglionic axons of parasympathetic neurons in the dorsal motor nucleus of the vagus project via cranial nerve X to ganglia in the wall of the gastrointestinal tract (the enteric nervous system) and to other parasympathetic ganglia in the region of the different abdominal viscera. The vagal motoneurons play a very important role in regulating motility (e.g., stomach contractions) and secretory functions (e.g., gastric acid) of these organs. The central nervous system coordinates the function of the gastrointestinal tract and the other viscera, coordinating the behavioral and the physiological responses associated with nutritional aspects of daily life. As Pavlov demonstrated, the sight or smell of food are powerful stimuli for gastric acid secretion, a process mediated by the appropriate vagal efferents.

Afferent/sensory vagal axons also innervate the various abdominal organs, with the central process of the vagal afferent neurons projecting to the nucleus of the tractus solitarius in the dorsal part of the medulla oblongata. Different vagal afferents are sensitive to stretch or to the local chemical environment. After a meal, products of food digestion activate special intestinal cells containing the hormone cholecystokinin. In addition to its well-known effects on gallbladder contraction (hence its name), cholecystokinin, by a local mechanism, activates vagal afferents in the duodenum. The information which reaches the medulla oblongata initiates a whole sequence of postprandial (after eating) ''satiety'' events. The individual may feel full, stop eating, and go to sleep. Postprandial satiety is not due to an insufficient amount of blood getting to the brain (a commonly held view). It is principally due to the action of specially stimulated vagal afferents.

If blood sugar falls to low values, this is detected by special sensory vagal nerve endings in the periphery (mainly in the liver) and neurons in the nucleus of the

tractus solitarius. One result is the secretion of the hormone adrenaline from the adrenal gland. Control of this secretion is principally via sympathetic nerves, with cell bodies in the thoracic spinal cord, controlled by presympathetic neurons in the rostral ventrolateral medulla oblongata. Neurons in the nucleus tractus solitarius project to the rostral ventrolateral medulla.

M. Vomiting

The act of vomiting involves patterned contraction of striated muscles of the abdominal wall, pharynx, larynx, tongue, and face, together with a reversal of normal smooth muscle action in the upper intestine and stomach and a relaxation of the esophageal sphincter. This complex sequence of events can be initiated either in the gastrointestinal tract or in the brain. Axons of the vagus nerve innervate the upper gastrointestinal tract. Serotonin, released by emetic agents from small cells in the intestinal epithelium, stimulates serotonin receptors on the distal endings of the vagal afferents, causing them to discharge. The central processes of the relevant vagal afferents project into the brain and synapse in the nucleus of the tractus solitarius just rostral to the obex, with probable collateral input to the area postrema. Currently, there is insufficient information concerning central interneuronal pathways linking the secondary sensory neurons in the nucleus of the tractus solitarius with the premotor neurons controlling the relevant motor pathways involved in the act of vomiting. Also, it is not understood how nausea and vomiting due to gastrointestinal upset interact with those which occur as part of motion sickness, when the initial abnormal signal presumably originates in the labyrinthine system.

Activation of special neurons in the area postrema can also elicit vomiting. The nerve cells in the area postrema are in a special relation to a dense network of capillaries so that the usual barrier between blood and brain is not operative. Nerve cells in this region are directly exposed to circulating chemical agents. Many drugs which induce vomiting act by stimulating receptors, especially dopamine receptors, on these neurons. The area postrema cells project widely in the brain, but their medullary connections presumably include either the nTS neurons, which receive the vagal inputs from the upper gastrointestinal tract, or the same interneurons and premotor neurons which mediate vagally induced vomiting.

The survival value of gastrointestinally elicited vomiting is obvious. Why whole body radiation and cancer chemotherapeutic agents affect the serotonin cells in the upper gastrointestinal tract is not clear. Nevertheless, drugs which block serotonin receptors on the distal endings of the vagal afferents have proven of great benefit in reducing the nausea and vomiting associated with anticancer treatments.

N. Passing Urine

Passing urine (micturition) depends on activation of appropriate parasympathetic motoneurons in the sacral region of the spinal cord. Distention of the bladder activates afferent nerves whose spinal input tends to initiate micturition, but efficient emptying of the bladder requires descending activation which originates in brain stem preparasympathetic neurons located in the pontine micturition center, probably comprising a small group of neurons (Barrington's nucleus) located just medial to the locus coeruleus. Normally, micturition is delayed by descending inhibitory activity originating in the cerebral cortex.

O. Blood Flow, Arterial Pressure, and Cardiac Function

1. Presympathetic Vasomotor Neurons in the Brain Stem and the Hypothalamus

When the cervical or upper thoracic spinal cord is transected, the arterial blood pressure decreases to very low levels because the rostral ventrolateral medulla oblongata contains presympathetic vasomotor neurons whose activity tonically excites the spinal preganglionic sympathetic neurons so that regional vasomotor tone and arterial pressure are maintained. The activity of the medullary neurons is maintained either by intrinsic pacemaker activity or by interactions between different neuronal groups in a manner which currently is not understood. The presympathetic vasomotor neurons in the rostral medulla include the C1 catecholamine neurons (with the requisite enzymes to synthesize adrenaline being present in several species, including rats, cats, and humans) and an approximately equal number of noncatecholamine bulbospinal neurons. More medially placed bulbospinal neurons in the raphe and parapyramidal region have a role in regulating the changes in skin blood flow associated with body temperature regulation and with

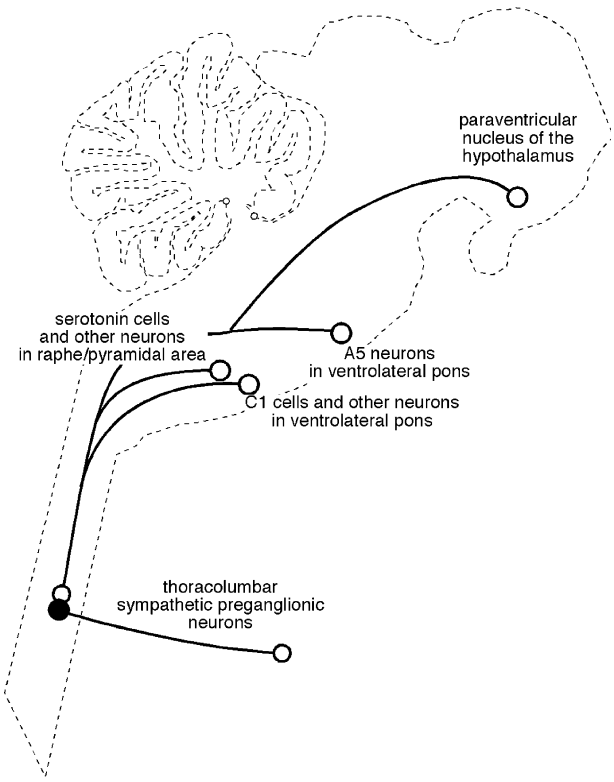

Figure 4 Schematic sagittal section through a rabbit brain showing the distribution of neurons (presympathetic motoneurons) with descending axons that innervate sympathetic preganglionic motoneurons in the intermediolateral columns of the thoracic and upper lumbar spinal cord. (modified with permission from Blessing, 1997).

cutaneous vasoconstriction in response to frightening or painful events. Other regions of the brain stem and the hypothalamus also contain presympathetic motoneurons (Fig. 4), but these cells have not been functionally characterized.

2. Inhibitory Cardiovascular Neurons in the Caudal Ventrolateral Medulla

The caudal ventrolateral medulla contains a group of GABAergic neurons with short axons projecting rostrally to innervate presympathetic vasomotor neurons in the rostral medulla. Discharge of the caudal vasomotor neurons inhibits the excitatory rostral bulbospinal neurons, thereby lowering arterial pressure. Since the caudal depressor neurons are tonically active, interference with their function removes the inhibitory control so that arterial blood pressure rises. It is possible that malfunction of the caudal vasodepressor neurons underlies some forms of hypertension.

3. Cardiovascular Secondary Afferent Neurons in the Nucleus of the Tractus Solitarius

Cranial nerves IX (glossopharyngeal) and X (vagus) include afferent neurons (cell bodies in nodose and petrosal ganglia) with distal processes specialized for the detection of arterial pressure, cardiac atrial pressure, arterial oxygen and content and blood acidity, and other chemoreceptors present in the lung and the heart. The central processes of these neurons project into the medulla oblongata as the tractus solitarius, synapsing principally in the caudal one-half of the nucleus of the tractus solitarius in the dorsal region of the medulla oblongata.

4. CNS Pathway Mediating the Baroreceptor–Vasomotor Reflex

When arterial pressure rises, the baroreceptor afferent neurons increase their discharge rate, thereby increasing the discharge of secondary afferent neurons in the nucleus of the tractus solitarius. These cells project to subclasses of the inhibitory vasomotor cells in the caudal ventrolateral medulla so that activation of the nucleus tractus solitarius cells increases the discharge of the inhibitory vasomotor neurons in the caudal ventrolateral medulla, reducing the activity of the sympathoexcitatory bulbospinal in the rostral medulla neurons and thereby lowering arterial pressure.

P. Breathing

When we breath in, the lungs inflate because contraction of the diaphragm and other respiratory chest muscles means that the pressure around the lungs becomes less than atmospheric pressure. The inspiratory respiratory muscles are innervated by somatic motor nerves (including the phrenic nerve) whose cell bodies are located in the C3 and C4 segments of the cervical spinal cord. These spinal motoneurons have no spontaneous activity. Transection of the upper cervical cord isolates them from descending excitatory control so that breathing ceases and survival means artificial respiration via a tracheal tube (positive pressure to the lung) or with an iron lung (negative pressure around the lung). Stimulating the phrenic nerve via an implanted pacemaker may also be possible.

The neurons that project from the brain to the cervical spinal cord to regulate spontaneous inspiration are located in the medulla oblongata, in the

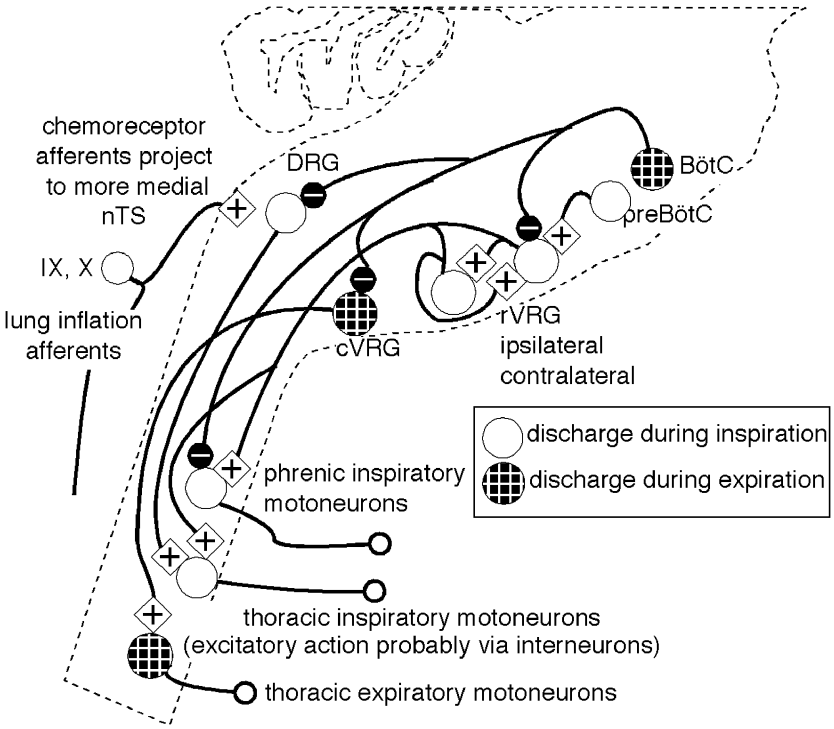

Figure 5 Schematic sagittal section of the rat brain stem summarizing the neuroanatomical and functional organization of the brain stem neural circuitry responsible for breathing (modified with permission from Blessing, 1997).

so-called rostral ventral respiratory group (rVRG). In turn, activity of rVRG neurons depends on net excitation from other medullary neurons either from the combined activity of a network of respiratory neurons or from the pacemaker activity of a particular group of respiratory neurons, probably the pre-Botzinger cells located in the ventrolateral medulla, rostral to the rVRG cells (Fig. 5).

During expiration, activity in rVRG neurons ceases so that the diaphragm and other inspiratory chest wall muscles no longer contract. Since lung tissue is elastic, the lungs deflate by themselves so the first part of expiration is passive. The final part of normal expiration, as well as lung deflation during forced expiration, depends on active contraction of the expiratory muscles in the chest and abdominal regions. These muscles are also innervated by spinal motoneurons activated by descending inputs from special expiratory motoneurons in the medulla oblongata, the Botzinger group, and the caudal ventral respiratory group, as shown in Fig. 5.

Other groups of respiratory neurons in the pons and the midbrain help to coordinate the activity of the medullary network. The cerebral hemispheres must contain the respiratory neurons which are responsible for voluntary breathing and for the voluntary modulation of breathing that occurs during activities such as speaking, singing, clearing one's throat, or blowing out a candle. The descending axons of these cells synapse either on unknown interneurons in the medulla oblongata or perhaps directly on rVRG neurons.

V. BRAIN STEM DYSFUNCTION IN DISEASE

Most people are used to the idea that dysfunction of one cerebral hemisphere can lead to paralysis of the other side of the body. This may occur, for example, with ischemia of brain tissue supplied by the internal carotid artery or the middle cerebral artery. Sudden impairment of the blood supply is also a common cause of brain stem dysfunction, but in this case it is the vertebrobasilar system of arteries that is at fault. Other disease processes (infection, neoplasm, and inflammation) may also affect brain stem function. The neurological symptoms and signs of brain stem dysfunction depend on the precise subregion affected.

Dysfunction of the upper brain stem (especially the more dorsal portions of the rostral pons), the midbrain region just ventral to the aqueduct, and the thalamus can cause the patient to be drowsy, stuporose, or unconscious. This presumably reflects damage to the ascending pathways described in Section IV.A.

Impairment of brain stem eye movement control systems includes supranuclear palsies (upper motoneuron lesions), internuclear ophthalmoplegias, and strabysmus or squint (crooked eyes) reflecting dysfunction of the relevant lower motoneurons or of the oculomotor, trochlear, and abducens nerves (cranial nerves III, IV, and VI) or dysfunction of the muscles moving the eyeballs.

In a supranuclear palsy, as occurs in a neurodegenerative disease known as Steele–Richardson syndrome or progressive supranuclear palsy, both eyes move conjugately (together) but particular directions of movement (particularly looking up) are poorly executed. Internuclear ophthalmoplegia reflects damage to the medial longitudinal fasciculus, a bundle of axons coordinating the relevant pontine and midbrain motoneurons, as may occur with small demyelinating lesions in the disease known as multiple sclerosis. When the patient tries to look to the right, the left eyeball fails to turn inward (adduct) and the outturned right eyeball develops nystagmus.

Young children with a chronic strabysmus must be treated or the brain will suppress the image from one eye (a condition known as amblyopia) so that the individual never develops stereoscopic (binocular) vision. Acute lower motoneuron lesions usually cause double vision (diplopia), which is worse when the patient attempts to look in the direction controlled by the affected nerve. This symptom occurs partially because there is minimal feedback to the brain concerning the actual spatial position of the eyeball (contrast, for example, the accuracy with which we can judge the spatial position of the tip of the tongue). The brain sends the appropriate movement commands to the cranial motoneurons controlling the eyeball muscles and then interprets visual inputs as if the commands have been successfully executed. If one eyeball is misaligned, the brain makes a mistake and the result is double vision, not a sensation that the eyeball is in the wrong position.

A person may suddenly lose the ability to move one side of the face so that it may be impossible to close one eye or to wrinkle up the forehead on one side. The corner of the mouth may droop on one side. This condition may occur with damage to cranial nerve VII (facial) in its course within the pons or, more commonly in the condition known as Bell's palsy, when a peripheral segment of nerve VII is inflamed by a viral infection.

Dysfunction of the vestibular apparatus or its connecting brain stem pathways can induce the sensation of vertigo, sometimes associated with nausea and vomiting. Vertigo, tinnitus, and deafness also occur in Mennier's disease or with an acoustic neuroma, a tumor of the intracranial portion of the vestibulocochlear nerve (cranial nerve VIII). Brain stem dysfunction can also cause difficulty with speaking or swallowing.

The pathways connecting forebrain regions with the spinal cord can also be affected during their course through the brain stem. The major motor pathways from each side of the forebrain travel down the front of the midbrain, pons, and medulla, close to the midline, so that basilar artery ischemia may affect both these "pyramidal tracts," resulting in motor paralysis on both sides of the body. In severe brain stem dysfunction, the patient may be unable to move any one of the four limbs (quadraplegia) or even the head or any of the facial muscles so that the only way the patient can signal "yes" or "no" is by moving the eyes from side to side. Such patients, with normal consciousness and normal higher intellectual function, are described as being "locked in."

Locked in patients are quite different from patients in the so-called "chronic vegetative state." This condition follows damage to the dorsal portion of the upper part of the brain stem with preservation of function in the pons and medulla. Patients in the chronic vegetative state have no voluntary movement and, presumably, no consciousness or thought processes. However, they have reflex movements and they can still breath and swallow. Their cardiovascular, renal, and gastrointestinal function is stable. If such patients are fed with nutritious food and their bowel and bladder wastes are dealt with, they may survive for years. In such patients, the preservation in the limbs of complex motor responses, such as movement of the arms during yawning, may give false hopes to relatives watching at the bedside.

Some patients do recover from a vegetative-like state so it may be difficult to decide whether or not to render life support to a particular patient for an extended time. A useful guide can be obtained from a knowledge of the cause of the brain stem injury, aided by modern investigative techniques such as magnetic resonance imaging (MRI). If a person becomes unconscious from a viral infection in the upper brain stem and the MRI is normal, then there is a chance of

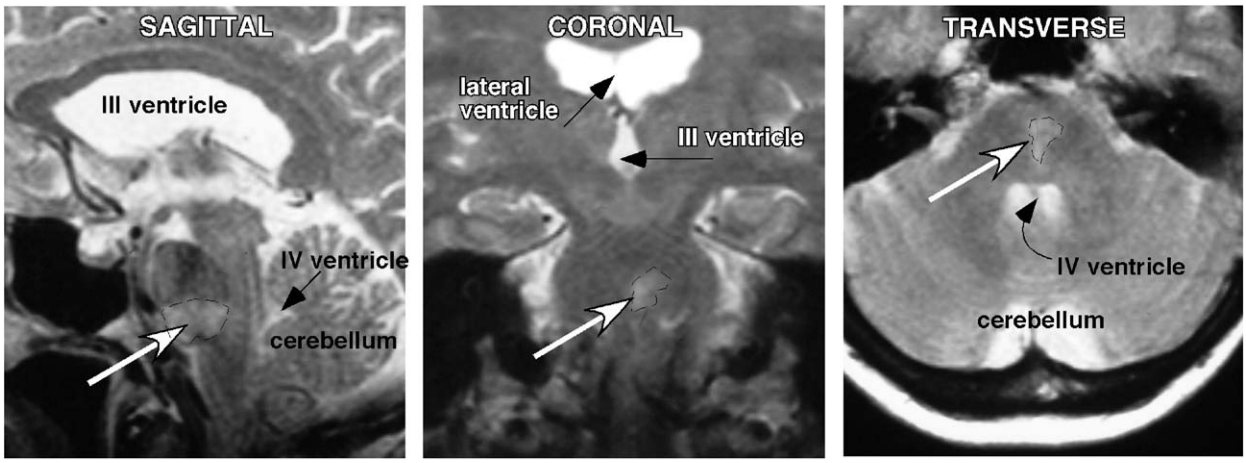

Figure 6 Magnetic resonance images in sagittal, coronal, and transverse planes through the brain stem of a 62-year-old woman with an ischemic stroke in the medial pons (arrows). The infarcted area of the brain is indicated by the dotted lines (MRI courtesy of the Department of Diagnostic Imaging, Flinders Medical Centre, Adelaide).

recovery to a normal life even if the person remains unconscious for months. If a motor vehicle accident or an ischemic stroke is the cause of the upper brain stem dysfunction, and the MRI shows strong evidence of structural damage, then recovery after being unconscious for as long as 1 month or even 1 week is extremely unlikely.

Extensive damage to the lower brain stem by any disease process usually ends the person's life because neural circuitry mediating vital respiratory and/or cardiovascular control no longer functions.

Sometimes, a small area of the brain stem can be affected by a focal disease process. The precise location of the damage can often be specified by particular combinations of physical signs, as in the following case: A 62-year-old woman presented with onset of motor dysfunction of her right hand and right leg (right hemiparesis), occurring in a stuttering fashion over a few hours. She was presumed to have ischemic damage (a cerebral infarct, a type of stroke) to the motor pathways in the left cerebral hemisphere (in the forebrain). However, the next day she developed double vision and was found to be unable to move her left eye to the left (failure of abduction to the left), indicating damage to the intramedullary course of the left sixth cranial nerve (abducent nerve). The combination of right hemiparesis and left sixth nerve palsy implied that the ischemic damage had occurred in the left lower brain stem, anteriorly where the intrapontine fibers of the left sixth nerve pass close to the descending corticospinal motor pathway, above the level where it crosses to the contralateral side (at the lower border of the medulla oblongata). An MRI scan confirmed the presence of a lesion situated anteriorly and medially on the left side of the pons (Fig. 6).

Broca's Area

MICHELLE CRANK and PETER T. FOX
University of Texas Health Science Center, San Antonio

GLOSSARY

Broca's aphasia General term for a group of speech disorders caused by injury or disease in Broca's area of the left hemisphere; selective loss of the ability to produce articulate speech despite preserved speech comprehension and not due to motor impairment.

Broca's area Area of the cerebral cortex responsible for motor speech planning usually located in the frontal lobe of the left hemisphere. The area is named for Pierre Paul Broca, who deemed the left inferior frontal gyrus to be the "seat of articulate language" in 1861. It is the first brain area for which a specific function was identified, "thus the existence of the first localization once admitted, the principle of localization by convolutions would be established."

functional magnetic resonance imaging Use of magnetic resonance imaging to detect physiological events; technique for mapping task-induced changes in regional neural activity by detecting changes in local blood flow, blood volume, and tissue oxygen content triggered by neuronal activity.

positron emission tomography Technique for scanning the brain in which radionuclides are used to determine oxygen utilization, glucose metabolism, and blood flow in the cerebral cortex; used for mapping brain functional organization and for detecting brain disorders.

Broca's area—the posterior, inferior portion of the human left frontal lobe—has the impressive distinction of being the first area of the human brain for which a specific function was proposed: articulatory control of speech. Since its original description in the mid-19th century, Broca's area has been the subject of thousands of scientific articles. Remarkably, present-day conceptualizations of the function of Broca's area are fundamentally similar to those originally proposed more than a century ago. During the past century, the technologies applied to the study of the human brain have steadily advanced. Early clinical and anatomical investigations have been bolstered by cortical electrical stimulation and, recently, by functional brain imaging. Although improvements in technology have provided finer functional descriptions and fractionations, the region of the brain called Broca's area is still firmly rooted in the classical descriptions of the 19th century.

I. CLASSICAL DESCRIPTIONS

A. Broca's Cases

Broca's area is named for Pierre Paul Broca, the French surgeon and anthropologist who identified the area and defined it as the seat of the faculty of articulate language in 1861. In his capacity as a general surgeon, Broca was called upon to treat a case of advanced gangrene of the leg. As Broca treated the patient, Leborgne, he learned that Leborgne was unable to speak due to a chronic brain lesion. Leborgne, who had experienced epileptic attacks since youth, lost his ability to speak at the age of 31. Ten years later he developed paralysis on his right side. Broca, examining him at the age of 51 determined that Leborgne could produce virtually no speech. He often said "tan" (and later became known as "Tan") and occasionally uttered the phrase "Sacre nom de Deiu." Tan's mouth, tongue, and larynx were intact,

indicating a central cause for the lack of speech. Tan could hear and comprehend speech because he responded correctly to questions that he could answer with motions of his left hand, such as indicating the number of years he had been without speech. Because of his loss of speech, Leborgne had been living in the Hospice of Bicetre, where he had been known for his vindictiveness and sometimes objectionable character. He thus seemed to have retained his intelligence despite his lack of articulation, until the paralysis and gangrene confined him to his bed.

One week after Broca's initial examination, Tan died of gangrene. Broca performed an autopsy and found that most of the left hemisphere of the brain was softened from the disease process. The anterior part of the hemisphere contained a large lesion, centered over the posterior aspect of the middle and inferior frontal gyri. The lesion also encompassed part of the anterior insula, the inferior marginal gyrus, and the striate body. Based on an examination of the surrounding, less damaged tissue, and the knowledge that the clinical course was progressive, Broca postulated that the lesion had begun in the third frontal gyrus and extended to surrounding tissue as the disease progressed.

Broca presented Leborgne's brain at a meeting of the Societe d'Anthropologie one day after the patient's death and then deposited the brain in the Musee Dupuytren. Figure 1 shows Leborgne's brain viewed from the left, with a lesion clearly visible in the third frontal convolution. Broca coined the term "aphemia" to describe the condition of loss of articulate speech coupled with the retention of hearing, comprehension, and intelligence. He inferred a correspondence between the anatomical and symptomatological periods of Leborgne's condition: The 10-year period of aphasia occurred while the lesion was confined to the frontal lobe, and as it progressed into the corpus striatum, the symptoms of paralysis of the right extremities developed. Broca concluded that the origin of the lesion, the second or third frontal gyrus, must be responsible for the loss of articulate language.

Even as he described this area and its importance to the study of language in the brain, Broca emphasized that the linguistic aspect of his discovery was less significant than its implications for the general theory of localization of function in the brain. Broca (as quoted in Von Bonin, 1960, p. 55) was well aware that this was the first strong evidence that specific mental functions were specifically localized:

> *The point is cerebral localization, not this or that school of phrenology… . If all cerebral faculties were as distinct and as clearly circumscribed as this one, one would finally have a definite point from which to attack the controversial question of*

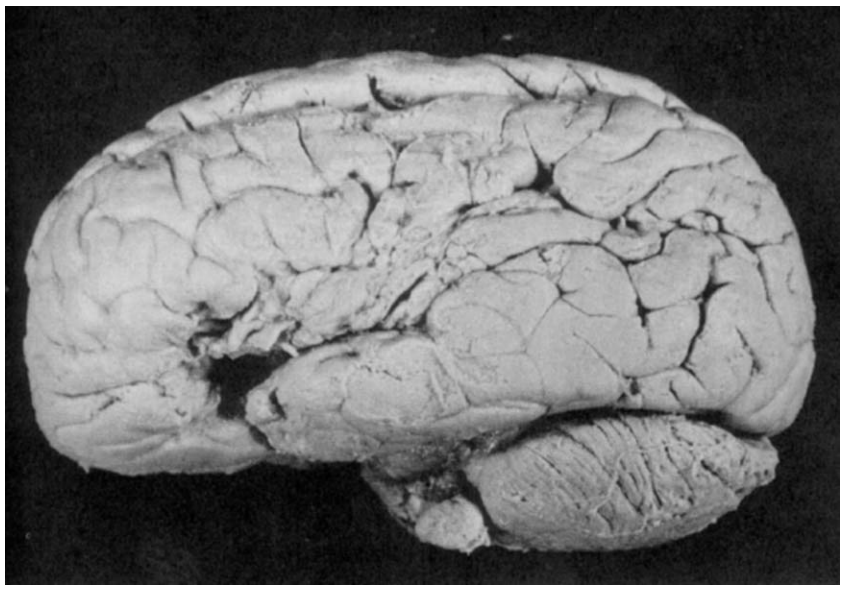

Figure 1 Photograph of Leborgne's brain, the first patient Paul Broca diagnosed with aphemia (later to be known as Broca's aphasia) in 1861. This is a view of the left hemisphere, in which a lesion is visible in the area of the third frontal gyrus, now known as Broca's area (reproduced with permission from Signoret *et al.* (1989), *Brain Language* **22,** 303–319).

cerebral localization. Unfortunately, this is not the case, and the greatest obstacle in this part of physiology comes from the insufficiency and the uncertainty of the functional analysis which necessarily has to precede the search of the organs which are coordinated to each function.

Broca's second case was a man named Lelong, who also had lost his ability to use articulate speech but whose aphemia was not complicated by other symptoms. At autopsy, Lelong's lesion proved much more circumscribed than Leborgne's but was also located in the posterior portion of the third frontal convolution. Broca subsequently chronicled 20 more cases in which patients with aphemia had lesions of the third frontal convolution, lending strong support to his hyopthesis originally based on a single case. Collectively, these cases paved the way for the systematic investigation of the functional organization of the human brain based on the analysis of clinical cases. For decades, lesion-deficit analysis was based on postmortem lesion localization. With the advent of X-ray computed tomography (CT) and magnetic resonance imaging (MRI), lesion localization has become premorbid and quantitative (e.g., describing lesion volume as well as location). This work, summarized in Section II, largely confirms Broca's original observations.

B. Importance to Theories of Localization and Lateralization

Broca advocated the principle of cerebral localization, which at the time was disputed by more traditional supporters of the concept that the brain acted as a whole. Many scientists agreed that the intellectual activities of the mind resided in the convolutions of the brain and that the most advanced functions were located in the frontal lobes, but they were not ready to locate specific functions in specific convolutions. Broca realized that if articulate language were proven to be located invariably in one place in all human brains, it would be a major step toward proving that all functions were localized. In his presentation of Leborgne's brain in 1861, he spoke in general on language and localization as an introduction to his clinical and pathological observations (as quoted in Von Bonin, 1960, p. 57):

There are in the human mind a group of faculties and in the brain groups of convolutions, and the facts assembled by science so far allow to state, as I said before, that the great regions of the mind correspond to the great regions of the brain.

He goes on to specify that the case of language could be evidence enough to draw some conclusions: "Thus the existence of the first localization once admitted, the principle of localization by convolutions would be established" (as quoted in Von Bonin, 1960, p. 58).

Broca was reluctant to state that Leborgne's case proved that language would be invariably located in the third frontal gyrus of the left hemisphere. He merely suggested that the theory of localization was highly probable, and that further observation would be needed to draw firm conclusions. He did, however, distinguish his version of the theory from an earlier phrenological idea, which placed the faculty of articulate language at a fixed point under a certain elevation of the skull. Broca did not support the theory of lateralization, which was even less widely accepted than localization. In fact, he reported it as a coincidence that his later cases were all documented lesions of the left hemisphere: "Remarkable, how in all these patients the lesion was on the left side. I do not dare to draw any conclusion from this and am waiting for new data" (as quoted in Schiller, 1979, p. 194).

He knew that the firm conclusion would be that each side of the brain had different functions, but he did not accept it, and he ceased to mention it in his later research on language. However, his placement of "the seat of articulate language" in the third frontal gyrus of the left hemisphere certainly fueled the debates over localization and lateralization, and his ideas were a starting point for those who did eventually draw firm conclusions about both issues.

C. Brodmann's Description of Broca's Area

In 1909, Korbinian Brodmann published a treatise, "Localization in the Cerebral Cortex," on histological localization in the cerebral cortex. He described his work in the introduction: "Localization which uses exclusively anatomical features as the basis for investigation, in contrast to physiological or clinical aspects" (as quoted in Garey, 1994, p. 117). The lasting result of this work was a scheme for the parcellation of the cerebral cortex into 50 distinct areas based on common anatomical features. The system is still used as a standard for cortical localization.

Broca's area was designated by Brodmann as area 44: "a well-differentiated and sharply circumscribed structural region that on the whole corresponds quite

well to the opercular part of the inferior frontal gyrus: Broca's area'' (as quoted in Garey, 1994, p. 117). Brodmann defined the anatomical boundaries of area 44 as the inferior precentral sulcus posteriorly, the inferior frontal sulcus superiorly, and the ascending ramus of the Sylvian fissure anteriorly, but he amended his description: ''As there is much variability and inconstancy of these sulci one will find rather mixed topographical relationships of these structural areas in individual cases'' (as quoted in Garey, 1994, p. 117).

In addition, Brodmann found enough similarity in the structure of area 44 to that of two other nearby areas, 45 and 47, that he grouped them into a subregion, the ''subfrontal subregion.'' A fourth area, 46, was also more loosely grouped with 44, 45, and 47 in the frontal region, and Brodmann said it was not distinguishable from surrounding areas by its cell structure. These areas are considered to be subdivisions of the more general Broca's area addressed in functional imaging literature today. Brodmann's identification of a cytoarchitectonic area matching the placement of Broca's ''third frontal convolution'' was a confirmation from yet another scientific discipline to add to Broca's own and subsequent clinical and physiological evidence.

D. Anterior/Posterior Dichotomy

That the functions of the cerebrum could be divided into motoric and sensory, with motor functions located in the anterior portion of the brain and sensory functions in the posterior, was a prevailing idea in the 19th century. Broca's postulate concerning the function of the inferior frontal convolution followed this broad division of function in that the portion of language that he had placed in the frontal lobe controlled the output of language. However, Broca considered articulate speech to be an intellectual function and not merely motoric. In this, Broca agreed with the school of thought that placed intellectual functions in the frontal lobes, relegating processes influenced by emotion and passion in the posterior lobes.

In 1874, Karl Wernicke described an area of the posterior, superior temporal lobe as being responsible for speech comprehension, including the understanding of word meaning (i.e., semantics). In doing so, Wernicke undermined Broca's speculations that Broca's areas supported cognitive aspects of language. This set a trend of localization of linguistic semantics to the posterior, superior temporal lobe (Wernicke's area) that has persisted in the clinical literature through the 20th century. Recently, through the use of functional imaging technology, higher order functions related to language have been returned to the frontal lobe. This shift has occurred with the subdivision of the frontal language area into more specialized semantic and articulatory areas. Those that involve semantics activate a distinct area anterior to Broca's classically defined seat of articulate language.

E. Recent Work: Finer Subdivisions

Recent work with clinical studies and functional imaging has shown that the single area Broca called the seat of articulate language can be subdivided into regions active in different types of language activities, such as making semantic versus orthographic or phonological judgments. It seems that three areas, the traditional Brodmann's area (BA) 44, BA 46/47, and the anterior insula, are all activated in speech tasks, but they are activated in different combinations in different speech paradigms. It seems that the higher order processes are activating the left anterior area, BA 46/47, and articulation is activating the more posterior BA 44 and the insula. However, imaging has also shown that these subdivisions work together, as Paulesu suggests in his theory of an articulatory loop for language processing. He suggests that Broca's area (BA 44), superior temporal gyri (BA 22/42), supramarginal gyri (BA 40), and the insulae all bilaterally activated in a phonological short-term memory task constitute a language circuit connecting the posterior and anterior areas. He links Broca's area to the subvocal rehearsal system active in working memory and temporal BA 22/42 to phonological processing independent of higher order memory function. This demonstrates the trend of returning the higher order processes to the frontal lobe. Overall, combining functional imaging with the methods of study already in use, such as Broca's own clinical and pathological observation and electrical stimulation studies, has allowed for a more detailed analysis of the function of the region around Broca's area.

II. ELECTRICAL STIMULATION

Electrical stimulation of the brain in awake subjects undergoing neurosurgery was introduced in the 1930s by Wilder Penfield and colleagues at the Montreal Neurological Institute. Penfield treated patients with

focal brain lesions, operating to remove damaged tissue. In doing so, Penfield performed intraoperative electrical stimulation mapping to identify areas of the cortex whose loss would be debilitating. Of relevance to this article, Penfield mapped language-related brain areas, compiling data from scores of cases to produce functional maps of language areas, including Broca's area. (The reader is encouraged to investigate the numerous journal articles and books published by Penfield and colleagues.) Today, the most prolific applicants of Penfield's intraoperative cortical mapping technique are George Ojemann and colleagues at the University of Washington. In a classic, 1982 review of his cases, Ojemann reported on more than 100 patients, indicating that the location and extent of Broca's area (and other language areas) are more complex and variable than previously thought, at least in a population of persons with chronic brain lesions. The technique of electrical stimulation mapping of the cortex allowed the study of language areas, and Broca's area in particular, to expand into testing the use of normal tissue in specific locations in conscious patients rather than simply documenting the effects of damage to areas of the cortex. Electrical stimulation mapping has emphasized the individual variability of language areas of the brain in clinical populations, and recent work seems to show that the classically defined Broca's area may not be necessary for speech processing. The works of Penfield and Ojemann have made a major contribution to the knowledge of the location and functions of Broca's area.

A. Penfield's Cortical Stimulation Studies

Penfield and Roberts used excision studies coupled with electrical stimulation studies to map language areas, and they concluded that Broca's area plays a role in ideational (as opposed to motor) speech but its excision did not produce permanent symptoms of aphasia; rather, speech is recovered at least to some extent. They used preoperative electrical mapping throughout the mid-20th century to identify areas of the cortex involved in language in order to avoid them when performing cortical excisions to treat epilepsy. When electric current was applied to the cortex at points potentially involved in language, two speech effects occurred that were termed positive and negative. A positive effect was stimulation of speech when motor areas for face and mouth were stimulated, and negative effects included interference of speech when ideational speech areas, such as Broca's, Wernicke's, and supplementary motor areas, were stimulated. Patients were awake, and they were asked either to perform a picture-naming task or to count aloud. The interference was only effective approximately one-half of the time, and movement induced in one spot at one time might not occur upon restimulation of the same spot in the same patient; thus, results were difficult to replicate and inexact. Compiling their data from several patients, Penfield and Roberts found that when Broca's area was stimulated, negative effects such as speech arrest, hesitation, slurring, repetition, confusion of numbers while counting, inability to name pictures with retained ability to speak, and difficulty in reading and writing resulted. They define Broca's area as consisting of the three gyri in front of the lower precentral gyrus. This includes BA 46/47, now separated from Broca's area proper by functional imaging literature. By including this area, Penfield and Roberts decreased the specificity of the area they were mapping. They also found that stimulation of sites outside Broca's area and other traditional language areas, such as Wernicke's area in the temporal lobe and the supplementary motor area, caused similar interruption of language. This suggested expansion of the traditional areas. The majority of their patients did have interference only in left Broca's stimulation, as opposed to its right hemisphere counterpart, which they concluded supported the idea of left hemisphere dominance for language. In observing cases of excision of part or all of Broca's area, Penfield and Roberts concluded that permanent aphasia did not necessarily result, but speech was recovered postoperatively in most cases. This suggests that Broca's area is not necessary for normal language function, and it complicates the picture created by their electrical stimulation studies, which show that Broca's area is a key language area.

B. Ojemann's Localization Mapping

Ojemann compiled data from 117 subjects in an electrical stimulation mapping study of language areas of the left hemisphere, and he concluded that language areas are variable mosaics of 1-cm^2 sites ranging across and beyond classically defined areas such as Broca's and Wernicke's. As in Penfield and Roberts' study, patients were asked to name line drawings of common objects while electrical current was delivered to random sites on the cortex in the area surrounding the proposed excision. Anatomical markers were used to relate the sites of stimulation in each different brain

to an arbitrary grid created using the Sylvian fissure and the rolandic cortex as landmarks. Not all patients had stimulation sites in all regions, but a map of the variability of language localization across all patients was created taking this into account. The most common finding was that sites where stimulation caused errors were separated by less than 1 cm in all directions from sites with no errors. The boundaries of these language areas were sharp in some cases, and in others they were surrounded by areas in which stimulation evoked single speech errors, suggesting a gradation from areas with no role in naming to areas essential for it. In an individual, these language areas were arranged in a mosaic pattern extending 1 or 2 cm^2. Ojemann's study shows the high degree of individual variability that exists for essential language areas coupled with discrete localization in a given individual. The combined area of the inferior frontal mosaics in a given individual is much less than that of traditionally defined Broca's area and less than the corresponding area identified by Penfield and Roberts as essential. Ojemann did not attempt to differentiate among BA 44 and BA 46/47, but he did demonstrate that the most posterior portion of the inferior frontal gyrus was one of the least variable areas. This would correspond to BA 44. His work was limited in the specificity of what part of language function was being deactivated by the stimulation; for example, failures of perception, motor control, naming, or consciousness could all potentially have caused patients to fail at the naming task. In addition, buried sites, such as the insula, could not be directly stimulated and thus may also be essential to language and were not detected by this method. A final limitation is that the technique is necessarily performed on patients with lesions or tumors, which adds the possibility that their language function may be altered from that of normal individuals as a result of their medical condition. Despite the limitations, electrical stimulation does identify areas of the cortex essential for language, and in this case Ojemann demonstrated the great individual variability of those essential language regions. This challenges the assumption that Broca's seat of articulate language is a clearly defined region easily generalized among individuals.

III. CLINICAL STUDIES

Clinical studies of aphasics defined Broca's research and conclusions; since then, clinical work has been expanded and refined, combining functional and anatomical imaging to show that lesions to Broca's area do not necessarily produce symptoms of Broca's aphasia.

A. Mohr's Analysis of Broca's Aphasia and Broca's Area

In 1976, Mohr demonstrated that the symptoms classically defined as Broca's aphasia did not correlate with lesions localized in Broca's area proper, BA 44/6; lesions in that area produced transient symptoms similar to those chronic ones associated with much larger lesions. Mohr began by describing the characteristics of the deficit associated with localized lesions of the third frontal convolution, or Broca's area as Broca defined it. Mohr stated the characteristics: Little persisting deficit in articulation seems to occur, and frequently no significant persisting disturbance in language function is present. He based his claims on personal cases of clinical and pathological correlation and an extensive review of cases reported in the literature since 1861 and more than 1 year of cases of stroke documented by Massachusetts area hospitals. Autopsy was the preferred method of analysis of the location of the lesion, but CT scans were also used in a few cases. He formulated a hypothesis of the function of Broca's area that the clinical data support. His current thesis envisions Broca's area as mediating a more traditionally postulated role as a premotor association cortex region concerned with acquired skilled oral, pharyngeal, and respiratory movements involving speaking as well as other behaviors, but not essentially language or graphic behavior per se. Mohr continued by categorizing Broca's aphasia as it was described originally by Broca (as aphemia) and then repeatedly confirmed by others since 1861. The clinical literature continued to rely on Wernicke's 1874 definition that stated three main aspects: Patients are mute, using only a few senseless syllables or swear words with preservation of muscular speech ability; speech comprehension is maintained, but not for complicated constructions; and written language is lost with spoken language. The lesions that produce these symptoms usually involve Broca's area proper, but they are more extensive. Broca's aphasia reflects a major infarction involving most of the territory of supply of the upper division of the left middle cerebral artery. It is observed only after the initial infarction. The initial syndrome is more severe, described traditionally as golobal aphasia. Mohr notes that Broca's original cases involved more extensive lesions;

however, Broca ignored the size and instead relied on the stroke theory of his time, which stated that large strokes always began as a smaller focus and spread slowly outward. Mohr's dissociation of Broca's area proper from the classically defined syndrome of Broca's aphasia suggested that in the clinical literature too much weight was placed on the original classification of the area with the syndrome, and as a result, too broad a range of function had been attributed to the area. Overall, his investigation proved that more detailed analyses would be necessary to determine the finer points of the function of Broca's area proper. Functional imaging technology has brought those details forward, and now experts continue to analyze the area both in clinical populations and with normal subjects.

B. Clinical Analysis of Syntax

Clinical investigations relating to syntactical analysis have associated some syntactic ability with Wernicke's aphasia that patients with Broca's aphasia do not possess. Even though the extent of lesions causing Broca's aphasia is greater than originally thought, it does include BA 44 and the surrounding areas, including portions of BA 46/47. This can be easily differentiated from the area of the temporal lobe responsible for Wernicke's aphasia. Swinney and Zurif tested Broca's and Wernicke's aphasia patients to compare their success and rates of processing traces in sentences. If Broca's aphasia patients cannot process one of the syntactic components of sentence structure, then the cortical area affected by the lesion in and around Broca's area may be responsible for that component of syntactic processing. In Swinney and Zurif's study, Broca's aphasics were less effective at processing than were Wernicke's aphasics, Swinney and Zurif suggest that a prima facie case can be made that long-distance dependency relations of the sort described here are especially reliant on some form of working memory capacity. This clinical work relates higher order memory and syntactic functions to areas of the frontal lobe responsible for Broca's aphasia and potentially to BA 46/47.

C. Clinical Analysis of Sub-Broca's Area

Clinical data on the anterior insula are sparse. The insula is included in analyses of Broca's area lesions and in descriptions of Broca's aphasia lesions. Clinical observations of selective stimulation of the insula, though few, show that it will cause speech arrest, and thus the area is linked to articulation. The most profound observations of the insula that demonstrate its function more directly have been made possible by functional imaging, and these observations are analyzed in the following section.

IV. FUNCTIONAL IMAGING

Functional imaging technology has freed studies of language in the brain from the lesion deficit framework and has allowed more detailed analyses of the functional organization of language in the brain. Whereas lesion studies may show what areas are necessary for normal language function, position emission tomography (PET) and functional MRI (fMRI) can reveal the complex association of specific areas that are utilized in normal speech and reveal activation of the same areas in other tasks to further specify or broaden their function. Comparison of images obtained from phonological and semantic processing tasks in visual and auditory modalities helps to identify regional cerebral blood flow (rCBF) activation patterns that clarify the role of Broca's area in relation to other language areas. Figure 2 shows a three-dimensional representation of the subdivisions of Broca's area apparent from functional imaging and the motor area for the mouth on the left (Fig. 2, top) and right (Fig. 2, bottom). The average positions (Table I) were calculated from a meta-analysis of functional imaging literature (Table II) reporting activation in standardized space, and relative intensities are based on z scores of activation.

A. Broca's Area Proper

Broca's area proper, BA 44/6, is attributed with a range of functions, but its exact role in language is debated based on the variety of different tasks that activate it. The basic point of agreement in the functional imaging literature is that this region is involved in articulation and transforming phonemes into speech motor plans, as indicated by its activation in overt speech tasks. Figure 3 shows a meta-analysis of the functional imaging literature reporting activation of BA 44/6 in overt or covert speech paradigms plotted as average three-dimensional coordinates. The studies used in the meta-analysis all involved

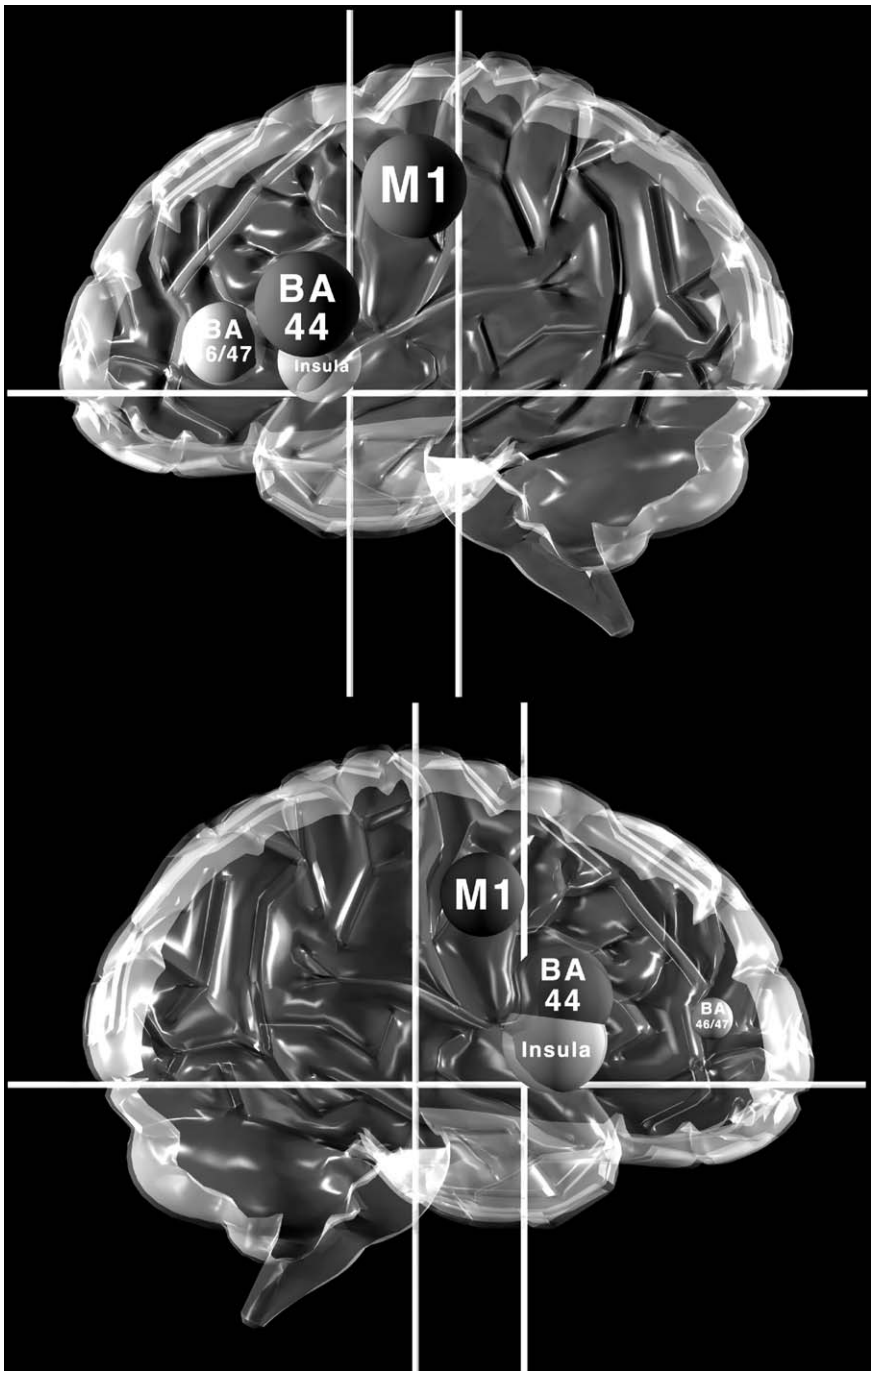

Figure 2 Three-dimensional representations of the three subdivisions of Broca's area and the motor area for the mouth are shown from the left (top) and right (bottom). The average positions (see Table I) were calculated from a meta-analysis of functional imaging literature (see Table II) reporting activation in standardized space, and relative intensities are based on *z* scores of activation. Broca's area proper, or BA 44/6, is active in both hemispheres, but it shows greater activation in the left hemisphere. Sub-Broca's area, or anterior insula, appears more evenly distributed between the hemispheres and demonstrates less intense activation than does Broca's area proper. Pre-Broca's area, or BA 46/47, is significantly lateralized to the left hemisphere, and the area shows the least intense activation of the three subdivisions. The motor area for the mouth is lateralized to the left hemisphere and shows activation on that side comparable to that of Broca's area proper. (See color insert).

Table I
Average Activation Coordinates for Language Areas

Area	*X* (SD)	*Y* (SD)	*Z* (SD)	*N*	Average *z* score
BA 44 left	−45.63 (4.64)	6.73 (10.14)	16.47 (4.74)	134	4.59
BA 44 right	39.5 (9.57)	6 (17.51)	16 (10.33)	33	4.91
BA 46/47 left	−39.61 (7.87)	19.75 (16.88)	10.45 (11.13)	131	4.21
BA 46/47 right	41.14 (5.94)	32.56 (8.28)	11.62 (17.09)	53	2.5
Insula left	−34.65 (3.07)	5.35 (9.09)	6.7 (5.29)	140	4.4
Insula right	39.75 (5.56)	4.5 (9.57)	8.25 (7.68)	36	4.95
M1-mouth left	−47.13 (3.12)	−11.85 (3.08)	36.77 (5.5)	101	5.24
M1-mouth right	49.05 (7.47)	−7.98 (4.55)	34.38 (7.97)	101	3.74

production of overt or imagined speech, although the individual tasks varied from repetition of printed or heard nouns to self-paced counting to narrative speech, and subtractions often did not remove the semantic component of tasks. The studies differentiated among the areas of M1-mouth and BA 46/47 in most cases; therefore, averaging in activation from these distinct areas did not shift the reported coordinates. Activation of Broca's area proper has been observed in other nonlanguage tasks, such as accessing verbal working memory and overt and imagined movement, so its function may need to be generalized from articulatory planning to somatosensory motor planning.

Table II
Meta-analysis of Functional Imaging Literature Showing Activation in Broca's Area

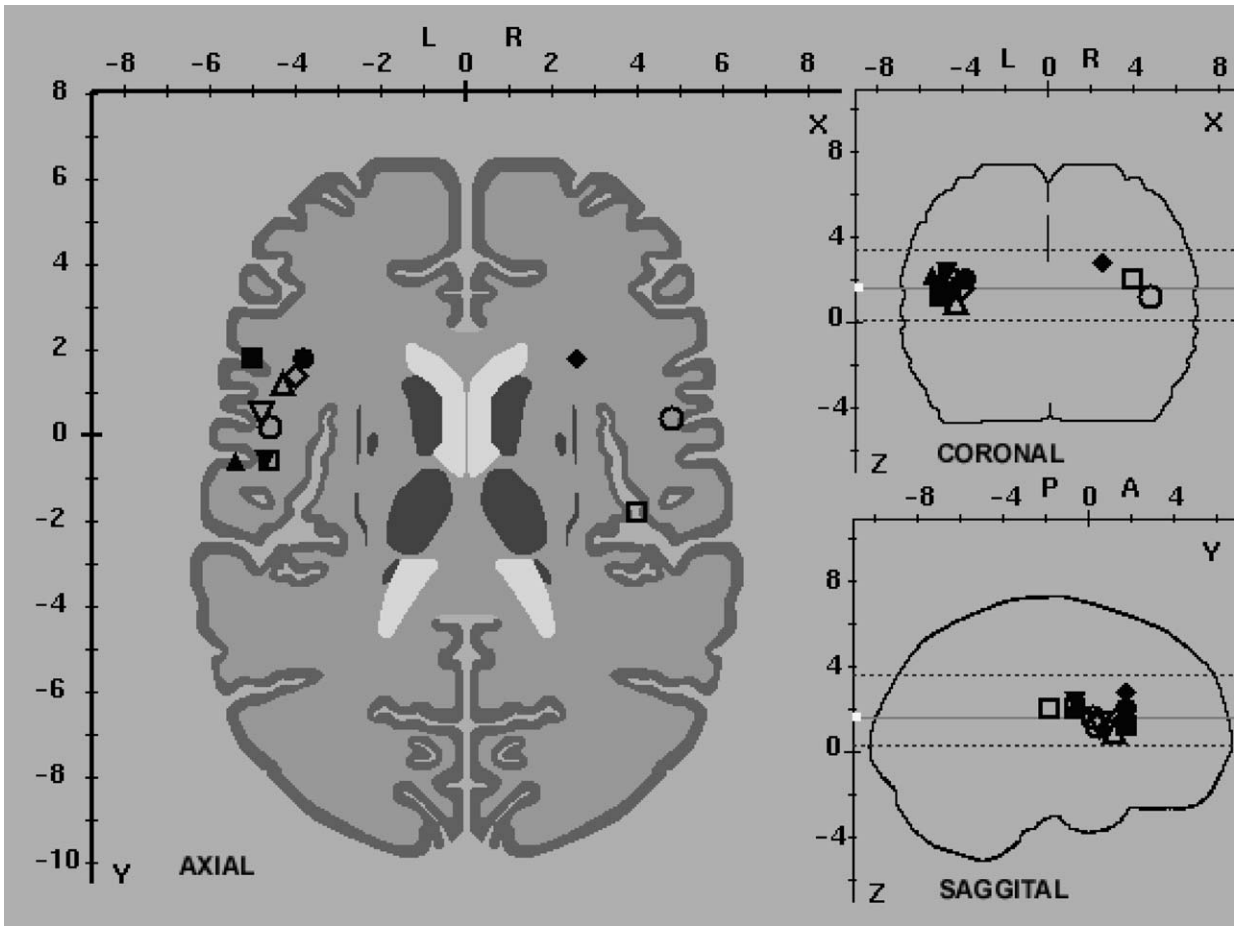

Figure 3 Activations in Broca's area proper, BA 44/6, are shown in a meta-analysis of functional imaging data for overt and covert speech paradigms (see Table II). Mean coordinates are normalized and reported in standard three-dimensional (Talairach) space, plotted with the BrainMap database on an axial cross section at $z=1.6$ cm. Each relevant reference listed in Table II is represented here by a mean coordinate with the following symbols: ■, Becker (1994); □, Bookheimer (1995); ●, Braun (1997); ▲, Fox (1999); ◆, Jennings (1998); ○, Paulesu (1993); ▼, Petersen (1988); △, Petrides (1993); ▽, Petrides (1995); ⊡, Weiller (1995); ◇, Wise (1991). The points are distributed in both hemispheres but are predominantly found on the left, demonstrating the low degree of lateralization of BA 44/6. For all meta-analyses, data were taken at face value, such that those points reported by the author to be within a given subarea are displayed there, although some points may appear to go beyond the Brodmann areas typically included in that subarea.

1. Overt Speech Activation

Posterior Broca's area is activated in fMRI and PET studies when overt speech is produced, specifically in repetition of words presented visually or aurally or generation of verbs or sentences in response to presented nouns. In trying to elucidate the exact reason for its activation, paradigms have been created in a hierarchical scheme. The most complex tasks, such as semantic processing, are performed along with phonological processing and a baseline rest condition so that subtracting one from another will isolate the activation area responsible for the semantic or phonological portions of the task. Often in studies in which Broca's area proper is activated, activation is explained simply by stating that the area is involved in spoken language production. It is credited with a phonological rather than a semantic aspect of language production, but even the nature of that phonological language role is questioned. Petersen found that areas near Broca's area proper are activated bilaterally during movement of the mouth and tongue, and he credits Broca's area with general motor rather than language-specific output planning. In addition to this broadening of the function of Broca's area, one study by Petrides stated that speech can occur without

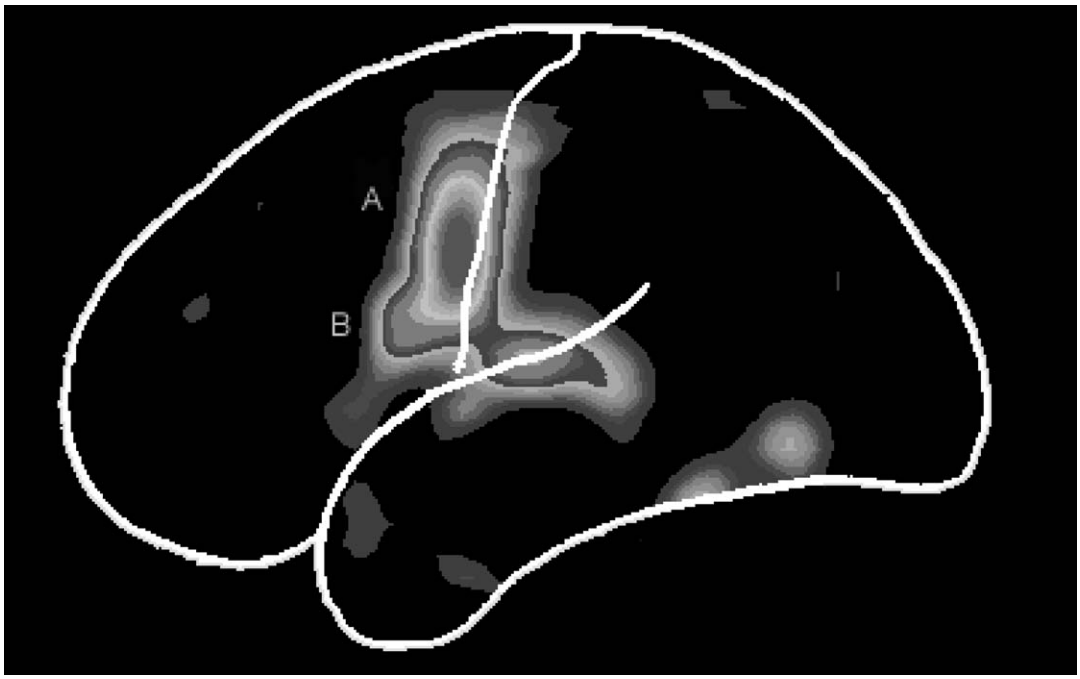

Figure 4 The pattern of activation for overt speech in the left hemisphere is shown through fMRI. The areas most active are Broca's area proper (B) and M1-mouth (A), whereas the prefrontal BA 46/47 shows no significant activation. The motor mouth area can be distinguished from Broca's area proper because the motor area extends well above BA 44/6.

activation of BA 44: It is possible that Broca's area may not necessarily be activated in all speech production tasks. In a study by Braun that compared stuttering to normal speech, a paced speech task and an overlearned speech task showed decreased activation of BA 44 relative to narrative, self-paced speech activation in normal subjects. Braun proposed that in slow or overlearned conditions, it is easier to process and produce language plans. Broca's area, which may be crucial in initial word production or monitoring, is not needed once the given words are learned: Phonological or semantic monitoring may be less critical to the degree that significant engagement of the neocortical language areas is no longer essential. Figure 4 demonstrates the pattern of activation in the production of overt speech, concentrating in BA 44/6 and the M1-mouth motor region.

2. Covert Speech Activation

The description of the function of Broca's area proper expanded from overt speech production when tasks involving inner, or covert, speech revealed activation and complicated the classical description. BA 44/6 is activated under conditions of covert verb generation in response to heard nouns presented at a slow rate. Wise postulated that Broca's area shows activation in an automatic, internal speech response to remembering words even though vocalization is not the goal: The act of retrieving words from semantic memory activates networks concerned with the production of speech sounds. Another aspect of covert speech is subvocal rehearsal, or internal repetition of speech often coupled with phonological working memory. Paulesu described an articulatory loop that he tested with a short-term memory task for letters and rhyming judgment for letters. Both tasks required subvocal rehearsal, and both showed strong activation in Broca's area, whereas only the memory task activated the left supramarginal gyrus. He concluded that Broca's area is crucial to the subvocal rehearsal system. Assuming a connection of Broca's area to subvocal rehearsal, Caplan set out to prove that Broca's area is involved in syntactic processing when subvocal rehearsal is prevented. Subjects judged the goodness of sentences that represented two distinct levels of syntactic difficulty, and as they made judgments they repeated the word "double" timed with a metronome. The task contrast showed increases in rCBF in Broca's area in judging the more difficult type

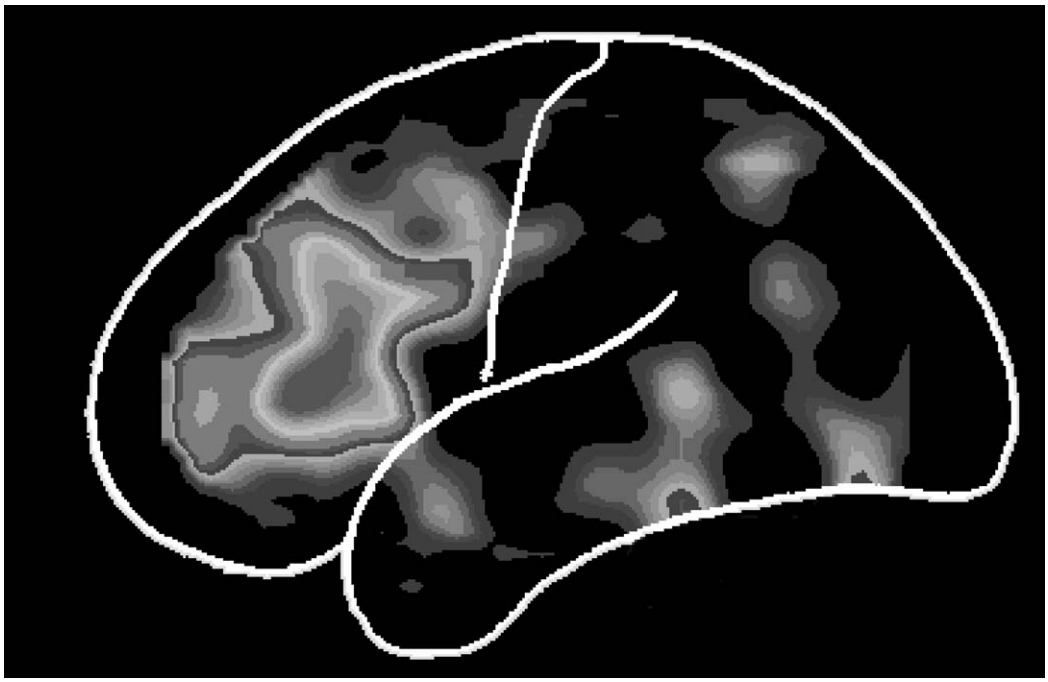

Figure 5 Covert speech, or thinking about words without vocalization, shows heightened activity in left pre-Broca's area, BA 46/47. This indicates that motor aspects of speech are not necessary for this area to be activated, and pre-Broca's is clearly defined in an area forward of Broca's area proper that is probably linked more closely to semantic processing of words than speech or phonological processing.

of sentences: The increase in rCBF in Broca's area reflects the demands of processing the more complex syntactic structure. The possible explanations given are maintenance of the complex structure in working memory or need for more intermediate constructs in computation of the more complex sentences; either explanation supports the addition of syntactic processing to the list of Broca's area functions. Figure 5 shows activation produced when thinking about words, including activation in BA 44/6.

3. Nonlanguage Activation

Movement in imaging tasks that does not incorporate speech shows activation in Broca's area. Both overt and imagined movements of the arm and hand cause activation in BA 44. This activation might be explained by subjects' unintentional performance of covert speech during the movement tasks. Parsons used a task that involved judging whether a presented drawing of a hand was of a right or a left hand, thus engaging the brain to shift the mental representations of its own hands to try to imitate the presented hands. Parsons suggested that since the activation was in the limb-contralateral hemisphere, it was correlated with the actions of the hand covertly moving: The activated BA 44 site subserves the mental simulation of reaching a specific limb into a specific target posture. Also, in a study of saccadic eye movements, activation was found in ventral BA 6, on the edge of Broca's area, when saccades were performed in the dark. This overt movement was performed in proprioceptive space, as opposed to a similar task of saccades to visual targets, performed in visual space, that activated the dorsal premotor area BA 8. This distinction between dorsal and ventral premotor activation suggests that BA 44/6 may be responsible for motor planning in somatic space for movement that cannot be calculated within the visual field. Saccadic eye movements in the dark as well as oral movement must employ somatic planning, and BA 44/6 may be the ventral, somatic counterpart to dorsal premotor areas.

B. Pre-Broca's Area

Semantic function in language, or analysis of word meaning, has been shown by functional imaging to involve the cortical areas immediately anterior to Broca's area proper, prefrontal BA 46/47. Figure 6

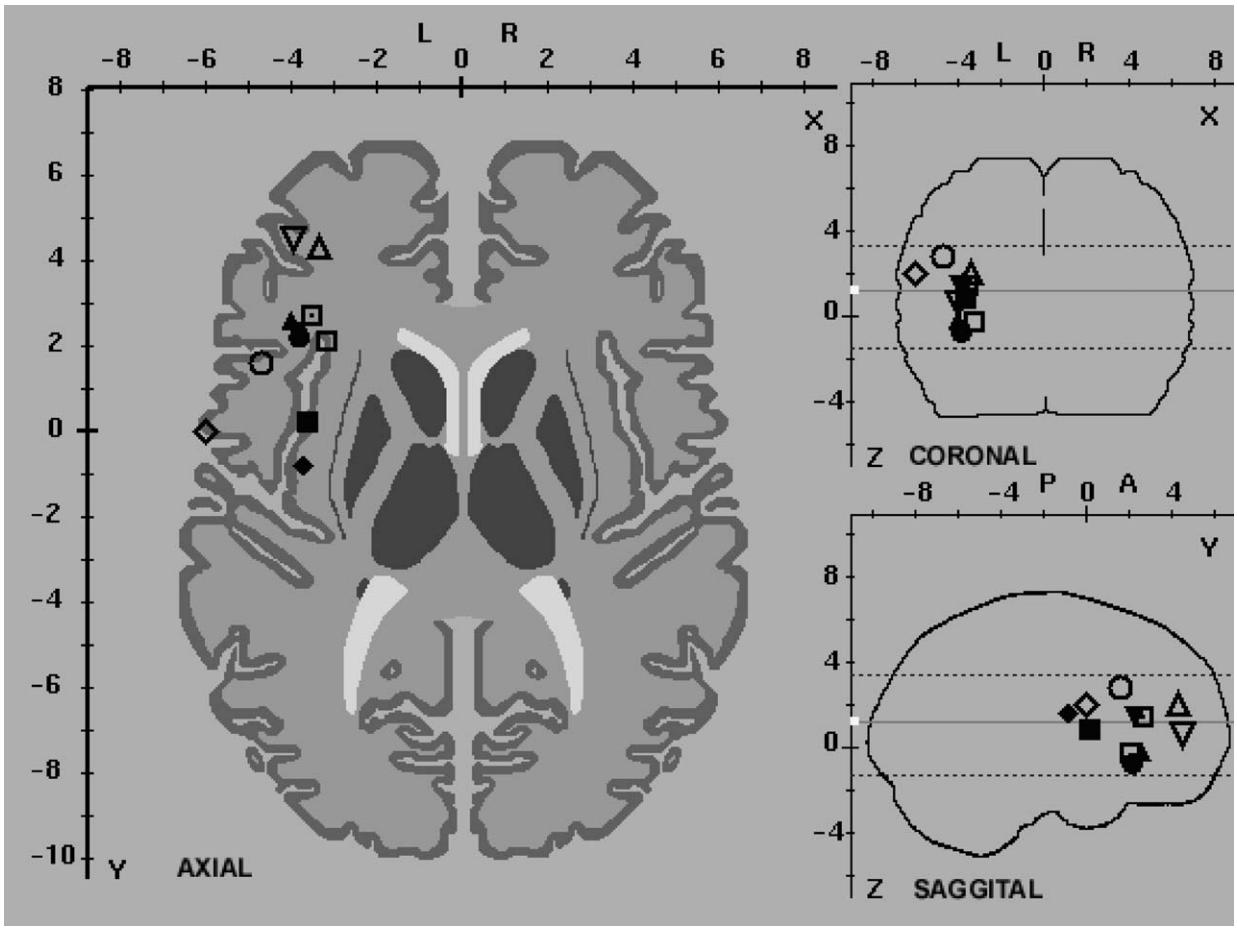

Figure 6 Activations in pre-Broca's area, BA 46/47, are shown in a meta-analysis of functional imaging data for covert speech paradigms. A set of mean coordinates was calculated from data reported from studies in Table II. The coordinates have been normalized and reported in standard three-dimensional (Talairach) space, plotted with the BrainMap database on an axial cross section at z=1.2 cm. Each relevant reference listed in Table II is represented here by a mean coordinate with the following symbols: ■, Becker (1994); □, Paus (1993); ●, Braun (1997); ▲, Buckner (1995); ♦, Raichle (1994); ○, Warburton (1999); ▼, Petersen (1988); △, Petrides (1993); ▽, Petrides (1995); ⊡, Weiller (1995); ◇, Wise (1999). There is a relatively wide spread of data represented in the mean points; this is due to the fact that the data reported by authors were taken at face value, even in cases in which mean coordinates go outside the usual Brodmann areas associated with pre-Broca's area. The data reflect the fact that activation of pre-Broca's area is strongly left lateralized, especially when compared with the activation patterns in Broca's area proper.

shows a meta-analysis of functional imaging data reporting activation in BA 46/47 in language paradigms. This region is often, but not always, activated when language tasks include semantic processing, but it does not become active in phonological tasks. Some studies that report activation in the left frontal lobe do not differentiate between activation in this area and in BA 6/44, and it has been hypothesized that as a result, some coordinates reported for what is traditionally considered Broca's area are shifted forward. However, language tasks are not the only tasks to activate BA 46/47. Episodic memory (i.e., memory of materials encountered in specific episodes) and implicit memory, (i.e., experience-induced changes in performance on indirect tests unrelated to the experience) have each been linked to BA 46/47. Like Broca's area proper, this area cannot be simply classified as a language processing area.

1. Overt Speech Activation

BA 46/47 is activated in tasks that involve narrative speech, verb generation, and stem completion, suggesting that the area plays a role in semantic

processing. Specifically, verb generation in response to visual presentation of nouns activates BA 46/47, but repetition of words does not. In Petersen's study of single-word processing, activation from repetition of visually represented words is subtracted from that of generation of verbs: A left inferior frontal area was identified that almost certainly participates in processing for semantic association. Word repetition activates areas responsible for phonological processing, and subtracting those away from areas highlighted by generation of verbs reveals BA 46/47 as an area responsible for semantic processing. Weiler modified this subtraction by substituting pseudowords in the repetition condition, which might further reduce incidental activation of semantic areas. He drew a similar conclusion from the results: A modulatory, controlling function of nonautomatic, intrinsic generation processing can be attributed to the lateral prefrontal cortex. In a task generating spontaneous narrative speech and one constructing sentences from provided verbs, Braun demonstrated activation of BA 47. In the same study, a paced narrative task and an automatic speech task showed no activation in the area, which Braun attributed to lower semantic processing demands in the structured and automatic tasks. The multiple variations of semantic processing that are required in these tasks provide convincing evidence that BA 46/47 plays a key role in analysis of word meaning.

2. Working Memory Activation

Semantic working memory is another function attributed to the region of 46/47. The concept of semantic processing is basically retrieving word meanings; therefore, the line differentiating semantic working memory from semantic processing is uncertain. Gabrieli offered a view of BA 46/47 activation based on his study of semantic versus phonological analysis of words: Left inferior prefrontal cortex is activated to the extent that semantic information must be held temporarily in working memory to answer a particular semantic question. He observed a decrease in activation in the area, caused by a decreased need for processing, during a semantic priming task in which subjects differentiated between nouns based on semantic categories (living/nonliving or abstract/concrete). Repetition priming refers to the increase in efficiency produced when a task is performed with a set of stimuli already presented versus performance with novel stimuli, and the improvement reflects implicit memory acquired the first time a stimulus is presented. Smith argued that the area is divisible into two sections: area 47, which is responsible for maintaining verbal information in working memory, and area 46, which regulates the manipulation of maintained information. Working memory tasks for different modalities, such as objects or faces, activate different areas of the prefrontal region, but those that deal with verbal, semantic information consistently utilize pre-Broca's.

3. Nonlanguage Activation

Pre-Broca's area is activated during imagined and executed movements when no language is produced, and one study suggests that it is not necessarily activated in semantic processing, suggesting more expanded functions. Actions unrelated to semantics and language, such as overt hand and arm movement and imagined movement, also activate BA 46. Stephan found that both preparation to move and motor imagery activated the area, and Parsons found similar activation in a task judging whether drawings were of left or right hands. Parsons credits the activation to demands on working memory. Bookheimer compared oral object naming, oral word reading, silent object naming, and silent word reading tasks with viewing meaningless line drawings. The oral object naming, silent object naming, and silent reading activated BA 47 significantly, but oral word reading did not. Bookheimer noted that this indicates that semantic processing does not occur in oral reading if BA 47 is responsible for semantics. She suggested an alternative: This region might reflect activation of an articulatory code or motor plan corresponding to the recognized visual form. The variety of activation beyond semantic analysis makes it difficult to conclude that BA 46/47 acts strictly in a semantic capacity when it is engaged, and further evidence is needed to draw firm conclusions beyond the general finding that the area aids in processing and retrieving word meanings.

C. Sub-Broca's Area

Language production tasks often activate the left anterior insula, or sub-Broca's area, located beneath BA 44/6. The anterior insula is most likely activated in phonological and articulatory planning of speech, as opposed to semantic or lexical processing, as a result of its proximity to Broca's area proper. Figure 7 shows a meta-analysis of functional imaging data for activation of anterior insulae, left and right, from paradigms involving language. The posterior portion of the insula

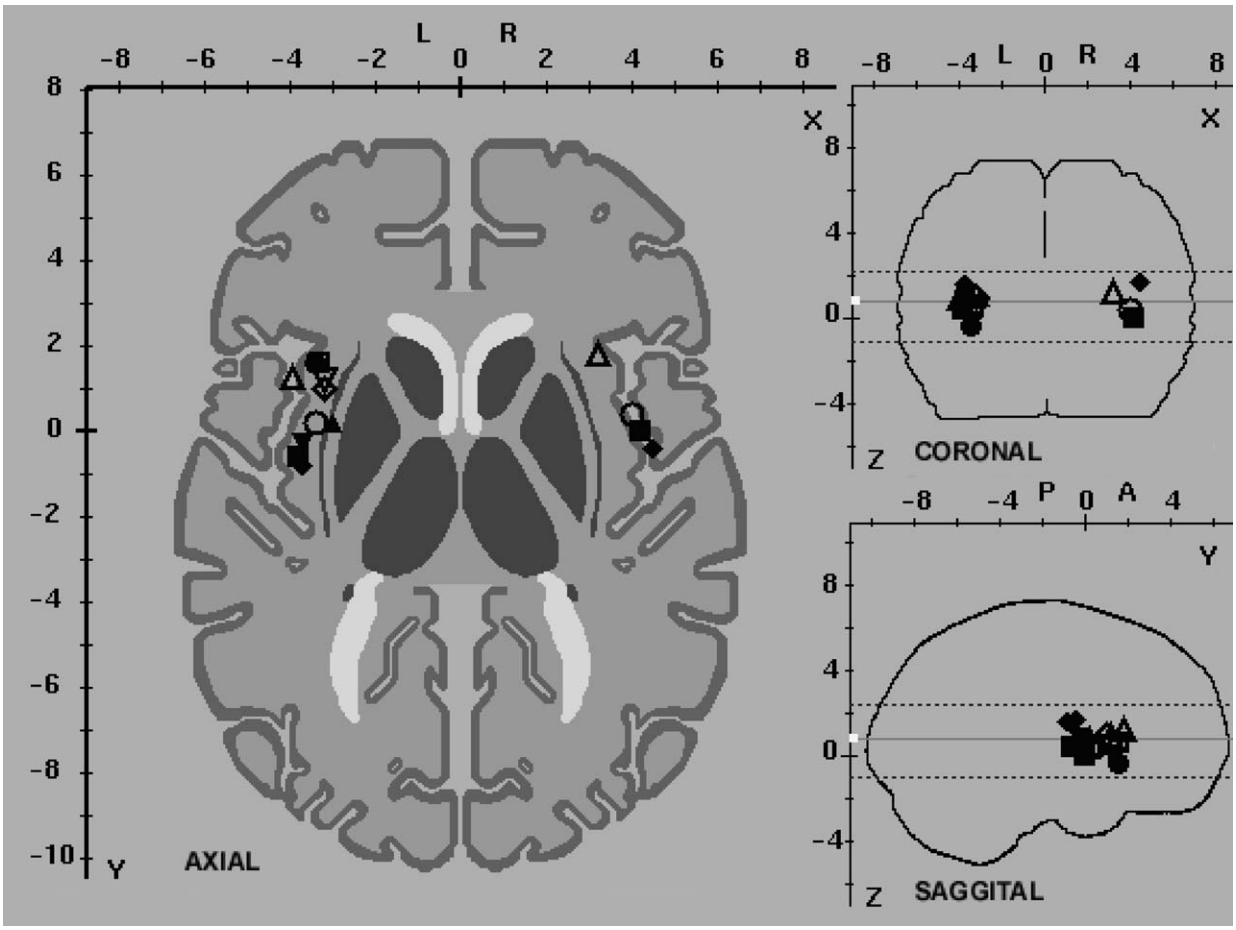

Figure 7 Activations in the anterior insula are shown in a meta-analysis of functional imaging data for left and right hemispheres from paradigms involving language. A set of mean coordinates was calculated from data reported from studies in Table II. The coordinates have been normalized and reported in standard three-dimensional (Talairach) space, plotted with the BrainMap database on an axial cross section at z=0.8 cm. Each relevant reference listed in Table II is represented here by a mean coordinate with the following symbols: ■, Becker (1994); □, Bookheimer (1995); ●, Braun (1997); ▲, Fox (1999); ◆, Raichle (1994); ○, Paulesu (1993); ▼, Fiez (1996); △, Price (1994); ▽, Rumsey (1997); ◇, Wise (1999). The distribution of activation points in both hemispheres shows that insular activation is not as strongly left lateralized as is activation of pre-Broca's area.

is associated with primary auditory and auditory association cortices and has been implicated in processing of auditory input. Braun related this function to a wide range of areas, noting that posterior insula serves as a parallel relay to prefrontal, motor, somatosensory, and cingulate regions of the brain. In addition to its role in speech, anterior insula has also been activated in overt and covert movement tasks. In general, functional imaging of the insulae is less abundant than that of BA 44/6 and 46/47. This trend may be due to the smaller size of the activated area combined with the less sensitive cameras and imaging equipment used in the past. In comparing language tasks that involve semantic, phonological, and articulatory processing, evidence indicates that left anterior insula is responsible for phonological and articulatory planning, but the area's relationship with semantics and the details of its role in articulation are debated.

1. Speech Activation

Left anterior insula is activated, often along with BA 44/6, in language tasks involving picture naming, practiced verb generation, reading aloud, and word repetition. All these tasks connect the area with language production, but the exact relationship of

the insular activation to the tasks follows two different trends of thought. Both agree that insula acts in articulatory planning, but they do not agree on its involvement in phonological and semantic analysis. The first set of opinions differentiated between automatic or rehearsed language tasks and novel tasks and proposed that insula is active in those tasks that are practiced. In a novel verb-generation task in a study by Raichle, the insula was inactivated relative to simple reading of nouns, and after the verb-generation task had been practiced the insula became active. In a silent counting task in a study by Fiez, insula was active, but when a verbal working memory component of retention of novel words was added to the task, insula became inactive. Fiez suggested that silent counting could be thought of as practiced speech. No distinction was made between phonological and articulatory functions in these studies; insular activation is attributed to the rehearsed nature of the speech, irrespective of the exact task being performed.

Another group of studies attempted to specify the purpose of insular activation based on the type of processing it performs or does not perform. Wise contrasted repetition of heard nouns with listening to nouns and anticipation of listening to nouns to differentiate between articulatory and phonological planning. Repetition is a task in which the phonetic plan (the selection and ordering of speech sounds and assignment of syllabic stress) is predetermined by input, and its execution is dependent only on the formulation of an articulatory plan. Left anterior insula was found to be active in both subtractions of listening and repeating nouns, which indicates its articulatory role. Rumsey showed that insula is inactive in orthographic decision making in a task in which subjects had to decide which of two homophones was a real word. She showed it is active in phonological processing in a task in which subjects had to decide which of two pseudowords would be the homophone of a real word. Price demonstrated that left anterior insula is active in a lexical decision-making task in which subjects had to identify real words among words with one incorrect letter substituted but not in a similar feature decision task in which subjects had to find false-font strings with ascending characters. Bookheimer argued that the insula is activated in articulatory coding. She differentiates between two types of motor speech pathways used in creating articulatory plans. Only one activates left anterior insula. She found activation in object naming, which she explained elicited a complete motor response: Subjects select a verbal label and the corresponding complete motor plan associated with that label. The alternate pathway that does not involve insula would be a sequential translation of orthographic units into sound patterns, as in word reading, with modification of the output based on auditory feedback. This differentiation of motor plan could explain Raichle's activation pattern in practiced word production if the practiced words are viewed and programmed as whole motor plans and not modified during production. Overall, activation in sub-Broca's area in speech production tasks indicates that the left anterior insula is active in articulatory planning and works closely with BA 44/6 in language tasks, but some details of the insula's role in language remain unclear.

2. Nonlanguage Activation

Nonlanguage tasks, such as overt and covert movement, activate the left anterior insula and demonstrate that the functions of the area extend to motor planning. Finger opposition and shoulder movement both activated insula in a PET study of movement by Colebatch, and imagined movement of a handheld joystick in a PET study by Stephan showed increased activation over a preparation to move baseline task. Right insula was activated by imagined movement of the hand in Parson's left/right hand decision study. He credited the insula with responding to somatosensory information from the body: The right insula activity observed is related to higher level somatic representation accompanying mentally simulated limb movement. Activation of left and right insulae in overt and covert movement shows that anterior insula is involved in complex nonspeech processes, and it demonstrates the need for more and varied functional imaging investigations of the relationship of language areas of the brain.

V. HEMISPHERIC LATERALITY

Hemispheric laterality of language function, still discussed and debated today, was introduced in the 19th century, and Broca brought it to the attention of the scientific community even though he did not believe in the theory. Although it is now well established that the left and right hemispheres of the brain are specialized for different functions and are anatomically asymmetrical, the exact nature of and reason for the differences have not been agreed on. The left hemisphere is generally described as dominant for

language, although individuals vary in the degree of dominance; however, as clinical, electrophysiological, and functional imaging data have shown, the right hemisphere plays an important role in language even in left-dominant individuals. Finding the basis for the laterality of language and its relationship to other characteristics, (e.g., gender) is another goal of functional imaging technology.

A. General Comments on Laterality

Even though language function has been placed in the left hemisphere historically, the right hemisphere has also been shown to be crucial for language function. One theory from 19th century science was that language dominance was connected with manual dominance since the majority of individuals were right-handed, the left side of the brain was known to control the right side of the body, and most cases of aphasia were documented with left hemisphere lesions. Right-handed individuals with aphasia and right hemisphere lesions in addition to left-handed aphasics with left hemisphere lesions have since been documented, and the connection between manual and language dominance has been severed. Another theory on laterality is that the left hemisphere is responsible for verbal functions, whereas the right is credited with visual and spatial perception. Both of these abilities have to do with language since visual and spatial perception influence visual language perception involved in reading and, as a result, in many functional imaging paradigms. The specific components of language have been placed in different hemispheres based on clinical and functional imaging data. For example, although the left hemisphere has long been thought of as responsible for semantics, the right hemisphere homolog to Broca's area has been shown to play a role in prosody, or the rhythmic and melodic qualities of speech production.

Stuttering studies are linked with the lateralization of language, and theories about reasons for stuttering revolve around hemispheric interactions in language. One long-standing explanation for stuttering is that it is a result of incomplete development of left hemispheric dominance for language, and another explanation is hyperactivity of the right hemisphere (nondominant for language), specifically the premotor cortex. In one PET study, Fox found overactivation in the right hemisphere motor language areas during stuttering and deactivation of left hemisphere auditory and frontal–temporal language production systems. When fluency was induced in speakers who usually stutter, the overactivations on the right decreased or disappeared and the left hemisphere deactivations were eliminated. Stuttering research is revealing complex interactions between the hemispheres in language production, and these interactions in such a clinical population may shed light on normal functional organization.

B. Laterality by Area

In the functional imaging literature, it is no longer a question of whether language is located in the left or right hemisphere but, specifically, which aspects and to what degree are those aspects of language located in which hemisphere. Each subdivision of Broca's area varies in the degree to which it appears on each side of the brain.

1. Broca's Area Proper Is Bilateral

Activation of BA 44/6 is found in both left and right hemispheres in right-handed individuals, although the majority of the activation is on the left and many studies do not focus on the right hemisphere's activation in language paradigms. Those that do report right hemisphere activation in PET and fMRI paradigms in normal subjects state that it is much weaker than corresponding left activation. Right Broca's is activated in some verb-generation and pseudoword repetition tasks as well as in verbal working memory tasks and a continuous performance task of identifying one letter in a stream of others.

2. Pre-Broca's Area Is Left-Lateralized

Few language studies report activation of right hemisphere BA 46/47, although there are a few paradigms that report activation below their individual standards for significance in reporting. This distinct left lateralization has not been explained in relation to more bilateral activation patterns in other language areas.

3. Sub-Broca's Area Is Bilateral

The anterior insula, although not always active along with Broca's area proper on the right, is more frequently active than BA 46/47 on the right. Since the left anterior insula has been linked to activation of Broca's area proper in tasks involving articulation, its

right-sided activation could be explained by a similar proximity argument to right BA 44/6.

C. Gender and Language Laterality

The effect of gender on laterality of speech functions has been and still is debated, with studies supporting male left lateralization and female bilaterality countered by others that demonstrate left lateralization in both genders. One study by Shaywitz shows that phonetic processing involving rhyme judgment clearly demonstrates male left lateralization in the inferior frontal gyrus and female bilaterality on the same task. A larger study of language comprehension by Frost demonstrated that men and women were both strongly left-lateralized in fMRI activation. This contradictory evidence demonstrates the need for continued, deeper investigation of the relationship between gender and hemispheric laterality.

VI. CONCLUSIONS

In closely examining Broca's area, several diverse literatures are available. Historical, electrical stimulation, clinical, and functional imaging studies contribute distinctive and sometimes seemingly contradictory viewpoints on the placement and function of Broca's original seat of articulate language. The way to reach firmer conclusions is to continue to find the discrepancies. In the future, more subdivisions may be created in Broca's area, and further extensions may be made into surrounding areas, for example, higher into BA 46 in order to relate higher order memory functions to current language functions.

Cancer Patients, Cognitive Function

CHRISTINA A. MEYERS
University of Texas M. D. Anderson Cancer Center

GLOSSARY

cytokines Molecules that communicate between immune cells and between immunocytes and other peripheral cells, such as fibroblasts and endothelial cells. They are involved in regulating the initiation and maintenance of the immune response.

paraneoplastic syndrome Brain dysfunction directly resulting from a cancer that is not present in the nervous system.

subcortical dementia Dysfunction or injury to the white matter tracts connecting the frontal lobe regions to subcortical targets, causing a clinical syndrome characterized by neurobehavioral slowing, memory loss, frontal lobe dysfunction, and mood changes.

Many cancer patients experience impairments of neurocognitive function, including memory loss, distractiblity, difficulty with multitasking, mood disturbance, and a myriad of other symptoms. Patients may also suffer from symptoms that compromise their ability to function adequately, such as fatigue and pain. The etiologies of these problems are diverse and include the direct effects of cancer within the central nervous system, indirect effects of certain cancers (the paraneoplastic disorders), and effects of cancer treatment on the brain. In addition to these cancer-related causes, patients may have co-existing neurologic or psychiatric disorders that affect their cognition and mood. Careful assessment of patients complaining of neurocognitive or behavioral problems is essential to provide appropriate interventions and to maximize their quality of life.

I. CANCER IN THE CENTRAL NERVOUS SYSTEM

Primary brain tumors, metastatic brain tumors, and leptomeningeal metastases directly alter the functioning of the brain and hence the individual's mental and cognitive functioning. Primary brain tumors are increasing in prevalence, with more than 29,000 new cases diagnosed each year in the United States. In addition, between 20 and 40% of patients with non-central nervous system (CNS) solid tumors develop brain metastases. Cognitive impairments are related to lesion location, tumor growth potential, and host characteristics.

A. Impairments Related to Tumor Site

Although the cognitive symptoms caused by tumors are relatively focal in nature (e.g., the symptoms correspond to expected brain–behavior relationships), the cognitive impairments tend to be less dramatic than those seen in patients with more sudden-onset lesions. Patients with left hemisphere tumors are thus more likely to have impairments of language function, verbal reasoning, and right-sided motor dexterity. Patients with right hemisphere tumors have more difficulties with visual–perceptual skills, visual

scanning, and left-sided motor dexterity. Memory loss is often seen in association with tumors of either hemisphere. Impairments of frontal lobe function (e.g., executive deficits manifested by impairments of cognitive flexibility, abstraction, motivation, planning, and organizational skills and also the ability to benefit from experience, personality changes, etc.) are ubiquitous in brain tumor patients because the frontal lobes comprise one-third of the cerebrum, and thus a large proportion of patients have frontal tumors. However, patients with nonfrontal tumors may also exhibit executive deficits because the frontal lobes have rich afferent and efferent connections with all other brain regions, disrupting the bidirectional modulatory influences on cognition and thus causing impairment in social functioning, motivation, and judgment.

B. Lesion Momentum

Individuals who present with low-grade tumors that have been present for many years may have no detectable changes in brain function due to cerebral plasticity and reorganization, whereas those with very rapidly growing tumors may have widespread impairment due to mass effect on adjacent brain regions. Patients with gliomatosis cerebri, a condition in which tumor cells diffusely infiltrate large brain regions, may have few focal impairments since neuronal function is not substantially altered. Patients with metastatic brain tumors may also present without focal or severe deficits since neuronal tissue is displaced by the lesion and not necessarily damaged.

C. Host Characteristics

The age of the patient is also a factor in the severity of neurobehavioral deficits. The incidence of histopathologically more aggressive tumors, such as glioblastoma multiforme, increases with age. However, histopathologically less malignant tumors, such as anaplastic astrocytoma, also behave more aggressively in the older patient. Older patients are also at higher risk for having other concurrent neurodegenerative illnesses, such as Parkinson's disease or vascular disease. Finally, very old and very young patients may be more sensitive to the toxic side effects of treatment.

II. CNS EFFECTS OF NON-BRAIN CANCER

Certain types of cancers cause brain dysfunction indirectly, causing paraneoplastic brain disorders. It has been estimated that 10% of cancer patients develop such a syndrome. Most commonly associated with small cell lung cancer (SCLC), paraneoplastic brain disorders typically manifest as a diffuse encephalomyelitis, including limbic encephalitis, cerebellitis, brain stem encephalitis, myelitis, and sensory or autonomic ganglionitis. The cognitive deficits associated with these disorders are of two types. Some patients develop a gradually progressive subcortical dementia that is difficult to distinguish from dementia due to other causes. The second form, paraneoplastic limbic encephalitis, is often characterized by the subacute, progressive onset of anxiety, depression, confusion, hallucinations, recent memory loss, or seizures. The onset of symptoms can precede the diagnosis of cancer even by years. These disorders have an autoimmune pathogenesis and are associated with high titer serum autoantibodies, usually of the IgG-1 subtype. The most common antibody identified in patients with paraneoplastic disorders is anti-Hu, which recognizes similar neuronal and autologous SCLC protein antigens. Recently, it has been determined that a large proportion of patients with SCLC experience subclinical alterations in memory and frontal lobe executive function prior to the institution of any treatment. A variety of anti-neuronal antibodies, particularly anti-Hu, have been found in 16% of SCLC patients without florid paraneoplastic neurologic disease, but correlation of subtle cognitive or neurologic dysfunction in SCLC patients with low titer antibody responses has not been performed. Other paraneoplastic syndromes include subacute cerebellar degeneration, which is associated with an anti-Purkinje antibody in ovarian cancer patients, and a rare autoimmune paraneoplastic encephalitis associated with testicular cancer.

Some cancer cells produce ectopic hormones or proinflammatory cytokines. These can have profound effects on brain function and are known to cause cognitive and mood dysfunction. For instance, the cytokines interleukin-1 (IL-1), IL-6, and tumor necrosis factor (TNF-α) are elevated in patients with acute leukemia and myelodysplastic syndrome. A more thorough discussion of the effect of cytokines on brain function is provided in Section III.C. A substantial proportion of untreated patients with these hematologic malignancies have neurocognitive impairments.

III. EFFECTS OF ANTINEOPLASTIC THERAPY

Chemotherapy, radiotherapy, immunotherapy, novel agents, and hormonal treatments all have potential neurotoxic side effects. Cognitive impairments due to treatment effects are generally not due to mood disturbance in the clinical trials that assess both cognition and mood.

A. Chemotherapy

Many cancer patients experience difficulties with short-term memory during cancer therapy. However, approximately 18% of cancer patients who have received standard-dose chemotherapy manifest persistent cognitive deficits after treatment is completed. The risk appears to be greater after high-dose chemotherapy with stem cell rescue—on the order of one-third of patients. This risk is evident 2 years after treatment, but the longer term effects of high-dose therapy remain unknown. Although most impairments related to chemotherapy are relatively diffuse, affecting sustained attention and speed of information processing, some agents have more circumscribed effects on the brain due to their mechanism of action. For instance, a mitotic inhibitor that binds to the colchicine receptor on tubulin and crosses the blood-brain barrier causes a highly specific decline in memory functioning. There are also many case reports of patients developing confusion and behavioral changes after the administration of chemotherapy agents not thought to cross the blood–brain barrier. The mechanism underlying these events is unclear and may reflect second messengers, metabolic disturbance secondary to other organ toxicities, differences between human subjects and the animals that were used for preclinical toxicity assessments, or unanticipated breach of the blood–brain barrier. Finally, some individuals may be at greater risk to develop neurotoxicity from chemotherapy due to preexisting host characteristics. For example, people with dihydropyrimidine dehydrogenase deficiency can develop severe neurotoxic reactions to 5-fluorouracil, a widely used chemotherapy agent.

B. Radiation Therapy

Radiation therapy to the brain is the mainstay treatment for primary and metastatic brain tumors. Due to the high incidence of cancer relapse in the brain, prophylactic brain irradiation is widely used in patients with lung cancer and acute leukemia. Cognitive domains impaired as a result of radiation therapy include information processing speed, executive functions, memory, sustained attention, and motor coordination. Anatomically, periventricular white matter hyperintensities are observed on neuroimaging. The pattern of deficits is consistent with those seen in other subcortical diseases of white matter such as multiple sclerosis. Children are particularly vulnerable to radiation injury to the brain. Even relatively low-dose cranial irradiation can cause mild declines in intelligence in older children, with more severe impairments in memory, acquisition of academic skills, and attentional skills in children treated before age 5. In both adults and children there is conflicting evidence whether concomitant chemotherapy is synergistically toxic. Finally, many patients with head and neck cancers, such as paranasal sinus tumors and anterior skull base tumors, receive local radiation that incidentally injures the brain.

C. Immunotherapy

Immunotherapy with proinflammatory cytokines is widely used in the treatment of chronic leukemia, renal cell carcinoma, and melanoma. As mentioned previously, cytokines have profound effects on brain function. In fact, more than half of patients receiving cytokine treatment have documented cognitive impairments, which is considerably higher than the rate of cognitive dysfunction in patients treated with cytotoxic agents only. Interferon-α(IFN-α) is the most widely used immunotherapy agent and has a wide array of effects on CNS function. Patients on IFN-α may develop cognitive deficits involving information processing speed, verbal memory, and frontal lobe executive functions as well as depression, a pattern suggestive of frontal–subcortical dysfunction.

Impairments of cognition and mood may occur separately or conjointly and often require dose reduction or termination of an otherwise effective treatment. In a few patients cognitive deficits do not appear to be reversible after treatment cessation. The length of treatment, dose, and route of administration are all important factors in the development of neurotoxic side effects. Mechanisms of IFN-α's action on the CNS include both stimulation and inhibition of the hypothalamic–pituitary–adrenal axis and release of neuroendocrine hormones, effects on thyroid function,

induction of secondary cytokines that are neurotoxic, and alterations of neurotransmitter pathways, particularly the opioid–dopamine and serotonergic systems.

Other cytokines have also been used in clinical trials against cancer, and the cognitive impairments tend to be similar to those seen with IFN-α. IL-2 and TNF can cause memory deficits, difficulties with motivation and flexible thinking, motor dyscoordination, depression, and anorexia. Visuoperceptual and language functions tend not to be affected. TNF exhibits dose-dependent toxicity such as decreased attentional abilities, verbal memory deficits, motor coordination impairments, and frontal lobe executive dysfunction. Headache, anorexia, stroke-like events (e.g., transient amnesia), and demyelination in the brain are also adverse effects of TNF. IL-1 and its receptors are found in many areas of the brain, particularly the hippocampus. IL-1 suppresses the influx of calcium into the hippocampus neurons, which may explain the preponderance of memory impairments in patients with IL-1-associated toxicity. The neurotoxic effects of IL-2 appear to be dose related and occur in nearly all patients treated with high dosages. The symptoms range from mild agitation, depression, and forgetfulness to frank confusion, dementia, and paranoia. TNF and IL-2 and TNF and IL-1 have been found to be synergistically toxic with the latter being associated with the development of multiple sclerosis plaques and gliosis. CNS expression of IL-6 has been associated with inflammatory neurodegeneration and learning impairments in mice and in patients with Alzheimer's disease.

In addition to their direct effects on brain function, these cytokines provoke a stress hormone cascade that can affect mood and cognition. The mechanism through which cytokines exert their influence is difficult to discern given their overlapping immunological, hormonal, and inflammatory effects. Cytokines act in cascades, making determination about specific effects of an individual cytokine even more difficult. Cytokines are thought to enter the brain via the circumventricular organs, particularly the organum vasculosum of the lamina terminalis. This structure is associated with the hypothalmus, which has connections with the brain stem, frontal cortex, and the limbic system. Treatments directed against cytokine neurotoxicity are symptomatic and include stimulant therapy for fatigue and neurobehavioral slowing, opiate antagonist therapy for cognitive deficits, and antidepressant therapy for mood disturbance.

D. Hormone Ablation Therapy

Hormone ablation is typically used to treat (i) prostate cancer, via either orchiectomy or androgen antagonists, and (ii) hormone receptor-positive breast cancer, with estrogen antagonists. There is a burgeoning literature on the effects of sex hormones on cognitive functioning. Serum testosterone may be related to spatial ability. Women on gonadotropin-releasing hormone agonists for gynecological problems, which inhibit both testosterone and estrogen release, have reported declines in their memory functioning and mood. These deficits appear to be reversed with estrogen replacement. Tamoxifen is the most widely used hormonal agent in the treatment of breast cancer. The most commonly reported adverse effects associated with Tamoxifen include hot flashes, nausea, and vaginal bleeding. Additionally, fatigue and inability to concentrate have been reported as well as mood changes, including depression, irritability, and nervousness. Although the pharmacodynamic properties of Tamoxifen, especially its CNS effects, are not well understood, there is reason to believe that Tamoxifen therapy is related to the cognitive and emotional difficulties some women experience secondary to its antiestrogen activities. Additionally, *in vivo*, *in vitro*, and animal studies suggest that Tamoxifen affects several other neurotransmitter (e.g., seratonin and dopamine) and cytokine (e.g., IL-1, IL-6, IFN-γ, and TNF) systems that are implicated in cognitive functioning. Major depression (which occurs in 1–15% of patients on Tamoxifen therapy) has been associated with increases in IL-1, IL-6, IL-2, TNF, and IFN-γ and is associated with symptoms such as psychomotor retardation, malaise, lassitude, anxiety, anhedonia, and sleep disturbances.

E. Adjuvant Medical Treatment

In addition to neurotoxic effects of primary cancer therapy, adjuvant medications may also cause neurocognitive symptoms, complicating the assessment of patients who are on multiple medications. Drugs with cognitive and mood effects include steroids, pain medications, psychotropic medications, and antiemetics. Immunosuppressive agents, such as cyclosporine, are widely used in bone marrow transplantation and may also cause adverse CNS effects. Neurotoxicity due to cyclosporine and other immunosuppressive agents may not always be reversible and can cause observable anatomic brain injury.

IV. COMORBID CONDITIONS

A. Neurologic Diseases

The elderly comprise the largest percentage of cancer patients. Patients in older age groups are not only at increased risk to develop cancer but also more vulnerable to age-related neurocognitive disorders unrelated to but coexisting with cancer, such as cerebrovascular disease and dementia of the Alzheimer's type. Cancer patients may also have a preexisting history of traumatic brain injury, developmental disorder, multiple sclerosis, and other conditions or diseases that affect cognitive functioning. These patients may be more vulnerable to develop neurotoxic side effects from cancer and cancer treatment and need to be monitored closely.

B. Sensory Impairment

Elderly patients may have difficulties with hearing or sight or they may suffer from general frailty. Many patients have also experienced ototoxicity and other sensory problems from chemotherapy. These sensory deficits reduce the amount of information patients are able to process and may lead to complaints of memory dysfunction. Some patients even manifest psychiatric difficulties, such as paranoia, because a relative sensory deprivation impedes their ability to appreciate what is going on around them.

C. Functional and Psychiatric Disorders

Stress, anxiety, depression, and other mood disorders can be reactive to the patients' current situation or can predate the cancer diagnosis. In either case, mood and adjustment disorders negatively affect patients' ability to focus, concentrate, and organize activities, leading to complaints of forgetfulness and other cognitive problems. Cancer patients are just as likely as the general population to suffer from major psychiatric disorders, such as bipolar illness, major depression, schizophrenia, and personality disorders. These disorders also have associated cognitive symptoms if they are not under good control with psychiatric management.

D. Fatigue, Pain, and Anemia

Fatigue is extraordinarily common in cancer patients and is now recognized as a more widespread and problematic symptom than pain. Cancer-related fatigue is defined as an unusual, persistent, subjective sense of tiredness related to cancer or cancer treatment that interferes with usual functioning. It can occur during active cancer treatment and it can persist long after treatment has ended. The causes are myriad and overlap considerably with those that can cause cognitive disorders. Fatigue may be physical in that the person has very little stamina or energy to perform usual activities. Fatigue can also be mental. Similar to patients with cognitive dysfunction, patients who suffer from mental fatigue often report that they are easily overwhelmed, that they have difficulty being organized and efficient in their daily activities, and that they have difficulty meeting deadlines or getting things done on time. Activities that used to be automatic now require more effort so that the patients become exhausted even performing routine tasks.

A similar situation exists for patients who experience pain. Patients in pain also suffer from deficits in attention and concentration, multitasking, and speed and efficiency of thinking. They may be on medications that are sedating and contribute to cognitive problems, and they are likely to be suffering from fatigue as well.

Anemia is very common in cancer patients undergoing active treatment. Cognitive deficits have been reported in well-dialyzed patients with end-stage renal disease who are anemic but do not have elevated uremia. Cognitive deficits are also exhibited by patients who have anemia due to iron deficiency. The cognitive problems observed on neuropsychological testing include deficits in attention, perceptual motor speed, memory, and verbal fluency and are accompanied by slowed auditory evoked potentials. There is a high degree of correlation between hemoglobin levels and fatigue. However, patients with anemia may experience cognitive difficulties separately from those due to fatigue alone, possibly due to reduced cerebral blood flow. These cognitive deficits and slowed evoked potentials often improve following reversal of anemia with erythropoietin or blood transfusion.

E. Other Medical Complications

Alterations of thyroid functioning are common in cancer patients and can be associated with cognitive and mood disorders. Patients are at risk for all types of infections and may develop significant cognitive problems or even delirium. Hepatic and renal dysfunction also can cause cognitive problems in acutely ill

patients. In these patients, treatment of the underlying disease will often result in resolution of the cognitive problems as well. Immunocompromised patients, such as individuals undergoing bone marrow transplantation, may be at risk for developing viral encephalitis and persistent amnesia following recovery from an acute viral infection.

V. ASSESSMENT

It is becoming increasingly common to assess cognitive functioning and symptoms experienced by cancer patients in clinical trials of new anticancer therapies. As defined by a working group of members of the Food and Drug Administration, National Cancer Institute (NCI), and the NCI Division of Cancer Treatment Board of Scientific Counselors, net clinical benefit of cancer therapy includes: (i) survival benefit, (ii) time to treatment failure and disease-free survival, (iii) complete response rate, (iv) response rate, and (v) beneficial effects on disease-related symptoms and/or quality of life. Especially for regimens that differ only slightly with respect to response and survival, the rationale for selecting a particular therapy may be highly related to the impact of that treatment on cognitive function, symptoms, and quality of life.

As can be seen from the previous discussion, the specific causes of cognitive dysfunction is critically important to guide interventions because the type of intervention most helpful will be dramatically different depending on the etiology. The specific intervention plan not only takes into account the underlying cause of the complaint but also needs to be individualized for the person because the impact of a cognitive problem will be different for different people. A practical system to evaluate the impact of neurocognitive dysfunction was developed by the World Health Organization, which classifies the impact of an illness in three domains; impairment, disability, and handicap. Impairment is the deficit in function. In the case of neurocognitive symptoms, the deficit is in the function of the brain and manifested by neurologic, cognitive and emotional changes. Formal assessment of neurocognitive function can help determine the etiology of the complaints and the profile of the cognitive changes, and it can also help in the institution of appropriate intervention strategies. Disability is the impact of the deficit in the patient's ability to perform usual work and home activities. The degree of disability for an individual patient will be at least partially related to age, the type of work performed, and the amount of support that is available. Performance and functional status measures may help to define the disability and help determine the need for more comprehensive assessments. Handicap is the impact of the disability on the person's overall satisfaction and well-being. Handicap is generally what is referred to when discussing quality of life (QOL) and is often assessed by QOL questionnaires. Again, handicap is very individual. One person can be handicapped by a relatively minor disability, whereas another individual suffering from a severe impairment may experience little handicap. For example, an impairment in multitasking caused by a difficulty with sustained attention is a common problem for cancer patients. This may not be particularly handicapping to a person who is self-employed and can work at his or her own pace at home. However, it might cause a secretary in a busy office, who needs to answer the phone while word processing, to lose his or her job. Thus, all three levels of function (deficit, disability, and handicap) need to be assessed for appropriate management of the patient.

Many cancer patients have difficulty resuming their normal activities following diagnosis and treatment. Unfortunately, neurobehavioral functioning is often the least addressed aspect of a medical evaluation unless very severe behavioral changes are apparent. Multidisciplinary assessment of neurocognitive complaints can maximize patients' ability to function at the highest level of independence and productivity for the longest duration of time. As cancer treatment becomes more successful there will be increasing numbers of patients who live longer and expect to return to their preillness level of functioning. The risks of treatment and impact on the patient's ability to perform activities of daily living must be addressed more comprehensively. Many intervention strategies are available, including pharmacologic management, behavioral strategies, life-style alterations, formal rehabilitation, and counseling.

VI. INTERVENTION STRATEGIES

A. Pharmacologic Treatment

Fatigue and neurobehavioral slowing are ubiquitous in cancer patients. Stimulant treatment can be very useful in the treatment of concentration difficulties, psychomotor slowing, and fatigue and can help to elevate mood as well. Aggressive treatment of mood disturbance, pain, and fatigue also has the potential to

improve neurocognitive functioning when these symptoms are affecting patient function. New agents are becoming available that intervene on a mechanism-based level, such as cytokine antagonists. In addition, agents that afford neuroprotection from the toxic effects of cancer therapies are currently being developed.

B. Rehabilitation

Physical and occupational therapy can be of tremendous benefit for patients who have developed weakness, generalized deconditioning, sensory neuropathy, or other nerve or musculoskeletal impairments from their cancer and cancer treatment. Both of these modalities can improve mobility and general physical stamina. Patients who have developed impairments of upper extremity function due to peripheral neuropathy from systemic therapy or focal radiation or from central lesions of the spinal cord or brain may benefit from occupational therapy to help improve function. Patients who have developed difficulties with swallowing, articulation, or even primary language problems may benefit from speech therapy.

Many cancer patients who experience neurocognitive declines can improve their function at home and in vocational and leisure pursuits and enjoy an improved level of independence and quality of life given the right support. Given that cancer patients tend to have fairly mild and restricted cognitive problems, they often respond very well to focused rehabilitation efforts. A preliminary study of cognitive and vocational therapy provided to brain tumor patients found that these patients required shorter stays, had less treatment, and had better overall outcome in terms of independence and productivity compared to patients with traumatic brain injuries. Cognitive rehabilitation is designed to improve independence level, whereas vocational rehabilitation is designed to improve productivity, which may include volunteer work, performing household activities, going back to school, working at a modified job, or maintaining competitive employment.

C. Education and Support

Patient and family education is also extremely important. Potential neurobehavioral symptoms may not be explained to the patient, sometimes because the primary physician is not aware of the impact of even subtle symptoms on social and vocational functioning. Patients and families may feel isolated and alone when they experience neurobehavioral symptoms. The more knowledge a patient and family have about the disease, treatment, and expected problems, the more effectively they can deal with the care of the patient. Even simple coping strategies, such as taking intermittent naps, writing notes, and taking special care to plan and organize activities, may be sufficient to effectively cope with symptoms. Support groups and counseling can also be very helpful in assuring patients and families that their experiences are not unusual and in helping them deal with the grief, anger, frustration, and other problems that are frequently manifested over the course of the disease.

It is imperative that in developing new treatments for cancer that provide improved outcomes in terms of survival, there is also consideration about the long-term sequelae of cancer treatment. Cancer survivors should be able to expect to return to a productive and fulfilling life following the cancer experience. Support for this effort will not only reduce disability and improve patient function and satisfaction but also reduce overall burden and cost to society that such disability causes.

Catecholamines

ARNOLD J. FRIEDHOFF† and RAUL SILVA
New York University Medical Center

GLOSSARY

antidepressant drugs Medications used to treat a variety of conditions, such as depression, panic attacks, and obsessive–compulsive disorder. Generally, there are four different groups: (i) the tricyclic antidepressants, which include imipramine and the related agents amitriptyline and nortriptyline; (ii) the monoamine oxidase inhibitors, such as tranylcypromine and phenelzine; (iii) the newest group, the serotonin reuptake blockers, which include anafranil, fluoxetine, sertraline, fluvoxamine, citalopram, and paroxetine; and (iv) others such as trazadone and bupropion.

antipsychotic drugs Medications used for a variety of conditions. The name is derived from the improvement they produce in certain psychotic behaviors, such as delusions and hallucinations. The first such agent, chlorpromazine, was synthesized circa 1950. New atypical agents include clozapine, risperidone, olanzapine, ziprasidone, and quetiapine. These medications are also called neuroleptics.

catecholamines Three endogenously produced substances—epinephrine, norepinephrine, and dopamine—that serve as neurotransmitters. They are powerful chemicals that can be found in neurons throughout the body. The effects of these compounds are responsible for the functioning of the brain even during the early fetal stages of life. They help regulate an endless number of functions ranging from thinking and mood to motor control.

limbic system A group of structures located in the brain that are involved in regulating emotion and its association with behavioral and mental functioning.

neurotransmitters Compounds that are released into interneuronal junctions called synapses. They are released from the axon of a presynaptic neuron and impact on the receptors of the postsynaptic neuron, the nerve cell on the other side of the synapse. This is the chemical means by which transfer of information occurs in the brain.

†Deceased.

Catecholamines comprise three endogenously produced substances—epinephrine, norepinephrine, and dopamine—that serve as neurotransmitters. They are powerful chemicals that can be found in neurons throughout the body. The effects of these compounds are responsible for the functioning of the brain even during the early fetal stages of life. They help regulate an endless number of functions ranging from thinking and mood to motor control. In this article, we review the structure, the anatomical distribution, and the role that these substances play in functioning and behavior.

I. NATURE OF THE CATECHOLAMINERGIC SYSTEMS

Catecholamines are relativity small organic molecules that function in the brain and elsewhere in the body, primarily in a regulatory or modulating role, to keep various systems functioning smoothly in response to demands of the internal and external environment. The most familiar of the three natural catecholamines is adrenaline, or epinephrine (Fig. 1). Its effects have been experienced by all of us, for example, in response to a frightening experience. Its release into the bloodstream from the neuronal cell bodies located in the medulla of the adrenal gland regulates heart rate and blood pressure and helps to put us into a readiness state for fight or flight. Norepinephrine, the closest chemical relative of epinephrine, is more prominently localized in the brain than epinephrine, but it is also found in so-called peripheral neurons (those neurons found outside of the brain). In the brain norepinephrine regulates mood and level of emotional arousal and

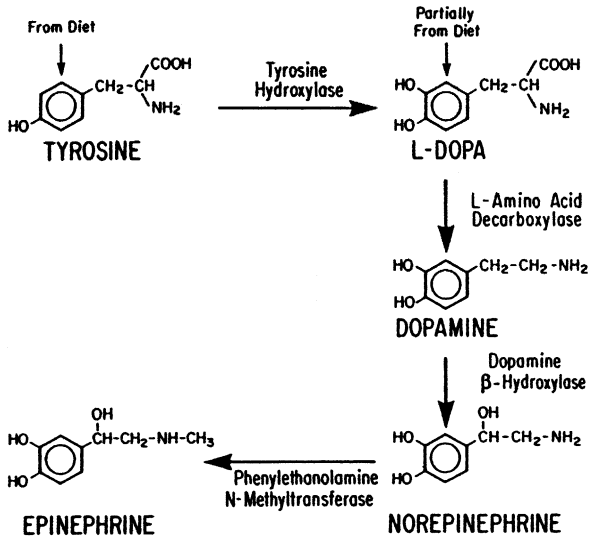

Figure 1 Pathway for biosynthesis of the major catecholamines (reproduced with permission from Friedhoff and Silva, 1993).

alertness. Dopamine, the third catecholamine, is prominently involved in regulating motor or movement functions and also in the coordination of associative thinking and integration of sensory motor function. Thus, key volitional acts such as movement and thinking are fine-tuned, integrated, and given emotional coloration through the actions of the three catecholamines.

A. Neurotransmission

Information transfer in the brain is carried out mainly by synaptic transmission, or the passage of a message across synapses or gaps between communicating cells. This occurs through a combination of electrical transmission that takes place within a neuron and the release of a chemical or neurotransmitter that crosses the synaptic gap and then acts on a postsynaptic neuron via specialized detection sites called receptors. However, there are some exceptions to this general model. For example, some neurons (not catecholaminergic) relate to each other entirely by change in electrical potential. In many cases involving the catecholaminergic system, other substances are coreleased with the neurotransmitter and modify or modulate its effect. The nature of the effector response can vary depending on the type of receptor, location of the membrane, and the nature of the neuromodulators. For example, the stimulation of β_3-adrenergic receptors located in adipose tissues will stimulate the breakdown of fats (lipolysis). This can be contrasted with the stimulation of different α_2-adrenergic receptors, one of which may inhibit the release of certain neurotransmitters at the presynaptic level of adrenergic nerve cells, thereby causing inhibition of norepinephrine release. Stimulation of another α_2-adrenergic receptor located on the membranes of the β cells of the pancreas will cause a decrease in insulin secretion.

The synapse is an important locus for the action of drugs that modify behavior. By blocking reuptake of transmitters, the effect of the transmitter can be enhanced or exaggerated. Conversely, by blocking receptors on postsynaptic cells, transmitter effect can be reduced. A third possibility, which has been exploited pharmacologically, is the modification of the ion exchange involved in electrical transmission. This too can have effects on motor and mental activity.

It should also be kept in mind that neurotransmission in the catecholaminergic system can be altered by impingement of other transmitter systems. One example is the glutamatergic system. Neural projections from this system can modulate dopamine release in the cortex. Pharmacologic antagonists of this system, such as phenylcyclidine, can increase dopamine outflow at the level of the striatum. Strikingly, in the behavioral realm, the administration of this agent produces a clinical picture that mimics the psychotic processes that have been associated with abnormalities in the dopaminergic system.

Finally, when discussing neurotransmission the termination of the signal is of paramount importance. If the transmitter is not removed from the synaptic cleft, a desensitization of the postsynaptic receptor will occur as a result of continued catecholamine exposure. Reuptake of neurotransmitters is a common mechanism for inactivation. This process facilitates the removal of the transmitter and affords the ability to reuse the molecule. There are transporter molecules located on the membranes of terminals that produce high-affinity bonds and facilitate these mechanisms. Theoretically, these molecules are also capable of releasing bonded substances and thus producing postsynaptic activation. Nonetheless, the catecholamine transporter is an exciting area of research.

B. Biosynthesis of Catecholamines

The starting point for the synthesis of all the catecholamines is L-tyrosine, which is a nonessential amino acid that can be found in the diet. Synthesis of these neurotransmitters may vary, depending on dietary

consumption of tyrosine-containing products. L-Tyrosine is hydroxylated (it gains an OH group) to form dihydroxy-L-phenylalanine, which is also known as levodopa or L-dopa. The enzyme responsible for this transformation is tyrosine hydroxylase. In dopaminergic neurons, L-dopa is metabolized to dopamine by means of the enzyme dopa decarboxylase. This enzymatic process occurs in the cytoplasmic component of neurons. In noradrenergic nerve cells and in the adrenal medulla, dopamine is transformed to norepinephrine. This is facilitated by the enzyme dopamine β-hydoxylase. It has been estimated that approximately 50% of the dopamine synthesized in neuronal cytoplasm of noradrenergic cells is metabolized to norepinephrine. Norepinephrine can then be transformed to epinephrine by the addition of a methyl group (CH_3) to its amino group through the action of the enzyme phenethanolamine-*N*-methyltransferase. This last step occurs in certain neurons of the brain and in the adrenal medulla (graphic and schematic representations of the biosynthesis and breakdown of catecholamines can be found in many of the references listed in Suggested Reading). In general, the enzymes described in this section are produced in the neuronal cell bodies and are then transported and stored in nerve endings. Therefore, the process of catecholamine biosynthesis takes place within these terminals. The catecholamines that are synthesized are then taken up and stored in vesicles (chromaffin granules) of the nerve terminals, which are located near the cell membrane. During neural transmission, catecholamines are released from these vesicles into the synaptic cleft. Although certain precursors of catecholamines (such as L-dopa) penetrate the blood–brain barrier, the catecholamines do not. Thus, all the catecholamines found in the brain are produced there.

The amount of catecholamines within the adrenal medulla and the sympathetic nervous system is generally constant; however, there are times when catecholamine levels in the body change dramatically. Initial changes that occur in the synthesis of these substances, in response to changes in demand, occur in minutes, whereas slower adaptational changes occur over much longer periods, even days in some cases. Catecholamines in the body are maintained at constant levels by a highly efficient process that modulates their biosynthesis, release, and subsequent inactivation. One example of a state with abnormal catecholamine levels is the condition known as pheochromocytoma, in which there is a tumor of the chromaffin cells of the medulla in the adrenal glands. It is characterized by hypersecretion of epinephrine, norepinephrine, dopamine, or dopa. In this condition urinary excretion of free catecholamines is also increased. The major clinical manifestations of this illness are high blood pressure, increased heart rate, sweating, rapid breathing, headaches, and the sensation of impending doom.

When an appropriate signal is received by a catecholaminergic neuron, it is transmitted down the axon to the presynaptic terminal, where it initiates the release of quanta of neurotransmitter into the synaptic cleft. The transmitter acts on receptors in postsynaptic neurons, resulting in the activation or inhibition of these cells.

C. Inactivation of Catecholamines

There are two major means for catecholamine inactivation: reuptake and enzymatic degradation. The reuptake system is fast and highly efficient. It operates through a rapid reuptake of released transmitters back into the presynaptic terminal. The involved transporter reuptake has two functions: (i) It rapidly inactivates transmission by removing transmitter from the synapse, and (ii) it conserves transmitter by restoring that which is not used in signal transmission. Catecholamines made in the neuron but not stored in the terminal vesicles are catabolized by a series of isoenzymes known as monoamine oxidases (MAO), which are located in most living tissues. There are two subtypes of MAO: MAO-A and MAO-B. In humans, MAO-B is four times more prevalent in the brain. The amount of MAO seems to increase with age. Another enzyme important in the breakdown of catecholamines released into the synapse is catechol-*O*-methyltransferase. Discussion of all the metabolic steps in degradation of catecholamines is beyond the scope of this article; however, it is important to note that drugs that increase catecholamine levels in the synapse, particularly the level of norepinephrine, are successful antidepressant medications.

The concentration of norepinephrine can be altered by two types of drugs: reuptake blockers, which prolong the life of norepinephrine in the synapse by preventing its reentry into the presynaptic neuron, and monoamine oxidase inhibitors, which interfere with breakdown by monoamine oxidase. From observations of the action of these drugs it has been proposed that depression is the result of low levels of norepinephrine in the brain; however, there is no direct evidence for this proposal. In support of the proposal, the antihypertensive drug reserpine, which depletes

norepinephrine and the other catecholamines, sometimes causes serious depression. Curiously, drugs that increase levels of serotonin, a noncatecholamine found in the brain, are also antidepressants. Norepinephrine and epinephrine also act as hormones when released from the adrenal medulla. Epinephrine is the principal catecholaminergic hormone produced in the medulla. Norepinephrine is the primary neurotransmitter in all postganglionic sympathetic neurons except for those that supply the vasodilator blood vessels of the skeletal muscular system and the sweat glands. The sympathetic nervous system and the parasympathetic nervous system make up the autonomic nervous system, which helps regulate the visceral functions of the body. The autonomic nervous system has control centers that are located in the spinal cord, hypothalamus, the reticular formation of the medulla oblongata, and other regions of the brain system. The centers located in the spinal cord and in the brain stem are regulated by the hypothalamus, which also communicates with the pituitary and cerebral cortex. This interconnection enables the complex orchestration of multiple somatic, visceral, and endocrinological functions.

The noradrenergic system has two major areas of origin in the brain: the locus coeruleus and the lateral tegmental nucleus. The projections of this system extend to all regions of the brain. As explained earlier, dopamine is the precursor in the synthesis of norepinephrine and epinephrine. In addition, dopamine has its own complex system and specialized function.

The dopamine system is composed of three subdivisions: mesocortical, mesolimbic, and nigrostriatal systems. The mesocortical system extends from the ventral tegmentum to a variety of areas, such as the olfactory tubercles, the accumbens, and the prefrontal cortex. The neurons of the mesolimbic system originate in the substantia nigra and the ventral tegmentum and project to the accumbens and amygdala. It is believed that the limbic system is probably more involved in regulating certain mental processes. The nigrostriatal system extends from the substantia nigra to the neostriatial regions. In addition to other functions, the nigrostriatal system is involved in movement. Disturbances of vital structures in this area are related to illnesses such as Parkinsonism.

D. Catecholaminergic Receptor Sites

Catecholamine receptors are proteins embedded in the plasma membrane of a neuron. Activation of these receptors by catecholamines can produce excitatory and/or inhibitory responses. In many cases, receptor number is increased or decreased as an adaptive response. For example, blockage of dopamine receptors by antipsychotic drugs, which are dopamine receptor antagonists, often results in a compensatory increase in the number of receptors. Many types of catecholamine receptors respond to one of the three catecholamines.

E. Dopaminergic Receptors

Five types of dopamine receptors have been identified. They are all called dopamine receptors because they all respond to dopamine and are relatively homologous in structure; however, two types, D_1 and D_2, can be discriminated pharmacologically by both agonists and antagonists. It is very likely that drugs selective for the other three types will also be found. The ability to selectively activate or inactivate different aspects of the dopaminergic system with drugs that act on one receptor type has made it possible to explore the role that the D_1 and D_2 dopaminergic system plays in behavior. The role of the other three types (D_3–D_5) is not clear.

1. D_1 receptors are found in the caudate nucleus and cortex. There are a variety of extraneural sites where these receptors are located, including the vascular structures of the brain, heart, and renal and mesenteric systems.
2. D_2 receptors have been identified in the putamen, caudate nucleus, and striatum as well as in limbic structures and in low density in the cortex. Two subtypes of D_2 receptors have been identified (D_{2a} and D_{2b}), but differences in anatomical location and physiological properties have not been worked out.
3. D_3 receptors have been identified in the limbic system.
4. D_4 receptors have recently been identified in the frontal cortex, basal ganglia, medulla, midbrain, and amygdala. The D_4 receptor demonstrates the greatest similarity to the D_2 family of receptors.
5. D_5 receptors have been identified in the caudate, putamen, olfactory bulb, and tubercle as well as in the nucleus.

F. Adrenergic Receptors

There are two types of adrenergic receptors, with subdivisions within each:

1. α-Adrenergic receptors α_1-Adrenergic receptors are located on postsynaptic effector cells such as those on the smooth muscles of the vascular, genitourinary, intestinal, and cardiac systems. Additionally, in humans these receptors are located within the liver. α_2-Adrenergic receptors inhibit the release of certain neurotransmitters. For example, at the presynaptic level in certain adrenergic nerve cells, these receptors inhibit norepinephrine release, whereas in cholinergic neurons they are responsible for inhibiting acetylcholine release. α_2-Adrenergic receptors are also located in postjunctional sites such as the β cells of the pancreas, in platelets, and in vascular smooth muscle. Although there are at least two subtypes of both α_1- and α_2-adrenergic receptors, the details concerning the actions and localization that would differentiate these particular subtypes have not been worked out.

2. β-Adrenergic receptors β_1-Adrenergic receptors have been located in the heart, the juxtaglomerular cells of the kidney, and the parathyroid gland. β_2-Adrenergic receptors have been identified in the smooth muscles of the vascular, gastrointestinal, genitourinary, and bronchial structures. Additionally, β_2-adrenergic receptors have been located in skeletal muscle and the liver as well as on the α cells of the pancreas, which are responsible for glucagon production. β_3-Adrenergic receptors are reported to be located in adipose tissue.

G. Plasma Catecholamines

The three catecholamines, when found intact in plasma, do not come from the brain because they cannot cross the blood–brain barrier; however, their metabolites can. Thus, metabolites in plasma originate both in brain and in peripheral tissues. Study of these metabolites has provided insight into the role that catecholamines play in behavior. However, direct study of catecholamines in living human brain tissue has not been possible. Fortunately, imaging technologies such as positron emission tomography (PET), magnetic resonance imaging, and single positron emission computerized tomography open up possibilities for visualizing catecholaminergic function in live conscious human subjects during waking hours. In addition, some of these imaging techniques can quantify neurotransmitter receptors and identify concentration differences at the synaptic level following psychopharmacologic administration. A variety of methods are available for measuring catecholamines in plasma.

II. IMPACT OF CATECHOLAMINES ON BEHAVIOR

Much of the information that is available concerning the functions of catecholamines in regulating human behavior directly results from the use of a group of medications often called psychotropic drugs and antidepressant medications called thymoleptics. Other medications that impact on catecholamines include psychostimulants, such as dextroamphetamine and methylphenidate (commonly known by its trade name, Ritalin) and L-dopa (which has been used to treat Parkinsonism), as well as a medication that was initially used to treat hypertension. Most of these drugs affect more than one system (e.g., dopaminergic, noradrenergic, or serotonergic systems). Catecholamines have been proposed as mediators of many psychiatric illnesses, including schizophrenia, Tourette's syndrome, depression, autism, attention deficit–hyperactivity disorder, stereotypic movements, tremors, and substance abuse. More generically, catecholamines also play a critical role in the stress response. Unfortunately, there is no definitive evidence for their role in the etiology of these illnesses. What is definite, however, is the role that catecholamines play in mediating the action of mood-altering and mind-altering drugs. There is speculation about which dopamine receptors these agents block to produce improvement, but the prevailing view is that the more traditional agents block D_2 receptors, whereas the newer atypical agents (such as clozapine) may also block D_4 (as well as D_1–D_3) receptors. These newer agents may also differ from the older agents in their ability to bind to serotonergic receptors of the 2A type. Nonetheless, as mentioned previously, the similarity between the D_2 and D_4 receptor families in terms of their structure and function lends insight into the pharmacologic efficacy of both newer and the more traditional antipsychotic agents on illnesses such as schizophrenia. The fact that agents that block dopamine receptors produce improvement in schizophrenia has led to the proposal that schizophrenia is caused by overactivity of the dopaminergic system. In support of this so-called dopamine hypothesis, one group has reported an increased density of D_2 receptors in brains of schizophrenic patients using PET. Increased density of D_2 receptors in postmortem brain tissue from patients with schizophrenia has also been reported. However, most patients have received neuroleptic treatment, which can cause these changes. Thus, it is not clear whether this increased density is an effect of the pathophysiology or the result of treatment. It is well established that reducing dopaminergic activity

with neuroleptics inhibits hallucinatory activity and normalizes delusional or paranoid thinking. It seems probable that the dopaminergic systems, particularly the D_2 and D_4 systems, have a physiological role in keeping thinking and level of suspiciousness in bounds. Curiously, patients who respond well to antipsychotic medication have a decrease in plasma homovanillic acid (HVA), the principal metabolite of dopamine, during treatment, whereas nonresponders do not. What is odd about this finding is that most plasma HVA does not come from the central nervous system.

Antipsychotics improve other symptoms associated with schizophrenia, such as impaired thought processes and attentional problems. Thus, it seems that the dopaminergic system may also regulate associative processing and attention. Drugs that improve psychotic symptoms have another important effect: They produce emotional blunting or so-called "flat affect." Inasmuch as these drugs reduce dopaminergic activity, it seems that dopamine may play a role in affect regulation.

Another illness that may illuminate the role of dopamine in regulation of behavior is Tourette's syndrome. This is an illness with onset usually between the ages of 4 and 8 years of age; however, it can occur at any time. It is characterized by rapid, repetitive movements known as motor tics that can be as simple as eye blinking or as complex as assuming contorted body positions. In addition to these movements, vocal tics occur ranging from repetitive coughing and throat clearing to shouting obscene words (coprolalia). These utterances can be a great source of embarrassment to the affected individuals. Both the vocalizations and the motor tics respond to antipsychotic drugs that are, of course, dopamine receptor blockers. This effect on Tourette's symptoms occurs even though the patients are not psychotic. Although dopamine is known to play a role in integrating motor movements, there is a distinct possibility that it may also inhibit socially undesirable movements and vocalizations.

It seems that Tourette's syndrome is in some way related to obsessive–compulsive disorder (this latter illness being particularly prevalent in families of Tourette's patients). Obsessive–compulsive disorder is often responsive to drugs that increase serotonergic activity. However, in one study, two dopamine agonists (methylphenidate and dextroamphetamine) were significantly more effective than placebo in reducing the symptomatology of obsessive–compulsive disorder. Thus, there appears to be a complex interaction between the serotonergic and dopaminergic systems in the regulation of psychomotor activity.

The study of psychological depression and its treatment can also help to illuminate the role of catecholamines in the regulation of behavior. Drugs such as the tricyclic antidepressants and the monoamine oxidase inhibitors, both of which increase norepinephrine in the synapse, are useful in treating depressed patients. As a result of these observations, it was first concluded that depression resulted from abnormally low activity of the noradrenergic system. It now appears, however, that increasing norepinephrine levels via drug treatment serves to compensate for unknown pathology in depression, affecting other transmitters besides norepinephrine.

These observations are nevertheless informative. It seems probable that norepinephrine, by regulating its own activity, and in concert with other transmitters, plays a role in the relief and prevention of depression if not in the cause of depression. Norepinephrine may regulate mood, level of emotional arousal, sleep/wakefulness states, and appetite (all of which are often disturbed in depression). However, as mentioned previously, it should be kept in mind that with the advent and demonstrated efficacy of the selective serotonin reuptake inhibitors in the treatment of major depression, the implications of abnormalities within the serotonergic system cannot be ignored.

Autism is a serious psychiatric condition that begins in infancy or early childhood. It is characterized by a qualitative impairment in interaction and socialization. Autistic children appear to be oblivious to their surroundings but ironically can react with a temper tantrum if a single toy is moved from its usual location. They often lack both verbal and nonverbal communication skills. Speech may be limited to repeating a word over and over (perseverations), and they may not even point to something they want in order to obtain it. Autistic individuals exhibit a restriction of activities and engage in a variety of odd behaviors, such as sniffing, twirling and spinning, and inordinate interest in the single function of an object (i.e., staring at a wheel spinning on a toy car for hours). They also sometimes present with violent or self-injurious behavior and temper tantrums. Some patients may possess striking talents beyond their apparent cognitive capacity (often referred to as savant-like traits). A few can masterfully play the piano without ever receiving instructions or memorize an entire city's bus routes.

The pervasive developmental disorders are illnesses that may vary in presentation. They may present with only one feature of autism or most of the features (but by definition not all). Although elevated serotonin levels in whole blood seem to be the most consistent

finding in autism, there have been reports of increased norepinephrine levels in the plasma of these children when compared to normal control groups. Additionally, the effectiveness of dopamine-blocking neuroleptics on attention and improvement of certain behaviors in autistic children cannot be ignored. One investigation of biological markers in children with pervasive developmental disorder reported that the group that responded to treatment had lower initial plasma levels of HVA.

Attention deficit–hyperactivity disorder (ADHD) is characterized by overactivity, fidgetiness, impulsivity, and distractibility. It is more frequently seen in males and there is usually a family history of the disorder. The illness begins in early life but often is not diagnosed until the child is in school because its pathology becomes more evident when more controlled behavior is required. There is strong evidence for the involvement of the catecholaminergic systems in this illness. Prevailing theories propose a decrease in turnover of both dopamine- and norepinephrine-like effects. Oddly, increases in noradrenergic activity in the activating systems of the brain produce emotional arousal and many of the attentional abnormalities of ADHD. In addition, normal adults given the psychostimulants used to treat ADHD in children show the expected activating effects. Interestingly, in the rat, many experimental manipulations have also implicated the dopaminergic system's role in locomotor activity. The quantification of motoric overactivity was directly correlated to two observations within the dopaminergic system. The first was the degree of dopaminergic damage sustained, and the second was onset of D_1 receptor supersensitivity.

Despite the fact that much of our knowledge regarding the impact of catecholamines on behavior has come from observations related to medication trials, recent advances in genetic techniques also further our hopes for future breakthroughs. Certain neurological illnesses, such as hereditary progressive dystonia and supranuclear palsies, have been linked to abnormalities in tyrosine hydroxylase gene expression. Pioneering efforts to investigate the genetic components of other neuropsychiatric conditions are under way. Two such illnesses may be schizophrenia and bipolar disorder. In these illnesses, classical modes of inheritance are not evident. However, there is clinical evidence via adoption, twin, and family studies that implicates a hereditary component to these illnesses. Being able to approach this problem from multiple perspectives employing the evolving fields of molecular biology and genetics may eventually result in the identification of the precise genetic deficits and locations of these complicated illnesses. Currently, several research groups are exploring catecholaminergic-related markers in these fields.

The role of catecholamines in substance abuse has received substantial attention. Most drugs of abuse behaviorally work on the premise of being strong positive reinforcers. These include agents such as nicotine, morphine, cocaine, and the amphetamine group. Increased dopamine levels in mesocortical regions have been identified with the use of amphetamines, cocaine, and even nicotine. In the case of cocaine and the stimulants, the increase is produced by blocking the dopamine transporter system. As discussed previously, dopamine has also been implicated in the production of hallucinations. Many of the agents that increase dopamine levels, such as L-dopa, amphetamines, and cocaine, are also capable of inducing hallucinations.

In the realm of stress, many different corporal systems interact to help the human organism respond. There is usually activation of the adrenergic neurons in the hypothalamus. There is a close link between the cortisol and adrenergic response. In fact, increases in norepinephrine induce cortisol-releasing hormone production. Stimulation of the adrenergic nervous system causes elevations in plasma epinephrine and norepinephrine levels. These produce an increase in glucose. Furthermore, epinephrine induces the breakdown of fats from adipose tissues. In these situations, epinephrine and norepinephrine promote increased heart rate and blood pressure. The purpose of these changes is to facilitate the delivery of needed material for fight or flight. Situations often perceived as stressful to the body include strenuous physical exertion, acute anxiety states, and serious cardiovascular compromise.

III. CONCLUSIONS

Catecholamines in the brain act at the highest levels of mental function. Although their role in specific mental disorders is not entirely clear, there is little doubt that they modulate, if not mediate, functions such as processing of associations, integration of thought processes with movement and speech, emotional tone or affect, mood, appetite, arousal, and sleep/wakefulness state. Most of these functions have not been successfully modeled in nonhuman species, leaving their study to be carried out in living humans. This

limitation has made more than inferential conclusions regarding behavioral and mental function impossible.

New technological advances in functional brain imaging and in studies of gene expression in accessible human cells have opened new windows into the brain, but definitive studies await further advances.

University of California, Los Angeles

GLOSSARY

category-specific agnosia A neuropsychological deficit in the ability to identify members of a specific natural category accompanied by a near normal ability to identify objects in other categories.

exemplars Items that qualify as category members, especially items that were seen during category learning.

explicit knowledge (declarative knowledge) Learned information that is available to awareness. Individuals are consciously aware that they learned this information, and it can be deliberately applied in order to make judgments.

implicit knowledge (nondeclarative knowledge) Learned information that is not available to awareness. Individuals show that they have learned this information through their performance, but they are not able to describe the information that is guiding their performance.

prototype The most typical example of a category. It is generally considered to be an arithmetic average of all exemplars of the category or an item containing the most frequently occurring features in the category.

Category learning in its broadest sense refers to all learning in which a response is generalized to multiple stimuli. Although all organisms exhibit category learning to some extent, humans in particular have a remarkable ability to learn to classify items based on extremely complex criteria. For example, a wine connoisseur is able to readily classify novel wines by grape, and an art historian can swiftly and accurately judge the period of a newly encountered painting. Human category learning also includes more mundane abilities, such as determining that a papaya is a fruit the first time one is tasted or being able to use nonverbal cues to determine a friend's mood.

I. INTRODUCTION

Given the ubiquity of category learning in human experience, it is likely that there are different types of category learning that depend on different neural systems. A major focus of research in cognitive psychology during the past several decades has been the development of category learning models that can broadly account for the behavior of human participants in category learning experiments in the laboratory. An approach that has recently gained favor is to acknowledge that different types of category learning exist and to more clearly delineate them based on their behavioral and neuropsychological characteristics.

II. RULE-BASED VS EXEMPLAR-BASED CATEGORIZATION

Many common categories can be objectively defined by a set of rules that define membership in the category. For example, a set of criteria must be met to classify an animal as a mammal (e.g., it must be warm-blooded). Given these criteria, an individual should be able to accurately classify new examples. For other categories,

the set of rules that define membership are less clear. Although many people may agree that a particular concerto sounds like a piece by Mozart, it is difficult to create a list of necessary and sufficient conditions that define the category of Mozart concertos other than the fact that they were composed by Mozart. In this case, one gets the sense that classification is occurring based on previous experience with different exemplars of the category. An exemplar-based strategy implies that an individual is classifying new items based on their similarity to previously experienced items in that category.

The fact that some categories can be readily defined by rules and others cannot does not necessarily indicate that two different category learning systems exist. Perhaps people are always using rules to classify, although sometimes those rules are difficult to verbalize and may be imperfect. For example, with enough insight, it seems possible to create a fairly valid set of explicit heuristics that would discriminate Mozart concertos from works by other composers. On the other hand, the existence of explicit rules that define category membership does not automatically mean that people are actually using those rules. People may judge that an animal is a mammal because of its similarity to other mammals rather than by checking whether a list of conditions is satisfied. The fact that people classify a cow as a mammal more readily than a whale demonstrates that the satisfaction of membership conditions is not the only factor influencing classification. Both rule-based and exemplar-based strategies are plausible, but it appears that people are biased to use one strategy over the other depending on the category type and the conditions of learning. Early in training, individuals might use rules to classify items if they are available, or they might try to induce rules if none are given. However, later in training, when they have had extensive experience with examples, they may base their category decisions on their previous experience with these examples. Figure 1 shows examples from two categories that can be classified according to a set of rules or according to similarity to other members of the category.

Neuropsychological data suggest that classification according to rules involves prefrontal cortex. One of the classic tests of prefrontal cortical dysfunction is the Wisconsin Card Sorting Test, in which the subject must induce a sorting rule (categorize by color, shape, etc.). Patients with prefrontal damage are particularly impaired when they must shift from one category to another. Neuroimaging studies have shown dorsolateral prefrontal activity in humans categorizing stimuli according to rules. Also, the application of rules requires working memory, an ability that has been strongly associated with prefrontal (especially dorsolateral) function. In order to determine whether an item satisfies a list of conditions, one must maintain these conditions in a short-term buffer and actively test the item against each condition. Putting demands on working memory by requiring subjects to perform a concurrent task has been shown to induce subjects to shift to an exemplar-based strategy from a rule-based strategy. The fact that young children do not use a rule application strategy as readily as adults do is also supportive of the idea that prefrontal cortex is important for rule-based classification. The frontal lobes mature relatively late in development, continuing into adolescence.

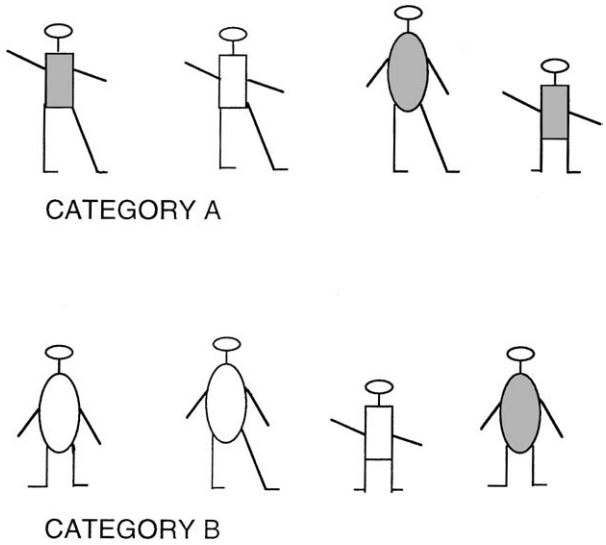

Figure 1 Two categories of stick figures. The figures in category A have at least two of the following three attributes: square body, shaded body, and long legs. The figures in category B have at least two of the following attributes: round body, white body, and short legs. Subjects may be inducing these rules during training, or they may be basing categorization judgments on similarity to previously experienced items in the two categories.

Classification rules tend to focus on individual attributes of stimuli. In addition to working memory, the application of rules requires the ability to selectively attend to attributes of the stimuli and to shift attention between different attributes. Neuroimaging findings are consistent with this idea in that posterior parietal brain regions are active during rule application. These regions are typically active in selective attention tasks and are damaged in patients exhibiting the neglect syndrome, especially when the lesion is on the right side.

III. EXEMPLAR-BASED CATEGORIZATION: GENERAL OR SPECIFIC?

Although people often make classification judgments on their previous experience with examples of the category, the type of exemplar-based information could take different forms. After experiencing many examples of a category, such as chairs, we may have formed an idea of what a typical chair looks like, and we may compare new examples to this typical chair and classify these new items as chairs depending on their similarity to this typical chair. This typical example, or category prototype, represents the average of experienced category exemplars. When additional exemplars are encountered, the representation of the prototype is modified to reflect the new experience. By this view, category knowledge takes the form of abstracted information that is distinct from memories of the individual exemplars. In support of this prototype view is the fact that category prototypes or average members of categories are much easier to classify than members that are very dissimilar from the prototype. People are much faster to acknowledge that a robin is a bird rather than a penguin or chicken. In fact, in artificial categories generated in the laboratory, speed and accuracy of classification can be predicted quite well by the similarity of an item to the prototype (Fig. 2).

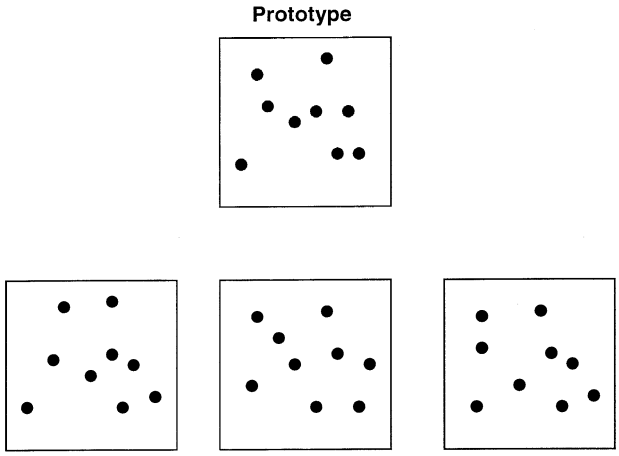

Figure 2 Illustration of a category based on a prototype. The top dot pattern serves as the prototype, and the patterns below are all distortions created by moving each dot in the prototype in a random direction. After studying a series of such distortions, subjects are very likely to classify the prototype as being part of the category.

However, such effects do not necessarily mean that people are using prototypes to make classification judgments. According to another view, people base their classification judgments on the average similarity to previously encountered items stored in memory. This view is appealing because of its parsimony in that one does not need to hypothesize a separate base of category-level knowledge. This view can also account for the superior classification of prototypes because the prototype is generally the item that is similar to the largest number of category members since it is the average of all experienced examples.

Based on experimental data, it is difficult to distinguish between the possibility that people use information general to the category to classify items or that they make comparisons to specific examples stored in memory. These two views often make similar predictions about which items are easiest and most difficult to classify. One approach to addressing this question has been to test patients with amnesia on category learning tasks. Because these patients have sustained damage to medial temporal lobe or midline diencephalic regions, they exhibit a profound deficit in declarative memory. Declarative memory refers to the conscious memory of facts and events. Declarative memory would be accessed on a recognition test of previously seen examples of a category. Because of their declarative memory deficits, amnesic patients should not be able to learn categories normally if this ability depends on declarative memory for examples. If, however, amnesic patients are able to learn to classify items based on category membership despite poor memory for the individual training examples, it would suggest that category-level information could be learned independently of exemplar memory.

In fact, there is evidence that amnesic patients can learn at least some types of categories normally. For example, amnesic patients have been shown to be able to perform normally on an artificial grammar learning task. In this task, subjects view a series of letter strings that were formed according to a finite-state rule system (Fig. 3). This rule system allows only certain letters to follow other letters. After viewing the strings, subjects are told for the first time that the items they had just seen all followed a set of rules and that their task is to classify a new set of items as following these rules or not. Although subjects typically believe that they did not learn anything about the grammatical rules, they nevertheless can reliably classify new items at a level that is significantly higher than chance. Amnesic patients perform as well as normal subjects on this task, although they are severely impaired in recognizing the letter strings that were used during training. Thus, it appears that subjects acquire information

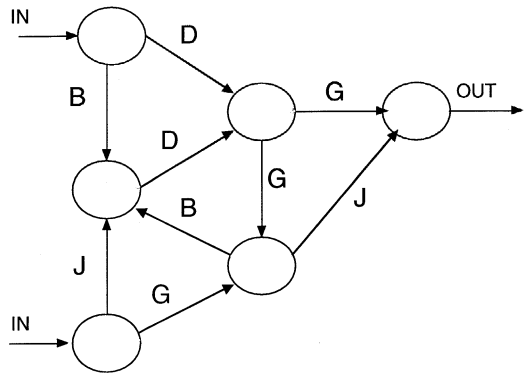

Figure 3 A rule system used to generate an artificial grammar. Letter strings are generated by traversing the diagram along the arrows from the "in" arrows to the "out" arrow. An additional letter is added as each arrow is traversed. For example, DGJ, BDG, JDGBDG, and GBDG are examples of letter strings formed according to the artificial grammar. In contrast, DDJ, BGDJ, and JDGB cannot be formed according to the rule system.

about the grammatical category that is independent of memory for individual exemplars.

The findings from amnesic patients suggest that information about categories can be acquired that is distinct from explicit memory for exemplars. However, these results do not preclude specific exemplar-based classification in other paradigms. It is likely that when subjects are given a small number of highly distinctive and memorizable exemplars, they will consider these in making classification judgments.

IV. EXPLICIT VS IMPLICIT KNOWLEDGE IN CATEGORIZATION

The issue of whether category learning is based on explicit or implicit knowledge has often been conflated with the question of the form of the information acquired. For example, the demonstration that performance on a certain task was mediated by fairly concrete properties of exemplars would often imply that this information was learned explicitly since this information would be apparent to subjects during training. Conversely, if it appeared that subjects were learning complex rules about the category, then it was assumed that this knowledge was implicit since subjects often cannot readily verbalize these rules. However, the issues of rule vs exemplar learning and abstract vs specific exemplar learning are both orthogonal to the question of whether this information is explicitly or implicitly learned. Just as subjects may be fully aware of applying explicit rules to a categorization task, they may also be consciously aware of memories of examples that are being used for comparison to new items. Likewise, category rules or exemplar information could be learned implicitly. Exemplar-derived information such as a prototype seems likely to be learned implicitly since people are not usually aware that they are forming the prototype during the training, and this knowledge is generally expressed only through classification performance. Item-specific information may also be learned implicitly. For example, priming is a form of implicit learning that is specific to particular stimuli and similar mechanisms could contribute to category learning in some circumstances.

Studies of artificial grammar learning illustrate the point that it is important to define what exactly is being learned in order to determine if learning is implicit or explicit in a particular category learning task. In the artificial grammar learning paradigm, several different types of learned knowledge may contribute to classification judgments. Although the category is operationally defined by adherence to the finite-state rule system, it appears that subjects base their judgments to a great extent on whether the test item contains bigrams and trigrams that occurred with high frequency in the training set. Thus, the fact that subjects cannot explicit state the grammatical rules does not necessarily mean that the knowledge they are using to make category judgments is implicit. They may be perfectly aware of which letter bigrams and trigrams were frequent in the training set and are using this information to make their judgments. It is therefore crucial to first understand what learned information subjects use for category judgments in order to attempt to test whether this information is implicitly learned or if subjects are explicitly aware of this information.

V. NEUROPSYCHOLOGICAL STUDIES OF CATEGORY LEARNING

One approach that has successfully demonstrated implicit learning of categories is the use of data from amnesic patients. The fact that amnesic patients are able to exhibit normal category learning in several paradigms suggests that implicit learning can support normal performance. In addition to their intact performance on artificial grammar tasks described previously, amnesic patients have been shown to perform normally on category learning based on similarity to a prototype, category learning based on feature frequency, and category learning based on probabilistic associations. In each case, amnesic

patients are severely impaired at recognizing training exemplars. Importantly, there are circumstances in which amnesic patients do not perform as well as normal subjects, particularly when there are a relatively small number of exemplars used during training that are highly memorizable. In those tasks in which amnesic patients are able to perform normally, it is likely that subjects are not basing their judgments on explicit comparisons to items stored in memory because the exemplars are not easy to memorize (letter strings and dot patterns) or a large number of exemplars are presented during training. These data further indicate that categorization can be accomplished using different kinds of knowledge depending on the task. It can be concluded that category learning does not necessarily depend on those medial temporal lobe structures that are required for explicit memory of exemplars.

If category learning can proceed independently of the brain system that supports explicit memory, it shows that other neural systems are capable of supporting this ability. Because there are multiple types of learned information that are used in different categorization tasks, it is highly likely that there is no single neural system involved in all category learning or even involved in all implicit category learning. Rather, different types of category learning are likely to depend on different brain systems. One system that has been linked with implicit learning is the basal ganglia. Damage to the basal ganglia as a result of Huntington's disease or Parkinson's disease impairs motor skill learning. Recent evidence suggests that the basal ganglia may be involved in nonmotor forms of implicit learning as well. These patients are impaired on classification tasks in which category membership is based on a nonverbal rule or a probabilistic association that is difficult to verbalize. For example, in the probabilistic classification task, a set of arbitrary cues (such as cards with geometric shapes) are probabilistically associated with one of two outcomes (such as rain or shine if a weather prediction cover story is used). Because of the probabilistic nature of the associations, memory for single trials is not very helpful for performing the task. Rather, information gleaned over multiple trials must be used to classify each instance. Patients with basal ganglia disorders exhibit severe impairments in this task. According to one model of implicit category learning, the connections from the striatum to the prefrontal cortex via the globus pallidus and thalamus are the basis for the associations between perceptual inputs and responses that are the basis for nonverbal rule learning. It may be that the striatum actually represents the rules, or that the rules just emerge as a property of these perception–action associations. These nonverbal rules are represented as associations between cues and responses (''If triangles appear, press sun key''). In contrast, for verbal rules that are learned declaratively, there is an explicit association between stimuli and outcomes (''If triangles appear, the weather will be sunny, so I should press the sun key'').

Another potential difference between basal ganglia-dependent category learning and learning that depends on the medial temporal lobe is the fact that the neostriatum may be the actual storage site for learned associations. In contrast, the role of the medial temporal lobe in explicit memory is time limited. Patients with medial temporal lobe damage are able to retain memories from long before their brain injury, demonstrating that the eventual storage sites of these memories are not in the medial temporal lobes. In models of neostriatal function, memories are stored in the connections within the basal ganglia or in the connections within the basal ganglia and thalamus. These models predict that damage to the basal ganglia would disrupt not only new nonverbal category learning but also previously learned nonverbal rules. These patients would not necessarily be impaired at categorizing stimuli based on previously learned explicit rules based on semantic knowledge (sorting fruits and vegetables into separate categories). However, there is some indication that these patients have difficulty with some previously learned implicit rules pertaining to language and social cognition, two domains in which rule learning appears to proceed implicitly.

VI. NEUROIMAGING STUDIES OF CATEGORY LEARNING

Functional magnetic resonance imaging (fMRI) studies also support the idea that there are multiple forms of categorization that depend on different brain systems. Application of explicit rules appears to activate frontal and parietal regions involved in working memory and selective attention. When nonverbal rules appear to guide responses, as in the probabilistic classification task described previously, activation has been reported in the caudate nucleus. Interestingly, this neostriatal activity was accompanied by a decrease in activity in the medial temporal lobe, suggesting that the explicit and implicit learning systems may act in a competitive manner.

Neuroimaging data also support the idea that there are different neural substrates for implicit category learning based on rules vs implicit category learning based on exemplar-based information. In addition to nonverbal rule learning tasks, amnesic patients are able to classify new items based on their similarity to a prototype abstracted from the training exemplars. Both types of category learning can proceed independently of the medial temporal lobe memory system. However, they appear to depend on different systems. Patients with Parkinson's disease are able to learn to classify dot patterns based on a learned prototype despite their impaired performance on nonverbal rule learning. Rather than a neostriatal locus, neuroimaging evidence suggests that learning about these naturalistic categories may rely on regions involved in perceptual processing. After viewing dot pattern stimuli that are all distortions of a prototype, viewing the prototype dot pattern is accompanied by a decrease in blood flow in occipital regions. This blood flow decrease is similar to what is seen in perceptual priming paradigms. Items that had been previously presented trigger less blood flow in occipital regions than do new items. This blood flow decrease can be understood in terms of a decrease in the resources required to process primed stimuli vs new stimuli. Priming has often been considered to result because of increased ease, or fluency, of processing old stimuli relative to stimuli that have not been recently processed. This is thought to occur because of residual activity in neural representations activated by the initial presentation of the item. Categorization judgments may also be influenced by perceptual fluency. Presentation of a set of exemplars would result in residual activity in the neural representations of each individual exemplar. Because the prototype is the average of all the training exemplars, one might expect that the prototype might enjoy the greatest amount of enhanced processing from the summed residual activity of all the training exemplars. Under this scenario, the prototype is not represented separately from the training exemplars but, rather, emerges as a consequence of the overlapping neural representations of category exemplars.

This process may account for categories such as dot patterns that are defined merely by perceptual features. Can a similar perceptual fluency mechanism account for prototype effects seen in semantic categories? For example, it is a well-known finding that subjects are able to confirm that a robin is a bird compared to confirming that a penguin is a bird. It may be that as exemplars of a category are encountered, a link between the representation of the item and its category is formed. These exemplar representations would partially overlap given the degree to which features were shared. When primed with a category name, items near the prototype would benefit from the fact that they are similar to many individual exemplars that have been linked to the category. Thus, semantic priming would result in stronger semantic priming for even novel items near the prototype because of the wide partial activation induced by these items. Again, this phenomenon would occur as a consequence of overlapping semantic representations of individual exemplars.

VII. THE REPRESENTATION OF CATEGORIES IN THE BRAIN

Category learning is accomplished by several different brain systems that are specialized for the acquisition of different forms of information used to make category judgments. As discussed previously, nonverbal rules may be stored in corticostriatal loops. Exemplar-based categories, which form the basis of our semantic knowledge of the world, appear to be stored in the cortex of the temporal lobe. This is particularly true for categories we learn about through visual experience with the world (e.g., animals and plants) and thus may be thought of as the output of the ventral visual stream, or "what" pathway. Categories of actions may be represented in frontal regions associated with movement planning. Data from fMRI studies have revealed that categories such as houses, faces, and chairs activate distinct regions of posterior temporal cortex (Fig. 4). Perhaps categories that are defined more conceptually than visually (animals that live in the jungle and things you can buy at a supermarket) are represented more anteriorly in the temporal lobe. Patients with anterior and lateral temporal lobe damage exhibit a breakdown in semantic knowledge including deficits in sorting items into categories that had been learned previously. This phenomenon is seen most readily in patients with semantic dementia, but it also occurs with the diffuse temporal lobe damage seen in Alzheimer's disease.

The existence of patients with category-specific agnosias has been used as support for the idea that stored semantic knowledge in the brain is organized to some extent by category. Patients have been described with specific deficits in identifying members of such categories as faces, animals, tools, or foods as the result of brain damage. It may be that knowledge about these different categories is stored separately in distinct

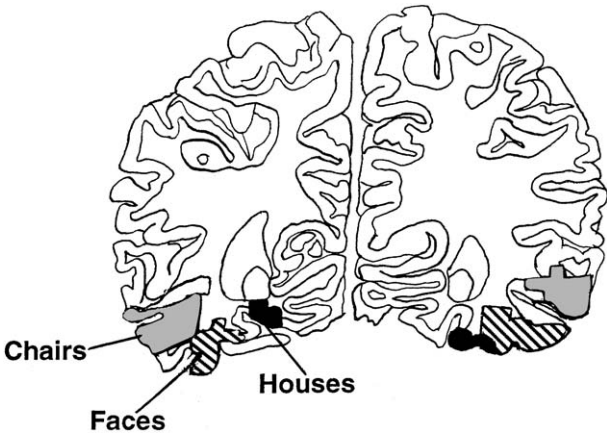

Figure 4 A coronal section showing regions in the ventral temporal lobe that are differentially activated by chairs, faces, and houses.

brain regions. In this view, damage to one region could disrupt knowledge of animals, for example, but not knowledge of other objects.

The view that there are category-specific regions of the brain has been challenged by the fact that different categories may have different processing requirements and thus brain specificity may reflect modules for different types of processing. For example, animals are composed of basically the same parts in the same configuration (eyes, legs, tail, etc.), and they are identified by the relative sizes and shapes of those parts. In contrast, tools generally contain parts that are present in some other tools but not others, and they are identified by the location of the parts relative to each other. A broom and a brush are differentiated by the relative position of the handle and bristles. Thus, brain regions associated with identifying animals may actually be important for processing the metric properties of the parts of items. ''Tool areas'' could actually be involved in processing the relationships between parts. It may be that knowledge about different category members is stored in a distributed fashion throughout the brain, but that specific cortical areas are involved in analyzing particular stimulus properties that are confounded with category membership.

VIII. CONCLUSION

Category learning can occur effortlessly, seeming to arise simply as a consequence of exposure to exemplars. In other cases, category learning results from explicit hypothesis testing to determine diagnostic rules. Because categories can be defined based on a wide range of information, it makes sense that multiple mechanisms would have evolved to allow humans to classify new instances based on previous experience. Being able to make predictions about new stimuli based on experience with members of the same category is highly adaptive. Thus, it is not surprising that multiple mechanisms evolved to enable this ability for a wide range of stimuli. Part of the challenge to cognitive neuroscientists is to precisely define the different forms of information acquired by subjects in category learning tasks in order to guide the search for neural substrates.

Cerebellum

MARCO MOLINARI
Rehabilitation Hospital and Research Institute, Santa Lucia Foundation, Rome

GLOSSARY

cerebellar cortex Formed by three cellular layers—the molecular, Purkinje, and granular layers.

cerebellar deep nuclei Three pairs of nuclei embedded in the cerebellar white matter in which the neurons projecting to extracerebellar structures are located. The vast majority of these neurons are excitatory.

climbing fiber Second largest component of fibers that reach the cerebellum. They are formed by axons of inferior olive cells and terminate on neurons located in the deep nuclei as well as on Purkinje cells.

dismetria Disturbance of the control of range direction and force of muscle contraction determining disruption of coordination of multijoint movements.

mossy fiber The largest group of fibers that reach the cerebellum. They terminate on neurons located in the deep nuclei as well as on granule cells.

Purkinje cell Only efferent cell of the cerebellar cortex. It has an inhibitory effect on the cerebellar deep nuclei.

The cerebellum is a portion of the brain that plays a key role in many aspects of human behavior. This article presents available data on the cellular and physiological organization of the cerebellar circuits, stressing from a multidisciplinary standpoint, the new functions that have been recently added to the traditional cerebellar repertoire of motor learning and motor control.

I. INTRODUCTION

The cerebellum (literally, ''little brain'') is located in the posterior cranial fossa. It represents 10% of the total brain volume and contains more than 50% of the total number of neurons of the central nervous system. Its general organization resembles that of the telencephalon with an outer mantle of gray matter, the cerebellar cortex, that covers an internal white matter in which the deep nuclei (i.e., the three pairs of deep cerebellar nuclei) are embedded. The cellular organization of the cerebellum is quite simple; its basic structure has been well-known since the beginning of the 20th century due to the work of Ramon y Cajal (Fig. 1). Because of the simplicity of the cerebellar anatomical organization and its remarkable similarity in all mammals, it seemed to be an easy field for investigating the relationships between brain structure and function; thus, it has always been a field of extreme interest for neuroscientists. Since the pioneering work at the end of the 19th century, the number of studies devoted to the cerebellum and its function has increased enormously and many theories on the cerebellar function have been proposed. Despite all these efforts, we still do not know exactly what the cerebellum is. In recent years, particularly due to unpredicted clinical and functional neuroimaging findings, the classical theories focused on the role of the cerebellum in motor control and motor learning have been reconsidered and new hypotheses have been advanced. In this article, after a general update on the available data regarding the anatomical and functional cerebellar organization, recent theories on the functions of the cerebellum are reviewed.

II. ANATOMY

When the occipital bone is opened, the dorsal surface of the cerebellum is clearly visible in the posterior cerebral fossa. The most prominent aspect of the cerebellar surface is the presence of many parallel convolutions that run perpendicular to its anteroposterior axis. In saggital sections, this chain of parallel convolutions has a characteristic appearance, like leaves stemming from the same trunk. This feature, defined by early anatomists as arbor vitae (''life tree''), is at the origin of the term folia (''leaves'') applied to the cerebellar convolutions. From medial to lateral, three major subdivisions are easily recognizable: a median one (the vermis) and two lateral parts (the hemispheres). Hemispheres and vermis are clearly separated only in the inferior surface where two longitudinal furrows are evident. In the dorsal surface, there is only a shallow groove between the vermis and the hemispheres and the folia run from one side to the other without obvious interruptions. A further subdivision of the hemispheres in an intermediate and a lateral part has been proposed on the basis of functional and connectional evidence, but it cannot be recognized on the basis of anatomical landmarks. Anatomical subdivision on the anteroposterior axis is mainly based on the features of the cerebellar foliation. Two deep transverse fissures divide the cerebellum into three major lobes. The primary fissure, clearly visible from the dorsal surface, separates the anterior lobe

from the posterior one. On the underside of the cerebellum, the posterolateral fissure separates the floccular nodular lobule from the posterior lobe. The appearance of the human cerebellum on nuclear magnetic resonance (NMR) scans is depicted in Fig. 2. Further subdivisions have been proposed based on smaller fissures or on the difference in the orientation of the folial chains (Fig. 3). A subdivision often applied is that proposed by Larsell in 1952. He divided the vermis into 10 lobules labeled with Roman numerals from I to X and also applied this division to the corresponding lobules of the hemisphere, adding the

prefix H to the Roman numerals. The cerebellum covers the fourth ventricle and is attached to the brain stem by three pairs of fiber bundles—the inferior, median, and superior cerebellar peduncles.

At the cellular level, the cerebellar cortex is extremely homogeneous in its organization. The intrinsic circuitry is based mainly on five types of neurons organized in three layers: the granular layer, in which granule cells are present, is closest to the white matter; the Purkinje cell layer is the intermediate one and is formed by a single line of Purkinje cells; and the molecular layer is the most external one, in which, beside the dendrites of the Purkinje cells and the parallel fibers of the granule cells, three types of interneurons are present (i.e., the Golgi, stellate, and basket cells).

Granule cells are the only excitatory neurons of the cerebellar cortex and represent by far the largest population of neurons in the cerebellum and possibly the whole brain. The short claw-like dendrites of each granule cell receive many terminals from many different mossy fibers; each terminal forms a complex synaptic arrangement, the glomerulus, in which a terminal from a Golgi axon also participates. The mossy fiber system is the main afferent system. It conveys all information reaching the cerebellum except for that originating from the inferior olives, which reaches the cerebellum through the climbing fibers. These latter fibers terminate directly on the proximal smooth branches of the Purkinje cells. Each Purkinje cell receives only a single climbing afferent, but each climbing fiber contacts up to 10 Purkinje cells. Purkinje cells present a dendritic tree that is relatively smooth in the basilar part but is full of spines in the distal part where terminals from many parallel fibers are present. The general branching of the Purkinje cell dendritic tree is flattened, with its main axis perpendicular to the main axis of the parallel fibers. This arrangement allows each Purkinje cell to be contacted by many different parallel fibers. Each fiber makes very few synapses over the same Purkinje cell but contacts many different ones. The axon of the Purkinje cells is the only way out of the cerebellar cortex and provides a powerful inhibitory control over the deep cerebellar nuclei and some vestibular nuclei.

Whereas the stellate and the basket cells provide a feed-forward inhibition over the Purkinje cells, the axons of the Golgi cells synapse over the incoming

mossy fibers providing a powerful inhibitory feedbackward control over the granule cells. Although all three types of interneurons are GABAergic, only the Golgi cells also colocalize glycine. Recently, a new type of cerebellar interneuron not expressing GABA or glycine was identified—the unipolar brush cell. These cells are located in the granular layer; they receive massive input from a single mossy fiber and their axons contact granule and Golgi cells. Their distribution is not uniform throughout the cerebellar cortex and their function is still a matter of debate. Another cell type recently characterized is that formed by the cells located just under the Purkinje cell layer: the Lugaro cells. These cells present their major cell and dendritic axes parallel to the Purkinje cell layer; they are inhibitory interneurons and their function must still be clarified.

Besides mossy and climbing fibers, a third, often neglected, afferent system has been known since the late 1960s. It is formed by beaded fibers that terminate throughout the cortical layers. This system is considered to play a modulatory role on the activity of the cortical circuits. These fibers originate from different extracerebellar sources of known modulatory function, such as locus ceruleus, raphe nuclei, or brain stem cholinergic cells, and from different nuclei of the hypothalamus.

On their way to the cerebellum, mossy fibers as well as climbing fibers give off collaterals for the deep cerebellar nuclei from which all the cerebellar output fibers originate. On their way to extracerebellar targets, deep cerebellar nuclei axons give off collaterals that contact granule cells or the neurons that give off mossy fibers in precerebellar nuclei. In addition to excitatory projecting neurons, deep cerebellar nuclei also contain small GABAergic cells that project to the inferior olive. The general schema of the cerebellar circuitry is shown in Fig. 4.

The strong anatomical and functional interrelationships between the deep cerebellar nuclei and the cerebellar cortex were clearly defined by Masao Ito, who proposed the term corticonuclear microcomplex (Fig. 5) to describe the basic functional mode of the cerebellum.

Parallel longitudinal zones can be identified in the cerebellar cortex on the basis of output organization and differences in the expression of certain proteins by subpopulations of Purkinje cells. These microzones are perpendicular to the main axis of the folia and they extend across one or more lobules, some of them spanning the entire rostrocaudal length of the cerebellum. These zones were identified and numbered and their connectivity was fully determined, demonstrating that this pattern is preserved in the corticonuclear projections as well as in the olivocerebellar ones. Therefore, each longitudinal zone projects to a specific sector of the deep nuclei and receives the same input from the inferior olive. This basic schema is repeated through the mediolateral extent of the cerebellum and can be identified as the basic functional module of the cerebellum (Fig. 6). The organization of the mossy fiber input is more complex and its relation to the microcomplex organization is still uncertain. Different brain stem and spinal centers project to the cerebellum through the mossy fiber system, terminating in lobule-specific patterns with a roughly preserved somatotopical pattern with the hindlimb located ventrally and face and forelimb located more rostrally in both anterior and posterior lobules. Within this general arrangement, the finer somatotopy is "fractured," as shown by Wally Welker in 1987, without preservation of the precise topographical relation between adjacent receptive fields (Fig. 7).

A. Cerebellar Afferents

1. Mossy Fiber Afferent System

As stated previously, the vast majority of cerebellar afferents reach the cerebellar cortex as mossy fibers. Spinocerebellar and trigeminal cerebellar mossy fibers convey interoceptive, proprioceptive, and exteroceptive information from limbs, trunk, and face. The input is directed to the cerebellum by second-order neurons and not directly by primary sensory neurons. The organization of the vestibulocerebellar system is different. The labyrinth sends afferents directly to the cerebellar cortex; in addition to these primary vestibular afferents, secondary vestibular fibers originating from the four vestibular nuclei also reach the cerebellum. These latter nuclei are also unique in the cerebellar organization since they are the only ones, besides the deep cerebellar nuclei, that receive Purkinje cell axons. This specific organization is confined to the oldest cerebellar region, termed the vestibulo- or archicerebellum.

Many different cell groups located within the reticular formation give origin to mossy fibers. The lateral reticular nucleus is the recipient of mainly spinal afferents but it also receives relevant amounts of fibers from the cerebral cortex and the red nucleus. Mossy fibers from the lateral reticular nucleus terminate bilaterally in the cerebellum with a clear ipsilateral

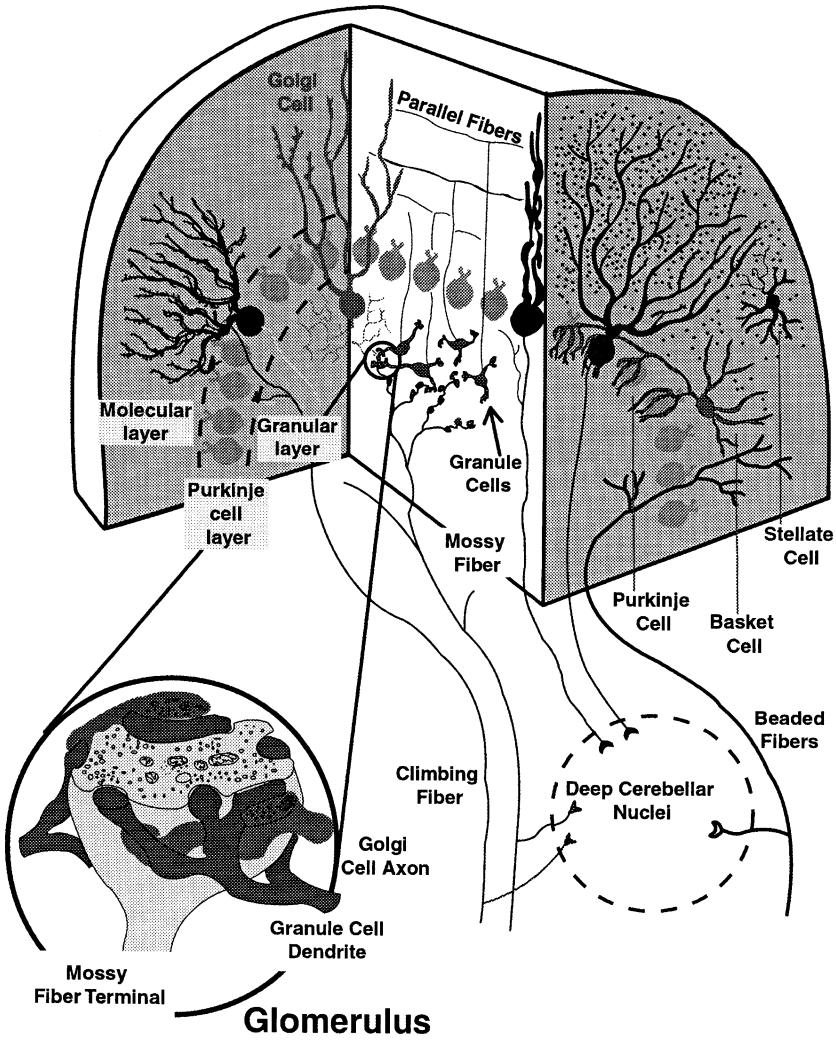

Figure 4 Schematic reconstruction of the circuitry of the cerebellar cortex. A single cerebellar folium has been sectioned vertically, both in longitudinal and transverse planes. (Lower left) Enlargement of a single glomerulus (modified with permission from L. Heimer, *The Human Brain and Spinal Cord*, Fig. 120, p. 213. Copyright © 1983 by Springer-Verlag).

prevalence. The paramedian reticular nucleus conveys information from the somatosensory and frontal cortices mainly to the vestibulocerebellum. The pontine reticular cells provide visual-related information from cortical and subcortical structures mainly to vermal lobules VII and VIII.

Many of the cerebral cortical areas are connected with the contralateral cerebellum through the pontine mossy fiber system, the largest group of mossy fibers. Corticopontine fibers originate from layer V pyramidal cells and their terminal fields are organized topographically with the anterior cortical region located medially and the posterior one located laterally. The topographic organization is maintained in the pontocerebellar projection to the contralateral cerebellum (Fig. 8). However, this projection is not strictly contralateral since both ipsilateral and bilateral fibers have been described.

2. Climbing Fiber Afferent System

There is only one known source of climbing fibers—the inferior olive. This structure receives information from a wide range of brain structures funneling data from the periphery (spinal cord, dorsal column nuclei, trigeminal and vestibular nuclei, and

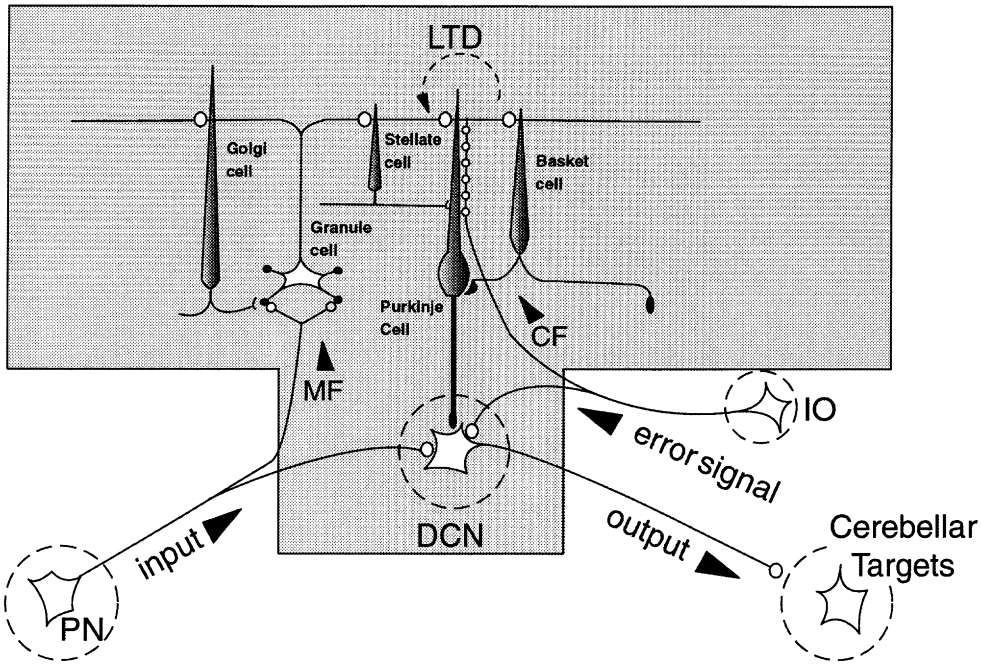

Figure 5 Cerebellar corticonuclear microcomplex as proposed by Masao Ito. nucleus of the solitary tract) and from higher brain structures (red nucleus, superior colliculus, pretectal area, and cerebral cortex) to the cerebellar cortex and deep nuclei. It is worth noting that a significant number of deep cerebellar nuclei fibers provide a return route from the cerebellum to the inferior olive cells.

Olivo cerebellaris projections are topographically organized in such a way that the different subnuclei of the inferior olive project to different longitudinal stripes of the deep cerebellar nuclei and the cerebellar cortex. This pattern coincides with the neurochemical pattern evidenced with zebrin and described previously. The overall organization is such that each inferior olive fiber sends one collateral to the deep cerebellar nuclei and one to the cerebellar cortex that project to the same sector of the deep nuclei.

B. Cerebellar Efferents

The only output system of the cerebellum is represented by the deep cerebellar nuclei. These nuclei receive massive projections from the Purkinje cells of the overlying cerebellar cortex. This connection is clearly topographic, with a general mediolateral and anteroposterior arrangement. Therefore, more medially placed Purkinje cells project to the medial nucleus, the most lateral ones project to the lateral nucleus, and the anterior lobe projects to the more anterior sectors of the nuclei, and the posterior lobe to the more posterior sectors. However, this general arrangement is not consistently maintained and some divergence and convergence have been reported. Virtually all climbing and mossy fibers give off a collateral for the cerebellar nuclei on their way to the cerebellar cortex. Thus, within the deep cerebellar nuclei there is a convergence of extracerebellar excitatory and Purkinje inhibitory synapses over the same projection neurons. The latter synapses greatly outnumber those of extracerebellar origin and are in a position, over the somata and proximal dendrites, to highly influence neuron firing. From the nuclei, efferent fibers leave the cerebellum mainly through the superior cerebellar peduncle; fewer fibers, mainly originating from the fastigial nucleus, leave the cerebellum through the inferior cerebellar peduncle. Once the brain stem is reached, both efferent systems give off an ascending and a descending branch.

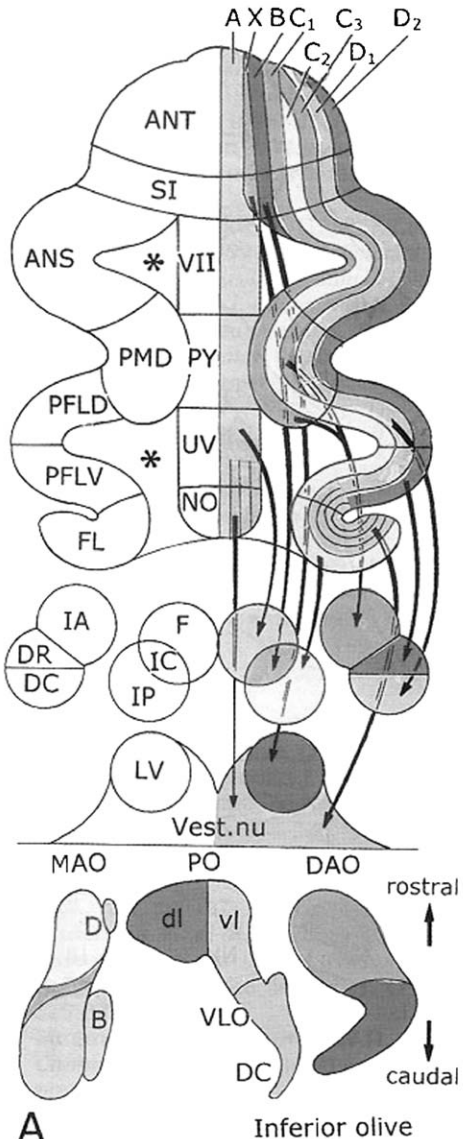

Figure 6 Zonal arrangement of corticonuclear and olivocerebellar projections illustrated on a flattened cerebellar cortex. Three groups of cerebellar nuclei with their corticonuclear projection zones can be distinguished: (i) the fastigial nucleus (F; the target nucleus of the vermal A zone), which is continuous through the intermediate cell group (IC; X zone) with the globose or posterior interposed nucleus (IP; C_2 zone); (ii) the emboliform or anterior interposed nucleus (IA; C_1 and C_3 zones) and the dentate nucleus, which can be subdivided into ventrocaudal (DC) and dorsomedial (DR) parts (target nuclei of the D_1 and D_2 zones, respectively); and (iii) the lateral vestibular nucleus of Deiters (LV; target nucleus of the vermal B zone). Zones in the flocculus and the nodulus project to the vestibular nuclei. The inferior olive is shown at the bottom of the figure in a horizontal projection. The zonal projections of the individual subnuclei are indicated with the same gray shading as shown in the top of the figure (reprinted from J. Voogd and M. Glickstein, The anatomy of the cerebellum. *Trends Neurosci.* **21,** pp. 370–375, copyright 1998 with permission from Elsevier Science).

The descending branch of the fastigial nucleus efferents is formed by ipsilateral, contralateral, as well as bilateral projections directed to many precerebellar nuclei, namely, the vestibular nuclei, the inferior olive complex, and large sectors of the reticular formation. The ascending branch is smaller and reaches several structures of the midbrain, the superior colliculus, and the dorsal thalamus.

Efferents from the interposed nucleus exit through the superior peduncle and are also organized in an ascending and a descending branch. Ascending fibers reach the red nucleus, where they terminate in the magnocellular part in a topographic manner, and the dorsal thalamus terminating in the VL nucleus as well as in the intralaminar nuclei. Descending interposed fibers terminate in reticular and inferior olive precerebellar structures.

The lateral nucleus is the recipient of the projections from the lateral part of the hemisphere and its efferents reach the contralateral parvicellular red nucleus and ventrolateral and intralaminar thalamic nuclei with the ascending branch. The descending branch is formed by fibers directed to the precerebellar stations that reach the lateral cerebellum: reticular formation, inferior olive, and the pontine nuclei. It is worth noting that the deep cerebellar nuclei also give off recurrent projections to the cerebellar cortex.

C. The Transcerebellar Loops

As already mentioned, many of the cerebellar circuits are organized in recurrent loops. This is particularly evident when the rubrocerebellar and cerebrocerebellar circuits are taken into account.

1. Rubrocerebellar Loop

A magnocellular and a parvicellular component can be recognized within the red nucleus. Both receive cerebellar fibers, the former from the interposed nucleus and the latter from the dentate nucleus. The two components project to different targets. Magnocellular cells give origin to rubrospinal fibers, whereas parvicellular cells project to the inferior olivary neurons and thus reverberate the information to the cerebellum through the climbing fibers. Within the red nucleus, there is a convergence of cerebellar and cortical inputs over the same neuron. This is particularly true in the parvicellular part, where cerebellar terminals tend to concentrate in the soma, and

proximal dendrites while cortical synapses are present in the distal dendritic branches. This arrangement is not fixed but can be functionally modulated as shown by lesion and inactivation experiments.

2. Neocortical Cerebellar Loop

The ascending branches of the efferents from the interposed and lateral nuclei and partially from the fastigial nucleus reach the contralateral thalamus and, in a much smaller amount, recross the midline in the thalamus, terminating ipsilaterally. This latter component is formed by axon collaterals of the main contralateral projection. Within the thalamus the cerebellar fibers terminate in the ventrolateral nucleus and in the intralaminar nuclei. The different cerebellar nuclei have segregated terminal areas within the thalamus, especially in higher mammals. Nevertheless, the precise relationships between cerebellar terminals and cortical and basal ganglia projecting thalamic cells must still be clarified. In general terms, cerebellar recipient thalamic nuclei project mainly to the frontal and prefrontal area, with some components reaching the posterior parietal association areas. The returning loop originates from layer V pyramidal cells located in almost all cortical areas except for the pole of the temporal lobe. These fibers do not reach the cerebellum directly; they terminate in a topographic pattern in the pontine nuclei, which in turn reverberate the information over the cerebellar cortex and deep nuclei.

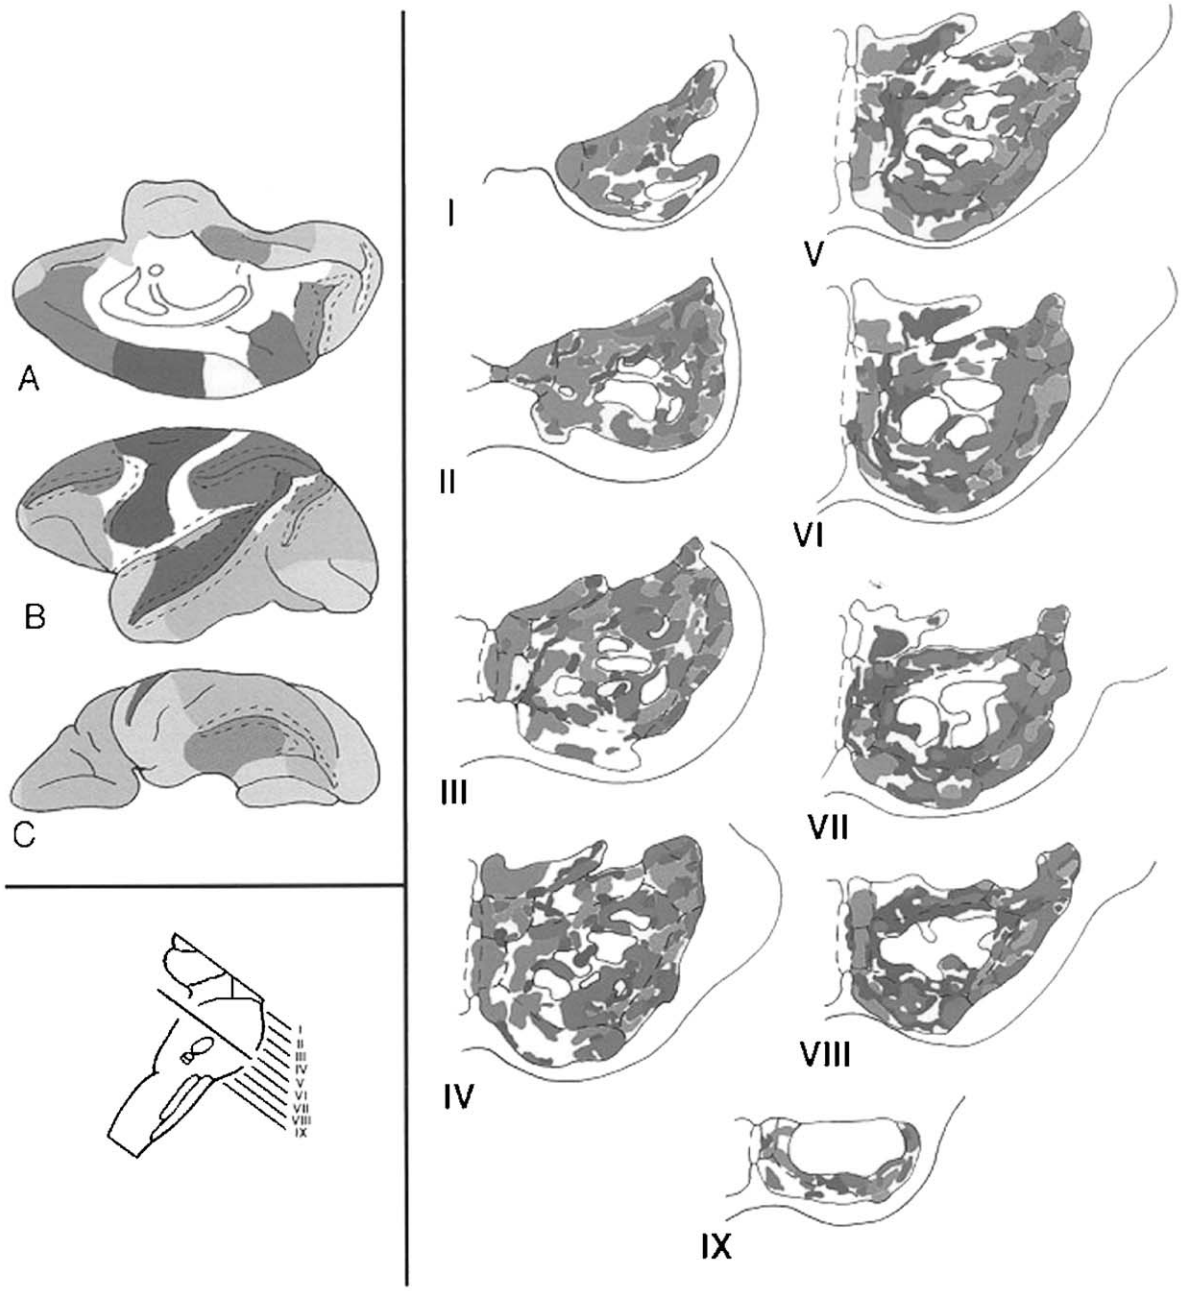

Figure 8 Composite color-coded diagram illustrating the distribution within the basilar pons of the rhesus monkey of projections derived from associative cortices in the prefrontal, posterior parietal, temporal, and parastriate and parahippocampal regions and from motor, premotor, and supplementary motor areas. The medial (A), lateral (B), and ventral (C) surfaces of the cerebral hemisphere are shown in the upper left. The plane of section through the basilar pons is shown in the lower left, and the rostrocaudal levels of pons I–IX are shown in the right. Cerebral areas that have been demonstrated to project to the pons using either anterograde or retrograde tracers are depicted in white, those areas studied with both anterograde and retrograde studies and found to have no pontine projections are shown on the hemispheres in light shading, and those with no pontine projections according to retrograde studies are shaded in gray. The dashed lines in the hemisphere diagrams represent the sulcal cortices. In the pons diagrams the dashed lines represent the pontine nuclei, and the solid lines depict the traversing corticofugal fibers. The associative corticopontine projections are substantial. There is a complex mosaic of terminations in the pons, and each cerebral cortical region has preferential sites of pontine terminations. There is considerable interdigitation of the terminations from some of the different cortical sites but almost no overlap (reproduced with permission from Schmahmann, 1997).

In Fig. 8, the pattern of the corticopontocerebellar loop is shown.

III. NEUROCHEMISTRY

A. Neurotransmission in the Cerebellar Circuits

As mentioned previously, the vast majority of the cortical interneurons are inhibitory and use GABA as a neurotransmitter. Although no other neurotransmitters have been shown for stellate and basket cells, in Golgi cells colocalization of GABA and other putative neurotransmitters has been shown. Approximately 70% of Golgi cells colocalize GABA and glycine, whereas choline acetyltransferase, the synthesizing enzyme for acetylcholine, has been found in approximately 5% of the Golgi cell population. The hypothesis that other neurotransmitters besides GABA are used by Golgi cells is confirmed by the presence of GABA, glycine, and NMDA receptors on granule cells that are the only target for Golgi axons.

Since the 1960s, Purkinje cells have been considered to use GABA as a neurotransmitter notwithstanding the extremely weak GABA or GAD labeling with immunohistochemical techniques. Recent *in situ* hybridization data have confirmed that Purkinje cell bodies and terminals do contain GABA. In particular, Purkinje cell terminals in the cerebellar deep nuclei have been shown to colocalize GABA and taurine, although the function of the latter amino acid is unknown.

The only excitatory circuitry of the cerebellar cortex is the granule cell parallel fiber one, and this circuitry employs glutamate as a neurotransmitter. The excitatory effect of glutamate as well as of parallel fiber stimulation on Purkinje cells has been widely studied and characterized at the molecular level.

Also, the two principal cerebellar afferent systems, the mossy fibers and the climbing fibers, are known to be excitatory in nature. Several lines of evidence indicate that glutamate is the main neurotransmitter of the mossy fibers. On the other hand, there is debate regarding which molecule is used by the climbing fibers; glutamate and aspartate are the main candidates. Other molecules have not been excluded. For instance, mainly on the basis of immunohistochemical evidence, acetylcholine has been proposed as a neurotransmitter for the mossy fibers originating in the medial vestibular nucleus and terminating in the flocculonodular lobe.

The so-called "third afferent system" is heterogeneous with respect to the site of origin and to the neurotransmitter employed. Noradrenergic beaded fibers have been described as originating from the locus ceruleus as well as from A8–A10 adrenergic cell groups in the mesencephalon. A diffuse serotonin system of beaded fibers has been observed immunohistochemically in the cerebellum. Surprisingly, these fibers do not seem to originate in the raphe but in a different part of the brain stem, such as the paramedian and lateral reticular formation, periolivary regions, and the lateral reticular nucleus. On the other hand, no data are available on the nature of the neurotransmitter employed by the raphe cerebellar projection that also sustains the beaded fibers.

B. Chemical Compartmentalization

Different chemical markers are unevenly distributed within the cerebellar cortex in adulthood or transiently during specific developmental phases. These chemical differences clearly challenge the idea of a uniform organization of the cerebellar cortex, and their correlation with functional diversities of the different cerebellar lobules might provide useful information to help clarify the cerebellar function. These many chemical markers include glycolipids as well as proteins. In the adult, these markers are mainly organized in seven sagittal bands of different intensities. In the anteroposterior dimension, chemical patterning of a lower number of markers has been shown. Karl Herrup and Barbara Kuemerle attempted to summarize the available data in a three-dimensional grid of the cerebellar cortex (Fig. 9).

IV. PHYSIOLOGY

The classical definition of the cerebellar function is that of fine-tuning for muscle control. This view derived mainly from the observation that in humans and in experimental animals, cerebellar damage impairs posture and fine coordination of movements. This was supported by a variety of experimental and clinical data. Nevertheless, there is still debate regarding which physiological events support the cerebellar function as motor controller. In general, it is believed that cerebellar control is involved with motor adaptation and motor learning more for compound limb movements than for simple movements.

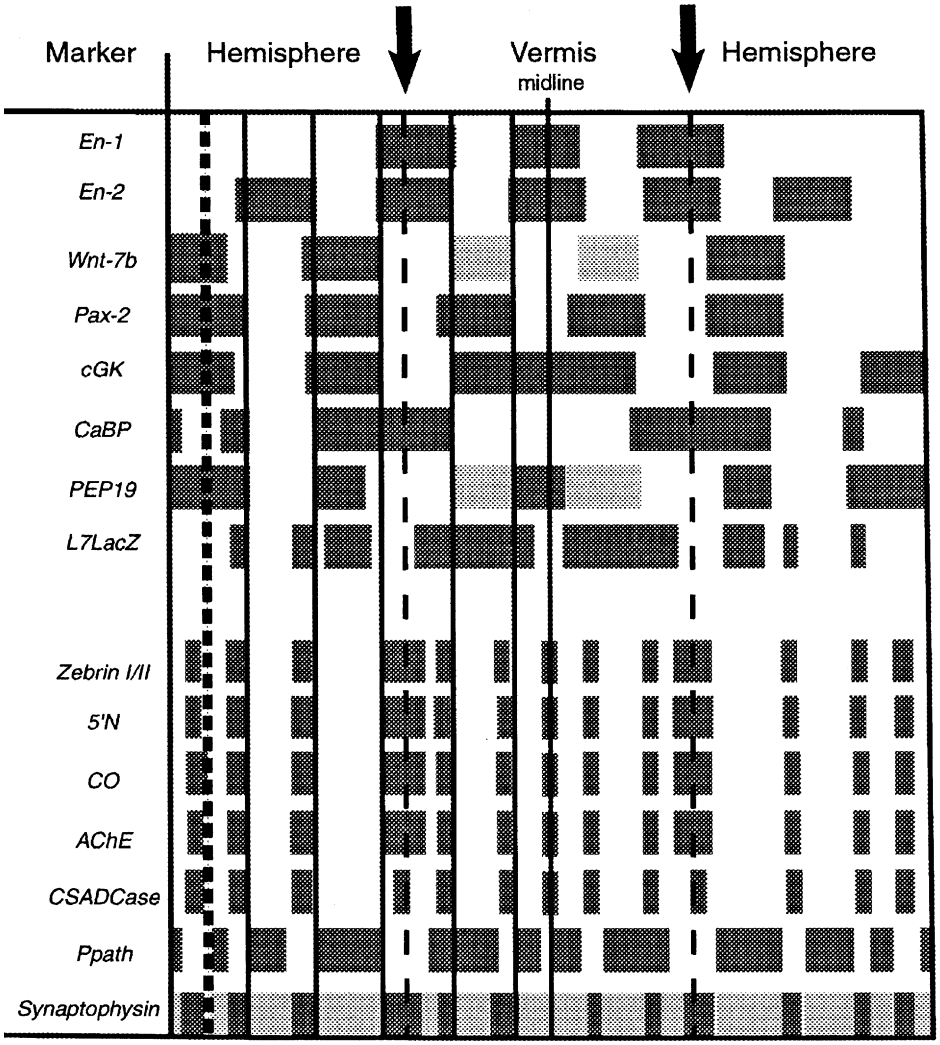

Figure 9 Mediolateral compartment boundaries of the vertebrate cerebellum according to a model proposed by Karl Herrup and Barbara Kuemerle. Six different compartments are located on either side of the cerebellar midline. Shaded boxes denote intensity of gene and antibody expression. Compartmental boundaries are represented by vertical solid lines and vermis–hemisphere junctions are represented by arrows and dashed vertical lines. The top half of the figure represents markers that are expressed transiently during development; the bottom half represents localization of stable markers in the adult cerebellum (from Herrup and Kuemerle, 1997. Reprinted, with permission, from the *Annual Review of Neuroscience*, Vol. 20. © 1997 by Annual Reviews. www.AnnualReviews.org).

For a long time, the most widely accepted theory on how the cerebellum acts was that proposed by David Marr and James Albus and further developed by Masao Ito. According to the Marr–Albus–Ito theory, the main focus of cerebellar activity is acquisition and control of skillful movements through the interactions between climbing fiber (CF) and mossy fiber (MF) inputs in the Purkinje cells (PCs). In resting conditions, PC activity is mainly under the control of the MF–granule cell–parallel fiber (PF) system, whereas the CF system modifies the pattern of PC activation by influencing the strength of the PF/PC synapses. In particular, the convergence of PF and CF activation over the same PC is considered to be capable of inducing a long-term depression (LTD) of the efficacy of PF/PC synapses. Thus, the correct setting for a given movement is coded in the PC–deep nuclei output system by the PF fibers; this pattern is tuned by the so-called "error signal" conveyed through the CF afferents. Although a great deal of experimental evidence can be interpreted according to the Marr–Albus–Ito theory, an increasing body of data challenge the role of LTD in motor learning and the importance of the cerebellum as a motor memory storage site. Most of

the evidence that indicates a primary role of the cerebellum in motor learning derives from experiments examining the substrate responsible for the acquisition of the nictitating membrane reflex in the rabbit or from those responsible for the vestibuloocular reflex (VOR). From these experimental approaches and from evidence derived from patients with cerebellar damage, two major hypotheses about the role of the cerebellum in motor learning have been drawn. First, the cerebellar role in learning is mainly related to participation in the execution of motor behavior (the performance hypothesis). Second, the main cerebellar role is that it acts as a storage site for the motor engrams of different motor tasks (the storage hypothesis). Despite the efforts of many different laboratories, the conflict between the storage and performance hypotheses has not been resolved and a comprehensive theory of the cerebellar role in motor control is far from established.

A different approach to the problem of the cerebellar function focuses on the importance of the cerebellum as a sensory acquisition device rather than a center for motor control and/or learning. This line of thought stems from the anatomical and physiological evidence of massive sensory information that is conveyed to the cerebellum. Recently, it has received important support from functional neuroimaging and experimental data. Within this line is the data acquisition hypothesis, suggested by James Bower and his group. It states that the cerebellum is specifically involved in monitoring and adjusting the acquisition of most of the sensory data on which the nervous system depends. According to this theoretical framework, motor deficits seen after lesion of the cerebellar circuits depend more on the disruption of the inflow of sensory information on which the motor system depends than on a lack of cerebellar control over the motor centers. This approach is in line with the organization of the fractured sensory map described previously. It has been proposed that a key for interpreting the spatial relationships among the different sensory representations is their need to cooperate for better active sensory exploration. The highly expanded and detailed representation of the whisker in the lateral hemispheres of the rat cerebellum seems to support this proposal. The massive cerebellar output toward the motor center is interpreted as the need for direct on-line control of fine movements to optimize the acquisition of sensory information by adjusting the position among the different tactile surfaces and between them and the object being explored.

Marco Molinari and collaborators have also shown the importance of the cerebellum in the acquisition of the sensory information required for implicit learning of a visuomotor task in cerebellar patients. These patients were severely impaired in the acquisition of a task that required a finger-tapping response to the presentation of visual stimuli in a random or fixed sequence. The deficit was particularly due to the inability to recognize the recurrence of the fixed sequence. As shown in Fig. 10, the declarative knowledge of the presented sequence was very poor in all groups of cerebellar patients. On the other hand, a

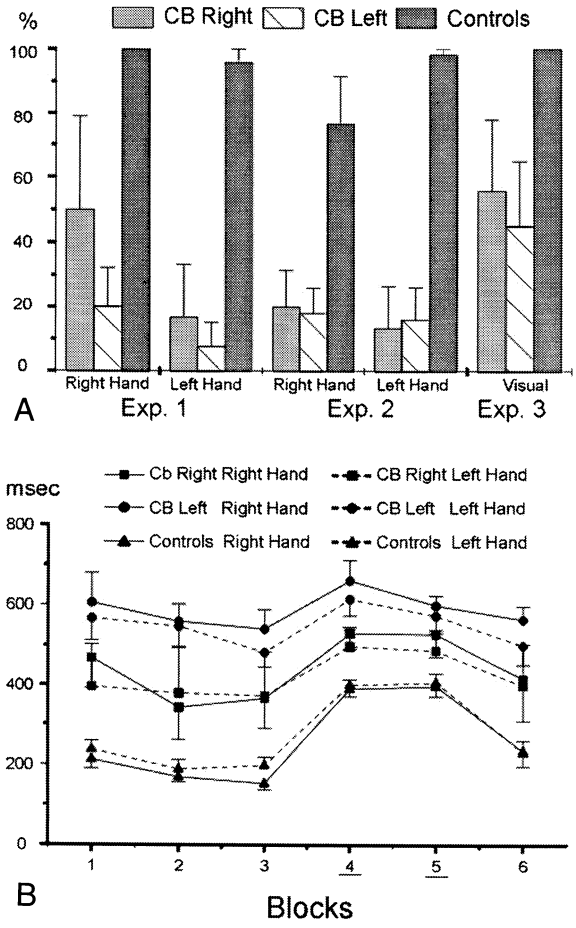

Figure 10 (A) Percentage of sequence items reproduced after a serial reaction time task based on an 8-digit sequence (Exp. 1), a 10-digit sequence (Exp. 2), and after visual presentation only (Exp. 3). (B) Reaction times (msec) after acquisition of a declarative knowledge of the sequence to be reproduced. Note that the presentation of random sequence (underlined blocks) induces an increase in the reaction times in all groups. CB right, group of patients with focal cerebellar lesion on the right side; CB left, group of patients with focal cerebellar lesion on the left side; controls, age- and education-matched control group. vertical bars, standard error (reproduced with permission from Molinari *et al.* (1997). *Brain* **120,** 1753–1762. Reproduced with permission of Oxford University Press).

clear modulation of the response was observed when the subjects received instructions about the digit sequence that would be used in the test. In this condition, a clear improvement in reaction times was observed. This suggests that cerebellar patients are particularly impaired in detecting a sequence and that performance can be improved if knowledge of the sequence has been previously acquired.

The importance of the cerebellum in sensory analysis has also been reported in other forms of learning—that is, in visual perceptual learning by Lucia Vaina and coworkers or in observational learning by Maria G. Leggio and coworkers. In the former functional magnetic resonance imaging (fMRI) study, clear cerebellar activation linked to an early phase of learning a motion perception task was observed. In the latter study, it was reported that lesioning the cerebellum can impair the acquisition of spatial strategies through observation. Both cases clearly demonstrate the role of the cerebellum in processing the sensory information required by the cortical modules during learning.

V. CEREBELLUM AND COGNITION

Possibly the most exciting aspect of cerebellar research in recent years is the converging evidence demonstrating the importance of the cerebellar computational properties for cognition. In 1986, in a seminal work, Henrietta Leiner, Alan Leiner, and Robert Dow challenged the scientific community's generally accepted dogma that the cerebellum is a pure motor structure. Their work was based mainly on anatomic and phylogenetic considerations and they proposed a significant role for the cerebellum in mental functions. Since then, clinical, experimental, and particularly functional neuroimaging data have been reported indicating cerebellar participation in a variety of cognitive functions from mood control to language, from attention to timing, and from spatial data management to memory. This completely new field in cerebellar research has profoundly affected our knowledge of what the cerebellum does and has forced us to reconsider the generally accepted theories on the cerebellar function.

A. Implicit Learning

The classical definition of implicit memory is that of Daniel Schacter—that is, "Implicit memory is revealed when previous experiences facilitate performance on a task that does not require conscious or intentional recollection of those experiences." In contrast to implicit memory, which emphasizes "implicitness" during retrieval, implicit learning primarily refers limited awareness/attention during encoding. This type of learning includes quite different phenomena, such as classical conditioning; learning of skills, procedures, or sequences; priming; and category learning. In many instances, the cerebellum has been considered to be the storage site of such information or directly involved in the acquisition of the implicit competence.

1. Conditioning

Classical eye blink conditioning may be the simplest form of implicit learning, and lesion studies have demonstrated that the cerebellum is essential for this type of conditioning. However, the learning vs performance argument has not been definitively solved in this paradigm either. In this line, although lesion studies in humans have demonstrated eye blink conditioning impairment in cerebellar patients, activation studies in normal volunteers have been controversial in demonstrating cerebellar activation during acquisition of the conditioning. Although this type of learning might appear to be quite different from cognitive functions such as language or working memory, its study is of extreme value since the same basic mechanisms might act independently from the characteristics of the information processed by the cerebellar circuits.

2. Vestibuloocular Reflex

The VOR evokes eye movements in the direction opposite of head movement in order to facilitate vision by minimizing image motion on the retina. This reflex is based on a relatively simple three-neuron arc and its association with the evolutionary old cerebellum, the flocculus, has provided researchers with a simple model for studying the functions of the cerebellum. The gain in the VOR is dependent on visual image motion and head rotation. Thus, by manipulating the ratio between image motion and head rotation it is possible to induce a slip of the image on the retina. If this happens, in order to reduce the retinal slip, adaptation in VOR gain must occur. Since a lesion of the cerebellar flocculus does not abolish the reflex but specifically affects its adaptation, this particular circuit has been identified as the modifiable part of the reflex circuits responsible for its adaptation. Thus, it has

been intensively studied as a model of implicit learning. This model has proven particularly useful in studying the neurophysiological and molecular bases of learning. According to the Marr–Albus–Ito theory, adaptation in the VOR is caused by modification in the output of the cerebellar cortex induced by interaction between the head rotation information carried by the mossy fibers and the image error information carried by the climbing fibers. In particular, this interaction induces LTD in the synapses of the Purkinje cells. Although there is consensus about the importance of the flocculus in the induction of VOR adaptation, its role in the retention of the adaptation is a matter of debate.

3. Motor Skill Learning

As previously mentioned, many theories on cerebellar function focus on motor learning as a key cerebellar function. Many data indicate that the cerebellum supports the acquisition and/or adaptation of simple forms of motor skills. Visuomotor and single joint movements adaptation are impaired in patients with cerebellar damage as well as in animals with permanent or transient inactivation. The cerebellar circuitry and learning-related changes in cerebellar activation have been observed during the acquisition of motor pursuit and trajectory tasks in fMRI studies. On the other hand, experimental evidence indicating a preeminent role of the cerebellar circuits in the acquisition of more complex motor skills is scarce.

In 1990, Jerome Sanes and coworkers reported motor skill learning impairment in cerebellar patients in a mirror tracing task. Recently, the ability of cerebellar patients to improve their performance in generating a trajectory connecting five points was studied by Helge Topka and coworkers. It was found that the patients were able to acquire the task similarly to controls but they were severely impaired in improving their skill at high speed. The authors suggest that these findings indicate a major role of the cerebellum in adaptation learning rather than skill learning.

4. Sequence Learning

Implicit learning of sequences has been investigated by many researchers under a variety of conditions and with many approaches. In general, sequence learning requires making a sequence of motor responses either directly or in response to an external visual or auditory pacing signal. Sequence learning is monitored by assessing performance levels or by recording reaction time from the external cue onset to motor response. In virtually all studies it was found that the cerebellum is required for the acquisition of this skill. However, the significance of the cerebellar contribution to sequence learning is unclear. Different hypotheses have been put forward that mainly stress the role of the cerebellum in timing or processing sensory information or in intervening in sculpturing the motor engram required by the response sequence. Recently, these hypotheses were reviewed by Valentino Braitemberg and coworkers.

B. Cerebellum and Language

Since the beginning of the 20th century, it has been known that cerebellar lesions induce speech deficits. However, these deficits were considered to be dependent on the lack of motor coordination during phonation. Recently, the pure motor nature of the cerebellar influence on speech was challenged on different grounds. Cerebellar activation was documented in language-related tasks independently from motor activity, and cognitive language deficits were also observed in patients with cerebellar damage.

One of the first examples of cerebellar activation in language-related tasks was observed during a verb-generation task. Subsequently, cerebellar activation was confirmed in tasks requiring different types of word generation. Clinically, agrammatic speech and verbal fluency impairment were reported in subjects with cerebellar damage.

Agrammatism is a specific linguistic impairment that does not affect syntactic knowledge; it is often described in patients with left frontal lobe damage. At least two different laboratories reported agrammatism in patients with focal cerebellar lesions. In both cases, the linguistic deficit was very specific. No impairments were detected on an extensive battery exploring general intelligence, orientation, memory, visuospatial skills, praxis, and frontal lobe functions. Language examination was normal for all parameters including sentence comprehension, with the notable exception of dysarthria and agrammatic speech. One group (Marina Zettin and coworkers) interpreted their finding as related to the development of compensatory mechanisms because of the articulatory difficulties due to dysarthric speech; the other group (Caterina Silveri and coworkers) proposed that cerebellar damage might induce agrammatism by affecting the coupling verbal working memory and application of syntactic

rules. According to their interpretation, the cerebellum acts as an "interareal functional coordinator" allowing the production of grammatically correct sentences.

Verbal fluency is the capacity to generate lists of words according to a given rule; it can be either a letter of the alphabet (e.g., retrieval of words that begin with the letter F) or a semantic category (e.g., retrieval of words from the semantic category of "animals"). The existence of verbal fluency deficits in both semantic and letter categories is controversial. Maria Leggio and coworkers reported that cerebellar patients are specifically impaired in the letter category task of word fluency with sparing of the fluency for the semantic category. A qualitative analysis of the strategies used for word grouping during word fluency performances revealed other characteristics of the cerebellar deficit. Although semantic clustering was well preserved in all cerebellar patients, phonological clustering was clearly impaired. The authors interpreted these findings to be due to cerebellar patients' difficulty in acquiring a relatively new verbal skill (phonemic grouping) even though they were not impaired when the verbal fluency was based on a commonly used and well-practiced verbal skill (semantic grouping).

Thus, currently there is little doubt that the cerebellum intervenes in cognitive functions related to language. However, the specific cerebellar contribution is still controversial. Lesion studies suggest that damage of the cerebellar circuits does not directly affect the mental linguistic system but may impair satellite functions, such as verbal working memory or the acquisition of new verbal skills. However, this suggestion needs to be confirmed, possibly with ad hoc fMRI experiments.

C. Cerebellum and Writing

Support for the hypothesis that the cerebellum is a cognitive controller outside the main cognitive processor but necessary for intermodule coordination derives from the observation that cerebellar patients can develop peripheral afferent dysgraphia. According to recent theories on the dysgraphias, peripheral afferent dysgraphia is characterized by two different groups of deficits. The first group, the so-called neglect-related features, is characterized by the tendency to write on the right-hand side of the page and by difficulty in maintaining horizontal lines. Omissions and repetitions of strokes and letters comprise the second group of dysgraphia deficits (feedback-related features). They have been related to defects of visual and proprioceptive feedback during writing movements. Interestingly, in cerebellar patients, in addition to handwriting difficulties consistent with movement dysmetria, some high-order problems are present with the characteristics of the feedback-related features of the peripheral afferent dysgraphia. It has been suggested that the lack of effectiveness of sensory feedback may be due to a complex disorder of sensory feedback related to a form of *inattention* to the feedback. In the case of cerebellar lesions, this *inattention* might be due to the uncoupling of motor planning and proprioceptive feedback.

It is interesting that in all linguistic problems reported, as well as in dysgraphia, an uncoupling of sensory feedback and motor output can be hypothesized. This supports the theory implicating the cerebellum in sensory acquisition and discrimination rather than in motor control.

D. Cerebellum and Working Memory

Working memory has been defined as the ability to maintain and manipulate information "on-line." It has been postulated that this function takes place through the interactions between a central processor (central executive), responsible for manipulating the information, and a rehearsal system, specifically devoted to keeping active the information to be manipulated. It is believed that this latter function is specialized according to different types of information. Furthermore, it is hypothesized that verbal information is retained over a short period of time through a mechanism defined as the phonological loop. Two independent subsystems, the phonological short-term store and the rehearsal system, have been identified within this phonological loop. The phonological short-term store is a limited-capacity store in which the verbal information is held for a short period of time. The rehearsal system is a process that recirculates stored phonological information to prevent its rapid decay. This recirculation is supposed to take place between the phonological short-term store and the phonological output buffer.

fMRI studies have been devoted to the analysis of brain activation during working memory tasks and in particular they have revealed several areas that are specifically active during verbal working memory tasks: left Broca's area, the supplementary motor area, and the cerebellum. It has been hypothesized that

recirculation of the information through these areas may represent the anatomical substrate of the rehearsal system of the phonological loop. A precise definition of the contribution of the different regions to the rehearsal mechanism is still lacking. A recent lesion study by Caterina Silveri and coworkers demonstrated verbal working memory impairment in patients with a right cerebellar lesion. The authors were able to identify the locus of functional damage in the rehearsal system, precisely in the phonological output buffer. This evidence indicates direct involvement of the right cerebellum in silent recirculation of verbal information independently from articulatory functions. This latter finding is in agreement with different fMRI data indicating a larger cerebellar activation in verbal working memory tasks than in silent articulatory rehearsal tasks.

E. Cerebellum and Psychiatric Disorders

Various reports suggesting a possible link between the cerebellum and emotional behavior have been published since the beginning of the 20th century. However, these findings have been overshadowed by the generally accepted view of the cerebellum as a pure motor structure. In the 1970s, the convergence of pathological observations and experimental findings induced some groups to implant a cerebellar pacemaker to treat intractable behavioral disorders. Since then, data have been collected linking gross cerebellar anatomical abnormalities to various psychiatric disorders. Schizophrenia has been linked to different types of abnormalities of the cerebellar vermis; patients affected by attention deficithyperactivity disorder have been shown to have a reduced volume of the posterior vermal lobules (VIII–X). Currently, there is substantial evidence linking the cerebellum with autism, although the precise loci of the cerebellar damage (i.e., vermal lobules VI and VII, dentatothalamocortical pathway, and serotonin innervation) must still be defined. Recently, neuropsychological and neuroimaging data have indicated a possible role of the cerebellum in mood control.

One of the main criticisms of the possible role of the cerebellum in controlling behavior has always derived from the lack of behavioral disorders in patients with cerebellar damage. More careful analysis of cerebellar patients allowed Jeremy Schamahmann to specifically define the cognitive affective pattern of cerebellar patients he defined as having the cerebellar cognitive affective syndrome.

Cerebral Circulation

JOHN A. JANE, Jr., AARON S. DUMONT, DANIEL E. COUTURE, K. MICHAEL WEBB, DILANTHA B. ELLEGALA, HAYAN DAYOUB, and NEAL F. KASSELL

University of Virginia, Charlottesville

GLOSSARY

aneurysm Focal arterial dilation.

anterior circulation Vessels supplied by the paired internal carotid arteries.

diencephalon Develops from the embryologic prosencephalon and includes the thalamus and hypothalamus.

dural venous sinus Valveless venous structures whose walls are formed by the two dural leaves; it provides the major venous drainage of the cranium.

endovascular therapy Therapy provided from within the vessel lumen utilizing catheter-based technology to treat a variety of vascular disease processes.

intracerebral hemorrhage Denotes the presence of blood within the brain parenchyma; may be spontaneous or secondary to trauma.

posterior circulation Vessels supplied by vertebrobasilar system.

radiosurgery Radiation therapy using stereotactic-guided focused external beam.

telencephalon Develops from the embryologic prosencephalon and denotes the cerebral hemispheres and basal ganglia.

vascular malformations A category of vascular disorders that includes arteriovenous malformations, cavernous malformations, venous malformations, and capillary telangiectasias.

vasculopathy All-encompassing term used to denote any disease of the blood vessels.

The cerebral circulation is formed by a complex vascular network. The cerebral vasculature is subject to a wide range of disorders, including ischemic and hemorrhagic stroke, vascular anomalies, and vasculopathy. Cerebrovascular diseases have the potential to compromise vital cerebral functions, leaving many neurologically devastated. Collectively, cerebrovascular disease poses an enormous societal burden. This article focuses on the specific pathophysiology, presentation, diagnosis, and treatment guidelines for each of these disorders.

I. ANATOMY OF THE CEREBRAL VASCULATURE

A. Normal Anatomy of the Cerebral Arterial Vasculature

1. General Considerations

Although the brain accounts for just over 2% of the body's total weight, it receives nearly 20% of the cardiac output. Whereas larger cerebral vessels are influenced by a balance of sympathetic and parasympathetic tone, vascular tone in medium and small cerebral vessels is altered primarily by the mechanism of autoregulation. Blood flow is tightly regulated at the

arterial level to maintain an average cerebral blood flow (CBF) of 50 ml/100 g/min.

Smooth muscle cells within the cerebral vessels vasoconstrict or vasodilate in response to wall stress and shear to maintain a constant blood flow over a wide range of blood pressures. Within the endothelial cell, a complex balance exists between calcium levels and phosphorylation states of myosin. Central to this balance are endothelium-derived relaxation factors (EDRFs) and endothelial-derived constricting factors (EDCFs). The EDRFs include nitric oxide (NO), prostacyclin, and endothelium-derived hyperpolarization factor; notable EDCFs are endothelin, angiotensin II, prostaglandin $F_{2\alpha}$, and the thromboxanes.

Through autoregulation, local vasculature can also increase CBF to compensate for increased neuronal activity and metabolism (CBF–metabolism coupling). Metabolites produced in the brain and throughout the body can also cause vessel changes and alter CBF. Carbon dioxide has potent vasoactive characteristics. Increased CO_2 causes vasodilatation and a resultant increase in CBF. CBF is less sensitive to arterial oxygen concentrations and increases only at significantly low oxygen levels. Extracellular pH, lactic acid, adenosine, and adenosine triphosphate also have vasoactive properties.

The blood supply to the brain, brain stem, and much of the spinal cord is derived from two paired vessels, the internal carotid and the vertebral arteries. The internal carotid arteries form the anterior circulation and supply most of the telencephalon and much of the diencephalon (Table I). The posterior circulation is a derivative of the vertebrobasilar system and supplies the brain stem and cerebellum as well as parts of the diencephalon, spinal cord, and occipital and temporal lobes (Table II).

2. The Anterior Circulation

a. Internal Carotid Artery The anterior circulation is supplied by the two internal carotid arteries (ICAs). The extracranial ICA is divided into two segments. The most proximal portion of the ICA is dilated and is termed the carotid bulb. The remaining distal portion then ascends through the neck to the skull base without branching. This distinguishes the extracranial ICA from the external carotid artery, which has numerous branches to the face and neck. The ICA then enters the skull base at the carotid canal, traverses the petrous portion of the temporal bone, passes through the cavernous sinus, and finally enters the subarachnoid space at the base of the brain. The ICA can therefore be divided into cervical, petrous, cavernous, and cerebral parts (Fig. 1).

The petrous portion of the carotid is composed of a vertical and horizontal segment. It has two possible branches, the caroticotympanic and vidian arteries, but neither is visualized in the majority of angiograms. The cavernous ICA begins at the level of the petrolingual ligament ascending vertically, then horizontally, and finally vertically again before ending at the level of the anterior clinoid. During its course it gives rise to the meningohypophyseal trunk, the inferolateral trunk, and the capsular arteries of McConnell. The meningohypophyseal trunk divides into the inferior hypophyseal artery, tentorial artery, and small clival arteries. The inferolateral trunk branches into arteries supplying several cranial nerves and the cavernous sinus dura. The capsular arteries, when present, supply the pituitary capsule.

After exiting the cavernous sinus, the supraclinoid ICA gives rise to its first intradural branch, the ophthalmic artery. The ophthalmic artery travels along with the optic nerve through the optic canal to the orbit, where its branches supply various orbital and ocular structures. The supraclinoid ICA also gives rise to the superior hypophyseal artery, which supplies the optic chiasm, pituitary stalk, and anterior pituitary gland. The ICA then proceeds superiorly adjacent to the optic chiasm and bifurcates into its terminal branches, the middle and anterior cerebral arteries.

Before bifurcating, it gives rise to two smaller branches, the posterior communicating artery (PCoA) and the anterior choroidal artery (AChA). The PCoA courses posteriorly, superior to the oculomotor nerve, and joins the posterior cerebral artery, thus creating an anastomosis between the anterior and posterior circulation. The AChA supplies important structures, including the optic tract, cerebral peduncle, internal capsule, thalamus, and hippocampus.

b. Anterior Cerebral Artery The anterior cerebral artery (ACA) runs medially, superior to the optic nerve, and enters the longitudinal fissure, where it arches posteriorly, following the corpus callosum, to supply the medial aspects of the frontal and parietal lobes (Fig. 2). Some of the smaller branches extend onto the dorsolateral surface of the hemisphere.

The proximal ACA gives rise to the medial lenticulostriate and perforating arteries, including the recurrent artery of Huebner, that supply the basal forebrain and optic nerves. The proximal ACAs are connected by the anterior communicating artery

Table I
Major Branches of the Anterior Circulation

Major vessel	Branches and the areas supplied
Internal carotid artery	Petrous portion
	Caroticotympanic artery
	Middle and inner ear
	Vidian artery
	Anastomoses with branches of the external carotid artery
	Cavernous portion
	Meningohypophyseal trunk
	Inferior hypophyseal artery
	Posterior pituitary capsule
	Marginal tentorial artery
	Tentorium
	Clival arteries
	Clivus
	Inferolateral trunk
	Capsular arteries of McConnell
	Anterior and inferior pituitary capsule
	Supraclinoid portion
	Ophthalmic artery
	Optic nerve, choroid, retina, conjunctivae, lacrimal gland, extraocular muscles, falx cerebri, anastomoses with external carotid artery
	Superior hypophyseal artery
	Pituitary stalk, anterior pituitary, optic chiasm
	Anterior choroidal artery
	Optic chiasm and tract, thalamus, internal capsule, cerebral peduncle, choroid plexus, medial temporal lobe
	Posterior communicating artery
	Thalamus, hypothalamus, internal capsule
	Anterior cerebral artery
	Middle cerebral artery
Anterior cerebral artery	Medial lenticulostriate arteries
	Optic nerve, optic chiasm, hypothalamus, fornix, striatum
	Perforating arteries
	Recurrent artery of Heubner
	Basal ganglia, internal capsule, portions of frontal lobe
	Anterior communicating artery
	Infundibulum, optic chiasm, hypothalamus
	Orbitofrontal artery
	Ventromedial frontal lobe, olfactory tract
	Frontopolar artery
	Medial frontal lobe, lateral surface of superior frontal gyrus
	Pericallosal artery
	Callosomarginal artery
	Along with pericallosal artery, their branches supply the anteromedial frontal and parietal cortex

(continues)

Table I *(continued)*

Major vessel	Branches and the areas supplied
Middle cerebral artery	M1 and M2
	Anterior temporal artery
	Anterior temporal lobe
	Lateral lenticulostriate arteries
	Basal ganglia, internal capsule
	M3 and M4
	Orbitofrontal and prefrontal arteries
	Middle and inferior frontal gyri
	Precentral, central and postcentral sulcus arteries
	Precentral, central, and postcentral gyri, anterior parietal lobe
	Posterior parietal artery
	Parietal lobules, supramarginal gyrus
	Angular artery
	Posterior superior temporal gyrus, supramarginal gyrus, angular gyrus
	Temporooccipital artery
	Posterior portions of temporal lobe
	Posterior, medial, and anterior temporal arteries
	Corresponding portions of temporal lobe

(ACoA) near their entrance into the longitudinal fissure. The ACA then gives rise to the orbitofrontal and frontopolar arteries before terminating into the pericallosal and callosomarginal arteries.

c. Middle Cerebral Artery The middle cerebral artery (MCA) begins at the ICA bifurcation and courses into the Sylvian fissure. Before entering the fissure, the MCA bifurcates and these branches ramify over the insula. After emerging from the fissure, the MCA spreads out to supply most of the lateral surface of the cerebral hemisphere (Fig. 2).

This large artery is subdivided into four segments. The first segment, M1, contains the bifurcation and ends at the entrance to the Sylvian fissure. The M1 segment gives rise to the anterior temporal and lateral lenticulostriate arteries supplying the basal ganglia and internal capsule. Within the Sylvian fissure, the M2, or insular, segment ramifies into 6–10 branches that course along the insula. The M3, or opercular, segment begins at the superior portion of the circular sulcus of the insula and ends as the MCA exits the Sylvian fissure to course along the cortical surface. Like the M2 segment, the M3 vessels also ramify and form the end arteries of the M4, or cortical, segment. These cortical vessels supply much of the lateral surface of the frontal, parietal, and temporal lobes.

3. The Posterior Circulation

a. Vertebrobasilar System The posterior circulation denotes the network of the two vertebral arteries (VAs) and the basilar artery (BA). The paired VAs then fuse at the junction of the medulla and pons to form the midline BA, which proceeds rostrally along the anterior surface of the pons (Fig. 3).

b. Vertebral Artery The VA ascends within the transverse foraminae of C6 to C1. After exiting the transverse foramen of C1 it angles posteromedially along the arch of C1 around its superior facet and then turns abruptly again to course rostrally alongside the medulla through the foramen magnum. Along its extracranial course, the VA gives rise to small unnamed muscular and segmental spinal arteries. The distal extracranial VA also supplies meningeal arteries that serve the dura of the posterior fossa.

Before the intracranial VAs join to form the BA, each vertebral artery gives rise to three branches: the posterior spinal, anterior spinal, and posterior inferior

Table II
Major Branches of the Posterior Circulation

Major vessel	Branches
Vertebral artery	Muscular arteries
	Deep cervical muscles
	Segmental spinal arteries
	Vertebral bodies, spinal cord
	Meningeal arteries
	Falx cerebelli, dura around foramen magnum and occipital bone
	Posterior spinal artery
	Posterior third of spinal cord
	Anterior spinal artery
	Anterior two-thirds of spinal cord
	Posterior inferior cerebellar artery
	Lateral medulla; cranial nerves IX, X, and XI; choroid plexus of fourth ventricle; cerebellum (posteroinferior portions, vermis, tonsils)
Basilar artery	Pontine perforating arteries
	Ventral pons and midbrain
	Anterior inferior cerebellar artery
	Cranial nerves VII and VIII, ventrolateral pons, medulla, cerebellum (flocculus, anterolateral portions)
	Superior cerebellar artery
	Deep cerebellar nuclei, superior portions of cerebellum, midbrain
	Posterior cerebral artery
Posterior cerebral artery	Posterior communicating artery
	Perforating arteries
	Cranial nerves III and IV, thalamus, hypothalamus, midbrain, internal capsule
	Posterior choroidal artery
	Choroid plexus of third ventricle, thalamus, fornix, tectum, pineal gland
	Anterior and posterior temporal arteries
	Posterior temporal and anterior occipital lobes
	Medial and lateral occipital arteries
	Occipital lobe and corpus callosum

cerebellar artery (PICA). The posterior spinal artery runs caudally along the dorsolateral aspect of the spinal cord and supplies the posterior third of that half of the spinal cord. The anterior spinal artery joins its counterpart from the opposite side, forming a single anterior spinal artery that runs caudally along the ventral midline of the spinal cord, supplying the anterior two-thirds of the spinal cord. PICA arises at the level of the medulla and, as its name implies, supplies much of the inferior surface of the cerebellum. It also supplies the choroid plexus of the fourth ventricle, cranial nerves (CNs) IX, X, and XI, and much of the lateral medulla.

c. Basilar Artery From its origin at the pontomedullary junction, the BA proceeds rostrally and, at the level of the midbrain, bifurcates into the two posterior cerebral arteries (PCAs). Before this bifurcation, it gives rise to numerous pontine perforating branches, the labyrinthine arteries, and two paired vessels—the anterior inferior cerebellar artery (AICA) and the superior cerebellar artery (SCA). The AICA arises just distal to the basilar origin and supplies the anterolateral cerebellum, the pons, and rostral medulla. The SCA arises proximal to the basilar bifurcation, courses inferior to the oculomotor nerve, and supplies the superior cerebellum, its deep nuclei, and much of the caudal midbrain.

The PCA curves over the oculomotor nerve, around the midbrain, and passes through the superior cistern. The proximal PCA sends perforators to the rostral midbrain, caudal diencephalon, and CNs III and IV. It also gives rise to several posterior choroidal arteries, which supply the choroid plexus of the third ventricle, thalamus, and pineal region. The anterior and posterior choroidal arteries form anastomoses in the vicinity of the glomus. The proximal PCA also gives rise to the posterior communicating artery, connecting the anterior and posterior cerebral circulation. The cortical PCA branches include the anterior temporal, posterior temporal, lateral occipital, and medial occipital arteries. These branches spread out to supply the medial and inferior surfaces of the occipital and temporal lobes. In effect, the PCAs supply areas that serve vision, visual memory, and eye motility.

4. The Circle of Willis

The circle of Willis is a polygonal arcade that connects the two halves of the anterior circulation with the posterior circulation. Its components include both ICAs and ACAs, the ACoAs, PCoAs, PCAs, and the BA (Fig. 4). In cases of major vessel occlusion, either within the circle of Willis or proximal to it, the communicating arteries theoretically permit vital anastomotic flow and prevent neurological damage. In

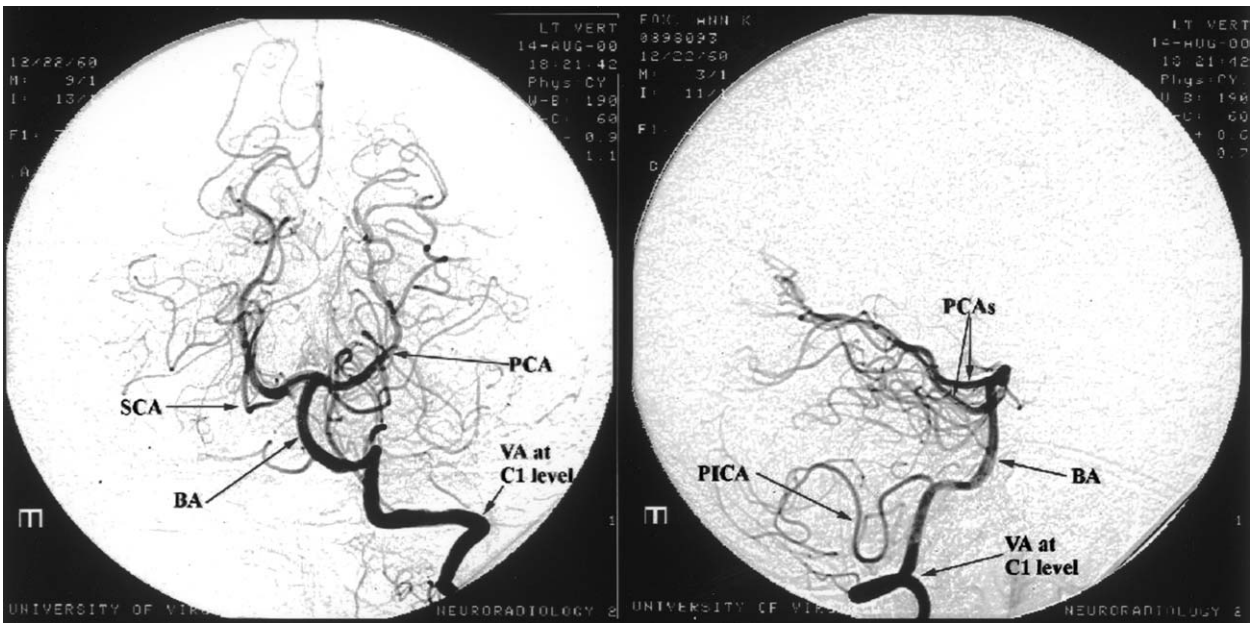

Figure 3 Angiograms after left vertebral artery injection. (Left) Frontal view shows left vertebral, basilar, and posterior cerebral arteries. (Right) Lateral view also reveals PICA.

fact, fewer than half the circles have the classical appearance and asymmetries are common. In rare cases, one of the communicating arteries may be missing, resulting in an incomplete circle.

Other routes of collateral circulation are available. Arterial anastomoses between the extracranial and intracranial carotid exist and may enlarge to a remarkable degree to compensate for slowly developing occlusions. The most important are anastomoses in the orbit between the ophthalmic artery and branches of the external carotid artery. In cases of proximal ICA occlusion, retrograde flow from the external carotid artery through the ophthalmic artery can reach the distal internal carotid territories.

B. Anatomy of the Cerebral Venous System

1. General Considerations

Although the extracranial veins of the scalp and face are not discussed in detail, they do communicate with the intracranial venous system and can have pathological importance. Scalp and facial veins may drain to the dural sinuses via emissary veins that pass through the skull and orbit. These extracranial veins also anastomose with both the cavernous sinus and the basilar, or clival, plexus. They play a relatively minor role in the normal circulatory pattern of the brain but can be important clinically as a nidus for fistula formation, as a path for the spread of infection, or as a collateral drainage system.

The principal route of venous drainage of the brain is through a system of cerebral veins that empty into the dural venous sinuses. The majority of dural sinuses join at the torcula of Herophili (confluence of sinuses) and then split into the left and right transverse sinuses, which flow into the sigmoid sinuses and ultimately into the internal jugular veins. The cerebral veins are conventionally divided into superficial and deep groups.

2. Dural Venous Sinuses

The major dural venous sinuses include the superior and inferior sagittal sinuses, the straight sinus, the superior and inferior petrosal sinuses, the occipital sinus, the transverse sinus, and the sigmoid sinuses (Fig. 5). The superior and inferior sagittal sinuses run in the midline along the superior and inferior edges of the falx cerebri (Fig. 6). The inferior sagittal sinus joins the vein of Galen to form the straight sinus, which then courses along the superior edge of the tentorium cerebelli. The occipital sinus originates at the posterior edge of the foramen magnum and meets the straight sinus and superior sagittal sinus at the torcula of Herophili. The superior petrosal sinus joins the cavernous to the sigmoid sinus and runs along the

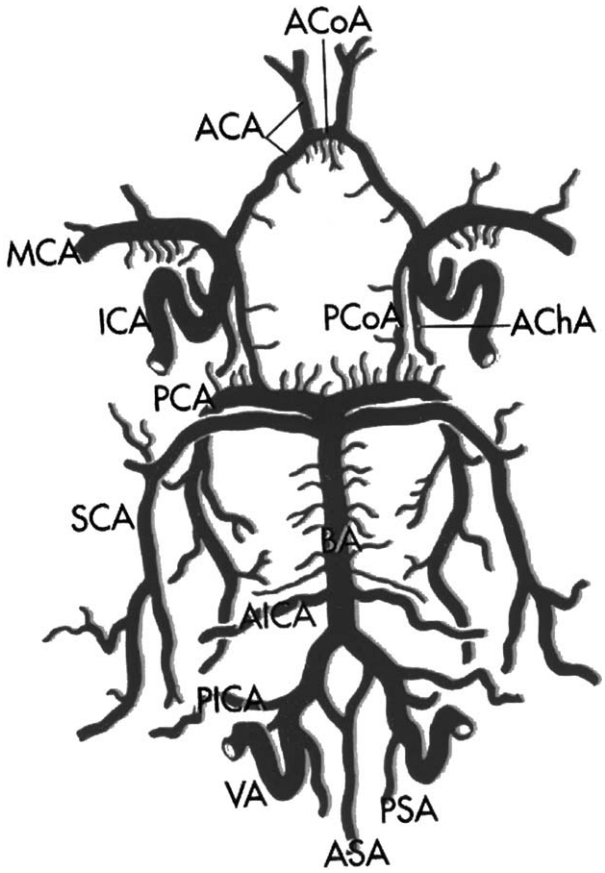

Figure 4 Circle of Willis. From Nolte (1993), *The Human Brain: An Introduction to Its Functional Anatomy*, 3rd ed. Mosby, St. Louis. Used with permission.

superior ridge of the petrous bone. The inferior petrosal sinus has variable tributaries but drains into the internal jugular vein at the jugular bulb.

3. Superficial Venous System

The superficial veins are quite variable and most are unnamed. Only three of these veins are reasonably constant (Fig. 7). The superficial middle cerebral vein runs along the lateral sulcus draining most of the temporal lobe into the cavernous sinus or into the nearby sphenoparietal sinus. The superior anastomotic vein, or vein of Trolard, typically travels across the parietal lobe and drains the superficial middle cerebral vein into the superior sagittal sinus. The inferior anastomotic vein, or vein of Labbe, travels posteriorly and inferiorly across the temporal lobe and connects the superficial middle cerebral vein with the transverse sinus.

4. Deep Venous System

The deep veins are more constant in configuration than are the superficial veins. The major deep vein is the internal cerebral vein, which is formed at the intraventricular foramen by the confluence of the septal vein and the thalamostriate veins (Fig. 5). The septal vein runs posteriorly across the septum pellucidum, and the thalamostriate vein travels in the groove between the thalamus and the caudate nucleus.

Immediately after forming, the internal cerebral vein bends sharply in a posterior direction. This bend is called the venous angle and is used in imaging studies as an indication of the location of the interventricular foramen. The paired internal cerebral veins proceed posteriorly through the transverse cerebral fissure and fuse in the superior cistern to form the unpaired great cerebral vein (or vein of Galen). The great cerebral vein turns superiorly and joins the inferior sagittal sinus to form the straight sinus. Along its short course, the great vein receives the basal veins of Rosenthal. The basal vein is formed near the optic chiasm by the deep middle cerebral vein, which drains the insula, and several other tributaries that drain inferior portions of the basal ganglia and the orbital surface of the frontal lobe.

II. STROKE

Stroke is characterized by the acute onset of a focal neurological deficit referable to an insult of the cerebral vascular system. Stroke is the third leading cause of death in the United States. There are approximately 500,000 new strokes each year causing 200,000 deaths. Many patients have significant functional impairment and require long-term medical or rehabilitative care, thus adding to the socioeconomic impact of stroke. Risk factors for the development of stroke include hypertension, hyperlipidemia, diabetes, cardiac disease (e.g., atrial fibrillation), vascular disease (such as sickle cell disease), and smoking.

Stroke may be classified into ischemic or hemorrhagic subtypes. Ischemic stroke is far more common, comprising approximately 85% of cases (Table III). Ischemic stroke may be either focal (affecting discrete regions) or global (affecting much of the forebrain with predilection for watershed regions between major vessels). Ischemic stroke may occur secondary to embolic or thrombotic phenomenon. Global ischemia usually results from systemic hypoperfusion as seen with cardiac arrest. Hemorrhagic stroke may be due to

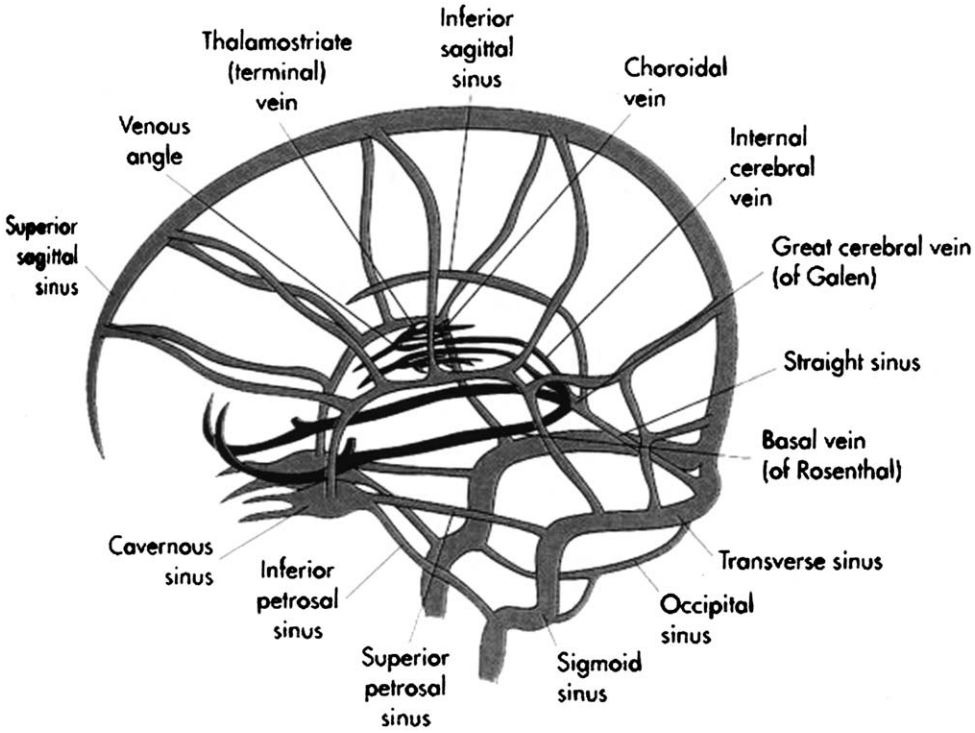

Figure 5 Superficial and deep venous systems. From Nolte (1993), *The Human Brain: An Introduction to Its Functional Anatomy*, 3rd ed. Mosby, St. Louis. Used with permission.

Table III
Classification System for Stroke

Ischemic (85%)
Focal
Embolic
Cardiac
Intraarterial
Aortic
Thrombotic
Large artery disease (intracranial and intracranial)
Small penetrating artery disease (lacunar)
Global
Systemic hypoperfusion (e.g., cardiac arrest)
Hemorrhagic (15%)
Subarachnoid hemorrhage
Intracerebral hemorrhage

subarachnoid hemorrhage (SAH) or intracerebral hemorrhage (ICH).

III. ISCHEMIC STROKE

A. Background and Pathogenesis

Ischemia is defined as a reduction in blood flow. Progressive ischemia first disrupts neuronal functioning and later threatens cell viability. Although variability in normal CBF exists, levels below approximately 20 ml/100 g/min result in electrophysiological and functional deficits. CBF levels below 10 ml/100 g/min result in disruption of membrane integrity and cellular death (as seen within an area of completed infarction). Intermediate levels of CBF (between 10 and 20 ml/100 g/min) are seen within the ischemic penumbra, the area of potentially viable tissue immediately surrounding the infarction. Salvaging the potentially amenable ischemic penumbra remains an area of intense research.

B. Patterns of Ischemia

Because cell injury can be reversible depending on the amount of time spent without adequate blood flow and oxygen, three distinct patterns of stroke have been defined. The first pattern is the transient ischemic attack (TIA), which is a transient focal neurological deficit lasting less than 24 hr but usually resolving between 10 min and 4 hr. A common type of TIA, known as amaurosis fugax, causes transient monocular blindness, which is often described as "a shade being pulled" over one eye. The second pattern is the reversible ischemic neurologic defect (RIND). A RIND is defined as a focal neurologic deficit lasting more than 24 hr but completely resolving within 1 week. The final pattern of ischemia is the cerebrovascular accident (CVA). A CVA is a permanent focal neurologic deficit that may improve over time to a limited extent.

C. Pathogenesis

1. Embolic CVA

The most common cause of stroke is the distal embolization of an atherosclerotic plaque within the carotid artery. As early as childhood, a collection of lipid-laden cells known as a fatty streak can be found in the aorta. Over time, and in conjunction with the risk factors mentioned previously, a central core of lipids and cell debris becomes surrounded by a fibrous cap of thickened intima and medial smooth muscle cells. Eventually, this plaque can ulcerate and embolizes to the intracranial circulation (Fig. 8). Also common are emboli from a cardiac mural thrombus in the setting of atrial fibrillation.

2. Thrombotic CVA

Thrombosis may affect both large and small vessels. Thrombosis of large vessels may occur extracranially (e.g., cervical carotid artery occlusion) or intracranially (e.g., MCA occlusion), with resulting systems predictable based on the region served by the affected vessel. Disruption of small penetrating arteries gives rise to lacunar infarction, which typically affects deep brain structures. Lacunar infarctions are thought to arise from chronic hypertension eventually leading to hyalinization and sclerosis of small arteries feeding deep brain neurons.

Figure 8 Carotid artery stenosis: angiogram of left common carotid artery with bifurcation into internal and external branches. Note the area of extreme stenosis of the internal carotid artery.

3. Global Ischemic CVA

Systemic hypoperfusion, as seen during prolonged cardiac arrest, results in diffuse forebrain injury not referable to a discrete vascular territory. Damage is most evident in watershed regions between neighboring vascular territories (e.g., between the ACA and MCA territories).

D. Stroke Syndromes

Ischemia involving individual vascular territories causes specific clinical stroke syndromes. The signs and symptoms that characterize each stroke syndrome can usually predict the specific vessel that is affected. Stroke syndromes have been described for specific regions of the brain and brain stem.

1. Cerebral Hemispheres

Because of its large diameter and high flow, the MCA is most commonly involved in embolic stroke. Occlusion of the superior division of the MCA results in a contralateral hemiparesis of the hand, face, and arm with concurrent sensory deficit. If the dominant cerebral hemisphere is involved, an expressive aphasia may result. The inferior division of the MCA supplies the superior aspect of the optic radiations and the parietal lobe, which regulates higher cortical functions such as spatial thought and recognition of the contralateral body. Thus, infarction results in a contralateral homonymous hemianopsia, combined with astereognosis, agraphesthesia, and contralateral hemineglect with a receptive aphasia if the dominant hemisphere is involved. More proximal lesions of the MCA cause a combination of the previously mention deficits.

Involvement of the ACA is less common and results in a contralateral hemiparesis and hemisensory deficit of the leg. Bilateral ACA infarcts can cause incontinence secondary to the inability to inhibit reflex bladder contractions. A left-sided occlusion of the recurrent artery of Heubner can cause motor aphasia as well.

Occlusion of the posterior cerebral and vertebrobasilar system causes neurologic deficits related to the functions of the occipital and medial temporal lobes, cerebellum, and brain stem. Unilateral occlusion of the PCA results in a contralateral homonymous hemianopsia that is more dense superiorly. Macular vision will often be spared because it is supplied by both the MCA and the PCA. Involvement of the dominant hemisphere results in anomic aphasia (difficulty naming objects), alexia without agraphia (inability to read without impairment of writing), and visual agnosia (inability to recognize objects placed on ipsilateral visual field). Bilateral occlusion of the PCA system can cause cortical blindness and memory impairment.

2. Basal Ganglia and Thalamus

Clinically significant lacunar infarctions typically occur in the internal capsule, thalamus, brain stem, and midbrain. The lesions are small in size but can cause widespread clinical symptoms because of the close proximity of deep brain pathways. As with cortical infarctions, distinct patterns of symptoms are evident and affect the contralateral face, arm, and leg. Lacunar infarcts cause pure motor deficits, whereas infarcts in the thalamus cause pure sensory signs and symptoms. In the internal capsule and thalamus, lacunar infarction typically causes either a pure motor or a pure sensory deficit, respectively, of the contralateral face, arm, and leg.

3. Brain Stem

In the brain stem, infarction may produce an ataxic hemiparesis characterized by contralateral hemiparesis with a cerebellar ataxia of the affected limbs. Midbrain infarction results in an ipsilateral oculomotor nerve palsy with contralateral hemiparesis, also known as Weber's syndrome.

Occlusion of the basilar artery causes neurological deficits referable to dysfunction of the pons and midbrain. With pontine involvement, patients may have hemi- or quadriplegia and constricted pupils, and they will often be comatose. Selective involvement of the dorsal pons will cause additional symptoms of eye bobbing and vertical nystagmus, whereas an infarction of the ventral pons results in the locked-in syndrome, characterized by quadriplegia with intact consciousness. Midbrain involvement results in oculomotor nerve palsy, hemiparesis, quadriparesis, and posturing, usually with impairment in the level of consciousness.

Occlusion of the posterior inferior cerebellar artery results in the lateral medullary syndrome in which a constellation of ipsilateral and contralateral symptoms may occur in various combinations. Ipsilateral symptoms include facial numbness, limb ataxia, Horner's syndrome, hoarseness, and dysphagia. The contralateral body experiences decreased pain and temperature sensation in the arm, trunk, or leg.

E. Treatment

1. Prevention

Treatment of the risk factors includes reduction of blood pressure and cholesterol, control of blood sugar, and cessation of smoking. Since plaque rupture and thrombosis lead to embolism, antiplatelet drugs (i.e., aspirin, ticlopidine, dipyridamole, and clopidrogel), alone or in combination, have been shown to significantly reduce the rate of stroke.

In addition, surgical removal of an atherosclerotic plaque from the carotid artery, known as carotid endarterectomy, has been shown to reduce the incidence of stroke in selected patients. In symptomatic patients with TIA or RIND, carotid endarterectomy has been shown to be more effective in preventing stroke and death than medical management alone in patients with more than 70% stenosis. Although carotid endarterectomy has been shown to reduce stroke rate in asymptomatic patients with severe stenosis, its efficacy against medical management alone and cost-effectiveness remain controversial. Advances in catheter-based technology have made angioplasty of the carotid artery with or without stent placement an option for certain patients unable or unwilling to undergo carotid endarterectomy.

2. Acute Management

Once a stroke has occurred, the immediate objective of treatment is to restore blood flow to the brain. Thrombolytic agents such as recombinant tissue plasminogen activator have been used to break up the occlusive intracranial emboli and restore blood

flow. Thrombolysis has been shown to improve neurologic outcome in patients with stroke if given within 3 hr after the onset of symptoms. However, the risk of intracranial bleeding is increased, thus limiting thrombolysis to patients without conditions predisposed to hemorrhage. Tests to locate the source of emboli, such as echocardiography and carotid ultrasound, are performed. Antiplatelet medicine is started, and anticoagulation with warfarin is begun for patients with clots outside of the carotid system, artificial cardiac valves, atrial myxoma, endocarditits, or atrial fibrillation. After the patient is medically stabilized, rehabilitation at home or specialized facilities can help the patient regain functional ability.

3. New Developments

Many of the developments in stroke treatment have focused on the prevention of embolism and restoration of blood flow after occlusion has occurred. Research has led to advances in preventing or reducing neuronal death after ischemia. The concept of excitotoxicity, by which cell injury and death occur because of excessive stimulation from excitatory amino acids, has provided a new paradigm of cell injury. Agents are being designed to block the receptors through which excitatory amino acids mediate their toxic effects. Other agents may limit injury by reducing neuronal metabolic requirements. These and other future developments may ultimately help to reduce the medical and social impact of this common disease.

IV. HEMORRHAGIC STROKE

Hemorrhagic stroke may result from either intracerebral or subarachnoid hemorrhage. Subarachnoid hemorrhage is most commonly secondary to trauma followed by aneurysmal rupture. Subarachnoid hemorrhage is discussed in the context of cerebral aneurysms. Intracerebral hemorrhage is discussed next.

A. General Considerations

Spontaneous intracerebral hemorrhage (SICH) is defined as hemorrhage in the absence of trauma. It remains a devastating condition that afflicts a significant proportion of the American population. The causes are varied and often associated with other life-threatening pathology. Proper diagnosis requires a thorough knowledge of the possible root causes. Therapeutic goals aim at short-term stabilization and long-term treatment of the inciting diseases.

B. Epidemiology

SICH affects nearly 40,000 Americans annually and is more common among people of Asian and African American descent. SICH in most populations carries a mortality rate of between 20 and 50% in the first month. Morbidity is also high, and only 10–20% live independently following the insult. Chronic hypertension and age are major risk factors. Hypertension is related to the majority of hemorrhages within the deep supratentorial gray matter, cerebellum, and brain stem. Patients presenting with deep-seated SICH tend to be males in their fifth and sixth decades. Younger populations and the elderly more commonly present with lobar hemorrhages.

C. Classification and Etiology

No accepted classification schema exists for SICH. A long list of cerebrovascular disorders are associated with SICH. Hypertensive hemorrhages account for the majority. Other common causes include cerebral amyloid angiopathy, rupture of arteriovenous malformations and aneurysms, postischemic hemorrhage, tumors, and anticoagulation. However, significant overlap exists between these conditions.

The etiology varies with age. Children to middle-aged adults present most commonly with lobar hemorrhages secondary to arteriovenous malformations. Patients in their fifth and sixth decades represent the majority of those presenting with SICH and most suffer from hypertensive hemorrhages. In the elderly population, cerebral amyloid angiopathy is the most common etiology.

In lieu of classification based on the underlying vascular disease or age stratification, ICH is often described based on the location. Hemorrhages can occur above and below the tentorium. Supratentorial hematomas account for the majority of SICH and are classified as lobar or deep (Figs. 9 and 10). Lobar hemorrhages can be secondary to hypertension but are commonly related to vasculopathies (e.g., cerebral amyloid angiopathy and vasculitis), vascular anomalies (e.g., aneurysms and arteriovenous malforma-

Figure 9 Axial noncontrasted CT scan revealing a large left temporoparietal intracerebral hemorrhage.

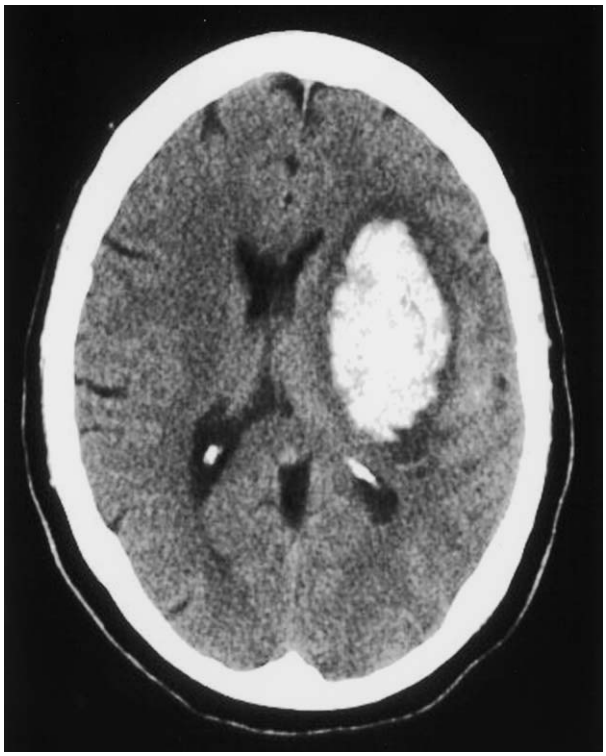

Figure 10 Axial noncontrasted CT scan revealing a typical large hypertensive putaminal intracerebral hemorrhage.

tions), coagulopathy, and tumors. Deep intracerebral hemorrhages are more prevalent than lobar homorrhages and are divided into basal ganglia and thalamic hemorrhages. Infratentorial hematomas are situated either within the brain stem or in the cerebellum.

D. Pathology

The most common etiology of SICH is chronic hypertension, and this population is the focus of this section. The other causes are discussed at length later. Chronic hypertension affects small perforating end arteries deep within the cortex of the brain, especially at the junction between gray and white matter. Lipohyalinosis and microaneurysm formation render the vessels friable and incapable of autoregulation. Abrupt changes in blood flow and blood pressure are thought to incite the hemorrhage. The most commonly affected vessels include the lenticulostriate arteries and perforators of the thalamus and brain stem. Basal ganglia hemorrhages are the most frequent, followed by lobar, thalamic, cerebellar, and pontine hemorrhages.

E. Clinical Presentation

The majority of SICH patients present with a decreased level of consciousness or coma. Other common symptoms include headache, nausea, and vomiting. More focal signs vary depending on location.

1. Supratentorial

a. Lobar Signs and symptoms of lobar hemorrhages depend on the cortical function of the affected region (Fig. 9). Parietal hemorrhages tend to cause contralateral motor and sensor deficits, whereas occipital hemorrhages cause visual disturbances. Dominant hemisphere lesions often disturb language function. Compared to patients with deep supratentorial hemorrhages, these patients are also more often alert and fewer present in coma. Seizure activity is also more commonly experienced in these patients.

b. Deep Deficits from basal ganglia hemorrhages are more often motor than sensory (Fig. 10). In

addition to contralateral hemiparesis or plegia, dominant hemisphere lesions are associated with aphasia. Contralateral neglect is prevalent in nondominant hemisphere hemorrhages. Visual disturbances are also common. Thalamic hemorrhage is also associated with these symptoms, although thalamic ICH typically produces more pronounced sensory findings. Extension of hematoma into the brain stem structures can cause vertical gaze palsy, anisocoria, and nystagmus.

2. Infratentorial

a. Cerebellar Cerebellar hemorrhages present with varying degrees of altered consciousness, headache, ipsilateral gaze palsy, and ipsilateral ataxia. Hemiparesis and hemisensory disturbances are uncommon. If the hematoma extends into the fourth ventricle, patients often present with hydrocephalus. Large hematomas are particularly dangerous because of their propensity to cause herniation and compression of the nearby brain stem. Mortality rates are high for patients who are comatose at presentation.

b. Brain Stem This particularly devastating form of SICH typically occurs in the pons secondary to rupture of the basilar artery pontine perforators. Brain stem hemorrhages cause combined motor and cranial nerve deficits. Patients often experience autonomic dysfunction and dysarthria. Intraventricular hemorrhage into the fourth ventricle is common and results in hydrocephalus.

F. Diagnosis

Patients' past medical histories often reveal the underlying vascular disorder. It is particularly important to pursue evidence of a previous bleeding disorder, malignancy, ischemic strokes, autoimmune disease, and hypertension. Medications should also be reviewed with special attention focused on anticoagulation therapy. A history of drug and alcohol use is also relevant. Certain drugs, such as cocaine and other stimulants, cause severe hypertension that causes SICH. Alcohol abuse can alter liver function and cause coagulopathy.

Laboratory evaluation can also be diagnostic and should include a complete blood count with differential, protime, partial thromboplastin time, serum chemistries, liver function tests, and erythrocyte sedimentation rate (ESR). These studies screen for hematological and coagulation disturbances as well as infectious and inflammatory diseases. The initial radiological test should be computed tomography (CT), which provides rapid and accurate information regarding hemorrhage location, size, and associated mass effect. Little value can be gleaned from magnetic resonance imaging (MRI) or cerebral angiography in elderly patients who have a history of hypertension and who present with a deep intracerebral hemorrhage. Younger patients without a hypertensive history deserve further radiographic evaluation to rule out vascular anomalies, vasculopathy, and tumors. In the remaining patients, MRI and angiography are performed when structural lesions are suspected. Hematoma can obscure the early MRI. To obtain adequate visualization of the affected region, MRI is often repeated after the hematoma has resolved.

G. Treatment

Patients are managed in neurological intensive care units. Control of the blood pressure is of primary importance particularly in the hypertensive patient. Correction of any coagulation disturbance also takes priority. Medical maneuvers to decrease intracranial pressure are performed with caution because hematoma size can actually increase if decompressed as tamponade is diminished. Patients with supratentorial hemorrhages and hydrocephalus are treated with external ventricular drains. Ventricular drains are used with reluctance in cerebellar hemorrhages for fear of causing upward herniation and death. Surgical evacuation is reserved for patients who present in relatively good neurological condition but deteriorate despite medical management, and only if the surgical approach does not require traversing eloquent brain. Hematomas commonly reaccumulate postoperatively and a high index of suspicion is used in these postevacuation patients who subsequently deteriorate. Stereotactic aspiration is another treatment option. This approach benefits from a lower morbidity, but the ability to effectively drain the hematoma has not been clearly established.

H. Summary

Spontaneous intracerebral hemorrhage is a devastating condition that affects a significant number of

Americans annually. Possible causes are protean, but most are secondary to chronic hypertension. Although management of this difficult pathology is primarily supportive, surgical intervention does benefit a subset of patients.

V. ANEURYSMS

A. General Considerations

Intracranial aneurysms represent focal arterial dilations of the cerebral vasculature. They are most commonly situated at major branching points of the intracranial vessels as they navigate through the subarachnoid space. Intracranial aneurysms have a propensity for spontaneous rupture and give rise to SAH. SAH secondary to aneurysmal rupture remains an immense source of morbidity and mortality in contemporary society. Continuing advancements in molecular biology, minimally invasive treatment modalities, and the refinement of microsurgical techniques offer renewed enthusiasm for the treatment of this condition.

B. Classification

Intracranial aneurysms are classified based on pathology, size, and location. Aneurysms may be saccular (berry), fusiform (atherosclerotic or dolechoectatic), miliary (Charcot–Bouchard or microaneurysms related to hypertension), or dissecting (Table IV). Saccular aneurysms comprise the vast majority and are most commonly related to hemodynamically induced degenerative vascular injury arising at the branching points of arteries (developmental/degenerative aneurysms). Saccular aneurysms may also arise from trauma (traumatic aneurysms); infection (mycotic aneurysms); tumors (oncotic aneurysms); high flow lesions, such as arteriovenous malformations (flow-related aneurysms); vasculopathies, such as fibromuscular dysplasia; and drug use such as cocaine.

Aneurysms may also be categorized by size. Aneurysms are denoted as small (<12 mm in diameter), large (12–5 mm), or giant (>25 mm) as described by Dr. Charles G. Drake. Aneurysms may further be described based on location (Table V). Aneurysms are grouped as arising in either the anterior or posterior cerebral circulations and are subsequently subclassified according to the specific vessel of origin.

Table IV
Pathological Classification of Intracranial Aneurysms

Saccular
Developmental/degenerative aneurysms
Traumatic aneurysms
Mycotic aneurysms
Oncotic aneurysms
Flow-related aneurysms
Vasculopathy-related aneurysms
Drug-related aneurysms
Fusiform
Related to atherosclerosis
Miliary
Related to hypertension (Charcot–Bouchard aneurysms)
Dissecting
Spontaneous or related to underlying trauma or vasculopathy

C. Epidemiology

The incidence of intracranial aneurysms varies depending on the source from which the data are gleaned. Large autopsy series indicate that approximately 1–8% of adults harbor intracranial aneurysms. Large proportions of these aneurysms are very small and therefore the prevalence based on autopsy is higher than that detected radiographically. Radiological series derived from cerebral angiographic studies reveal that between 0.5 and 3% of the population is afflicted. Clinical series have confirmed an annual incidence (per 100,000 population) of 6–19. Collectively, these data demonstrate that between 1 and 12 million Americans have intracranial aneurysms, and that approximately 30,000 persons per year suffer SAH.

Aneurysmal SAH has enormous import to society. Aneurysmal rupture is responsible for 0.4–0.6% of all deaths, and despite an overall decrease in stroke rate, the incidence of aneurysmal SAH remains unaltered. Aneurysmal SAH is associated with a mortality rate of more than 25% and a significant morbidity rate exceeding 50%. Furthermore, it is estimated that approximately $1.75 billion and $522 million are spent annually on the care of patients with ruptured and unruptured aneurysms, respectively, in the United States.

SAH from aneurysm rupture most frequently occurs between the ages of 40 and 60. Aneurysms are rarely found in children, which lends credence to the assertion that most aneurysms arise from hemody-

Table V
Intracranial Aneurysms by Location

Location	Incidence (%)

namic vascular injury. Additionally, studies consistently reveal a female preponderance (54–62%).

D. Natural History

Much effort has focused on the natural history of intracranial aneurysms. Traditionally, the risk of rupture for the asymptomatic unruptured aneurysm has been estimated at 1.0–1.4% per year, with cumulative rates of rupture described as 10% at 10 years, 26% at 20 years, and 32% at 30 years. Recently, the rate of rupture of aneurysms less than 10 mm in diameter in patients without a history of other ruptured aneurysms was less than 0.05% per year. The rate for aneurysms less than 10 mm in diameter in those with a history of SAH from a separate aneurysm was 0.5% per year. The annual rupture rate of aneurysms that were 10 mm or larger in diameter was less than 1% per year in those with or without a prior history of SAH from a separate aneurysm.

Ruptured aneurysms have a very high risk of early and late rebleeding. Rebleeding often causes mortal injury and is associated with a 70% mortality rate. The risk of rebleeding is maximal in the first 24 hr (approximately 4%) and diminishes to 1 or 2% per day for the first 2 weeks. After the first month, the rate appears to stabilize at approximately 3% per year.

E. Pathological Characteristics

Aneurysms arise predominantly at the branch points of the major intracranial vessels and rarely occur outside of the cerebral circulation. To explain the observed paucity of extracranial saccular aneurysms, it has been postulated that the intracranial arteries are predisposed as a result of the thinness of their walls (aneurysms have an attenuated tunica media and an absence of an external elastic lamina) combined with minimal perivascular support.

The pathogenesis of cerebral aneurysms is incompletely understood but is likely complex and multifactorial involving a congenital predisposition and superimposed environmental factors. Evidence for a congenital component arises from observations of familial cases and the increased incidence of aneurysms in disorders such as autosomal-dominant polycystic kidney disease, fibromuscular dysplasia, aortic coarctation, and connective tissue disorders such as Marfan's syndrome and Ehlers–Danlos syndrome. In support of an environmental component, data reveal a clear age-related component (increased incidence with increasing age and rarity of aneurysms in children) and the *de novo* development and/or growth of aneurysms after unilateral carotid occlusion. Additionally, cigarette smoking has been consistently reported to confer predisposition to aneurysmal SAH in large series across different populations. Furthermore, injury to the vessel walls by various insults, such as infection, trauma, and neoplastic growth, also gives rise to aneurysm formation.

Histopathological characteristics of aneurysms are well documented. The tunica media is attenuated or absent. Inflammatory and atherosclerotic changes contribute to defects in the tunica elastica and media.

These changes occur primarily at points of marked hypertensive and hemodynamic stress.

As depicted in Table V, aneurysms are most frequently located in the anterior circulation. Regions of particular predilection include the anterior communicating artery complex, the internal carotid artery and posterior communicating artery, or the bifurcation/trifurcation of the middle cerebral artery complex (Fig. 11). Aneurysms arising in the posterior circulation are most frequently found at the BA bifurcation followed by the posterior inferior cerebellar–vertebral artery region (Fig. 12). Multiple intracranial aneurysms are commonly encountered, and data demonstrate that multiple aneurysms are found in 20–30% of patients.

F. Clinical Manifestations

Aneurysms most often present subsequent to SAH. They also may manifest secondary to mass effect (compression of adjacent structures) or cerebral ischemic symptoms, or they may simply be detected as an incidental finding during a test done for other indications.

1. Subarachnoid Hemorrhage

Aneurysmal rupture normally gives rise to blood in and around the basal cisterns in the subarachnoid space (subarachnoid hemorrhage) but may hemorrhage into the ventricular system (intraventricular hemorrhage), brain parenchyma (intracerebral hemorrhage), or, rarely, the subdural space leading to subdural hemorrhage. This rupture presents clinically as the sudden onset of severe headache (often described as the ''worst headache of my life'') and is often associated with signs of meningeal irritation (such as nausea/vomiting, meningismus, photophobia, and phonophobia). Aneurysmal SAH often occurs during straining or exertion, such as with exercise, intercourse, or a bowel movement. SAH may also lead

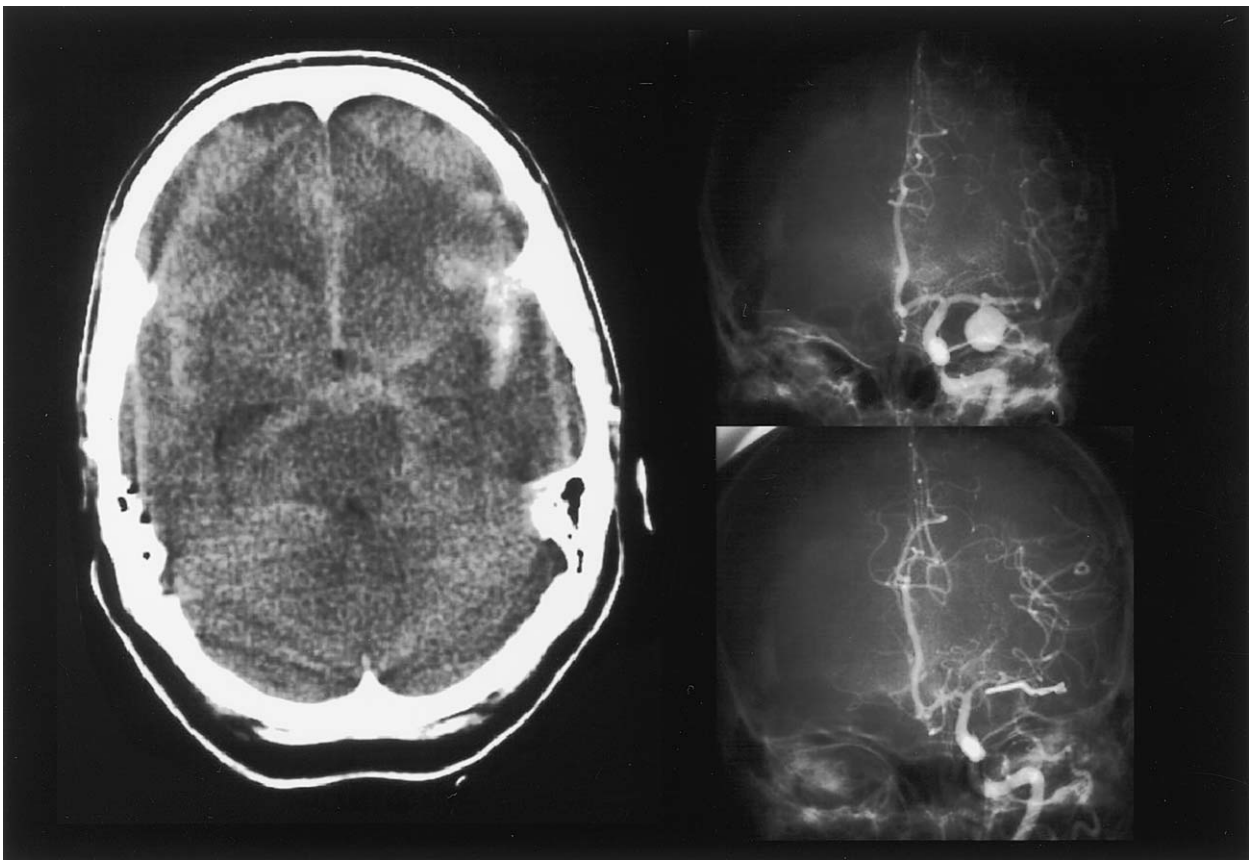

Figure 11 Anterior circulation aneurysm. (Left) Axial noncontrasted CT scan revealing subarachnoid hemorrhage in basal cisterns and Sylvian fissure. Subarachnoid blood predominates in the left Sylvian fissure. (Right, top) Frontal view of angiogram after left ICA injection revealing large MCA bifurcation aneurysm. (Right, bottom) Same view angiogram postoperatively revealing aneurysm clip across aneurysmal neck with no residual aneurysm filling.

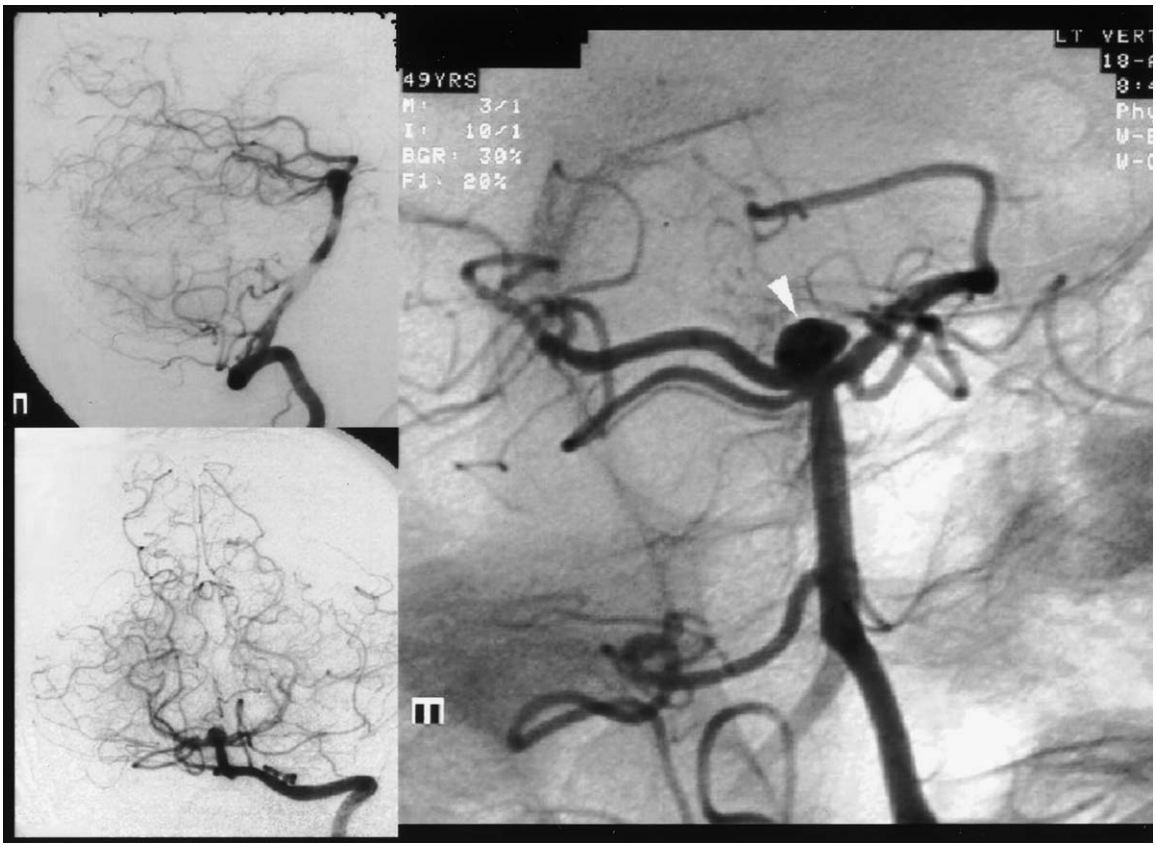

Figure 12 Posterior circulation aneurysm: angiograms after left vertebral artery injection. (Left, top) Lateral projection reveals basilar bifurcation aneurysm. (Left, bottom) Frontal view of same aneurysm. (Right) More superiorly projected frontal view provides optimal view of aneurysm.

to seizures. In more severe cases, SAH may lead to a decreased level of consciousness and various global and focal neurological deficits may be elicited during physical examination. Ophthalmologic examination may reveal unilateral or bilateral subhyaloid hemorrhages in nearly 25% of patients with SAH. These are venous in origin and are situated between the retina and vitreous membrane.

Symptoms preceding the major SAH, such as atypical headaches or neck stiffness, have been ascribed to small hemorrhages and are termed ''sentinel leaks'' or ''warning headaches.'' These symptoms occur in as many as 70% of patients, leading about half of these patients to seek medical attention. Many of these patients are misdiagnosed, which may have future catastrophic repercussions.

SAH may be complicated by cerebral vasospasm and ischemic stroke resulting from the delayed narrowing of intracranial vessels. The incidence of vasospasm begins to increase 3–5 days posthemorrhage, peaks between 7 and 10 days, and diminishes over 2 or 3 weeks. Clinically significant vasospasm occurs in 25–30% of patients, although angiographic evidence is seen in approximately 60–70% of cases.

The most significant predictor of the development of cerebral vasospasm following aneurysmal SAH is the amount and location of subarachnoid blood visualized by CT imaging as popularized by Fischer (Table VI). Approximately 50% of patients with symptomatic vasospasm develop infarction despite therapy. In addition, 15–20% of patients with symptomatic vasospasm will develop a disabling stroke or die of progressive ischemia. Cerebral vasospasm remains the leading treatable cause of death and disability attributed to aneurysmal SAH.

SAH may also be complicated by hydrocephalus. Acute hydrocephalus occurs in 25% of patients with aneurysmal SAH, most often with intraventricular and/or blood in the ambient cisterns. Many patients develop chronic communicating hydrocephalus.

The most important predictor of the outcome of patients suffering from SAH is based on the patient's

Table VI
Fischer Grade Computed Tomographic Scan Classification of Subarachnoid Hemorrhage

Grade	Description
1	No blood detected
2	Diffuse deposition or thin layer of blood, with all vertical layers of blood (interhemispheric fissure, insular cistern, and ambient cistern) <1 mm thick
3	Localized clots or vertical layers of blood 1 mm or more in thickness (or both)
4	Diffuse or no subarachnoid blood but with intracerebral or intraventricular clots

Table VII
Hunt–Hess Clinical Grading Scale for Subarachnoid Hemorrhage

Grade	Clinical conditon
1	Asymptomatic or mild headache and mild nuchal rigidity
2	Cranial nerve palsy, nuchal rigidity, and moderate to severe headache
3	Drowsy, confused, or mild focal deficit
4	Stupor, moderate to severe hemiparesis, and early decerebrate posturing
5	Comatose and decerebrate posturing

Table VIII
World Federation of Neurological Surgeons Clinical Grading Scale for Subarachnoid Hemorrhage

Grade	Glasgow coma scale	Motor deficit
0	15	Absent
1	15	Absent
2	13–14	Absent
3	13–14	Present
4	7–12	Present or absent
5	3–6	Present or absent

condition at presentation. Multiple grading systems have been proposed but the most widely utilized are the Hunt–Hess scale and the scale of the World Federation of Neurological Surgeons (Tables VII and VIII). The World Federation of Neurological Surgeons scale is based on the universally recognized Glasgow coma scale.

2. Mass Effect

Aneurysms, particularly large or giant, may compress adjacent structures and cause neurological deficits. Mass effect commonly causes headache or a third cranial nerve palsy from compression at the junction of the PCoA and the ICA. Other symptoms/signs may include visual field defects, trigeminal neuralgia, brain stem dysfunction, cavernous sinus syndrome (compression of structures traversing the cavernous sinus), seizures, or endocrinologic symptoms due to disruption of the hypothalamic–pituitary axis.

3. Cerebral Ischemia

Embolization of intraaneurysmal thrombus may lead to cerebral ischemic symptoms in the distribution of the cerebral vasculature occupied by the aneurysm. This is a rare presentation of an unruptured aneurysm.

4. Incidental Finding: The Asymptomatic Aneurysm

Widespread adoption of CT and MRI has increasingly led to the discovery of asymptomatic intracranial aneurysms. The discrepancy between the incidence of aneurysms as detected by autopsy and the incidence of SAH apparent in the preceding discussion of epidemiology is resolved by the fact that most aneurysms never rupture.

G. Diagnosis

1. Subarachnoid Hemorrhage

The most common cause of spontaneous (i.e., nontraumatic) SAH is aneurysmal rupture. SAH is first suspected based on clinical presentation. The first diagnostic study performed is usually a noncontrasted CT scan. CT is very sensitive in detecting acute blood and detects between 90 and 95% of patients correctly within 24 hr posthemorrhage. This sensitivity, however, diminishes as blood is rapidly cleared from the subarachnoid space and is approximately 30% sensitive at 2 weeks following hemorrhage. CT can also suggest aneurysm location. For example, blood in the interhemispheric fissure is suggestive of rupture of an ACoA aneurysm, blood in the Sylvian fissure suggests rupture of a MCA aneurysm, and blood in the fourth

ventricle is indicative of a PICA hemorrhage. CT scanning is also used to ascertain the risk of development of cerebral vasospasm. The amount and location of the subarachnoid blood are evaluated according to the Fischer grading system (Table VI).

If CT imaging is negative and the clinical suspicion of SAH is still high, the next diagnostic modality of choice is lumbar puncture. Frank blood in the cerebrospinal fluid (CSF) is not diagnostic and often due to poor lumbar puncture technique. In contrast, xanthochromia (yellow discoloration) of the supernatant which results from the breakdown of blood products within the CSF is diagnostic of SAH. MRI plays a limited role in the diagnosis of SAH and is insensitive in the detection of acute blood. It may be implemented in demonstrating subacute and/or chronic subarachnoid blood after the CT scan normalizes.

2. Intracranial Aneurysms

Three diagnostic modalities are most commonly used to make the diagnosis of intracranial aneurysms: cerebral angiography, MR angiography (MRA), and CT angiography (CTA). Conventional angiography remains the gold standard and provides the most information pertaining to the diagnosis and definitive description of an aneurysm's anatomical configuration (Fig. 11). Conventional angiography, however, is an invasive technique with associated risks, such as stroke, renal failure, and hematoma and/or pseudoaneurysm formation at the puncture site. In contemporary practice, the mortality rate is less than 0.1% and the rate of permanent neurologic injury is approximately 0.5% following cerebral angiography.

MRA is noninvasive and requires no intravascular contrast administration and thereby poses minimal risk to patients. MRA can detect aneurysms as small as 2 mm; however, the critical size for detection from prospective studies is approximately 5 mm. Although MRA may be effectively implemented in the screening for intracranial aneurysms, it is rarely sufficient for adequate surgical planning. CTA has also been the subject of recent interest in the diagnosis of intracranial aneurysms. Helical (spiral) CTA appears to be as sensitive as MRA. It defines the aneurysm's relation to important bony landmarks and is particulary useful when cranial base surgical techniques are being contemplated. CTA is also compatible with older ferromagnetic clips that preclude the use of MRA.

3. Screening for Asymptomatic Aneurysms

Screening for asymptomatic aneurysms in selected patients has been a matter of controversy. A recent large prospective study provided additional guidance in this area. Screening of first-degree relatives of patients suffering aneurysmal SAH was undertaken using MRA. Implementation of a screening program for first-degree relatives of patients with sporadic SAH did not appear to be warranted because the resulting slight increase in life expectancy did not offset the risk of postoperative sequelae.

SAH from aneurysmal rupture is a devastating event. Surgical treatment of unruptured lesions is associated with a relatively low rate of morbidity ($<5\%$) and mortality ($<2\%$) and eliminates the risk of future SAH. Furthermore, evolving minimally invasive strategies, such as endovascular techniques using Guglielmi detachable coils (GDCs) and intracranial stents, offer promise in support of the screening programs and aggressive management of unruptured intracranial aneurysms. Currently, however, widespread screening for asymptomatic intracranial aneurysms does not seem warranted, but future studies may reveal subsets of patients for whom screening has proven efficacy.

H. Treatment of Intracranial Aneurysms

1. General Considerations

Definitive treatment of intracranial aneurysms is aimed at excluding the aneurysm from the cerebral circulation with preservation of the parent artery. Exclusion of the aneurysm from the cerebral circulation, by means of clip placement across the aneurysm neck surgically or with the placement of GDCs endovascularly, theoretically eliminates the risk of future rupture and its associated disability. Alternatively, small intracranial aneurysms, in select locations such as the cavernous sinus, may be observed with caution. Treatment of complications associated with aneurysmal SAH, such as seizures, cerebral vasospasm, and hydrocephalus, is also executed as necessary.

2. Microsurgery

Surgical clipping of intracranial aneurysms remains the definitive treatment and is well validated with proven long-term efficacy (Fig. 11). In experienced

hands, aided by the operating microscope, microinstruments, and microsurgical principles, aneurysm clipping carries relatively low morbidity and mortality directly attributable to surgery. Aneurysms by virtue of their size, anatomical configuration, or location not easily amenable to standard techniques may require specialized adjuncts, including hypothermic circulatory arrest and vascular bypass grafts. Additionally, occlusion of the parent vessel with surgical or endovascular technology may be necessary, with or without concomitant bypass grafting, when clipping cannot be implemented.

The timing of surgery for ruptured intracranial aneurysms remains a matter of controversy. There is general consensus that "good-grade" patients (Hunt–Hess grades 1–3) should undergo early surgery (within the first 48–72 hr) because recurrent hemorrhage is the major cause of death in patients who survive the initial hemorrhage. For "poor-grade" patients and those who are otherwise medically unstable or who bled several days earlier and are experiencing symptomatic vasospasm, surgery is delayed until the patients are stabilized and deemed capable of making a meaningful recovery (or until 10–14 days posthemorrhage in patients experiencing significant vasospasm). However, some centers have advocated early surgery in poor-grade patients and have achieved reasonable results. Some of these patients deemed to be too unstable for surgery may undergo early endovascular treatment.

3. Endovascular Therapy

The 1990s were characterized by the rapid emergence and refinement of endovascular techniques as a minimally invasive means of treating intracranial aneurysms. Endovascular placement of GDCs has been demonstrated to be a safe treatment modality for select patients. Currently, endovascular treatment is utilized predominantly for patients thought to be poor surgical candidates and for aneurysms anticipated to be difficult to treat surgically. GDCs evoke thrombosis within the aneurysmal sac, thereby isolating it from the circulation. Recently, placement of coils concomitantly with intracranial stents to facilitate satisfactory packing and to prevent migration of the coils has been described. Currently, long-term validation of endovascular treatment is not available. With design and implementation of new endovascular techniques and as long-term validation emerges, endovascular therapy is predicted to become an increasingly important treatment modality.

I. Summary

Intracranial aneurysms are a common and potentially devastating disorder of the cerebral circulation. Intracranial aneurysms may be classified by pathological basis, size, or location. The pathogenesis is not completely understood but is likely multifactorial, combining both a genetic predisposition and environmental factors. Aneurysms may present as a result of hemorrhage and its associated complications (such as seizures, vasospasm, and hydrocephalus), from compression of adjacent structures (mass effect), as cerebral ischemia, or may be discovered incidentally. Diagnosis is based on history and physical examination augmented with imaging techniques such as CT or MRI and cerebral angiography. Treatment of intracranial aneurysms endeavors to eliminate the aneurysm from the cerebral circulation while ensuring patency of the parent vessel and surrounding perforating vessels.

VI. VASCULAR MALFORMATIONS

Contemporary understanding and treatment of intracranial vascular malformations have evolved considerably during the past three decades. Advances are attributable to the evolution of neuroimaging, endovascular therapy, microsurgical technique, and stereotactic radiosurgery. Intracranial vascular malformations may be divided into four subcategories: arteriovenous malformations (AVMs), cavernous malformations, venous malformations, and capillary telangiectasias. Rational therapy is contingent on an understanding of the characteristic features of each malformation. A multimodal "team" approach encompasses specialists in microsurgery, radiosurgery, and endovascular therapy and is increasingly required to provide optimal care.

A. Classification

Vascular malformations may be divided into four distinct categories, each with unique anatomical, pathological, radiological, and clinical features. The four traditional subtypes are AVMs, cavernous malformations, venous malformations, and capillary telangiectasias. This classification system is a generally useful template, although there is often considerable overlap between malformations subjected to careful scrutiny.

B. Arteriovenous Malformations

1. Epidemiology and Natural History

AVMs are approximately one-seventh to one-tenth as common as cerebral aneurysms with between 2500 and 3000 new cases presenting each year. An estimated 280,000 patients are afflicted with AVMs in the United States. There appears to be a slight male preponderance between just over 1:1 (male to female) to 2:1.

The natural history of AVMs is incompletely understood. The annual risk of hemorrhage is noted to be 4 and 2% for symptomatic and asymptomatic AVMs, respectively. The average time between initial symptoms (related to hemorrhage or seizures) and rehemorrhage is 8 years. Each hemorrhagic episode appears to be associated with a 20% risk of major neurologic morbidity and a 10% mortality. There is an increased risk of rupture with smaller malformations, AVMs with associated aneurysms, a single draining vein, deep venous drainage, or venous stenosis.

2. Pathological Characteristics

AVMs are congenital lesions consisting of rudimentary arteries feeding directly into veins without intervening capillary or venule networks (Fig. 13). They are normally high-pressure, high-flow malformations with a predilection for damage of surrounding parenchyma upon rupture. Involved veins are "arterialized," becoming dilated, elongated, and tortuous under direct arterial pressure. Vasculopathic changes, such as stenosis or thrombosis of feeding arteries and draining veins, are common. AVMs often assume a conical configuration, with the base located near the cortex and the apex extending to the ventricular system. Gliotic brain tissue may be found encompassed within the malformation. As a consequence of arterial shunting, adjacent brain is subject to poor perfusion and ischemia. Flow-related aneurysms are noted in approximately 8–12% of cases, either on feeding vessels or within the nidus (intranidal). Eight-five percent of AVMs are located supratentorially and 15% are found in the posterior fossa.

3. Clinical Manifestations

AVMs most frequently present as a consequence of hemorrhage in patients in their third and fourth decades. Unlike with rupture of cerebral aneurysms, early rebleeding (within 2 weeks) and cerebral vasospasm are rare because hemorrhage secondary to AVMs is predominantly located intraparenchymally rather than within the subarachnoid space. Neurologic improvement is often seen as the clot regresses and is resorbed, and it provides rationale for delayed surgery 1–4 weeks after hemorrhage when the clot is organized and the brain less friable. Seizures are the second most common presentation of patients with AVMs, being noted in 11–33% of cases. Seizures are thought to be related to gliosis in the adjacent brain resulting from hemosiderin deposition and inflammation. Additionally, patients may present with the new onset of headache (from stretching of the dura, elevated venous pressure, or hydrocephalus) or progressive neurological deficit or cognitive decline (from arterial steal or venous hypertension).

4. Diagnosis

Cerebral angiography remains the gold standard for diagnostic evaluation of putative AVMs (Fig. 13). It provides detailed information regarding the configuration and vascular dynamic properties (such as flow rate, arterial steal/venous hypertension, and collateral flow). MRI and CT imaging are also useful adjuncts. Based on lesion size, location, and pattern of venous drainage, operative risk is assigned to a given patient's AVM via the Spetzler–Martin classification scale (Table IX).

5. Treatment

Comprehensive management of patients harboring AVMs involves three main therapeutic modalities: endovascular therapy, microsurgery, and stereotactic radiosurgery. Endovascular therapy, applying catheter-administered materials for embolization, is a useful adjunct to microsurgery and stereotactic radiosurgery to diminish the degree of arterial shunt. Embolization is rarely curative alone, however. Within 1 week following embolization (to prevent recanalization of embolized vessels), microsurgery may be performed to excise the lesion. Surgical risk is ascertained from the Spetzler–Martin scale preoperatively. In younger patients possessing superficial lesion in noneloquent areas, microsurgery is clearly the treatment of choice (Fig. 13). Microsurgery is also more effective than radiosurgery in ameliorating symptoms of intractable epilepsy and headaches. Stereotactic radiosurgery is reserved for patients with small (<3 cm), unruptured AVMs in eloquent brain substance with deep venous drainage. Stereotactic radiosurgery invokes vascular injury and produces delayed thrombosis after months

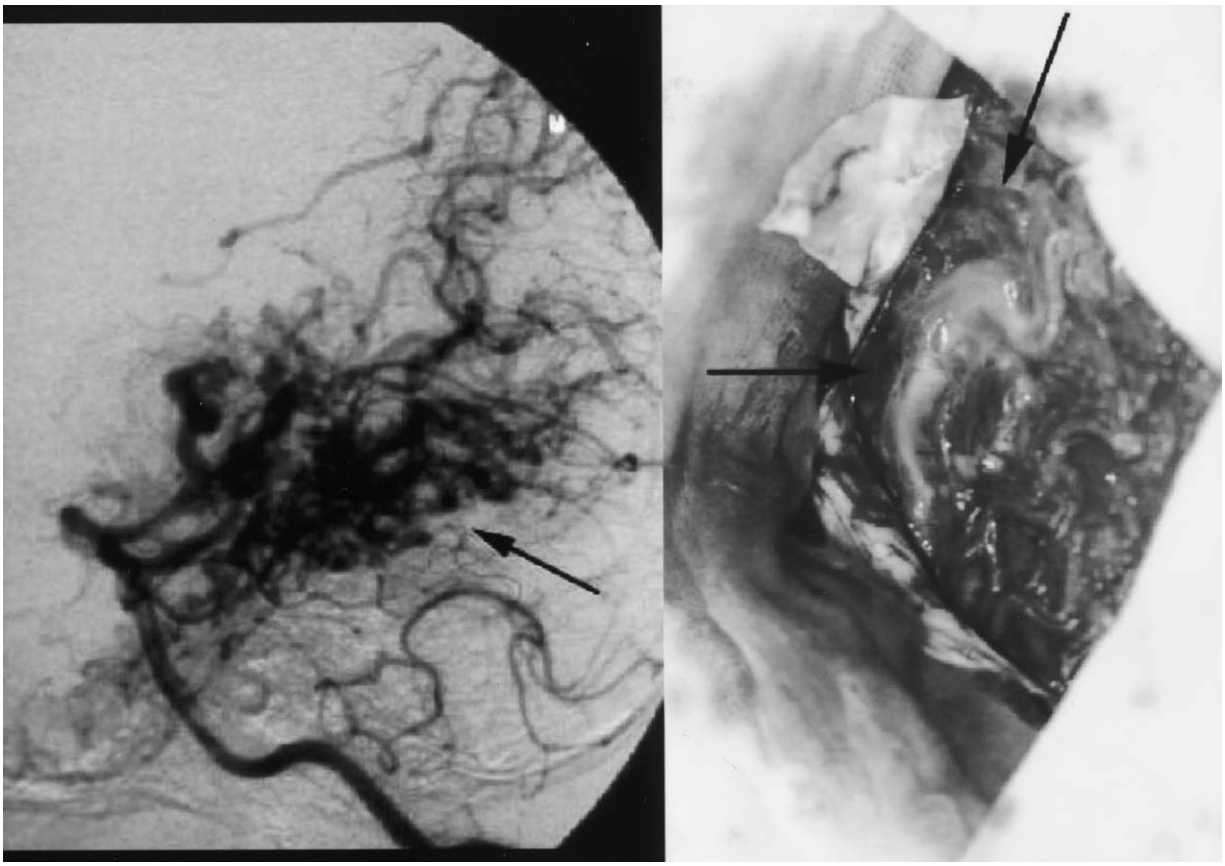

Figure 13 Arteriovenous malformation. (Left) Lateral view of angiogram after left vertebral injection. Arrow indicates AVM. (Right) Intraoperative photograph shows the same AVM immediately evident after durotomy.

Table IX
Spetzler–Martin Classification Scale for Operative Risk in Patients with AVMs[a]

Characteristic	Points assigned
Size	
Diameter <3 cm	1
Diameter 3–6 cm	2
Diameter >6 cm	3
Location	
Noneloquent site	0
Eloquent site (sensorimotor, language, visual, hypothalamus or thalamus, internal capsule, brain stem, cerebellar peduncles or nuclei)	1
Pattern of venous drainage	
Superficial only	0
Any deep	1

[a]Scores of 4 or 5 are associated with the greatest risk of persistent postoperative neurological deficits.

to years. Thus, unlike surgery, protection from hemorrhage imparted from radiosurgery is delayed. Radiosurgery's benefits diminish and its adverse effects (damage to adjacent parenchyma) increase as the size of the lesion increases. Radiosurgery may be a viable option for the treatment of deep, residual AVMs after attempted microsurgical resection.

C. Cavernous Malformations

1. Epidemiology and Natural History

Cavernous malformations (or cavernous angiomas) affect both sexes equally. Estimates of lesion prevalence vary between 0.02 and 0.9% depending on the criteria and methods utilized for definition. Patients typically present in the second to fourth decades of life. Familial forms, characterized by multiple lesions and an autosomal-dominant inheritance pattern, are well described and prevalent in the Hispanic population.

The natural history of cavernous malformations is not well defined. Cavernous malformations are known to be dynamic lesions that change in size and imaging characteristics with time. New lesions are also known to develop over time. Subclinical microhemorrhages are thought to be very common. Previously asymptomatic lesions have a 1% annual incidence of hemorrhage. Once symptomatic, cavernomas rupture at an annual rate of 4.5%. Hemorrhage occurs commonly in the familial forms, deeply located lesions, lesions with associated venous malformations, in pregnant patients, and in patients who have received whole brain irradiation.

2. Pathological Characteristics

Cavernous malformations represent a lobulated collection of dilated endothelial-lined sinusoidal spaces. There is normally no intervening brain parenchyma. They are low-flow lesions that expand by internal thrombosis and hemorrhage within the sinusoidal spaces. Hemorrhage in various stages may be found within the lesion. Neighboring brain is well demarcated by hemosiderin stained, gliotic borders. The walls of the malformation lack smooth muscle and elastic lamina and are thus not true arteries or veins. Venous malformations are found in association with cavernous malformations in 15% of cases. Eighty percent of lesions are supratentorial but may occur at any location. Multiple lesions are demonstrated in 50–80% of cases.

3. Clinical Manifestations

Seizures are the most common manifestation of supratentorial cavernous malformations. Surrounding hemosiderin and gliosis is thought to be responsible for this epileptogenicity. Symptomatic hemorrhage and headache are the next most common presentions. Cavernous malformations are also frequently found incidentally in radiographic studies performed for other indications.

4. Diagnosis

Cavernous malformations cannot be visualized with angiography and are best delineated by MRI. With MRI, cavernous malformations appear as a central focus of mixed signal intensity representing hemorrhage of various stages (''popcorn-like'') surrounded by a hypointense rim of hemosiderin from multiple microhemorrhages (Fig. 14).

5. Treatment

Cavernous malformations that are asymptomatic are not generally treated because of their low risk of hemorrhage ($\sim$1%/year). Microsurgical resection is indicated for symptomatic supratentorial lesions. Brain stem cavernous malformations are considered for surgical resection when there is repeat hemorrhage, progressive neurological deficit, and superficial location. Stereotactic radiosurgery remains an experimental treatment option.

D. Venous Malformations

Venous malformations are composed of histologically normal veins that radially converge on a single draining vein with interposed normal brain (as opposed to cavernous malformations with no interposed normal brain). This pattern has been described as a ''spoke wheel'' or ''caput medusae'' and is best seen in the venous phase of angiographic studies (Fig. 15). There is no arterial inflow. Venous malformations are located within the white matter commonly adjacent to an ependymal surface. Venous malformations are clinically silent and are considered benign. If a hemorrhage or seizure occurs, an associated AVM or cavernous malformation should be suspected.

E. Capillary Telangiectasias

Capillary telangiectasias consist of nests of dilated capillaries with interposed normal brain substance. They are clinically silent lesions and rarely exceed 1 cm in size. They are most frequently seen in the pons and are detected only in contrast-enhanced MRI studies. Capillary telangiectasias may represent a precursor or transitional form of cavernous malformations.

F. Summary

Vascular malformations represent an important disorder of the intracranial vasculature. Vascular malformations may be categorized as arteriovenous malformations, cavernous malformations, venous malformations, and capillary telangiectasias. Each subtype possesses its own unique natural history, clinical manifestations, and imaging characteristics. Different treatment paradigms have been established for each malformation. A multimodal approach to

Figure 14 Cavernous malformation: T1-weighted axial MRI, with arrows marking typical brain stem cavernoma with "popcorn" appearance.

treatment encompasses the disciplines of microsurgery, endovascular therapy, and stereotactic radiosurgery. Effective treatment of the most complex vascular malformations is being increasingly realized.

VII. DURAL ARTERIOVENOUS FISTULAE

Dural arteriovenous fistulae (DAVF) are arteriovenous shunts involving the dura and epidural space. DAVF are located within the dural wall of a venous sinus rather than within the sinus. DAVF are most commonly situated in the transverse and sigmoid sinuses followed by the cavernous sinus. In approximately 7% of cases, multiple DAVF may be encountered. They account for 10–15% of all intracranial AVMs and may be of congenital or acquired origins.

It is hypothesized that acquired DAVF may result from antecedent venous stenosis, thrombosis, or occlusion of a dural venous sinus. With recanalization, normally present microscopic arteriovenous shunts may enlarge, forming multiple microfistulae and giving rise to a DAVF (DAVF have microfistulae and not nidi *per se*). Angiogenesis has also been proposed to play a role in the development of AVF.

DAVF are encountered across all age groups including children. Most symptomatic lesions, however, are seen between the fifth and seventh decades. Clinical signs and symptoms are variable and commonly include headache and bruit (with involvement of the transverse and/or sigmoid sinuses), retroorbital pain, proptosis, chemosis, and ophthalmoplegia (cavernous sinus lesions). Other less common manifestations include cranial nerve palsies, tinnitus, and dementia.

A preponderance of DAVF behave benignly and may even spontaneously regress. In contrast, some DAVF present with hemorrhage or neurological decline. Clinical presentation, neurological status, and long-term prognosis of those individuals harboring DAVF are most closely governed by the pattern of venous drainage.

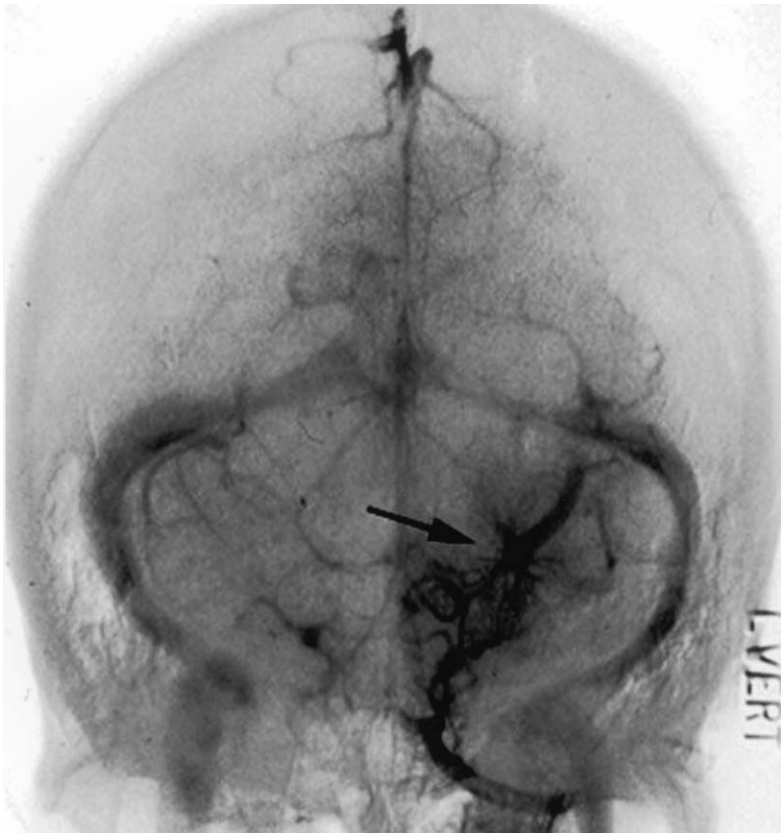

Figure 15 Venous angioma: frontal view of venous phase angiogram with arrow indicating the caput medusa appearance.

Classification schemes have been proposed by Borden and colleagues and Cognard and colleagues. In the Borden scheme, type I DAVF have dural venous sinus outflow only, type II DAVF have dural venous sinus outflow with retrograde leptomeningeal (or cortical) venous drainage, and type III DAVF have retrograde leptomeningeal (or cortical) venous drainage only. Type I DAVF are typically benign, and types II and III are increasingly associated with hemorrhage and aggressive clinical courses.

CT and MRI may help to reveal the lesion (and detect hemorrhage if present). Ultimately, cerebral angiography is necessary to accurately define the anatomic and hemodynamic characteristics.

Treatment is undertaken after careful review of the clinical and radiological characteristics in each case. Treatment options include conservative management (careful observation), microsurgery, radiosurgery, endovascular therapy (transarterial or transvenous embolization), or combinations thereof. The availability of long-term follow-up data will help to validate current treatment paradigms.

VIII. VASCULOPATHIES

Vasculopathies represent a broad category of disorders involving blood vessels. The most common are the vasculitides, moyamoya disease, fibromuscular dysplasia, and cerebral amyloid angiopathy.

A. Vasculitides

1. General Considerations

The vasculitides are a diverse group of infrequent disorders characterized by underlying inflammation and necrosis of the blood vessel wall. They are heterogeneous with respect to presentation, distribution, size of the affected vessel, and underlying etiology. Central nervous system (CNS) vasculitis is a potentially serious disorder with symptoms arising from ischemia or hemorrhage. Rapid diagnosis and treatment are prerequisite to favorably altering the disease course.

2. Classification

The vasculitides are generally divided into primary and secondary disorders (Table X). The primary vasculitides are subdivided based on the size of the vessel affected (i.e., large, medium, or small). Large-vessel vasculitides include temporal arteritis, Takayasu's arteritis, and primary angiitis of the CNS. Polyarteritis nodosa and Kawasaki disease typify the medium-vessel vasculitides. The small-vessel vasculitides include Churg–Strauss syndrome and Wegener's granulomatosis. The secondary vasculitides represent the most frequent cause of CNS vasculitis. They are a varied group and result from underlying autoimmune diseases, intoxications, and infectious and neoplastic processes.

Table X
Classification of Vasculitides Affecting the Central Nervous System

Primary vasculitides	Secondary vasculitides
Large vessel	Autoimmune diseases
Temporal arteritis	Systemic lupus erythematosis
Takayasu's arteritis	Sjogren's syndrome
Primary angiitis of the central nervous system	Behcet's syndrome
Medium vessel	Toxic
Polyarteritis nodosa	Infectious
Kawasaki's arteritis	Neoplastic
Small vessel	
Churg–Strauss syndrome	
Wegener's granulomatosis	

3. Pathogenesis

The pathogenesis of vasculitis is complex and not well understood. There is increasing evidence that antineutrophil cytoplasmic antibodies (ANCAs) play a role in the immunopathogenesis of the vasculitides by activating neutrophils and thereby causing endothelial injury. Various immunological mechanisms have been proposed, but ultimately inflammation causes leukocytes to adhere to the vessel wall. The inflammation is usually segmental in nature, with skip lesions of intense inflammation interrupting otherwise normal vasculature. One or more layers of the vessel wall can be affected. The inflammation tends to resolve, leaving fibrosis and hypertrophy, which cause secondary occlusion.

4. Clinical Presentation

Vasculitis can present with CNS symptoms and signs alone or combined with nonspecific or multiorgan symptoms. The sequelae depend on the number, size, and site of the involved blood vessels. Focal injuries tend to cause wall rupture and hemorrhage. Segmental injuries affect the entire wall circumference and tend to cause stenosis, occlusion, and infarction. Collectively, patients can present with cerebral ischemia, encephalopathy, intracerebral hemorrhage, or seizures.

5. Diagnosis

The diagnosis of vasculitis can be difficult. A complete history and physical examination, augmented with appropriate laboratory tests, are necessary. A complete blood count should be performed and markers of inflammation, such as ESR and C-reactive protein, will be elevated. Other laboratory tests that can help diagnose the cause include liver and renal function tests, complement levels, cryoglobulin levels, Rh factor, anti-nuclear antibody, c- and p-ANCA, serologies for hepatitis B and C, lupus anticoagulant, and anti-cardiolipin antibody. A brain meningeal biopsy is the gold standard in diagnosis and confirmation.

Imaging studies can also facilitate the diagnosis. MRI and angiography may detect CNS lesions but there are no pathognomonic MRI findings. CT and MRI changes will occur in areas of ischemia or hemorrhage. MRI is more sensitive for identifying small foci and for detecting multiple CNS lesions. MR angiography may show narrowing of the larger intracranial vessels but standard angiography is necessary to delineate many of the subtle changes characteristic of vasculitis (Fig. 16). These include multiple arterial occlusions, especially of the small vessels over the convexity, segmental stenosis of intracranial vessels sometimes separated by dilations causing a beaded appearance, and intracerebral aneurysms. However, none of these findings are specific to vasculitis.

6. Treatment

Treatment varies with the specific condition. After the specific syndrome is identified, the inciting agents are avoided and the underlying condition is treated. Steroid administration is the mainstay of treatment and can be guided by the size of the involved vessels. Large-vessel involvement responds well to corticosteroids alone, whereas small- and medium-sized vasculitides respond better to a combination of cyclophosphamide and steroids. Steroids should be

decreased to the lowest effective dosage to minimize side effects. Low-dose methotrexate, V immunoglobulin, or plasmapheresis can be used in difficult or select cases. Hypertension should be treated along with any underlying conditions. Surrogate markers of inflammation, such as erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), antinuclear antibody (ANA), and antinutrophil cytoplasmic antibody (ANCA), can be used to follow the course of the disease.

7. Summary

The vasculitides are a clinically and pathologically heterogeneous group of disorders characterized by inflammation of the blood vessels that may represent a primary or secondary disease process. Additional insight into the pathoetiology will enhance our ability to effectively diagnose and treat these disorders.

B. Moyamoya Disease

1. General Considerations

Moyamoya disease is a rare progressive occlusive cerebrovascular disorder. It is characterized by progressive occlusion of the distal portions of the internal carotid arteries and proximal portions of the anterior and middle cerebral arteries (Fig. 17). A compensatory network of small collateral vessels form in the adjacent areas at the base of the brain producing the characteristic appearance of a puff of smoke (moyamoya is Japanese for "wavering puff of smoke"). Symptoms are due to cerebral ischemia and/or hemorrhage and can occur on alternating sides because of the bilateral nature of the disease. Although some patients present with only headache or visual disturbance, symptoms can include serious neurological deficits such as hemiparesis, motor aphasia, seizure, and mental alteration.

2. Epidemiology

Moyamoya is particularly prevalent in Japan and Korea, where 10% of patients have a family history of the disease. This increased incidence in Asian populations and familial occurrence has also led to the hypothesis of HLA gene involvement. The disease is more prominent in females, with a ratio of 1:1.8. It is rare, with a reported incidence of 0.35 per 100,000 people, but it is probably underdiagnosed because it is

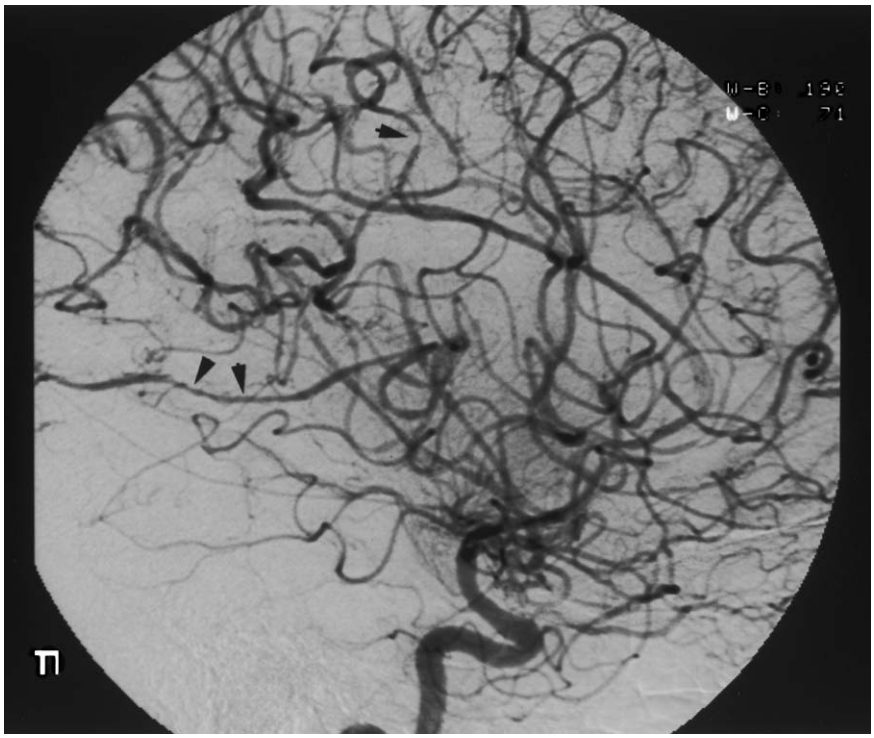

Figure 16 Cerebral angiogram of a patient with vasculitis revealing multiple focal areas of abnormal stenosis followed by dilatation throughout the brain.

often asymptomatic. The age distribution is bimodal, with the first peak occurring between the ages of 10 and 14 and the second between ages 40 and 49.

3. Pathogenesis

Histopathological changes occur in the terminal ICA and proximal ACA and MCA. Vessel walls display multilayered intimal fibrous thickening and markedly wavy, often duplicated or triplicated, internal elastic lamina. The thickened intima contains an increased number of smooth muscle cells but no inflammatory infiltrate, atherosclerosis, or fibrinoid necrosis. The media is usually atrophic. Varying degrees of intimal thickening are evident.

Moyamoya is an entity of unknown etiology. Both a congenital component (due to polygenic inheritance) and an acquired component (due to trauma, infection, brain tumor, radiation, or autoimmune disease) have been proposed. Recently, aberrations of vascular growth factors and cytokines have been implicated. Basic fibroblast growth factor (b-FGF) has been reported to be significantly higher in the CSF of patients with moyamoya disease than in patients with arteriosclerotic cerebrovascular occlusive disease. Increased activity of b-FGF and b-FGF receptors has also been noted in the superficial temporal artery wall.

4. Clinical Features

The clinical characteristics vary depending on the age of diagnosis. Among pediatric patients the initial symptoms are mainly due to cerebral ischemia (TIAs) and are recurrent and progressive. Their symptoms can be induced by crying, coughing, straining, or hyperventilation. In most children, the vascular obstructions rapidly progress and well-developed moyamoya vessels are noted within 2 or 3 years of the first attack. Whereas only 10% of children suffer intracranial hemorrhage, the incidence exceeds 60% in adults. Hemorrhage most often occurs in the basal ganglia, thalamus, or ventricle. Vascular obstructions in adults progress slowly if at all.

5. Diagnosis

The diagnostic criteria of the disease are based mainly on angiographic findings and the following guidelines have been proposed by the Ministry Health Welfare Japan:

- Stenosis or occlusion of the intracranial internal carotid artery or the adjacent ACAs and MCA
- Abnormal vascular network adjacent to the stenosed artery identified during the arterial phase of angiography

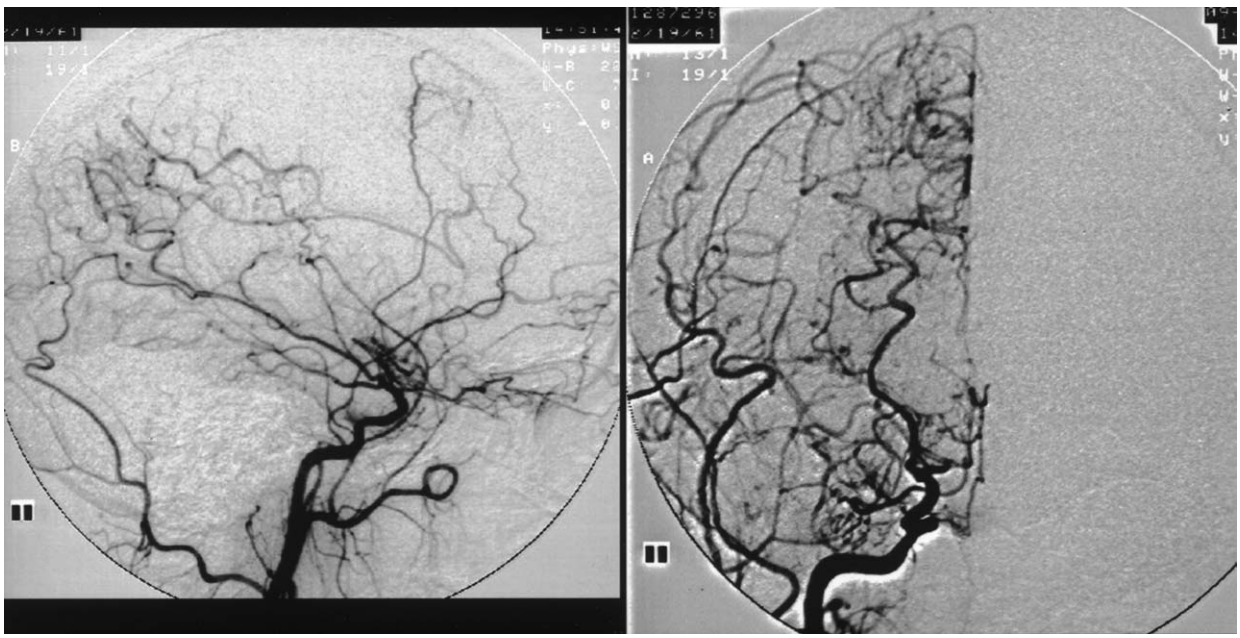

Figure 17 Moyamoya: AP and lateral cerebral angiogram revealing right middle cerebral artery occlusion with prominent collateral lenticulostriate and leptomeningeal vessels giving a characteristic "puff of smoke" appearance.

- Bilateral findings on angiography
- No other identifiable cause

The angiographic findings must be present bilaterally for definite diagnosis but many believe unilateral lesions progress to become bilateral. MRI and MRA have made the diagnosis of moyamoya possible without exposing patients to the invasiveness of conventional angiography. Common MR findings include multiple dilated abnormal vessels at the basal ganglia and/or thalamus, narrowing or occlusion of major arteries of the circle of Willis, parenchymal changes including ischemic infarctions predominantly in watershed areas, intracranial aneurysms (especially in the posterior circulation and moyamoya vessels), and intracerebral hemorrhages. Electroencephalograph (EEG) can also help in diagnosis of children with moyamoya disease. In more than half the cases a characteristic EEG finding termed ''rebuildup'' can be found. The rebuildup is considered to be related to decreased perfusion reserve of the ischemic brain.

6. Treatment

The hemodynamics of moyamoya disease are characterized by low CBF with extremely high vascular resistance in the collaterals at the base of the brain. Revascularization has been shown to be useful in preventing further ischemic attacks but does not prevent rebleeding in the hemorrhagic group of adults with moyamoya disease. Several surgical revascularization procedures are used in moyamoya disease to decrease hemodynamic stress and thereby reduce moyamoya vessel prominence and increase collateral circulation. These include direct, indirect, and combined revascularization techniques. Direct bypass can be accomplished with superficial temporal artery to MCA anastomoses. Indirect bypasses include omentum transplantation, encephalo-galeo-synangiosis, encephalo-myo-synangiosis, encephalo-duro-arterio-synangiosis, encephalo-myo-arterio-synangiosis, and encephalo-duro-arterio-myo-synangiosis. Surgical revascularization is controversial in adult moyamoya disease because it does not necessarily prevent rebleeding.

C. Other Vasculopathies

1. Fibromuscular Dysplasia

Fibromuscular dysplasia (FMD) is a rare vascular disorder of unknown etiology that primarily affects branches of the aorta. It is the second most common cause of extracranial carotid stenosis. The renal artery is often affected as well. Although the specific genetic defect is not known, it has been suggested that FMD is inherited as an autosomal-dominant trait with incomplete penetrance in males.

FMD affects the cervical arteries and occurs mainly in women. Fifty percent of patients present with multiple, recurrent symptoms due to cerebral ischemia or infarction. FMD has been reported to cause ''spontaneous'' dissection in young adults and subarachnoid hemorrhage. Twenty to 50% of patients with FMD are found to have intracranial aneurysms and patients may be at higher risk for carotid dissection, arterial rupture, and carotid cavernous fistula. The most common complaint from patients suffering from FMD is headaches, which are commonly unilateral and may be mistaken for migraines.

Diagnosis is made with angiography. The most common finding on angiogram is the ''string of beads'' sign due to multiple rings of segmental narrowing alternating with dilation in the carotid and vertebral arteries representing fibrodysplasia of the media (Fig. 18). Less commonly, focal tubular stenosis or diverticular outpouchings of the arterial wall can be found.

Anticoagulation or antiplatelet therapy may be helpful in the treatment of FMD. Surgical management is hampered by the often difficult access to, and friability of, the vessels involved. Transluminal angioplasty may also be effective.

2. Cerebral Amyloid Angiopathy

Cerebral amyloid angiopathy (CAA) is a condition characterized by pathological deposition of β-amyloid protein within the media of cerebral and leptomeningeal vessels. The most common presentation is dementia. Severe CAA is associated with vasculopathic changes, vessel rupture, and cerebral hemorrhage. Approximately 10% of patients develop ICH and patients may present with recurrent lobar hemorrhages or a TIA-like prodrome.

The white matter of the brain is most commonly involved and CAA does not affect areas outside of the CNS. There is increased incidence with age, and it is present in nearly 50% of people over the age of 70. It is a part of a family of conditions characterized by amyloid deposition, including Alzheimer's disease. Many believe similar genetic factors are involved (such as the apolipoprotein E ε_2 and ε_4 alleles).

Diagnosis of CAA may be challenging because of the difficulty in distinguishing it from other causes of lobar hemorrhage. Contrast angiography is usually

normal. Gradient-echo MRI may identify multiple petechial hemorrhages and hemosiderin deposits, but this is not specific to the disease. The definitive diagnosis of CAA requires a brain tissue biopsy revealing amyloid deposition. This can be difficult to obtain due to the sometimes sparse and segmental nature of the disorder. Additionally, β-amyloid protein is present in a relatively large percentage of the population, which may further confuse the diagnosis. Patients may develop fibrinoid necrosis of vessel walls, and this is a more specific finding and good indicator of cases at risk for hemorrhage. CAA is often diagnosed in retrospect at autopsy.

The disease is largely untreatable, although there is increasing use of anticoagulant and thrombolytic therapies to prevent recurrent hemorrhage. Current studies are examining techniques to block the molecular and cellular steps involved in the pathogenesis of the disease.

IX. CEREBRAL BYPASS PROCEDURES

Bypass grafts are employed to circumvent restrictions to cerebral blood flow. The more commonly employed conduits include saphenous veins, superficial temporal arteries, and occipital arteries. Bypass procedures may route blood from the extracranial circulation (carotid or vertebral) to the intracranial circulation [extracranial–intracranial (EC–IC) bypass] or directly reconstruct the intracranial circulation (intracranial bypass). Using these procedures, neurosurgeons successfully treat complex vascular lesions that would otherwise result in ischemic morbidity.

Cerebral bypass procedures have been incorporated in the management of patients with difficult aneurysms, neoplastic disease, and traumatic arterial dissection and in patients with ischemic disease refractory to medical therapy. Vascular neurosurgeons employ bypass techniques to redirect flow around giant aneurysms that cannot be directly clipped and require parent vessel occlusion. Cerebral bypass has also been employed in the successful management of symptomatic traumatic internal carotid artery dissection. Skull base surgeons use bypass techniques when faced with tumors encasing large cerebral arteries whose removal requires vessel sacrifice. Despite the negative results of the Cooperative Study of Extracranial–Intracranial Arterial Anastomosis, with appropriate preoperative selection, patients with focal intracranial vascular disease may still benefit from EC–IC bypass. This is particularly true for those patients who have been screened with ancillary tests, such as xenon CT with and without acetozolamide challenge, documenting inadequate cerebrovascular reserve and collateral flow.

Figure 18 Right carotid angiogram revealing extensive fibromuscular dysplasia with a characteristic "string of beads" pattern or alternating zones of luminal dilatation and constriction (arrow).

X. CONCLUSION

The cerebral circulation is eloquently complex and serves as host to many vascular disorders of immense societal significance. Stroke, aneurysms, AVMs, and vasculopathies are potentially devastating cerebrovascular disorders. Advances in our understanding of the molecular and cellular features of cerebrovascular disease, coupled with refinements in multimodal therapies, promise to reduce the enormous personal and societal burden of these disorders.

Cerebral Cortex

DAVID F. CECHETTO and JANE C. TOPOLOVEC
University of Western Ontario

GLOSSARY

agnosia The inability to recognize objects by touch or sight (tactile and visual agnosia) or lack of recognition of what is heard (auditory agnosia).

apraxia The inability to carry out purposeful movements even though there is no muscular weakness.

cortical column Sensory cortical areas are organized in units of neurons from the surface of the cortex to the underlying white matter. Each unit of neurons responds selectively to a specific afferent stimulus.

corticofugal Projections from the cerebral cortex.

corticopetal Projections to the cerebral cortex.

functional neuroimaging Techniques such as positron emission tomography and functional magnetic resonance imaging that utilize cerebral metabolism and blood flow as indicators of activity in specific regions of the brain.

receptive field The receptive field of a neuron is the area in the periphery (area of skin or location in the visual field) that, when stimulated maximally, excites or inhibits that cell.

The cerebral cortex is an extensive layer of gray matter that covers the superior surface of the brain. It receives sensory information from the internal and external environments of the organism, processes this information and then decides on and carries out the response to it. Different regions of the cerebral cortex are specialized for specific functions, such as somatic sensory and motor, visceral sensory and motor, and integrative cognitive functions. All of this information fits within the many grooves and convolutions of the cortex. These folds increase the surface area of the brain while enabling it to fit in the small volume of the skull.

The bulk of the cerebral cortex is comprised of the neocortex. The phylogenetically older parts of the cortex include the paleocortex (olfactory cortex, entorhinal and periamygdaloid areas) and the archicortex (the hippocampal formation). The neocortex is the primary focus of this article.

I. CYTOARCHITECTURE AND NEUROCHEMISTRY

A. Overview

The cerebral cortex is composed of an enormous number of neurons (10^{10}). These neurons in the human are responsible for the high-order cognitive processing or the conscious mind. It is in the cerebral cortex that the sensory signals generated in the body terminate. These sensory inputs are then processed at several different levels and the integrated information is used in the generation of specific actions. In order to accomplish this highest order of processing, the cerebral cortex is composed of a relatively thin layer

of cells and fibers, from 2 to 4 mm thick, that have multiple local interconnections. To receive information regarding the external and internal milieu and to generate commands to control the muscles and organs, the cerebral cortex has both direct and indirect connections with all other regions of the brain and spinal cord. The surface area of the cortex is extensive (approximately 250,000 mm^2) due to the numerous folds in the cortical sheath and it accounts for approximately 40–50% of the mass of the brain. The folds permit the cerebral cortex to contain a large number of neurons and to develop many specialized regions that represent various parts of the body.

B. Cortical Layers

Although there are regional variations, the cerebral cortex is generally organized into six distinct layers based on cell types and the organization of the myelinated axon fibers when examined in stained sections (Fig. 1). The outermost layer, known as the *molecular* layer, is a fiber- and synapse-rich layer with few cell bodies. The cells in layer 1 are primarily neuroglial or nonpyramidal neurons. This layer contains many axons that run parallel to the surface of the cerebral cortex. Layer 2 is known as the *external granular* layer and contains primarily small pyramidal neurons with their apical dendrites directed toward the

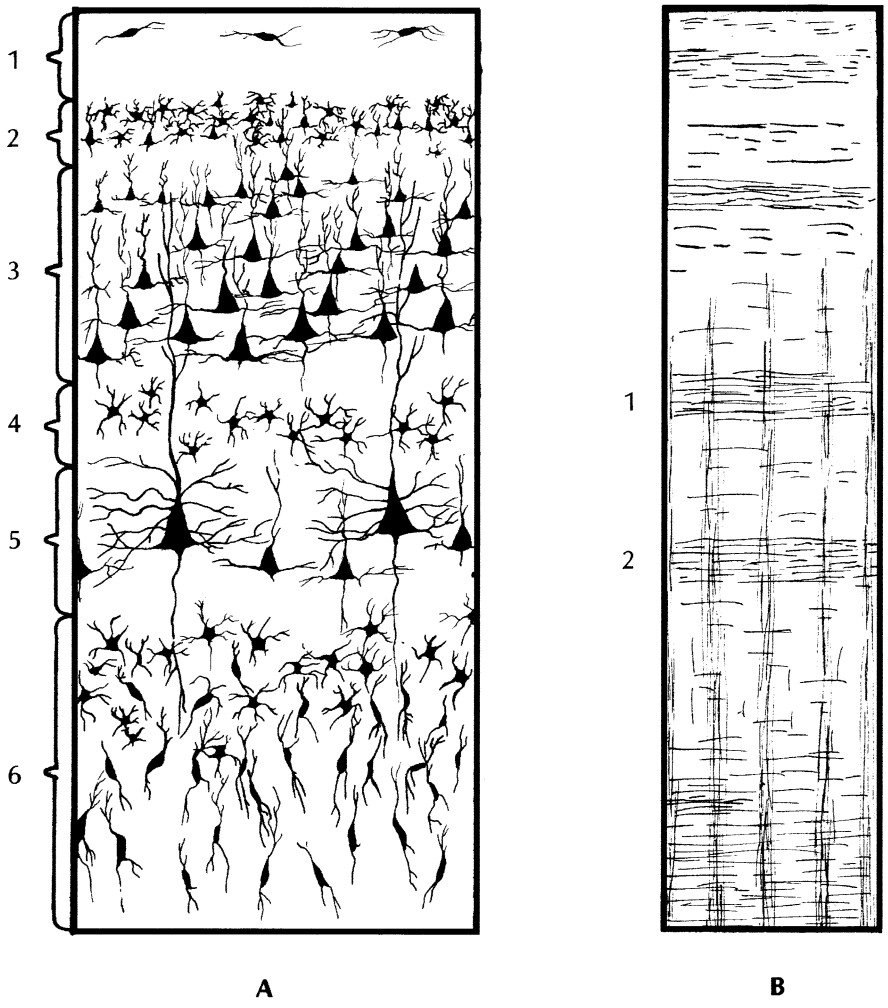

Figure 1 Histology of the six layers of the cerebral cortex illustrating the types and arrangements of neurons (A) and myelinated nerve fibers (B) Numbers 1–6 in A indicate the layers of the cerebral cortex. Numbers 1 and 2 in B indicate the bands of Baillarger (reproduced with permission from J. A. Kiernan, *Barr's, the Human Nervous System*. Lippincott-Raven, Philadelphia, 1998).

surface of the brain. The third layer of cells is quite thick, containing many pyramidal neurons, and its name, the *external pyramidal* layer, is derived from these cells. These pyramidal neurons are of medium size and the size increases toward the deepest part of layer 3. The apices of these pyramidal neurons also extend toward the surface of the brain. The pyramidal neurons in this layer form connections with other regions of the cerebral cortex, including the opposite (contralateral) side of the brain. The *internal granular layer*, or layer 4, contains numerous small cells that are densely packed together. Some of these small cells are stellate (star-shaped), whereas others are small pyramidal cells. As will be discussed later, this layer is particularly prominent in regions of the cortex dedicated to receiving sensory information. The fifth layer of the cerebral cortex, the *internal pyramidal* (or *ganglionic*) layer, contains both medium-sized and large pyramidal neurons that, like other pyramidal cells, have their dendritic apices extending toward the exterior surface of the brain. In the region of the motor cortex some of these cells are very large and are known as the pyramidal cells of Betz. Neurons of layer 5 give rise to the bulk of the axons, corticofugal fibers, projecting to subcortical regions. Sometimes, layers 4 and 5 have a condensation of horizontal fibers that are called the bands of Baillarger. These horizontal fibers are seen in myelin-stained tissue (Fig. 1B). The deepest and final layer 6, the *multiform* (or *polymorph*) layer, is composed of small neurons that can be stellate, pyramidal, or another type of cell with elongated cell bodies called fusiform neurons. This layer also gives rise to corticofugal fibers terminating primarily in the thalamus. Beginning in layer 3 and through layer 6, the pyramidal neurons send axons internally that form bundles of myelinated fibers. As each layer containing pyramidal neurons contributes to these bundles they become progressively thicker.

C. Regional Differences in Cytoarchitecture

Based on microscopic differences in the organization of the six layers, multiple distinct regions of the cerebral cortex can be defined. One of the best known maps of the cytoarchitecture of the cerebral cortex is that of Brodmann, which lists 52 different areas. Although there are subtle differences that are used to distinguish these many areas, the most simplified point of view is to consider only two major types of neocortex. The first is *agranular* cortex in which there is a relative lack of the granular layers 2 and 4, which contain the small, densely packed cells, whereas the third and fifth cortical layers, containing the larger pyramidal cells, are very well developed. This type of cortical layering is most frequently associated with motor regions of the cerebral cortex. The second, or *granular*, type of cortex is characterized by well-developed granular layers 2 and 4 with numerous small, stellate cells. This type of cortical region is usually associated with those areas receiving major inputs from the sensory relay nuclei of the thalamus. In particular, the axons conveying sensory inputs from the thalamus have large terminal plexi in the granular layer 4.

It is the pyramidal cells that send efferent projections from the cerebral cortex to subcortical areas as well as to other regions of the cortex on the same or the contralateral side. The pyramidal neurons of layer 6 are primarily responsible for the cortical outputs to the thalamic nuclei, which in turn send axonal projections back to the same cortical region, terminating in a different layer. However, the pyramidal neurons of layer 5 send projections to other subcortical sites, primarily in the midbrain, brain stem, and spinal cord, whereas the primary source of efferents to cortical regions is layer 3.

D. Neurochemistry

Several classes of neurotransmitters have been identified in the cerebral cortex, including excitatory amino acids, γ-aminobutyric acid (GABA), neuroactive peptides, and monoamines. The excitatory amino acids, glutamate and aspartate, are the primary neurotransmitters of cortical projections. They are quick acting and potent to enable fast transfer of information with high fidelity. These neurotransmitters act primarily on *N*-methyl-D-aspartate (NMDA), α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA), kainate, L-ammonophosphonobutyric acid, and metabotropic receptors, all of which are more prevalent in sensory than motor regions.

GABA is localized in a wide variety of nonpyramidal cells and is often colocalized with neuroactive peptides. It acts on $GABA_A$ and $GABA_B$ receptors to regulate information within small regions throughout the cortex. GABA is the primary inhibitory neurotransmitter of the central nervous system.

Cholecystokinin, vasoactive intestinal polypeptide, neuropeptide Y, somatostatin, substance P, and corticotrophin-releasing factor are all considered to

be neuroactive peptides that influence neurotransmission by modulating the effects of excitatory amino acids and GABA. Moreover, some of these peptides may mediate their effects by altering blood flow and metabolism in local regions of the brain.

The fourth class of chemical mediators found in the cerebral cortex are monoamines and include noradrenaline, serotonin [or 5-hydroxytryptamine (5-HT)], and dopamine. These monoamines are the primary source of input to the cortex from extrathalamic sources and have different patterns of distribution throughout the cortex. Noradrenergic axons (mostly originating from neurons in the locus coeruleus in the pons) innervate primary motor and somatosensory areas and the nearby regions in the frontal and parietal lobes. Noradrenaline acts on α_1, α_2, β_1, and β_2 receptors, which are more prominent in prefrontal, motor, and somatosensory regions. Serotonergic fibers originate primarily from the raphe nuclei and the midbrain tegmentum of the brain stem. They innervate diffuse areas of the cerebral cortex to act on the 5-HT (5-HT_1–5-HT_7) receptor. Dopamine fibers preferentially innervate motor and association cortical areas to modulate the connections between association areas and descending motor systems. These fibers, which act on the dopamine receptor (D_1 and D_2 receptor subtypes), originate in the substantia nigra and ventral tegmental area of the midbrain.

Another class of neurotransmitter is acetylcholine. Cholinergic fibers, which originate in the basal nucleus of Meynert and diagonal band of Broca, innervate diffuse cortical areas, including limbic, primary sensorimotor, and association areas. Acetylcholine acts on muscarinic and nicotinic receptors mainly on pyramidal but also on nonpyramidal cells. The monoamines and acetycholine are not necessarily excitatory or inhibitory; they act to modulate and enhance the inputs from the thalamus and other cortical areas.

II. INTRINSIC CIRCUITS

A variety of techniques have proven useful in delineating the intrinsic organization of cortical circuits. In particular, the recent developments in histochemical methods coupled with intracellular recordings and dye labeling have enabled investigators to unravel the neuronal organization of the local circuitry of the cortex (Fig. 2). As indicated previously, the layers of the cortex can be characterized by the arrangement and density of stellate and pyramidal neurons. The

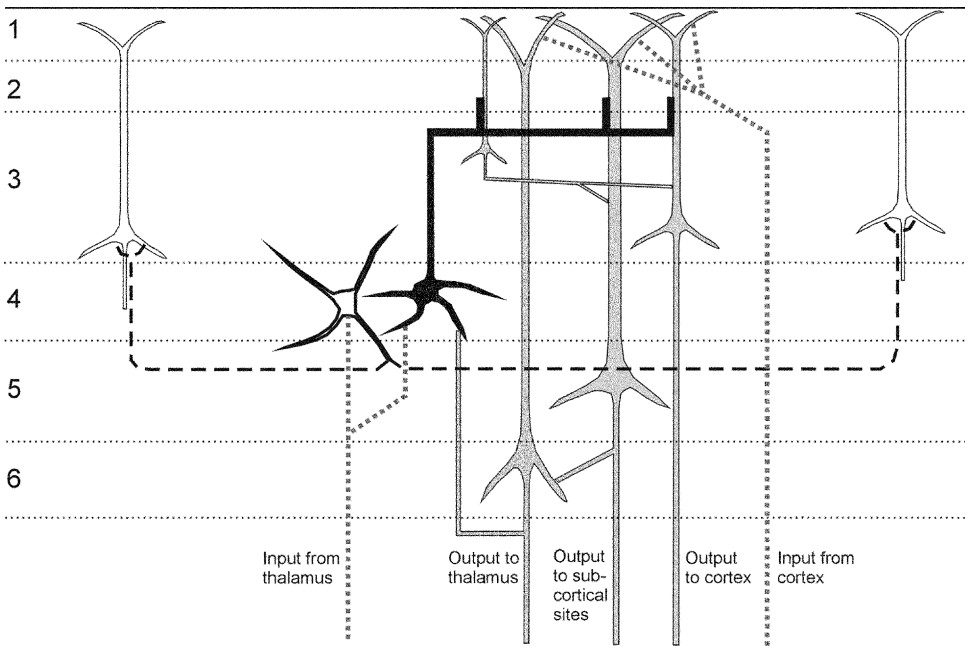

Figure 2 Intrinsic circuitry of the layers of the cerebral cortex. Indicated are inhibitory projections (dashed, heavy line) from aspiny inhibitory neurons (open cell with heavy lines), pyramidal neurons in gray, a stelate neuron in black and pyramidal neurons in adjacent columns (open cells with thin lines.).

pyramidal neurons are responsible for the output of the cerebral cortex, are excitatory in nature, and utilize the excitatory amino acids, aspartate and glutamate, as neurotransmitters.

These projection neurons have apical dendrites that ascend to the outer layers of the cortex and often form apical tufts that receive connections within layers 1 and 2. Other dendrites project from the bases of pyramidal neurons. The stellate neurons, like the pyramidal cells, have spiny dendrites and are excitatory. These spiny stellate cells, primarily seen in layer 4, are local circuit neurons and the axons do not project out of the cortical layers.

Another type of cell that is abundant within the layers of the cerebral cortex is the local circuit neurons with aspiny dendrites. These smooth neurons are inhibitory in nature and have axons that in the neocortex are restricted to a discrete region of the cortical layers. Unlike the stellate and pyramidal neurons, the axons of these neurons can arise from any site on the cell body. The neurotransmitter of these neurons is GABA and these cells often colocalize neuropeptides such as somatostatin, substance P, vasoactive intestinal polypeptide, or cholecystokinin.

The primary corticopetal fibers to the cerebral cortex are from the sensory and motor nuclei of the thalamus. However, there are many other sources for cortical inputs. Basal forebrain nuclei contain acetylcholine neurons with extensive projections to the cerebral cortex. The reduction in this forebrain cholinergic innervation is an important contributor to Alzheimer's disease. The noradrenergic neurons of the locus coeruleus in the pons diffusely innervate the cerebral cortex and appear to play a role in modulating the signal-to-noise ratio of specific cortical inputs. The raphe nuclei of the brain stem are the source of a serotonergic input, which is primarily inhibitory. Finally, the cortex has extensive interconnections that can be from the opposite hemisphere, from adjacent gyri of the same lobe, and from other lobes.

A typical local circuitry in sensory cortex is shown in Fig. 2. The thalamocortical input primarily provides an excitatory termination on the intrinsic stellate neurons in layer 4 and to some extent in layer 6. In fact, in sensory cortex, small columns of neurons are formed such that the cells in the column selectively receive input from a specific sensory stimulus. Inputs from other regions of the cortex or other subcortical sites terminate on pyramidal neuron dendrites in layers 1–3. The stellate neurons in layer 4, receiving the thalamocortical input, terminate on apical dendrites of pyramidal cells in layers 2 and 3. These pyramidal neurons in layers 2 and 3 project back onto layer 5 pyramidal cells, which then project back to pyramidal cells of layers 6, which in turn project back to layer 4, completing a local circuit in the cortical column. In addition, in layer 4, the pyramidal neurons will excite aspiny inhibitory neurons that send an inhibitory impulse to adjacent columns of the cortex.

III. TOPOGRAPHY

A. Sulci, Fissures, and Lobes

In addition to the cytoarchitectonic method of creating divisions, the extensive folding of the cerebral cortex also provides a means of identifying distinct regions in the cerebral cortex (Fig. 3). It is this extensive folding that greatly increases the surface area and thus the volume of the cerebral cortex. Although the folds delineate some of the functional areas of the cortex, the borders between the cytoarchitectonic divisions and the major and minor folds do not necessarily correspond.

The two deepest grooves on the brain are known as fissures. The longitudinal fissure separates the right and left cerebral hemispheres, and the transverse fissure separates the cerebral hemispheres from the cerebellum. The smaller and plentiful grooves on the cerebral hemispheres are known as sulci, whereas the folds or ridges of brain between the sulci are called gyri. Some of the sulci and gyri are relatively consistent in all individuals and are used as anatomical landmarks to identify separate regions of the cerebral cortex. The cerebral cortex is divided into five lobes: the frontal, parietal, occipital, temporal, and insular lobes. The central sulcus (rolandic sulcus) can be seen on the superior surface of the human brain just slightly behind the midpoint between the anterior and posterior poles. This sulcus then descends inferiorly and anteriorly over the lateral surface of the cerebral hemisphere and separates the frontal and parietal lobes. The central sulcus serves as the demarcation between motor and sensory cortices. Immediately anterior to the central sulcus in the frontal lobe lies the precentral gyrus, which is used as a landmark for the primary motor area. The primary somatosensory area is located in the postcentral gyrus, found immediately posterior to the central sulcus in the parietal lobe. The parietooccipital sulcus is located on the medial surface of the cerebral hemisphere and, as the term implies, it is the major landmark demarcating the

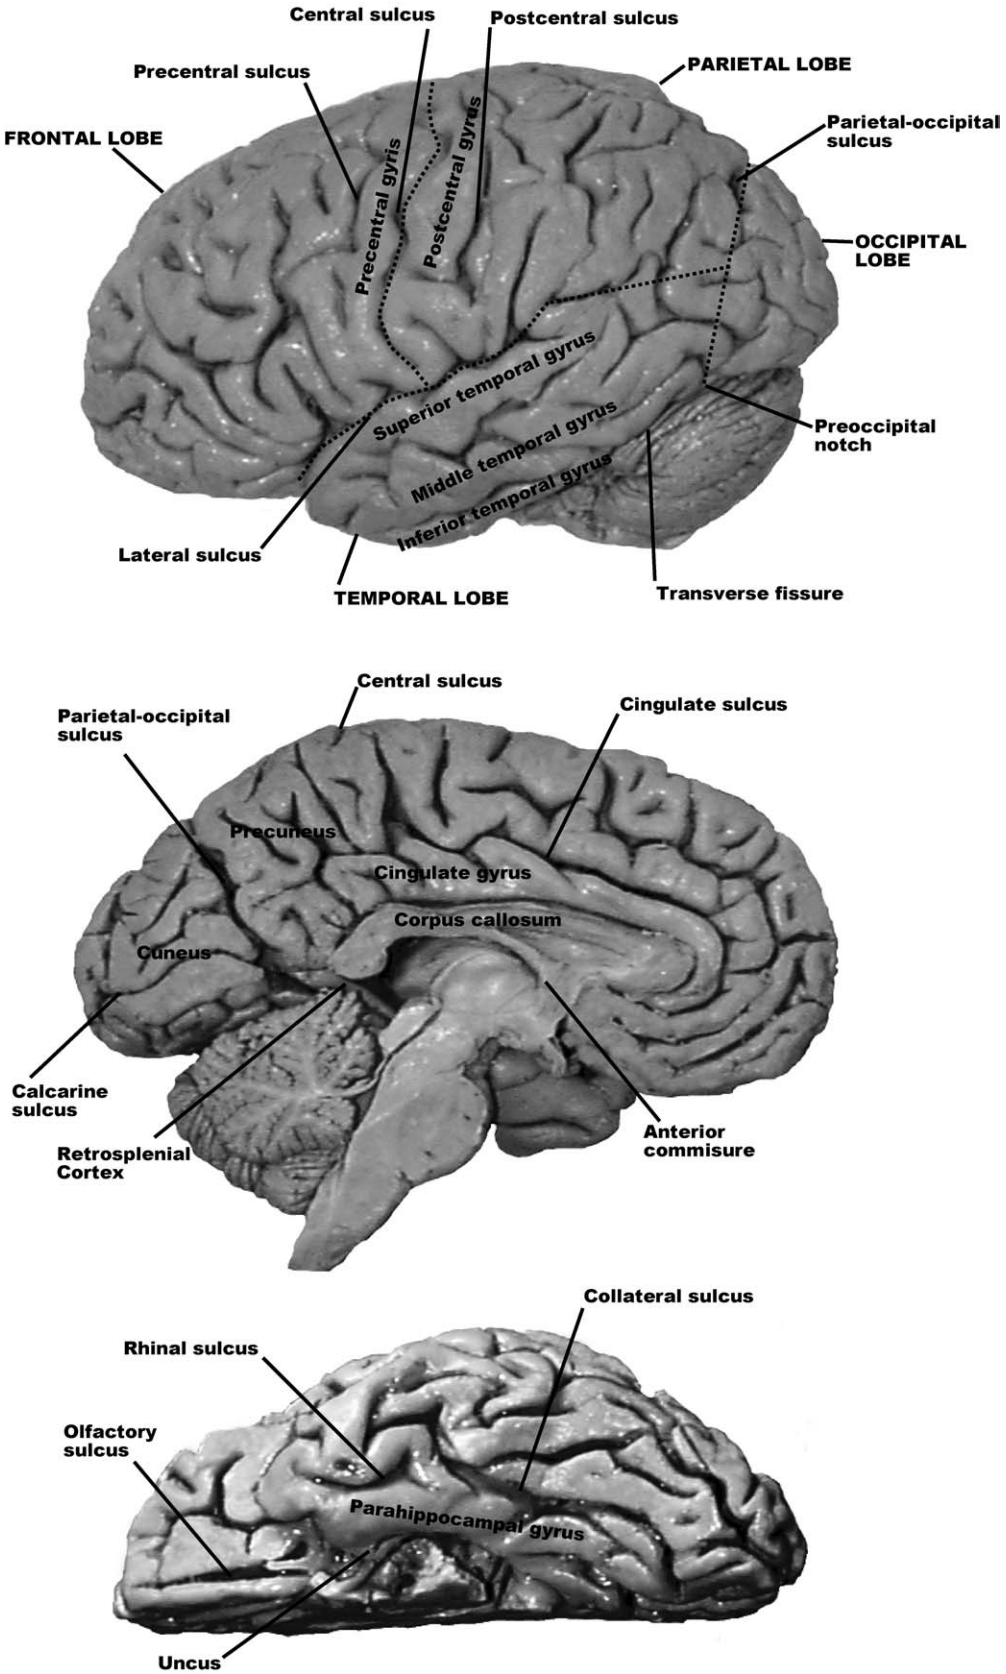

Figure 3 Gyri and sulci on the lateral (top), medial (middle), and inferior (bottom) surfaces of the left cerebral hemisphere.

parietal from the occipital lobes. The parietooccipital sulcus starts at the superior surface of the human brain and extends inferiorly along the medial surface until it merges with the calcarine sulcus, which starts at the most posterior part of the cerebral cortex (the occipital pole) and extends anteriorly along the medial surface of the hemisphere until it meets the parietal–occipital sulcus. The primary visual cortex is located along the calcarine sulcus. On the lateral surface, the occipital lobe is defined by a line joining the parietal–occipital sulcus and the preoccipital notch.

The lateral sulcus (Sylvian fissure) is a very deep fold seen on the lateral surface of the hemisphere running in an anterior to posterior direction and serves to separate the temporal lobe from the frontal and parietal lobes. On the lateral surface of the temporal lobe are three gyri—the superior, middle, and inferior temporal gyri—which are separated by the superior and inferior temporal sulci. The primary auditory cortex is located on the superior surface of the superior temporal gyrus. The final lobe of the cerebral cortex is the insular lobe (island of Reil). It cannot be seen from a surface view of the brain because it is buried deep within the lateral sulcus. In the human brain, the insular cortex is circumscribed by the circular sulcus. The gustatory (taste) discrimination and visceral sensory cortex is located in the anterior part of this lobe.

The "limbic lobe" of the cerebral hemispheres consists of the cingulate gyrus, the parahippocampal gyrus, and the retrosplenial cortex. The limbic lobe is part of the limbic system, which also includes structures such as the amygdala and hippocampal formation (both in the temporal lobe), the mammillary bodies of the hypothalamus, and the anterior nucleus of the thalamus. The cingulate cortex can be seen on the medial surface of the brain, lying above the corpus callosum and beneath the cingulate sulcus. The parahippocampal gyrus can be found on the medial and inferior part of the temporal lobe bounded laterally by the collateral sulcus and the rhinal sulcus more at the anterior aspect. The lateral olfactory area, in which the fibers of the olfactory tract end, is found on the inferior surface of the cortex. This olfactory region includes the uncus, which is the part of the rostral medial parahippocampal gyus that hooks backwards; the entorhinal cortex, which is found in the anterior part of the parahippocampal cortex; and cortex in the region of the limen insulae in the anterior part of the insular cortex. The corticomedial nuclei of the amygdala also receive olfactory tract terminals and are considered to be part of the lateral olfactory area.

B. Fibers

Immediately underneath the cerebral cortex lies a complex array of neural fibers involved in conveying information to and from other cortical and subcortical sites. There are three main types of fiber. The *association* fibers transmit nerve impulses between gyri in the same hemisphere. They can be relatively short, such as those connecting adjacent gyri, or long, connecting gyri in different lobes. Any one gyrus both projects to and receives input from a number of other cortical regions. *Commissural* fibers connect the gyri in one cerebral hemisphere to the corresponding gyri in the contralateral hemisphere. The majority of the commissural fibers are contained within the corpus callosum. However, the temporal lobes utilize both the corpus callosum and the anterior commissure for connecting fibers. The third class are the *projection* fibers, which provide connections between the cortex and subcortical sites such as the basal ganglia, thalamus, brain stem, and spinal cord. The projection fibers from the cerebral cortex initially form a spreading fan shape known as the corona radiata. At a deeper level, the corona radiata coalesces into a compact fiber bundle, the internal capsule. The ascending fibers enter the corona radiata after going through the internal capsule.

IV. LOCALIZATION OF FUNCTION

The term functional localization is used to indicate that certain functions can be localized to particular areas of the cerebral cortex. The mapping of cortical function began with inferences made from the deficits produced by cortical lesions in humans. Subsequently, techniques such as single-cell recording and electrical stimulation of cells in the cerebral cortex have been used in animals, nonhuman primates, as well as humans undergoing surgery for diseases such as epilepsy and Parkinson's disease to map out functional areas of the brain. This research has generated important findings, such as the somatotopic organization of both sensory and motor systems. Recently, research into functional localization in the cerebral cortex has been aided by the introduction of cerebral metabolism and blood flow imaging methods.

Functional neuroimaging techniques such as positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have been used to confirm previous knowledge about localization of

function within the cerebral cortex as well as to conduct studies in healthy human subjects that were previously not possible. PET has been available for nearly 20 years. It involves monitoring the changes in metabolism or blood flow of a radiolabeled substance in response to a cognitive or sensorimotor task. PET studies have furthered our understanding of the organization of the somatomotor cortex, enabled us to examine visual perception, and begun to shed light on higher cognitive processes such as learning and attention. Moreover, we can localize receptors and determine the sites of action of different drugs in both healthy individuals and those inflicted with disorders such as epilepsy and schizophrenia.

fMRI is a relatively new (approximately 10 years) method that monitors local changes in blood oxygen levels that accompany the performance of a task. With its greater spatial resolution, fMRI has enabled more detailed studies of cortical function. For instance, a recent fMRI study demonstrated that the face representation in the somatosensory cortex, as described by Penfield, is in fact incorrect and is actually inverted along the central sulcus. In addition, it has been demonstrated that the topography in the motor planning areas (Brodmann area 6) is based on function (i.e., learned behaviors localized topographically) rather than on somatotopy. Recently, fMRI has been used to assess complex processes such as pain perception and to assess the effect of analgesic drugs on the areas of the cerebral cortex that are activated (Fig. 4).

Thus, both PET and fMRI have been used to study a wide range of processes, including sensation, perception, and attention in healthy human subjects, as well as changes in cerebral cortex function in patients suffering from neurological disorders. Numerous studies employing these techniques have contributed greatly to our knowledge of functional localization in the cerebral cortex.

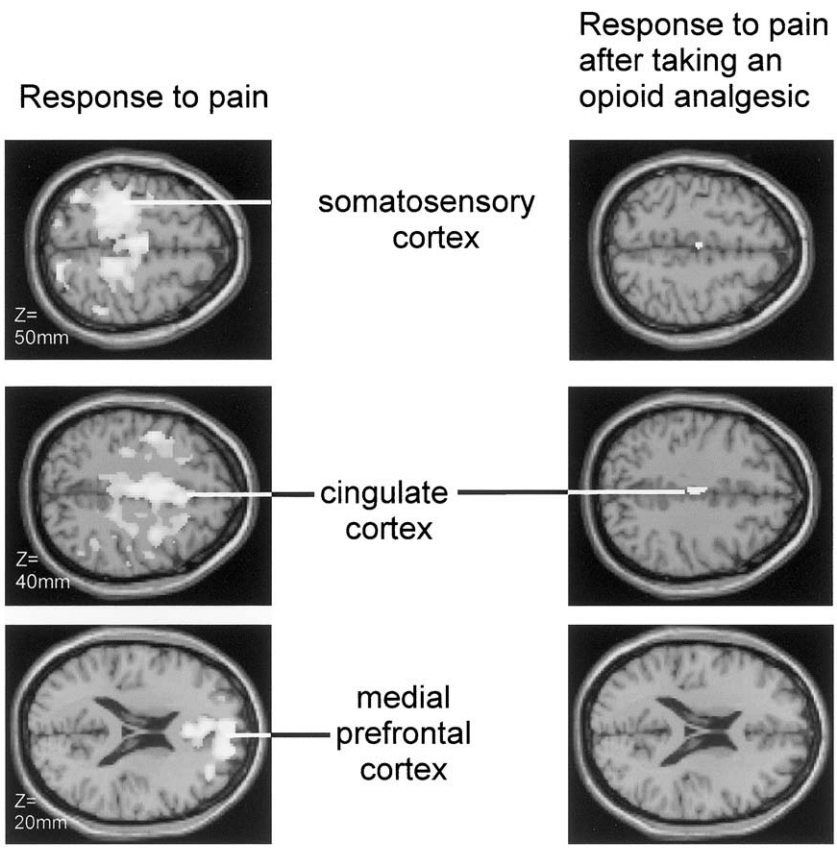

Figure 4 Images obtained using fMRI in response to a painful stimulus induced by stimulation of the ulnar nerve in the right arm. The images, taken at three different levels in the brain, illustrate sites of activation in the cortex (white) to the painful stimulus before (left) and after (right) administration of an analgesic (remifentanil). The top of each image represents the left side of the brain. Note the typical contralateral activation of the somatosensory cortex in response to the peripheral stimulus.

V. SENSORY SYSTEMS

Sensory systems are responsible for detecting changes in an organism's environment. There are three general classes of sensory systems: those concerned with the external environment (exteroceptive), those concerned with the inner environment (interoceptive), and those that monitor the positions of the body (proprioceptive). There are several different sensory systems localized in the cerebral cortex, including the somatosensory, visual, auditory, vestibular, taste, and olfactory systems. Within each of these systems there is a hierarchical organization for information processing such that input from sensory receptors in the periphery is relayed through the thalamus, first to the primary sensory cortex, then the secondary sensory cortex, and finally to the cortical association areas. The primary sensory cortices are involved in detecting, localizing, and discriminating the different properties of a stimulus, be it tactile, visual, auditory, etc. The secondary sensory cortices receive this information and integrate it with previous memories of the stimulus to help identify it. The sensory association areas, in turn, receive and integrate information from different sensory modalities to provide conscious perception of the stimulus and initiate plans for behavioral action in response to it.

A. Somatosensory System

Sensory information (proprioception, touch, pain, temperature, and vibration) from receptors in the skin, joints, and muscles throughout the body is relayed to layer 4 of the primary somatosensory cortex (SI) from the ventral posterior nuclei of the thalamus. SI is located along the postcentral gyrus of the parietal cortex and is divided into four parts based on cytoarchitecture and somatic inputs (Brodmann areas 3a, 3b, 2, and 1). The way in which sensory information (the location and intensity of a stimulus) is encoded and represented in SI is determined primarily by three principles of cortical organization: cortical receptive fields, preservation of somatotopy, and the columnar organization of the cortex.

The pyramidal cells in SI are continuously active, and this activity can be enhanced or inhibited by a stimulus acting at a specific location on the skin. This location in the periphery, where stimulation maximally activates a given cell in SI, is termed the *receptive field* for that cell. The receptive field for each cell in the cortex has a gradient of excitation, such that stimulation at the center of the field maximally excites the cell, and this excitation diminishes toward the outer edge of the field. There is also a less prominent inhibitory gradient that may extend beyond that of the excitatory one (inhibitory surround). This organization of the receptive field is the basis for *lateral inhibition* of sensory input, which enhances the ability to detect the precise location of a stimulus (Fig. 5).

Preservation of *somatotopy* refers to the fact that at all levels of the central nervous system, the organization of somatosensory input from the periphery is maintained. For instance, somatosensory information for discriminative tactile sensation enters the dorsal column of the white matter of the spinal cord in a medial–lateral manner, such that sensory information

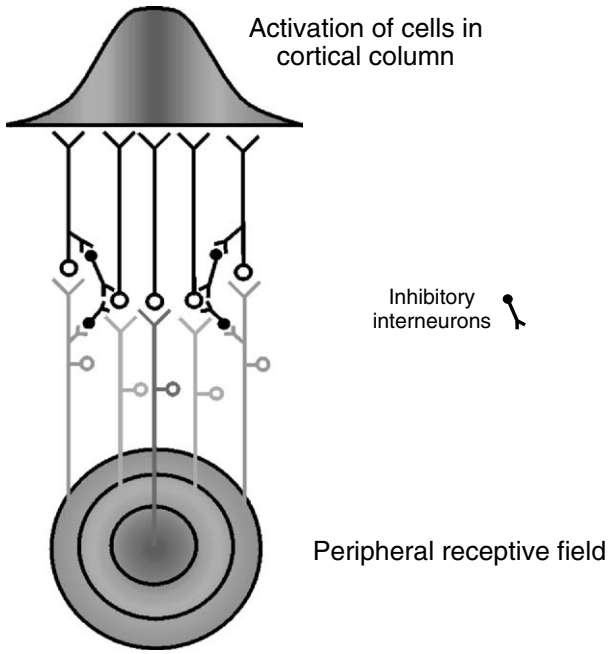

Figure 5 Schematic model of a peripheral excitatory receptive field with inhibitory surround. This provides an anatomical basis for the process of lateral inhibition of sensory input. Stimulation at the center of the receptive field maximally excites the sensory cells, which relay this excitation to a cortical column in the primary somatosensory area. Stimulation of cells in the outer edge of the receptive field suppresses the ascending sensory input by activating cells that synapse upon inhibitory interneurons. This pattern of firing is preserved as the information ascends the neuraxis, such that cortical neurons innervated by input from the center of the receptive field will be maximally activated, whereas the immediately adjacent cells in the cortex will be suppressed. This lateral inhibition acts to enhance the contrast between the stimulation site and peripheral areas to enable precise localization of the stimulus.

from the lower body lies medially and that of the upper body is organized laterally in the dorsal column. This organization is preserved throughout the brain stem, at the thalamic relay nuclei and ultimately in the primary somatosensory area of the cerebral cortex. The somatotopic organization in SI dictates that sensory input from the lower body is represented along the medial surface of the postcentral gyrus, whereas the upper body and head are represented along the lateral convexity of the gyrus. An interesting feature of somatotopy in SI is that those areas of the body that have large numbers of sensory receptors, such as the hands and mouth, have disproportionately much larger areas of SI cortex devoted to them. Moreover, the receptive fields in these areas of the skin are much smaller and more numerous than areas such as the trunk that are not concerned with precise discrimination of the stimulus.

Finally, in addition to its laminar organization as described previously, the cerebral cortex also possesses *columnar* organization, such that the cells in any given column of cortical tissue (from the cortical surface to the underlying white matter) respond maximally to a specific modality of stimulation. For instance, an edge placed on the skin with a specific orientation will optimally activate one cortical column, whereas the adjacent column will maximally respond to a slightly different orientation.

The primary somatosensory cortex uses these features in discriminating the intensity and location of a stimulus or detecting the shape or texture of an object. For example, the activation of a population of neurons on the medial surface of the postcentral gyrus indicates that a precise area of the lower body is being stimulated. The intensity of the stimulus is determined by the frequency of firing of the neurons and by the number of neurons recruited. Finally, the precise nature of the stimulus (pressure, touch, and direction of hair movement) is determined by which cortical columns respond.

Projection fibers from layers 2 and 3 of the trunk representation of SI innervate the contralateral SI as well as the secondary somatosensory cortex (SII). SII is located in the upper bank of the lateral sulcus, just inferior to the central sulcus (Fig. 6A). It is believed to have poor somatotopy, and the cells within SII have bilateral receptive fields, suggesting more of an integrative rather than a discriminative function. Information from SII is relayed to the posterior parietal cortex, which is considered to be the somatosensory association area (Brodmann areas 5 and 7). This area is involved in high-level integration of somatosensory information to enable learning and memory of the surrounding tactile and spatial environment. SI also has direct projections to subcortical structures (the basal ganglia, brain stem, and spinal cord) via pyramidal cells from layer 5 and to the ventral posterior nuclei of the thalamus from layer 6.

B. Visual System

The primary visual cortex (Brodmann area 17) is located in and on either side of the calcarine sulcus, on the medial surface of the occipital lobe. It functions primarily in discerning the intensity, shape, size, and location of objects in the visual field. As with other cortical areas, the primary visual cortex is composed of six layers. Visual input from the lateral geniculate nucleus of the thalamus terminates primarily in layer 4. This input is then relayed through layers 2 and 3 to secondary and association visual areas. In addition, an intracortical loop is established, with information from layers 2 and 3 being transferred to layer 5 and then to layer 6. Visual information is also relayed to the brain stem from the layer 5 of the cortex and back to the lateral geniculate nucleus of the thalamus from layer 6.

As in the primary somatosensory cortex, cells in the primary visual area are continuously active and respond maximally to specific stimuli within their receptive fields. The primary visual cortex also possesses columnar organization with each column of cells preferentially responding to a specific visual stimulus, such as a line of a specific orientation. In addition, it is retinotopically organized with the upper half of the visual field represented in the cortex inferior to the calcarine sulcus and the lower half of the visual field represented in the cortex superior to the calcarine sulcus. Moreover, there is a disproportionately large amount of cortex reserved for the area of the retina with the highest density of receptors (the macula).

The primary visual cortex, or striate cortex, sends information to the secondary visual, or prestriate cortex (Fig. 6B; Brodmann areas 18 and 19), and to the inferior temporal cortex (Brodmann areas 20 and 21). These secondary visual areas are important for color, motion, and depth perception. Information from the occipital cortex is further transmitted to two separate association areas of the cerebral cortex: superiorly to the parietal lobe (Brodmann areas 5 and 7) for processing of spatial features and movement and inferiorly to the temporal lobe for object recognition.

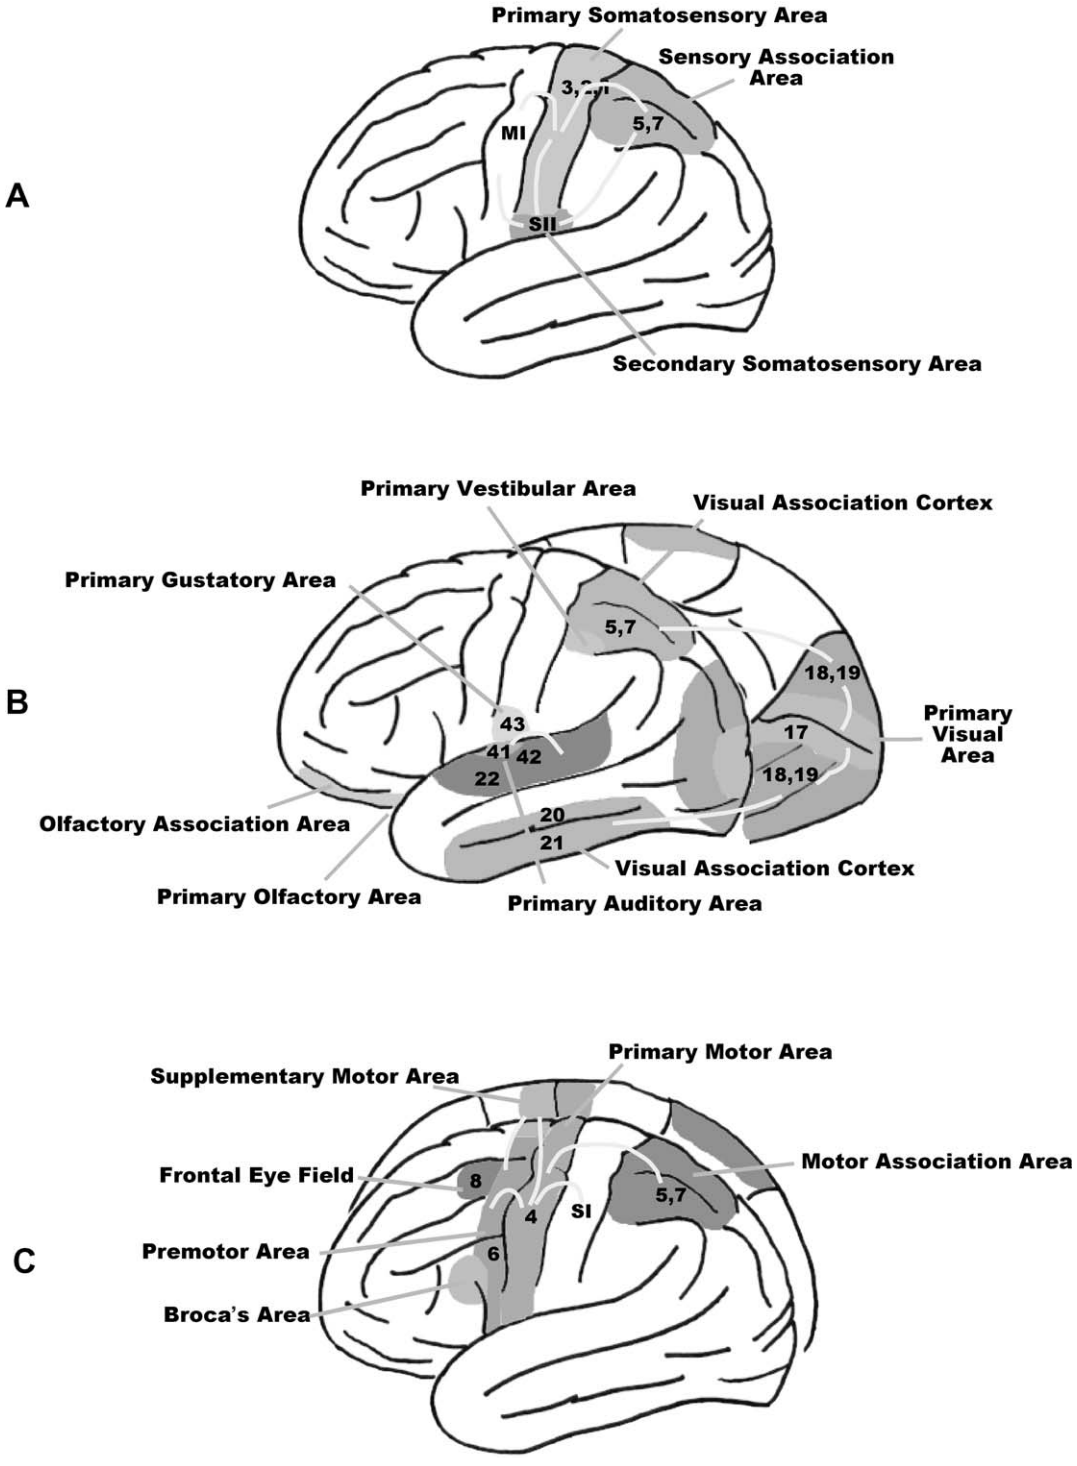

Figure 6 Schematic diagram of the localization of sensory and motor functions in the cerebral cortex. (A) Connections of the somatosensory system. (B) Connections of the visual, auditory, vestibular, gustatory, and olfactory sensory areas. (C) Connections of the somatomotor system. Numbers indicate Brodmann's areas. MI, primary motor area; SI, primary somatosensory area; SII, secondary somatosensory area.

C. Auditory and Vestibular Systems

The primary auditory cortex (Fig. 6B; Brodmann area 41) is located along the upper bank of the superior temporal gyrus, within the lateral sulcus on two gyri known as Heschl's gyri. Similar to other sensory cortices, the primary auditory cortex is organized in columns, such that each column of cells responds maximally to an acoustic stimulus of a specific frequency. Moreover, it is organized tonotopically (the anterior auditory cortex receives signals initiated by sounds with higher frequencies, whereas the posterior cortex receives lower frequency sounds) to enable the discrimination of the pitch of sounds. The auditory association cortex (Brodmann areas 22 and 42), which is concerned with the memory and classification of sounds, is inferior and posterior to the primary auditory cortex, along the superior bank of the middle temporal gyrus.

Movements and positions of the head are monitored primarily by the vestibular system. The primary vestibular cortex in humans is thought to occupy a region just posterior to the primary somatosensory cortex in the parietal cortex.

D. Olfactory System

Fibers from the olfactory bulb terminate in the corticomedial nucleus of the amygdala as well as the entorhinal (Brodmann area 28) cortex of the temporal lobe, comprising the primary olfactory cortex. The information is then relayed to additional areas of the limbic system such as the hypothalamus, which is important for controlling appetite, digestion, and feeding behaviors, and to the mediodorsal nucleus of the thalamus. From the thalamus, the olfactory information is sent to the orbitofrontal cortex (the olfactory association area), which also receives input from other cortical areas such as the somatosensory and visual association areas and insula and limbic system. Although there is segregation of sensory function throughout the cerebral cortex, these systems act in concert to mediate our conscious perception of the surrounding environment.

E. Pain System

Historically, the involvement of the cerebral cortex in the perception of pain (nociception) was an issue of controversy due to failure to elicit a painful response during stimulation of areas of the cortex as well as the lack of analgesia following cortical lesions. However, electrophysiological recording and neuroimaging techniques clearly indicate that numerous areas of the cerebral cortex do act synchronously to mediate the perception of pain and the responses to it. Such techniques have identified several cortical areas that are involved in nociception, including the primary and secondary somatosensory (SI and SII), the inferior and superior parietal, the insular, anterior cingulate, and medial prefrontal cortices.

There are believed to be two pathways, or streams, that mediate the perception of somatic pain, namely the medial and lateral pain pathways. The lateral pain pathway includes the ventral posterolateral and ventral posteromedial nuclei of the thalamus and their projections to SI of the parietal cortex. These thalamic nuclei and SI encode the type, temporal pattern, intensity, and topographic localization of a painful stimulus. Thus, the lateral pain pathway is believed to mediate the sensory-discriminate component of pain perception. Conversely, the medial pain pathway is thought to be concerned with the affective or emotional component of pain. Nociceptive information from the ventral posteroinferior, mediodorsal, and intralaminar nuclei of the thalamus is relayed to cortical areas such as SII, inferior parietal cortex, insular, anterior cingulate, and prefrontal cortices. The neurons in these areas generally have large, bilateral receptive fields and poor, or absent, somatotopic organization, consistent with their role in the affective–emotional dimension of pain perception.

Pain perception at the level of the cerebral cortex is complex and mediated by numerous interacting systems. For instance, all of the previously mentioned areas, particularly those involved in the affective–emotional component of pain processing, also have connections with diffuse areas of the limbic system and influence the ascending pain pathways. These connections likely mediate factors such as cognition, mood, and attention in response to a noxious stimulus.

There is an increasing amount of information regarding the neurochemistry of nociceptive connections at the cortical level. In the somatosensory cortices, excitatory amino acids acting on NMDA, AMPA, and metabotropic glutamate receptors likely mediate the transfer of nociceptive information from the thalamus to the cortex. In addition, there are large pools of GABAergic inhibitory interneurons in the sensory cortices that may modulate this transfer. Moreover, cytokines and neurotrophins may influence

neurotransmission via glutamate NMDA and GABA receptors.

VI. SOMATOMOTOR SYSTEM

Motor function is mediated by several areas of the prefrontal cortex, including the primary motor cortex, the motor planning areas (premotor area, supplementary motor area, Broca's area, and the area corresponding to Broca's area in the right hemisphere), and the cortical eye fields.

The primary motor cortex (MI) functions to mediate control of voluntary movements. It is located anterior to the central sulcus in the precentral gyrus (Fig. 6C; Brodmann area 4) and is the origin for some of the fibers of the corticospinal tract. All these fibers originate in layer 5 of the six-layered primary motor cortex and are pyramidal-type neurons. Primary motor cortex is an example of agranular cortex.

Similar to the primary somatosensory cortex, MI is somatotopically organized such that the lower body representation lies on the medial surface of the cortex, within the longitudinal fissure, whereas the upper body and face representations lie laterally along the precentral gyrus. In addition, there are large, disproportionate areas for the hand and mouth. MI receives input from numerous cortical areas, including SI (Brodmann areas 1–3), SII (Brodmann area 5), and premotor and supplementary motor areas (area 6), as well as input from the cerebellum, basal ganglia, and ventrolateral nucleus of the thalamus. The supplementary and premotor areas are collectively termed the motor planning areas and are responsible for organizing and planning complex movements.

The supplementary motor area (superior Brodmann area 6) is found anterior to the lower leg area of the primary motor cortex (medial surface of the medial frontal gyrus). It receives input from the prefrontal association cortex for planning of complex bimanual and sequential movements and for coordinating motor responses to sensory stimuli. Furthermore, efferent projections from the supplementary motor area are sent to the spinal cord and brain stem in addition to the primary motor cortex.

The premotor area (inferior Brodmann area 6), anterior to the primary motor area on the lateral surface of the prefrontal cortex, receives information from the prefrontal association cortex and sends output to the brain stem, basal ganglia, and cerebellum, in addition to the primary motor cortex. The premotor area is important for planning and control of visually guided movements. Located just rostral to the premotor area in the prefrontal cortex is the frontal eye field (Brodmann area 8), which controls voluntary conjugate movements of the eyes, independent of visual stimuli.

Finally, there are two areas that control the motor planning of speech and gestures associated with speech. Broca's area is located anterior to the premotor area in the inferior prefrontal cortex, usually in the left hemisphere. It is responsible for the motor programming of speech, whereas the corresponding area in the contralateral hemisphere (usually the right) is concerned with the planning of nonverbal communication such as gestures.

VII. CORTICAL ASSOCIATION AREAS

Three areas, the prefrontal, parietal, and temporal cortex, integrate and interpret sensory stimuli of all modalities and plan and execute behaviors in response to the stimuli. The prefrontal cortex corresponds to Brodmann's areas 9–12 and has extensive connections with parietal, temporal, and occipital lobes that provide information on sensory experiences. It is also reciprocally connected to the hippocampus and amygdala and receives a major input from the mediodorsal nucleus of the thalamus. This diverse anatomical arrangement suggests that the prefrontal cortex has multiple complex functional roles. The prefrontal association area, in the anterior prefrontal lobe, mediates personality, self-awareness, and executive functions (the planning and execution of a goal). The main symptoms seen with lesions of the prefrontal association area, as seen after frontal lobotomy, are loss of foresight, failure to anticipate, lack of drive and initiative, lack of spontaneity, apathy, and some subtle cognitive deficits. In addition, dysfunction of the prefrontal cortex has been implicated in schizophrenia. PET and fMRI in schizophrenic patients demonstrate impairments in activation or metabolism in the prefrontal area during certain behavioral tasks. Postmortem studies indicate that there are cytoarchitectural changes as well as neurotransmitter and neurotransmitter receptor deficits in schizophrenic patients.

The posterior parietal cortex consisting of Brodmann's areas 5 and 7 is situated between the somatosensory region of the postcentral gyrus and the visual cortex, from which it also receives inputs. Long

association fibers also connect this region with the premotor and prefrontal association cortices. These anatomical arrangements allow the parietal association cortex to receive and integrate multimodal sensory information and to send this integrated view of the environment to the premotor and prefrontal association areas to initiate the appropriate behavior. Lesions of the superior parietal association cortex usually result in a lack of attention to objects or events in the space contralateral to the damage, a phenomenon known as cortical neglect. Such lesions lead to tactile agnosias, which is the inability to recognize objects by touch. Auditory agnosia, which is the inability to recognize what is heard, occurs when there is bilateral damage to the auditory association area behind the primary auditory cortex. Visual agnosia, which is the inability to recognize objects by sight, is the result of damage to the inferior part of the occipital and temporal lobes with damage to the visual association cortex.

Other lesions, which interrupt connections between the parietal association cortex and the premotor cortex, lead to apraxia or the inability to carry out learned movements even though there is no weakness or lack of sensation. The parietal association area, particularly the inferior region, shows a high degree of lateralization. In most individuals, the left inferior parietal association cortex is concerned with language processing, whereas the right is involved in spatial relationships.

The lateral and ventral temporal cortex is also considered association cortex and demonstrates a high degree of lateralization. Lesions of the left temporal cortex result in deficits in understanding spoken and written language, whereas damage to the right temporal lobe leads to problems using visual, tactile, or auditory information to identify complex shapes or sounds. There is a dorsal–ventral organization within the temporal association cortex such that the auditory representation is located in the more superior regions, whereas the visual component is found in the inferior temporal cortex.

VIII. VISCERAL REPRESENTATION AND FUNCTION

In recent years, considerable progress has been made in determining the role of the cortex in autonomic control in health and disease. Characteristics of the cardiovascular responses elicited from the insular cortex have been determined as well as the efferent and afferent pathways, the nature of the responses, the control of tonic sympathetic activity, and the neurotransmitters mediating these responses. Very early experiments demonstrated that "sham rage" could be induced in cats following crude decortication. Upon innocuous stimulation, such as stroking the fur, cats would demonstrate all the somatomotor and autonomic manifestations (piloerection, dilatation of the pupils, retraction of the nictitating membrane, panting, and tachycardia) of rage. Ablation of the orbitoinsular region of the frontal lobes in cats resulted in a syndrome similar to that of complete decortication or complete removal of the frontal lobes. These studies suggested that the insular cortex might play a role in the tonic regulation of autonomic (particularly sympathetic) responses. Stimulation studies have supported this view. Electrical stimulation of the insular cortex in a variety of mammals, including humans, elicits changes in blood pressure, heart rate, respiration, piloerection, pupillary dilatation, gastric motility, peristaltic activity, salivation, and adrenaline secretion. Phasic microstimulation of the rat insular cortex linked to the R wave of the electrocardiogram (ECG) evokes tachycardia or bradycardia responses without accompanying changes in blood pressure or respiration, and prolonged stimulation in the insular cortex generates progressive degrees of heart block and increased plasma norepinephrine and can cause death in asystole. Accompanying cardiac structural changes are myocytolysis and subendocardial hemorrhages in the vicinity of the origin of the bundle of His, suggesting increased cardiac sympathetic activity. Finally, the efferent pathways and neurotransmitters for these autonomic responses from the insular cortex have been determined. It is clear that a mandatory synapse is located in the lateral hypothalamic area and that the primary neurotransmitter in this region is glutamate acting at NMDA receptors.

The insular cortex is considered to be the visceral sensory cortex on the basis of anatomical and physiological evidence. The earliest demonstration of general visceral input to a cortical level was an investigation in cats that showed that stimulation of the cephalic end of the severed cervical vagus nerve resulted in an increase in the rate and amplitude of cortical electrical activity in the orbitoinsular region. Recent anatomical results in the rat have indicated that the insular cortex might be organized in a viscerotopic manner. The recording of individual neurons in response to activation of specific visceral receptors demonstrated that neurons responding to gustatory inputs were located in the

dysgranular region of the insular cortex. General visceral inputs were primarily located in the granular region of the insular cortex in the rat. In this region, there was a separation between the regions receiving gastric inputs compared to the cardiopulmonary responsive neurons. The distribution of arterial baroreceptor responsive neurons was extensively mapped in the rat insular cortex, which demonstrated that significantly more neurons responding to blood pressure changes were located in the right insular cortex than in the left. This granular insular cortex in which the cardiopulmonary information terminates may be the critical region in the lateral frontal cortex mediating central autonomic manifestations of emotional behavior as predicted by the early experiments demonstrating sham rage.

Gustatory or taste input is considered to be a special visceral sensation. Gustatory input is relayed ipsilaterally from the thalamus to the primary gustatory area, which is located near the face region in the primary somatosensory cortex. Although a cell in the gustatory cortex can be activated by any number of taste stimuli, it will have a preference for one of the four basic taste qualities (sour, sweet, bitter, and acidic). The detection and subsequent identification of a particular taste is not mediated by individual cells in the cortex; rather, the quality of the taste is determined by the pattern of firing in a group of activated cells. The anterior insular cortex (secondary gustatory cortex) also receives gustatory input and this area integrates the gustatory information with input from the olfactory system. Information from both the primary gustatory area and the insula is integrated with other sensory information in the orbitofrontal cortex.

Recent evidence has shown for the first time that it is possible to obtain a clear representation of visceral sensation in the human insular cortex similar to that observed in the rodent. fMRI was used to identify regions of the human brain that were activated in response to a series of tests designed to stimulate cardiopulmonary and gustatory receptors. Cardiopulmonary activation included maximal inspiration, Valsalva's maneuver, and maximal handgrip to elevate arterial blood pressure. These maneuvers consistently resulted in discrete changes in activity in the anterior insular cortex, with a time course corresponding to the changes in arterial blood pressure and heart rate they produced (Fig. 7). Gustatory stimuli, such as salt and sucrose perfusion of the tongue, resulted in activation of the inferior anterior insular cortex.

Several investigations have indicated that the insular cortex may mediate the cardiovascular consequences of stroke. Middle cerebral artery occlusion (MCAO) in the cat and rat results in an increase in blood pressure, norepinephrine level, sympathetic nerve activity, myocytolysis, and death. These changes resemble those seen clinically and are obtained only when the insular cortex is included in the infarct. Asymmetry of responses elicited from the cerebral cortex is an important topic in many types of behavioral investigations. There is evidence that stimulation of the insular

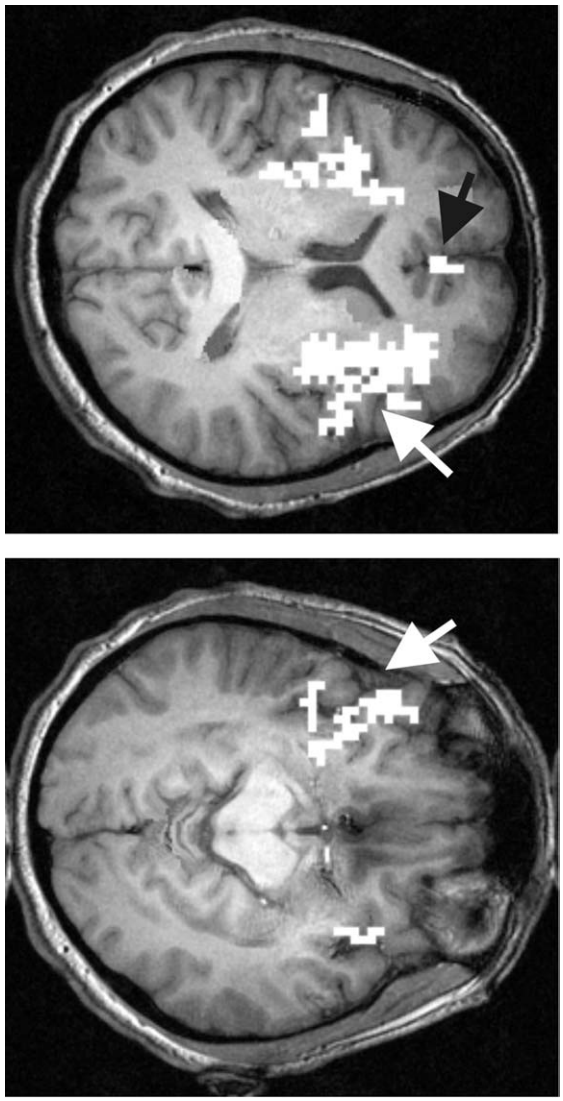

Figure 7 Activation of visceral regions of the cortex in response to an increase in arterial blood pressure. White arrows indicate activation in the anterior insular cortex, and the black arrow shows medial prefrontal cortex activation. The top of each image represents the left side of the brain.

cortex in the human also elicits different results from each hemisphere. In the MCAO model in the rat, right-sided stroke results in a significantly higher increase in mean arterial blood pressure, sympathetic nerve activity, and plasma norepinephrine and an increase in the QT interval of the ECG. Finally, the animal stroke model has clearly shown that the cardiovascular consequences of stroke are more severe with increasing age. The aged animals had significantly increased mortality following the stroke and prior to death exhibited significantly elevated sympathetic nerve activity, plasma norepinephrine concentration, and prolonged QT interval of the ECG. Clinical studies have confirmed the importance of the insular cortex in mediating the cardiovascular consequences of stroke. Plasma norepinephrine levels, changes in circadian blood pressure, and incidence of cardiac arrhythmias correlate highly with percentage insular infarction. These investigations also confirm observations of right hemispheric dominance for sympathetic effects. There is some indication that the left insular cortex is predominantly responsible for parasympathetic effects since left insular stimulation in humans results in more frequent parasympathetic responses (bradycardia) compared to right insular stimulation, which yielded increased blood pressure and heart rate (sympathetic effects). Recently, it was shown in a group of patients with lesions mainly confined to the left insular cortex that there was an increased basal cardiac tone associated with a decrease in heart rate variability.

Anatomical and functional data clearly indicate that another cortical site in the medial prefrontal cortex plays an important role in determining the autonomic responses of the organism to complex behaviors. This medial prefrontal cortical area is considered to be visceral motor cortex. Compared to the insular cortex, considerably less is known regarding the specific role of the medial prefrontal cortex in autonomic control. A variety of autonomic responses can be elicited by stimulation of the medial prefrontal cortex. In fact, complete cessation of heartbeat may occur in monkeys during stimulation of the medial frontal cortex. The medial prefrontal cortex has extensive connections with both the limbic and the autonomic systems of the brain. It receives inputs from the insular and entorhinal cortices, the hippocampus, amygdala, the visceral relay nuclei of the thalamus, and pontine and medullary autonomic control sites. The medial prefrontal cortex has descending projections to many autonomic sites, including the insular cortex, the amygdala, the visceral relay nuclei of the thalamus, hypothalamus, and brain stem autonomic control nuclei.

IX. CORTICAL PLASTICITY

In the past 10 years, many observations have indicated that the cerebral cortex in the adult is not as hardwired as previously thought. Although the concept of plasticity was associated with the developing brain, it was not thought to be possible in the mature central nervous system. It has been demonstrated that a major change in sensory input can result in a reorganization of the cerebral cortex. Either an increase in afferent activation or a deficit in sensory input can cause substantial changes in cortical representation. For example, in blind subjects who rely extensively on Braille for reading, it has been shown that cortical representation for the digits that are utilized can be substantially increased. Deafferentation due to amputation of a limb or digit or severing of afferent nerves leads to an invasion of the dennervated cortical region by an adjacent intact region. For example, amputation of a digit results in encroachment of the cortical region previously representating the digit by the areas representating adjacent digits. In addition, the smaller region that represents the amputated digit has a greater degree of representation by the remaining stump and a much reduced area in the region previously representing the distal skin of the digit. The extent of the invasion can be quite substantial. Deafferentation of an upper limb by severing the dorsal roots results in an invasion of the region representing the face by as much as 15–20 mm.

The immediate response in the cortex is an expansion of representation from an adjacent region into the region previously serving the deafferented limb or digit. At a later stage, the topography in the region is reorganized based on the extent of use or level of afferent input that is being received. The mechanisms responsible for this cortical plasticity are thought to be the same for both the expansion of a cortical region in response to an increase in peripheral input and the invasion of a cortical area following the deafferentation of a peripheral input. In the case of the deafferentation of a digit or limb, there are two distinct phases. For several weeks, the region of the cortex for representation of the deafferented limb or digit becomes totally silent. At a later stage, 6 months or longer, the invasion by the adjacent region takes place.

Currently, there are two proposed mechanisms for how this large amount of cortical plasticity can occur. First, it is known that connections from adjacent regions already exist. These residual connections are present but are not responsive to afferent input. When the cortical region loses its primary input these silent

connections begin to respond to afferent input. This causes changes in neurotransmitters levels and the numbers of neurotransmitter receptors, which in turn results in an increase in the synaptic representation of the alternative region. This increase in synaptic representation may even lead to sprouting of nerve terminals resulting in an even greater degree of spreading of the cortical reorganization. A mechanism restricted to the cortex is supported by evidence that local microstimulation in the cortex is sufficient to produce an increase in cortical representation similar to the effect of an enhancement of peripheral afferent input. However, this may not account for the complete extent of cortical reorganization that occurs. There is good evidence that a great deal of reorganization takes place at subcortical levels. It is postulated that small amounts of reorganization at thalamic and brain stem levels will be amplified at the level of the cerebral cortex.

X. FUTURE DIRECTIONS

This overview of the current state of knowledge on topics related to the cerebral cortex clearly indicates that there are numerous exciting avenues for future research. For instance, there is much to be learned about the molecular nature of processing in the brain. The localization of different receptors and receptor subtypes, the interactions of the neurotransmitters on specific regions of these receptors, and the subsequent intracellular signaling cascades are all important to understanding processing of neural signals in the intrinsic circuitry of the cortical columns and how this is transformed into cognitive processes, such as attention, memory, and personality. Understanding the molecular nature of the cells of the cerebral cortex also has important developmental and clinical implications.

It is also critical to continue to explore mechanisms of cortical plasticity. The specific genes that control plasticity in the developing compared to the mature cerebral cortex need to be determined to provide insight into potential repair mechanisms for neurotrauma or neurodegenerative diseases. In this respect, investigations into therapeutic methods such as the use of neurotrophic factors and neuronal stem cells following stroke or other causes of cerebral cortex injury are providing exciting results. These potential gene therapies will also be of interest to investigators studying the neurodegenerative cerebral cortex disorders such as Alzheimer's disease and schizophrenia.

Finally, neuroimaging methods such as PET and fMRI will continue to be powerful tools to unravel the manner in which the cerebral cortex functions in the human to produce complex behaviors and cognition. This technology will be of fundamental importance in the future for not only localizing areas of the cortex devoted to particular functions but also for identifying the network of connections throughout the brain that mediate the higher cognitive functions that are unique to the human or conscious mind.

Cerebral Edema

DAVID S. LIEBESKIND
University of California, Los Angeles

GLOSSARY

cytotoxic Harmful to cells.

diuresis Increased removal of water.

edema The excessive accumulation of fluid in tissue.

ependyma The thin membrane that lines the ventricles of the brain.

extravasation The leakage and spread of fluid from vessels into the surrounding tissues.

herniation The abnormal protrusion of tissue that results in compression of neighboring structures.

interstitium The small tissue space between structural elements.

osmolarity The concentration of a molecule dispersed in a fluid.

osmole A molecule dissolved in a fluid.

parenchyma The functional part of an organ.

pinocytosis A cellular transport mechanism that functions through cytoplasmic engulfment of fluid.

transudation The passage of a fluid through a membrane.

vasogenic Resulting from changes in blood vessels.

Cerebral edema is a heterogeneous condition defined as the volumetric increase in brain tissue resulting from the accumulation of water. Elements of cerebral edema form integral components of the pathophysiology of many neurologic diseases.

I. PATHOPHYSIOLOGY

The concept of cerebral edema has been recognized for more than 2000 years, yet an understanding of the complex physiology of this condition has evolved only within the past 30 years. Ancient Greek authors used the term "$\sigma\iota\delta\eta\mu\alpha$" to describe the swelling of the brain that resulted from compound skull fractures. Hippocrates noted that removal of the overlying skull bones allowed the injured brain to swell outward, thus minimizing compression of normal tissue trapped within the cranial vault. The Monro–Kellie doctrine later recapitulated this concept, affirming that when "water or other matter is effused or secreted from the blood vessels … a quantity of blood equal in bulk to the effused matter, will be pressed out of the cranium." This indiscriminate concept of brain swelling was cited in a diverse range of clinical settings until 1967, when Igor Klatzo defined the modern classification of edema based on pathophysiology. Cerebral edema, according to Klatzo, was defined as "an abnormal accumulation of fluid associated with volumetric enlargement of the brain." This entity was divided into vasogenic edema, characterized by derangement of the blood–brain barrier (BBB), and cytotoxic edema, related to intracellular swelling in the absence of changes at the BBB. The term cytotoxic edema has recently been reserved for states associated with toxin-induced cellular swelling. Klatzo emphasized that these two forms usually coexisted. In 1975, Robert Fishman added interstitial edema as a distinct entity by describing the transependymal flow of cerebrospinal fluid (CSF) into the periventricular white matter in individuals with acute obstructive hydrocephalus; this form was later termed hydrocephalic edema. In similar fashion, ischemic

Table I
Classification of Cerebral Edema

Type	Location	Site	Blood–brain barrier	Pathogenesis	Clinical correlation
Vasogenic	Extracellular	White matter	Disrupted	Vascular permeability	Lead encephalopathy
					Neoplastic disease
					Infection
					Fulminant hepatic failure
					Traumatic brain injury
					High-altitude cerebral edema
Cytotoxic	Intracellular	White or gray matter	Intact	Cellular injury	Toxin exposure
					Ischemia
					Traumatic brain injury
					Fulminant hepatic failure
					Reye's syndrome
Hydrocephalic	Extracellular	White matter	Intact	Transependymal pressure	Hydrocephalus
Ischemic	Intra- and extracellular	White and gray matter	Disrupted	Hypoxia	Ischemia
Hydrostatic	Extracellular	White and gray matter	Disrupted	Hydrostatic pressure	Hypertensive encephalopatby
Osmotic	Intra- and extracellular	White and gray matter	Intact	Osmotic pressure	Hyponatremia
					Dialysis disequilibrium
					Diabetic ketoacidosis

edema was described, incorporating elements of both cytotoxic and vasogenic forms. Additional classifications based on mechanism and location of excess fluid include hydrostatic edema and osmotic edema. Hydrostatic edema results from increased hydrostatic forces with associated disruption of the BBB, as occurs in the setting of hypertensive encephalopathy. Osmotic edema has been ascribed to states of plasma hypoosmolarity that result in cellular swelling with preservation of the BBB. Table I summarizes the nomenclature of cerebral edema. This classification scheme emphasizes the predominant form of edema associated with several clinical scenarios and delineates the corresponding pathophysiology. The remainder of this article utilizes this classification of cerebral edema, emphasizing the role of each form in a variety of clinical encounters.

Consideration of the specific pathophysiologic mechanisms is crucial for establishing a fundamental approach to the various forms of cerebral edema. Each form of cerebral edema results in a net gain of water in the brain, although different mechanisms determine the specific location of water accumulation and resultant pathology. Numerous descriptions fail to distinguish cerebral edema from other causes of intracranial hypertension. Cerebral edema may result in intracranial hypertension, but the two conditions are not synonymous because intracranial hypertension may result from increased cerebral blood volume or increased CSF content. This review specifically focuses on cerebral edema, in distinction from other causes of intracranial hypertension. Various forms of cerebral edema may coexist and are often closely interrelated. One form of edema may also lead to the development of another, particularly in vasogenic and cytotoxic edema. For these reasons it is particularly important to consider the time course involved in specific clinical scenarios. The underlying processes must be delineated to understand and develop rational therapeutic approaches that focus on the particular pathophysiologic mechanism.

A. Distribution of Fluid in the Brain

The normal water content of the human brain is approximately 80% by weight, with higher amounts of

water in the gray matter than in the white matter. Fluid is distributed among the intraluminal cerebrovasculature, the intracellular space of the parenchyma, the extracellular space of the interstitium, and the ventricular system. Therefore, a complex interaction of morphologic features and biochemical processes exists to maintain the normal fluid balance of the brain. An increase in the intravascular plasma volume of the cerebral circulation may lead to fluid engorgement of the brain. Although such an increase in cerebral blood volume is not inherently pathologic, an associated alteration of the BBB may cause fluid to extravasate into the extracellular compartment. Increased water content in the interstitial space may result from obstruction of CSF outflow in the ventricular system with resultant transependymal exudation of fluid. Fluid homeostasis within the intracellular compartment may be altered by many factors, thus leading to cellular edema. To define characteristic features of specific forms of cerebral edema, the location of edema fluid accumulation as extracellular, intracellular, or both proves to be a useful tool, as does the predilection for gray or white matter involvement.

B. Fluid Dynamics of the Intracranial Compartment

Intracranial volume is limited by the confines of the adult calvarium. An increase in the volume of one fluid compartment results in compensatory decrease in the others. Displacement of CSF and venous blood compensates for pressure differentials transmitted between compartments. These volumetric changes in response to pressure differences define the brain's compliance. Under normal physiologic conditions, changes in the intracranial volume are associated with minimal or insignificant fluctuations in the intracranial pressure (ICP), but considerable increases in ICP may occur as the intracranial volume increases and brain compliance decreases. The relationship between intracranial volume and ICP is illustrated in Fig. 1. ICP is commonly evaluated by measuring the opening pressure of the CSF in the lateral decubitus position or with a ventriculostomy or subdural monitor in the neurointensive care unit. ICP normally ranges from 15 to 20 mmHg. Focal elevations in ICP may lead to displacement of brain tissue with herniation, precipitating neurologic deficits that may be fatal. Neuropathologic correlates of herniation are illustrated in Fig. 2.

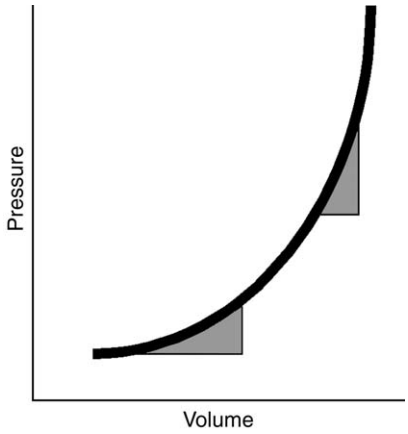

Figure 1 Intracranial volume and ICP correlation, demonstrating that relatively larger pressure increments result from decreasing compliance with volume increases.

Changes in ICP may affect cerebral perfusion pressure (CPP). The CPP is equal to the difference between the mean arterial pressure and the ICP. In normal circumstances, autoregulation of vasomotor tone in the cerebral circulation allows for maintenance of an adequate CPP, coupling brain metabolism with cerebral blood flow. Autoregulation is predominantly mediated at the arteriolar and capillary level under the influence of vasoactive factors and direct innervation from the sympathetic nervous system. Cerebral capillary function is regulated by many substances, including adenosine, vasoactive intestinal peptide, and arachidonic acid metabolites. Numerous disease states including cerebral ischemia and head trauma interfere with this protective mechanism. As the ICP exceeds a critical threshold of 20–25 mmHg, CPP decreases, with significant decrements resulting in cerebral ischemia.

A simplistic approach to fluid dynamics in the intracranial compartment is derived from the application of Starling's law, which states that fluid flux is dictated by a balance between hydrostatic forces and osmotic gradients. The complex structural and functional properties of the BBB result in a highly modified form of Starling's law with dynamic homeostasis influenced by local and systemic mediators, although the concept of balanced hydrostatic and osmotic forces is preserved. Plasma flow across the BBB is driven both by hydrostatic forces determined by the relatively constant CPP and by osmotic forces principally determined by the concentration gradient of sodium ions. Under pathologic conditions, the osmotic forces are modified by the generation of idiogenic osmoles, substances produced by brain parenchyma to prevent

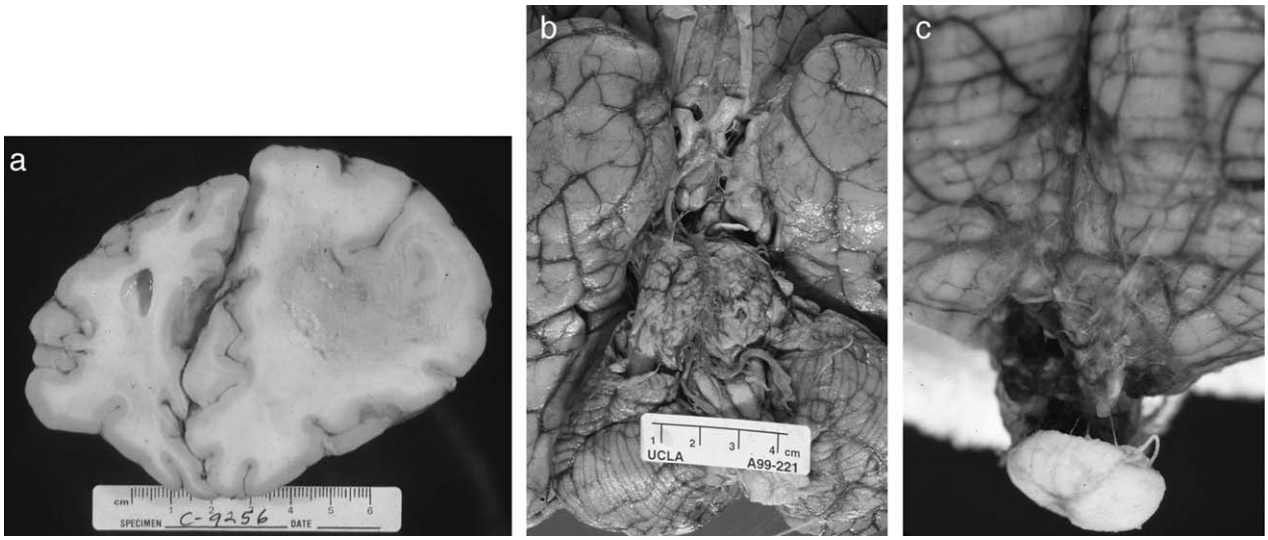

Figure 2 Neuropathologic features of herniation syndromes demonstrated in gross brain specimens. (a) Subfalcine midline shift due to a frontal lobe glioma. rapid fluid loss with resultant cellular shrinkage. These idiogenic osmoles included the following: alanine, aspartate, betaine, choline, GABA, glutamate, glutamine, glycerophosphorylcholine, glycine, lysine, *myo*-inositol, phosphocreatine, serine, taurine, and threonine.

C. The Blood–Brain Barrier

The BBB maintains the flux of ions, water-soluble nutrients, and metabolites to titrate the specific composition of extracellular fluid in the central nervous system. The brain parenchyma is contained within an immunologically separate compartment under tight volumetric control. This compartmentalization is achieved and maintained by a combination of specific morphologic features and biochemical factors.

The BBB consists of endothelial cells bridged by tight junctions and adjoined by foot processes of astroglia. Endothelial cells form the inner lining of all vessels and have common properties that include a nonthrombogenic luminal surface, a basement membrane, and the production of active substances. Astrocytic foot processes extend to form a tight network that enmeshes the outer surface of brain capillaries. The endothelial architecture of the cerebral circulation is distinct from other vascular territories. Early in life, the cerebrovascular endothelium becomes almost completely impermeable, thereby isolating the brain from the systemic circulation. The BBB exists throughout the central nervous system, leaving only specific areas, such as the choroid plexus and the circumventricular organs, devoid of this structure. The choroid plexus is responsible for the production of CSF, modifying plasma from the cerebral circulation to maintain the protective fluid compartment of the ventricular system. The CSF circulates from the ventricular system into the subarachnoid space where it functions as a cushion for the brain, protecting it from trauma. The circumventricular organs include chemosensitive and neurosecretory sites that are involved in body fluid turnover, regulation of fluid osmolarity and extracellular sodium content, and cardiovascular function.

Several structural features of the BBB account for the specialized function of this cellular layer. Complex interendothelial junctions prevent even small ions from entering the brain parenchyma. Only lipid-soluble substances are allowed to diffuse through this layer. Pinocytosis, the transport of materials within small intracellular vesicles, is necessary for most substances to traverse the endothelial layer. Electron microscopy of the BBB demonstrates the close opposition of endothelial cells, including a paucity of vesicular transport and a high density of mitochondria. The mitochondrial content of brain endothelia is approximately 10 or 11%, compared to 2.7% in other

blood vessels. This elevated concentration of mitochondria is necessary for the high rate of metabolic activity that occurs. The passage of polar molecules, including many amino acids, is accomplished by several specialized transport systems.

The functional properties of the BBB include a high transendothelial potential and resistance, with a high reflection coefficient and low hydraulic conductivity. The intracellular compartment of the endothelial layer has marked enzyme activity associated with multiple transport systems. Water transport across the BBB is under close neurogenic and endocrine control. Biologically active agents that alter the BBB include substance P, adenosine nucleotides, endothelin-1, calcium entry blockers, metalloproteinases, cytokines, vascular endothelial growth factor or vascular permeability factor (VEGF/VPF), and antibodies to filamentous hemagglutanin. Several cytokines, including interleukins, tumor necrosis factor-α (TNF-α), and platelet-activating factor (PAF), are active at the BBB. Vasoactive substances can increase BBB permeability by activating cyclic nucleotide-generating enzymes or by increasing the rate of lipolysis through phospholipases. Vasodilators such as arachidonic acid, noradrenaline, and histamine may also increase cytoplasmic ionized calcium and activate microvascular guanylate cyclase. These actions result in increased pinocytosis and macromolecular transport. Modulation of BBB permeability has been the focus of recent therapeutic interventions for brain tumors, employing steroidal substances and chemotherapeutic agents.

D. Cellular Elements

Although the BBB serves as the major regulatory site of fluid exchange in the central nervous system, multiple actions at the cellular level in the brain parenchyma further influence fluid homeostasis. These cellular elements include the neuroglia, mainly astrocytes, and the neurons. Neuroglia were once thought to form an inactive architectural framework that supported the neuronal population. Further investigation revealed that neuroglia play an important role in the maintenance of fluid composition and volume. These cells contain numerous membrane surface ion channels that exchange molecules between the intracellular space and the extracellular milieu of the interstitial space and thereby adjust the electrochemical gradients influencing excitatory thresholds and the release of neurotransmitter substances. Glutamate, the main excitatory neurotransmitter of the central nervous system, is ubiquitous in the intracellular space. Efficient uptake systems in glial and neuronal tissue clear glutamate from the extracellular space.

Volumetric changes are energy dependent and modified by fluid osmolarity, principally determined by the sodium concentration. Sodium is exchanged with potassium at the Na^+/K^+ ATPase channel, requiring energy from the release of ATP. This channel is oxygen dependent and therefore sensitive to hypoxic stress. As the astrocytic sodium concentration increases, cellular volume expands and vice versa. Glial swelling represents a normal component of homeostasis, although extreme states occur in pathologic conditions such as hypoxia.

Although sodium shifts are the principal determinant of cellular volume changes, the measurement of sodium concentrations in abnormal hyperosmolar states has revealed that other substances might account for the osmolar increase. Specific identification of these substances has proved difficult, but the concept of idiogenic osmoles has been advanced. These molecules are produced under conditions of hypoosmolarity in order to compensate for volume decreases. During the resolution phase of systemic hyperosmolar states, a differential equilibration of inorganic ions such as sodium relative to idiogenic osmoles results in cellular swelling. Throughout this regulatory volume decrease of brain cells, organic osmolytes leave the cell through a molecular pore or ion channel, termed the voltage-sensitive organic anion channel (VSOAC). Osmotic swelling normally activates the VSOAC, although this pathway may fail under pathologic conditions.

E. Classification of Cerebral Edema

1. Vasogenic Edema

Vasogenic edema results from increased permeability of the BBB. This form of cerebral edema occurs in the setting of brain tumors, abscesses, meningitis, lead encephalopathy, traumatic head injury, ischemia, and intracerebral hemorrhage. Klatzo developed an animal model to study the neuropathology of cold-induced vasogenic edema. A metal probe cooled with liquid nitrogen caused focal swelling of astrocytic foot processes, with the majority of fluid accumulation occurring in white matter.

Several mechanisms have been implicated in BBB disruption associated with vasogenic edema. Controversy has focused on the respective roles of increased

pinocytotic transport, opening of interendothelial tight junctions, and mediators affecting vascular permeability. Pinocytosis refers to the vesicular transport of material across the endothelial cell layer. Cyclic nucleotide-generating enzymes in the endothelial cytoplasm that are linked to receptors on the cell surface trigger this process. Leaky interendothelial tight junctions allow for the exudation of plasma proteins with associated fluid shifts. Extravasation of blood cells occurs only when severe damage occurs. Extravasation of fluid with engorgement of the interstitial space undoubtedly interferes with structural elements of the parenchyma and may lead to further injury due to impaired diffusion of essential substances. The mediator concept of vasogenic edema theorizes that autacoids released from injured brain tissue induce increased vascular permeability. Numerous substances illustrate this capability. Bradykinin and histamine alter the integrity of the BBB by opening tight junctions, increasing vesicular transport, and simultaneously producing relaxation of cerebral arteries with resultant increases in cerebral blood flow. The combination of these effects results in cerebral edema. The effects of bradykinin and histamine have been linked to stimulation of specific receptors. Elevations of bradykinin and histamine also occur in brain tissue following trauma, ischemia, and experimental cold-induced injury. Although inhibition of bradykinin reduces cerebral edema, similar antagonism of histamine has failed to produce a similar effect. Arachidonic acid has also been implicated in the pathogenesis of vasogenic edema. This substance is a free fatty acid that is a major component of brain cells and subcellular organelles. The liberation of arachidonic acid with resultant increases in concentration has been demonstrated following trauma and ischemia, although the mechanism of subsequent BBB breakdown is unclear. Arachidonic acid has a variable effect on the cerebral vasculature. Glucocorticoid inhibition of arachidonic acid production may reduce cerebral edema, but this effect seems to be dependent on etiology. Atrial natriuretic factor (ANF) is a peptide that relaxes smooth muscle and increases renal excretion of sodium and water. Animal models have demonstrated ANF to be effective in reducing cerebral edema. Glucocorticoids are able to regulate the expression of the ANF gene, suggesting a possible role in the response of cerebral edema to steroid therapy.

The roles of nitric oxide and oxygen-derived free radicals have also been the focus of much attention. A free radical is defined as an atom or molecule with an unpaired electron in its outer orbit. Oxygen free radicals play a key role in the development of vasogenic edema. The deleterious effects of oxygen-derived free radicals cause secondary injury following ischemia and head trauma. These substances participate in an iron-catalyzed reaction that leads to lipid peroxidation. The extravasation and subsequent degradation of red blood cells liberate heme compounds and iron, promoting this process. The scavenging action of superoxide dismutase limits the cascade of free radical production. The vasodilatory effects of nitric oxide are well established, and endothelial nitric oxide production causes disruption of capillary integrity. Despite these findings, nitric oxide has not been shown to produce cerebral edema and inhibition of this substance in experimental models of cerebral edema has yielded discrepant results.

2. Cytotoxic Edema

In contrast to the initial events that characterize vasogenic edema, cytotoxic edema occurs in the absence of permeability changes at the BBB. Cytotoxic edema is typified by intracellular accumulation of fluid associated with toxin exposure, ischemia, head trauma, or Reye's syndrome. The experimental animal model of triethyl tin intoxication has been used as the prototypical example of this condition. Cellular swelling affects neurons, glia, and endothelial cells, although the majority of research focuses on astrocytic swelling. The mechanism of astrocytic swelling is complex, involving the activation of ion channels and free radical injury to the cellular membrane. Cytotoxic edema is most commonly precipitated by failure of the Na^+/K^+ ATPase channel due to energy depletion. Secondary events are associated with mediators including glutamate, potassium, free fatty acids, and lactoacidosis. Under normal conditions, the permeability of the astrocytic membrane to sodium is very low and must involve the activation of specific transporters. Several protective mechanisms contribute to an increase in the intracellular sodium concentration when the extracellular fluid composition becomes altered. Increased neuronal metabolic activity and other causes of acidosis encourage the astrocytic uptake of sodium due to activation of the Na^+/H^+ channel. Astrocytes also accumulate sodium in a dependent fashion because of glutamate clearance from the extracellular space. These increases in intracellular sodium result in intracellular fluid accumulation, most prominently at the endfeet that contribute to the BBB. Despite the relative abundance

of oxygen and nutrients at this location, the high density of Na^+/H^+ and Na^+/HCO_3^- cotransport systems can predispose this region to early manifestations of swelling. Astrocytic swelling may have deleterious effects due to the release of excitatory amino acids. Excitatory amino acids, including glutamate, taurine, and aspartate, are released through reversal of normal uptake systems and swelling-induced efflux via anion channels. The release of glutamate stimulates neurons and leads to increases in intracellular calcium and subsequent disruption of normal cellular architecture. Excessive stimulation of excitatory receptor sites may lead to further neuronal injury.

3. Hydrocephalic Edema

Obstruction of CSF outflow from the ventricular system results in hydrocephalus with ventricular dilatation. Progressive CSF accumulation exerts pressure across the ependymal lining of the ventricles. At a critical stage, this force causes the leakage of CSF across the ependyma into the interstitial space. For this reason, hydrocephalic edema is often referred to as interstitial edema. The periventricular white matter tracts are usually involved, whereas the BBB remains intact.

4. Ischemic Edema

Cerebral ischemia triggers a cascade of molecular interactions that culminate in a combination of cytotoxic and vasogenic edema referred to as ischemic edema. This composite of edema patterns evolves with the duration of ischemia. Immediately after the onset of cerebral ischemia, cytotoxic edema develops. The critical step in this process is energy depletion leading to failure of the Na^+/K^+ ATPase pump. The initial increase in astrocytic water content may be transient and fully reversible if reperfusion occurs. If ischemia persists, increasing astrocytic swelling jeopardizes the integrity of the BBB. In cases of permanent ischemia, the breakdown of the BBB occurs after a delay. At the periphery of the ischemic territory, vasogenic edema predominates because acidosis and loss of autoregulatory function produce a reactive hyperemia. Temporary cerebral ischemia results in a biphasic disturbance of the BBB. After a delay, a secondary opening of the BBB occurs due to the release of mediators on the abluminal side from ischemic parenchyma. These substances include kinins, free fatty acids, free radicals, serotonin, and prostaglandins. Early disruption of the BBB is proportional to the intensity of reactive hyperemia. Subsequent changes in vascular permeability also impair the clearance of materials from brain parenchyma. The accumulation of lactic acid may be an important variable in the severity of postischemic edema.

5. Hydrostatic Edema

Elevated hydrostatic pressure due to arterial hypertension and vasodilation may result in increased fluid flux across the capillary wall. Dysautoregulation of the cerebrovasculature limits the ability of blood vessels to vasoconstrict in response to arterial pressure elevations. A transudative fluid with low protein content accumulates in the interstitial space. This process is normally prevented by the opposing ICP and osmotic pressure gradients that retain fluid in the vascular space. The most common clinical example of hydrostatic edema formation is hypertensive encephalopathy. In this condition, intraarterial pressure exceeds the upper limits of cerebral autoregulation. Conditions of systemic hypoosmolarity decrease the osmotic forces that normally retain fluid in the vascular space. Similarly, abrupt decreases in ICP (e.g., mass resection) may precipitate edema formation as the result of acute changes in transmural hydrostatic forces.

6. Osmotic Edema

An alteration in the osmotic pressure gradient with relative hyperosmolarity of the brain parenchyma with respect to plasma encourages the accumulation of fluid in the brain. The development of osmotic edema requires integrity of the BBB. An osmotic discrepancy commonly results from hyponatremic states including water intoxication, the syndrome of inappropriate antidiuretic hormone (SIADH) secretion, cerebral salt wasting, and iatrogenic error with inappropriate administration of hypotonic solution. Although sodium is usually the primary determinant of serum osmolarity, other metabolic derangements may produce a state of relative hyperosmolarity within the brain parenchyma and subsequent formation of osmotic edema. These conditions include dialysis disequilibrium, diabetic ketoacidosis, and rapid correction of hypernatremia. Hyperosmolarity of brain parenchyma has been attributed to the generation of idiogenic osmoles as a protective measure during systemic hyperosmolar states. The temporal profile of changes in osmotic pressure gradients appears to be a critical factor in the development of osmotic edema.

II. CLINICAL MANIFESTATIONS

Cerebral edema is associated with a wide spectrum of clinical disorders. Edema can either result from regional abnormalities related to primary disease of the central nervous system or be a component of the remote effects of systemic toxic–metabolic derangements. In either scenario, cerebral edema may be a life-threatening complication that deserves immediate medical attention. Several challenges surround the management of cerebral edema, because the clinical presentation is extremely variable. This variability reflects the temporal evolution of a diverse combination of edema types because most forms of cerebral edema have the capacity to generate other types. The specific clinical manifestations are difficult to categorize by type and are better described by precipitating etiology. In other words, it is essential to outline the prominent forms of edema that are present in a given clinical scenario. The location of edema fluid determines symptomatology. Focal neurologic deficits result from isolated regions of involvement, whereas diffuse edema produces generalized symptoms such as lethargy. The following sections address the clinical manifestations of cerebral edema that are associated with a diverse range of clinical disorders, first describing primary pathology of the central nervous system followed by the neurologic consequences of systemic disorders.

A. Cerebrovascular Disease

Cerebral ischemia frequently causes cerebral edema. Global ischemia may result from cardiac arrest or sustained hypotension, whereas focal ischemia may be the product of thromboembolic occlusion of a cerebral artery. Tissue hypoxia that results from ischemic conditions triggers a cascade of events that leads to cellular injury. The immediate effect of hypoxia is energy depletion with resultant failure of the Na^+/K^+ ATPase pump. The onset of ischemic edema initially manifests as glial swelling occurring as early as 5 min following interruption of the energy supply. This cytotoxic phase of edema occurs when the BBB remains intact, although continued ischemia leads to infarction and the development of vasogenic edema after 48–96 hr. The development of vasogenic edema usually occurs only after reperfusion or in the setting of transient ischemia. Elevations of systemic arterial pressure with a loss of cerebral autoregulation may further the development of cerebral edema by increasing hydrostatic pressure gradients across a disrupted BBB. Conversely, a reduction in CPP coupled with changes in the microcirculation, including elevation of cerebrovascular resistance, may induce detrimental effects by limiting the distribution of essential nutrients. Secondary ischemia may also result from BBB breakdown or from the effects of free radical-related amplification of neuronal injury. Clinical symptoms are initially representative of neuronal dysfunction within the ischemic territory, although the spread of edema may elicit further neurological deficits in patients with large hemispheric infarction. This clinical syndrome involves increasing lethargy, asymmetrical pupillary examination, and abnormal breathing. The mechanism of neurologic deterioration appears to involve pressure on brain stem structures due to the mass effect of infarcted and edematous tissue. Elevation of ICP may be generalized or display focal gradients that precipitate herniation syndromes. Herniation may lead to compression and infarction of other vascular territories, in turn initiating a new cycle of infarction and edema.

Hemorrhagic infarction is frequently the cause of elevations in ICP, but the contribution of cerebral edema has been controversial. Intracerebral hemorrhage presents with focal neurologic deficits, headache, nausea, vomiting, and/or evidence of mass effect. The edema associated with intracerebral hemorrhage is predominantly vasogenic (Fig. 3), climaxing 48–72 hr following the initial event. Secondary ischemia with a component of cytotoxic edema may result from impaired diffusion in the extracellular space of the perihemorrhage region. Expansion of the hematoma volume or extension of edema may precipitate cerebral herniation. Figure 4 demonstrates uncal herniation that resulted from expansion of a hematoma. Other forms of hemorrhage, including hemorrhagic transformation of ischemic territories and subarachnoid hemorrhage, may be associated with edema that results from the noxious effects of blood degradation products.

Cerebral venous thrombosis may lead to venous stasis and elevations of cerebral venous pressure. These conditions are attributable to the absence of an autoregulatory mechanism within the cerebral venous circulation. The effect of elevated venous pressures is therefore greater than similar increases in the arterial system. The clinical manifestations of cerebral venous thrombosis are highly variable. Individuals may be asymptomatic, and others may suffer a progressive neurologic deterioration with headaches, seizures, focal neurologic deficits, and severe

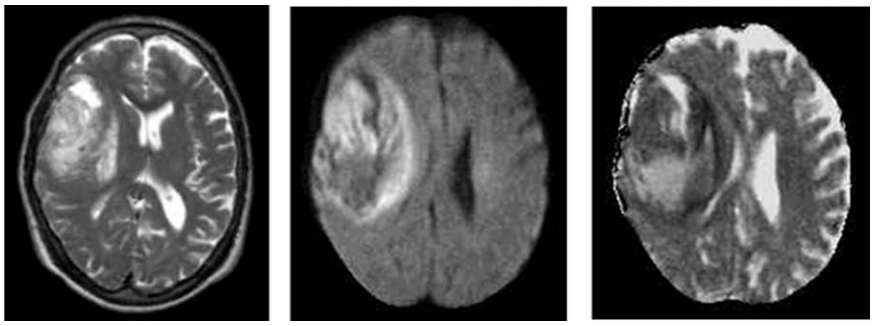

Figure 3 Intracranial hemorrhage depicted by MRI. T2-weighted sequence showing hyperintensity associated with vasogenic edema in the right frontal lobe.

obtundation leading to death. Parenchymal venous congestion and elevation of venous pressures can lead to disruption of the BBB, the formation of vasogenic edema, and perivascular hemorrhage. Further increases in venous pressure lead to a reversal of the normal hydrostatic pressure gradients, and thus reduce capillary perfusion pressure. Fluid distension of the extracellular space also impairs the diffusion of nutrients. These changes induce the formation of cytotoxic edema that may ultimately result in ischemic venous infarction (Fig. 5).

Figure 4 Coronal brain slices illustrating uncal herniation due to hematoma expansion. (Courtesy of Harry V. Vinters, M.D.)

B. Traumatic Brain Injury

Focal or diffuse cerebral edema of mixed types may develop following traumatic brain injury (TBI). Following contusion of the brain, the damaged BBB permits the extravasation of fluid into the interstitial space. Areas of contusion or infarction may release or induce chemical mediators that can spread to other regions. These potentially deleterious mediators include lysosomal enzymes, biogenic amines including serotonin and histamine, excitatory amino acids, arachidonic acid, and components of the kallikrein–kinin system. These factors activated during tissue damage are powerful mediators of extravasation and vasodilation. TBI is associated with a biphasic pathophysiologic response heralded by a brief period of vasogenic edema immediately following injury, followed after 45–60 min by the development of cytotoxic edema. Vasogenic edema may be detected by neuroimaging modalities within 24–48 hr and reach maximal severity between Days 4 and 8. Although cerebral blood flow decreases for the initial few hours following head injury, a reactive hyperemic response that exceeds metabolic demands may exacerbate vasogenic edema. Autoregulatory dysfunction is a common sequela of TBI that may promote the formation of hydrostatic edema in regions where the BBB remains intact.

Recent efforts have also demonstrated a prominent role of cytotoxic edema in head-injured patients.

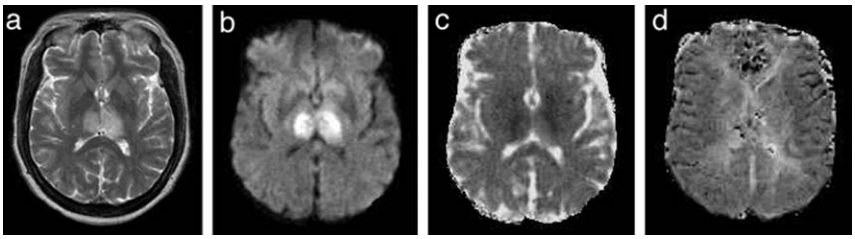

Figure 5 Multimodal MRI of cerebral venous thrombosis. Ischemic edema of the thalami manifest as hyperintensity on (a) T2-weighted sequences and (b) DWI. (c) ADC hypointensity corresponds to the cytotoxic component. (d) Focal hyperintensity suggests increased regional cerebral blood volume.

Tissue hypoxia with ischemic edema formation and neurotoxic injury due to ionic disruption contribute to this cytotoxic component. In addition, osmotic edema may result from hyponatremia, and hydrocephalic edema may complicate the acute phase of TBI when subarachnoid hemorrhage or infections predominate. Conspicuous diffuse axonal injury may produce focal edema in white matter tracts experiencing shear-strain forces during acceleration/deceleration of the head (Fig. 6). Arterial hypotension may aggravate the clinical expression of cerebral edema. Episodic hypotension is a common occurrence in the head-injured patient, exacerbated by hypovolemia and the cardiodepressant effect of sedative medications. When autoregulation is preserved, arterial blood pressure may have a significant effect on ICP levels. As CPP decreases with arterial hypotension, compensatory cerebral vasodilation leads to increased cerebral blood volume and thereby raises ICP. Conversely, therapeutic maintenance of CPP encourages vasoconstriction with subsequent reduction in ICP. These changes in cerebral blood volume influence the severity of edema through modulation of the overall water content of brain tissue. Although the degree of edema has not been directly correlated with outcome, ICP elevations illustrate the ability to predict poor clinical outcome. Raised ICP attributed to cerebral edema is the most frequent cause of death in TBI. The effects of herniation due to a traumatic epidural hematoma and diffuse axonal injury are demonstrated in Fig. 7. The pathogenesis of cerebral edema in the immature brain stands is the subject of much controversy in attempts to address the relatively higher frequency and severity of edema in pediatric head-injury patients. Sustained posttraumatic cerebral hypoperfusion and a greater susceptibility to excitoxic injury have been suggested as alleged factors in this process.

C. Neoplastic Disease

The detrimental effects of cerebral edema considerably influence the morbidity and mortality associated with brain tumors. Cerebral edema commonly occurs with brain tumors and frequently hampers the postoperative course of patients undergoing resection. Postoperative edema may worsen after partial resection, climaxing 36–72 hr later. This exacerbation results

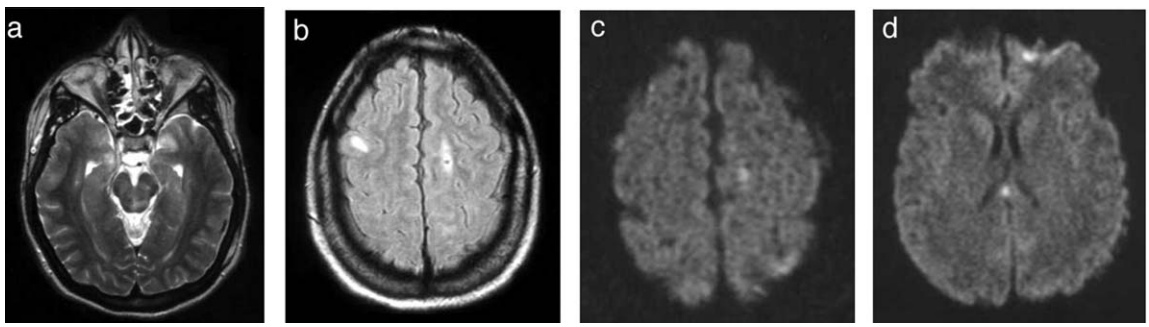

Figure 6 Diffuse axonal injury associated with acute TBI demonstrated by MRI. Hyperintensity of (a) the midbrain on T2-weighted sequences, the frontal lobe white matter on (b) FLAIR imaging and (c) DWI, and (d) the corpus callosum on DWI reveal injury to vulnerable sites.

from either hydrostatic pressure changes or a reaction to the distribution of tumor cells and necrotic debris. Chemotherapeutic agents and radiation have also been shown to disrupt the BBB and encourage the formation of edema. The introduction of steroids decreased the operative mortality rate of brain tumors by a factor of 10. Despite frequent references to peritumoral edema, alterations in tissue permeability with fluid accumulation may occur at distances remote from the actual lesion. Tumor-associated edema continues to be a formidable challenge, producing symptoms such as headache and focal neurologic deficits and, occasionally, considerably altering the clinical outcome. The predominant form of tumor-associated edema is vasogenic, although cytotoxic edema may occur through secondary mechanisms, such as tumor compression of the local microcirculation or tissue shifts with herniation. Individuals with hydrocephalus can also develop hydrocephalic edema because of ventricular outflow obstruction. Histologic studies of tumor-associated edema reveal pallor of astrocytes, with swollen and vacuolated myelin sheaths within white matter tracts, whereas gray matter is affected to a lesser degree. Ultrastructural studies indicate that tumor microvessels that significantly differ from normals suggest a possible explanation for the formation of vasogenic edema. Endothelial cells are plump and contain an increased proportion of microvilli, a higher density of pinocytic vesicles, and no tight junctions. Tumor cells and their secretory products alter vascular permeability and induce angiogenesis, the formation of new capillary blood vessels. This complex cascade of events involving biochemical and morphological alterations is guided by the interaction of numerous factors, including fibroblast growth factor, angiogenin, TNF-α, transforming growth factors-α and -β, platelet-derived endothelial growth factor, interleukin-8, and VEGF/VPF. VEGF/VPF interacts with a receptor that is amplified in tumor vessels to cause transient increases in vascular permeability. Immunologic mechanisms may cause cellular injury, thereby modifying microvascular permeability. Inflammatory processes act by macrophage and polymorphonuclear leukocyte release of specific proteolytic enzymes, specialized granules, and PAFs. Superoxide anion radicals and products of the arachidonic acid cascade, including prostaglandins, thromboxane, and leukotrienes, further increase the vascular permeability underlying the vasogenic component of tumor-associated edema. The degree of tumor-associated edema varies with the pathology of brain tumors. Metastatic lesions, most gliomas, and meningiomas cause extensive edema, whereas oligodendrogliomas cause less tumor-associated edema. Diffuse edema associated with glioblastoma multiforme is demonstrated in Fig. 8.

D. Hydrocephalus

Isolated hydrocephalic edema may result from acute obstructive hydrocephalus with impairment of CSF drainage. Transependymal pressure gradients result in edema within periventricular white matter tracts. The rapid disappearance of myelin lipids under pressure causes the periventricular white matter to decrease in volume. The clinical manifestations may be minor, unless progression to chronic hydrocephalus becomes apparent with symptoms including dementia and gait abnormalities.

E. Infections

A combination of vasogenic and cytotoxic edema arises from many infectious processes within the central nervous system. Other forms of edema may also occur in infections, including hydrocephalic edema secondary to CSF obstruction and osmotic

Figure 8 Axial section of a gross brain specimen revealing diffuse edema surrounding the necrotic core of a glioblastoma multiforme. (Courtesy of Harry V. Vinters, M.D.)

edema due to SIADH. Numerous infectious agents have direct toxic effects generating vasogenic edema through alteration of the BBB and cytotoxic edema from endotoxin-mediated cellular injury. Bacterial wall products stimulate the release of various endothelial factors, resulting in excessive vascular permeability. This injurious effect is augmented by a hyperemic response within the first 24–48 hr that elevates ICP to precarious levels. Associated immunologic and inflammatory responses can also engender cerebral edema. Cerebral edema is a critical determinant of morbidity and mortality in pediatric meningitis. Abscess formation or focal invasion of the brain results in an isolated site of infection surrounded by a perimeter of edema encroaching on the neighboring parenchyma. This ring of vasogenic and cytotoxic edema may produce more symptoms than the actual focus of infection. Similar regions of focal or diffuse edema may accompany encephalitis, particularly viral infections such as herpes simplex encephalitis.

F. Hypertensive Encephalopathy

Hypertensive encephalopathy is a neurologic emergency characterized by exceedingly elevated blood pressures with the subsequent development of focal cerebral edema. This potentially reversible condition presents with rapidly progressive neurological signs, headache, seizures, altered mental status, and visual disturbances. The clinical and neuroradiologic presentation of hypertensive encephalopathy shares similarity with the reversible posterior leukoencephalopathy syndrome, a clinical entity that encompasses multiple disorders with a common predisposition for the development of focal cerebral edema. The pathogenesis of edema formation is controversial but is thought to involve elevated hydrostatic forces due to excessive blood pressure, with lesser degrees of involvement attributed to vasogenic edema and secondary ischemic components. The contributions of autoregulatory dysfunction and BBB leakage compared to hydrostatic causes of plasma extravasation continue to be controversial. The rate of blood pressure elevation is a critical factor, because hypertensive encephalopathy usually develops during acute exacerbations of hypertension. Chronic hypertension has induced adaptive modifications of cerebral resistance vessels, thereby minimizing the harmful effects of elevated hydrostatic forces. Early recognition and treatment of hypertensive encephalopathy may reverse cerebral edema, preventing permanent damage to the BBB, and ischemia, although severe cases may be fatal.

G. Seizures

Recent advances in neuroimaging have yielded additional information regarding the development of cerebral edema associated with seizures. Although cerebral edema is unlikely to be clinically manifest following most seizure activity, additional pathophysiologic insight has been gleaned from recent reports of magnetic resonance imaging (MRI) in status epilepticus (Fig. 9). Prolonged seizure activity may lead to neuronal energy depletion with eventual failure of the Na^+/K^+ ATPase pump and concomitant development of cytotoxic or ischemic edema. Unlike ischemia produced by occlusion of a cerebral artery, a more heterogeneous cellular population is affected. The reactive hyperemic response driven by excessive metabolic demands increases the hydrostatic forces across a BBB already damaged by the vasogenic component of ischemic edema. The disruption of normal ionic

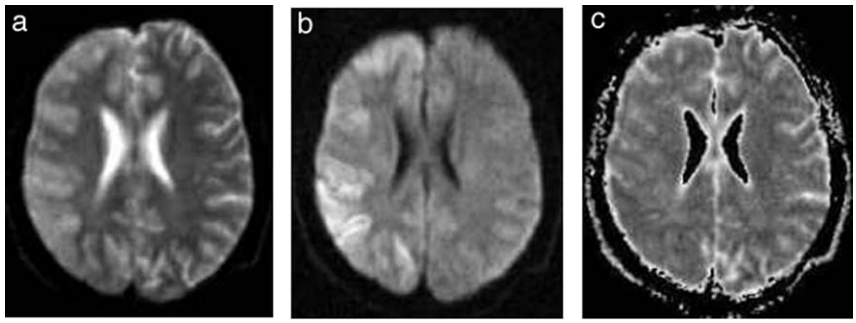

Figure 9 MRI of status epilepticus reveals evidence of cytotoxic edema within cortical structures, illustrated by (a) T2-weighted and (b) DWI hyperintensity, with (c) mild hypointensity on ADC maps.

gradients, extracellular accumulation of excitotoxic factors, and lactic acidosis further exacerbate vasogenic edema. Consequently, cessation of seizure activity usually results in the complete resolution of cerebral edema.

H. Hyponatremia and Hypernatremia

Altered osmotic homeostasis commonly results from hyponatremia and hypernatremia. Osmotic cerebral edema relates to hypoosmolar states such as hyponatremia and the resolution phase of hyperosmolar conditions, including hypernatremia. Hyponatremia may present with alterations in mental status with obtundation and seizures, although there appears to be wide individual variability in adaptation to hyponatremic states. The relative hyperosmolarity of brain parenchyma encourages osmotic edema formation. Dehydration or excessive sodium lead to the compensatory generation of idiogenic osmoles in the brain to maintain cellular volume. Clinical symptoms of hypernatremia include mental status changes with irritability, restlessness, muscle twitching, hyperreflexia, and seizures. During recovery from hypernatremia, the slower dissipation of idiogenic osmoles leads to excessive water shifts into the brain parenchyma. During hyponatremia and the resolution stage of hypernatremia, the rate at which osmotic homeostasis is restored is a critical determinant of clinical sequelae.

I. Dialysis Disequilibrium

The abrupt onset of neurologic symptoms following hemodialysis has been attributed to cerebral edema. Although much speculation focuses on differential fluid shifts related to a rapid decrease in blood urea nitrogen, the specific cause of this osmotic edema remains controversial. A reverse urea effect theorizes that the BBB prevents urea concentrations in the brain from decreasing with serum levels during and immediately following dialysis. A relative hyperosmolar state within the brain encourages the formation of osmotic edema. This fluid shift depends on the rate of dialysis and may be reversed by increasing serum osmolarity. The reverse urea effect hypothesis has been disputed and recent attention has focused on the role of idiogenic osmoles, which has been suggested because urea levels do not fully explain changes in CSF and serum osmolarity measurements. The generation of these organic acids as a protective mechanism against dehydration has been speculated to account for postdialysis decreases in intracellular pH. The clinical manifestations are usually transient and may be avoided or minimized by employing slower rates of solute removal, increasing plasma osmolarity with mannitol, or modifying dialysis solutions.

J. Diabetic Ketoacidosis

Diabetic ketoacidosis may be complicated by rapid neurologic deterioration with severe brain injury due to osmotic cerebral edema. Hyperglycemia produces serum hyperosmolarity with the generation of idiogenic osmoles within brain cells in an effort to prevent cell shrinkage. During the treatment of diabetic ketoacidosis, rehydration with hypotonic solution and administration of insulin result in dramatic fluctuations in osmotic gradients. The osmoprotective molecules within brain cells result in the rapid accumulation of water with cellular volume expansion. The duration of diabetic ketoacidosis may influence

the degree of idiogenic osmole formation. Unfortunately, the consequences of cerebral edema in this setting may be severe with a high mortality rate. Poor outcomes may be avoided by conservative treatment of hypovolemia employing isotonic solution, gradual reduction in serum glucose, and maintenance of normal serum sodium concentrations adjusted for hyperglycemia.

K. Fulminant Hepatic Failure

Intracranial hypertension secondary to cerebral edema frequently complicates the course of patients with fulminant hepatic failure. The devastating effects of cerebral edema contribute to the high mortality of this condition, with cerebral edema noted in 50–80% of cases at autopsy. Although the progressive obtundation of fulminant hepatic failure may be confused with hepatic encephalopathy, important differences exist. The rapid demise associated with fulminant hepatic failure results from a combination of cytotoxic and vasogenic edema (Fig. 10), whereas edema is not seen in cirrhotic patients dying in hepatic coma. The pathogenesis of cerebral edema formation in fulminant hepatic failure has been attributed to the detrimental effects of ammonia. Due to an incomplete urea cycle in the brain, astrocytes detoxify ammonia to glutamine. Excessive production of glutamine leads to excitotoxic neuronal damage and astrocytic swelling, although osmotic compensation occurs in chronic liver disease. This cytotoxic process is aggravated by an influx of water resulting from a combination of augmented cerebral blood flow and disturbed autoregulation. Additional toxic injury is incurred by circulating endotoxins and cytokines, with excessive production of nitric oxide. The necrotic liver releases vasoactive substances producing dramatic cardiovascular instability. These fluctuations in cardiovascular function can complicate surgical transplantation, but autonomic stability is restored following removal of the diseased liver.

L. Toxic Encephalopathy

Although a wide spectrum of substances have toxic effects that can ultimately result in cerebral edema, a direct causal relationship has been established for only a few toxins of clinical significance. Children and adolescents appear to be particularly vulnerable to these toxic exposures. Adolescents ingesting large doses of vitamin A may develop pseudotumor cerebri and visual loss. Organic tin compounds used for the treatment of furunculosis and the use of hexachlorophene as a disinfectant may precipitate cytotoxic edema. Acute intoxication with aluminum, copper, or zinc may mimic dialysis disequilibrium. The majority of substances have been associated with cytotoxic edema, although lead encephalopathy is characterized by diffuse vasogenic edema. Lead encephalopathy causes diffuse vascular injury followed by extravasation of protein-rich fluid into the extracellular space. These changes correlate with the diffuse enhancement noted on contrast computed tomography (CT).

M. Reye's Syndrome

Reye's syndrome manifests with the development of lethargy, irritability, and progressive obtundation in children and young adults following viral infections. The neurologic symptoms have been attributed to diffuse cytotoxic edema documented at autopsy. The

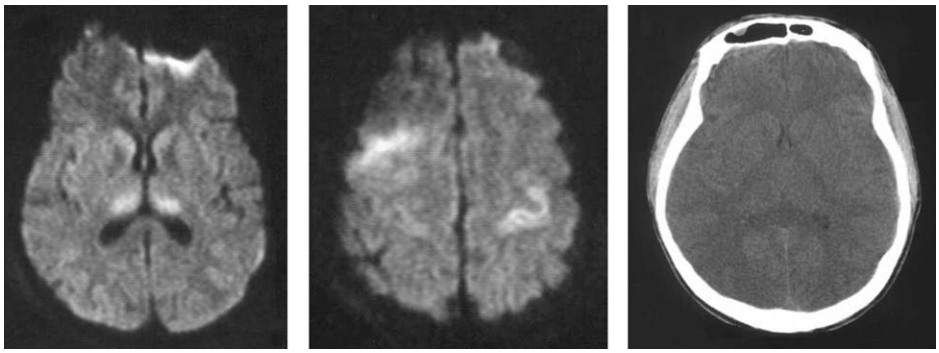

Figure 10 Cytotoxic edema of fulminant hepatic failure illustrated by DWI hyperintensity in (a) bilateral thalami and (b) bilateral frontal cortices. Diffuse vasogenic edema is demonstrated (c) by CT 3 days later.

pathogenesis of this syndrome revolves around the associated hepatic impairment. Toxic effects related to fatty infiltration of the liver and elevated serum ammonia are suspect. Aspirin therapy for fever due to influenza and other viral infections are also implicated as precipitating factors, although the underlying pathophysiology is uncertain.

N. High-Altitude Cerebral Edema

An uncommon presentation of vasogenic edema occurs at high altitudes. Acute mountain sickness and high-altitude cerebral edema (HACE) encompass a spectrum of changes initiated by hypoxia associated with acclimatization. The symptoms of headache, gastrointestinal disturbance, dizziness, fatigue, and insomnia occasionally progress to obtundation and death. The pathophysiology of this potentially reversible form of vasogenic edema is highly complex. Upon arrival at higher altitudes, compensatory elevation of cerebral blood flow with vasodilation gradually decreases over 2 or 3 days in response to increasing arterial oxygen saturation. The hypoxic stimulus also activates angiogenic factors, including VEGF and nitric oxide, leading to increased vascular permeability. The reversible vasogenic edema of white matter structures can evolve to include secondary cytotoxic edema resulting from ischemia. The administration of oxygen and osmotic diuresis may help to decrease the severity of the vasogenic edema, although it may take days for resolution of severe HACE.

O. Hyperthermia

The pathophysiology of this rare cause of cerebral edema is poorly understood. Although the fatal consequences of heat stroke have been recognized since ancient times, the underlying mechanisms await clarification. Scant pathologic material suggests a combination of cytotoxic and vasogenic components, secondary to an increase in BBB permeability due to the release of multiple chemical factors and direct cytotoxic damage. Age and physiologic state of the individual appear to be important determinants of clinical outcome in hyperthermic injury.

III. DIAGNOSIS

Prior to the advent of sophisticated neuroimaging techniques, a precise diagnosis of cerebral edema relied on the histopathologic examination of brain tissue by biopsy or at autopsy. Figure 11 illustrates the gross appearance of diffuse cerebral edema noted at autopsy. Although a demonstration of increased parenchymal water content confirmed the presence of cerebral edema, the underlying pathogenesis was largely obscured by the ultimate changes prior to tissue sampling. The invasive nature of brain biopsy limited the study of the dynamic aspects of cerebral edema. Even the inferential evidence derived from detailed neuroradiographic studies including cerebral angiography and ventriculography demanded an invasive procedure. Radionucleide scanning introduced a diagnostic tool for the demonstration of vasogenic edema of various etiologies. The development of CT further refined the delineation of cerebral edema. Unfortunately, the characteristic CT hypodensity of edematous brain parenchyma may be similar to the appearance of chronic infarction and lipid-containing

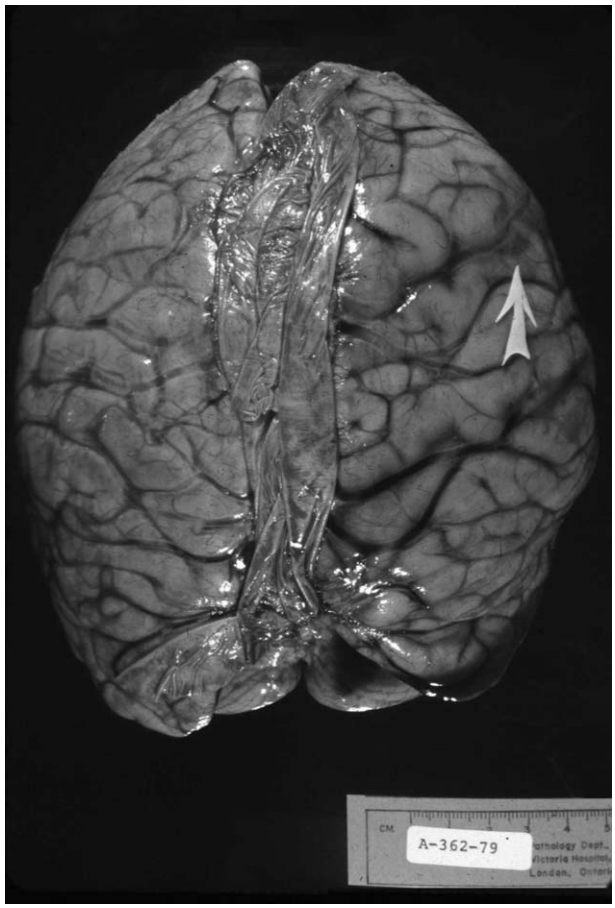

Figure 11 Diffuse cerebral edema with swollen gyri and focal cortical contusion (arrow) noted at autopsy. (Courtesy of Harry V. Vinters, M.D.)

structures. The introduction of MRI revolutionized the understanding of cerebral edema, allowing for the serial study of dynamic pathophysiologic changes associated with various types of edema. Current diagnostic approaches are based on measures that assess ICP, CT, and advanced MRI techniques when available.

A. Intracranial Pressure Monitoring

ICP elevation can infer the presence of cerebral edema. Symptoms of elevated ICP include headache, nausea, vomiting, and altered level of consciousness, which may be superimposed on focal neurologic deficits. When ICP reaches a critical threshold, herniation syndromes may ensue. The initial presentation of this clinical scenario demands an emergent CT scan of the head to identify the underlying process and assess the degree of parenchymal injury. Although neuroimaging methods routinely diagnose the presence of cerebral edema, ICP monitoring devices may detect the evolution of edema in patients expected to develop this complication. A diagnostic lumbar puncture may be performed safely on most patients whose imaging does not indicate a mass lesion to identify elevations of CSF pressure. ICP monitoring by ventriculostomy can be employed to permit drainage of CSF in hydrocephalic conditions. Continuous ICP monitoring is also possible with subarachnoid bolts, fiberoptic catheters, and subdural and epidural devices. These instruments may reflect focal pressure fluctuations and thus may not correlate with global changes in ICP. The utility of additional diagnostic measures such as electro encephalograph, transcranial Doppler ultrasonography, and somatosensory-evoked potential monitoring currently remains under investigation.

B. Computed Tomography

In contrast to the indirect diagnostic information provided by ICP measurements, CT technology may noninvasively illustrate the volumetric changes and alterations in parenchymal density resulting from cerebral edema. Expansion of brain tissue due to most forms of edema may be detected on CT, although diffuse processes including fulminant hepatic failure or osmotic edema may be more difficult to discern. Diffuse swelling may be recognized by a decrease in ventricular size with compression or obliteration of the cisterns and cerebral sulci. Cellular swelling associated with cytotoxic and ischemic edema can manifest as subtle enlargement of tissue with obscuration of normal anatomic features, such as the differentiation between gray matter and white matter tracts. Vasogenic edema may also cause tissue expansion, although the associated density changes may be more prominent. In contrast to the increased volume of brain tissue noted in most forms of edema, hydrocephalic edema may be suspected in cases in which ventricular expansion has occurred. Extensive volumetric changes and the associated pressure differentials resulting in herniation may be noted on CT as shifts in the location of various anatomic landmarks.

The increased water content associated with edema causes the density of brain parenchyma to decrease on CT. The attenuation effects of other tissue contents complicate precise correlation of water content with density on CT. Although slight decrements in tissue density result from cytotoxic and osmotic processes, more conspicuous areas of hypodensity result from the influx of fluid associated with disruption of the BBB in vasogenic edema. The injection of a contrast agent permits enhanced visualization of vascular structures and thereby further defines regions of extravasation where the BBB has been altered. Contrast CT improves the demonstration of infectious lesions and tumors that present with significant degrees of vasogenic edema.

The differentiation of specific forms of edema is limited with CT, but this modality may provide sufficient information to guide therapeutic decisions in many situations. CT perfusion, a new dynamic imaging study, allows for the determination of cerebral blood volume based on serial density changes associated with a contrast bolus injection. CT may be inferior to MRI in the characterization of cerebral edema, but logistic constraints may preclude MRI in unstable trauma patients, uncooperative patients, and patients with contraindications due to the presence of metallic implants or pacemakers.

C. Magnetic Resonance Imaging

Volumetric enlargement of brain tissue due to edema is readily apparent on MRI and the use of gadolinium, an MRI contrast agent, enhances regions of altered BBB. Differences in water content may be detected on MRI by variations in the magnetic field generated primarily by hydrogen ions. T2-weighted sequences

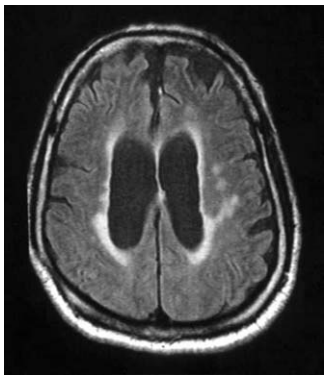

Figure 12 Periventricular FLAIR hyperintensity due to hydrocephalic edema.

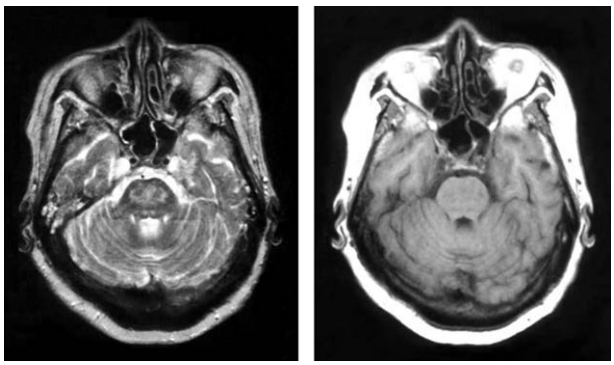

Figure 13 Central pontine myelinolysis illustrated as (a) T2-weighted hyperintensity and (b) T1-weighted hypointensity in the pons.

and fluid-attenuated inversion recovery (FLAIR) images reveal hyperintensity in regions of increased water content. Reversible T2 hyperintensities of the white matter may be seen in HACE and hypertensive encephalopathy. FLAIR images eliminate the bright signal from CSF spaces and are therefore helpful in characterizing periventricular findings such as hydrocephalic edema (Fig. 12). These conventional MRI sequences are more sensitive in the detection of lesions corresponding to hypodensities on CT. MRI is also superior in the characterization of structures in the posterior fossa (Fig. 13). Recent advances in MRI technology make it possible to specifically discern the type of edema based on signal characteristics of a sampled tissue volume. This discriminatory capability resulted from the development of diffusion imaging techniques. The use of strong magnetic field gradients increases the sensitivity of the MR signal to the random, translational motion of water protons within a given volume element or voxel. Cytotoxic edema and cellular swelling produce a net decrease in the diffusion of water molecules due to the restriction of movement, imposed by intracellular structures such as membranes and macromolecules, and diminished diffusion within the extracellular space due to shrinkage and tortuosity. In contrast, the accumulation of water within the extracellular space as the result of vasogenic edema allows for increased diffusion. Diffusion-weighted imaging (DWI) sequences yield maps of the brain, with regions of restricted diffusion appearing bright or hyperintense. The cytotoxic component of ischemic edema has been demonstrated on DWI within minutes of ischemia onset. DWI has also been used to grade the severity of TBI, because cytotoxic injury is thought to accompany severe trauma. Apparent diffusion coefficient (ADC) maps may be generated from a series of DWI images acquired with varying magnetic field gradients. ADC elevations, resulting from vasogenic edema, appear hyperintense on ADC maps, whereas decreases in ADC due to cytotoxic edema appear hypointense (Fig. 14). These maps may be sampled to measure the ADC of a given voxel for multiple purposes, such as differentiating tumor from tumor-associated edema. The vector of water diffusion in

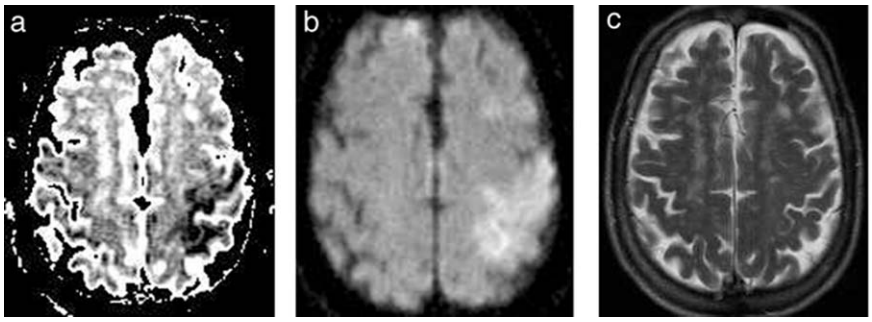

Figure 14 The cytotoxic component of acute cerebral ischemia is demonstrated by ADC hypointensity (a). The ischemic region appears hyperintense on DWI (b), whereas T2-weighted sequences may be unrevealing at this early stage (c).

each of three orthogonal planes also helps to differentiate types of edema. Isotropic diffusion refers to relatively equivalent vectors in all three planes, whereas anisotropic diffusion exists when these effects are disproportionate. Vasogenic and interstitial edema produce anisotropic diffusion patterns. In contrast, cytotoxic edema is less anisotropic. Anisotropic measurements may therefore be helpful in the characterization of cerebral edema.

The recent development of perfusion-weighted imaging (PWI) with MR technology provides parametric maps of several hemodynamic variables, including cerebral blood volume. Elevations in cerebral blood volume associated with cerebral edema are detectable by this technique.

Simultaneous acquisition of multiple MRI sequences enables the clinician to distinguish various forms of cerebral edema. T2-weighted sequences and FLAIR images permit sensitive detection of local increases in water content. Gadolinium-enhanced T1-weighted sequences reveal sites of BBB leakage that may be present surrounding tumors (Fig. 15) or abscesses. DWI localizes abnormal areas of water diffusion, with ADC maps differentiating various forms of edema. PWI can detect regional elevation of cerebral blood volume. The composite interpretation of these studies has revolutionized the diagnosis of cerebral edema. These images often reflect the combined effects of multiple types of edema. For instance, the cytotoxic component of ischemic edema will cause a reduction in the ADC, whereas the vasogenic component will counter this trend. A pseudo-normalization of the ADC may result from these opposing influences. Serial imaging with this noninvasive modality also allows for the temporal characterization of edema evolution. The relative contributions of cytotoxic and vasogenic edema with respect to the ADC during acute ischemic stroke and TBI have been investigated in this manner. The main limitations of this technology logistically relate to cost, availability, contraindications, and its restricted use in critically ill individuals.

IV. TREATMENT

The treatment of cerebral edema should be implemented once the primary disease process has been addressed and the degree of edema warrants intervention. Treatment is usually warranted when the edema is severe and attributable clinical signs and symptoms exceed the manifestations of the primary injury. Because a combination of edema types are usually involved, generalized approaches are often focused on decreasing ICP. Several strategies have been shown to be successful in reducing ICP, although their efficacy varies with the underlying disease, but detrimental effects may also result. The treatment of cerebral edema should therefore consider the primary etiology, the predominant type of edema, and the temporal evolution of the underlying pathophysiologic processes. The following sections summarize the principal therapies for cerebral edema and briefly highlight interventions that focus on specific aspects elucidated from continued research efforts.

A. Head Elevation

Elevation of the head minimizes the contributory effects of increased cerebrovascular venous pressure and outflow resistance. Compression of neck veins can

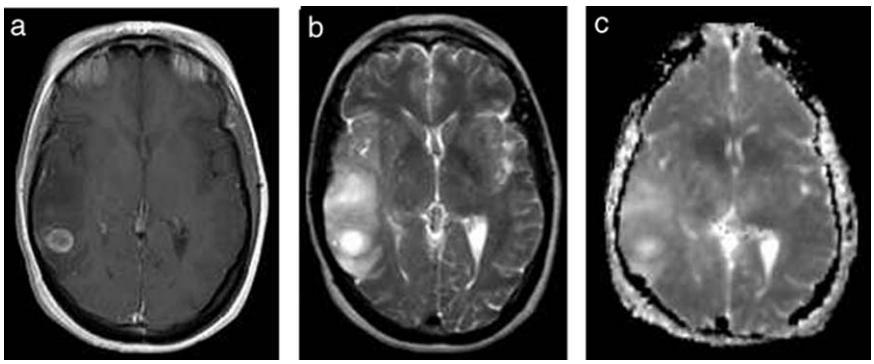

Figure 15 Disruption of the BBB in vasogenic edema associated with a glioma appears hyperintense on gadolinium-enhanced MRI (a). Peritumoral vasogenic edema is demonstrated by hyperintensity on T2-weighted sequences (b) and ADC maps (c).

be avoided by keeping the head in midline position. Prevention of increased intracranial venous pressure may be achieved if the head of the bed is placed at an angle of 30°, although greater angles may theoretically compromise CPP.

B. Diuretics

Rapid and dramatic reductions of most forms of cerebral edema may be accomplished with the use of osmotic diuresis. Osmotic diuretics elevate intravascular osmolarity, minimizing or reversing the osmotic pressure gradients that may participate in cerebral edema formation. Considerable integrity of the BBB is required because extravasation of osmotic agents across this interface may diminish their beneficial effect and potentially cause unintended fluid flux into the brain. Mannitol may also increase cerebral blood flow by reducing blood viscosity, leading to vasoconstriction and a resultant reduction in ICP. Other potentially effective osmotic diuretic agents include urea, glycerol, and hypertonic glucose or saline. However, excessive urea enters cells and causes an unwanted rebound increase in ICP. Chronic or excessive hyperosmolar states may precipitate renal injury. Loop diuretics including furosemide may also be beneficial, although hypovolemia may worsen neurologic outcome. Acetazolamide lowers ICP by decreasing production of CSF. Chronic use of acetazolamide is not recommended because this therapy may result in systemic acidosis.

C. Hyperventilation

Hyperventilation induces rapid, transient reductions in ICP because substantial decreases in pCO_2 cause vasoconstriction and decreased cerebral blood flow. Autoregulatory capability is required for this response. This measure is effective in many forms of edema, although there is a theoretical risk of causing injury due to hypoxia associated with excessively diminished cerebral blood flow. A target pCO_2 of 25–30 mm Hg is recommended when hyperventilation is employed.

D. Cerebrospinal Fluid Drainage

ICP may be diminished by drainage of CSF through a ventricular catheter. Although this reduction in ICP may be beneficial in many forms of cerebral edema, it is particularly effective in the treatment of hydrocephalic edema. Clinicians utilize this intervention when preliminary measures such as osmotherapy have failed. The presence of small ventricles may impair drainage due to the collapse of the ventricular walls around the catheter tip. Lumbar puncture for CSF drainage is not recommended because resulting pressure gradients may precipitate herniation syndromes.

E. Blood Pressure Modification

Alteration of hydrostatic forces in the cerebral circulation is possible through titration of systemic arterial pressure. Reductions of systemic arterial pressure with antihypertensive agents decrease pressure gradients that may precipitate or exacerbate hydrostatic, vasogenic, and ischemic edema. This concept forms the basis for the treatment of hypertensive encephalopathy and related conditions. Although hydrostatic gradients do not mediate the initial changes in vasogenic edema, these forces may encourage extravasation across a damaged BBB. This effect may contribute to the pathogenesis of reperfusion injury following lysis of an arterial occlusion or surgical repair of a hemodynamically significant arterial stenosis. The presence of ischemia limits blood pressure reduction because decreased CPP may precipitate further ischemic injury.

F. Corticosteroids

The use of high-dose glucocorticoids has been shown to produce dramatic reductions in cerebral edema in certain conditions. These agents may stabilize and accelerate repair of the BBB, reduce capillary permeability, improve brain availability of glucose, and alter production of chemical mediators that lead to cerebral edema. Glucocorticoids may also decrease production of CSF, thereby reducing ICP. These agents are particularly effective in edema resulting from tumors and meningitis. Most clinical studies have failed to demonstrate a benefit of glucocorticoids in the setting of TBI. The use of high-dose glucocorticoids may have detrimental effects when used to treat ischemic edema.

G. Barbiturates

Barbiturates reduce the metabolic demands of the brain and cause vasoconstriction in the cerebral

circulation. Preliminary studies suggest that these drugs may effectively lower ICP. Nonetheless, the alleged benefits in clinical outcome have not been demonstrated in studies of TBI and cardiac arrest.

H. Surgical Interventions

The presence of an intracranial mass lesion may require urgent neurosurgical attention. Surgical excision of an edematous lesion or increasing the size of the cranium via hemicraniectomy may reduce further formation of vasogenic edema and eliminate compression of normal brain parenchyma. Rebound edema formation may complicate the perioperative course. Careful control of ventilation and systemic arterial pressure, as well as preoperative administration of glucocorticoids, may minimize the detrimental effects of this complication.

I. Hypothermia

The induction of hypothermia may be an effective treatment for cerebral edema due to vasoconstriction of the cerebral vessels, a reduction in metabolic demands of the brain, and decreased production of CSF. However, the degree of hypothermia may be difficult to control and systemic complications resulting from cardiac arrhythmias, fluid shifts, and increased susceptibility to infection restrict the use of this treatment.

J. Nonsteroidal Antiinflammatory Drugs

Nonsteroidal antiinflammatory drugs (NSAIDs), including ibuprofen and indomethacin, interfere with the production of prostaglandins and have been shown to decrease extravasation in animal models of cerebral edema. Other mechanisms include modulation of endothelial permeability in tumor vessels and peritumoral regions. Clinical studies of NSAIDs for reduction of cerebral edema have been conducted in TBI and tumor-associated edema. These substances may be useful in individuals with tumor-associated edema who are intolerant to steroids or dependent on chronic steroid use.

K. Hyperbaric Oxygen

Increasing inspired pO_2 by administration of hyperbaric oxygen causes vasoconstriction with reduction of cerebral blood flow, cerebral blood volume, and, consequently, ICP. This therapeutic intervention is frequently used in the setting of HACE to diminish the hypoxic stimulus in the formation of cerebral edema.

L. Other Neuroprotective Agents

Many of the previously mentioned interventions have theoretical neuroprotective effects that reduce cytotoxic injury in the formation of cerebral edema. Other potential neuroprotective substances include inhibitors of excitotoxic amino acids, bradykinin release, leukocyte adhesion, and metalloproteinases, modulators of calcium influx, promoters of membrane repair, and free radical scavengers. Preliminary experimental studies of several agents are encouraging, although their efficacy has yet to be demonstrated in clinical trials.

V. CONCLUSIONS

The catastrophic consequences that may result from cerebral edema have provided a perpetual impetus for research in the pathophysiology of this clinical entity. Elucidation of the underlying mechanisms allows for the classification of several forms of cerebral edema. The evolving knowledge of this combined entity emphasizes the critical role of water homeostasis in human physiology and its interaction with the complex biochemical alterations that underlie many neurologic diseases. Noninvasive neuroimaging techniques have revolutionized the identification of specific edema types, but these findings often do not correlate with clinical symptomatology. Therapy is usually reserved for secondary elevations in ICP, at a stage when the consequences prove life threatening and multiple edema types are present. Further diagnostic research efforts may provide early detection and detailed characterization of cerebral edema. This information allows the development of rational therapeutic interventions targeting biochemical factors that are specific to disease-state and temporal patterns. A combination of such interventions that modulate multiple aspects of cerebral edema may prove most efficacious.

Cerebral Palsy

STEPHANIE WATKINS and ANGELA ROSENBERG
University of North Carolina, Chapel Hill

GLOSSARY

ambulation The act of walking.

Apgar Quantitative assessment of a newborn's medical status after birth.

asphyxia A life-threatening condition in which oxygen is prevented from reaching the tissues due to an obstruction within the respiratory system.

contracture Fibrosis of the muscle tissue with subsequent muscular shortening.

decubitus ulcer Ulceration of the skin due to continuous pressure on one area of the body.

dysarthria The inability to pronunciate words in a clear manner.

dyskinesia Involuntary movements that appear as fragments of normally controlled smooth facial and limb movements.

gait The manner in which an individual walks.

intrathecal Within the meninges of the spinal cord.

meconium The first stool of a newborn infant; may indicate fetal distress if observed in the amniotic fluid.

scoliosis Deviation of the spine that may be congenital or acquired due to abnormalities of the vertebrae, muscles, or nerves.

subarachnoid space The space between the pia and the arachnoid meninges of the spinal cord and brain.

subluxation The partial dislocation of a joint

tone The normal state of partial contraction of a resting muscle.

Cerebral palsy is a disorder of posture and movement that is nonprogressive in nature. The disorder may be viewed as an artificial or umbrella term encompassing a group of symptoms occurring secondary to an insult to the immature brain. This insult may occur pre-, peri-, or postnatally. Sequelae include impairments in the control of selective movement, abnormalities in muscle tone, and impaired activation between agonist/antagonist musculature. Impairments in speech, vision, hearing, cognition, and seizure disorder are also frequently associated with this disorder.

I. EPIDEMIOLOGY

Since the 1950s, the prevalence of cerebral palsy (CP) has fluctuated. During the early 1950s, the prevalence of CP was reported to be between 2 and 2.5 per 1000 live births. A 1996 analysis of the periods between 1954–1958 and 1967–1970 reported the prevalence of CP decreased 40% with concurrent improvements in access to obstetrical and pediatric care as reported by Hagberg and Hagberg. During the period from 1970 to 1982, the prevalence once again increased to the rate of the 1950s. Apparent advancements in medical technology, allowing infants to survive at a lower

gestational age and weight, accounted for this rebound in prevalence of reported cases.

In recent years, the prevalence of CP among live births in developed countries has continued to increase, with the exception of normal birth weight infants, for whom prevalence rates have remained stable. Overall, prevalence rates between 1.06 and 2.5 per 1000 children have been reported. This increase in the existing number of cases has been attributed to increased survival rates of preterm, low-birth-weight infants. A 1996 study by Suzuki *et al.* reported an increase in prevalance of 9-fold among low-birth-weight infants (1500–2499 g) and an increase of 41-fold among very low-birth-weight infants (<1500 g). In 1996, Pharoah *et al.* reported an increase in prevalence of CP among infants weighing less than 1000 g with low-birth-weight babies (<2499 g) accounting for 50% of CP cases. Additionally, perinatal mortality appears to be on the decline, with surviving babies having a higher risk for cerebral damage.

II. ETIOLOGY

In 1862, William John Little, an orthopedic surgeon, was the first to address and hypothesize on the etiology of CP. Little described developmental motor abnormalities in children as "spastic rigidity." He hypothesized that prolonged premature labor, breech delivery, or birth asphyxia were the causes of cerebral damage resulting in impairments in posture and movement. However, since the 1860s, discussion has continued regarding the exact cause of CP because the clinical manifestations of the disorder consistently result in few homogeneous patterns of symptoms.

Today, multiple risk factors contributing to the diagnosis of CP have been identified. However, in most cases, the underlying mechanism remains unknown. Researchers have not been able to link the exact timing of risk factors to resultant lesions in the developing brain. Two etiologies that do produce homogeneous clinical patterns are maternal iron deficiency and Rh incompatibility. Mothers who suffer from an iron deficiency during pregnancy give birth to children who display spastic diplegia with deaf mutism, and infants born with Rh incompatibility experience choreoathestosis and deafness. However, the majority of risk factors that are identified as contributing to CP do not necessarily lead to the disorder.

Risk factors contributing to the origin of CP have been contemplated for both the term and the preterm infant. Risk factors have been identified prior to conception and in the pre-, peri-, and postnatal stages of development (Table I). For full-term infants, the best predictors of the disorder have been reported as neurological abnormalities at birth, including low Apgar scores, abnormalities in respiration, abnormal reflex responsiveness, and neonatal seizures. In many cases, the cause remains unknown or is attributed to prenatal factors. In 1993, Naulty *et al.* reported that for 60% of term infants with CP there appeared to be no identifiable cause.

Since the time of Little, asphyxia during delivery has received much attention from the scientific community as a core etiological factor. However, recent data suggest that most cases of CP do not result from lack of oxygen due to human error during delivery. In fact, the rate of asphyxia at birth has decreased from 40/100,000 births in 1979 to 11/100,000 births in 1996, whereas the incidence of CP has not declined.

The Collaberative Perinatal Study (CPS) of the National Institute of Neurological and Communication Disorders and Stroke, one of the largest longitudinal studies to date, collected data from 43,437 full-term children to identify fetal, intrapartum, and neonatal events in child development. To date, this is the largest and most complete set of prospective data on the study of CP completed in the United States. In 1989, Naeye and colleagues used these data to report that birth asphyxia alone, not attributed to chronic antenatal hypoxia, as a whole accounted for only 6% of all cases of CP (Table II). According to this study, gas anesthesia during labor, maternal seizures, maternal diabetes mellitus, and neonatal hypoglycemia were not associated with a higher than expected frequency of CP. Moreover, congenital disorders accounted for four times as many cases of quadriplegic CP as did birth asphyxia. Congenital abnormalities accounted for 60% of the cases not of this clinical type.

Based on data collected by the CPS, Nelson and Ellenberg supported these findings, reporting that only 9% of CP cases were caused by birth asphyxia alone. Among those cases for which asphyxia may account, it was noted that oxygen deprivation frequently was not measured directly. Rather, asphyxia was inferred from low Apgar scores and signs of fetal distress that may include abnormal respiration, abnormal fetal heart rate, the presence of meconium, low cord blood pH, seizures, and abnormal reflex responsiveness. When investigated, these signs more often related to congenital disorders rather than asphyxia.

Further studies reported similar findings. Congenital malformations of the central nervous system (CNS)

Table I
Risk Factors Associated with Cerebral Palsy[a]

Prenatal	Perinatal	Postnatal
Developmental problems of the fetus	Abnormal presentation of the fetus[b]	Infections (bacterial,viral, parasitic)
Congenital brain malformation	Infection during delivery (hyperbilirubina, blood incompatibility)	Near drowning
Maternal infection	Premature separation of the placenta	Accidents
Maternal seizures	Birth asphyxia: tight nuchal cord	Toxins
Exposure to radiation	Prolonged labor[c]	Brain Trauma
Prescribed thyroid hormones or estrogen in pregnancy	Maternal anesthesia	Birth Weight $<$2001grams
Genetic abnormalities	Gestational age $<$32 weeks	Neonatal seizures
Nutritional deficits		Bilirubin encephalopathy
Preeclamsia[d]		
Chemical teratogenesis		
Maternal mental retardation		
Maternal hemorrhage		
Multiple births		
Long intervals between menstrual cycles prior to pregnancy		
Short ($<$3 months) or long ($>$3 years) interval between pregnancies		

[a]Adapted from Kuban and Leviton, *N. Engl. J. Med.* **330**(3), 188–195 (1994); Nelson and Ellenberg, *N. Engl. J. Med.* **315**(2), 81–86 (1986); and Dzienkowski *et al.*, *Nurse Practitioner* **21**(2), 45–59 (1996).
[b]Abnormal presentation of the fetus may be an indicator of preexisting difficulty as reported by the *New England Journal of Medicine*.
[c]Nelson and Ellenberg reported prolonged labor was not a significant predictor of CP.
[d]In 1999, Nelson and Grether reported premature infants of preeclampsic mothers were less likely to have CP compared to other causes of prematurity.

and non-CNS were reported by Mettau in 1993 as three times more frequent in children with CP than in the general population. In 1990, Torfs *et al.* supported these findings, reporting that 78% of children diagnosed with CP did not have asphyxia at birth.

Table II
Categories of Risk Factors Associated with CP[a]

Chronic antenatal hypoxia	Nonasphyxial
Maternal anemia	Congenital malformation
Continuation of pregnancy $>$42 weeks	Birth trauma
Preeclampsia	Intoxication
Multiple fetuses	CNS infections
Subnormal maternal blood volume expansion in first trimester	Breech delivery
Decrease in maternal blood pressure in third trimester	

[a]Adapted from Naeye *et al.*, *Am. J. Dis. Child* **143,** 1154–1161 (1999).

Aside from birth asphyxia, several other etiological factors have received attention. One-half of all cases of CP have been attributed to prenatal malformations, prenatal strokes, congenital taxoplasmosis, rubella cytomeglavirus, and herpes infections. Maternal infections have been linked to offspring diagnosed with CP, including those for which women have a fever of more than 30°C during delivery, as well as a diagnosis of chorioamnionitis or congenital rubella. In 1997, Grether and Nelson reported a nine-fold increase in the risk of spastic CP in offspring associated with maternal infection. Genetic factors have also been implicated in a small number of cases. Gustavason and colleagues in the late 1960s reported that one-third to one-half of the cases of congenital ataxic CP with associated mental retardation are genetically predetermined.

The majority of events leading to CP are thought to occur during the perinatal period. With the brain still in a stage of rapid growth at birth, complications such as intracranial hemorrhage and periventricular

leukomalacia (PVL) are often associated with a diagnosis of CP. Low-birth-weight infants are at a greater risk of developing PVL with a subsequent diagnosis of CP. PVL has been associated with low blood pressure and neurochemically mediated injury to the white matter. When compared with intracranial hemorrhage, PVL has been reported to be a more accurate predictor of CP. However, questions remain as to whether the resultant CP is attributable to perinatal/postnatal complications or preexisting pathologic conditions contributing to prematurity and potential injury of the developing brain *in utero*.

Despite improvements in medical technology, the rate of CP has continued to rise. With the asphyxial origin of CP being challenged, the debate continues regarding the factors that contribute to CP as well as the developmental stage (pre-, peri-, or postnatal) in which these factors affect the developing brain.

III. DIAGNOSIS

Many behavioral characteristics are indicative for the early detection and diagnosis of CP (Table III). However, the diagnosis of CP is a complicated one, often determined by physical exam in conjunction with a thorough medical history, neurological exam, and the exclusion of differential diagnoses. Currently, there is no one test to determine a diagnosis of cerebral palsy.

Table III
Behavioral Characteristics Associated with Cerebral Palsy[a]

Less than 6 months	6 months to toddler
High-pitched cry	Instability in sitting
Oral hypersensitivity	Oral hypersensitivity
Lethargy	W-sitting
Irritability	Excessive arching of the back
Abnormal primitive reflexes	Inability to perform age-appropriate motor skills (e.g., sitting by 7 months)
Diminished head control	
Stiff or floppy posturing	
Inability to perform age-appropriate motor skills (e.g., rolling by 4 to 5 months)	

[a]Adapted from Dzienkowski *et al.*, *Nurse Practitioner* **21**(2), 45–59 (1996).

In addition, initially identified motor impairments may change across the child's life span, thus adding to the difficulty of diagnosis. It is presumed that maturation of the basal ganglia and neuronal myelination must occur prior to the emergence of spasticity, dystonia, and athetosis. Therefore, the clinical signs displayed by the child may change over time. In the early 1980s, Nelson and Ellenberg found that 118 of 229 children diagnosed with CP at 1 year were free of motor handicaps by age 7. Caution is therefore advised regarding definitive diagnoses and subsequent prediction of outcomes at a young age.

IV. CLASSIFICATION

Cerebral palsy is a global term that requires a classification system to further define the clinical picture. However, classification is often challenging given that a diagnosis of CP represents a collection of many symptoms in the absence of a standard clinical picture.

The most widely used classification system for this disorder was developed by the American Academy of Pediatrics (AAP). The AAP classifies CP using two scales based on symptoms rather than etiology. The *motor classification* scale characterizes the quality of movement, whereas the *topography scale* describes affected body parts.

Characteristics of movement quality are described as spastic, athetoid, rigid, ataxic, hypotonic, or mixed (Table IV). Lesions in specific regions of the brain have been associated with specific abnormalities of movement. The motor area of the cerebral cortex, including the prefrontal cortex, premotor cortex, and primary motor cortex, is commonly affected. Specifically, involvement of the motor cortex, which projects to and from the cortical sensorimotor areas, is associated with a diagnosis of spastic cerebral palsy. Damage to the basal ganglia results in a diagnosis of dyskinesia or athetosis. The basal ganglia functions to regulate voluntary motor function, thus modulating purposeful movement and suppressing unnecessary motion. Lastly, the cerebellum, functioning to control coordination, timing, and sequencing of movement, is associated with an ataxic movement disorder.

Topographically, the individual is described as having one limb involved (monoplegia), one half of the body involved (hemiplegia), both legs involved (diplegia), or both legs and one arm involved (quadriplegia). Therefore, an individual with

Table IV
Definitions of Motor Characteristics[a]

Characteristic	Definition
Spasticity	Characterized by sudden muscle contractions that are convulsive in nature with persistent rigidity; increased resistance to passive movement that is velocity dependent; diminished threshold for stretch response and clonus; Involvement usually is greater in antigravity muscles
Athetosis	Writhing, uncontrolled movements with poor coordination and midrange control
Rigidity	Resistance to slow-speed passive movement from both the agonist and the antagonist; lead pipe resistance throughout the range of motion; cog wheel discontinuous resistance throughout the range of motion
Ataxia	Poor coordination and timing with voluntary movement; deficits in balance, equilibrium, and depth perception
Hypotonia	decreased ability of the muscle to generate force; diminshed muscle tension at rest; excessive joint mobility

[a]Adapted from Minear (1956). *Pediatrics* **18,** 841–852.

velocity-dependent resistance to passive movement involving the right half of the body would be classified as having right spastic hemiplegic cerebral palsy.

Until recently, a classification system was not in place to provide a functional picture of the individual with cerebral palsy. In 1997, Palisano *et al*. developed the *Gross Motor Function Classification System for Cerebral Palsy* to provide a method to standardize clinical observations of child function. In addition to providing a numerical classification of function, the scale standardizes communication between professionals. Palisano *et al*.'s purpose was to describe discrete levels that represent present motor performance and limitations based on self-initiated movement. The classification system emphasizes sitting and walking and ranges from level 1 to level 5, with distinctions between levels based on functional limitations and the need for an assistive device, assistive technology, and/or mobility aides. The classification system uses the concept of disability as defined by the International Classification of Impairments, Disabilities, and Handicaps (ICIDH) of the World Health Organization and the concept of functional limitation as outlined in the disablement model as described by Nagi. The ICIDH defines disability as "the restriction or lack of ability to perform an activity in the manner or within the range considered normal for a human being" (1980). Nagi defines functional limitation as a "limitation in performance at the level of the whole person" (1965).

V. IMPAIRMENTS AND MANAGEMENT

Treatment of the individual with CP is focused on maximizing functional independence while preventing the occurrence of secondary conditions. Associated primary conditions include abnormalities of posture and movement as well as learning disabilities, seizures, and problems with vision, hearing, and speech. Over time, movement abnormalities often place abnormal stresses on joints, resulting in secondary conditions such as joint contractures and bony deformities. Treatment interventions may include but are not limited to pharmacological therapy, surgery, physical therapy, occupational therapy, and speech therapy.

Movement and postural abnormalities may be divided into musculoskeletal impairments and neuromuscular impairments. Musculoskeletal impairments include loss of joint range of motion, bony abnormalities, and strength deficits that frequently develop over time as sequelae of the initial injury. Neuromuscular impairments include abnormal selective muscle control, inefficient regulation of muscular activity, a decreased ability to learn new movements, and abnormalities in tone.

In individuals without CP, muscles are phased in and out with coactivation of synergistic musculature during an activity. However, in the individual with CP, inappropriate muscular sequencing and coactivation of agonist and antagonist musculature occurs during voluntary movement, according to Naher and colleagues and Knutsson and Martensson. As a result, compensatory movement patterns are often seen with movement initiation. Individuals with hemiplegic CP may initiate walking on the uninvolved side of their body, whereas those with diplegia may use their head, neck, trunk, and arms to facilitate movement. A decreased ability to maintain and anticipate postural adjustments is also a common manifestation of the disorder. Muscular contraction for stability in anticipation of postural changes is often inadequate, creating difficulties with postural control.

Despite the variety of impairments noted previously, much of the emphasis of treatment continues to be placed on the management of spasticity. Although the precise mechanism underlying spasticity remains unknown, it has been established that the stretch reflex is exaggerated due to overactivity of the alpha motor neurons. Cortical impairment is thought to interrupt descending modulating pathways to the lower alpha motor neurons that inhibit the motor unit. This prolonged disinhibition of the alpha motor neuron results in a velocity-dependent increase in the tonic stretch reflex.

Spasticity is frequently associated with CP and often results in limited selective muscle control, improper timing and sequencing of movement, and the inability to move against gravity. Therefore, functional independence is affected, often resulting in an altered ability of the individual to sit, stand, crawl, and walk. However, despite negative sequelea, spasticity may serve a functional purpose in some individuals. It is important to evaluate the contribution of spasticity toward individual function and quality of movement prior to initiating treatment focused on spasticity reduction.

VI. PHARMACOLOGICAL INTERVENTION

A. Oral Medications

In the 1990s, Albright reported that oral medications, including benzodiazepines and skeletal muscle relaxants, had been used with limited success to diminish the effects of spasticity. Diazepam, a benzodiazepine, facilitates the inhibitory response of γ-aminobutyric acid (GABA) neurotransmitters by increasing the conductance of chloride ions upon binding to $GABA_A$ receptors. This results in a presynaptic inhibition at the spinal cord level with resultant relaxation of skeletal muscle. Use of this agent has been associated with adverse effects including sedation and a potential for dependency.

Muscle relaxants used in the treatment of spasticity include dantrolene sodium and baclofen. Dantrolene sodium acts directly on the skeletal muscle by inhibiting the release of calcium from the sarcoplasmic reticulum. The result is an interference with the excitation–contraction coupling and a resultant reduction in contractile force of the muscle. Side effects from dantrolene sodium use include drowsiness and a suggested increase in seizure activity in children with CP.

Baclofen is a skeletal muscle relaxant frequently used in the management of spasticity. It acts throughout the central nervous system and has been shown to be most effective when used to treat spasticity of spinal origin. In spasticity of cerebral origin, spasticity reduction has been reported as mild due to poor lipid solubility of the drug. In actuality, only a small amount of baclofen penetrates the blood–brain barrier, requiring higher doses to achieve an effect. Upon entry, baclofen binds to $GABA_B$ receptors to prevent the uptake of calcium necessary for the release of excitatory neurotransmitters, such as aspartate and glutamate. The effect is a decrease in the release of neurotransmitters in the excitatory pathways resulting in a reduction of muscular spasticity. Compared with dantrolene sodium, baclofen use has fewer side effects, with no associated increase in seizure activity. However, drowsiness is frequently experienced.

B. Non-oral Medication

To avoid the side effects frequently associated with oral dosing, other routes of drug administration have been explored including the use of botulinum toxin A injections and intrathecal baclofen pumps.

Botulim toxin A, a toxin produced by *Clostridium botulinus*, is commonly used to inhibit spasticity associated with CP. It acts at the muscle site and is useful in targeting spasticity in isolated muscle groups. The toxin blocks the presynaptic release of acetylcholine from the motor nerve terminal resulting in chemical denervation of the muscle or paralysis. The toxin has a binding affinity for the neuromuscular junction and is injected directly into the affected muscle belly. The degree of paralysis is dose dependent and reversible. Postadministration, the nerve terminal regenerates, requiring the toxin to be reinjected for continued effects.

One side effect of the injection is transient muscle weakness, but this is minimal due to the small amount of toxin actually entering the systemic circulation. The use of botulinum toxin A has been reviewed regarding its efficacy to improve function. Many studies have found the toxin to be effective in reducing spasticity in the upper and lower extremities, with effects beginning 12–72 hr after injection and lasting 2–4 months. In 1995, Denislic and Meh reported improvements in functional hand movement and foot posture. In 1994, Cosgrove and colleagues reported that the injections resulted in few side effects, with improved walking

ability and tone reduction in the lower extremities after 3 days. Despite its reported effectiveness toward spasticity reduction, botulinum toxin A has shown little effect on tremor reduction. Nonetheless, it continues to be used as a conservative approach to delaying surgical intervention or simulating its effects.

Intrathecal baclofen (ITB), approved in 1996 to treat spasticity of cerebral origin, is an alternative formulation to oral blacofen. Utilizing a programmable pump implanted under the skin of the lower abdomen, baclofen is delivered directly into the cerebral spinal fluid (CSF) via a catheter fed posteriorly into the intrathecal (subarachnoid) space of the thoracic spine. The catheter is placed via lumbar puncture at vertebral level L3–L4 or L4–L5 and advances to the L1 vertebral region, where the anatomical curvature of the spine provides a more open area to distribute medication. The drug is delivered to the superficial layer of the spinal cord, binds to the $GABA_B$ receptors, and reduces spasticity using only a few millimeters of active drug. Intrathecal administration delivers four times the concentration of oral baclofen at the site of action at 1/100th of the oral dose. The smaller dose translates into a lower systemic concentration and therefore less systemic side effects such as somnolence.

In addition to the benefit of reducing the effects of somnolence, dosing of ITB may be titrated to accommodate daily variability in patient symptoms. The level of baclofen may be adjusted to moderate spasticity that interferes with gait or other activities of daily living. Furthermore, drug levels may be adjusted to accommodate changes in environmental conditions that may alter spasticity, such as temperature, stress, and hunger. Even though ITB use has fewer systemic side effects when compared with oral dosing, risks associated with ITB use include infection, disconnection and leaks of the catheter, adverse effects (hypotonia, seizures, nausea, and vomiting), and drug overdose.

Spasticity reduction in children with CP using ITB has been consistently reported. However, reports have been inconsistent regarding the effect that ITB has on functional improvements in movement. Further prospective research is needed to scientifically evaluate the effects that ITB has on gait and activities of daily living. The following guidelines have been established to determine individual candidacy for ITB use [from Barry *et al.*, *Pediat. Phys. Therapy* 2000 **12**(2), 77–86].

At least 4 years of age
Adequate body size to accommodate the pump
The presence of hypertonicity
The absence of infection
Medical stability

However, specific selection criteria have not been established.

VII. SURGICAL PROCEDURES

A. Selective Dorsal Rhizotomy

Selective dorsal rhizotomy (SDR) is a surgical procedure that involves severing specific sensory nerves that innervate the lower extremities. This selective denervation reduces abnormal excitatory peripheral sensory input to the spinal cord. Lumbosacral sensory nerves (L2–S2) are exposed and separated into component rootlets. These rootlets are then electrically stimulated and abnormal responses are recorded as well as visually observed. The rootlets producing abnormal responses are then severed, reducing spasticity while preserving tactile and proprioceptive sensation.

The primary purpose of this procedure is to improve or enable ambulation; however, increased joint range of motion and improved ease of positioning may be additional benefits. Ideal candidates for SDR are children between the ages of 4 and 6 who are diagnosed with either spastic hemiplegic or diplegic CP and have the ability or the potential for ambulation.

The procedure is irreversible, with associated risks of paralysis, permanent loss of bowel and bladder control, leakage of spinal fluid, infection, loss of sexual function, and permanent loss of sensation. Temporary side effects, which usually disappear after several weeks, include sensory loss, numbness, or an uncomfortable sensation in the limbs supplied by the severed nerve. Postsurgical treatment involves months of intensive physical therapy to strengthen weak muscles and to develop new movement patterns. Contraindications to SDR suggested by some surgeons include muscle tendon contractures, a history of orthopedic surgery, and hip displacement. The following are guidelines for SDR (from www.ccmckids.org/departments orthopaedics/orthoed4.htm):

Two years of age or older
Diagnosis of spastic diplegic or quadriplegic CP
Difficulty with ambulation due to spasticity
Adequate muscle strength
No previous history of orthopedic surgery

Ability to actively participate in physical therapy
Family that can provide follow-up physical therapy

B. Orthopedic Procedures

Due to immobility frequently associated with spastic CP, many individuals experience loss of joint range of motion and abnormal formation of bony structures. Functional problems often arise as a result of orthopedic impairments. An individual may experience problems with posture and pain as well as difficulty with environmental accessibility, ambulation, and daily hygiene.

Orthopedic surgery is utilized in an effort to correct joint contractures, improve musculoskeletal alignment, and improve joint stability and muscular balance. In contrast to neurological treatment, the neurological patterns of the muscle are not altered, but the influence of the muscle on the joint structure may change.

Orthopedic surgery includes both soft tissue and bony procedures. Soft tissue procedures include tendon lengthening, tendon transfers, and neurectomies. Tendon lengthening is used to increase range of motion within a joint. The tendon is released or lengthened in an effort to increase passive joint range of motion while preserving tension within the muscle. Tendon transfers involve the relocation of spastic muscles to improve functional alignment. Finally, neurectomy, removal of the nerve, is used predominantly for nonambulatory children in combination with other surgical procedures.

In general, bony procedures are indicated for severe deformities that are not correctable by soft tissue procedures. These procedures may be used to improve joint stability, to realign a bone with its muscular attachments, and for bone grafting. Osteotomies (surgical realignment of the bone) and arthrodesis (surgical fusion of a bone over a joint space) are common procedures. Derotation osteotomy (correction of internal rotation deformity of the hip) is a common procedure indicated for children who exhibit excessive femoral anteversion with resultant turning in of their feet during ambulation. Arthrodesis may be indicated in the absence of muscle tone, in the presence of severe deformity, or with gross loss of function (Table V).

Spinal scoliosis and hip subluxation, with subsequent hip dislocation, are common orthopedic concerns. Nonambulatory children diagnosed with spastic CP often exhibit an extensor tonal pattern of hip flexion, adduction, and internal rotation. Suggested contributing factors to subluxation of the hip include the strong pull of the adductor and flexor muscles of the hip joint in conjunction with weak hip abductor and extensor musculature.

Risk factors associated with hip subluxation include an increased femoral neck shaft angle (valgus), femoral anteversion, and a shallow acetabulum. With subluxation of the hip, there is a break in the Shenton line of the femur with exposure of more than a third of the femoral head. However, a portion of the femoral head remains in contact with the acetabulum. Limited hip abduction of less than 45° is often an early clinical sign of hip instability. When left untreated, subsequent dislocation usually follows within 2 years, between 5 and 7 years of age.

Hip subluxation and ensuing dislocation may result in pelvic obliquity, difficulty with ambulation, pain, seating problems, decubitus ulcers, and hygiene

Table V
Common Orthopedic Impairments and Associated Surgical Procedures for Children with CP[a]

Orthopedic problem	Implications	Surgical procedure
Hip adduction contracture	Scissor gait, difficulty with hygiene, predisposes hip to subluxation	Adductor release or transfer
Hip flexion contracture	Crouch gait pattern, lumbar hyperlordosis	Psoas tendon tenotomy
Increased femoral anteversion	Feet turned in during ambulation	Derotational osteotomy
Knee flexion contracture	Crouch gait	Hamstring lengthening
Ankle equinovalgus	Painful calluses and blisters on the inner foot	Arthrodesis, calcaneal osteotomy
Ankle equinus	Lack of heel strike during ambulation	Gastrocnemius tendon lengthening

[a]Adapted from Renshaw (1996).

problems. Therefore, surgical treatment for early signs of hip instability is focused on preventative measures. An adductor tenotomy is often performed to reduce the power of the adductor muscle force on the hip joint. Iliopsoas muscle lengthening may be simultaneously performed. With these simple surgical procedures subsequent hip dislocation may be preventable.

Scoliosis is often a concern with regard to children who are nonambulatory and remain in a seated position for prolonged periods of time. Children with CP who are diagnosed with quadriplegia, exhibit poor sitting balance, pelvic obliquity, multiple spinal curves, and are young in age are at a greater risk for scoliotic curve progression. Nonsurgical management may include the use of orthoses, electrical stimulation, and therapeutic exercise. However, nonsurgical methods are less effective when used to treat CP-related scoliosis compared to scoliosis of an idiopathic origin. Therefore, spinal fusion is warranted in most cases in an effort to balance the spine over a level pelvis.

C. Nonsurgical Treatment

A variety of nonsurgical techniques are employed to prevent secondary problems that frequently interfere with functional movement, such as loss of joint range of motion, muscular weakness, and spasticity. Assistive devices including walkers, crutches, and manual or power wheelchairs may be used to facilitate mobility.

Neuromuscular electrical stimulation (NMES), the use of electrical current to stimulate muscle and nerve fibers, is one method used in an attempt to temporarily reduce spasticity, increase joint range of motion, strengthen the muscle, and facilitate motor control. NMES may also be used for muscle reeducation. In the child with CP, NMES is frequently utilized to facilitate motor performance as well as sensory input to the muscle. For example, electrodes may be placed over a weak muscle to elicit a muscular contraction as the child engages in a purposeful activity. NMES may also be used to treat scoliosis as well as to improve the quality of gait.

Therapeutic electrical stimulation (TES) is an alternative type of electrical stimulation that delivers electrical current at a low intensity as the individual sleeps. The purpose of TES is to improve strength of nonspastic musculature in individuals who undergo a SDR. The current is delivered above the threshold for sensation without producing a muscle contraction and is hypothesized to increase muscle growth with subsequent improvements in strength through increased local blood flow. In 1997, Steinbok and colleagues reported functional improvements as a result of TES, but further empirical research is needed.

To promote proper joint alignment, the individual may undergo assessment and fabrication for an orthosis. The goal of the orthosis is to assist with proper alignment and stability of the foot and leg during weight bearing in an effort to improve efficiency and ease of gait. Among those individuals who are nonambulatory, orthoses may be fabricated to maintain proper joint alignment in an effort to prevent joint contractures.

Orthoses are commonly custom made from plastic material, but lightweight metal and leather are also options. In an effort to provide joint stability, orthoses are available with varying levels of support. Shoe inserts offer the least amount of support, assisting with foot position during ambulation. Ankle–foot orthoses (AFOs) and knee–ankle–foot orthoses (KAFOs) provide additional stability to the ankle and leg. The AFO extends above the ankle to the midcalf, assisting with ankle control, whereas the KAFO extends above the knee to the thigh, providing support to both the ankle and knee joints. KAFOs therefore provide the greatest amount of support to the lower extremity.

AFOs and KAFOs are the most common orthoses prescribed for individuals with CP. The orthoses usually fit inside of the shoe, facilitating stability of the leg, ankle, and foot as the foot contacts the floor while standing or walking. Orthoses are commonly fabricated when the child with CP begins to stand, but they may be utilized at an earlier age to promote joint alignment.

Splinting and therapeutic exercise are also options to maintain or promote functional joint range of motion. In the event that joint motion is limited, serial casting, utilized to lengthen hypoextensible muscles, may be a viable option.

VIII. HABILITATION

Habilitation of the individual with CP is frequently accomplished by using a multidisciplinary approach that involves the input of a variety of professionals in collaboration with the child and the family. Although CP is nonprogressive in nature, the manifestations of the disorder may change over time. As the individual progresses from childhood to adulthood, the goal of habilitation is to prevent secondary conditions such as

muscle contractures or obesity and to assist the individual in interacting independently within many environments. Therefore, habiliatation often emphasizes facilitation of functional activities and the use of environmental adaptations.

A. Speech Therapy

In the rehabilitation of the individual with CP, the primary role of the speech/language pathologist/therapist is to address communication and feeding needs. Common sequalae of the disorder treated by speech therapists include impairments of articulation that may include mild to severe dysarthria, difficulties with swallowing, saliva management, and nutritional problems. Due to poor motor control, individuals may exhibit problems with the coordination of swallowing with breathing, difficulty with collection and organization of food, and problems with drooling.

To facilitate management of swallowing and eating, positioning and oral sensorimotor training may be used. As the child with CP ages, it is hoped that natural speech will improve. However, if a child does not exhibit the ability to functionally communicate and interact with the environment, the use of augmentative or alternative communication may be explored. Augmentative communication involves the use of aids to supplement existing vocal communication. Alternative communication is defined as communication without verbal ability.

Augmentative and alternative communication techniques are widely available and vary in cost and complexity of use. Low-cost techniques include the use of sign language, gesturing, or pointing or eye gaze in conjunction with a picture board. For those individuals possessing the cognitive skills for complex language, computer-driven devices with high-quality voice output and visual imaging systems are available.

B. Occupational Therapy

Occupational therapy facilitates function of the individual to promote accomplishment of occupational pursuits. Occupational pursuits vary depending on individual age or interest and may include hobbies, sports, or vocational pursuits. Occupational therapists frequently assist the individual in performing meaningful tasks in three performance areas: self-care, work, and play. Overall performance level of the task and barriers to performance may be analyzed by the occupational therapist. Specific components of the task, including sensory processing, perceptual processing, attention, neurological status, motor control, cognition, and psychosocial processing, may also be assessed.

Therapeutic techniques implemented to assist the individual with independent task performance may focus on the task, the person, and the environment. For example, the individual may perform muscle strengthening or range of motion exercises to build strength and joint motion required to perform the task. The use of task adaptation may also be addressed. A universal holder to stabilize the hand during writing, switches for communication, and adaptive utensils for feeding are three examples. Environmental modifications, such as the installment of ramps to access a playground, may also be implemented.

In the area of task adaptation, occupational therapists serve a vital role in determining the appropriate type of augmentative/alternative communication aide that may be necessary to accomplish daily tasks. To promote independence in daily activities, electronic aids and/or devices are available to assist the individual to access and control his or her environment. Switches are useful to teach children cause-and-effect relationships and may be used as electronic aids for a variety of daily tasks. Examples include head switches or hand switches to activate a toy, blender, or television. Keyguards preventing unwanted keystrokes, touch screens, mobile arm supports, and computer mice with various methods of activation, are but a few of the devices available to improve computer accessibility for an individual with a disability.

C. Physical Therapy

When providing services for individuals with CP, the primary role of the physical therapist is to facilitate independent mobility. For individuals capable of functional movement, independent mobility may require the use of an assistive device such as a walker or orthoses. For individuals incapable of functional movement, the physical therapist frequently serves to ensure proper positioning to prevent the development of secondary conditions such as joint contractures, bony deformities, or skin breakdown. In the child, treatment is often facilitated through play, with an emphasis on age-appropriate developmental milestones such as rolling, sitting, standing, and walking. Moreover, the focus is on the promotion of movement

patterns to encourage independence at home and at school.

In the adult, emphasis is placed on mobility necessary for the accomplishment of functional activities of daily living. With all individuals and families, the physical therapist aims to facilitate individual assumption of their own health and the prevention of secondary conditions.

In addition to hands-on intervention, physical therapists provide insight regarding environmental accessibility, activity adaptations, and proper positioning to facilitate the use of augmentative/alternative communication devices.

IX. LEGISLATION

During the past decade, several pieces of legislation have served to expand the rehabilitation options and societal opportunities for individuals with disabilities. The Rehabilitation Act of 1973 set a precedent for legislative support regarding the rights of individuals with a disability. The act prohibits discrimination of qualified individuals with disabilities from federally funded programs. Therefore, programs receiving federal money are required to make reasonable accommodations in order that individuals with a disability may participate.

In 1975, the Individuals with Disabilities Education Act was implemented to ensure that children with disabilities have the right to a free and appropriate public education in the least restrictive environment. Prior to its implementation, the rehabilitation or education of children with disabilities primarily occurred in state institutions. Today, the law supports individualized goal planning, written in collaboration with the family and educational staff, supporting a child's full participation in family, school, and community life. Children with disabilities therefore have the right to fully participate with their peers in school-related educational, sport, and recreational activities.

A third piece of legislation, the Americans with Disabilities Act, was implemented in 1990 to ensure environmental accessibility for individuals with disabilities. The law mandates that public or private facilities receiving federal financial support eliminate architectural barriers for public transportation and new facility construction as well as guarantee reasonable accommodations in all aspects of employment. Therefore, these laws have progressively opened doors for enhanced career and recreational opportunities for all individuals with disabilities.

X. COMMUNITY RECREATION/LEISURE

Community recreation and leisure activities can provide individuals with CP a source of enjoyment and a lifelong opportunity for general fitness and wellness. Specifically, community recreational opportunities provide an outlet to engage in physical activity in addition to promoting independence and self-sufficiency.

As individuals with CP age, they experience the normal sequala of the aging process in addition to already existing impairments in movement. Weak muscles may exhibit a decrease in strength, and joints may become less flexible. Therefore, greater effort may be required to perform activities of daily living. Community recreation may assist the individual in retarding this process by providing physical activities that promote muscle strengthening, endurance, and joint flexibility. Finally, involvement in community recreation and fitness can provide a social outlet, improve cardiovascular fitness, assist with weight control, and assist in the prevention of osteoporosis.

In the past, the use of progressive resistive exercise in individuals with CP was a concern. Resistive training was thought to increase recruitment of overactive spastic musculature. However, recent work by Damiano and colleagues has reported resistive exercise to be a safe and effective method to improve strength and motor performance. Through a progressive series of studies, researchers have found that the use of resistive exercise does not elicit or inadvertently strengthen overactive antagonist spastic musculature.

In children with CP, the literature has supported the use of resistive exercise to improve muscle strength and functional movement. Moreover, Damiano and colleagues reported improvements in quadricep muscle strength in conjunction with improvements in walking speed in children with CP. O'Connell and colleagues also documented a correlation between muscular endurance and the ability to perform aerobic and anaerobic wheelchair tasks.

With regard to cardiovascular fitness, individuals with CP frequently exhibit lower cardiovascular fitness levels. Although researchers have shown that cardiovascular fitness can improve in individuals with CP, further research is needed.

As with all individuals seeking to engage in new physical activities, individuals with CP should obtain medical clearance prior to participation in a community recreation or sporting activity. Many individuals pursue inclusive recreational and sport activities through local community organizations such as the

YWCA. In addition, sporting opportunities specifically targeted for individuals with CP are organized by the Cerebral Palsy Athletic Association and the Cerebral Palsy International Sports and Recreational Association. The Cerebral Palsy Athletic Association provides the following sporting opportunities: archery, boccia, bowling, track and field, cross-country, cycling and tricycling, equestrain, powerlifting, slalom, soccer, swimming, table tennis, target shooting, and wheelchair team handball.

The number of nationally recognized recreational opportunities available to individuals with disabilities continues to grow.

XI. CAREERS AND AVOCATIONS

Individuals with CP reflect societal patterns when choosing career and avocational pursuits. While some choose to work in the service sector, others pursue careers in law, education, or medicine. As a result of supportive legislation for individuals with a disability, positive changes in employment rates have occurred. Although competitive employment rates for individuals with CP ranged from only 17 to 35% during the past several decades, a positive change was reported in 2000 by Murphy and colleagues. Fifty-two percent of individuals with CP were employed in competitive work, with 7% employed in semicompetitive work and 18% employed in sheltered work.

With supportive public policy, medical advancements, and assistive technologies, physical and environmental barriers may no longer impede professional success. Currently, individuals with disabilities are becoming autonomous productive members of society as reflected by increases in employment. Thus, the groundwork for vocational opportunities has been laid, empowering individuals with CP to have the freedom to pursue their dreams.

Cerebral White Matter Disorders

CHRISTOPHER M. FILLEY
University of Colorado School of Medicine and Denver Veterans Affairs Medical Center

GLOSSARY

Binswanger's disease A vascular disease of the brain in which ischemic demyelination and infarction primarily affect the cerebral white matter.

demyelination A neuropathological process in which myelin is stripped away from axons, with or without associated axonal and/or neuronal damage.

leukodystrophy A genetic disorder of white matter characterized by abnormal myelin metabolism in the brain.

magnetic resonance imaging A powerful neuroradiological technique that permits detailed noninvasive views of the brain white matter.

multiple sclerosis An idiopathic, inflammatory, demyelinative disease of the central nervous system.

myelin The fatty insulation of many axons in the brain that helps increase the conduction velocity of neurons by the phenomenon of saltatory conduction.

neural networks Integrated systems of gray and white matter in the brain that subserve elemental and higher cerebral functions.

toluene leukoencephalopathy A disorder of brain white matter caused by excessive exposure to toluene vapor.

white matter dementia A dementia syndrome resulting from primary or selective involvement of cerebral white matter.

white matter tracts Collections of myelinated fibers connecting cortical and subcortical gray matter regions in the brain.

The cerebral white matter constitutes approximately one-half the volume of the human brain. White matter establishes anatomic connectivity between cortical and subcortical gray matter regions within and between the hemispheres, and it enables more efficient neuronal transmission and cerebral function. Disorders of the cerebral white matter comprise a diverse group of neuropathologic conditions, of which multiple sclerosis is the best known. Neurologic dysfunction is well-known to be associated with these disorders, and neurobehavioral syndromes including dementia are also being increasingly recognized. Recognition of these clinical phenomena represents an opportunity to improve the care of individuals with these disorders and to expand our understanding of the human brain.

I. CEREBRAL WHITE MATTER

The human brain is that portion of the central nervous system within the cranium. Twelve pairs of cranial nerves provide conduits for special senses, general sensation, and motor function, mainly for the head and neck. The brain is continuous caudally with the spinal cord, which in turn is connected to numerous peripheral nerves that travel to and from the entire body. Thus, the brain, at the highest level of the nervous system both literally and figuratively, exerts control over all aspects of bodily function. The brain is best known for its gray matter—the neocortex and a variety of subcortical structures—but white matter also forms a considerable portion of the brain and has an important role in many of its operations. The white matter of the cerebrum—those fibers and tracts that are found within and between the paired cerebral hemispheres—serves to connect various gray matter regions into functionally unified neural networks. The

study of the organization of these networks, currently understood at only a rudimentary level, is one of the major goals of contemporary neuroscience. Here, the anatomy, physiology, development and aging and neuroimaging of the cerebral white matter are reviewed.

A. Neuroanatomy

White matter is so named because of its glistening white appearance on the cut surface of the brain. This feature is attributable to myelin, a fatty substance that wraps around the axons of cerebral neurons as they course through the brain. Myelin is a complex mixture of lipids (70%) and protein (30%) manufactured by oligodendrocytes, cells of glial origin that are analogous to the Schwann cells of the peripheral nervous system (Fig. 1). At the microscopic level, white matter consists of collections of axons coated with myelin; these axons travel together in various fiber systems called tracts to form structural connections between many different gray matter regions.

At the macroscopic level, white matter makes up about 50% of the adult cerebrum. Three kinds of white matter fiber systems are recognized. First are the projection fibers, which travel corticofugally (from the cortex) or corticopetally (to the cortex) in relation to more caudal destinations. An example of a corticofugal tract is the corticospinal tract, and the optic radiation from the thalamus to the occipital lobe is a corticopetal tract. Second, there are several tracts of commissural fibers that connect the two hemispheres. The most prominent of these is the corpus callosum, a massive structure carrying approximately 300 million axons. Finally, various association fibers serve to connect cortical regions within each hemisphere. There are numerous short association fibers (arcuate or U fibers) that link adjacent cortical gyri, and there are five long association tracts—the superior occipitofrontal fasciculus, the inferior occipitofrontal fasciculus, the arcuate fasciculus, the cingulum, and the uncinate fasciculus—that connect more remote cortical areas (Fig. 2).

Two other anatomic observations are relevant. First is the close relationship of white matter with the frontal lobes, the largest of the human cortical regions: The cerebral white matter is most abundant under the frontal lobes, where all the major association tracts have one of their termini. These features imply that the frontal lobes exert a unique influence in part through the actions of the white matter. Second, there is a higher proportion of white matter compared to gray matter in the right hemisphere than in the left hemisphere. This asymmetry suggests a functional specialization of the hemispheres whereby the white matter in the right cerebrum plays a distinctive role.

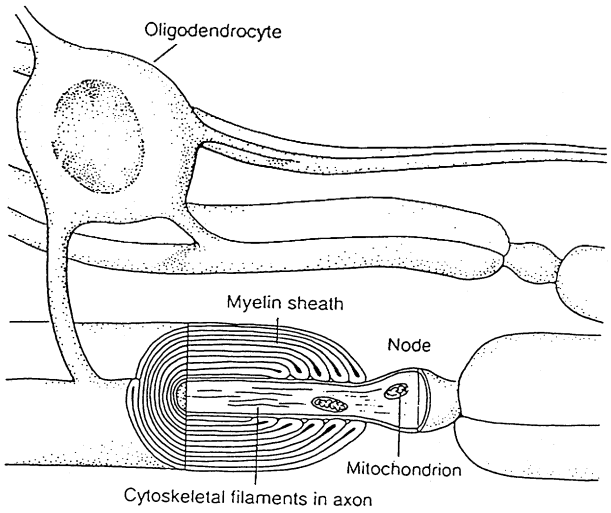

Figure 1 Schematic diagram of the relationship between the oligodendrocyte, myelin sheath, and axon in the brain (reprinted with permission from E. R. Kandel, T. M. Jessell, and J. H. Schwartz, *Principles of Neural Science*, 3rd ed., p. 44. McGraw-Hill, New York, 1991).

B. Neurophysiology

The brain is an electrical organ, and the conduction of electrical impulses from one neuron to another is fundamental to brain activity. A variety of neurotransmitters serve as chemical messengers between neurons, but transmission of impulses within each neuron is equally critical. The continuous process of neuronal communication depends on the integrity of white matter. Myelinated fibers are essential for the rapid and efficient propagation of neuronal information.

The basic physiologic phenomenon in neurons, whether in the central or peripheral nervous system, is the action potential. This is an electrical event in which the neuronal membrane is rapidly and transiently reversed from its resting potential of -70 mV by the influx of positively charged sodium ions. This "all-or-none" potential quickly ends with the efflux of potassium ions, and then follows a short time, the refractory period, during which no impulse can be

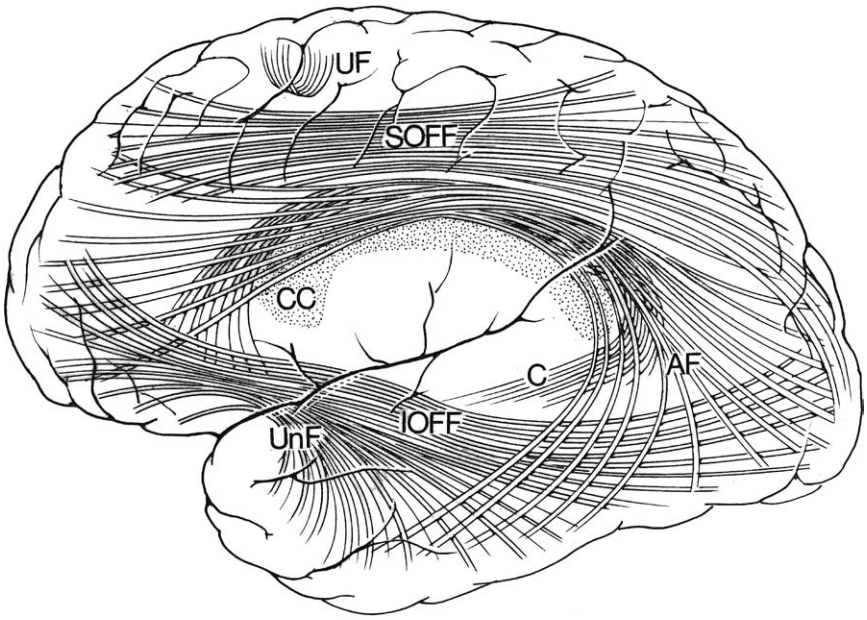

Figure 2 Major white matter tracts in the cerebral hemispheres. UF, U or arcuate fibers; SOFF, superior occipitofrontal fasciculus; IOFF, inferior occipitofrontal fasciculus; AF, arcuate fasciculus; C, cingulum, UnF, uncinate fasciculus; CC, corpus callosum (reprinted with permission from C. M. Filley, *Neurobehavioral Anatomy*, p. 188, Univ. Press of Colorado, Niwot, 1995).

propagated. The resting membrane potential is restored by the action of the sodium–potassium pump, an energy-dependent process requiring the hydrolysis of adenosine triphosphate (ATP), in which sodium is extruded from the cell and potassium taken in.

The primary role of myelin is to increase the conduction velocity of neurons as they propagate action potentials. Myelin is laid down in such a fashion that short segments of the axon, called nodes of Ranvier (or simply nodes), are left unmyelinated (Fig. 1). These nodes contain high concentrations of sodium channels, and the action potential can "jump" sequentially from one node to the next as the depolarizing current shunts the current rapidly forward along the axon (Fig. 3). This phenomenon, known as "saltatory conduction," greatly increases neuronal conduction velocity.

C. Development and Aging

The white matter of the brain undergoes a continuous process of remodeling throughout the life span. It has

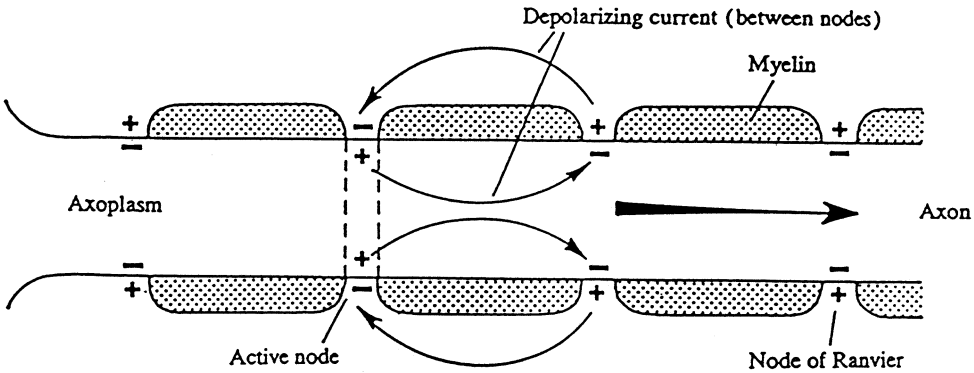

Figure 3 Illustration of saltatory conduction in a myelinated nerve. The action potential is propagated by sodium influx at the nodes of Ranvier, and the impulse "jumps" rapidly throughout the entire length of the axon (adapted from B. Pansky, D. J. Allen, and C. G. Budd, *Review of Neuroscience*, 2nd ed., p. 357. Macmillan, New York, 1988).

been estimated that the ratio of cerebral gray to white matter at age 50 is approximately 1 : 1, whereas in infancy and old age there is a relative preponderance of gray matter. In comparison to gray matter, white matter requires a longer time to develop and then is preferentially lost in senescence.

During development, white matter requires several decades to complete its formation. Myelination of the brain begins *in utero* and continues until adulthood. As a general rule, myelination occurs earlier in areas devoted to elemental motor and sensory functions and later in areas concerned with higher cerebral functions. Thus, the cerebral commissures and the association areas, for example, are not fully myelinated until the third decade of life. Because there is a strong likelihood that the degree of myelination parallels functional maturity, the fact that frontal lobe myelination is not complete until young adulthood suggests that the integrity of white matter contributes importantly to the maturation of personality and comportment.

In contrast, aging in the brain involves not only a loss of neurons and their dendritic trees but also a selective loss of white matter. Recent findings from neuroimaging and autopsy studies have led to a revision of the traditional view that neuronal loss is the major characteristic of brain aging. It now appears that whereas neuronal loss is not as marked as previously thought, gradual loss of white matter in aging is a consistent observation. The implications of this white matter change are not entirely clear, but as in development, there may be a clinical correlation. For example, the cognitive slowing often seen in the elderly may be explained in part by the loss of white matter.

D. Neuroimaging

The study of cerebral white matter has been dramatically facilitated in the past three decades by the development of powerful neuroimaging techniques. Computerized tomography (CT) scanning became available in the 1970s, and for the first time a noninvasive image of the brain *in vivo* became easily obtainable. Magnetic resonance imaging (MRI) was introduced in the 1980s and offered much improved visualization of brain structures, particularly white matter. MRI has been a most significant advance in the understanding of white matter disorders, revolutionizing the diagnosis of multiple sclerosis (MS) and rapidly expanding the list of disorders with white matter pathology that were previously difficult to detect. Another development in the field of MRI is the advent of diffusion weighting, a means by which specific white matter tracts can be identified. Recently, functional imaging techniques have attracted much interest, including positron emission tomography and functional MRI, both designed to evaluate the metabolic activity of brain regions. Although these instruments are most suited to imaging gray matter areas with high metabolic activity, they are likely to assist in the study of white matter function by identifying cortical and subcortical regions participating in neural networks that also include white matter tracts.

II. NEUROLOGIC DISORDERS

Disorders of the cerebral white matter comprise a widely diverse group of neuropathologic conditions. Many of these disorders are well-known in neurology, but others have been recently discovered with the use of MRI, and the number of entries on this list is likely to continue growing. This section reviews the cerebral white matter disorders using a classification system based on known or presumed etiology. Major categories are presented with the disclaimer that some diseases have an unknown etiology and are included in the category that is most appropriate given this uncertainty. Individual disorders are included if there is sufficient neuropathologic or neuroimaging evidence indicating that the cerebral white matter is involved. The intent is to provide an organizational framework for considering these disorders; exhaustive discussions can be found in standard textbooks of neurology.

A. Genetic Diseases

Many genetic diseases can affect the cerebral white matter. These are rare diseases that usually present in infancy or childhood but may occasionally appear in adulthood. Many of these diseases have a progressive and irreversible course, but effective medical treatment is available for some.

1. Leukodystrophies

The best known genetic cerebral white matter disorders are the leukodystrophies, a group of inherited diseases that disturb myelin metabolism and lead to severe neurologic dysfunction and early death. These diseases have been termed "dysmyelinative" because

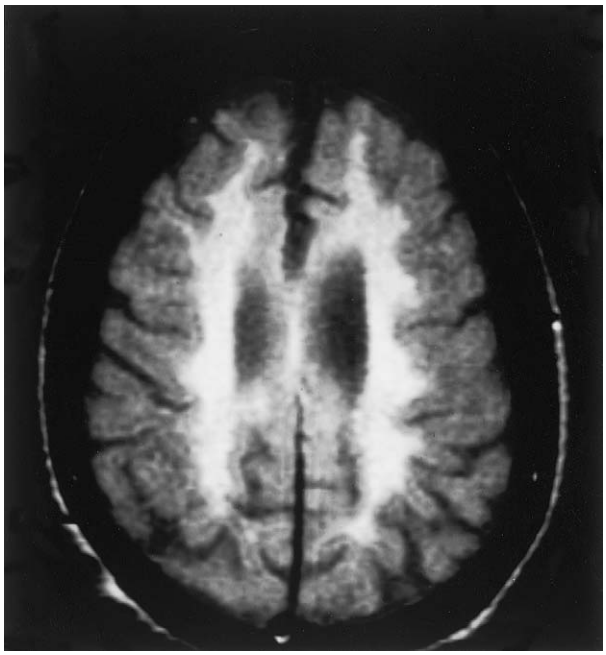

Figure 4 MRI scan of a patient with metachromatic leukodystrophy. There is severe and diffuse dysmyelination of the cerebral white matter (reprinted with permission from *Neuropsychiatr. Neuropsychol. Behav. Neurol.* **6,** 142, 1993).

of the metabolic dysfunction that prevents the normal myelination of the nervous system. The leukodystrophies usually present in early life and have an irreversibly progressive course. The most common of these is metachromatic leukodystrophy (MLD), an autosomal-recessive disease characterized by deficiency of the enzyme aryl sulfatase A; this defect leads to an accumulation of sulfatide in myelin, from which clinical deficits arise. Manifestations of MLD include mental retardation, dementia, spasticity, visual loss, and peripheral neuropathy, and in adults psychosis has been frequently observed. MRI is helpful in identifying the leukodystrophy, which is diffuse and severe (Fig. 4). Leukodystrophies are typically autosomal recessive; an exception is the X-linked disease adrenoleukodystrophy. Treatment has been supportive, since medical interventions have been largely unsuccessful. Recent studies of bone marrow transplantation with hematopoeitic stem cells, however, have shown promising results in MLD and globoid cell leukodystrophy.

2. Aminoacidurias

Phenylketonuria and maple syrup urine disease are inborn errors of metabolism that produce disturbed brain myelination. Cognitive and motor dysfunction are typical, and these have been attributed to white matter pathology. MRI has documented changes in myelination that were previously found on neuropathologic examination. If these diseases are detected in the neonatal period and treated with proper dietary management, an excellent outcome can often be achieved.

3. Phakomatoses

These disorders, also called neurocutaneous syndromes, all involve structural brain lesions in combination with an abnormality of the skin. The three most common phakomatoses are neurofibromatosis, tuberous sclerosis, and the Sturge–Weber syndrome. Although a variety of structural changes can be seen in the brains of these patients, white matter lesions are often seen on MRI scanning and may contribute to neurobehavioral dysfunction.

4. Mucopolysaccharidoses

Of the six major mucopolysaccharidoses, Hurler's syndrome and Hunter's syndrome are the two with the most prominent neurologic sequelae. Cerebral white matter neuropathology is present and may result both from the primary dysmyelination associated with the disease and from associated hydrocephalus.

5. Myotonic Dystrophy

This is an autosomal-dominant disease that has been recognized to affect cognition as well as the muscular system. Recent studies using MRI scanning have disclosed a high frequency of white matter lesions in the brains of myotonic dystrophy patients. Although the neuropathology of these lesions remains obscure, evidence suggests that they contribute to cognitive dysfunction.

6. Callosal Agenesis

This is an uncommon brain malformation that is usually idiopathic but thought to be of genetic origin in some cases. Mental retardation is common, although some individuals have relatively preserved cognitive function. The contribution of the corpus callosum malformation to impaired cognition is difficult to assess because these patients often have other problems, such as additional malformations, epilepsy, and hydrocephalus.

B. Demyelinative Diseases

This group of diseases has long been the most familiar of all the white matter disorders. Multiple sclerosis is the prototype white matter disease of the central nervous system, affecting the spinal cord as well as the brain, and has been a major clinical and research interest of neurologists since the time of Jean Marie Charcot, who made many important observations about the disease in the late 19th century. In part because they tend to affect patients at early stages in life, demyelinative diseases are a significant source of neurologic disability. Study of these diseases has also been stimulated by the likelihood that their pathogenesis can shed light on many aspects of neural dysfunction.

1. Multiple Sclerosis

MS is an inflammatory, demyelinative disease of the central nervous system. Young adults are primarily affected, and women are more vulnerable than men. The etiology of MS is unkown, despite many suggestions that it has a viral cause and that there are genetic influences on susceptibility. The disease is characterized clinically by lesions disseminated in space and time; that is, the lesions affect different regions of the brain or spinal cord and do so at different times. MRI has notably improved the detection of demyelinative lesions in the brain and has evolved to be the most useful method of confirming the diagnosis. Demyelinative plaques in MS are typically periventricular on MRI scanning and become confluent when the disease is severe (Fig. 5). The course of MS is most often relapsing–remitting, implying that patients have episodic exacerbations followed by complete or partial recovery over weeks or months. Others have primay progressive disease, in which continual decline is seen without recovery, and still others experience secondary progressive MS, in which an initial relapsing–remitting pattern is succeeded by a progressive course later in the disease. Common manifestations of MS are paresis, sensory loss, visual loss from optic neuritis, diplopia, vertigo, and bladder dysfunction. Neurobehavioral dysfunction involving memory loss, dementia, depression, emotional incontinence, euphoria, and psychosis are also well described and may be independent of elemental neurologic deficits. Life expectancy is only modestly reduced in MS, but the quality of life may be seriously compromised by loss of the ability to work and the disruption of social relationships. Until recently, treatment of MS was limited to supportive care and the use of corticosteroids to reduce the duration of exacerbations. In the past decade, three new immunomodulatory drugs have been added to the pharmacopoeia of MS patients—interferon-β_{1a}, interferon-β_{1b}, and glatiramer. These agents are given on a regular basis and can reduce relapse rate and possibly functional disability in individuals with relapsing–remitting MS.

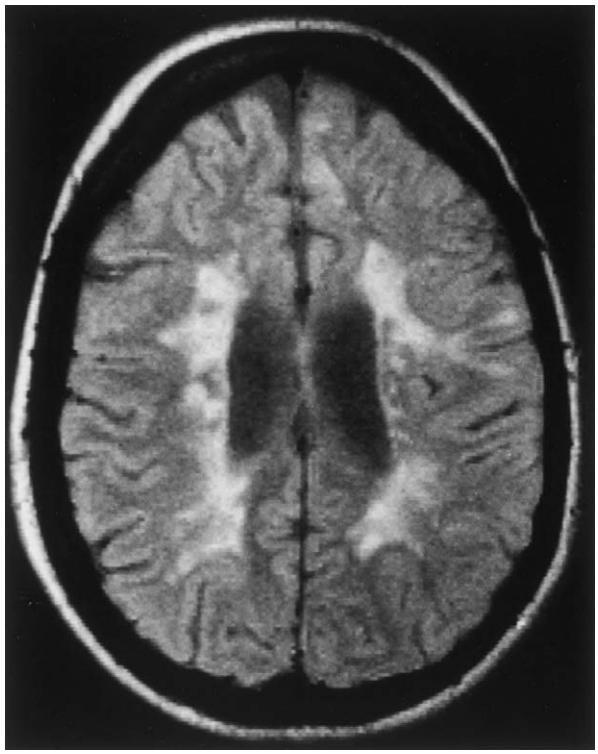

Figure 5 MRI scan of a patient with MS. Multifocal demyelination throughout the cerebral hemispheres is apparent (reprinted with permission from *Neuropsychiatr. Neuropsychol. Behav. Neurol.* **4,** 245, 1988).

2. Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is a monophasic demyelinative disease of the brain and spinal cord. ADEM typically occurs in children and follows an infection with an exanthematous rash or a vaccination; the presentation is one of rapidly evolving multiple symptoms and signs related to extensive demyelination. The disease may be severe, with a substantial fatality rate and often significant neurologic or neurobehavioral disability in survivors.

3. Neuromyelitis Optica

This disease, also known as Devic's disease, is characterized by the acute onset of unilateral or bilateral optic neuritis in close temporal association with transverse or ascending myelitis. The disease often affects children but can be seen at all ages. The course may range in severity from a single episode from which the patient recovers to a fatal outcome. Neuromyelitis optica is probably an uncommon variant of MS because many survivors go on to develop typical features of the disease as time elapses.

4. Schilder's Disease

In 1912, the entity Schilder's disease was introduced into the literature as a fulminant disease of children with diffusely affected cerebral white matter. Much confusion has surrounded the status of this condition, but later analyses have securely identified three different diseases falling under this eponym: adrenoleukodystrophy, subacute sclerosing panencephalitis, and true Schilder's disease. The disorder is best considered a rare variant of MS usually affecting children and causing severe mental deterioration, progressive disability, and often death as a result of marked cerebral demyelination.

5. Balò's Concentric Sclerosis

This disease is an even rarer MS variant that resembles Schilder's disease clinically but features a different neuropathology. In contrast to widespread areas of myelin destruction, concentric sclerosis manifests as a series of alternating bands of myelin destruction and preservation in concentric rings. Corticosteroid therapy may be helpful in this disease as in Schilder's disease.

C. Infectious Diseases

Many different infectious diseases attack the cerebral white matter. In these diseases, an inflammatory pattern of white matter changes is seen and an infectious agent has been identified in each. The infections discussed later may in some cases involve white and gray matter structures alike, and it may be unclear how much of the clinical picture can be attributed to white matter pathology. However, there is in general a sufficient burden of white matter disease to merit consideration of these diseases in this section.

1. AIDS Dementia Complex

With the emergence of infection with the human immunodeficiency virus (HIV) in the past two decades, neurologic involvement in patients with the acquired immunodeficiency syndrome (AIDS) has been frequently recognized. HIV is a neurotrophic virus, and AIDS may now be considered a disease of the nervous system as well as the immune system. All parts of the nervous system may be affected by AIDS—the brain, meninges, spinal cord, nerve roots, peripheral nerves, and muscle—causing a wide array of neurologic syndromes. One of the most severe of these syndromes is the AIDS dementia complex, a typically late complication of AIDS characterized by progressive and irreversible cognitive and behavioral decline accompanied by a variety of motor signs, including spasticity, ataxia, and gait disorder. In terms of mental function, affected individuals manifest apathy, impaired memory, and cognitive slowness in the setting of progressively enlarging ventricles and patchy or diffuse leukoencephalopathy on neuroimaging studies. Neuropathologic studies have shown diffuse and multifocal rarefaction of the white matter and lesser involvement of subcortical gray matter. The syndrome is likely due to HIV invasion of the brain, although whether the virus exerts its effect directly or indirectly remains uncertain. Treatments for the AIDS dementia complex have been limited, and the onset of dementia usually heralds a fatal outcome soon thereafter.

2. Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is an opportunistic infection of the cerebral white matter that frequently appears in patients with AIDS. The infectious agent is a member of the papavovirus family known as the JC virus. The virus infects oligodendrocytes, and demyelination is seen pathologically. Multifocal nonenhancing white matter involvement is typically seen on MRI scanning. The course of PML is invariably progressive, and attempts to treat the disease pharmacologically have been disappointing.

3. Varicella Zoster Encephalitis

The varicella zoster virus is a member of the herpes family that typically causes a painful disease of the peripheral nervous system and skin known as shingles. In immunocompromised patients, however, multifocal leukoencephalitis with both demyelination and

ischemia of the white matter may occur. Treatment with the antiviral drug acyclovir may be successful.

4. Subacute Sclerosing Panencephalitis

Subacute sclerosing panencephalitis (SSPE) is a rare disease of children and adolescents caused by the measles virus. Although the neuropathology may also involve cerebral cortex, white matter involvement is prominent. It remains unclear why the measles virus reactivates in some children to cause this devastating disease. A subacute course of progressive dementia advancing to death occurs, and no effective treatment to arrest or cure SSPE has been found.

5. Lyme Disease

Lyme disease is a systemic disorder due to infection with the spirochete *Borrelia burgdorferi*. Neurologic manifestations may be central or peripheral, and in the brain a fluctuating meningoencephalitis may occur. Because effective treatment with tetracycline is available, there have been few autopsied cases, but MRI scans have revealed white matter changes in the cerebrum and brain stem.

D. Inflammatory Diseases

These diseases are characterized by an inflammatory process in the brain unrelated to an infection. Because excessive immune system activity is implicated in each, corticosteroids are typically used in their treatment. As is true of infectious diseases, these disorders may involve gray matter in addition to white matter, but prominent white matter involvement has been documented as one aspect of each of the entities discussed here.

1. Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE), also known simply as lupus, is a multisystem disease with protean clinical manifestations. When SLE affects the brain, causing what has been variously known as lupus cerebritis or neuropsychiatric lupus, a wide range of neurobehavioral features may follow. In many cases, multifocal white matter lesions are seen on brain MRI that likely represent ischemic lesions and infarcts related to the vasculopathy that is characteristic of SLE. Treatment often includes immunosuppressive drugs and anticoagulation, but the efficacy of these modalities is uncertain.

2. Polyarteritis Nodosa

This connective tissue disease most often affects the peripheral nervous system and produces a syndrome of multiple nerve involvement known as mononeuropathy multiplex. The brain is less commonly involved, but there may be white matter infarcts on MRI related to arteritis.

3. Behcet's Disease

This is a systemic vasculitis featuring oral and genital lesions, intraocular lesions, skin and joint involvement, and thrombophlebitis in addition to neurologic manifestations. An acute or subacute meningoencephalitis may occur. MRI has been reported to reveal multifocal white matter lesions.

4. Sjögren's Syndrome

This uncommon autoimmune disease may have neurologic manifestations, the most frequent of which is a sensory neuropathy. The brain may also be affected, and the likely mechanism is small vessel disease from vasculitis or vasculopathy. MRI scans have revealed subcortical white matter hyperintensities in some patients with Sjögren's syndrome.

5. Isolated Angiitis of the Central Nervous System

Despite a lack of systemic markers of vasculitis or inflammation, this autoimmune disease may affect the brain to cause headache, confusion, and multifocal neurologic deficits. The pathogenesis involves a vasculitis that causes multiple strokes affecting white or gray matter.

6. Sarcoidosis

This is a systemic inflammatory disease with the characteristic pathologic finding of noncaseating granulomata. Neurosarcoidosis may affect the central nervous system and cause a wide range of neurologic manifestations. Periventricular abnormalities are seen on MRI in about one-third of patients with neurosarcoidosis; these may represent subependymal granulomas, areas of infarction secondary to granulomatous angiopathy, hydrocephalic edema from basal

meningeal involvement, or opportunistic infection such as PML.

E. Toxic Leukoencephalopathies

The cerebral white matter is vulnerable to a wide range of intoxications from physical and chemical insults. Of all the clinical areas in which MRI has been able to demonstrate white matter lesions, one of the most fruitful has been the toxic disorders. New drugs that affect the white matter, both therapeutic and illicit, are being introduced at a rapid rate into society, and their effect on white matter may be made visible by MRI.

1. Radiation

Cerebral irradiation is an established therapeutic modality in the treatment of primary and metastatic brain tumors. It has become clear in the past two decades that one of the side effects of brain irradiation is leukoencephalopathy. Three phases of white matter disease following irradiation are recognized. The first is an acute reaction, in which confusion or transient worsening of preexisting neurologic deficits occurs during treatment. CT or MRI scans show mild diffuse changes in the white matter that have been attributed to edema. This syndrome is fully reversible. The next phase is the early delayed reaction, which occurs weeks to months after treatment and may involve a variety of neurobehavioral deficits, including somnolence, apathy, memory loss, or dementia. More extensive white matter changes can be seen on neuroimaging studies, and cerebral demyelination is the neuropathologic correlate. This syndrome is also reversible in most cases. The most ominous reaction is the late delayed reaction, which develops 6 months to 2 years after treatment and features a progressive dementia that is due to widespread demyelination and necrosis. Treatment for all these phases is supportive, although corticosteroids are often employed with variable efficacy.

2. Therapeutic Drugs

As the development of new drugs for treating medical diseases steadily advances, so does the potential for toxicity from these agents. Many new drugs have been found to cause leukoencephalopathy, although the mechanism by which this toxicity occurs is obscure.

a. Chemotherapeutic Agents As in the case of cerebral irradiation, the white matter is the target of many of the pharmaceutical agents used in the treatment of cancer. The growing list of antineoplastic agents associated with leukoencephalopathy results in part from improved supportive care of cancer patients that has permitted higher doses and longer survival periods during which adverse effects may appear.

In general, these drugs cause a syndrome that is clinically, neuroradiologically, and neuropathologically similar to radiation leukoencephalopathy. Neurobehavioral features are particularly characteristic and may include lassitude, drowsiness, confusion, memory loss, and dementia. Methotrexate was the first antineoplastic drug found to cause leukoencephalopathy, which is its most common and significant toxicity. 1,3-Bis(2-chloroethyl)-1-nitrosourea is also well recognized to cause white matter changes. Other drugs have often been recognized as white matter toxins because of findings on MRI. Little is known of treatment other than minimization of exposure and supportive care.

b. Immunosuppressive Agents Organ transplanation has become commonplace in recent decades, and immunosuppression has become a necessary component of postoperative care to prevent organ rejection. Two drugs, cyclosporine and tacrolimus, have been associated with leukoencephalopathy. Reversibility has been observed with cessation of therapy.

c. Antimicrobials Two antimicrobial agents may result in leukoencephalopathy. Amphotericin B is a mainstay of fungal infection treatment, and white matter damage is one of its many toxicities. Hexachlorophene is an antiseptic agent that can cause this syndrome if absorbed through the skin in sufficient quantity.

3. Drugs of Abuse

The neurotoxicology of illicit drugs is not well understood in general. Drug abusers often abuse more than one agent, and it is difficult to determine the effects of one drug in isolation. There are examples, however, of relatively pure syndromes of impairment, and certain drugs have a known or putative effect on the cerebral white matter.

a. Toluene This drug, methylbenzene, is an organic compound widely used in industry and is the major solvent found in spray paints. Occupational

Figure 6 MRI scan of a patient with toluene leukoencephalopathy. The cerebral white matter is severely affected, and there is also marked ventricular enlargement and brain atrophy (reprinted with permission from *Neurology* **40,** 533, 1990).

exposure to toluene occurs in painters and other workers, but it is debated whether low-level toluene exposure has any deleterious effects. In contrast, toluene abuse may have dramatic sequelae. Intentional inhalation of toluene vapors from products such as spray paint leads to euphoria, and abuse of toluene over extended periods may produce severe leukoencephalopathy. Clinical studies of individuals who inhaled toluene fumes on a regular basis for months to years have documented dementia, ataxia, and various other neurologic deficits. Cognitive dysfunction is particularly devastating, and the severity of the neurobehavioral deficits approximately correlates with the duration of exposure to toluene. MRI scans reveal diffuse white matter change in the cerebrum (Fig. 6) and cerebellum, and autopsy studies disclose diffuse myelin loss without damage to cortical or subcortical gray matter. Abstinence arrests the neuropathologic process, but there may be little recovery of function if enough white matter damage has occurred. Toluene leukoencephalopathy offers one of the best examples of a major neurologic and neurobehavioral disorder caused by selective white matter involvement.

b. Ethanol The neurology of alcohol has received much attention, and many classic neurologic syndromes—including acute intoxication, withdrawal states, cerebellar ataxia, and peripheral neuropathy—are well recognized in alcohol abusers. However, the pathophysiology of alcohol's effects on the brain are not as well understood. A nutritional deficiency of thiamine (vitamin B_1) is known to cause the Wernicke–Korsakoff syndrome, in which acute confusion, ophthalmoplegia, and a gait disorder can herald the onset of severe amnesia; however, other mechanisms may also contribute to neurobehavioral dysfunction. Substantial evidence, both in humans and in laboratory animals, has been gathered for a direct toxic effect of alcohol on cerebral white matter. Thus, in contrast to the isolated amnesia of the Korsakoff's syndrome, it may be appropriate to consider the syndrome of alcoholic dementia, in which more widespread intellectual deterioration occurs in the setting of toxic white matter damage.

c. Heroin This narcotic drug does not cause leukoencephalopathy when abused by the usual routes of inhalation or injection, but the syndrome has been reported to appear after the inhalation of heroin pyrolysate, a form of the drug resulting from the heating of heroin on tin foil. Memory loss, dementia, akinetic mutism, cerebellar signs, and impaired gait may ensue. Neuroimaging and neuropathologic studies demonstrate white matter degeneration, but the specific toxic agent remains unknown.

d. Methylenedioxymethamphetamine Methylenedioxymethamphetamine (MDMA), also known as ecstacy, has recently become widely popular. Leukoencephalopathy has been reported in individuals exposed to MDMA, possibly related to its effects on serotonergic neurons.

4. Environmental Toxins

Although there are few environmental toxins that affect the white matter, others may be unrecognized. The chemical diversity of the toxins that are known suggests a variety of mechanisms.

a. Carbon Monoxide Carbon monoxide (CO) is a ubiquitous molecule in industrialized society, and human exposure may be accidental or related to suicide attempt. The usual picture of CO intoxication results from cerebral hypoxia that predominantly affects the neocortex, hippocampus, basal ganglia, and cerebellum. A syndrome of leukoencephalopathy may be seen in some patients, however, and typically

develops days or weeks after exposure. This syndrome may produce abulia, parkinsonism, dementia, and akinetic mutism. Recovery is variable, and a decrease in abnormal white matter signal on MRI may parallel clinical improvement.

b. Arsenic Arsenic neurotoxicity is rarely encountered and typically involves the peripheral nervous system. Acute and prolonged encephalopathy may also be seen, and available neuroimaging and neuropathologic information suggests that white matter hemorrhage and necrosis are responsible. Treatment with chelating agents may be effective.

c. Carbon Tetrachloride This is a widely used hydrocarbon in home and industrial settings. The primary toxicity of this chemical falls on the kidneys and liver, but neurotoxicity has occasionally been reported. Severe hemorrhagic white matter changes in the cerebrum, cerebellum, and brain stem may follow carbon tetrachloride exposure.

F. Metabolic Disorders

The cerebral white matter is vulnerable to certain metabolic disturbances. Although this category of disease is more likely to affect gray matter because of the great sensitivity of neuronal cell bodies to metabolic dysfunction, the white matter is particularly susceptible to some metabolic disturbances. The pathogenesis of these disorders is incompletely understood.

1. Cobalamin Deficiency

A lack of cobalamin, or vitamin B_{12}, is a well-known cause of the spinal cord disease known as subacute combined degeneration. Less commonly, cobalamin deficiency may cause neurobehavioral manifestations ranging from personality change to dementia. As in the spinal cord, the brain white matter is affected by vitamin B_{12} deficiency, a finding that may be visible on MRI scanning. Replacement of cobalamin can result in substantial clinical improvement and resolution of neuroradiologic abnormalities.

2. Folate Deficiency

Folate, or folic acid, deficiency is a less common cause of mental status change than cobalamin deficiency. Sporadic case reports indicate that neurobehavioral dysfunction can be seen with folate deficiency, and that replacement of the vitamin can be beneficial. There is also evidence that white matter changes in the brain result from a lack of this vitamin.

3. Hypoxia

As mentioned previously, hypoxia can occasionally cause damage to the cerebral white matter. Diminished oxygenation from any cause can lead to delayed postanoxic demyelination. If the patient survives, treatment is supportive, and the degree of recovery is inversely related to the severity of anoxic injury.

4. High-Altitude Cerebral Edema

This is a potentially fatal disorder seen in persons at high altitude who have acute mountain sickness or high-altitude pulmonary edema. Affected individuals may experience an acute confusional state and ataxia, often in association with white matter hyperintensities on MRI that are particularly prominent in the splenium of the corpus callosum. The syndrome is reversible with removal from altitude and supportive care, and it is thought to be due to vasogenic edema that has a predilection for the white matter.

5. Central Pontine Myelinolysis

In this disorder, most often seen in alcoholics, damage to brain stem and cerebral white matter is seen in patients who have a rapid correction of hyponatremia. Pronounced neurobehavioral and neurologic dysfunction can be observed. The condition is thought to stem from osmotic demyelination. Although early reports suggested a poor prognosis, later experience has demonstrated that recovery can often occur.

6. Marchiafava–Bignami Disease

This disease is also seen most frequently in alcoholics, but its etiology is unclear because nondrinkers may occasionally be affected as well. There is extensive demyelination of the corpus callosum, and often extracallosal white matter damage is also seen. Neurobehavioral deficits are paramount and recovery is variable.

G. Vascular Diseases

All areas of the brain, including both gray and white matter, are vulnerable to vascular insults. Vascular lesions of the cerebral white matter have recently been better recognized because of the ready availability of MRI scanning, and a growing understanding of the importance of these lesions is emerging. Most of the work in this area has been done with older adults, in whom white matter changes on MRI, whether pathologic or associated with normal aging, are frequently encountered.

1. Binswanger's Disease

In this disease, also known as subcortical arteriosclerotic encephalopathy, there is diffuse ischemic damage to the cerebral white matter along with a scattering of lacunar infarcts. Deep gray matter structures are also affected to a variable extent. Nearly all reported patients have had hypertension. Affected persons develop an insidious dementia with prominent neuropsychiatric features, focal neurologic signs, gait disorder, and incontinence. MRI scans have shown marked leukoencephalopathy, and the severity of clinical involvement is generally commensurate with the degree of white matter abnormality. The pathophysiology involves ischemic demyelination as a result of hypoperfusion of the cerebral white matter. Treatment is limited to prevention of disease progression by attention to cerebrovascular risk factors; specific pharmacologic treatment targeted to cholinergic and other systems has been considered, but its efficacy is unknown.

2. Leukoaraiosis

Leukoaraiosis (LA) is the term applied to the frequent finding in older persons of white matter changes on neuroimaging studies that take the form of low densities on CT and hyperintensities on T2-weighted MRI scans. Much controversy has swirled around both the origin and the significance of these findings. Many neurologically normal older people, for example, have apparently incidental white matter changes on CT or MRI. Neuropathologic studies of these changes have suggested that they are ischemic in origin, and that when they are more severe white matter infarction can be seen. Regarding clinical significance, it appears that white matter infarcts, even a single one, may have neurobehavioral sequelae if careful evaluation is undertaken, and that multiple infarcts clearly can lead to dementia. Whether white matter ischemia alone has neurobehavioral effects remains unclear, although evidence is accruing that these effects may be detectable when a certain threshold of involvement is reached. On this basis, it has been suggested that LA lies on the same continuum as Binswanger's disease.

3. CADASIL

Newly described in the past decade, CADASIL (cerebral autosomal-dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is a genetic disorder of cerebral white matter in which ischemia and infarction slowly erode neurologic and neurobehavioral function. The disease is known to be caused by one of several mutations in the notch 3 region of chromosome 19, and characteristic granular osmiophilic material is seen in the walls of arterioles on electron microscopy. The clinical course begins in adulthood and may be characterized by neuropsychiatric dysfunction, migraine, stroke, and dementia. MRI scans regularly show leukoencephalopathy, even in individuals who are asymptomatic. Treatment is limited to supportive care and prevention of cerebrovascular risk factors that can exacerbate the process.

4. Migraine

This is a common syndrome of recurrent headache that is most often seen in young adults who are otherwise healthy. Even though these headaches are sometimes referred to as "vascular" headaches, the pathophysiology may not primarily implicate vascular mechanisms. It has been noted that migraineurs have slightly more MRI hyperintensities than do age-matched control subjects, and it is possible that episodic intracerebral vasoconstriction participates in their development. Clinical mainfestations of these changes have not been established, and no specific treatment other than migraine control is indicated.

5. Periventricular Leukomalacia

Recent improvements in neonatal care have led to the increasing survival of premature babies. One neurologic complication encountered in these very vulnerable infants is periventricular leukomalacia, a destructive disorder of white matter related to perinatal asphyxia. Extensive cerebral white matter injury can be seen that leads to hydrocephalus or brain atrophy. The cortex and deep gray matter are relatively normal, implying a

special vulnerability of white matter to asphyxia. Cerebral palsy and mental retardation are frequent long-term sequelae and may be severe.

6. Eclampsia

This is a disorder of pregnancy involving hypertension, proteinuria, and peripheral edema. In addition to seizures, which are characteristic of the disorder, affected patients may experience headache, visual disturbances, focal neurologic deficits, and mental status alterations including coma. MRI scans reveal white matter hyperintensities, often with a posterior predominance. These changes are reversible, indicating that they result from temporary extravasation of fluid into the white matter from vessels with a damaged blood–brain barrier.

7. Hypertensive Encephalopathy

As in eclampsia, this disorder is characterized by reversible changes in the cerebral white matter that represent edema rather than infarction. Hypertensive encephalopathy develops when blood pressure rises abruptly, and clinical features include headache, papilledema, nausea, vomiting, and mental changes ranging from confusion to coma. The exact pathophysiology is still debated, but control of elevated blood pressure effects prompt recovery.

8. Cerebral Amyloid Angiopathy

This disorder, often but not always seen in patients with Alzheimer's disease (AD), has long been known to be a cause of lobar hemorrhage. It has recently been recognized that deposition of amyloid in cerebral arterioles may also lead to leukoencephalopathy, presumably because of hypoperfusion in arterioles supplying the deep white matter. Thus, white matter changes that are sometimes seen in patients with AD may be related to this condition, and in other patients, the clinical and neuropathologic picture may resemble that of Binswanger's disease.

H. Traumatic Disorders

Physical injury to the brain may take many forms. In recent years, there has developed a better understanding of the range of neuropathology that may occur and the clinical consequences of these injuries. Damage to the cerebral white matter has emerged as a prominent component of brain injury.

1. Traumatic Brain Injury

The problem of traumatic brain injury (TBI) represents one of the most important in neurology and medicine. At least 500,000 new cases of TBI occur annually in the United States, many of which are severe enough to cause lifelong disability. In the majority who have less serious injuries, cognitive and emotional dysfunction often cause significant disruption during the process of recovery. TBI has many effects on the brain, depending on the type and severity of the injury and associated systemic injuries, but the most consistent neuropathology in TBI is a phenomenon called diffuse axonal injury (DAI). Experimental and clinical studies have confirmed that TBI causes shearing injury of axons mainly in the white matter of the cerebrum, corpus callosum, and brain stem. These changes can be seen on MRI in many cases and have been well documented in postmortem brains. DAI is present in brain injuries ranging from concussion to severe TBI, and the clinical severity is largely determined by the degree of shearing injury. DAI is thought to produce prominent disturbances of arousal, attention, memory, executive function, and comportment, all of which play a role in the clinical symptomatology of TBI of any severity. Treatment depends on degree of injury, but in general, rehabilitation measures are the mainstay; these may involve a combination of drug therapy, psychological assistance, and physical, occupational, and speech therapy. The outcome for mild TBI is generally favorable despite often long periods of seemingly slow progress, but moderate or severe TBI often portends a lifetime of problematic deficits in cognition, emotion, and behavior.

2. Shaken Baby Syndrome

In the past three decades, there has been growing awareness of the problem of child abuse involving the violent shaking of babies. This is a special category of TBI in which blunt head trauma may not occur but diffuse axonal injury is nonetheless present. Babies with this injury may present with signs ranging from lethargy and irritability to seizures and coma. Neuroimaging studies show diffuse white matter damage, and autopsy studies have documented diffuse axonal injury resulting from extreme rotational force. If infants survive such a catastrophe, the outcome may be lifelong severe impairment or lesser degrees of disability.

3. Corpus Callosotomy

This procedure causes an iatrogenic lesion and is undertaken in an effort to control intractable epilepsy. The rationale is that seizures that begin in one hemisphere can be contained therein by severing the callosal connections to the other hemisphere. Because naturally occurring lesions of the corpus callosum are uncommon, these patients have provided a source of investigation for callosal function. In general, the effects of such a dramatic procedure are surprisingly inapparent, and patients function relatively normally. The "unity of consciousness" is well integrated despite the two halves of the brain being anatomically separated. However, detailed testing may reveal callosal deficits, such as left unilateral ideomotor apraxia, agraphia, hemialexia, and tactile anomia.

I. Neoplasms

Brain tumors, whether benign or malignant, typically involve widespread cerebral areas that include both gray and white matter. This is particularly true of those tumors that induce surrounding edema and thus affect even more adjacent tissue. Thus, neoplasms in general are not well suited to considering the effects of discrete focal lesions on brain function. Nevertheless, some tumors have a predilection for gray or white matter, at least early in their course, and some preliminary clinical correlations can be made.

1. Gliomatosis Cerebri

This rare neoplasm has the greatest selectivity for the cerebral white matter of any brain tumor. Patients with this lesion present with personality changes, cognitive decline, focal neurologic signs, and seizures, and they are found to have diffuse neoplastic invasion of the white matter on neuroimaging studies. The origin of the tumor is debated because neuropathologic study has not identified any characteristic histopathology. Due to the high malignancy of this tumor, the prognosis is poor.

2. Diffusely Infiltrative Gliomas

The three types of glioma are the astrocytoma, the oligodendroglioma, and the ependymoma. All these malignancies arise from white matter, and a variety of subtle personality and cognitive changes may be detected before seizures, focal neurologic signs, and hydrocephalus develop. The white matter is also implicated in the neurobiology of gliomas by virtue of the fact that they spread throughout the brain along white matter tracts. The prognosis of these tumors is generally unfavorable despite vigorous surgical and medical treatment.

3. Primary Cerebral Lymphoma

In the usual case, this tumor is derived from B lymphocytes and may be either uni- or multifocal. Brain lymphoma tends to occur in patients who are immunocompromised because of AIDS or the chronic use of immunosuppressive drugs. Periventricular white matter involvement is common, and lymphoma often appears in the differential diagnosis of AIDS patients with white matter lesions on MRI. Personality and cognitive changes along with focal motor deficits are common with this lesion. Because of the high radiosensitivity of this tumor, the prognosis is relatively favorable.

J. Hydrocephalus

Hydrocephalus is a condition of an excessive fluid collection in the brain. Normally, the ventricles of the adult brain contain approximately 25 ml of cerebrospinal fluid, and an increase in this amount may be pathologic. There are situations in which hydrocephalus *ex vacuo*—excessive fluid that simply replaces lost brain tissue—may be of little consequence or even normal, but hydrocephalus that compromises brain function is clinically significant. The reason for this is primarily the effect of excess fluid on the cerebral white matter that surrounds the lateral ventricles.

1. Congenital Hydrocephalus

This term refers to hydrocephalus occurring *in utero* or early in the postnatal period that causes an actual increase in head size because the cranial bones of the skull are not fully fused until the end of the second year of life. Because the brain expands under internal pressure and the skull is soft and malleable, the head measurably enlarges. The common etiologies of this problem are germinal matrix hemorrhage in preterm infants, fetal and neonatal infections, Chiari malformation, aqueductal stenosis, and the Dandy–Walker syndrome. Symptoms may be irritability, poor feeding, torpor, and coma. If treatment with the use of a shunting procedure is not undertaken, mental retardation is frequent.

2. Occult Tension Hydrocephalus

In this situation, hydrocephalus becomes evident only after the cranial sutures have closed and the skull is no longer expandable. The disorder may actually be arrested and never clinically apparent, but in other cases there may be headache, cognitive slowing, inattention, perseveration, and other signs of frontal dysfunction. Eventually, gait disorder, dementia, and incontinence may develop. Shunting procedures may be very effective.

3. Normal Pressure Hydrocephalus

Normal pressure hydrocephalus (NPH) was first described in 1965 and generated substantial enthusiasm because it was thought to represent a dementia syndrome that could be treated successfully with shunting procedures. The clinical features of NPH include dementia, gait disorder, and incontinence, reflecting primary involvement of the subfrontal white matter. The disorder sometimes follows TBI, infection, or subarachnoid hemorrhage but is frequently idiopathic. Although undoubtedly some cases exist that have been successfully reversed with a shunt, these cases are disappointingly rare; moreover, complications of the shunt procedure are common. Nevertheless, NPH is a good example of dementia due to potentially reversible structural involvement of the cerebral white matter.

III. FUNCTIONS OF CEREBRAL WHITE MATTER

From the foregoing review of cerebral white matter disorders, it is apparent that a wide range of clinical manifestations can occur. Because disturbed functions can often be correlated with specific lesions, these clinical features provide an opportunity to consider the operations of the cerebral white matter in the normal brain. Although many questions remain unanswered about the role of white matter in the many different spheres of brain activity, it is possible to provide some detail on this topic and, by implication, a overview of the importance of white matter in general. These functions of cerebral white matter are differentiated between those that are neurologic and those that are neurobehavioral. This distinction is used to highlight the emerging understanding that white matter lesions may interfere with higher cognitive and emotional functions of the brain as well as elemental functions, such as vision, motor ability, and somatic sensation.

A. Neurologic Functions

Among its many functions, the brain is well-known to control bodily activities such as vision, movement, and sensation. These functions are also shared by many nonhuman animals, and the descriptor "elemental" is thus appropriate to categorize these in a broad sense. Cerebral white matter disorders clearly disturb these functions. The clinical significance of deficits in elemental function needs little explanation; patients with MS, for example, may suffer greatly from chronic problems, including blindness and paralysis. The neurology of white matter disease has mainly concentrated on these deficits, which may be disabling even in the absence of superimposed neurobehavioral deficits.

1. Vision

Of all the sensory systems, the greatest amount of neural tissue is devoted to vision, and blindness is one of the most disabling sensory losses. White matter plays a crucial role in vision; the optic tracts and the thalamocortical radiations convey visual input from the eyes to the occipital cortex for central processing. A variety of visual deficits may follow cerebral white matter lesions; examples include blindness from bihemispheric demyelinative disease in patients with MS and hemianopia from a vascular lesion in the occipital white matter.

2. Motor Function

The capacity to engage in motor activity is essential for successful existence. Motor function is subserved by a highly organized multilevel neural system in which cerebral white matter plays a vital role. The corticospinal and corticobulbar tracts provide controlling input to lower systems in the spinal cord and brain stem, respectively. Lesions of these tracts may produce paresis, paralysis, spasticity, incontinence, dysarthria, and dysphagia. A wheelchair-bound existence from the effects of motor system lesions is one of the most feared sequelae of cerebral white matter disorders.

3. Somatic Sensation

Just as the capacity for movement is critical, so is the ability to receive stimuli from the external environment. Cerebral white matter participates in the somatosensory system at the level of thalamocortical radiation that transmits somatic sensory information received by the thalamus to the parietal cortex.

Numbness, tingling, and impaired function can occur with lesions involving this sensory system.

B. Neurobehavioral Functions

The higher functions of the brain include the cognitive and emotional aspects of human behavior. These have traditionally been attributed to the activities of the cerebral cortex, and the term "higher cortical function" has become entrenched in much of the literature because of this assumption. However, much evidence has demonstrated that the cerebral white matter is also important in the mediation of higher brain operations. This evidence comes primarily from the study of neurobehavioral dysfunction in individuals with lesions of the cerebral white matter. It may therefore be appropriate to use the term "higher cerebral function" in describing the neurobehavioral repertoire of human beings. The white matter participates in distributed neural networks that mediate all aspects of higher brain function.

1. Cognition

Cognition can be considered generally to be those mental capacities such as attention, memory, language, visuospatial skills, and reasoning that are commonly referred to as "thinking." Whereas these abilities clearly cannot proceed normally without a functioning cerebral cortex, white matter also makes an important contribution to normal cognition by joining cortical and subcortical areas into unified neural networks that subserve neurobehavioral capacities. Therefore, white matter lesions interrupt normal behavior by disconnecting components of these networks, even though these components may themselves be intact. One of the most common neurobehavioral deficits in patients with white matter disorders is cognitive dysfunction, and in many patients this loss of intellectual ability reaches a level that meets criteria for dementia. This syndrome is due to widespread white matter involvement that disrupts many cognitive domains simultaneously. Evidence indicates that a specific neurobehavioral pattern may characterize this syndrome; this "white matter dementia" may involve deficits in sustained attention, memory retrieval, visuospatial skills, frontal lobe function, and psychiatric status, with relative preservation of language, procedural memory, and extrapyramidal function. This profile of deficits and strengths is consistent with that which would be expected from the higher concentration of white matter in the frontal lobes and the right hemisphere. In other cases, in which there is more focal white matter involvement, specific neurobehavioral syndromes have been convincingly described, including amnesia, aphasia, alexia, apraxia, agnosia, executive dysfunction, and callosal disconnection. Thus, depending on its location, cerebral white matter disease may interfere with cognition as a whole or with selected cognitive domains.

2. Emotion

Emotion has long defied precise definition, but it is useful in a general sense to regard emotion as those mental activities approximately equivalent to "feelings." Emotions are powerful motivators in human life and clearly have their origin in brain activity. The neurosciences heretofore have not devoted as much attention to emotions as to cognition, but data are accumulating to indicate that this large group of human afflictions can be understood in terms of disorders of the brain, including those affecting cerebral white matter. White matter systems in the frontal and temporal lobes are most directly involved with emotion, and in particular, those tracts intimately connecting structures of the limbic system are thought to be of primary importance. Many individuals with cerebral white matter lesions experience changes in emotional status. Depression appears to be the most common syndrome, and it may result from white matter lesions interfering with the activity of neurotransmitter systems mediating mood as well as from the patient's psychological reaction to the disease. Other syndromes commonly encountered include bipolar disorder, emotional incontinence, euphoria, and psychosis. Because the study of neurobehavioral aspects of white matter is still in an early stage, more recognition and understanding of these and other syndromes is likely in the future.

IV. CONCLUSION

Disorders of cerebral white matter are common, and their clinical sequelae have been found to range from the subtle to the catastrophic. The number of disorders affecting this subdivision of the brain is substantial, and more are likely to be added as new clinical, neuroradiologic, and neuropathologic information appears. Although elemental neurologic dysfunction has been well established and is important in the

clinical manifestations of these disorders, a growing recognition of neurobehavioral dysfunction has emerged in recent years. Thus, the clinical impact of cerebral white matter disorders may be more significant than is currently appreciated.

Much work remains to be done on the etiology, pathogenesis, and treatment of these disorders. Given the wide variety of neuropathology that can occur, these tasks will require the contribution of neuroscientists and clinicians from many specialty areas. However, as a general rule, the prognosis for white matter disorders appears to be more favorable than that for gray matter diseases. In contrast to many disorders of gray matter that involve irrevocable destruction of neuronal cell bodies, there is frequent sparing of axons despite damage to myelin, and effective treatment seems more feasible. This therapeutic opportunity is another incentive to pursue the study of this group of disorders.

Finally, the cerebral white matter disorders offer a unique insight into brain function. The profound impairments that can attend lesions of white matter serve to illustrate that these tracts are essential components of distributed neural networks that subserve both elemental and higher cerebral functions. This principle is particularly well applied to the phenomena of cognition and emotion, in the operations of which the white matter plays an indispensible role. By considering the deficits that follow white matter lesions, an elegant view of the structure and function of the normal brain can be achieved. The prospects for continued advances in this area are bright, and these advances promise to assist both in the understanding of the human brain and in the alleviation of some its more tragic afflictions.

Cerebrovascular Disease

JOHN R. ABSHER
Absher Neurology and Wake Forest University Baptist Medical Center

GLOSSARY

autoregulation The brain's ability to control blood flow across a wide range of systemic blood pressure.

embolism The passage of clot, bubbles, or other discrete objects through the bloodstream.

infarction Irreversible tissue damage resulting from inadequate oxygen delivery, such as that due to hypoxia or ischemia.

ischemia Insufficient blood flow leading to reversible tissue injury that may progress to infarction or resolve without causing tissue damage.

neuroprotection Drug treatments that prevent, inhibit, or block processes that damage the nervous system.

thrombolysis The process of dissolving blood clots in order to restore blood flow.

thrombosis Coagulation of blood, the process of clotting, resulting in thrombus formation.

Cerebrovascular diseases are disorders or diseases of brain (cerebral) blood vessels, cerebral blood flow (CBF), or cerebral oxygenation. The vessels that supply blood to and from the brain constitute the cerebral vasculature. The brain typically derives its blood supply from four large arteries. Smaller arteries and arterioles supply the microvasculature. The microvasculature drains into intracerebral veins that then drain into the venous sinuses. The venous sinuses empty into the deep veins of the neck. Cerebrovascular disorders may originate within any segment of the cerebral vasculature, from cardiac or arterial disease, systemic emboli, hypercoagulable states, hypotension, and many other conditions. Even when CBF is normal and the vessels are healthy, oxygen delivery or oxygen metabolism may be inadequate to maintain brain viability. In this article, current concepts and advances in cerebrovascular disease are summarized.

I. INTRODUCTION

The field of cerebrovascular disease is focused largely on stroke, the sudden interruption of cerebral blood flow (CBF) or oxygen supply that results in brain failure. The field is concerned with chronic, progressive conditions that may limit blood flow and oxygenation (e.g., high blood pressure, pulmonary disease, and arteriosclerosis) as well as acute, devastating events (e.g., sudden occlusion of a cerebral artery due to cardiogenic cerebral embolism or ruptured aneurysm with brain hemorrhage). Risk factors contributing to stroke, such as chronic hypertension and diabetes, are encompassed by the study of cerebrovascular disorders. All events surrounding the actual stroke and its immediate management are thus central to the field. This includes all manner of testing related to the detection, treatment, and understanding of brain damage and dysfunction due to cerebrovascular disease. The prevention and post-acute management of stroke, including risk factor modification and rehabilitation, are also fundamental to the field. The cerebrovascular disorders are ubiquitous and may affect individuals of any age, and the study of cerebrovascular disease is a multidisciplinary medical specialty.

Advances in clinical diagnosis, testing, and therapy have led to substantial gains in the field of cerebrovascular disease, and these gains are emphasized in this article. Large epidemiologic studies have improved our understanding of demographics and stroke risk factors. Knowledge about the underlying causes of stroke and the mechanisms of tissue injury has prompted interest in the primary prevention of stroke through risk factor modification. Neuroprotective interventions are being developed to stop the process of tissue injury during the stroke, and tissue plasminogen activator (tPA) is now available for patients with acute stroke. Multidisciplinary stroke care teams and specialized stroke units have evolved that include interventional neuroradiologists, neurosurgeons, neurointensivists, and neurologists. Functional restoration and cognitive rehabilitation have become important aspects of neurorehabilitation. Novel methods for predicting which patients are most likely to benefit from therapy are emerging, such as transcranial magnetic stimulation and functional magnetic resonance imaging (fMRI). The detection and characterization of cerebrovascular disease are facilitated by the growth of MRI. There are now several advanced neuroimaging techniques for cerebrovascular diseases, including MR angiography (MRA), diffusion weighted imaging, perfusion weighted imaging, and MR venography (MRV). It is now possible to distinguish acute from chronic cerebral ischemia, and to estimate the age of an intracerebral hemorrhage. Cerebral blood flow may be quantitated using computed tomography (CT), single photon emission computed tomography (SPECT), and positron emission tomography (PET). Cerebral blood flow may be estimated using transcranial Doppler (TCD) and MRA. These and other advances have substantially lowered the risk of stroke and improved the outlook for those who experience a stroke.

A. Financial and Societal Significance

Advances in health care policy research have clarified the costs associated with the cerebrovascular diseases. Direct costs include hospital and nursing home care expenditures, physician and other professional service costs, pharmaceutical costs, home health care costs, and the cost of durable medical equipment. Indirect costs include lost productivity from work due to morbidity and mortality. The direct costs of stroke are approximately $30 billion annually, and indirect costs are approximately $20 billion (i.e., $50 billion annually in the United States alone). For Americans aged 40 and older, the average in-hospital and physician costs for stroke were $11,010 based on 1995 data. In 1996, the average cost of a stroke from hospital admission to discharge was $18,244 for people under the age of 65. Table I shows these costs in relationship to other vascular diseases and emphasizes the tremendous financial impact of stroke on society.

B. Cerebrovascular Disease Demographics

Cerebrovascular disease is estimated to affect 600,000–730,000 individuals each year in the United States, and it is currently the third leading cause of death behind cardiovascular diseases and cancer. Seventy-two percent of all persons with stroke are at least 65 years of age, and 29% of these individuals die within a year of the stroke. Although the stroke death rate decreased by 13.9 (per 100,000 people per year) from 1987 to 1997, the prevalence of stroke (the number of people alive who have had one or more strokes) increased by 6.6% during the same period. This paradox relates to the demographic shift in the population, the expansion of the proportion of the population aged 65 and older. Thus, although the age-specific incidence and

Table I
Costs and Demographics of Stroke[a]

	Cost (billions)				
Disease	Direct	Indirect	Total	Annual deaths	Prevalence
Coronary heart disease	55.20	63.00	118.20	466,101	12,200,000
Stroke	30.60	20.70	51.30	159,791	4,400,000
Hypertensive disease	26.10	11.10	37.20	42,565	50,000,000
Congestive heart failure	20.30	2.20	22.50	45,419	4,600,000
All cardiovascular disease	185.80	140.80	326.60	953,110	59,700,000

prevalence of stroke is declining (i.e., the incidence and prevalence at a specific age), overall stroke prevalence continues to climb.

The frequency of stroke varies considerably from one geographic area to another. In the Russian Federation, the annual stroke death rate per 100,000 people is 374 for men and 231 for women aged 35–74. This was the highest rate for both men and women among the data reported in the 1998 World Health Statistics Annual. The country with the lowest risk is Switzerland (for both men and women), where the annual stroke death rates are less than 10% of those reported for the Russian Federation. Within the United States, the state with the highest stroke death rate is South Carolina (87.9 per 100,000 people); its rate is nearly twice as high as that of New York, the state with the lowest stroke death rate (45.1). Several southern states besides South Carolina have high stroke death rates, including its closest neighbors, North Carolina (81.5) and Georgia (75.6) (Fig. 1).

C. Stroke Risk Factors

Stroke risk factors are very well understood. Both modifiable and nonmodifiable risk factors are important. The nonmodifiable stroke risk factors are age, ethnicity, and sex. There are several modifiable stroke risk factors, including hypertension, hypotension, diabetes, atrial fibrillation, congestive heart failure, coronary artery disease, smoking, hyperlipidemia, homocysteinemia, obesity, alcohol intake, and sedentary lifestyle. In addition, there are numerous predisposing factors, or stroke etiologies, including genetically inherited hematologic conditions (e.g., sickle cell disease and protein C deficiency), vascular malformation, connective tissue diseases, vasculitis, substance abuse, trauma with arterial dissection, and patent foramen ovale (Table II).

The most important modifiable stroke risk factor, hypertension, is estimated to affect approximately 50 million Americans (23% of the U.S. population), or 44% of Americans at least 65 years of age. Approximately one-third of all strokes directly relate to the impact of hypertension. Hypertension increases the risk of stroke up to 400%; the relative risk of stroke among persons with hypertension is four times higher than that among individuals lacking this risk factor. As many as 246,500 strokes might be prevented by eliminating the adverse impact of hypertension (i.e., 35% of 700,000 annual strokes). The odds that a person with hypertension will die of stroke decreases from 4 at age 50 to 1 by age 90, suggesting that the impact of hypertension declines considerably with age. The prevalence of hypertension among individuals with stroke increases substantially with age, from about 45% at age 50 to 70% at age 70. Thus, if one lives long enough with hypertension, there is a very high probability that one or more strokes will occur, either silently (without the patient's knowledge) or symptomatically (with evident problems such as paralysis, numbness, and unsteadiness).

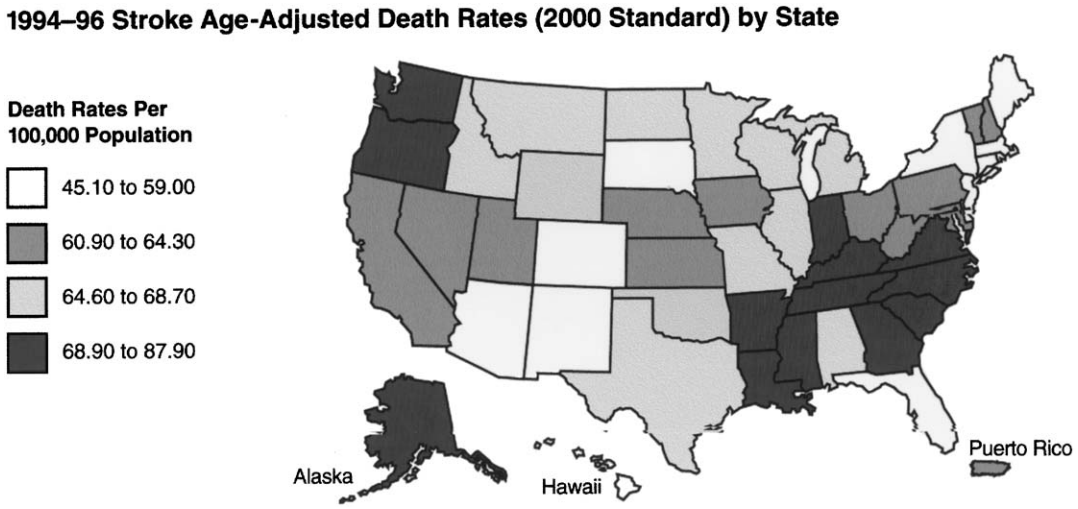

Figure 1 US map showing stroke rates by state. The annual stroke death rates for each state are depicted. Note the "stroke belt" within the southeastern U.S. (reproduced with permission, © *2000 Heart and Stroke Statistical Update*. Copyright American Heart Association).

Stroke is more common among individuals with diabetes mellitus. When stroke does occur, it is more likely to be fatal among diabetics than among nondiabetics. After controlling for other stroke risk factors, the relative risk of stroke is 1.5–3.0 among diabetics, and the impact is greatest for elderly women. Diabetes affects about one-fifth of the population, and the attributable risk of stroke is about half that of hypertension.

The prevalence of diabetes differs by racial group. For example, the prevalence of physician-diagnosed diabetes in adults aged 20 or older is 5.4 and 4.7% for non-Hispanic white men and women, respectively; for non-Hispanic blacks, the percentages are 7.6 and 9.5 for men and women; for Mexican Americans, the prevalence of diabetes is 8.1% for men and 11.4% for women. Approximately half of American Indian women aged 45–74 have diabetes. Thus, the risk of diabetes is considerably higher among minority populations than among non-Hispanic whites.

Smoking is the leading preventable cause of death in the United States and a major stroke risk factor. The risk of stroke from any cause is 1.5, but the risk of subarachnoid hemorrhage is 10 times greater among smokers than among nonsmokers. The number of cigarettes per day correlates with stroke risk. After smoking cessation, the stroke risk returns to baseline within 2–5 years.

The Honolulu Heart Program study revealed a continuous and progressive increase in coronary heart disease and thromboembolic stroke rates with increasing cholesterol levels. When the highest and lowest quartiles were compared, the relative risk of stroke was 1.4. This study helped to confirm the long-held suspicion that hyperlipidemia is an independent risk factor for stroke. Two large studies examined a lipid-lowering drug (provastatin) compared to placebo and showed a 19–31% reduction in stroke. Given the strong biological plausibility of the relationship, and the beneficial effects of cholesterol reduction on stroke risk, it seems clear that hyperlipidemia is a significant stroke risk factor.

Low blood pressure is also an important modifiable stroke risk factor. If blood pressure is insufficient to maintain blood flow to the brain, stroke will result. Certain vascular territories may be more prone to cerebral ischemia. For example, intracranial arteriosclerosis impairs the brain's ability to regulate CBF and cerebral perfusion pressure downstream from a significant narrowing (i.e., cerebral autoregulation). Chronic hypertension impairs autoregulation and increases the risk of stroke within the microvasculature. Hypertensive women seem to be more susceptible than men to stroke and silent stroke as a result of nocturnal blood pressure decline, which has been associated with the accumulation of cerebrovascular damage in many studies. Certain types of antihypertensive medications (short-acting calcium channel blockers) are more likely to lead to significant nocturnal blood pressure decline than others. Currently, there is no reliable way to determine whether blood pressure might be low enough to increase stroke risk or to determine whether specific vascular territories might be more sensitive to blood pressure decline than others.

D. Ethnic and Racial Issues

African Americans are the largest minority group in the United States, although by the Year 2009, Hispanic Americans are expected to outnumber African Americans. African Americans are far more likely to die of stroke than are whites or Hispanic Americans, and this is true for both ischemic and hemorrhagic cerebral infarction. Hispanic Americans are no more likely than non-Hispanic whites to die of ischemic infarction, but they are more likely to die of intracerebral hemorrhage. The reasons for these differences in stroke risk are incompletely understood but may relate in part to the higher prevalence of cardiovascular risk factors in the African American population. Other factors, such as socioeconomic status, educational

level, and genetic predisposition, may contribute to the high rate of stroke among African Americans.

In general, African Americans are more likely to have hypertension, diabetes mellitus, obesity, congestive heart failure, and a smoking history than are whites. Furthermore, stroke risk factors differ from one subgroup of African Americans to another. For example, hypertension affects 16% of West African blacks, 26% of Caribbean blacks, and 33% of U.S. blacks. Socioeconomic status is correlated with lifestyle and health outcomes, with lower socioeconomic groups being more likely to have poor diet, poor cardiovascular risk factor control, and lower physical activity level. However, the influence of education, income, and other socioeconomic surrogates of stroke risk is complex and requires further exploration.

Genetic influences are likely to contribute to excess stroke risk among African Americans. Sickle cell disease is a genetically inherited hemoglobinopathy that accounts for a substantial number of strokes, and the disorder is more prevalent among blacks than other racial groups. Ten percent of individuals with sickle cell anemia will have at least one stroke, and 47–93% will have recurrent stroke, with 80% of recurrences occurring within the first 36 months. Three-fourths of the strokes are ischemic, and one-fourth are hemorrhagic. Hemorrhage is more likely to occur in the elderly, whereas ischemic infarction affects children and young adults.

The presence and severity of intracranial atherosclerosis are also likely to relate to genetic factors; African Americans, Hispanic Americans, Japanese, and Chinese individuals are more likely than whites to have stroke on the basis of intracranial atherosclerosis. Extracranial disease (e.g., common carotid artery and internal carotid artery) is more prevalent among whites. Attempts to explain these racial differences have failed to identify other factors, besides perhaps sex.

Although there are clear racial differences in the occurrence of stroke subtypes, including stroke due to intracranial atherosclerosis, stroke risk factor variations across ethnic groups may be partly responsible. For example, intracerebral hemorrhage, subarachnoid hemorrhage, and lacunar infarction (small strokes <2 cm in diameter) are more common among African Americans, whereas cardioembolic strokes are less frequent. Lacunar infarctions directly relate to hypertension, diabetes, and smoking, which are all more common among African Americans than among whites. The risk of intracerebral hemorrhage may also relate to the greater prevalence of hypertension, but the reason for the twofold greater risk of subarachnoid hemorrhage among African Americans remains unexplained. It is also uncertain why cardioembolic strokes are less frequent among African Americans than among whites.

The epidemiology of stroke among Hispanic Americans is quite different from that of African Americans. Overall, Hispanic Americans are less likely than non-Hispanic whites to have a stroke. Death from stroke is more likely among younger Hispanic Americans, and less likely among the elderly Hispanics, in comparison to non-Hispanic whites. Hemorrhages are more common among young Hispanics than among non-Hispanic whites or Native Americans. The presence of hypertension as a stroke risk factor is higher (79%) among Hispanics than among non-Hispanic whites (63%), according to the Northern Manhattan Stroke Study, after controlling for the influence of socioeconomic status. Diabetes is more prevalent among Hispanic Americans (41%) than among non-Hispanic whites (26%), but cardiac disease was nearly twice as common (61 vs 32%) among non-Hispanic whites. Cholesterol levels are generally lower for Hispanic Americans, but alcohol consumption was more prevalent (37 vs 23%). Since alcohol consumption is related to the risk of intracerebral hemorrhage, this difference may partly explain the higher rate of intracerebral hemorrhage among Hispanic Americans.

Several other factors may uniquely affect the Hispanic American population. They have the highest poverty rate (30.3%) and are more likely than non-Hispanic whites to have 5 years of schooling or less (10.3%). Twenty-nine percent of Hispanic Americans speak English poorly or not at all, and 10% speak only Spanish. The language barrier may account for the observation that Hispanic Americans with acute stroke reach the emergency room with the same rapidity as non-Hispanic whites but access to neurological care is delayed. Hispanic Americans are the least likely racial group to be eligible for intravenous thrombolysis, which must be administered within 3 hr of stroke onset.

E. Impact on Health and Quality of Life

Stroke produces devastating effects on quality of life. In one large study, more than half of individuals at risk for stroke perceived "major stroke" to be "equivalent to or worse than death." Even mild language,

cognition, and motor deficits are perceived as severe deficits, greatly reducing quality of life. Initial stroke symptoms include weakness in 88% of stroke survivors, sensory deficits in 50%, and visual, cognitive, or speech impairments in 30–48%. Depression affects almost one-third of patients with stroke and half of those with left frontal lobe stroke. Caregivers are susceptible to anxiety (58%), depression (50%), fear, frustration, impatience, and resentment. Functional impairments following stroke may become the responsibility of these caregivers if other sources of social support are not sufficient, and such caregivers may be forced to leave the workforce temporarily or permanently. These intangible and indirect costs of stroke are among the most devastating to the family and the most difficult to measure. Thus, stroke substantially diminishes caregiver quality of life, and only recently have quality of life assessments begun to reveal the true impact of cerebrovascular disease.

II. OVERVIEW OF STROKE ETIOLOGIES

A. Cardiogenic Stroke

Approximately 20% of ischemic strokes are due to cardiogenic cerebral embolism. When other cardiogenic causes of stroke are included, almost one-third of all strokes relate to some form of cardiac disease. The cardiac conditions most likely to produce cardioembolic stroke are atrial fibrillation, endocarditis, diseased or prosthetic cardiac valves, rheumatic heart disease, dilated cardiomyopathy, and acute myocardial infarction. In addition, cardiac surgery is a cause of cerebral embolism.

Although embolism is the most important cardiogenic stroke mechanism, cerebral ischemia and ''watershed'' infarction may result from impaired cardiac output and low blood pressure. The longer systemic circulation is disrupted, the less oxygen is available to maintain cerebral viability. Consequently, global brain injury and damage are frequent sequelae of cardiac arrest. Cardiac arrest produces the most devastating form of stroke, hypoxic–ischemic encephalopathy with or without coma and brain death. There have been major advances in understanding the process of global ischemia and in predicting the outcome from hypoxic–ischemic coma. As a result of large studies of patients with this condition, the likelihood of meaningful recovery at 1 year can be predicted with substantial accuracy based on the presence or absence of key signs on neurological examination at specific time points following the insult. The ability to provide such prognostic information to families has been a major advance in stroke management because physicians are now better informed during discussions regarding organ donation and end-of-life decision making.

Atrial fibrillation affects 1% of the U.S. population, and the risk increases substantially with age. By age 65, 6% of individuals have atrial fibrillation, and 10% of individuals aged 75 or older are affected. In the absence of valvular disease, atrial fibrillation carries a stroke risk of 5% per year. In patients with concurrent hypertension, diabetes, coronary artery disease, congestive heart failure, or prior stroke, the risk increases to 6% per year. The identification of spontaneous echo contrast (''smoke'') during transesophageal echocardiography indicates a 14% annual risk of stroke, in contrast to a 4% risk when smoke is not evident. Treatment with warfarin decreases the risk of ischemic stroke by 68%. Patients younger than 60 years of age without concurrent stroke risk factors may not require warfarin for their ''lone'' atrial fibrillation. Instead, such individuals are often treated with antiplatelet therapy.

Infective endocarditis produces cerebral embolization and damages cardiac valve leaflets, which may become caked with fibrous tissue and bacteria (vegetations). These vegetations embolize and produce stroke in 15–20% of patients with subacute bacterial endocarditis, the most common form of infective endocarditis. It is now apparent that anticoagulation is contraindicated in subacute bacterial endocarditis. Vegetations may be identified with transesophageal echocardiography, a significant advance in the management of this disorder. Nonbacterial thrombotic endocarditis occurs in association with cancer and other chronic diseases. Platelet and fibrin deposits on the mitral and aortic valves embolize to the brain in a high percentage of cases.

Prosthetic heart valves may become damaged, infected, leak, or dislodge. The risk of cerebral embolization is 3 or 4% per year for patients on anticoagulant therapy with mechanical mitral valves, and 1 or 2% for mechanical aortic valves. The risk of cardioembolic stroke is 0.2–2.9% for patients with bioprosthetic heart valves (e.g., porcine valves).

These risks are small in comparison to the stroke risks associated with severely diseased cardiac valves. Rheumatic heart disease affects the valves and leads to cardiogenic embolism in approximately 20% of cases. In the presence of mitral stenosis, 15–17% of patients

have left atrial thrombus. When combined with atrial fibrillation, the risk of cerebral embolization increases by 17-fold. The severity and duration of mitral stenosis also increase the risk of embolization. Calcific aortic stenosis is found in 1% of patients with transient ischemic attacks or stroke. The emboli are usually small and often lead to transient monocular blindness or retinal ischemia. Mitral annular calcification and mitral valve prolapse have not been definitively linked to cardioembolic stroke risk.

Dilated cardiomyopathy carries a risk of embolization as high as 3.5%. Many causes have been proposed, including infection (e.g., viruses and Chagas disease), immunologic disorders, toxic agents (alcohol and chemotherapeutic agents such as Adriamycin), poor nutrition, pregnancy, and genetic factors. Chronic atrial fibrillation develops in 20–30% of patients. Ventricular thrombi were found in 78% of cases in one autopsy series of 152 patients. Transthoracic echocardiography detects thrombi in 11–58% of cases, and transesophageal echocardiography is even more sensitive.

Acute myocardial infarction and stroke commonly occur together. Left ventricular thrombus, a potent source of cerebral emboli, is evident in 30–35% of cases of acute myocardial infarction. Hyokinesia or akinesia, with injury to the endocardial surface, is more likely to occur with transmural, anterior wall infarcts. Thus, anterior myocardial infarction is most commonly related to stroke. Two or 3% of patients with acute myocardial infarction will have stroke within 1 month, and 10–15% develop stroke within 2 years of the myocardial infarction. The majority of strokes occur within the first 10 days.

Patent foramen ovale is thought to relate to paradoxical cerebral embolization by providing a mechanism for systemic emboli to bypass the lungs and proceed directly to the brain. In patients with stroke from unknown cause, 40% have patent foramen ovale, compared to 10% of controls. When no other cause of stroke can be identified, the occurrence of patent foramen ovale is 54%, suggesting that patent foramen ovale is an independent risk factor for stroke.

B. Large Extracranial Artery Diseases and Stroke

Aortic arch atheromatous plaque thickness directly relates to the risk of stroke. The recurrence rate for stroke is 11.9 per 100 person years when aortic wall thickness reaches 4 mm, in comparison to 3.5 per 100 person years in patients with aortic wall thickness less than 4 mm. Transesophageal echocardiography has substantially improved the detection of aortic arch disease, which had previously been very difficult to assess without angiography.

Extracranial carotid artery disease is an important cause of stroke. Carotid stenosis becomes more likely with advancing age and occurs in approximately 2–7% of individuals aged 50 or older. However, carotid stenosis of over 80% affects only 1% of the general population. Carotid artery dissection and giant cell arteritis may also lead to extracranial stenosis and stroke. Arterial dissection occurs most frequently in the setting of minor or major trauma but may occur spontaneously. The vessel wall develops a hemorrhage, which expands and narrows the lumen. The smooth lining within the vessel (endothelium) often becomes irregular and serves as a nidus for clot formation. The hemorrhage may grow sufficiently to cause stenosis and occlusion of blood flow through the damaged artery, or the clots that form at the site of the endothelial damage may embolize to the brain. In giant cell arteritis, inflammation within the wall of extracranial vessels, most often the carotid arteries, leads to ischemia and stroke. Permanent blindness results in 40–50% of cases because the blood supply to the eye is compromised, and strokes occur in approximately 10% of cases. Headache and jaw pain induced by chewing (jaw claudication) are important clues to the possibility of giant cell arteritis. An elevated erythrocyte sedimentation rate is typically found, but confirmation of the diagnosis requires temporal artery biopsy. The disorder increases in incidence with age, affecting 2.6 per 100,000 persons 50–59 years of age each year and 44.6 per 100,000 over 80 years of age each year. Whites are seven times more likely to be affected than African Americans, and women are three times more likely to have the disease than men.

The vertebral arteries may be affected by both dissection and giant cell arteritis. In addition, vertebrobasilar insufficiency may result from subclavian steal syndrome. This disorder most often occurs in the setting of severe stenosis of the subclavian artery, proximal to the origin of the left vertebral artery, due to atherosclerotic plaque. Blood may be "stolen" from the left vertebral artery, which supplies blood to the left arm rather than to the brain. Transient ischemic attacks and episodic loss of consciousness (syncope) are frequent symptoms of the disorder; large differences in blood pressures are typically encountered when the right and left arms are compared. Surgical

correction of the stenosis may prevent stroke and cure the syncope.

Fibromuscular dysplasia is an uncommon disorder affecting young women more often than men. A muscular band constricts large extracranial arteries, leading to ischemia or infarction. Several areas of narrowing may occur within a single vessel, leading to an appearance resembling a string of beads on catheter angiography. The renal arteries are often involved, and renovascular hypertension may result.

C. Intracranial Arterial Disease and Stroke

Intracranial arterial disease may lead to ischemic and hemorrhagic strokes. Aneurysms and arteriovenous malformations (AVMs), intracranial atherosclerosis, and vasculitis are some of the major diseases of intracranial arteries producing stroke. Approximately 80% of nontraumatic subarachnoid hemorrhage is due to ruptured intracranial aneurysm. Arteriovenous malformations carry a 40–50% lifetime risk of rupture with subsequent fatal or disabling hemorrhagic stroke. Central nervous system vasculitis may occur with or without coexisting systemic vasculitis. Fibromuscular dysplasia rarely affects intracranial arteries. Cerebral amyloid angiopathy may lead to both ischemic and hemorrhagic stroke. Migraine may cause sufficient constriction of intracranial arteries to produce ischemia and infarction. Vasospasm (constriction of vessels due to contraction of vascular smooth muscle) is common following subarachnoid hemorrhage. Toxic substances such as cocaine and other stimulants may lead to arterial spasm and vasculitis, with subsequent stroke.

D. Extracranial Venous Disease and Stroke

There are two situations in which extracranial venous disease may lead to stroke. Internal jugular vein occlusion may prevent drainage of the brain. Venous thromboembolism may cause paradoxical cerebral embolization. These pass through the right ventricle of the heart in most patients to produce pulmonary emboli. In patients with patent foramen ovale or other intracardiac shunt, venous blood and clots may pass from the right side of the heart to the left, where cerebral embolization is possible. This right-to-left shunting is enhanced by increasing intrathoracic pressures (Valsalva maneuver) or right heart pressures (e.g., pulmonary hypertension and right-sided heart failure). Hypercoagulable states may predispose to thrombotic disorders of the extracranial venous system.

E. Intracranial Venous Disease and Stroke

Within the brain, there are several large veins that drain into the venous sinuses. Sagittal sinus thrombosis is the most serious disorder of the intracranial venous pathways. This condition frequently leads to headache (80%), swelling of the optic nerve (papilledema, 50%), motor or sensory deficits (35%), seizures (29%), hemorrhage (50%), and death (5–10%). Contrast enhanced CT scanning allowed superior sagittal sinus thrombosis to be diagnosed by showing the "empty delta" sign. Now, MR is the preferred test, showing increased signal intensity on T1, T2, and proton density weighted images. The clot can be directly visualized using such routine MR techniques, and MRV can easily demonstrate the absence of venous blood flow caused by the thrombus. Although angiography will demonstrate the problem during the venous phase of contrast washout, MRI techniques have reduced the need for angiography for the diagnosis of sagittal sinus thrombosis.

F. Respiratory Disease and Stroke

Respiratory disturbances may cause stroke if the oxygen delivery to the brain is sufficiently impaired. For example, sleep apnea is associated with a tendency to stroke and silent stroke as well as vascular dementia. Occlusion of the airway leads to cessation of air movement (apnea), causing oxygen levels to fall (desaturation) and carbon dioxide levels to increase (hypercarbia). Oxygen desaturation may be so severe that cardiac rhythm disturbances occur. Hypercarbia stimulates respiratory drive and increases CBF, and these responses to the apnea may maintain oxygen delivery within acceptable limits. The recognition that this common sleep disorder increases the risk of stroke and silent stroke has led to improved surveillance and treatment.

Many other disorders may affect oxygen delivery and contribute to stroke. Chronic obstructive pulmonary disease, myasthenia gravis, motor neuron disease, myopathy, myositis, botulism, neuromuscular blockade, neuropathy, brain stem stroke, cervical

spine trauma, seizures, and many other conditions can affect respiratory drive or effectiveness. Even when respiratory mechanisms are intact and adequate oxygen delivery is achieved, gas exchange within the lungs may be impaired so that hypoxia and hypercarbia result. For example, emphysema, pneumonia, pulmonary embolism, and other pulmonary disorders may impair the ability for oxygen to pass from the inspired air into the bloodstream. Carbon monoxide binds to hemoglobin, thus preventing oxygen binding. Hydrogen sulfide and hydrogen cyanide are poisons that can block oxygen delivery and metabolism. Our understanding and awareness of cerebrovascular insufficiency on the basis of respiratory pathology has improved in conjunction with major advances in the fields of pulmonary medicine and critical care neurology.

G. Microvascular Disease of the Brain

Age, hypertension, diabetes, and smoking all cause damage within the microvasculature. These damaged vessels may leak protein that deposits in the walls, producing stiffness and hardening. Microvascular damage makes it difficult for the vessels to dilate and constrict. When flow through these small vessels is sufficiently diminished, a small (lacunar) stroke or silent stroke may result. Risk factor modification is the key to preventing microvascular disease and subsequent stroke. Microvascular disease of the brain affects half of all people aged 70 or older, according to large MR studies that have been done. These areas of MR signal abnormality may be due to demyelination or ischemic damage, and the demyelinating lesions are thought to have an ischemic basis as well (i.e., ischemic demyelination). Microvascular disease of the brain also relates in part to impaired blood flow during periods of relative hypotension, which leads to ischemia in brain areas with disturbed autoregulation. Stroke leads to a breakdown in cerebral autoregulation within the ischemic zone, and vascular damage from hypertension, amyloid angiopathy, atherosclerosis, and other disorders may compromise cerebral autoregulation as well. Research is under way to determine the ischemic threshold in a clinically useful way so that hypotensive ischemia within compromised vascular territories might be avoided. Currently, there is no way to know when blood pressure has been lowered sufficiently to compromise susceptible vascular territories.

H. Hematologic Disorders and Stroke

Disorders of the blood and blood products are a relatively common cause of stroke. Many hereditary conditions lead to a predisposition to the development of thrombosis, including Leiden factor V mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency. Anticardiolipin antibodies and antiphospholipid antibodies may increase stroke risk as well. Sickle cell disease, SC disease, and polycythemia rubra vera also predispose to coagulation and stroke. An overabundance of platelets (thrombocytosis) may also produce a hypercoagulable state and increase stroke risk. When there are clotting factor deficiencies, such as in hemophilia, there is an increased risk of hemorrhagic stroke. Thrombocytopenia, hepatic failure, and disseminated intravascular coagulation may also lead to brain hemorrhage.

I. Other Causes of Stroke

There are many other causes of stroke, most of which are rare. Inflammatory disorders can cause thickening of the vessel walls, with obstruction of blood flow, hemorrhage, and multifocal infarction. There are several forms of angiitis or vasculitis (Table II), including Moyamoya disease, Wegener's granulomatosis, and polyarteritis nodosa. Some forms of vascular disease are notoriously difficult to diagnose, and the vascular pathology is poorly understood (e.g., the vasculopathy of systemic lupus erythematosus). Traumatic causes of stroke include air, fat, and marrow embolism. Increased intracranial pressure resulting from trauma can lead to reduced cerebral perfusion pressure with watershed ischemia and infarction. Infections may cause stroke due to associated inflammatory changes in the vasculature (e.g., herpes zoster). Developmental vascular anomalies, such as cavernous, venous, or capillary malformations, may lead to stroke. Cardiac abnormalities such as atrial septal aneurysm can predispose to cardiogenic cerebral embolism. Infection or thrombus formation within the cavernous sinus obstructs venous flow leaving the brain and may cause stroke. Neoplasm is commonly encountered in association with nonbacterial thrombotic endocarditis, a notoriously devastating cause of cardiogenic embolism. Atrial myxomas are tumors within the atrium that may produce tumor emboli. Cryoglobulinemia is one of the many causes of hypercoagulable state that may produce stroke. The

list of stroke etiologies is extensive, and Table II is therefore incomplete.

III. DIAGNOSTIC TECHNIQUES

A. Clinical Assessment

The evaluation of stroke has recently become a medical emergency due to the availability of effective acute therapy. Stroke patients who are treated by neurologists fare better than those treated by nonspecialists and have shorter lengths of stay, lower hospitalization costs, improved functional outcome, and improved levels of satisfaction. The neurological history and examination are essential aspects of the acute evaluation. Abnormalities of relevance may be identified literally from head (e.g., papillary asymmetry) to toe (e.g., Babinski sign). Neuroimaging, neurosonology, cardiac evaluation, and hematologic testing are all important aspects of stroke management. A team approach is ideal in such situations.

B. History and Physical Examination

Information may be obtained from the patient, family members, or others during the history. A thorough history includes questions about each stroke risk factor, such as smoking, alcohol use, prior stroke, prior myocardial infarction, and family history of cardiac or cerebrovascular disease. The symptoms being experienced are defined in terms of onset, duration, exacerbating and relieving factors, fluctuations in intensity, associated or antecedent symptoms, and progression. The time of symptom onset is explicitly defined to clarify eligibility for thrombolytic therapy. Patients who awaken after prolonged sleep with stroke symptoms or who are found in an incapacitated state after an unknown length of illness are questionable candidates for thrombolytic therapy, which must be administered within 3 hr of stroke onset. A history of gastrointestinal hemorrhage or recent surgery is especially important since these may preclude the use of thrombolytic therapy. Measurement of blood pressure, respiratory rate, and heart rate (vital signs) is the first step in the examination. The carotid arteries, subclavian arteries, and heart are auscultated. The stool is tested for occult blood. The nail beds, conjunctivae, integument, and extremities are examined. Cranial nerves, motor power and tone, muscle stretch reflexes, coordination, tactile sensation, postural stability, and gait are all carefully assessed. Mental status is assessed, and detailed cognitive testing may sometimes be required.

The fields of neuropsychology, behavioral neurology, neuropsychiatry, and cognitive neurology have been strengthened through the study of patients with cerebrovascular diseases. The observation that specific lesions within the brain are commonly associated with specific patterns of impairment has led to clinically relevant and feasible "neurobehavioral" tests that may be used at the bedside. A skilled neurologist can identify cognitive or behavioral disturbances that provide important information about the site(s) of damage within the brain, and its severity, using such bedside neurobehavioral testing. Sometimes neurobehavioral alterations are the only evidence of stroke apparent on detailed examination. For example, damage within the left temporal lobe may produce severe language comprehension abnormality and rambling, nonsensical speech (Wernicke's aphasia) without other stroke symptoms, such as paralysis, numbness, ataxia, or visual loss. A thorough neurological examination, augmented when appropriate by neurobehavioral testing, is an important aspect of stroke management.

C. Neuroimaging

1. Computerized Tomography

CT is obtained urgently to exclude intracerebral hemorrhage and to identify whether imaging evidence of acute infarction exceeds one-third of the middle cerebral artery territory. In the presence of hemorrhage or large stroke, thrombolytic therapy is contraindicated. A "hyperdense MCA sign" (Fig. 2) may indicate thrombus within the middle cerebral artery and correlates with a worse outcome. Early changes of stroke may not be evident on CT for several hours after the stroke. Sudden deterioration may suggest hemorrhagic transformation of a stroke, a repeated episode of bleeding from subarachnoid hemorrhage, expansion of the size of ischemic infarction, repeated embolic infarction, deterioration due to brain swelling, or many other possibilities. Because CT is widely available and can be obtained very rapidly, it is frequently used for reassessment after such changes. In uncooperative patients, in patients that require ventilatory assistance (or other hardware that may not be exposed to the strong magnetic field of an MR machine), and in emergency situations, CT is still the test of choice.

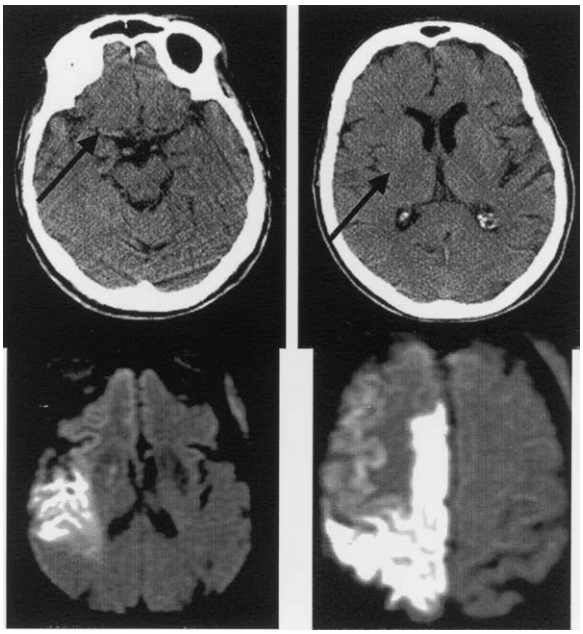

Figure 2 Acute ischemic stroke, CT, and diffusion weighted MR. The top images are slices from a CT scan obtained within hours after an acute middle cerebral artery (MCA) stroke. The "dense MCA sign" can be seen (top left, arrow), but little evidence of stroke is noted (top right, arrow). In contrast, the acute diffusion weighted MRI shows substantial hyperintensity in the ischemic area [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

Three advances in CT have increased its clinical utility. First, contrast agents provide important information about the integrity of the blood–brain barrier. In malignancy, infection, inflammatory disorders, and subacute stroke, contrast material will often escape from the vessels, producing enhancement. Contrast enhancement begins about 3 days after a stroke and may persist for weeks. Second, CT angiography is now available. Vascular contrast agents attenuate the CT signal so that high-quality images of cerebrovascular anatomy can be derived using this technique. Third, contrast materials may be combined with CT to produce quantitatively accurate information about the volume of blood within a specific brain area. The inflow (time to peak) or washout (clearance) of contrast material (e.g., Xe or iodinated contrast agents) provide quantitative information about CBF through a brain area or vessel. These techniques are becoming more widely available and are increasingly important for acute stroke management.

2. Magnetic Resonance

The use of MR to produce brain images has revolutionized the field of cerebrovascular disorders. The underlying physical principles of MR scanners enable the measurement of a large variety of phenomena, depending on the imaging technique that is utilized. Many new MR techniques have been developed and these are summarized in Table III. MRI can be useful prior to stroke (e.g., to detect silent stroke or to reveal

[a]Note that some neuroimaging techniques (e.g., PET) are not commonly used for clinical purposes. There are several new neurosonology and magnetic resonance imaging techniques (see text for details) not listed in the table. CT, computed tomography; MR, magnetic resonance; MRA, MR angiography; MRV, MR venography; FLAIR, fluid attenuation inversion recovery; SPECT, single photon emission computed tomography; CBF, cerebral blood flow; HMPAO, [^{99m}Tc]*d*,1-hexamethylpropylene amine oxime; DWI, diffusion weighted imaging; PWI, perfusion weighted imaging; and ADC, apparent diffusion coefficient.

evidence of arterial narrowing predisposing to later stroke), during the acute stages of stroke (e.g., to identify viable brain tissue at risk for infarction that may be salvaged by intraarterial or intravenous thrombolysis, as in Fig. 3), and following a cerebrovascular diagnosis (e.g., to clarify whether a hemorrhagic area was really due to stroke rather than hemorrhage into a rapidly growing brain tumor). These benefits are achieved without undue risks; the presence of a cardiac pacemaker, brain aneurysm clip, or the presence of other metallic foreign bodies (e.g., metal in the eye) are the only contraindications to brain MR. MR is useful in the imaging of both ischemic and hemorrhagic processes (Figs. 3–5).

The earliest sign of ischemic infarction apparent on MR is the loss of the normal intravascular "flow void" due to slow flow or occlusion within an intracranial vessel. This finding is similar to the "dense MCA sign" described in CT images of acute stroke. Arterial hyperintensity may be apparent on fluid attenuation inversion recovery (FLAIR) images almost immediately after stroke. Venous hyperintensity on FLAIR imaging suggests venous thrombosis, which may be confirmed with MRV (Fig. 6). Two to 4 hr following acute ischemic infarction, subtle changes in the shape of cortical gyri may become evident due to cytotoxic edema, which causes neural tissue to swell. Diffusion weighted MR reveals abnormalities within 30 min of acute ischemic infarction and is rapidly becoming a valuable technique for acute stroke imaging (Figs. 2 and 3). The majority of acute ischemic infarcts can be identified using diffusion MR, which reportedly detects 97% while remaining normal in 100% of individuals lacking acute ischemic infarction. Signal hyperintensity on T2 and proton density images becomes apparent within 8 hr of an ischemic infarction as a result of vasogenic edema, the process whereby water extravasates from damaged vessels into the

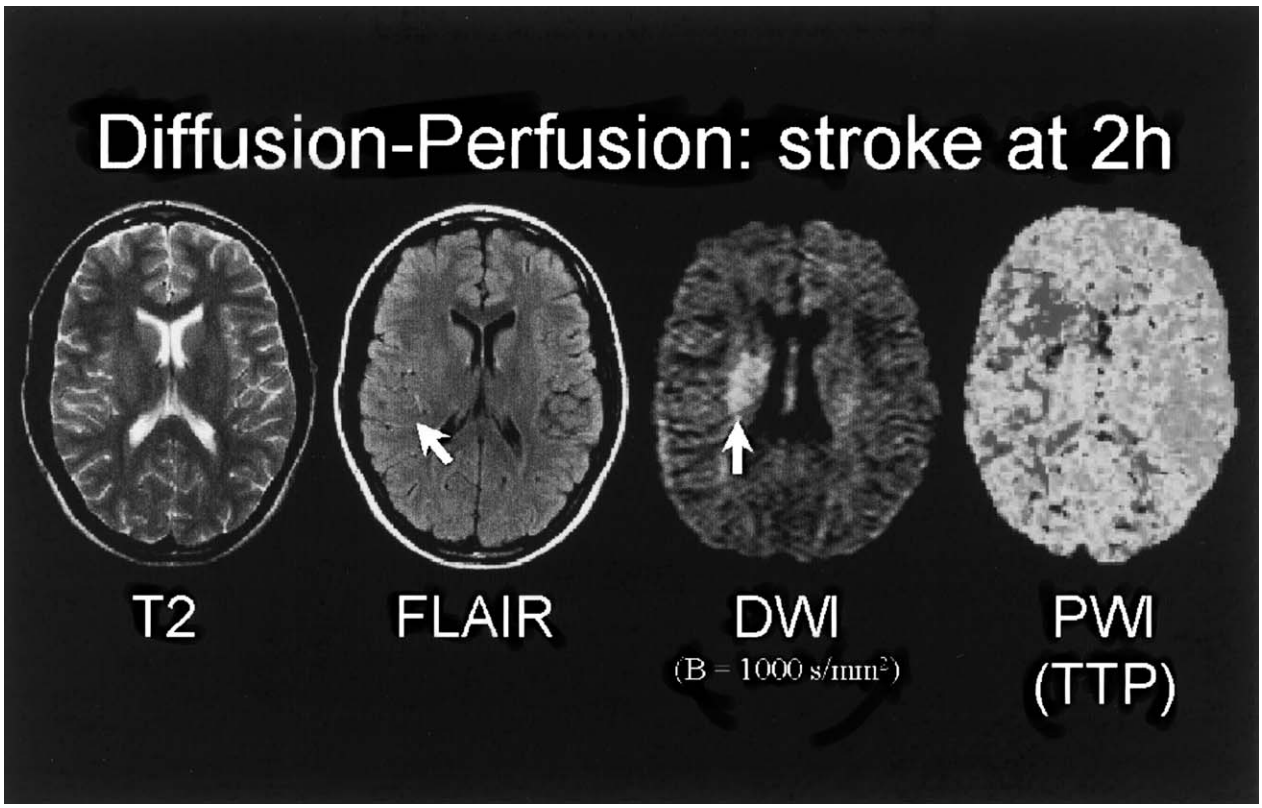

Figure 3 Acute ischemia; MR techniques compared. Two hours after stroke, the T2-weighted MR (left) may be completely normal. Fluid attenuation inversion recovery (FLAIR) imaging may reveal hyperintense vessels in the region of the infarction (arrow). The diffusion weighted image (DWI) reveals an area of infarction (as shown in Fig. 2). Perfusion weighted imaging (PWI) shows a large area of diminished perfusion that has not yet become infarcted, as shown by the discrepancy between the DWI and the PWI. This "mismatch" corresponds to a large area of brain tissue that is potentially at risk for infarction [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

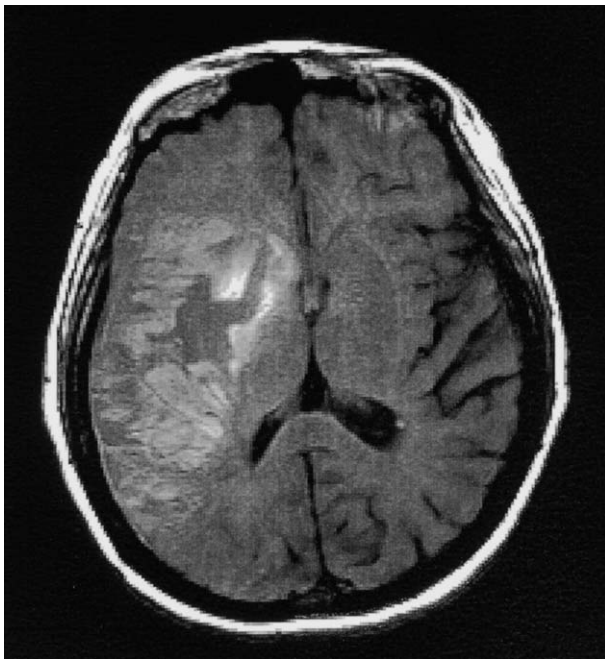

Figure 4 Acute hemorrhage seen on MR. This is a T1-weighted MR, without contrast, demonstrating hemorrhagic transformation within a large middle cerebral artery stroke within 7 days following the stroke [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

surrounding tissues. By 16–24 hr following ischemic infarction, there is usually enough vasogenic edema to cause T1 signal hypointensity. Within 5–7 days after ischemic infarction, there is parenchymal enhancement following injection of gadopentate dimeglumine. The new blood vessels that form within damaged areas surrounding a complete infarction have an imperfect blood–brain barrier, allowing contrast to leak into surrounding tissues.

Hemorrhages may be evident on MRI, but the time course and evolution are much more complex than with ischemic infarction. For example, subarachnoid or intraventricular hemorrhages evolve differently than subdural or epidural hematomas. Intraparenchymal hematomas are different as well. FLAIR images enable detection of oxygenated hemoglobin in acute subarachnoid hemorrhage, and the superiority of CT scanning for the purpose of acute detection of subarachnoid hemorrhage has thus been challenged. Acute intraparenchymal hemorrhages may be missed by T1, T2, and proton density images; these techniques do not show alteration in signal intensity (i.e., decreases) for 1–3 days due to the gradual accumulation of deoxygenated hemoglobin. As red blood cells degrade, deoxygenated hemoglobin is converted to met-hemoglobin, which may appear hyperintense on T1 images 3–7 days after a hemorrhage. There is gradual accumulation of hemosiderin as the breakdown of hemoglobin continues from 1 to 4 weeks. Met-hemoglobin is typically hyperintense on T1, T2, and proton density images, whereas hemosiderin (which accumulates after 4 weeks) produces low signal intensities on T1, T2, and proton density images. Figs. 7 and 8 illustrate the typical progression of brain hemorrhage seen with MR techniques.

MR techniques are important for visualizing the arteries supplying the brain. MRA allows the visualization of intracranial and extracranial arteries of medium and large caliber. Turbulent flow will produce flow signal dropout, which may lead to false interpretations of vessel occlusion. Even relatively large aneurysms may be missed with MRA, and the technique has not yet replaced catheter angiography as the gold standard for defining cerebrovascular anatomy. MRV is sensitive to blood flowing at slower velocities, such as the blood within cerebral veins and sinuses. MRV is thus an important tool for detecting sagittal sinus thrombosis, cortical vein thrombosis, and other disorders of the cerebral veins.

Perfusion imaging (T2*) allows qualitative evaluation of CBF. Areas of relatively reduced CBF can be identified, and a "diffusion–perfusion mismatch" may indicate a large area of brain in danger of complete infarction (Fig. 3). Changes in CBF are being utilized to map the parts of the brain that participate in various kinds of neurological or cognitive functions. Functional MRI (fMRI) may soon become an essential part of the management of cerebrovascular disorders. Not only will it enable detection of diffusion–perfusion mismatch in acute stroke patients eligible for intravenous or intraarterial thrombolysis but also fMRI may facilitate appropriate selection of arteries that might safely be sacrificed in the management of arteriovenous malformation. Magnetic resonance spectroscopy (MRS) allows the breakdown products of tissue destruction to be measured quantitatively. Thus, MRS may become an important method of detecting the presence of injury or measuring the effect of neuroprotective interventions. Its use in clinical practice is currently limited.

3. Neurosonology

The field of neurosonology has emerged as a key aspect of cerebrovascular disorders. Several distinct

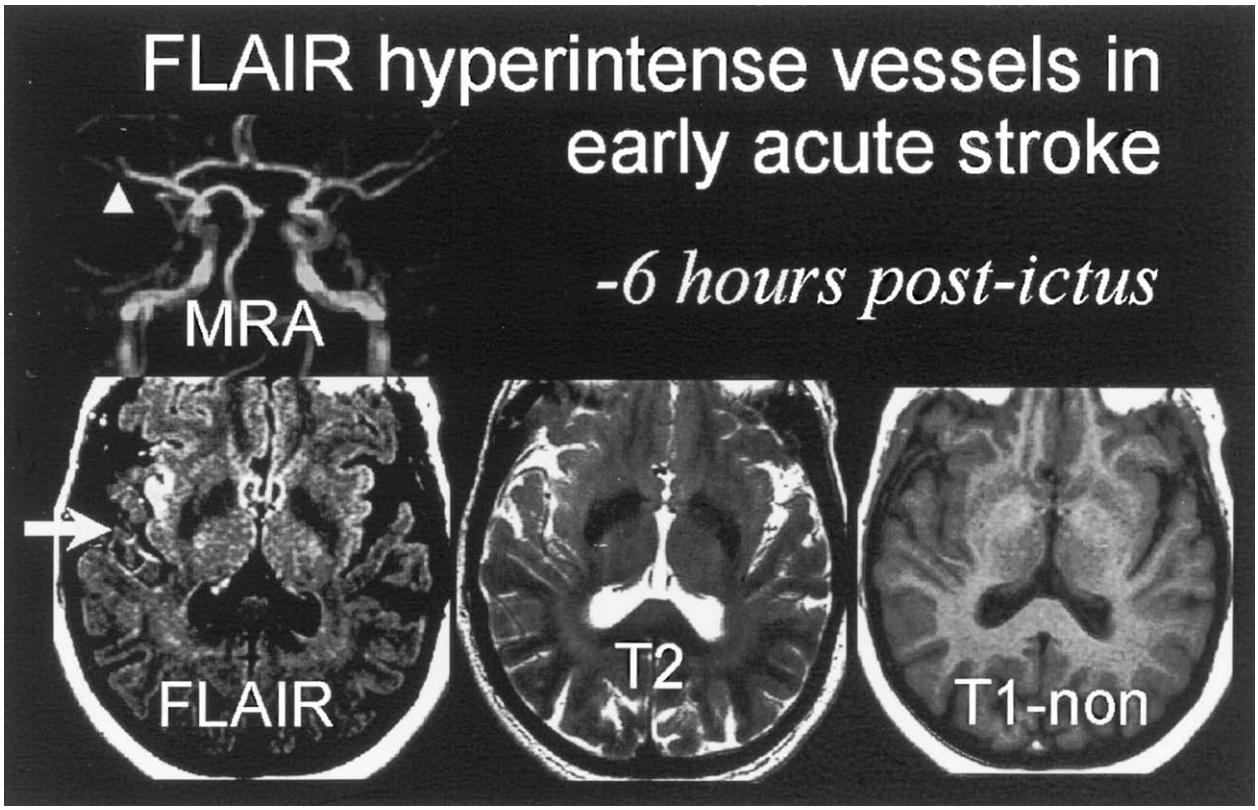

Figure 5 Hyperintense vessel on FLAIR and MRA in acute stroke. The occluded middle cerebral artery is seen on MRA (arrow head, top left) 6 hr following stroke. Hyperintense vessels are noted on FLAIR imaging (arrow, bottom left). The T2 and T1 noncontrast images are normal [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

techniques have been developed to image vascular anatomy and stenosis due to plague, to measure flow velocity by Doppler shift analysis, and to quantitate flow. Neurosonology techniques are noninvasive, safe, reliable, economical, and informative.

a. B-Mode Imaging of the Carotid and Vertebral Arteries Cross sections and longitudinal sections depicting arterial anatomy are readily obtained using B-mode (brightness-mode) ultrasound. Such images depict the thickness of the vessel wall (which correlates with stroke risk in the carotid circulation and in the aorta) and the presence and thickness of plaque. Intraplaque hemorrhages (which increase stroke risk) can be identified with an accuracy of 90%, sensitivity of 96%, and specificity of 88%. Ulceration is difficult to identify with accuracy. Homogeneity can be assessed as well. Heterogeneous plaques are associated with increased stroke risk because they are more likely than homogenous plaques to contain hemorrhage. The characterization of plaque heterogeneity and typology is ongoing, and further research will be required to determine the clinical significance of findings such as ulceration.

b. Doppler Ultrasound of the Carotid and Vertebral Arteries Ultrasound echoes returning from a target, such as blood flowing through a vessel, experience a change in their frequency in direct proportion to blood flow velocity. These Doppler shifts are analyzed using fast Fourier transformation to generate a blood flow velocity spectrum. Mean flow velocity, peak systolic velocity, end diastolic velocity, and a variety of other important indices may be derived. Faster flow velocities generally indicate greater stenosis, unless critical stenosis is present. These principles are used to grade the degree of carotid artery stenosis as A (normal), B (1–15% stenosis), C (16–49% stenosis),

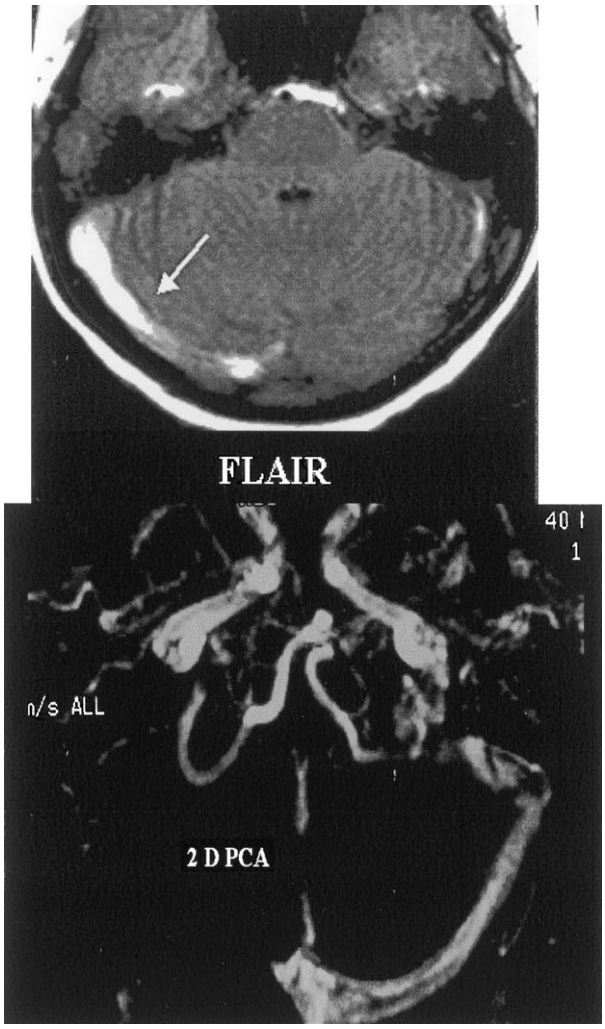

Figure 6 MRV and FLAIR imaging shows transverse sinus occlusion. The top image (arrow) reveals an area of hyperintensity on FLAIR imaging. The hyperintensity corresponds to a thrombus within the right transverse sinus. The bottom image is a magnetic resonance venogram showing lack of venous blood flow through the occluded transverse sinus, manifested as an absence of normal (bright) flow signal. The opposite transverse sinus (shown on the right) has the normal appearance of bright signal, indicating venous blood flow (graphic provided by Rohit Bakshi, M.D.).

D (50–79% stenosis), D+ (80–99% stenosis), or occlusion. Because the degree of stenosis closely relates to stroke risk, noninvasive vascular testing with Doppler ultrasound is extremely valuable in the management of cerebrovascular disease. The combined use of B-mode and Doppler spectrum analysis is called duplex sonography and is currently the preferred tool for extracranial vascular screening in patients with stroke. Testing of the vertebral arteries is limited by the vertebrae but may still provide important diagnostic information (e.g., reversal of flow in the left vertebral artery suggests the subclavian steal syndrome). The direction of flow is easily determined using Doppler ultrasound.

c. Transcranial Doppler Ultrasound of Intracranial Arteries TCD provides a noninvasive method for determining intracranial hemodynamics. The direction of flow within the major intracranial vessels can be determined to rule out significant extracranial stenosis (e.g., subclavian steal) or intracranial disease. Normal ranges for flow velocity have been determined for most large intracranial vessels, and flow velocity changes also may confirm intracranial stenosis. For example, TCD is utilized to detect vasospasm following subarachnoid hemorrhage. TCD can also detect emboli, which appear as high-intensity signals within the Doppler spectrum. Embolus detection is useful for identifying intracardiac shunts, such as patent foramen ovale, and for the detection of microemboli resulting from cardiac surgery. TCD is used for intermittent assessment of vascular patency following thrombolysis, to assess vascular reactivity during provocative tests such as carbon dioxide inhalation or acetazolamide administration, and to continually monitor intracranial flow during surgical procedures. Flow changes have recently been related to cognitive activity.

Vascular reactivity is typically assessed by combining TCD with hyperventilation or carbon dioxide inhalation. The former can reduce middle cerebral artery flow velocity within 15 seconds, and lower it by 35%. In contrast, carbon dioxide inhalation can increase flow velocity by as much as 52.5%. A 1000-mg dose of acetazolamide intravenously can begin to increase flow velocity within 3 min, reaching a peak flow velocity 35% higher than baseline within 10 min. Patients with cerebrovascular risk factors and reduced ability to increase flow velocity in response to carbon dioxide inhalation (i.e., reduced "cerebral perfusion reserve") are at higher risk for stroke than individuals with normal reserve. By lowering blood pressure in a controlled fashion, the ability of the cerebral circulation to maintain CBF during periods of hypotension can be measured using TCD. The blood pressure threshold leading to a sudden and severe decrease in flow velocity is defined as the lower limit of cerebral autoregulation. Future research will determine whether determination of the lower limit of cerebral autoregulation will have clinical applicability in preventing strokes attributable to hypotension.

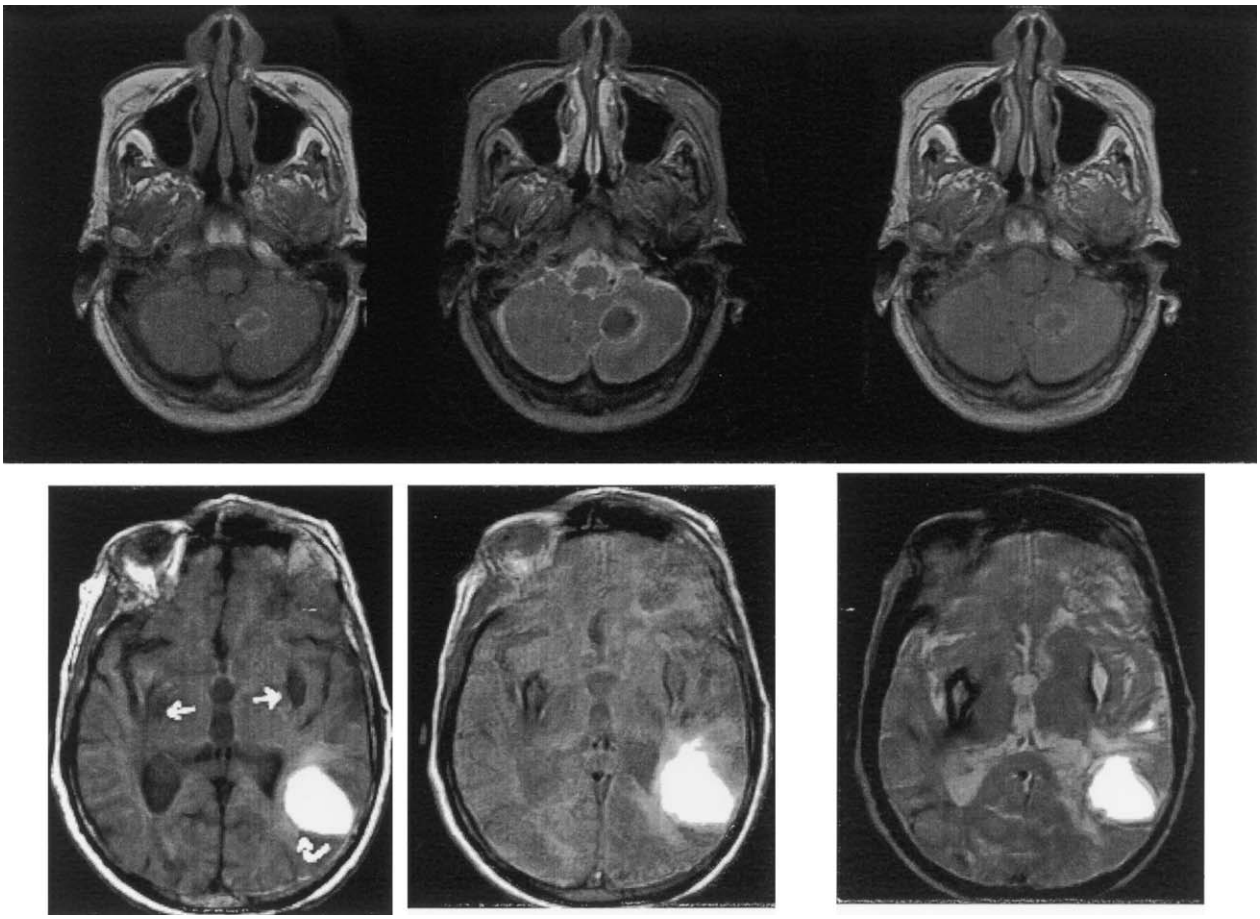

Figure 7 Evolutionary changes of acute and chronic hemorrhage. The top images depict an acute (3 days) cerebellar hemorrhage. Deoxyhemoglobin in the core of the hemorrhage is isointense to slightly hypointense on T1 (left) and proton density (right) images, whereas it is clearly hypointense on T2-weighted imaging (top center). Met-hemoglobin is hyperintense on T1 and proton density imaging but hypointense on T2. Thus, the combination of these techniques differentiates these two hemoglobin degradation forms. The bottom images depict bilateral, chronic (>4 weeks), basal ganglia hemorrhages (straight arrows). A large, late subacute hemorrhage (curved arrow) is shown also. The chronic hemorrhages are hypointense due to a rim of hemosiderin and ferritin. The bright signal within the late subacute hemorrhage (approximately 4 weeks) is due to extracellular met-hemoglobin accumulation. Thus, the age of these hemorrhages can be readily determined using a combination of MR techniques [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

d. New Ultrasound Techniques (Power Doppler, Color Velocity Flow Imaging, Three-Dimensional Doppler Imaging, etc.) A variety of new neurosonology techniques are being developed. Power Doppler measures the intensity of the returning echoes rather than the frequency shifts, and it may be useful for low-flow states. Color velocity flow imaging, or volume flow, computes quantitative blood flow values from mean flow velocity over a fixed period of time through a vessel of known size. Three-dimensional Doppler imaging has been used to noninvasively map aneurysms and other vascular abnormalities. It seems likely that there will be many important clinical applications of these techniques in the future.

D. Nuclear Medicine

1. Positron Emission Tomography

PET can be used to measure brain metabolism, CBF, and the quantity of specific receptor types within the brain. The technique requires administration of a radionuclide that emits positrons during radioactive

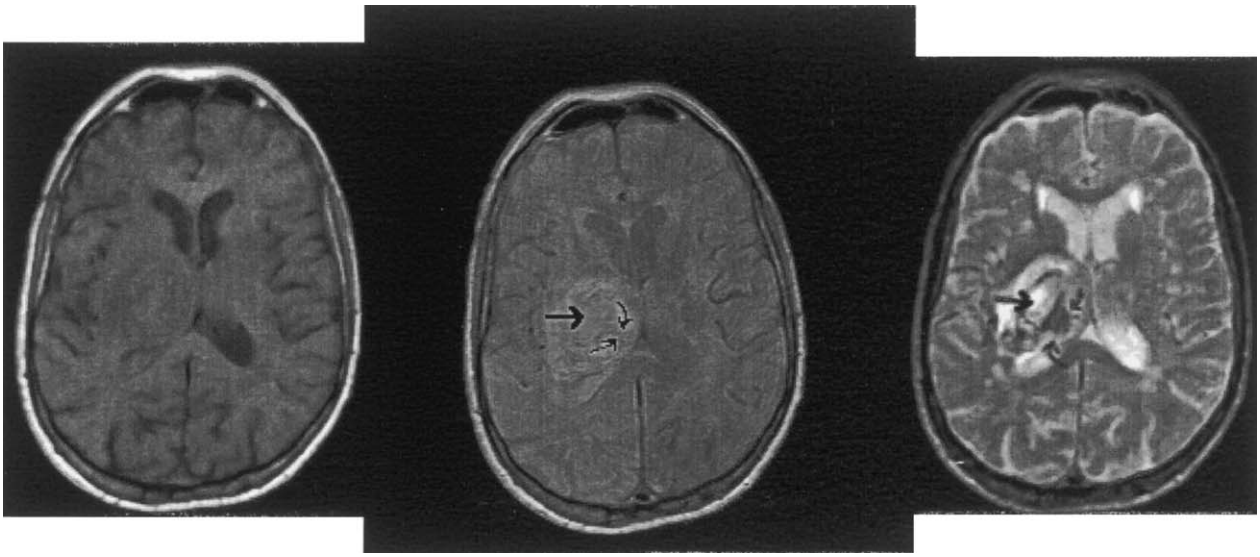

Figure 8 Early acute brain hemorrhage. Oxyhemoglobin and deoxyhemoglobin are mixed in the acute stage of hemorrhage (<24 hr). The T1-weighted image (left) shows only mild hypointensity and mass effect. The proton density image (center) shows hyperintensity in the area of hemorrhage. The T2-weighted image shows hyperintensity (straight arrow) as well as hypointensity (curved arrows), corresponding to oxyhemoglobin and deoxyhemoglobin, respectively. A hyperintense rim of edema is visible around the hematoma on proton density and T2-weighted imaging [adapted with permission from R. Bakshi and L. Ketonen, Brain MRI in clinical neurology. In *Baker's Clinical Neurology* (R. J. Joynt and R. C. Griggs, Eds.). Copyright Lippincott, Williams & Wilkins, 2001].

decay. The scanner detects the gamma rays that are emitted when a positron with an electron and both are annihilated. This technique, annihilation coincidence detection, permits the location and quantity of radioactive decay to be mapped within the brain.

Using ^{15}O tracer PET for imaging, quantitative determination of CBF, blood volume, the rate of oxygen metabolism, and the oxygen extraction fraction can be determined. Brain areas where there is inadequate CBF to satisfy metabolic demands ("misery perfusion"), areas where there is more than enough blood flow to meet metabolic requirements ("luxury perfusion"), and areas of frank ischemia leading to a reduction in brain metabolism can be mapped. Although these techniques revolutionized understanding of the pathophysiology of stroke, they are available only in specialized PET imaging centers that have a cyclotron available to generate ^{15}O. Thus, clinical PET is seldom utilized in the management of acute stroke. [^{18}F]fluorodeoxyglucose PET uses a much longer half-life radionuclide (^{18}F vs ^{15}O) to demonstrate a "patchy" pattern of metabolic compromise in patients with vascular dementia, corresponding to sites of repeated vascular injury.

2. Single Photon Emission Computed Tomography

SPECT requires administration of a radionuclide that emits alpha particles. The alpha particles collide with surrounding electrons, which then emit photons that scatter into detectors. Computers then determine the location of the emitting sources and create tomographic images mapping the quantity and location of emissions. The technique is useful for measuring CBF, both quantitatively and qualitatively. Quantitative measures of CBF may be obtained using the ^{133}Xe inhalation technique, whereas relative measures of CBF are obtained following injection of [^{99m}Tc]*d*, 1-hexamethylpropylene amine oxime (HMPAO).

3. Activation Procedures

Both PET and SPECT may be used to measure a change in CBF. By injecting only a portion of the HMPAO tracer during one condition (baseline) and injecting another dose during a second condition (e.g., following carbon dioxide inhalation or acetazolamide infusion), the brain images obtained during these two

conditions may be compared. The same technique (split-dose injection) may be used in PET scanning. In PET it is more common to utilize a short-lived radionuclide such as ^{15}O so that many separate images of CBF may be obtained during a single scanning session. Each of these CBF maps can be compared, but usually mean CBF images are compared to measure CBF changes from one condition (e.g., rest) to a second condition (e.g., activation). In clinical practice, HMPAO SPECT is often used to distinguish vascular dementia from degenerative dementia (as described previously) or to demonstrate impaired CBF distal to an occluded vessel, as in vasospasm following subarachnoid hemorrhage. HMPAO SPECT demonstrates CBF changes in response to acetazolamide or carbon dioxide, and impaired reactivity is associated with greater stroke risk. Thus, HMPAO SPECT provides clinically useful information about cerebral physiology and may supplement the information obtained from TCD.

E. Catheter Angiography

Cerebral angiography involves insertion of a catheter into the arterial system, injection of iodinated contrast agents into the cerebral circulation, and rapid acquisition of plane radiographs of the head. Vascular anatomy is demonstrated clearly using this technique, which is the gold standard for defining cerebrovascular anatomy. Aneurysms, AVMs, angiomas, and other vascular malformations are detected and classified. Arterial narrowing due to atherosclerosis, vasculitis, vasospasm, arterial dissection, or external compression is visualized. Microvascular disease may not be evident. The risk of complications is approximately 1 in 10,000, and catheter angiography is being utilized less frequently for routine diagnosis as MRA becomes available. Instead, catheter angiography is increasingly restricted to those situations in which interventional radiology procedures or surgery may be needed.

IV. THERAPEUTIC ADVANCES

The various treatments available for stroke are summarized in Table IV. These treatments include agents that directly interfere with coagulation, techniques to obliterate vascular obstruction or structural abnormality, and methods to bypass the obstruction physically or chemically (hyperbaric oxygenation and retrograde cerebral perfusion).

Table IV
Treatments for Stroke

Treatment type	Examples
Antiplatelet agents	Aspirin
	Dipyridamole
	Ticlopidine
	Clopidogrel
Anticoagulants	Heparin
	Low-molecular-weight heparins
	Warfarin
Thrombolytics	Streptokinase
	Urokinase
	Pro-urokinase
	Tissue plasminogen activator
Surgery	Aneurysm clipping
	Arteriovenous malformation resection
	Endarterectomy
	Subclavian thrombectomy
	Valve replacement
	Inferior vena cava filter
	Patent foramen ovale repair
	Atrial septal aneurysm repair
Radiation	Gamma knife
Endovascular therapy	Thrombectomy
	Angioplasty
	Coils
	Stents
	Balloons
	Glue
Cognitive rehabilitation and neurorehabilitation	Memory, language, and attention therapy
	Physical, occupational, speech, recreational therapies
	Assistive devices and adaptive equipment
Other	Hyperbaric oxygen
	Retrograde transvenous neuroperfusion
	Neuroprotective drugs

A. Antiplatelet Agents

Antiplatelet drugs used in the treatment of stroke include aspirin, dipyridamole, ticlopidine, and clopidogrel. Aspirin has been shown to improve the outcome from acute stroke without increasing the risk of brain hemorrhage. The combination of aspirin and

dipyridamole is more effective than aspirin alone in preventing stroke. Antiplatelet agents reduce the risk of nonfatal stroke by 25% overall and by 31% in high-risk patients (those with acute myocardial infarction or prior myocardial infarction, stroke, or transient ischemic attack). A subset of studies revealed a 24% reduction in subsequent disabling or fatal stroke and a 17% reduction in nondisabling stroke among treated high-risk patients. Ticlopidine reduced nonfatal stroke or death rates more than aspirin during the first year after transient ischemic attack or minor stroke, but by 3 years there was no difference between these agents. Clopidogrel is more effective than aspirin, reducing the risk of ischemic stroke, myocardial infarction, or death by 8.7% compared to aspirin. Clopidogrel is recommended for the treatment of stroke patients who also have peripheral vascular disease. Clopidogrel has fewer hepatic and hematologic side effects than ticlopidine, and it is the preferred alternative for patients allergic to or intolerant of aspirin.

B. Anticoagulants

There are no compelling data to support the widespread use of heparin in acute stroke. The Ischemic Stroke Trial examined the outcome of approximately 20,000 patients treated acutely with heparin with or without aspirin. Although a significant reduction in recurrent ischemic strokes was found among patients treated with heparin, this group also experienced significantly more hemorrhagic strokes. The routine use of heparin for acute stroke is thus not supported by the literature, even in specific circumstances such as presumed cardioembolic stroke, progressing stroke, and vertebrobasilar ischemia. Anticoagulation therapy appears to lower the risk of recurrent stroke in the setting of aortic arch atherosclerosis, but cholesterol emboli are often produced by such pathology. Thus, the optimal management of aortic arch disease is uncertain. It is also unclear whether anticoagulation or thrombolytic therapy can prevent cardiogenic embolization in the setting of acute myocardial infarction. In the setting of atrial fibrillation, however, anticoagulation is recommended. Treatment with warfarin decreases the risk of recurrent ischemic stroke by 68%. Patients younger than 60 years of age without concurrent stroke risk factors may not require warfarin for their "lone" atrial fibrillation. Instead, such individuals are often treated with aspirin to prevent future stroke. When acute stroke is complicated by atrial fibrillation, anticoagulation with intravenous heparin is typically utilized, despite relatively limited data supporting this practice. Low-molecular-weight heparins (LMWHs) have recently been utilized in such situations because they have lower rates of hemorrhagic complications and there is less need for blood testing compared to heparin therapy. Efficacy in the prevention of pulmonary emboli and peripheral venous thrombosis has been established. Preliminary research reveals that the rate of death or dependency 6 months following stroke is lower with LMWH treatment than without, and high-dose treatment is more effective than low-dose treatment. Additional research is under way to establish the efficacy of LMWH therapy in acute ischemic stroke. Because LMWHs are given by injection, they are not currently used for long-term stroke prevention, except perhaps for rare patients unable to tolerate all antiplatelet agents and warfarin. Oral forms of LMWH would be a welcome development.

C. Thrombolytics

Thrombolytic therapy has revolutionized the management of acute stroke. Prior to the demonstration that tPA was effective for acute ischemic stroke, aspirin, heparin, and supportive care were the mainstays of acute stroke management. Thrombolysis using tPA may now be done via intravenous injection or intraarterial injection. A favorable outcome is substantially more likely for patients who receive such treatment within 3 hr of stroke onset. The risk of hemorrhagic complications increases greatly when patients are treated more than 4 hr after the stroke, when severe hypertension complicates the treatment, and when more than one-third of the middle cerebral artery vascular territory appears damaged on CT scans. If none of these poor prognostic indicators are present, and if the patient lacks a history of recent surgery, stroke, transient ischemic attack, or anticoagulant therapy, then tPA may be administered acutely.

D. Cardiothoracic Surgery

Surgery on the heart may be helpful in preventing stroke. The aortic and mitral valves are the most common valvular sources of cerebral emboli. Valve replacement can reduce stroke risk. Intracardiac shunts may be repaired to prevent "paradoxical" embolism. Surgery may be done to remove clots from within the left atrium or atrial appendage. Atrial septal

aneurysms may be repaired. Aberrant conduction pathways producing arrhythmias may be ablated or removed. Subclavian stenosis may be surgically repaired, thus eliminating subclavian steal syndrome. Finally, coronary artery bypass grafting reduces the risk of myocardial infarction, a definite cause of stroke. Thus, there are many indications for cardiac or thoracic surgery to reduce stroke risk.

E. Vascular Surgery and Neurosurgery

The most common vascular or neurosurgical procedures done to prevent stroke are carotid endarterectomies. In 1989, there were approximately 70,000 carotid endarterectomies performed in the United States, and approximately half of these were for asymptomatic carotid stenosis. At that time, the value of surgery for stroke prevention was controversial. The Asymptomatic Carotid Artery Study (ACAS), the European Carotid Surgery Trial (ECST), and the North American Symptomatic Carotid Endarterectomy Trial (NASCET) demonstrated the benefit of surgery for both asymptomatic and symptomatic carotid artery stenosis. In the NASCET, carotid endarterectomy decreased the risk of stroke over 2 years by 17% compared to medical management in symptomatic patients with 70–99% stenosis. With greater than 80% internal carotid stenosis, carotid endarterectomy provided an absolute risk reduction of 11.6% in stroke and death end points over a 3-year time period. A smaller benefit (6.5% absolute risk reduction over 5 years) was evident for carotid endarterectomy in symptomatic patients with 50–69% stenosis compared to medical management. The results of the ECST were similar. In asymptomatic individuals with high-grade stenosis ($>70\%$) reported in the ACAS, the relative risk reduction over 5 years was 53%, but the absolute risk reduction was only 1.2% per year. Thus, the number of strokes prevented by carotid endarterectomy in asymptomatic stenosis of $>70\%$ is similar to the benefit seen with symptomatic stenosis of 50–69%.

Surgical repair of other vascular abnormalities is also possible. Extracranial aneurysms of the carotid arteries may be surgically repaired to prevent rupture. Intracranial aneurysms are usually clipped, but endovascular therapies are increasingly utilized for surgically inaccessible or giant aneurysms; detachable coils may be inserted into the vessels (Fig. 9), or balloons may be inserted. These techniques may lead to successful clot formation and obstruction of blood flow into the aneurysm, thus reducing the risk of rupture. Surgical removal of AVMs may be quite successful, although large AVMs may also require adjunctive endovascular therapy. For example, large and complex AVMs supplied by several vessels may need to be obliterated partially by intraarterial glue therapy prior to surgical resection. In patients with paradoxical cerebral embolization from lower extremity deep venous thrombosis, an inferior vena cava filter (Greenfield filter) may be inserted, or the intracardiac shunt may be surgically repaired.

F. Gamma Knife Therapy

AVMs have been treated successfully with focused radiation therapy. The Gamma Knife is a radiation therapy instrument that delivers several beams of radiation to a precise target. Each individual beam delivers a relatively small radiation dose to brain tissue. However, when the beams converge at the site of an AVM, the radiation dose is sufficient to produce damage. The blood vessels within the AVM degenerate and the adjacent tissue may be scarred as well (Fig. 10). This procedure has been used to obliterate AVMs that are located in surgically inaccessible areas of the brain. The risks of surgery, angiography, and endovascular therapy are avoided. Other vascular abnormalities such as aneurysms may be treated using the Gamma Knife. This technique represents a substantial advance in the available options for treating AVMs and other vascular anomalies

G. Endovascular Techniques

Some of the most recent advances in stroke therapy relate to the development of new catheters for interventional neuroradiology procedures. There are now catheters that can inflate a balloon within an area of stenosis to open a lumen within an atherosclerotic area of the vessel (cerebral angioplasty). Angioplasty and intraarterial papaverine injections have recently been used to successfully manage vasospasm following subarachnoid hemorrhage. A small loop or snare may be guided to the site of a thrombus using a catheter so that the thrombus may be removed directly through the catheter. Mechanical disruption of the clot or embolectomy (removal of the embolus) may allow recanalization of the vessel, with restoration of CBF. Thin wires may be inserted through the catheter to achieve recanalization through a recently occluded

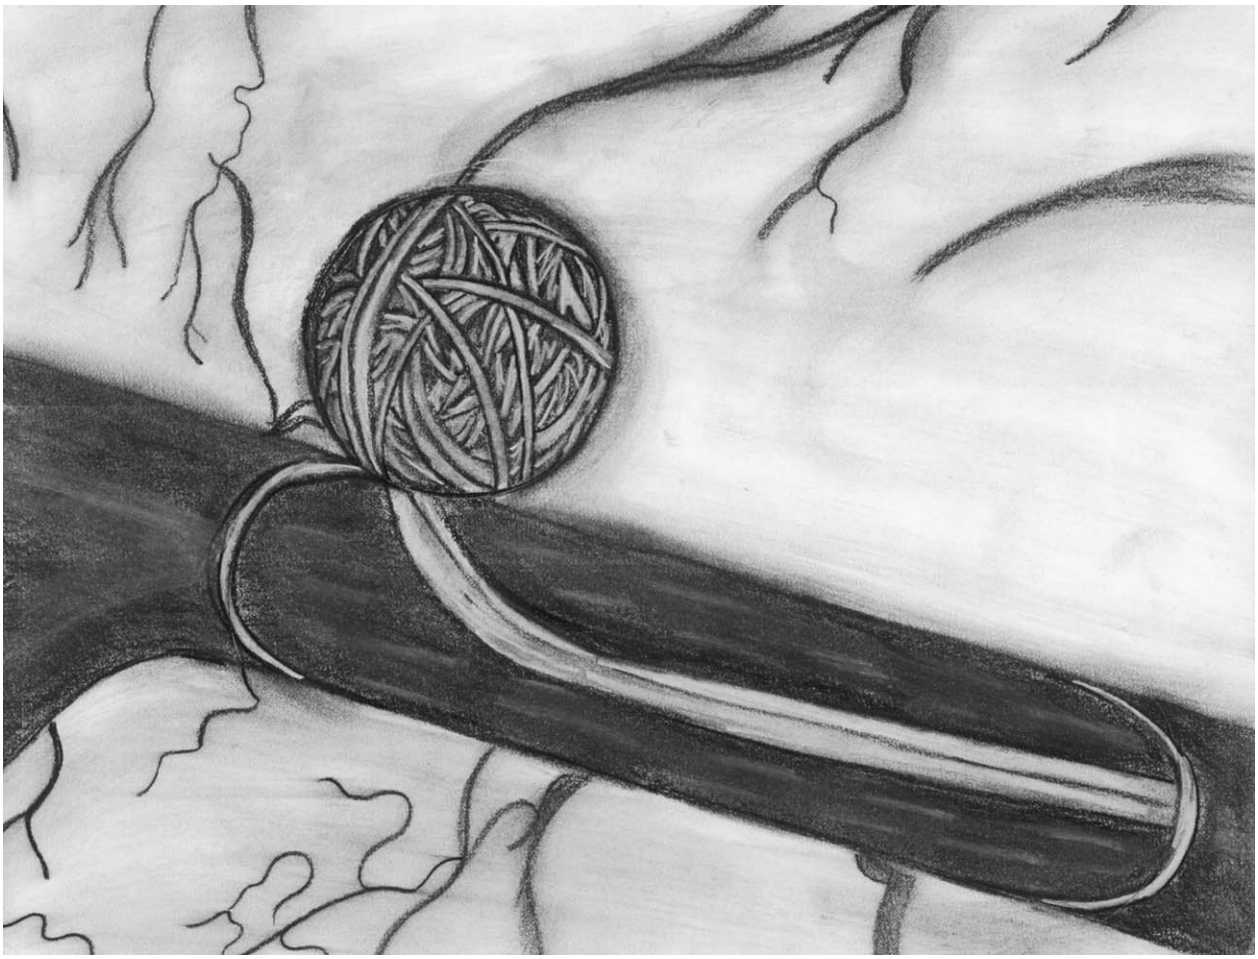

Figure 9 Intravascular coil within an aneurysm. This is a drawing showing how a catheter may be used to insert a detachable coil into an aneurysm. The wall of the vessel is cut away so that the catheter can be seen within the lumen. The coil is inserted through the catheter, and this partly occupies the aneurysm cavity. The coil may be detached so that it remains in the aneurysm permanently. A similar technique may be utilized to insert balloons into giant aneurysms (not shown) (drawing by Adam Bourgoin).

arterial segment. Catheters may deploy intravascular stents that remain in the vessel lumen to maintain vascular patency. Glue may be administered through the catheter to occlude feeder vessels within a large AVM. Test occlusion of such vessels using a balloon (or anesthetic injection into the vessel) may prove that sacrificing the vessel surgically (e.g., to remove an AVM) would not produce unacceptable complications. Balloons or coils (Fig. 9) may be deployed into a large aneurysm to promote coagulation within the lumen of the aneurysm. If blood cannot enter the lumen, the risk of rupture is substantially reduced. Specially formed catheters allow cannulation of small branches of intracranial arteries. Intraarterial thrombolysis may be applied specifically to the vessels that are occluded. Recently, TCD has been used to agitate the clot following thrombolytic administration, and this technique increases the rate of recanalization. These and other evolving endovascular techniques promise to revolutionize the management of acute stroke.

H. Cognitive Rehabilitation and Neurorehabilitation

Neurobehavioral and neuropsychological testing is useful for predicting the outcome of stroke (prognosis) and in selecting the most appropriate forms of therapy to be administered during rehabilitation. Cognitive rehabilitation utilizes neurobehavioral and neuropsychological information in treatment strategies

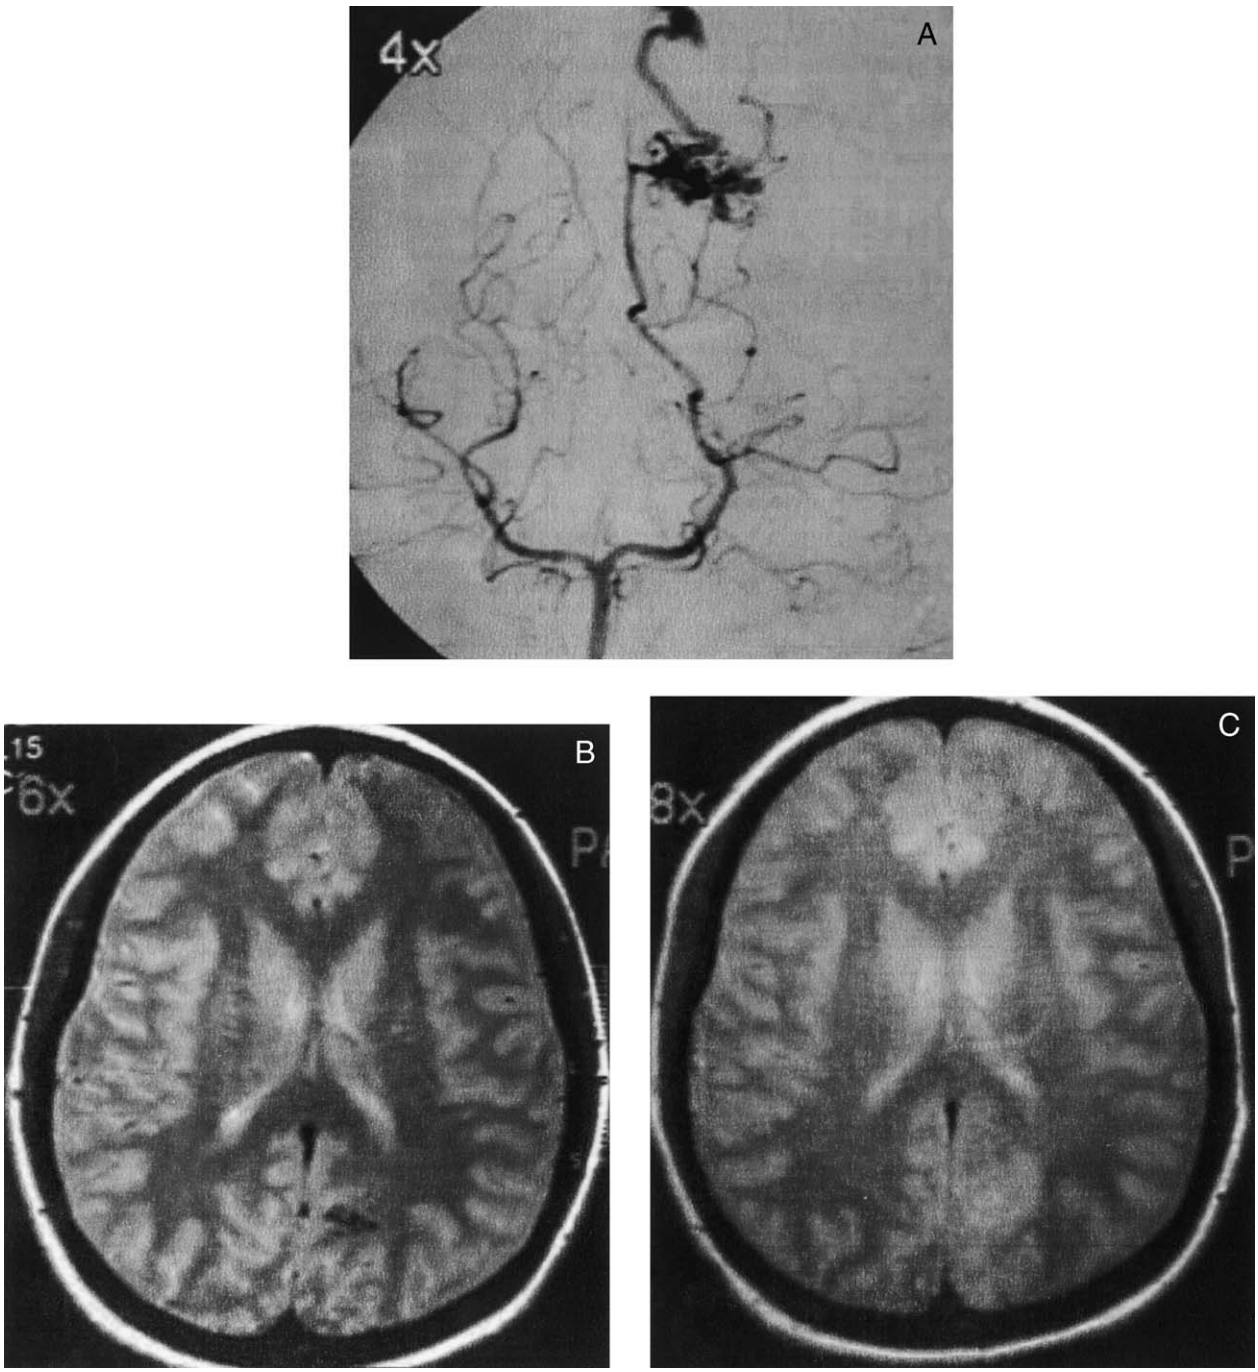

Figure 10 Successful Gamma Knife therapy. A conventional (catheter) angiogram depicts a moderate-sized arteriovenous malformation. This is a cluster of vessels that appears as a dark mass in Fig. 10A. (B) Flow voids (hypointense) corresponding to this AVM. (C) Following treatment with the Gamma Knife, the AVM has been obliterated, leaving only mild hyperintensity in the area that previously revealed flow voids.

designed to enhance functional recovery of memory, language, and attention following stroke. Neuropsychologists, physiatrists, neurologists, speech therapists, occupational therapists, recreation therapists, and other rehabilitation specialists may work together in multidisciplinary cognitive rehabilitation programs.

Functional brain mapping with fMRI, CBF PET, and electrophysiological brain mapping have revealed important information about the mechanisms of functional restoration and recovery. The clinical application of these techniques is just beginning to become integrated into the recovery phases of stroke management.

I. Experimental Therapies

Hyperbaric oxygen therapy has proved to be successful in the treatment of certain forms of stroke. For example, decompression sickness occurs when nitrogen bubbles form within the bloodstream. The hyperbaric chamber causes the nitrogen bubbles to dissolve and delivers oxygen to ischemic brain tissue. The same treatment may be utilized for air embolism, which occurs as a result of trauma, surgery, or vascular procedures. In each of these cases, the cause of the occlusion (i.e., a bubble) is dissolved by the pressure, while hyperbaric oxygen maintains viability within the ischemic brain areas. Now that thrombolysis and endovascular techniques are available to dissolve, recanalize, or remove an intravascular clot, it is possible that hyperbaric oxygen therapy may be combined with such procedures in the treatment of acute stroke. Currently, this hypothesis is under investigation.

By forcing oxygenated arterial blood backward through the venous system, ischemic areas may be supplied with needed oxygen even when the arterial supply is occluded. This technique, called retrograde transvenous neuroperfusion (RTN), is being actively studied to measure its effectiveness as an acute stroke intervention. In a small clinical trial involving eight subjects, RTN has shown promise for the management of acute stroke. Its effect may be almost immediate, in contrast to the effect of thrombolytic therapy, and it may be further increased by simultaneously employing hypothermia to reduce cerebral metabolic demands.

Neuroprotective drugs are under active development. The idea is to arrest the pathophysiologic mechanisms that lead to tissue damage and irreversible injury. If CBF or oxygen delivery could then be restored, a larger volume of intact and viable brain tissue would be available to promote functional recovery. Although the core region of infarction is not likely to be impacted by such an approach, the surrounding "ischemic penumbra" could in theory be rescued completely. Animal studies have shown the feasibility of this approach, but to date there are no effective neuroprotective drugs available for use in humans.

Advanced imaging techniques are being developed and promoted faster than they can be evaluated. Many of these techniques (FLAIR, MRA, MRV, etc.) have rapidly revealed their clinical utility, whereas others (MR spectroscopy and CBF PET) have limited clinical utility due to lack of availability, complexity, expense, or other factors. Despite these limitations, advanced brain imaging techniques enable brain areas at risk of permanent damage to be identified (Fig. 3) quickly and efficiently. This ensures that future research will be able to combine neuroimaging with clinical interventions to demonstrate the relative potencies of various medical therapies for acute stroke, neuroprotective interventions, endovascular techniques, or surgical procedures.

V. CHALLENGES FOR THE FUTURE

The number of people with stroke is increasing, despite the substantial gains in stroke prevention and treatment and reduced stroke risk for all age groups. The demographic shift in the population (i.e., the "graying" of America) accounts for this paradox. The great challenge of the future will be to respond intelligently to this situation. Quality of life will become increasingly important. Elderly individuals may survive a stroke only to be left incapacitated or demented due to vascular damage. Advances in public policy and the ethics of end-of-life care are required. For example, medical futility policies may be adopted to permit a physician to cease health care services that have no meaningful chance of improving quality of life in a hopelessly devastated stroke victim. Public education initiatives could substantially shorten the delay between stroke onset and emergency evaluation. Now that effective acute stroke intervention is available, the public must be educated about the importance of seeking immediate attention for "brain attacks." The reasons for socioeconomic and racial differences in stroke and cerebrovascular death rates must be understood so that preventable morbidity and mortality may be avoided. Such sociocultural developments have far greater potential to influence the future of cerebrovascular diseases than any technical innovation.

The technical challenges within the field of cerebrovascular diseases are considerable. A team approach to the management of cerebrovascular disorders will become the standard of care because the complexity of the field overlaps many clinical specialty areas. Basic

research must achieve meaningful neuroprotection so that the process of brain damage may be temporarily arrested while CBF and oxygenation are restored acutely. The stroke team must learn to mobilize quickly to administer neuroprotection and deliver acute stroke therapy, such as intravenous thrombolysis. These teams must learn to cooperate with regard to research so that the utility of diagnostic and therapeutic approaches can be validated. Idiosyncratic approaches to stroke care will be stifled by the purchasers of health care in favor of evidence-based interventions. The nuts and bolts of stroke care will be studied ever more closely to determine which practice variations are most damaging and which are most helpful. Quality of life assessments will become the standard of care, and the development of advanced directives will be promoted aggressively as a component of routine health maintenance. Approaches to the diagnosis and treatment of stroke that previously might have entered the clinical arena with little or no validation must now be examined to establish safety and efficacy in comparison to accepted standards and with proper attention to functional outcomes, advanced directives, cost, and other sociocultural considerations. Advanced brain imaging techniques will be employed to assist in the process of predicting stroke outcome, and functional brain imaging (in combination with sophistical clinical assessments) will become an indispensable aspect of cognitive and neurorehabilitation. The field of stroke has advanced tremendously during the past 25 years, and the next 25 years will be even more rewarding.

Chemical Neuroanatomy

YURI KOUTCHEROV, KEN W. S. ASHWELL, and GEORGE PAXINOS
University of New South Wales

GLOSSARY

chemoarchitecture Differentiation between neuronal populations and brain areas based on variation in distribution of chemical compounds.

cytoarchitecture Differentiation between neuronal populations and brain areas based on variation in cell size, morphology, and density.

immunohistochemistry A histological technique that uses specific antibodies for visualizing chemical compounds.

Chemical Neuroanatomy is a modern methodology that identifies and classifies brain structures and pathways by their chemical characteristics. Because chemical characteristics of a brain structure are related to the function of its constituent neurons, chemical neuroanatomy allows insights into the physiological, pharmacological, and clinical significance of neuroanatomy. In other words, chemical neuroanatomy creates meaningful structural references within the general scope of brain and whole body physiology and psychology.

I. CHEMOARCHITECTURE

Chemical neuroanatomy has been used to establish the organizational plan of brain regions in experimental animals and to infer their human homologies. It has also been used to identify chemically specified connections in animals. Finally, it has been used to derive an hypothesis on the function of brain pathways and nuclei. Chemical neuroanatomy has developed as a branch of the structural brain mapping methodology that previously was almost entirely based on cytoarchitectonic consideration of cell shape, size, and density. The insubordination of chemically specified neurons to classic cytoarchitectonic boundaries required a more meaningful delineation of the brain—one that incorporates the information about the distribution of neuroactive substances, connectivity, and function. In this respect, chemical neuroanatomy opened a new dimension in neuroscience and allowed greater precision, resolution, and reliability in differentiating cell groups and brain areas.

Scientists have made use of chemical neuroanatomy in studying affiliations of neurons in experimental animals. Knowing the neurotransmitter carried by a neuronal projection precisely characterizes the pathway. This approach has not been extensively followed in the human; consequently, we only mention it in passing. Once the cells of origin and the terminal fields of a pathway have been chemically specified in experimental animals, then scientist can search for homologous cells and terminals in the human.

Chemical neuroanatomy is used to identify and correlate functional networks across species, particularly when focused on a specific neuroactive circuit

within the brain. Thus, chemical characteristics of brain structure reflect numerous important qualities of the neuronal cell groups, including neurotransmitter or neuromodulator content, receptor arsenal, structural proteins, intrinsic metabolic characteristics as reflected by enzyme activity profiles, and genotype.

In the human brain, chemical neuroanatomy is an essential method of investigation because conventional functional studies as well as neuroanatomical tracing techniques, as routinely performed on laboratory animals, are virtually impossible in humans. Noninvasive imaging techniques, including functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) are useful clinical tools, but their resolution is often disappointingly low for testing modern hypotheses. At the same time, pathological investigations base their conclusions largely on detailed structural and cytoarchitectonic comparisons with normal human neuroanatomy. Importantly, existing presumptions about the organization of the normal human brain are largely made by extrapolating findings from laboratory animals to humans on the basis of structural homology.

For most of the 20th century the understanding of human neuroanatomy was obtained mainly from cytoarchitectonic observations. Thus, the most widely used maps of the human cortex were produced by Brodmann in 1909 on the basis of Nissl substance and myelin staining, whereas the most detailed neuroanatomical description of the human hypothalamus was published by Brockhaus in 1942 and was also based on early cytoarchitectonic techniques. Without detracting from the historical significance of these fundamental studies, it is easy to see the main shortcoming of early neuroanatomical techniques, namely, their distance from mechanisms underlying human brain function. One of the most exciting developments in neuroanatomy was the identification of chemical coding for individual neural pathways and the proliferation of chemoarchitectonic techniques, which allow almost unlimited scope in the classification of neuronal groups. Importantly, chemical neuroanatomy establishes a bridge between structural and functional characteristics of neuronal populations in the brain.

Studies using chemical neuroanatomy were first carried out in rats, in which it was logistically and technically easier to apply. It was not until the 1980s that the chemoarchitectonic techniques of histo- and immunohistochemistry reached sufficient sensitivity that allowed them to be applied in full capacity to human brain tissue. Thus, it became increasingly possible to reveal the distribution of some of the neurotransmitters, receptors, and enzymes of importance in the human brain and then make cross-species comparisons. An advantage of chemoarchitecture is that each chemical substance offers a different view of the organization of the central nervous system, with successive stains revealing more of the areas of interest. Of course, there are significant species differences and any given substance may have inconsistent distributions in otherwise homologous nuclei and areas. Nevertheless, in terms of overall value, chemoarchitectonic delineations have become a preferred method in comparative neuroscience.

Chemoarchitectonic studies are also very important for the understanding, diagnosis, and treatment of neurological and psychiatric disorders, such as obesity, Alzheimer's, disease, Parkinson's disease, Huntington's disease, depression, and schizophrenia. In the past 50 years, researchers have compared the distribution and content of neuroactive chemical compounds of brains from individuals affected with various diseases with those of the brains of control subjects. This has led to development of pathological models of neurochemical imbalance in animals and to extrapolation of these models into the human using chemical neuroanatomy.

In chemical neuroanatomy, the first and most obvious question for the investigator is the choice of the chemical marker. Naturally, the neuroactive profile of neurons offers grounds for determining the organization of neuronal groups within a species and for comparing them across species. For example, dopamine, norepinephrine, epinephrine, and γ-aminobutyric acid (GABA) are neuroactive chemical compounds that can characterize neuronal subgroups. The term chemoarchitecture implies the use of chemical compounds for differentiation between neuronal populations. These compounds are not only neurotransmitters but also can be enzymes, receptors, peptides, and molecules related to neuronal metabolism, such as calcium-binding proteins. Cross-referencing patterns of distribution of many chemicals from different brains or, better yet, studying distribution patterns of different chemicals on the adjacent sections of one brain provide high resolution and reliability in identifying neuronal cell groups.

II. ENZYMES

An important part of chemical neuroanatomy was historically based on the distribution of various enzymes and enzymatic markers. In the mid-20th

century, Koelle and Friedenwald developed a simple and sensitive histochemical method for revealing acetylcholinesterase (AChE), the degradative enzyme for acetylcholine. The application of AChE staining has consequently proven very useful in distinguishing brain areas (Fig. 1), although failure to colocalize AChE-positive neurons with catecholamines, the then darlings of the neuroscience community, dampened the interest of researchers in enzyme expression in the human. A comprehensive delineation of the rat brain by Paxinos and Watson was done largely on the basis of AChE reactivity with Nissl staining used as a second criterion. In the past 30 years, AChE histochemistry was successfully used for delineations of the brain in many mammalian species. Most important, AChE histochemistry works well on the fresh (unfixed) postmortem human brain, which allows this method to be successfully applied to the neuroanatomical delineation of the human brain. For example, in 1995 Paxinos and Huang mapped the entire human brain stem using AChE reactivity as a primary chemoarchitectonic criterion. AChE staining was also used in pathological studies of the brains of patients with Alzheimer's disease and was recently employed as a relatively simple method for revealing the organization of the human hypothalamus (Fig. 1).

Another example in which enzyme distribution was instructive was the identification of the neuronal circuitry containing catecholamines (dopamine, noradrenaline, or adrenaline) by the localization of the enzymes related to catecholamine synthesis. Using immunohistochemical techniques, researchers determined distributions of tyrosine hydroxylase (TH), aromatic amino acid decarboxylase, dopamine β-hydroxylase, and phenylethanolamine-*N*-methyltransferase and were able to the delineate the relevant nuclei and subnuclei in the brain. In contrast, initial studies that aimed at directly localizing catecholamine molecules through chemical reaction with aldehydes were greatly limited by an inability to distinguish between the different catecholamines. The application of enzyme immunohistochemistry allowed the identification of 15 groups of catecholaminergic neurons in the mammalian brain. These cell groups were not confined to traditional cytoarchitectonic boundaries and consequently were termed A1–A16 (there is no A3 cell group), extending throughout the mammalian brain from the medulla to olfactory bulbs. In the human, as in the rat, the majority (A1, A2, and A4–A10) of catecholaminergic neuronal groups were found in the brain stem, where, for example, tyrosine hydroxylase immunostaining has been used to delineate the intermediate reticular zone. Four prominent tyrosine hydroxylase-positive catecholaminergic cell groups (A11–A15) are located in the hypothalamus (Fig. 2) and one (A16) is located in the substantia innominata of the ventral forebrain. The latter cell group is thought to be homologous to the rat's catecholaminergic cell group in the olfactory bulb. Subsequent work has shown that cell groups such as the Al and Cl catecholaminergic neurons are critical for autonomic control in experimental animals and also that these cell groups are strikingly similar in rat and human. Many studies used multiple markers to confirm a high degree of conservation in the chemical identity of brain stem neurons in general between rat, monkey, and human.

Neuronal nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d) is an enzyme that synthesizes the interneuronal messenger nitric oxide, hence the reason for the current intense interest in this protein. With respect to neuroanatomy, histochemistry reveals a restricted distribution of this enzyme in the brain, a feature that allows accurate identification of exquisitely detailed subnuclear structures. For example, NADPH-d reactivity has revealed the otherwise ambiguous supraoculomotor cap and the dorsolateral subdivision of the periaqueductal gray in the midbrain of the rat, rabbit, cat, monkey, and human. This finding allowed reliable identification of the interspecies homology for these microscopic subnuclear structures. Interestingly, the supraoculomotor cap has also been identified as being AChE positive.

NADPH-d reactivity has also been shown to reveal specific neuronal groups in the hypothalamus, thalamus, and medulla. It is a primary marker for the islands of Calleja in the ventral forebrain and reveals neuronal subpopulations in the human cortex. As an enzymatic neurochemical marker, NADPH-d histochemistry holds significant potential in current neuroanatomy and has been selected for delineation in popular atlases of rat and monkey brains.

III. CALCIUM-BINDING AND STRUCTURAL PROTEINS

There are many protein molecules that bind Ca^{2+} and whose distribution is instructive in brain delineations. The most frequently used are the vitamin D-dependent calcium-binding protein calbindin D-28K, parvalbumin, S-100, and calretinin. The functional significance of these molecules remains unclear, and the main interest in them is derived from the large variability

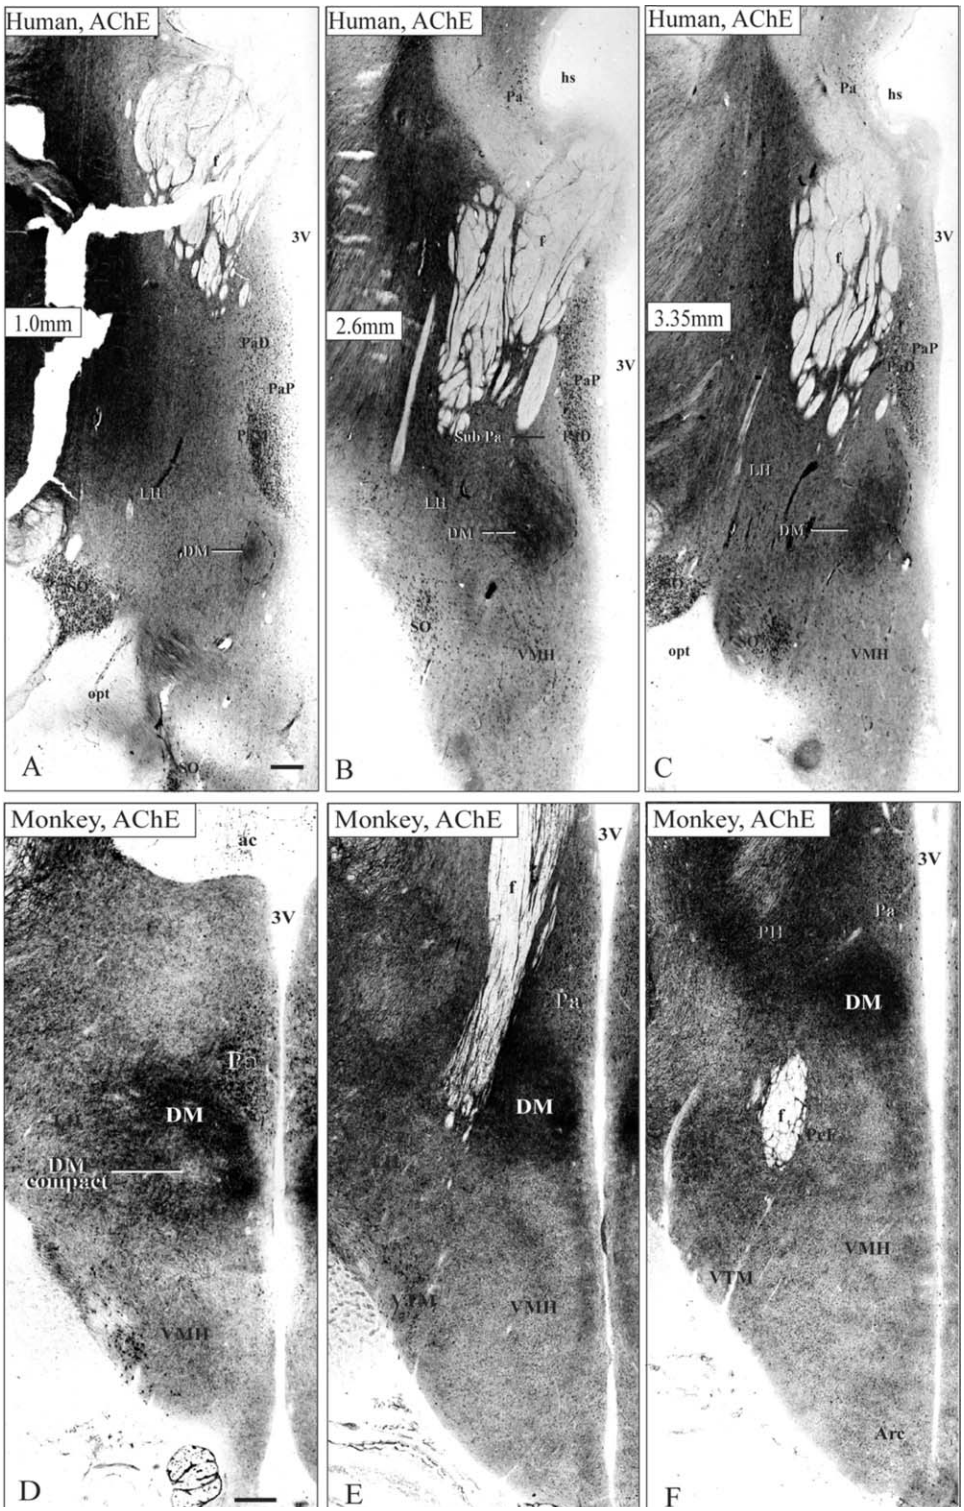

Figure 1 Photomicrographs of a series of coronal sections stained for acetylcholinesterase (AChE) that reveals the other wise vague boundaries of the dorsomedial nucleus at three rostrocaudal levels of the human (A–C) and monkey (D–F) hypothalamus. Stereotaxic coordinates are indicated on the left side of the photomicrographs for the human. Note the area between DM and Pa labeled in B as Sub Pa in the human but absent in the monkey. Also note an AChE-negative compact DM prominent in the monkey (D) but not in the human (A). Scale bar=1 mm.

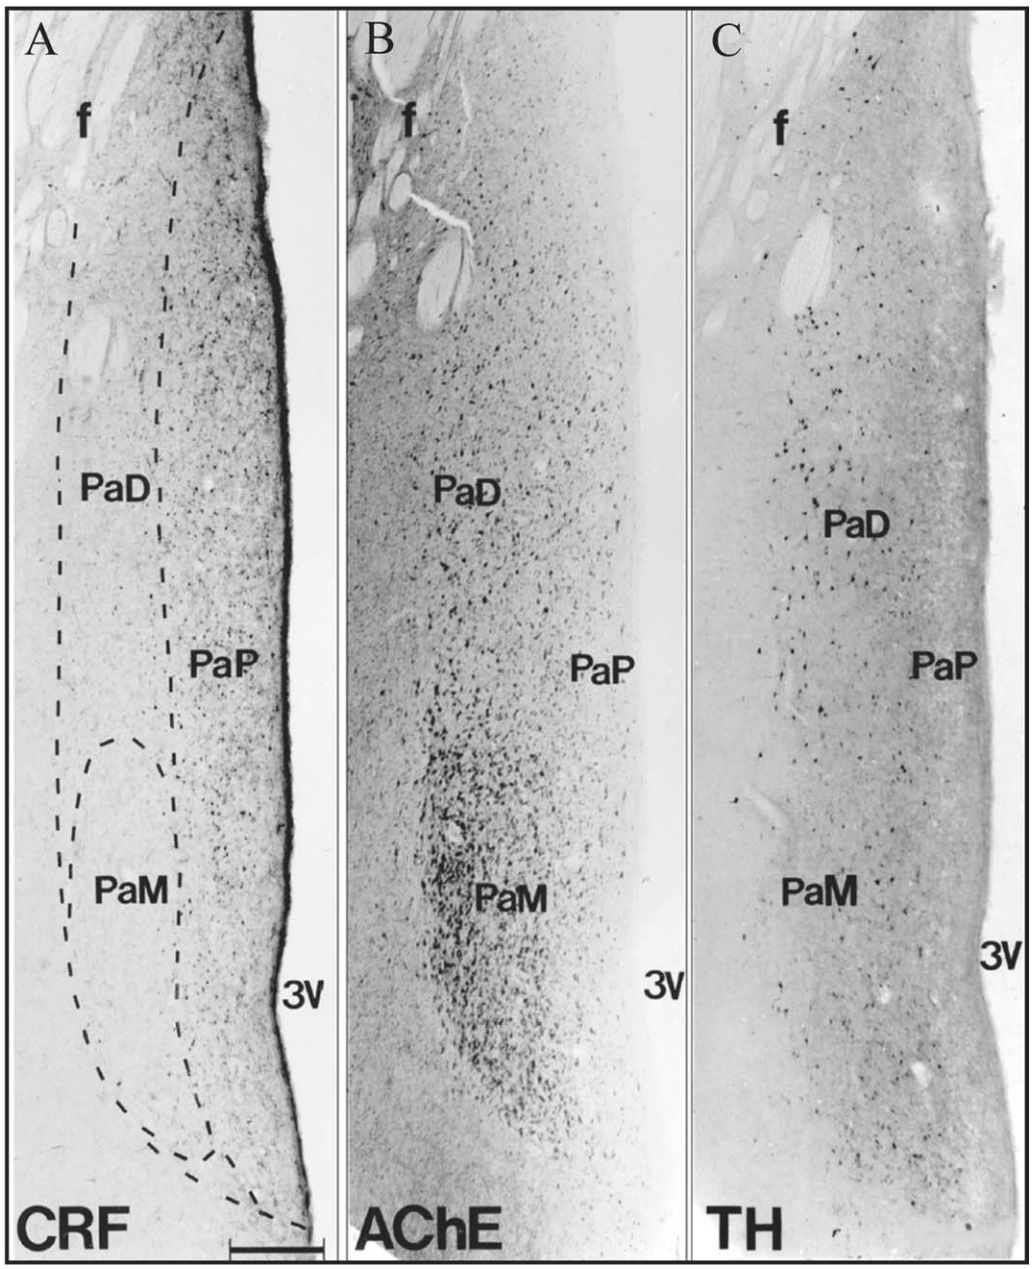

Figure 2 Adjacent coronal sections of the human hypothalamus processed alternately with immuno/enzyme histochemistry for corticotropin-releasing factor (CRF), acetylcholinesterase (AChE), and tyrosin hydroxylase (TH) that reveal the subnuclei organization of the human Pa. In each photomicrograph the third ventricle is to the right. Subnuclear boundaries are indicated by a dashed line in the CRF immunoreacted section. Scale bar=0.5 mm for all photomicrographs.

with which these molecules are distributed in different brain structures. Thus, above all, calcium-binding proteins are chemical markers differentiating brain structures with high resolution and consistency across species.

In the brain, calcium-binding proteins were successfully used to reveal the organization of the human thalamus, striatum, and hypothalamus. In the thalamus and hypothalamus, the content and morphological distribution of calbindin D-28K, parvalbumin, and calretinin varied greatly and consistently between different areas and cell groups. For example, distributions of calbindin and calretinin complement each other in differentiating the shell and core regions of the

accumbens nucleus, whereas parvalbumin is a distinct marker of the ventral pallidum. The distribution of calcium-binding proteins has been utilized in two ways; one related to the presence of the specific protein and another related to the structural boundaries this protein reveals. The first approach infers homology on the basis of similar chemical content of the putative homolog across species. For example, neurons of both the rat and the human medial preoptic nucleus (MPO), which is thought to be important for the regulation of sexual behavior, contain calbindin D-28K. The second approach infers homology on the basis of unambiguous borders as revealed by the distribution of these substances.

Among structural proteins, neuroanatomists often use the distribution of labeling by a monoclonal antibody directed against nonphosphorylated epitopes on neurofilament B protein [Sternberger Monoclonal Inc. 32 (SMI32)]. Immunohistochemical staining for SMI32 has been successfully used as an anatomical marker in the cortex, thalamus, and hypothalamus of the monkey and human. Hof suggested that the large size of SMI32-positive neurons found in the monkey and human cortex reflects the large distances to their neuronal targets. Recently, the pattern of SMI32 staining in the medial preoptic nucleus of the hypothalamus, an important regulatory center for sexual behavior, helped to establish a homology between the lateral MPO in the rat, monkey, and human hypothalamus (Fig. 3).

Occasionally, homologous nuclei in different species do not correspond fully in their chemical profile. For example, no one would dispute the homology of the basal nucleus of Meynert in the rat and human established on the basis of cyto- and chemoarchitecture. However, with respect to some substances, including calbindin D-28K, these cells have opposite profiles in the rat and human. However, the use of multiple markers, including calcium-binding proteins, affords greater confidence about the borders of this nucleus, revealing proportions and position that correspond to the homologous structure in the rat.

IV. PEPTIDES

The development of diverse antisera for a variety of peptides augmented the tool kit of chemical neuroanatomy. Neuropeptides are largely neuron-specific chemical compounds that, depending on the neuropeptide, are characteristic of specific neuronal subgroups. For example, vasopressin is characteristic of large cells in the lateral magnocellular subnucleus of the paraventricular hypothalamic nucleus. The neuropeptides are widely distributed and numerous, and for the sake of nomenclature they have been classified into families. For example, tachykinins (literally "fast acting") constitute a family of small, structurally related peptides that share a similar carboxy-terminal sequence but differ with respect to their function and distribution. The distribution of substance P, the most widely known tachykinin, was useful for the differentiation of four of nine subnuclei of the dorsal motor nucleus of the vagus nerve. Within these subnuclei, substance P staining revealed three different types of neurons. The neuropeptides, of course, are likely to be products of neuronal metabolism and thus a reflection of functional characteristics of the particular neurons. This does not mean that all the peptides are neurotransmitters or neuromodulators, but it does imply that the neuropeptide "alphabet" can be used for chemical coding of the neuronal groups that serve similar functions and are characterized by similar projections. In the *Rosetta stone* Greek was the common denominator between hieroglyphics and English. Likewise, the presence of a neuroactive substance in similar locations in the rat and the human brain can betray a structural homology.

The corticotropin-releasing factor (CRF) (or hormone) is a neuroendocrine peptide found in the cortex, basal telencephalon, brain stem, and hypothalamus. The best known function of CRF is to initiate the response in the hypothalamo–pituitary–adrena1 axis, but it is also implicated in stress responses, metabolic regulation, and food intake. Recent studies have found increases in the number of CRF-positive neurons in the human hypothalamus with age. Another report showed colocalization of CRF with nitric oxide synthase in a subgroup of cells in the human hypothalamus and suggested the possible involvement of these neurons in schizophrenia and depression. The distribution of CRF is very specific. Thus, in neuroanatomy CRF distribution has been used in the human brain to distinguish the subcompartmental organization of specific nuclei in the medulla and hypothalamus. For example, in the paraventricular hypothalamic nucleus, CRF neurons are confined to the parvicellular compartment, whereas the neurons that contain oxytocin are found primarily in the dorsal compartment. Applying these two markers to the same brain allowed researchers to distinguish between these subcompartments, which otherwise appear to be amalgamated, and it also allowed the establishment of subcompartmental homologies between human and rat paraventricular nucleus (Figs. 2 and 7).

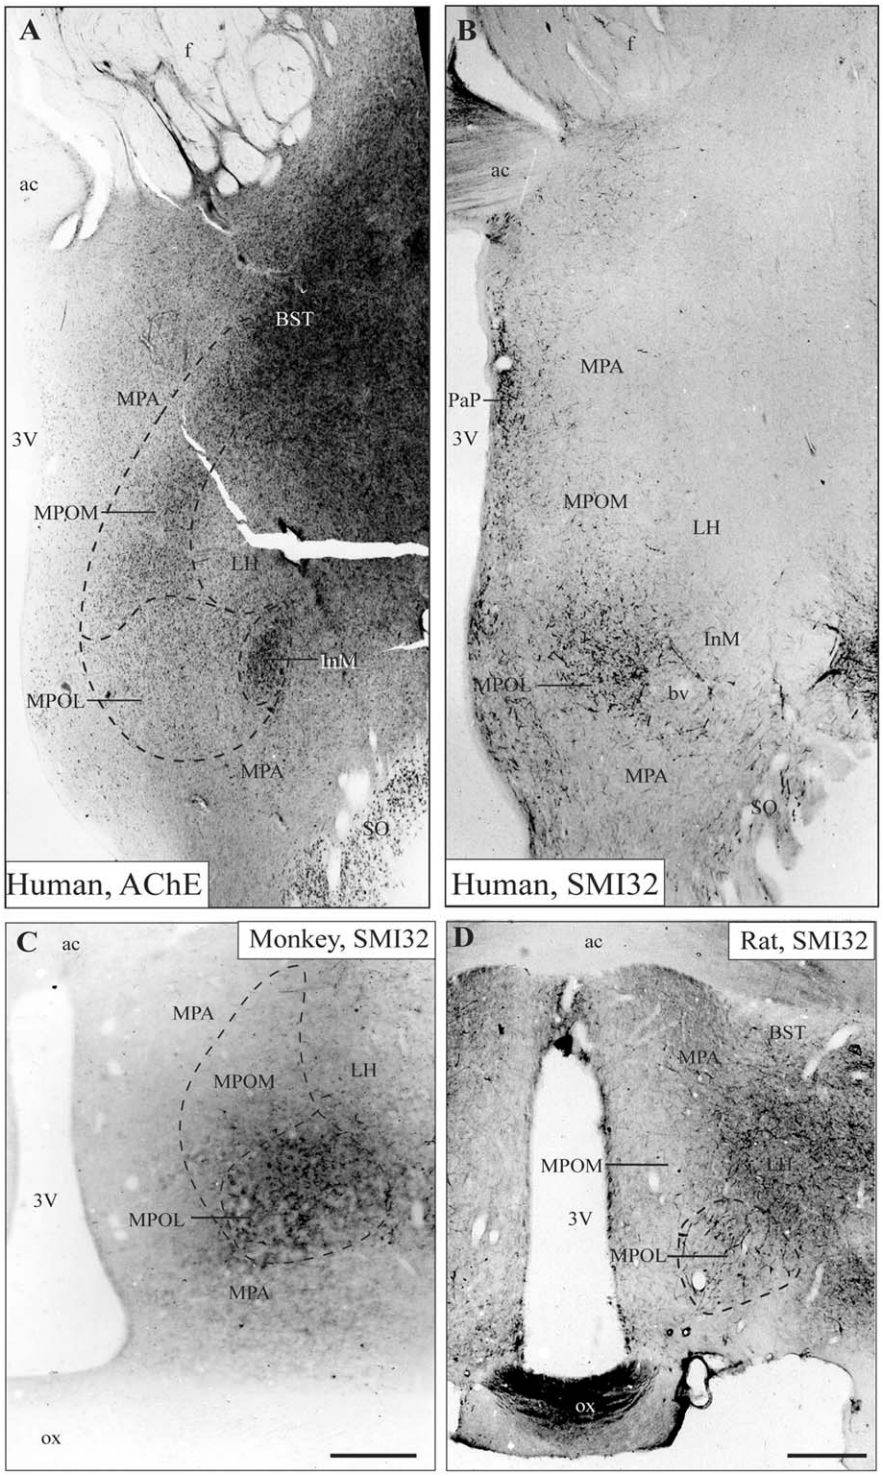

Figure 3 Photomicrographs of coronal sections through the human (A and B), monkey (C), and rat (D) anterior hypothalamus processed enzymatically and immunohistochemically for (A) AChE and (B) SMI32 showing complimentary distribution of these substances and revealing the three constituent subnuclei of the MPO. Sections in A and B are virtually adjacent. In all three species the lateral subnucleus of the medial preoptic nucleus (MPOL) contains SMI32 immunorecative neuropil, whereas the medial MPO (MPOM) is SMI32 negative. Acetylcholinesterase reactivity also reveals the celebrated sexually dimorphic (or intermediate InM) nucleus. Scale bar=1 mm (C) and 0.5 mm (D).

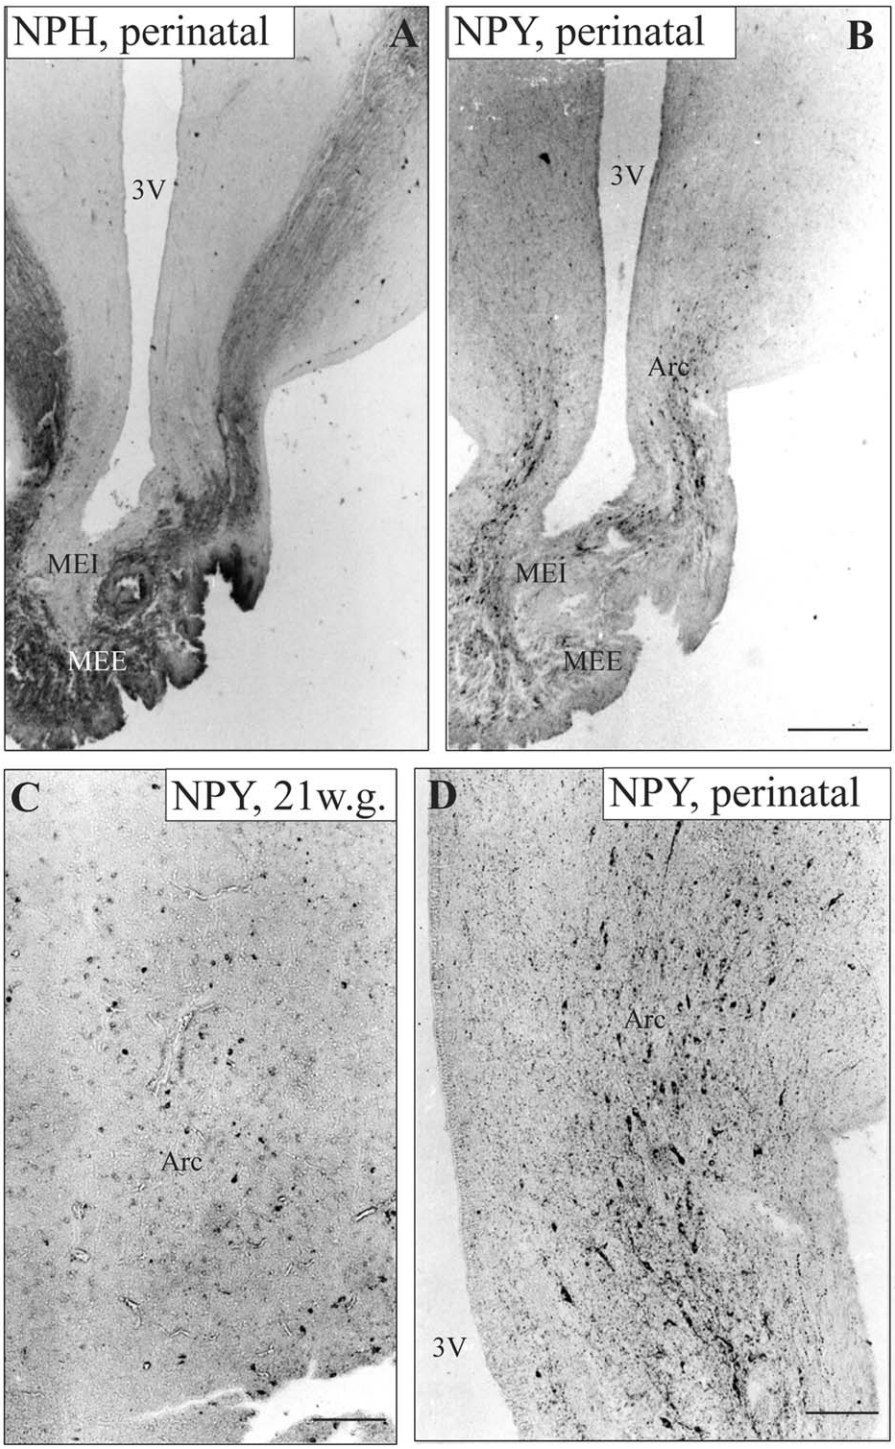

Figure 4 Photomicrographs of adjacent coronal sections through the human hypothalamus (demonstrating differential distribution of NPH-positive fibers (A) and neuropeptide Y (NPY)-positive cells and fibers (B). Immunoreactivity reveals details of intrinsic organization of the arcuate hypothalamic nucleus. (C) First appearance of NPY-positive neurons in the arcuate nucleus at 21 weeks of gestation. (D) Area of arcuate nucleus in B at higher magnification showing a population of morphologically developed NPY-positive neurons. (Reproduced from *J. Comp. Neurol.* with permission from John Wiley & Sons, Inc., 2002).

Neuropeptide Y (NPY) is a peptide that belongs to the pancreatic polypeptide family and is abundant throughout the central and peripheral nervous systems in both human and rat. In the brain, NPY is found at high concentrations in the mesencephalon, medulla, cortex, hippocampus, amygdala, ventral and dorsal striatum, and hypothalamus. As a neuroactive molecule, NPY has been implicated in the regulation of feeding behavior and autonomic and endocrine activity. Particularly instrumental for these ideas was the discovery of NPY-containing networks in the hypothalamus, where this peptide is confined approximately to specific neurons in the arcuate (Fig. 4) and suprachiasmatic nuclei and to fibers and neuronal terminals in the paraventricular and dorsomedial nuclei. Mapping the distribution of NPY in the human brain contributed greatly to the delineations of some functionally significant nuclei and areas. Thus, for example NPY defines the otherwise ambiguous and poorly visible ventral marginal hypothalamic zone, which has been implicated in the regulation of feeding.

V. RECEPTORS

Neuroanatomical delineations based on receptor distributions have been popular in pharmacological and neuroanatomical studies since the late 1960s and 1970s, particularly with the development of autoradiographic techniques. As a clear advantage, receptors were often confined to a small area in the brain and thus differentiated specific neuronal projections with great accuracy. This has not only given neuroanatomical delineations a greater precision and resolution than ever before but also helped our understanding of how drugs work in the brain. For example, neuroanatomical maps of receptors not only reveal the presence of a receptor specific for a certain drug in the brain but also reveal the specific circuitry to which it belongs. This, in turn, points to a mechanism of drug action. For example, Paxinos and Watson originally delineated the intermediate reticular zone in the rat brain on the basis of a band of negative AChE staining between the gigantocellular and parvicellular reticular nuclei. The area remained ambiguous until another group of researchers demonstrated that the zone exclusively contains angiotensin II receptors in the rat and human brain. Intense angiotensin II receptor binding in the intermediate reticular zone and no binding in the neighboring gigantocellular or parvicellular nuclei revealed clear boundaries of the structure and unambiguously pointed to its homology between rat and human.

The neurokinin B receptor (NK3) is an integral component of the neural circuitry of neurokinin B, which in turn is a member of the tachykinin family of peptides (also including substance P and neurokinin A). NK3 is also an important element of the hypothalamic neuronal circuitry regulating blood pressure. Recent studies used immunohistochemistry to reveal the distribution of NK3 in the human hypothalamus and to compare this with the distribution of the receptor in the rat hypothalamus, in which the structure–function associations are better studied. The strongest NK3-like immunoreactivity in the human hypothalamus was found in neurons of the paraventricular nucleus (Pa), specifically in the parvicellular and posterior Pa subnuclei, thus distinguishing these structural subcompartments (Fig. 5). Another prominent population of NK3-positive cells in the human hypothalamus was found in the perifornical nucleus, distinguishing it from the rest of the lateral hypothalamic area. In cross-species comparison there appeared to be a large degree of similarity in the distribution of NK3 in the human and rat hypothalamus.

In the past two decades, the technique of *in situ* hybridization became available, and with its myriad of probes it allowed further characterization of the cell groups (Fig. 6). The presence of mRNA indicates a condition for protein production within specific neurons. A clear advantage of the method is that the mRNA signal is quantifiable. The quantity of signal can then be compared across species or between human brains. The distribution of mRNA generally falls within the boundaries defined by chemoarchitecture but in some rare cases it has been known to differ with the location of the corresponding protein. As an alternative technique to histo- and immunohistochemistry, *in situ* hybridization provides an important confirmation of existing neuroanatomical delineations.

In describing chemical neuroanatomy as a methodology to reveal the organization of the human brain, it is useful to demonstrate the application of the approach in specific areas of the brain.

VI. HYPOTHALAMUS

It became clear from animal experiments that the small area of the hypothalamus contains a structural maze of

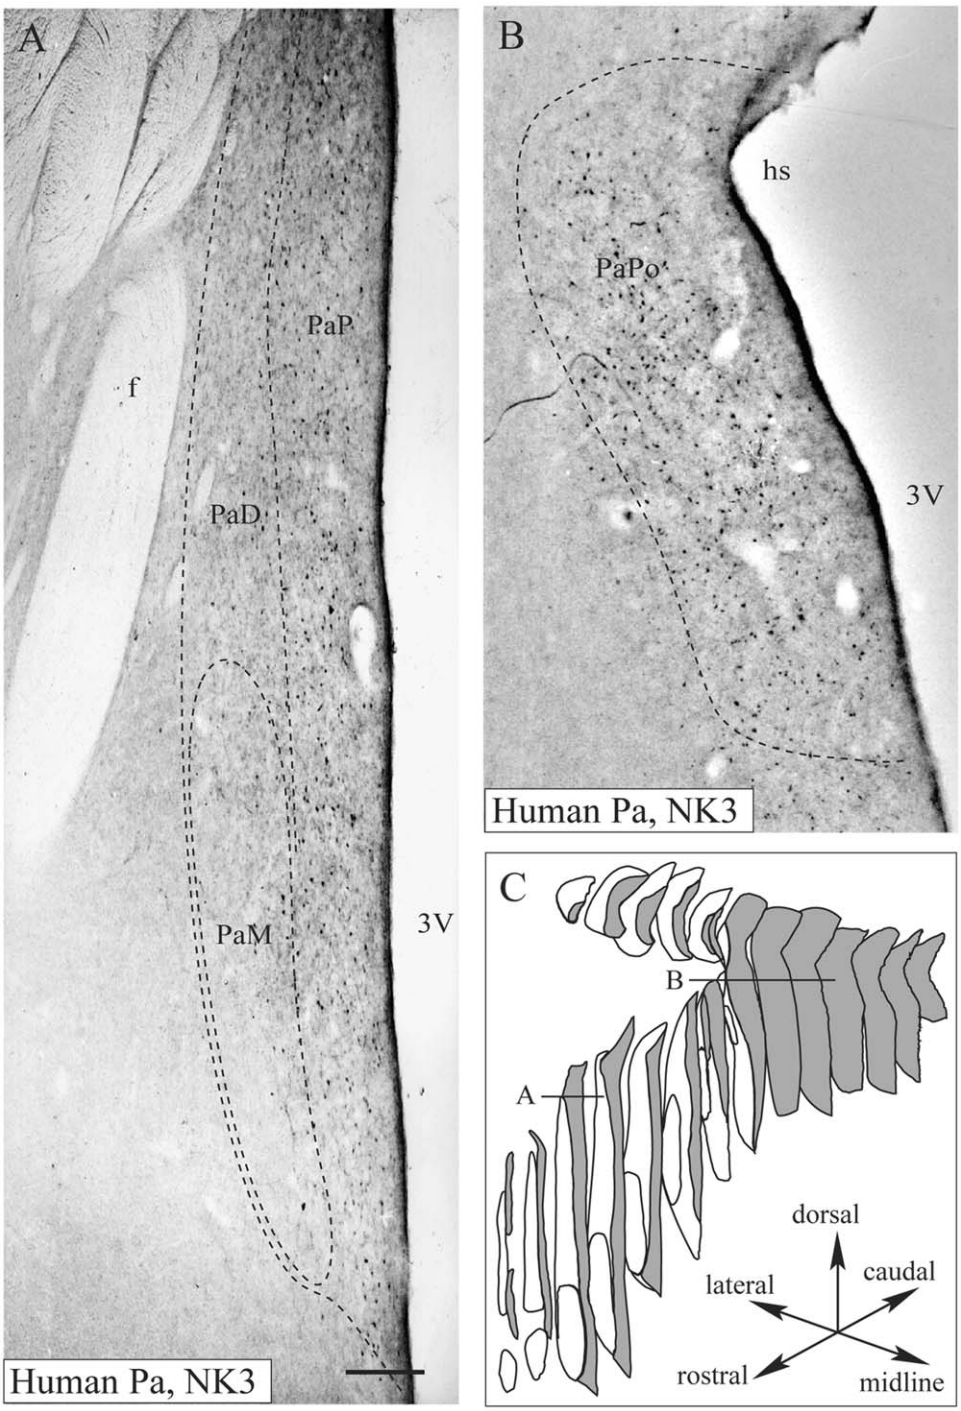

Figure 5 Photomicrographs of coronal sections from the human hypothalamus demonstrating the distribution of NK3 in different subcompartments of the paraventricular nucleus (A and B). Scale bar=0.35 mm. (C) The schematic diagram shows the parts of the Pa from which these sections were taken. neural relays that integrate fundamental autonomic, endocrine, and behavioral responses into an elegant strategy regulating homeostasis and reproduction. These relays are cyto- and chemoarchitectonically distinct nuclei, which also differ with respect to their affiliations and functions. Extrapolations to humans of the conclusions obtained from studies on experimental animals have been based on the rationale that

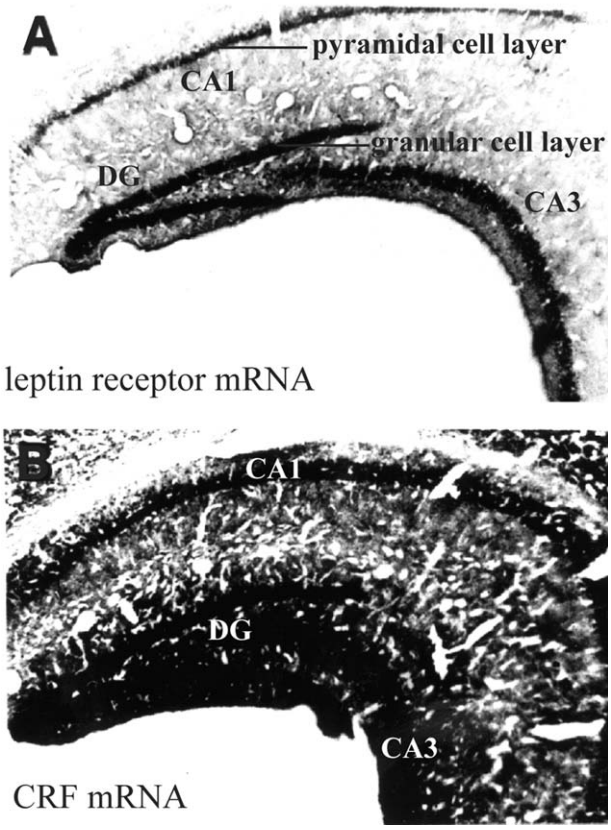

Figure 6 These photomicrographs of coronal sections through the hippocampal region demonstrate an example of nonradioactive *in situ* hybridization signal obtained with two different probes directed against leptin receptor mRNA (A) and against CRF mRNA (B).

homologous structures have analogous function across mammals. The homologies are established on the basis of chemoarchitecture.

The past century has seen comprehensive cytoarchitectonic and comparative studies, which have provided plans for the structural organization of the human hypothalamus. However, apart from the work of Saper and that of Braak and Braak, these studies relied on cytoarchitecture and myeloarchitecture for their delineations. Cytoarchitecture, when used as a single comparative criterion, has shortcomings because the cell groups in the adult human hypothalamus are dispersed and certainly less obvious with respect to their subnuclear boundaries than they are in the rat. As a consequence of ineffectual comparative investigations, there is confusion regarding the terminology of the human hypothalamic cell groups. The basic organizational plan of the hypothalamus is thought to be well preserved throughout the mammalian lineage. It became apparent that to produce a unified nomenclature it is necessary to study human and rat hypothalami in parallel, using the same criteria for the establishment of homologies. Thus, current neuroanatomical studies of the human hypothalamus use cytoarchitecture, chemoarchitecture, topography, subnuclear organization, and pattern of development as criteria for cross-species homologies.

For example, the chemoarchitecture of the human paraventricular hypothalamic nucleus was recently studied with the aid of three-dimensional computer reconstruction (Fig. 7). Chemoarchitecture revealed five subnuclei in the adult human Pa. The most prominent of these is the magnocellular subnucleus (PaM), occupying the ventrolateral quadrant of the Pa and composed of a concentration of large arginine–vasopressin (AVP)- and acetylcholinesterase (AChE)-positive cells and small calbindin (Cb)-positive neurons. Rostrally, the PaM is succeeded by the small anterior parvicellular subnucleus (PaAP), which contains small AChE-, AVP-, and TH-positive cells. Dorsal to the PaM is the dorsal subnucleus (PaD), containing large spindle-shaped TH-, oxytocin (OXY)-, and AChE-positive cells as well as a population of Cb-positive neurons. Abutting the wall of the third ventricle and medial to PaD and PaM is the parvicellular subnucleus PaP. The PaP contains small cells immunoreactive for corticotropin-releasing factor (CRF), NK3, and nonphosphorylated neurofilament protein SM132. The posterior subnucleus (PaPo) is situated posterior to the descending column of fornix; it replaces all previously mentioned subdivisions caudally and is a chemoarchitectonic amalgam that includes dispersed large AChE-, TH-, OXY-, and AVP-positive cells as well as small NK3-, CRF-, SMI32-, and Cb-immunoreactive neurons. The distinctions between Pa subnuclei were further validated by the recent demonstration of different developmental patterns for the subnuclei during fetal gestation (Fig. 8). It is appropriate to mention that the latter study also relied on chemoarchitecture. These findings indicated the homology between the human PaM and PaD and the magnocellular subnuclei of the rat Pa and also between the human PaP and PaPo and the medial parvicellular and posterior subnuclei of the rat.

Apart from the already mentioned CRF, several other releasing hormones have been localized in the human hypothalamus. Most of these molecules are characterized by limited distribution, which benefits the accuracy of identification of the corresponding neuronal structure. Thus, neurons containing growth hormone-releasing hormone (GRH) in the human brain are found exclusively in the arcuate nucleus of

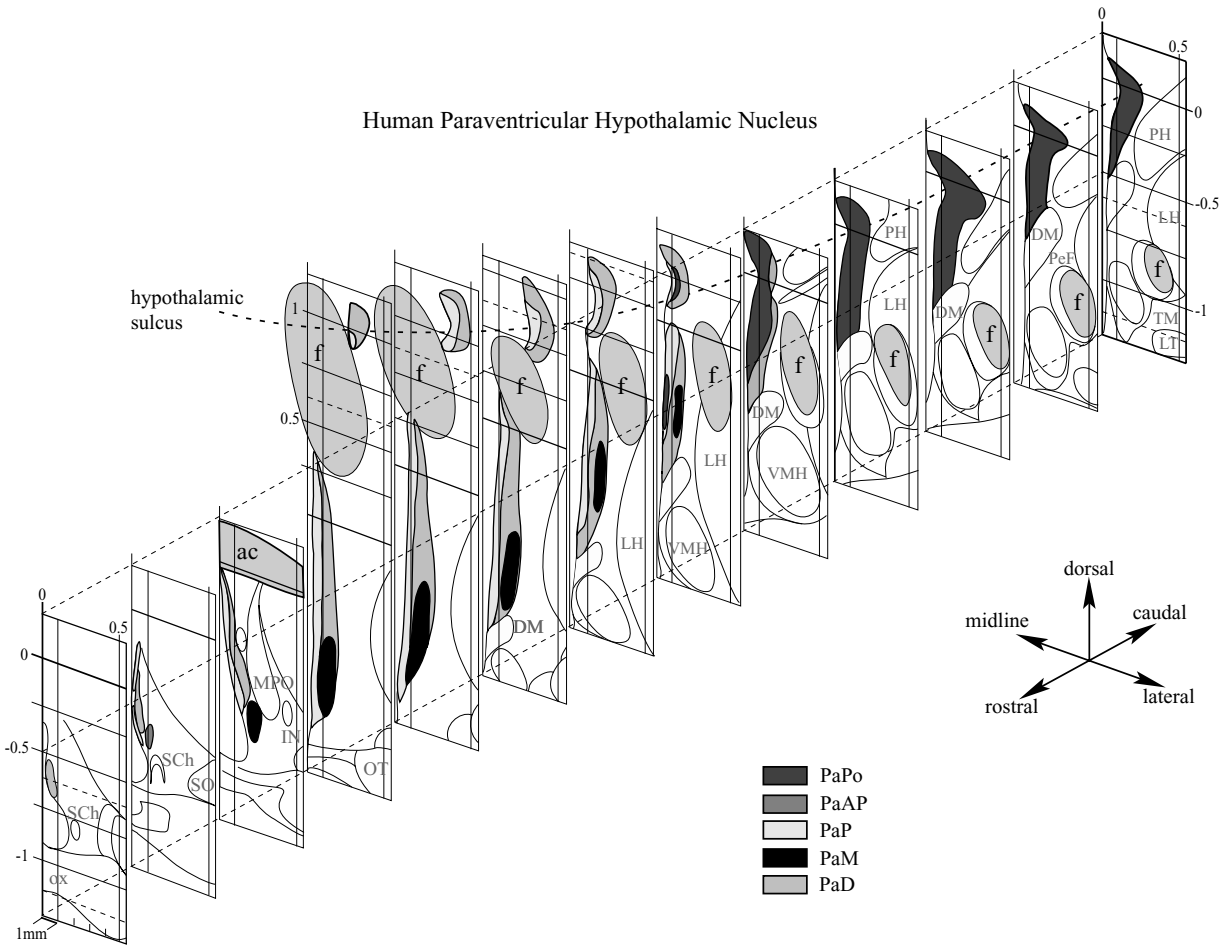

Figure 7 A model of the human Pa showing the subnuclei delineations based on computer-generated plots of six histochemical markers (AChE, SMI32, Cb, TH, NK3, and CRF) and verified with the distribution of AVP, OXY, and NPH. The third ventricle wall lies to the right. (Reproduced from *J. Comp. Neurol.* **423** with permission from John Wiley & Sons, Inc., 2000).

the hypothalamus. Some GRH-immunoreactive fibers are also found dorsally in the periventricular area, dorsomedial hypothalamic nucleus, and on the boundary of the ventromedial hypothalamic nucleus. Luteinizing hormone-releasing hormone (LHRH) has been found in the human hypothalamus within distinct neuronal groups, including the arcuate nucleus, the periventricular nucleus, the medial preoptic area, and the premammillary area.

Neurons of arcuate and periventricular hypothalamic nuclei also contain somatostatin, whereas fibers containing somatostatin are also found extending into the median eminence. Somatostatin is a peptide that inhibits the release of growth hormone (somatotropin) from the anterior pituitary. As such, somatostatin is a release-inhibiting factor. The distribution of somatostatin-immunoreactive neurons extends beyond the hypothalamus, with somatostatin-containing neurons found in the diagonal band of Broca, medial septal nuclei, nucleus basalis of Meynert, striatum, bed nucleus of stria terminalis, amygdala, and as far caudal as the periaqueductal gray and brain stem reticular formation. Concurrent autoradiographic studies revealed somatostatin binding sites in the human brain stem tegmentum, basal forebrain, and striatum. A decade of research on the distribution of the hormone-releasing factors established the location of these distinct chemically coded networks and contributed to neuroanatomical delineation of the human brain.

Recent chemoarchitectonic studies demonstrated the presence of an important feeding regulatory molecule orexin (hypocretin) in the lateral hypothalamic neurons of humans, rats, and mice. The report also distinguished between two populations of neurons

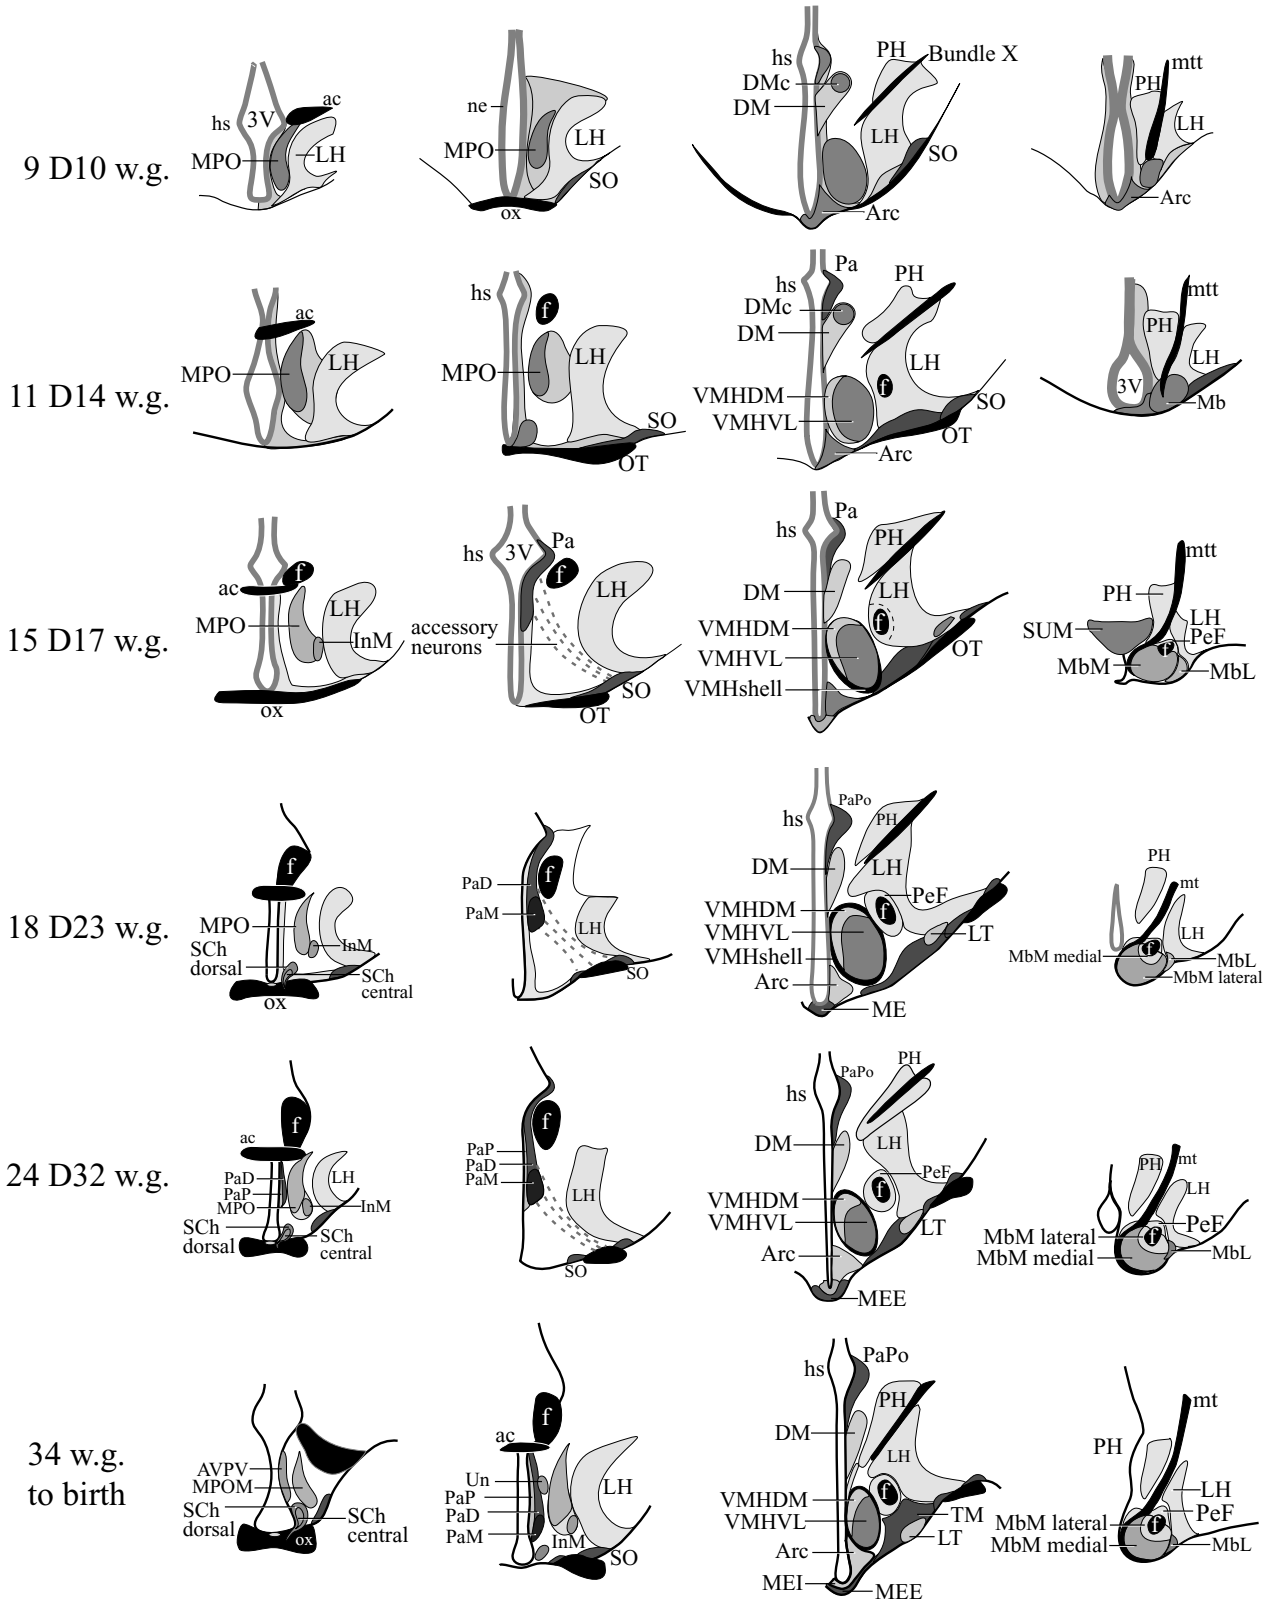

Figure 8 Diagram showing the organization of major cell groups in the developing human hypothalamus depicted at landmark stages of fetal differentiation. Grayscale represents hypothalamic structural entities revealed by cytoarchitecture of the neuroepithelial primordia and transient chemoarchitectonic labeling. Note that these diagrams are not to scale. (Reproduced from *J. Comp. Neurol.* with permission from John Wiley & Sons, Inc., 2002).

in the lateral hypothalamus, one containing orexin- and another expressing melanin-concentrating hormone. Functional evidence as well as the strong relationship of orexin and melanin-concentrating hormone containing cells in the lateral hypothalamus to both the NPY and agouti gene-related protein systems suggest an important role for these neuronal groups among hypothalamic networks regulating feeding. These findings reinforce the importance of comprehensive use of chemoarchitecture in comparative studies of the adult human brain.

Chemoarchitecture is also useful in the study of the fetal brain. Thus, several chemoarchitectonic studies of the human fetal hypothalamus reported on the development of the hypophyseal portal plasma system, CRF-containing circuitry, GRH neurons, and somatostatin-, oxytocin-, vasoperessin-, and neurophysin-containing cells. Another recent study has proved the benefits of using a combination of peptide, receptors, and structural and calcium-binding protein markers on a series of fetal brains at different stages of development to provide insight into the structural development of the human hypothalamus (Fig. 8). Substances that revealed some aspects of synaptogenesis, such as GAP43 and SYN, and an antibody directed against a cell surface membrane glycoconjugate, 3-fucosyl-*N*-acetyl-lactosamine (FAL or CD15) were also found to be useful in the delineation of developing hypothalamic cell groups.

In the fetus, the structural differentiation of the lateral and posterior hypothalamus is apparent at 9 weeks of gestation, when these structures are marked by strong immunoreactivity for GAP43, a nerve terminal membrane phosphoprotein associated with the development and restructuring of axonal connections. This suggests that within the hypothalamus, synaptogenesis is well under way in the lateral and posterior hypothalamic areas as early as 10 weeks of gestation. In addition, GAP43 immunoreactivity clearly reveals, at 13 weeks of gestation, the otherwise ill-defined bundle x, which separates LH ventrally from posterior hypothalamic area (PH) dorsomedially. Following the emergence of GAP43, another significant event in the differentiation of the lateral and posterior hypothalamic areas is the appearance of large Cr- and Cb-immunoreactive neurons at 13 and 16 weeks of gestation, respectively, and their persistence into the postnatal period. The mature morphological appearance of these neurons is reached by approximately 16 weeks of gestation, when they spread far laterally, abutting the *pallidum* and dorsally mingling with the zona incerta. Observations from the human fetus are consistent with reports on Cb immunoreactivity in the developing rat hypothalamus suggesting similarities between the area in the rat and human. In human fetuses chemoarchitecture also reveals distinct differences between the constituent structures of the *lateral hypothalamic zone*. For example, cells in PH, but not LH, show FAL immunoreactivity from 18 weeks of gestation until birth. Furthermore, the LH area contains Cr- and Cb-positive neurons and GAP43 immunoreactivity early in fetal gestation, unlike the adjacent tuberomammillary nucleus, which acquires Cb-positive neurons only late in gestation.

The distinction between the perifornical hypothalamic nucleus and lateral hypothalamic area in the rat has been demonstrated by chemoarchitectonic and functional studies. Until recently, the adult human perifornical nucleus was mainly defined by topographic criteria because cytoarchitectonically it largely resembles surrounding structures. According to a recent chemoarchitectonic study in the human fetus, perifornical hypothalamic nucleus (PeF) is formed as a result of passive displacement of LH neurons medially. The studies' conclusions were based on differentiation patterns of calbindin-, calretinin-, and neuromedin K receptor-immunoreactive neurons. Thus, during gestation, the neurons of the lateral hypothalamus, which develop early, are progressively displaced laterally by the successive waves of neurons of the *midline* and *core* zones, which develop later. In contrast to LH neurons, the neurons of the PeF that originate from the lateral hypothalamic zone remain anchored in the perifornical position, possibly by virtue of their dendrites invading the fornical bundle.

VII. CORTEX

The cortex appears curiously homogeneous given the extensive variety of its functionally diverse areas. Mapping the cortex and distinguishing between the functionally different areas has always been a challenge because of the large size and convolution of the cortical mantle and the subtlety of cyto- and myeloarchitectonic differences between areas. Chemoarchitecture, on the other hand, is a reliable tool that can provide distinct characteristics distinguishing one cortical area from another on the basis of neuroactive content, which in itself is functional evidence. It must be acknowledged, however, that chemoarchitectonic boundaries between areas of the cortex are far less obvious than those in the subcortex.

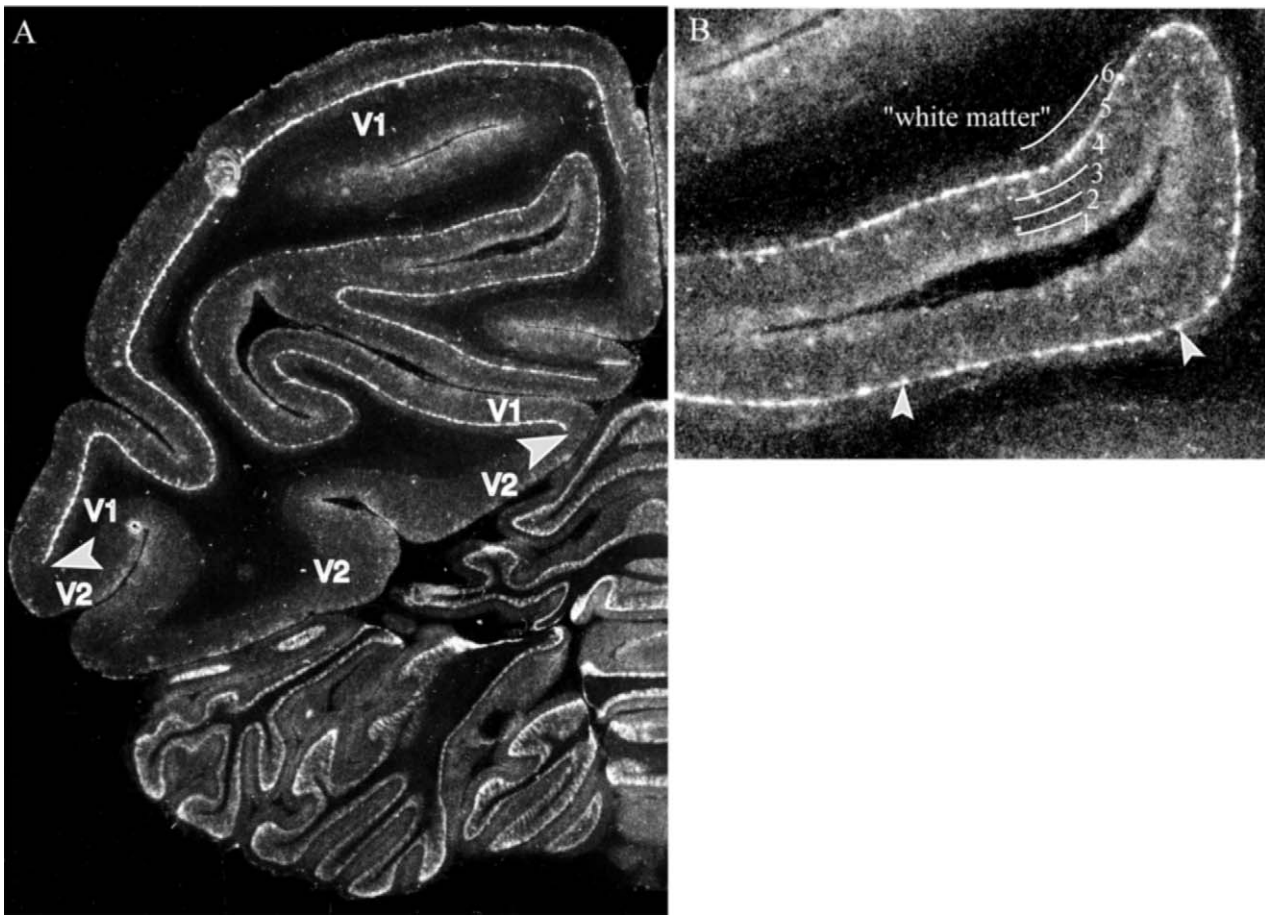

Figure 9 Photograph of an autoradiograph of a coronal section through the visual cortex showing the distribution of ^{125}I-salmon calcitonin binding. Large arrows indicate precise boundaries between V1 and V2. (B) A segment of the autoradiograph at higher magnification demonstrates 200-μm periodicity of binding (small arrows) that may be related to ocular dominance columns or to cytochrome oxidase blobs, which are characteristic of V1. Note how the binding is confined to lamina 5 of the V1.

Therefore, in anatomical studies of the cortex chemoarchitecture is used as an aid to cytoarchitectonic guidelines rather than as a primary delineation criterion. Chemical differences, however subtle, between neuronal populations in different cortical areas and cortical layers are never the less pivotal criteria for understanding the structural organization of the human cortex.

Chemoarchitectonic boundaries often correspond to the boundaries of cortical areas as identified by functional studies. For example, the boundaries of the primary visual cortex (area V1) are apparent by the prominent acetylcholinesterase reactivity that abruptly stops on the border between V1 and V2. Such chemical characteristics bring credibility to the otherwise ambiguous boundaries between these cortical areas. Apart from differentiating areas of the cortex, chemoarchitecture also distinguishes between neuronal populations in different cortical layers. For example, calcitonin receptor binding is abundant and exclusive for V1, but within that area it is confined to neurons of layer 5, which further characterizes these cells (Fig. 9).

As in the subcortex, the best results for structural differentiation of neuronal groups in the cortex are achieved through combining different chemical markers. Strong SMI32 immunoreactivity reveals a distinct population of large pyramidal cells in lower layer III and in layer V, calbindin immunoreactivity distinguishes pyramidal neurons in layers II and III, and immunoreactivity for the glutamate synthesizing enzyme glutaminase is characteristic of pyramidal cells in layers II, III, V, and VI. The combined use of histochemical markers for NADPH-d and the immunohistochemical technique for visualizing NPY revealed two populations of neurons that contain both

markers. This finding prompted the distinction of these groups of nonpyramidal, peptidergic neurons in layers V and VI of the human cerebral cortex.

There are reports of several populations of nonpyramidal neurons containing peptides and characterized by specific morphology and laminar distribution. Chemoarchitectonic characteristics are of assistance in classifying these neuronal groups. For example, immunoreactivity for TH characterizes a population of spindle-shaped neurons found to be numerous in the infragranular layers of the cortex. Cholecystokinin-immunoreactive neurons characterize a population of bipolar cells in the subgranular layers, whereas coexpression of NPY and substance P characterizes another prominent population of multipolar neurons in the deep layers of cortex and in the white matter. It should be reiterated, however, that although chemoarchitecture is informative for differentiation of some areas of the cortex, the difference is generally less striking than in the subcortex.

VIII. CONCLUSION

Chemical neuroanatomy offers a wide range of techniques for identification and classification of neuronal groups in the brain. Chemical markers are a meaningful criterion for characterizing and mapping neuronal groups in the human brain, and chemoarchitecture can be used as a *Rosetta stone* to establish homologs of subnuclei and chemically specific circuitries in the human brain corresponding to those of the rat.

Chemical neuroanatomy is an exciting and quickly developing field of neuroscience. Particularly useful for the study of the human brain and constantly stimulated by new techniques, chemical neuroanatomy continues to evolve both in significance and in sophistication.

GLOSSARY

associative attention Attention focused on stimuli that predict the occurrence of reinforcement (reward or pain) and call for action.

brain electrical source analysis A dipole localization algorithm used to model the intracranial sources of electrical fields that generate scalp event-related potentials.

discriminative training-induced neuronal activity Significantly greater neuronal firing frequencies in response to a positive conditional stimulus than to a negative conditional stimulus. Discriminative training-induced neuronal activity occurs in many brain areas as early as 15 msec after conditioned stimulus onset.

duration coding Greater neuronal firing in response to a brief than to a more enduring positive conditional stimulus.

error-related negativity Electrical negativity found in event-related potential recordings from mid-frontal regions of the scalp. The peak of the error-related negativity occurs approximately 100 msec after the onset of an erroneous response.

executive attention A process guided by an individual's plans and goals, which comes into play when routine or automatic processes are insufficient for the task at hand, such as when novel or conflict-laden situations are encountered.

positive conditional stimulus A stimulus employed in studies of classical and instrumental conditioning. The occurrence of a positive conditional stimulus predicts reinforcement (reward or pain). A negative conditional stimulus predicts that no reinforcement will occur.

salience compensation An attentional process of cingulate cortex that amplifies the neural representation of nonsalient but associatively significant stimuli in order to ensure that such stimuli receive processing that is commensurate with their associative significance. Duration coding is an example of salience compensation.

Early and highly influential accounts of cingulate cortical function were presented by J. W. Papez and Paul MacLean, who argued, in essence, that activity in neural circuitry involving cingulate cortex and related structures of the brain's limbic system is the neural substrate of emotional experience. Recent studies have implicated cingulate cortex in pain perception and in the cognitive processes of attention, response selection, learning, and memory. Morever, changes in the cingulate cortex have been found relevant to the etiology of schizophrenia and Alzheimer's disease. This article emphasizes developments concerning the behavioral and cognitive functions of cingulate cortex. A particular emphasis of this article is the integration of many recent findings from laboratories of behavioral neuroscientists concerning neuronal firing patterns and effects of experimental brain lesions on behavior in animals with a large body of recent data from laboratories of cognitive neuroscientists concerning experimental analyses of human cognition using neuroimaging methods such as positron emission tomograpy, functional magnetic resonance imaging, and high-density electroencehpalographic recording. Before addressing these issues, however, some basic facts and definitions are reviewed.

I. CINGULATE CORTEX: WHAT AND WHERE?

Cingulate cortex is located in the medial walls of the cerebral hemispheres and is a subset of "limbic

cortex." Limbic cortex includes all areas that receive fibers of anterior thalamic neurons. By modern convention, the subset of limbic cortex constituting cingulate cortex includes Brodman's areas 24 and 29 in small animals such as rabbits and rats. These and an additional area (23) constitute cingulate cortex in primates. A cytoarchitectural map of the primate limbic cortex is shown in Fig. 1.

Brodman's areas 24 and 29 are often referred to respectively as anterior and posterior cingulate cortex. Neurons in both areas receive afferent fibers from the anterior medial (AM) thalamic nucleus. However, the anterior cingulate cortex (area 24) is also innervated by projections of the medial dorsal (MD) and parafascicular thalamic nuclei. Neurons in the posterior cingulate cortex (area 29) receive projections from all members of the anterior group of nuclei, the anterior ventral (AV), anterior dorsal, and the AM nuclei, as well as the ventral anterior and lateral dorsal thalamic nuclei. Neurons in midline and intralaminar thalamic nuclei send axons to both the anterior and the posterior cingulate cortex.

Cingulate cortical neurons are robustly responsive to multimodal (auditory, visual, somatic sensory, and visceral) stimuli, and they are richly innervated by fibers of the pons and midbrain that distribute the biogenic amines (dopamine, norepinephrine, and serotonin) as well as acetylcholine. Whereas norepinephrine, serotonin, and acetylcholine fibers fairly uniformly innervate both the anterior and the posterior cingulate cortex, only anterior cingulate cortex receives appreciable amounts of dopamine. Many additional afferent systems course to the cingulate cortex, including fibers from visual cortex, hippocampus, subiculum, entorhinal cortex, and amygdala. Cingulate cortical neurons send efferent fibers to most of the aforementioned thalamic areas, the subiculum, entorhinal cortex, and pons and to many areas of the striatal motor system, including the caudate nucleus, nucleus accumbens, and zona incerta. Moreover, in primates, cingulate cortical neurons project to multiple areas of the motor and premotor cortex. Thus, numerous parallel pathways exist whereby cingulate neurons can modulate motor output systems of the brain. Finally, the work of Patricia Goldman-Rakic and colleagues has demonstrated direct reciprocal projections of cingulate cortical neurons in primates to the lateral prefrontal and parietal cortex, areas involved in high-level perceptual and mnemonic functions.

II. FUNCTIONS OF THE CINGULATE CORTEX

A. Associative Attention

As students of cognition are aware, the term attention has multiple interpretations. Research in the area of behavioral neuroscience with rabbits and rats indicates that the attention supported by cingulate cortex is selective attention or attention focused on particular stimuli. The stimuli that are selectively processed by cingulate cortical neurons are those that predict important outcomes, such as reward or aversion. Also, in most if not all cases they are "task-relevant" stimuli (i.e., stimuli that require a particular action).

The selective processing of stimuli by cingulate cortical neurons emerges as the subjects learn that a given stimulus predicts an important outcome and requires action. Thus, the attentional process of cingulate cortex that is invoked by such predictive stimuli is a learned or "associative" process of the brain. Stimuli that signal important outcomes and call for action produce large neuronal activations in cingulate cortex, whereas stimuli that predict that no important event will occur and that no action is needed do not elicit ample cingulate cortical neuronal discharges. An apt characterization is that cingulate cortex mediates associative attention to significant stimuli. Findings in support of these propositions are reviewed next.

1. Cingulate Cortical Neuronal Activity

a. Discriminative Neuronal Activity Data supporting the hypothesis that cingulate cortex mediates associative attention to significant stimuli are afforded by studies of neuronal activity in multiple brain sites during discriminative instrumental learning of rabbits. In these studies the rabbits occupied a large rotating wheel apparatus. They learned to step in response to a tone cue, a positive conditional stimulus (CS^+), in order to prevent a foot-shock scheduled for delivery 5 sec after the CS^+. They also learned to ignore a different tone, the negative conditional stimulus (CS^-), that was not followed by the foot-shock.

Recordings of neuronal activity in multiple areas of cingulate cortex and in related areas of the thalamus exhibited the development, during behavioral learning, of massive discriminative multi-, and single-unit neuronal responses. Discriminative neuronal responses are significantly greater firing frequencies in response to the CS^+ than to the CS^-. They occur at brief latencies (15–100 msec) and persist for varied durations, with some neurons exhibiting discrimination during the full interval preceding response or shock (Fig. 2).

The discriminative neuronal activity represents an associative or learned activity of cingulate cortical neurons. It is not simply a frequency-specific response of the monitored neurons because the discriminative response is observed in many subjects given different (counterbalanced) sets of acoustic frequencies as CS^+ and CS^-. Discriminative activity develops as a result of the associative pairing of the CS^+ with the foot-shock reinforcer. A different neuronal response (either no response or one of significantly reduced magnitude) occurs to the CS^-, which is not predictive of the foot-shock. Thus, the activity of cingulate cortical neurons in these studies may be viewed as a neuronal code for the associative significance of the discriminative cues. It can be said that cingulate cortical neurons "learn" to respond selectively to stimuli that predict the occurrence of significant events and require action, which in these studies is the locomotor response needed to avoid the foot-shock.

Discriminative activity also occurs during learning of a reward-based response, wherein rabbits approach and make oral contact with a drinking spout inserted into the experimental chamber following CS^+ presentation. The rabbits also learn to inhibit responding when the spout is inserted following CS^- presentation and oral contact with the spout does not yield water reward. Once again, neurons in cingulate cortex encode the associative significance of the conditional stimuli, i.e., they produce greater discharges in response to the CS^+ than to the CS^-. These data rule out the possibility that cingulate cortical neurons encode the emotional value (pleasant or unpleasant) of the reinforcer predicted by the CS^+, i.e., differential firing to stimuli that predict pleasant versus unpleasant consequences. Rather, cingulate cortical neurons encode stimuli that predict important events and call for action, whether the events are good or bad.

Discriminative neuronal activity in cingulate cortex has also been reported by Shirley Buchanan, Donald Powell, and Charles Gibbs during classical Pavlovian conditioning of heart rate and eyeblink responses in rabbits. Also, early studies of Menachem Segal and James Olds and recent studies of Takenouchi and colleagues demonstrated the occurrence of neuronal responses in anterior and posterior cingulate cortex that are specific to stimuli that predict reinforcement during appetitive conditioning.

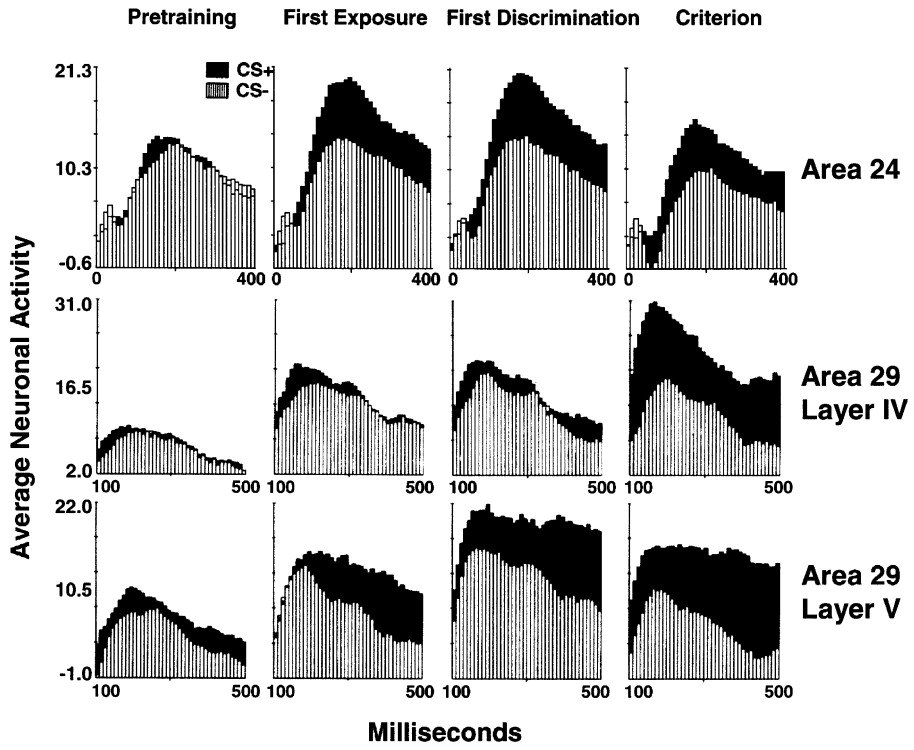

Figure 2 Average anterior (area 24) and posterior (area 29, cellular layers IV and V) cingulate cortical integrated unit activity elicited by CS^+ and CS^- in rabbits during pretraining, first exposure session, first significant behavioral discrimination, and criterial behavioral discrimination in a discriminative avoidance task. The neuronal activity for area 24 is plotted in the form of standard scores normalized with respect to the pre-CS baseline for 40 consecutive intervals following CS onset. Area 29 data are plotted starting 100 msec after tone onset.

The development of discriminative neuronal activity during conditioning supports the idea that cingulate cortex mediates associative attention to significant cues. The fact that the activity is time-locked to the onset of the CS^+ and CS^- and occurs as early as 15 msec after tone onset, at least 2 sec earlier than the learned avoidance response, suggests that it promotes learning-based stimulus selection. The early, stimulus-locked, CS^+-specific brain activation could be involved in capturing attention and thereby enhancing stimulus evaluation and response mobilization processes.

b. Duration Coding and Salience Compensation The brief-latency discriminative neuronal responses are positioned temporally to maximize resources for subsequent processing of and responding to the eliciting cue. Accordingly, Stephen Sparenborg and Michael Gabriel showed that testing with non-salient cues, such as a brief (200-msec) CS^+ and CS^-, is associated with greater brief-latency anterior and posterior cingulate cortical discriminative neuronal responses than are observed when testing is carried out with more enduring and therefore more salient cues (e.g., a 500- or 5000-msec CS^+ and CS^-; Fig. 3). The enhanced neuronal coding of brief stimuli is referred to as duration coding. Duration coding may be thought of as an instance of salience compensation, i.e., a process of cingulate cortex that amplifies the neural representation of nonsalient but associatively significant stimuli in order to increase the likelihood that such stimuli receive processing that is commensurate with their associative significance.

c. Premotor Activity As discussed later, neuroanatomical and neurophysiological data indicate a close association between cingulate cortex and the brain's motor system. One illustration of this involvement in motoric processing is the finding that approximately half of all single neurons studied in anterior and posterior cingulate cortex during discriminative avoidance learning exhibited premotor firing ramps, i.e., progressive increments of firing frequency during the 5-sec interval from CS^+ to the scheduled foot-shock,

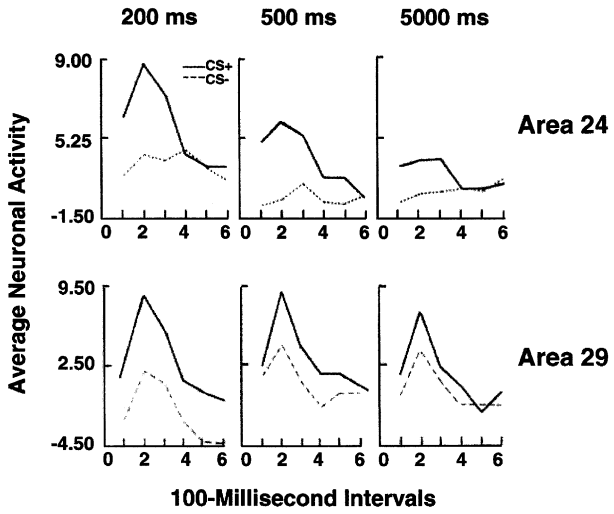

Figure 3 Average multi-unit spike frequency recorded in well-trained rabbits in anterior cingulate (area 24) and posterior cingulate (area 29) during separate counterbalanced sets of three training sessions in which brief (200-msec), intermediate (500-msec), or long (5000-msec) CSs were presented. The neuronal activity following CS onset is in the form of standard scores normalized with respect to the pre-CS baseline in six consecutive 100-msec intervals after CS onset. Data shown for area 29 were obtained from records that exhibited discriminative TIA in the later stages of learning.

in anticipation of the behavioral avoidance response (Fig. 4). Also, in recent studies by Takenouchi and colleagues, neuronal firing in ventral portions of the anterior cingulate cortex was correlated with the onset of consummatory behavior (licking a drinking tube) during appetitive conditioning of rats. This premotor firing of cingulate cortical neurons may represent a neural "command volley" projected from cingulate cortex to cortical and striatal motor areas to trigger the learned response. Thus, in addition to the encoding of significant stimuli, cingulate cortical neurons appear to be involved in the initiation or triggering of learned motor responses.

2. Brain Damage

a. Experimental Lesions If cingulate cortical neurons mediate associative attention to significant stimuli, then damage in cingulate cortex should interfere with learning about such stimuli. This expectation was confirmed by studies that showed that combined lesions of both the anterior and the posterior cingulate cortex severely impaired the ability of rabbits to exhibit discriminative avoidance learning. An equivalent impairment of learning was found following bilateral combined lesions of the anterior and MD thalamic nuclei (i.e., areas of the thalamus that reciprocate connections with cingulate cortex). The interdependence of the thalamic and cingulate cortical processes was indicated by studies that showed that the training-induced, attention-related activity of cingulate cortical neurons did not develop in subjects that had been given thalamic lesions.

The fact that the lesions prevented the rabbits from learning to respond behaviorally to the CS^+ could be interpreted as a motor problem such as an inability to initiate locomotion on cue. That this was not the case was indicated in a study that showed that rabbits with lesions were substantially impaired in learning to inhibit the previously described reward-based approach response to a drinking spout that was inserted into the experimental chamber following CS^- presentation (when approach and oral contact with the spout did not yield water reward). The rabbits with lesions responded equally often to the spout, whether its insertions were preceded by the CS^+ or the CS^-, whereas sham lesion controls discriminated significantly between the CS^+ and CS^-. These results show that cingulothalamic circuitry is critical for rabbits' ability to base behavioral responding on particular discriminative cues (as in the case of discriminative avoidance learning) or learning to inhibit a well-established response on cue (as in the approach learning task). These findings are in keeping with the notion that the cingulothalamic circuitry is not specialized for particular kinds of behavioral outputs, such as active movement or "inhibitory" omission of movement. Rather, this circuitry enables subjects to predicate their performance of context-appropriate, goal-directed instrumental behavior on the occurrence of discrete cues that predict significant outcomes and call for action. A wide variety of distinct forms of behavior can come under stimulus control as a result of cingulate cortical processing. This stimulus-oriented contribution of cingulate cortex is consistent with the hypothesis of an involvement of cingulothalamic circuitry in associative attention to significant stimuli.

b. Exposure to Cocaine *in Utero* Exposure of human fetuses to cocaine during gestation is associated with a variety of developmental, neurocognitive deficits, including impaired attention, habituation, arousal, recognition memory, and language development. Adult rabbits exposed to cocaine *in utero* (4 mg/kg of cocaine given intravenously twice daily to gestating dams) exhibited morphological and

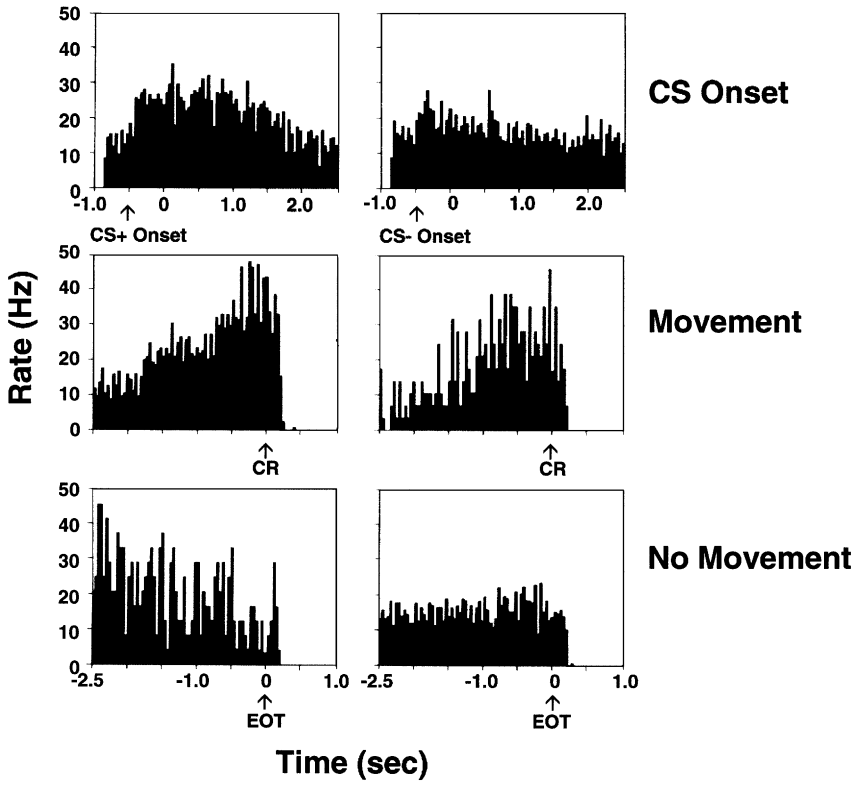

Figure 4 Histograms indicating anterior cingulate cortical single-unit activity related to CS^+/CS^- onset and avoidance responses, where each bar indicates the average firing rate in hertz for the cell during a 40-msec interval. (Top) CS onset-related activity; (middle) premotor discharges preceding the conditioned response (CR); (bottom) neuronal firing on CS^+ and CS^- trials in which no response occurred and the trial terminated (EOT). All histograms represent data obtained from the same neuron.

biochemical abnormalities in the anterior cingulate cortex relative to controls exposed to saline injections. No changes were found in the visual cortices of the subjects exposed to cocaine.

In addition, exposure to cocaine was associated with attenuated anterior cingulate cortical training-induced discriminative neuronal activity and deficient avoidance learning. Specifically, when brief (200-msec) and therefore nonsalient discriminative stimuli (CS^+ and CS^-) were employed for training, cocaine-exposed rabbits performed significantly fewer learned responses than saline-exposed controls in the first session of conditioning. The first-session learning deficit found with brief stimuli could have resulted from compromised salience compensation mechanisms in anterior cingulate cortices of the rabbits exposed to cocaine. Note, however, that with continued training beyond the first session the cocaine-exposed rabbits did attain normal asymptotic performance levels as rapidly as did saline controls. Moreover, learning was entirely normative, even in the first session, in cocaine-exposed subjects when the CS^+ was more enduring (500 msec) and thus more salient.

Very similar results were obtained in studies of Pavlovian conditioning of rabbits' eyeblink response. Rabbits exposed to cocaine *in utero* were able to acquire the conditioned eyeblink response as rapidly as controls when a salient CS^+ and a nonsalient CS^- were used. However, acquisition was significantly retarded in cocaine-exposed rabbits when a nonsalient CS^+ and a salient CS^- were used. These results were obtained when the stimuli were of different modalities (a salient tone and a less salient flashing light) and when they were of the same modality (tones of varying intensity).

The absence of behavioral learning during the first discriminative avoidance conditioning session with the brief (200-msec) stimuli was accompanied by an

absence of discriminative neuronal activity in the anterior cingulate cortex. Moreover, when behavioral discrimination did occur in later stages of training, so also did discriminative neuronal activity in the anterior cingulate cortex in rabbits exposed to cocaine. Thus, the loss of discriminative neuronal activity in anterior cingulate cortex was, arguably, the neural basis of the impaired discriminative behavior. This possibility received further support from previous demonstrations that lesions confined to the anterior cingulate cortex or to the MD thalamic nucleus impaired learning in the early stages of behavioral acquisition, but these lesions also allowed learning to occur to normative asymptotic levels.

A particularly intriguing finding during training of cocaine-exposed rabbits with the brief conditional stimuli was a dramatic alteration of the poststimulus firing profiles of anterior cingulate cortical neurons. Specifically, the neuronal response profiles of the cocaine-exposed rabbits lacked the firing pause, which occurred robustly in controls from 40 to 80 msec after CS onset and which is a consistent feature of the CS^+- and CS^-- elicited poststimulus histograms of neurons in cingulate cortex (Fig. 5). Loss of the brief-latency inhibitory "pause" component of neuronal response was a most robust cocaine-related neuronal phenomenon. Indeed, the magnitude of the inhibitory pause was significantly increased in the saline-exposed rabbits trained with 200-msec stimuli compared to saline-exposed rabbits trained with 500-msec stimuli. These findings suggested that the inhibitory pause is a dynamic feature that reflects the associative attentional processing "demand" that is operating in a given situation. The absence of the inhibitory pause in rabbits exposed to cocaine may thus be a direct neurological indicant of impaired associative attention, which is in turn the basis for the observed retardation of the discriminative neuronal activity and behavioral learning in rabbits exposed to cocaine *in utero*.

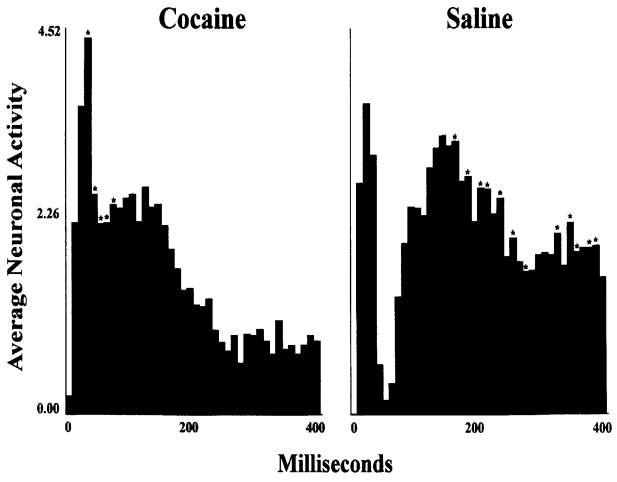

Figure 5 Average anterior cingulate cortical multi-unit spike frequency in 40 consecutive 10-msec intervals after onset of a brief (200-msec) CS in rabbits exposed to cocaine *in utero* and in saline-exposed controls. Asterisks indicate the occurrence of a significantly greater discharge for the indicated interval compared to the discharge in the corresponding interval for the other experimental group (cocaine or saline). Reproduced by permission from Harvey and Kosofsky, 1998, *Cocaine: Effects on the Developing Brain*, Ann. N.Y. Acad. Sci. **846,** 208.

The inhibitory pause in anterior cingulate cortex may function to reset active neurons by halting ongoing firing, thereby maximizing the number of neurons available for processing the incoming stimulus. Inhibitory feedback produced by activation of GABAergic neurons in response to cue-driven inputs is likely to be involved in resetting. The failure of the resetting mechanism in rabbits exposed to cocaine means that neurons already engaged in rapid firing could not contribute to stimulus processing. The resulting reduction in the number of participating neurons could impair processes such as the recruitment of existing modified synapses involved in classifying the incoming stimulus or retardation of synaptic plasticity development needed for the production of discriminative neuronal activity.

Research of Eitan Freidman and colleagues has shown that D_1 dopamine receptors in the anterior cingulate cortex are decoupled from their G proteins in rabbits exposed to cocaine *in utero*. Thus, the failure of the resetting mechanism in exposed rabbits could be a result of impaired activation of GABA neurons normally mediated by stimulation of D_1 dopamine receptors in the anterior cingulate cortex.

B. Executive Attention

New neuroimaging techniques have yielded an explosion of data in cognitive neuroscience concerning brain activation accompanying task engagement of human subjects. Studies employing position emission tomography (PET), functional magnetic resonance imaging (fMRI), high-density electroencephalography (EEG) for these analyses have repeatedly indicated an involvement of anterior cingulate cortex in cognition-relevant processing.

Results and interpretations converge intriguingly with the aforementioned findings in rabbits, rats, and primates in indicating a critical involvement of anterior cingulate cortex in processes subserving attention. Michael Posner and Gregory Di Girolamo provided an integrative account of anterior cingulate cortical function derived from the results of imaging studies and other findings in cognitive neuroscience. Building on the prior theoretical work of Donald Norman and Timothy Shallice, Posner and DiGirolamo proposed that anterior cingulate cortex mediates executive attention, which is part of a more general executive control function. Executive attention comes into play when routine or automatic processing is insufficient for the task at hand, such as when novel or conflict-laden situations are encountered. Guided by the individual's overall plans and goals, executive attention selectively activates and inhibits particular inputs, schemas, and behaviors to deal with the problematic circumstances. Paraphrasing Norman and Shallice, Posner and DiGirolamo argue that executive attention will likely be recruited in situations that involve planning and decision making, error detection, novelty and early stages of learning, difficult and threatening situations, and overcoming habitual behavior.

1. Review of Evidence

Activation of the anterior cingulate cortex as assessed by PET and fMRI is significantly enhanced in response to stimuli that require a particular response from multiple alternative responses, such as when subjects verbally generate uses of visually or acoustically presented words denoting familiar objects (e.g., the response "drive" to the stimulus "car"). In most of these studies a subtraction method is employed whereby the brain activation found during a control condition (merely reading and pronouncing the stimulus words) is subtracted from the scores obtained in the "generate uses" condition. Thus, anterior cingulate cortical activation above and beyond that involved in pronouncing visualized words is associated with the need to generate a response from a set of possible alternative responses. It is argued that executive attention reflected by anterior cingulate cortical activation is brought into play as a result of the conflict created by the multiple response alternatives in the generate uses condition. The activation produced in the generate uses condition declined as the subjects were repeatedly exposed to the same words and thus generated the same uses. According to the theory, the generation of uses became routinized with repetition and thus no longer required executive attention.

Additional support for a role of the anterior cingulate cortex in executive attention is the observed activation of cingulate cortex during performance in Stroop tasks, wherein subjects are required to name the color of visually presented words in a congruent condition (e.g., the word "red" printed in red ink) or in an incongruent condition (e.g., the word "green" printed in red ink). In some of these studies, a neutral condition is also employed in which, for example, subjects must give the ink color of noncolor words. The results of multiple Stroop experiments suggest the following generalization: The anterior cingulate cortex is activated significantly in all three of the aforementioned conditions. However, the extent of activation appears to depend on the degree to which the irrelevant dimension (word meaning) corresponds to the relevant dimension (word color). High correspondence, such as when both dimensions refer to color (as in the incongruent condition), creates maximal conflict and invokes substantial anterior cingulate cortical processing.

In keeping with the indication that the degree of conflict determines the magnitude of anterior cingulate cortical activation, several studies have shown substantial activation in association with dual-task performance, such as when subjects concurrently perform a generate-use task and a motor sequencing task. The results showed that performance in the dual-task situation elicited greater activation of anterior cingulate cortex than did performance in either task singly. Because the two tasks did not conflict at the sensory or motor levels, the dual-task-specific activation was assumed to reflect competition for central processing resources rather than sensory or motor processes. These studies also showed declining anterior cingulate cortical activation as the tasks became well learned, but ample activation was reestablished simply by instructing the subjects to attend to the well-learned tasks. These results are consistent with the hypothesis that anterior cingulate cortical processing is recruited in response to conflict and interference among central aspects of task-relevant processing.

Recent work using event-related potential recordings derived from multiple scalp locations in human subjects has yielded an intriguing result. A marked electrical negativity occurs 100 msec after an erroneous key press in a discriminated reaction time task (Fig. 6). Brain electrical source analysis of data yielded by large arrays of simultaneously recorded scalp EEG records was employed in attempts to localize the brain areas in

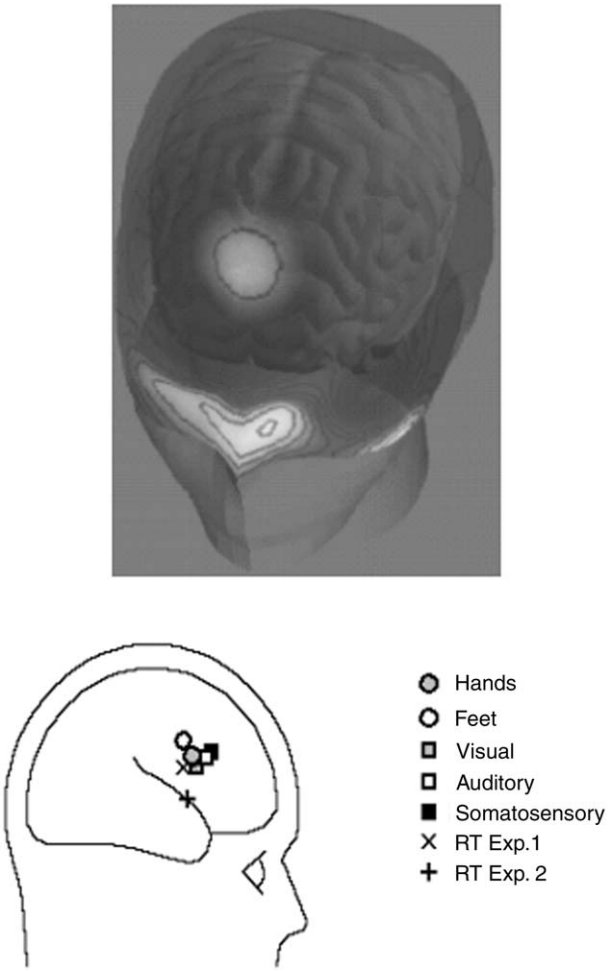

Figure 6 A three-dimensional and sagittal view of the human brain illustrating the source of error-related negativity (ERN) found after brain electric source analysis of event-related brain potentials. (Bottom) The results of several ERN studies that have demonstrated that the source of the ERN is not affected by response modality (subjects responding with their feet or hands) or error feedback modality (visual, auditory, and somatosensory). Also shown is the ERN source for two reaction time experiments, one involving a decision of whether a number was ''smaller than/larger than'' (RT Exp.1) and another involving a classification of words into semantic categories (RT Exp. 2). [Reprinted from Holroyd, C. B., Dien, J., and Coles, M. G. (1998). Error-related scalp potentials elicited by hand and foot movements: Evidence for an output-independent error-processing system in humans. *Neurosci. Lett*. **242,** 65–68, with permission from Elsevier Science].

which the error-related negativity (ERN) is generated. The results of separate studies by William Gehring and colleagues and by Stanislas Dehaene and colleagues indicated that anterior cingulate cortex is a likely intracranial source of the ERN (Fig. 6). These results are consistent with the hypothesis that anterior cingulate cortex is involved in mediating processes of executive attention that are recruited by the occurrence of errors.

2. Executive Attention and Response Selection

One problem with the concept of executive attention is that it includes multiple processes, including selection of input channels, schemas, and responses in accordance with the individual's overall plans and goals. It seems unlikely that all these processes are strictly localized within the cingulate cortex. Even the most cingulate-centered view of the universe must acknowledge the likely importance of continuous exchange of information between cingulate cortex and other brain modules that comprise a larger circuitry and supply information needed for the computation of executive functions. A clear understanding of how the components of executive attention are allocated among cingulate cortex and related areas of brain circuitry remains to be worked out. Nevertheless, a series of recent findings, reviewed in this section, indicate that response selection is an important aspect of cingulate cortical function.

First, there appears to be considerable regional specialization in cingulate cortex with respect to particular response modalities. Studies by Nathalie Picard and Peter Strick have indicated the existence of multiple areas of cingulate cortex, each containing neurons that project to the primary motor cortex in primates. Studies employing PET in human subjects indicate that some of the projecting areas may be associated with distinct response modalities. Similarly, Thomas Paus and colleagues showed that different areas of the anterior cingulate cortex were activated in the same subjects when they performed tasks involving oculomotor, manual, and spoken responses. Also, neurophysiological investigations by Keisetsu Shima and colleagues using primate subjects indicated the existence of two distinct cingulate cortical areas involved in mediating self-paced and stimulus-triggered forelimb movements.

In addition, U. Turken and Diane Swick reported studies of a patient (DL) who had undergone surgery for removal of a brain tumor. The surgery resulted in a circumscribed right hemispheric lesion in a region of the anterior cingulate cortex that had been implicated by neurophysiological studies in hand and arm movements of primate subjects. DL exhibited entirely normal performance in Stroop-like and divided attention tasks when responses were orally reported. However, DL showed a dramatic deficit in the same tasks when manual responses were required. Because

DL showed only a manual impairment, the authors argued that executive functions were intact in DL. Thus, they interpreted the results as favoring the idea that command signals originating in lateral prefrontal areas are sent to motor output areas through the anterior cingulate cortex, where correct response output is facilitated and incorrect response output is suppressed. They concluded that executive functions reside in the prefrontal areas, whereas cingulate cortex performs a "final check" on the already-selected output.

A somewhat different view is afforded by recent findings of Michael Millham, Marie Banich, and colleagues, who employed fMRI imaging and a variant of the color–word Stroop task wherein participants were required to respond selectively to information about the color of a word while disregarding the word's meaning. They sought to address the issue of whether activity in the anterior cingulate cortex is engaged in attentional selection generally or is more specifically related to response conflict. To disentangle these two possibilities, these authors asked whether cingulate cortical processing on incongruent trials is engaged by both response and nonresponse conflict or by only one of these varieties of conflict. Participants indicated the ink color of the word (yellow, green, or blue) via a keypress. Half of the incongruent trials were response eligible in that the word named one of the eligible responses (e.g., the word "blue" printed in green ink). These trials engender conflict at both the response and nonresponse levels. The other half of the incongruent trials were response ineligible in that the word did not name an eligible response (e.g., the word "purple" printed in green ink). These trials engendered conflict at the nonresponse level but not at the response level (Fig. 7).

The pattern of results indicated that the anterior cingulate cortex is specifically involved in detecting the potential for error at the response level. As found in previous studies, both dorsolateral prefrontal regions and the anterior cingulate exhibited greater activation in response to incongruent trials than in response to neutral trials. However, further analysis indicated that the enhanced activation that occurred in anterior cingulate cortex on incongruent trials occurred only on response-eligible trials, not on response-ineligible trials. (In contrast, dorsolateral prefrontal cortex showed the difference on both response-eligible and response-ineligible trials.) These results thus suggest that anterior cingulate activation is driven exclusively by response conflict, and not by conflict related to stimulus-selection processes.

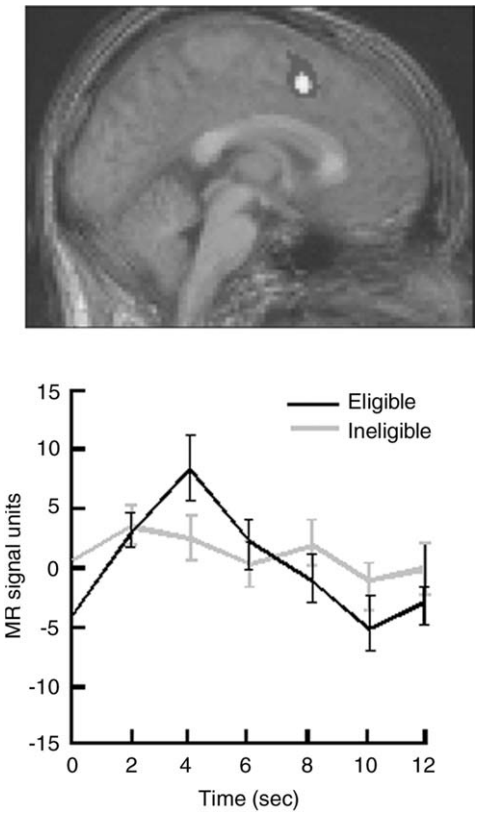

Figure 7 A saggital fMRI image and corresponding line graph depicting the increased activation of the anterior cingulate during response-eligible vs response-ineligible trials in a modified Stroop task.

III. INTEGRATION: ASSOCIATIVE ATTENTION AND EXECUTIVE ATTENTION

Executive attention and associative attention refer to two theoretical accounts of cingulate cortical function. Although they originate from research in cognitive neuroscience and behavioral neuroscience, respectively, the two theories nevertheless converge on an attribution of cingulate cortical involvement in attentional processes. However, the use of the term attention in both instances does not indicate how much convergence has occurred. Here, we attempt an explicit comparison of the two theories and the data on which they are based in an effort to highlight key similarities and differences.

A. Similarities

An important area of similarity concerns the observation that associative attention in animals appears to

become engaged in several of the very situations regarded by cognitive neuroscientists as likely to engender executive attention. These include difficult and threatening situations, the early stages of learning, and overcoming habitual behavior. Specific involvement of associative attention in the early stages of learning and in difficult and threatening situations is indicated by findings that massive and robust training-induced discriminative neuronal activity (TIA) in the anterior cingulate cortex develops in the first session of discriminative avoidance learning and declines in later sessions as discriminative behavior reaches asymptotic levels. This early acquisition of TIA does not occur during reward-based discriminative approach learning, as indicated by recent studies of John Freeman and David Smith in the laboratory of Michael Gabriel. Moreover, various manipulations that eliminated anterior cingulate cortical TIA (lesions in anterior cingulate, amygdala, or auditory cortex and exposure of subjects to cocaine *in utero*) resulted in a failure of rabbits to acquire discriminative avoidance responses in the early sessions of training. Note that despite the early learning deficit that is associated with anterior cingulate cortical lesions and with loss of anterior cingulate cortical TIA, the subjects in these studies did acquire the discriminative behavior to normal asymptotic levels, an accomplishment due at least in part to processes of posterior cingulate cortex. Finally, lesions of the amygdala that eliminated TIA in the anterior cingulate cortex blocked discriminative avoidance learning (which is acquired rapidly) but had no impact on concurrently administered and much more slowly acquired discriminative approach learning in the same subjects.

Evidence that cingulate cortical processes are invoked when animals are engaged in overcoming habitual behavior has been provided in several studies demonstrating a dramatic increase in the magnitude of discriminative TIA during the early sessions of reversal learning, wherein the cues serving as CS^+ and CS^- during original learning to asymptotic levels of discriminative behavior are interchanged. Although the hypothesis that anterior cingulate lesions will specifically impair discriminative instrumental learning of the reversal problem has not been tested, this hypothesis has been confirmed by Shirley Buchanan and Donald Powell in studies of discriminative eyeblink conditioning in rabbits.

A particularly compelling instance of convergence has to do with the general conclusion that executive attention can be invoked to varying degrees, depending on the amount of conflict present in a given situation (see Section II.B), such as when one of many possible responses must be generated in response to a given input or when the ink color and name of a word signal different behavioral responses. These examples generally correspond to instances in which particular inputs pose high processing demands. This facet of executive attention appears to have associative attentional counterparts. The large magnitude of anterior cingulate cortical discriminative neuronal activity during the initial sessions of avoidance training (with declining discharge magnitudes later in training) could represent an increase in associative attention for production of an active response on cue in the early stages of learning, when a clearly conflicting response tendency (to "freeze" in response to a painful shock) is at maximum levels. This example of convergence is in keeping with the "response-selection" notion of cingulate cortical functions (see Section II.B.2).

Also of relevance is the observation of salience compensation (see Section II.A.1.b). In this instance, the anterior cingulate cortex appears to allocate its associative attentional response in accord with an assessment of two factors, stimulus significance and stimulus salience. Only associatively significant stimuli that call for action provoke cingulate cortical neuronal firing. However, associatively significant stimuli of low salience evoke greater cingulate cortical neuronal responses than stimuli of high salience, when both stimuli are of equivalent associative significance. Anterior cingulate cortical neurons provide processing resources to increase the likelihood that a weak but important stimulus will be attended to. This example of convergence is suggestive of cingulate cortical engagement in high-demand stimulus processing situations with no response-selection component.

A prima facie case can be made for convergence of cognitive and behavioral neuroscience data regarding error-related processing. Results analogous to the error-related potential were found in a study of multi-unit activation following various trial outcomes during performance of rabbits in a discriminative avoidance task. Anterior cingulate cortex was the only one of four distinct cingulothalamic areas examined to exhibit a statistically reliable posttrial increase of neuronal firing following "error trials" during avoidance conditioning [i.e., trials in which the rabbits failed to respond (and received shock) following presentation of the CS^+]. Although the observed activation followed the presentation of the shock, it was not a direct sensory response to the shock because it was measured 5–15 sec after shock termination and was not exhibited by cingulothalamic neurons in the other

areas; these other neurons nonetheless exhibited brief, short-latency responses to the shock. In keeping with the intriguing findings of Donald Price and colleagues that anterior cingulate cortex has a unique role in mediating pain aversion, the sustained response to the shock in the anterior cingulate cortex may reflect neural coding of the aversiveness of the shock experience and the perceived failure to avoid the shock. It is possible that errors committed by human subjects give rise to a similar process, error-related pain, and that this is the process detected by studies of the ERN.

A final comment here concerns the apparent disagreement between the executive attention theory and the associative attention theory regarding cingulate cortical functions. Milham and colleagues concluded that anterior cingulate cortical processing is invoked specifically by conflict at the response level. Other aspects of executive attention, such as selection of task-relevant stimulus dimensions, are attributed by these researchers to related areas such as the dorsolateral prefrontal cortex. This idea may seem to be in conflict with findings that inspired associative attention theory—that robust discriminative TIA develops during instrumental avoidance learning in rabbits—results that clearly suggest an involvement of cingulate cortex in stimulus selection processes. It is important to note, however, that discriminative TIA illustrates selection of a specific task-relevant stimulus, not selection of a task-relevant stimulus dimension. The latter process is attributed by Milham and colleagues to the dorsolateral prefrontal cortex. Keeping in mind the presence of cingulate cortex (and the absence of dorsolateral prefrontal cortex) in small mammals such as rats and rabbits, it is worth considering that the selective reinforcement-based coding of significant stimuli in the service of response selection processes is indeed a province of the cingulate cortex, whereas more complex functions, such as selection of task-relevant stimulus dimensions and the control of such processes by linguistic instructions, may be conferred by areas of prefrontal cortex that simply do not exist in the smaller mammalian species. The consequences of dimensional selection in these areas are relayed to cingulate cortex wherein they contribute to response selection. Thus, the cingulate cortex in rats and rabbits is involved in stimulus selection and response selection processes, but stimulus selection in cingulate cortex deals not with selection of stimulus dimensions but rather with specific values of particular physical stimuli. Perhaps the cingulate cortex represents the sole resource for these processes in rats and rabbits. In primates, cingulate cortex is fed by additional areas gained during the course of evolution. These areas confer processing flexibility, including the capacity to form dimensional sets and response sets on the basis of linguistic instructional inputs.

B. Differences

In considering differences between executive attention and associative attention, the term "associative" is critical. This term is used in acknowledgment of the substantial evidence that cingulate cortical associative attention is a product of a learning process and that cingulate cortex is an important substrate of learning and memory. It will be argued specifically that cingulate cortex is involved in response and memory retrieval.

In contrast, executive attention as discussed by cognitive neuroscientists is quite separate from associative learning or memory. For example, it is argued that executive attention is invoked in early stages of learning or when habitual behavior must be revised, but in these instances executive attention acts as an external agent that intervenes to facilitate processing when new learning is needed rather than a process that is a product of learning or that subserves retrieval of learned information. Moreover, cingulate cortex does not appear to be included on the list of brain areas (e.g., hippocampus and prefrontal cortex) that cognitive neuroscientists believe to be involved in learning and memory.

One could argue that no learning process is involved in the evocation of anterior cingulate cortical activation in tasks that require executive attention. The subjects are simply given task-relevant instruction. They perform the experimental task and exhibit differential brain activation depending on the stimulating conditions. However, consideration should be given to the possibility that the task-related instructions instill a memory and a plan of action. The instructional memory functions as does reinforcement in a discriminative conditioning study, informing the subject as to which stimuli are significant and require action. The neural representation of the instructional memory could induce synaptic plasticity fostering incremented neuronal firing in response to the critical stimuli as well as associative pathways for selection of appropriate behavioral output.

Regarding the apparent functional duality being imputed to cingulate cortex, how can one area of the brain subserve both attention and memory retrieval?

The answer proposed is that these processes are fused as a unitary function of cingulate cortex as discussed later. The difficulty lies in the assumption that our human linguistic distinctions denote corresponding, distinct neural functions. We invite the reader to consider the possibility that the brain does not always respect the linguistic categories of neuroscientists.

1. Involvement of Anterior and Posterior Cingulate Cortex Respectively, in Early and Late Stages of Discriminative Learning

Generally supportive of cingulate cortical involvement in response and memory retrieval processes is the necessity of an intact cingulate cortex for a variety of forms of learning, including discriminative avoidance learning (see Section II.A). Also supportive is the massive TIA that develops during learning in cingulate cortex. Since it depends on the prediction of reinforcement by CS^+ and the prediction of no reinforcement by CS^-, the TIA is clearly a product of a learning process.

Particularly compelling is the correspondence between TIA development and the effects of restricted lesions. As indicated previously, discriminative TIA in the anterior cingulate cortex develops early in training, within the first 30 trials of discriminative avoidance learning (15 with CS^+ and 15 with CS^-), and damage in the anterior cingulate cortex or in the related MD thalamic nucleus has been associated in several studies with a deficit of behavioral performance in the early stages of learning. A case in point is described in Section III.A. In contrast, discriminative activity in layer IV of the posterior cingulate cortex and in the AV thalamic nucleus develops late, after the development of significant discriminative behavioral responding. Lesions in these areas are associated with normal behavioral acquisition followed by significant loss of performance efficiency in the later stages of training, when asymptotic performance is first attained in controls, and during subsequent overtraining. The correspondence between the training stage-specific behavioral deficits and the stages of training in which TIA develops in anterior and posterior cingulate cortex is consistent with a role of these areas in learned response retrieval.

Timothy Bussey, Barry Everitt, Trevor Robbins, and John Parkinson and colleagues at Oxford University have provided support for the early and late contributions of anterior and posterior cingulate cortex, respectively, to behavioral learning. Late-stage involvement of posterior cingulate cortex was indicated in studies involving both pre- and postsurgical training in a conditional discrimination task in which rapidly or slowly flashing lights predicted which of two levers, when pressed, would yield a reward. Posterior cingulate cortical lesions did not block acquisition of this discrimination but the lesions did impair performance in the late stages of training. Inexplicably, in this study the rats with anterior cingulate lesions did not differ from controls or were facilitated relative to controls. However, other studies of this group have supported an early contribution of anterior cingulate cortex to learning. These studies involved the Pavlovian conditioning of orienting behavior often referred to as "autoshaping." In Pavlovian conditioning the CS^+ is followed by reward delivery and the CS^- is not, without regard to the subjects' responses. Autoshaping refers to the fact that subjects acquire approach responses to the site of CS^+ delivery, but they do not approach the site of CS^- delivery. The approach responses to the CS^+ occur before the subjects actually approach and consume the reward. The rats given lesions in the anterior cingulate cortex failed to attain a significant level of discriminative autoshaping but they did show a trend toward significance in the late training stages. In a subsequent test session with reinforcement omitted, the control subjects showed robust discrimination and the animals with lesions also showed discrimination, although to a lesser degree. The authors stated that although anterior cingulate lesioned animals were significantly impaired at autoshaping, there was evidence that they were beginning to learn toward the end of the experiment. The aforementioned studies with rabbits suggest that this later learning was a product of posterior cingulate cortical involvement.

2. Complementary Functions of the Early and Late Circuits

It is interesting to consider the functional significance of the respective early and late involvement of anterior and posterior cingulate cortex in learning. Anterior cingulate cortex appears to be specialized for rapid encoding of novel CS^+-reinforcement contingencies in the early stages of training, as indicated by early discriminative TIA. A brain circuitry that is organized for such rapid encoding is not likely to handle well consistent coding of repetitive, enduring CS^+-reinforcement contingencies. For this reason, there exists a complementary system centered in the posterior cingulate cortical and anterior thalamic circuitry that does not encode stimulus reinforcement contingencies

until they have proven reliable through repetition (i.e., this system exhibits late discriminative TIA).

Intriguingly, as shown by John Freeman and Michael Gabriel, repetition of trials is not the only way to produce the late TIA in the posterior cingulate cortical circuit. TIA also develops when there is a substantial (48-hr) delay between an initial training session and a later training session. During this interval behavioral responding also improves significantly, a phenomenon referred to as "incubation." These results suggest that in addition to trial repetition, covert processing during the intersession interval can engender the late-developing TIA in the posterior cingulate cortex and in related anterior thalamic nuclei.

3. The Early Circuit and Working Memory

The rapid coding of associatively significant stimuli exhibited by anterior cingulate cortical neurons is quite similar to neuronal activity recorded in the pioneering studies of Patricia Goldman-Rakic in the lateral prefrontal cortex of primates—activity that Goldman-Rakic interprets as reflecting the operation of a working memory process. The shared properties of the neuronal activity in these regions suggest a role of the anterior cingulate in working memory processes. Clearly, a functional kinship between the anterior cingulate and lateral prefrontal areas would not be surprising because both areas are closely interconnected in primates and share common anatomical associations with the MD nucleus and the hippocampus. Of course, as mentioned previously, the lateral prefrontal cortex is absent in rabbits and rats, suggesting that anterior cingulate cortex may be the sole center of a rudimentary working memory circuit in these animals—a memory circuit that has achieved substantial elaboration during the course of mammalian evolution.

4. Context-Specific Retrieval Patterns in the Late Circuit

Additional evidence in support of the retrieval hypothesis is afforded by consideration of the distinctive training stage-related posterior cingulate cortical and anterior thalamic TIA. Extensive multi-site recording in these areas during discriminative avoidance learning has demonstrated unique topographic distributions of brief-latency CS^+- elicited neuronal activity across distinct nuclei of the anterior thalamus and the layers of posterior cingulate cortex. Certain thalamic nuclei and cortical layers are maximally activated by the CS^+ in the initial session of training, different areas are activated maximally in intermediate training stages, and other areas are activated maximally in late stages of acquisition, as asymptotic discriminative performance occurs. These changing patterns thus afford a "temporal tag" that codes the "age" of a given habit or memory and that could be used as a cue for retrieval.

In a different study it was shown that the same physical cues elicited different patterns of activation depending on whether the subjects were engaged in the performance of the moderately learned discriminative avoidance habit or (in a separate training apparatus) the well-learned discriminative approach habit. Thus, the elicited patterns coded the specific habit being practiced. The fact that different patterns are elicited by the same physical stimuli in the same subjects depending on which of two discriminative tasks is being engaged means that the patterns could uniquely retrieve habit-specific (context-appropriate) memories and learned behavior. Thus, the distributions of activation changed systematically, not only across time (training stage) but also with respect to the training context. Therefore, the patterns afford potentially a neural representation of both spatial and temporal aspects of the training context. These habit-specific patterns, elicited at brief latency (80 msec) by the cue (CS^+) that calls forth the learned response, are arguably the brain's earliest sign (in the millisecond series) of context-specific retrieval. Thus, the patterns could contribute to pattern separation, the property of retrieval whereby different behavioral responses and/or memories are retrieved in response to very similar and thereby confusable eliciting cues. Pattern separation defeats intertask proactive and retroactive interference.

5. Retrieval and Firing Ramps in Cingulate Cortex

Also consistent with the idea of a cingulate cortical role in response retrieval is the finding described earlier that many cingulate cortical neurons show firing ramps or progressive firing rate increments in advance of the performance of learned responses. Thus, whereas the brief-latency cue-elicited patterns of cingulate cortical activation may represent initial stimulus evaluation constituting the earliest sign of retrieval in the brain, the pre-response firing increments may represent the final command volley calling for execution of the learned response. In the language of executive attention, this activity could be viewed as a direct neural indicant of response selection. Thus, the notions of

response selection and response retrieval have a great deal of common meaning.

6. Dependence of TIA Patterns on the Hippocampus

Studies have indicated that the brief-latency, habit-specific patterns of activation found in the posterior cingulate cortex and related anterior thalamic areas depend on input from the subicular complex of the hippocampal formation, which is an origin of substantial fiber projections to the anterior thalamus and to the posterior cingulate cortex. Damage to the subicular complex alters and degrades the exquisite training stage-related patterns of activation found in cingulate cortex, although basic discriminative TIA remains intact in subjects with subicular complex damage. Any role that the stage-related patterns play in response retrieval would presumably be diminished or abolished in subjects with hippocampal formation damage.

Recent experiments have indicated that the context-specific patterns of activation exhibited in the posterior cingulate cortex and related areas of the thalamus are not essential for simple cued instrumental learning, such as discriminative avoidance and approach learning, which are mediated by basic, nonpatterned discriminative TIA. However, the patterns are important when the subject is confronted with a more challenging retrieval problem, such as when the subject is required to perform two discriminative tasks, approach and avoidance, with reversed cues (i.e., the CS^+ in one task is the CS^- in the other and vice versa). In this case, fornix lesions that disconnect the subicular complex and the anterior thalamus significantly impair dual-task performance, whereas performance in either task singly is not affected.

It is important to note that the functions of cingulate cortex are not restricted to simple acts of retrieval such as occur in instrumental approach and avoidance learning. There is evidence of cingulate cortical involvement in more complex forms of learning in animals and in humans. From the pioneering work of James Ranck, John O'Keefe, Lynn Nadel, Philip Best, Bruce McNaughton, Howard Eichenbaum, Carol Barnes, and Jeffrey Taube, the existence of place cells and head direction cells has been well established. Place cells are sensitive to the location of the subject (i.e., a given cell fires only when the subject occupies a particular area of the experimental environment). Head direction cells are sensitive to the points of the compass (i.e., a given cell fires when the subject is oriented in a particular direction). Place cells are abundant in the hippocampus, a structure that is closely interconnected with the cingulate cortex and has been widely implicated in spatial learning in animals as well as in human episodic and declarative memory. Recently, it has been found that head direction cells and place cells are present in cingulate cortex and in related areas of the thalamus. Moreover, damage in cingulate cortex has been shown to disrupt behaviors (such as acquisition in the Morris water maze) that depend on spatial processing. It is generally well-known that visuospatial information that defines a learning environment contributes importantly to the retrieval of context-appropriate memory and behavior. A commonly held interpretation of head direction and place cells is that they reflect neurological processes whereby information about the spatial context is used to retrieve context-appropriate behaviors and memories.

7. Retrosplenial Amnesia

Additional evidence for a cingulate cortical involvement in memory processes is indicated by the report of Dawn Bowers and colleagues on the amnesic patient TR, who sustained circumscribed damage in the left retrosplenial cortex, a subdivision of the posterior cingulate cortex. As a result of the lesion, TR developed retrograde amnesia for events occurring 9–12 months before the lesion and virtually complete anterograde amnesia (amnesia for events after the lesion). Of particular interest is the finding that TR was impaired on making judgments about the temporal order of visually presented sentences and faces, but TR was unimpaired in making recognition judgments of the same items. In other words, he was able to report accurately that he had seen a sentence or face before but could not accurately report the order in which the material had been presented. TR was impaired in making judgments about which of two target words in a list occurred more recently, even when the most recent target was the last stimulus presented, suggesting that the inability to "time-tag" new information took place early in the process of memory acquisition. The deficit in recall of temporal order extended only to recently acquired information because TR performed at control levels on a task that required the temporal ordering of remote memory (memory for public events from 1930 to 1970). The specific deficit in temporal ordering is intriguingly concordant with the hypothesis that the training stage-related peaks of activation in the posterior circuit represent a temporal context code that is used for mnemonic retrieval.

8. Memory Consolidation and the Cingulate Cortex

Memory consolidation refers to processes whereby memories become less susceptible to interference and disruption with the passage of time. It is commonly held that consolidation is based on rearrangements of the circuitry and neuroanatomical substrates involved in memory storage and retrieval. Thus, for example, it has been proposed that the hippocampus and neocortex are critically involved in the initial encoding of complex memory in humans but as the "age" of a given memory increases its dependence on the hippocampus decreases.

Previously, it was indicated that anterior and posterior cingulate cortex are critically involved respectively in mediating the early and late stages of discriminative avoidance learning of rabbits. Therefore, it might be assumed that the posterior cingulate cortex and related thalamic areas are the final sites of habit storage and retrieval. However, it is now known that neither anterior nor posterior cingulate cortex, or the related areas of the limbic thalamus, are involved in mediating discriminative avoidance learning in animals that are highly overtrained. Cingulothalamic lesions that normally block learning and prevent the expression of the learned behavior in subjects that are trained to asymptotic levels before they receive the lesions do not impair performance when they are induced after rabbits have been given extensive post asymptotic overtraining. Thus, in highly overtrained rabbits the brain processes involved in storage and retrieval of the discriminative avoidance habit occur entirely within noncingulate circuitry. These results are in accord with the findings concerning retrosplenial amnesia, suggesting that posterior cingulate cortex is involved in the mediation of memory for recently established memories but not for long-stored, "remote" memories. Similarly, lesions in the hippocampus, a region that is closely interconnected and highly interactive with posterior cingulate cortex, are associated with loss of recent memory but not of remote memory. The areas that mediate storage and retrieval of these remote memories have not been definitively identified, although it is widely assumed that the neocortex plays an important role.

IV. CONCLUSION

Studies carried out by behavioral neuroscientists using rats and rabbits have shown that the cingulate cortex is a critical substrate of instrumental learning of goal-directed behavior. Cingulate cortical neurons in these animals code associatively significant stimuli and exhibit context-specific topographic patterns that could mediate cued retrieval of context-appropriate learned behavior. These functions occur as a result of intimate interactions of hippocampal and cingulothalamic brain regions. Studies of cognitive neuroscientists concerning brain activation during cognitive task performance in human subjects have recently yielded many important findings, promising for the first time major advances in understanding complex cognitive processes of the human brain. These studies have yielded results that are fundamentally in agreement with the results of the studies on rats and rabbits. However, cognitive neuroscientists have discussed cingulate cortex as involved in attentional processes, with particular reference to response selection. They have not explicitly included cingulate cortex as an important component of the brain's memory system. However, given the findings of behavioral neuroscience and the very close neuroanatomical association of cingulate cortex with other structures (e.g., the hippocampus and parahippocampal cortex) that are acknowledged by a consensus of neuroscientists as components of the memory system, it is very likely that there will soon occur an even greater convergence of behavioral and cognitive neuroscience on a common mnemonic interpretation of cingulate cortical function.

Circadian Rhythms

CHARLES A. FULLER and PATRICK M. FULLER
University of California, Davis

GLOSSARY

circadian rhythm A term coined by Franz Halberg in 1959 to describe the approximately 24-hr biological cycles that are endogenously generated by an organism (Latin: *circa*=about, *dies*=day).

entrainment When an exogenous stimulus achieves both phase and period control of one or more circadian oscillators, entrainment has occurred.

free-running rhythms Rhythms that persist even when an animal is isolated from external time cues. These rhythms do not damp out, are self-sustained, and have a period that is close to 24 hr.

masking Light and other stimuli can superimpose direct effects on the level of a variable that can alter the amplitude and waveform of circadian rhythms. These exogenous influences are referred to as "masking effects." Masking may cause an observed rhythm to inaccurately reflect the underlying circadian pacemaker.

phase The instantaneous state of an oscillation (i.e., maximum or minimum) defined by the value of a rhythmic variable and its time derivative. Often, in order to facilitate comparisons between rhythms or between rhythms and cyclic time cues, the time of a specific phase is chosen as a cycle reference point.

phase angle The difference in time between the phases of a rhythm and the entraining cycle or between two different rhythms. The phase angle is usually measured in fractions of the entire period.

phase response curve (PRC) A plot of the magnitude and direction of a phase shift as a function of the circadian phase at which a phase-shifting stimulus (typically light) is applied.

zeitgeber German for "time giver;" an environmental time cue such as sunlight, food, noise, or social interaction that is capable of entraining the biological clock to a 24-hr day.

Biological rhythms are oscillations in an organism's physiology and behavior. These rhythms span a wide range of frequencies, ranging from fractions of a second to a year. Many rhythms exhibit a periodicity close to that of the 24-hr geophysical cycle that results from the daily rotation of the earth around its axis. Biochemical, physiological, and behavioral rhythms that oscillate with a period close to 24 hr are termed circadian rhythms. Circadian rhythms are generated by an endogenous pacemaker, are self-sustaining, and persist in the absence of time cues. It has been hypothesized that the original adaptive role for circadian organization was to ensure that phases of DNA replication sensitive to damage by high ultraviolet light levels in the primitive day were protected by being synchronized to night. Examples of human circadian rhythms are shown in Fig. 1. These include the daily oscillations of the sleep–wake cycle, body temperature, growth hormone, cortisol, and urinary potassium excretion. Circadian rhythms provide temporal organization and coordination for physiological, biochemical, and behavioral variables in all eukaryotic organisms and some prokaryotes. Without this important temporal framework, an organism will experience, minimally, a severely reduced homeostatic capacity. Circadian desynchronization can be likened to a symphony without a conductor—each instrument section may be fully functional, but the sections collectively are unable to harmonize. The medical importance of circadian rhythms is just beginning to be appreciated in the clinical arena. For example,

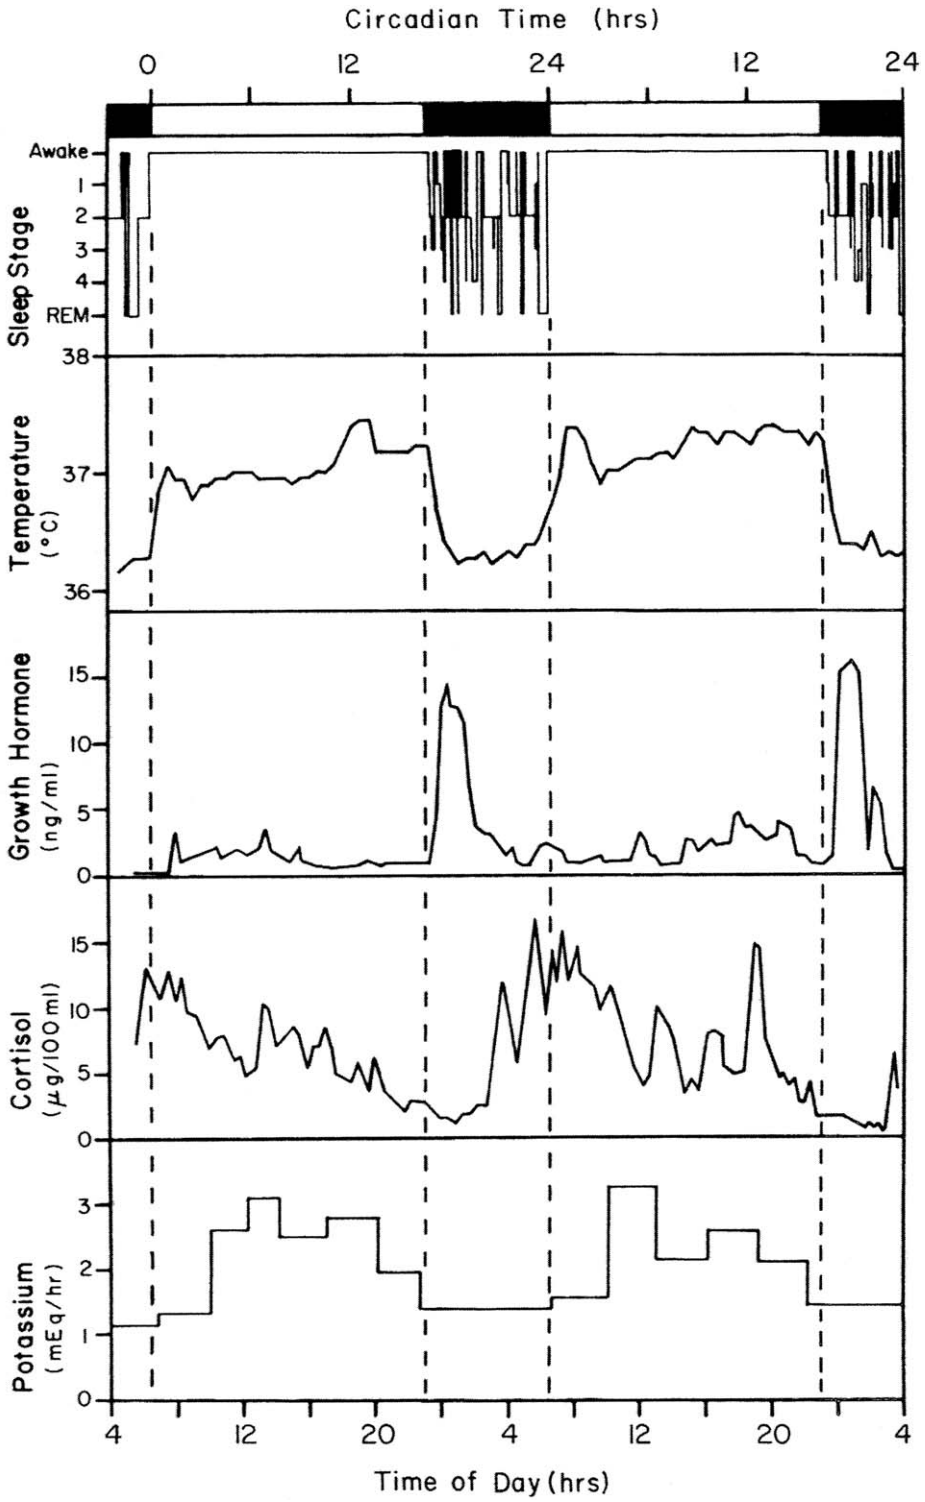

Figure 1 A representative panel of human circadian rhythms. Starting from the top panel: Rhythms in sleep, body temperature, plasma growth hormone, plasma cortisol, and urinary potassium excretion. These data represent 48 hr of data from a subject entrained to a 24-hr day (LD 16:8; 16 hr of light and 8 hr of dark). The light and dark periods are shown at the top of the data panels. Harvard University Press, Cambridge, MA].

circadian rhythms are now recognized as important variables in the diagnosis and treatment of many pathophysiological conditions. Many of the properties of circadian rhythms are analogous to physical oscillators, and, consequently, much of the terminology used to describe rhythms is derived from oscillator theory. All biological rhythms are characterized by fundamental parameters, which include period length, rhythm mean, circadian waveform, and circadian amplitude. Each parameter describes an important property of the circadian timing system. Figure 2 illustrates the important parameters of biological rhythms, zeitgebers, and reference time scales. After decades of circadian rhythm research, several generalizations can be made about circadian rhythms: (1) circadian rhythms are ubiquitous, they are present in all eukaryotes and some prokaryotes; (2) circadian rhythms are genetically determined, not learned; (3) circadian rhythms are generated by an endogenous, self-sustained pacemaker; (4) in an environment without external time cues, circadian rhythms persist with a period that approximates 24 hr; (5) the period of the circadian pacemaker is temperature-compensated; and (6) the circadian pacemaker can be entrained to external time cues.

I. INTRODUCTION

As a consequence of the Earth's daily rotation about its axis, all terrestrial organisms have evolved in an environment with alternating cycles of light and dark. During the course of evolution, organisms have adapted to the challenge of living with a light–dark

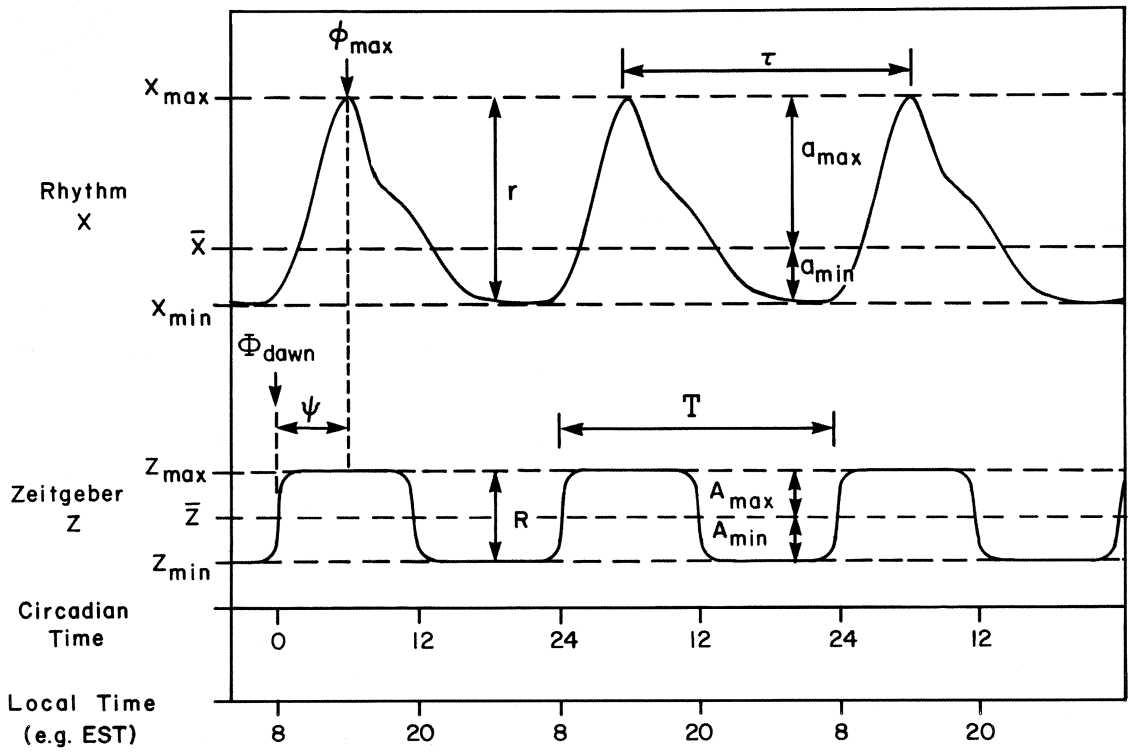

Figure 2 The important parameters of biological rhythms, zeitgebers, and reference time scales. Top panel, rhythm of a biological variable, x; bottom panel, cycle of an environmental zeitgeber, Z, which entrains the rhythm. These variables are plotted against two different time scales. The local time scale indicates the time of day at which the biological measurement was made. The circadian time scale standardizes the relationship of the biological variable to the zeitgeber cycle by defining circadian time 0 as dawn. The parameters for the zeitgeber are given in captial letters and those for the rhythm in lower case. Identified for rhythm and zeitgeber cycles are the mean values of the variable (x and Z), the maximum and minimum values (x_{max}, x_{min}, Z_{max}, Z_{min}), the ranges of the oscillations (r and R), the periods of the oscillations (τ and T), the amplitudes (a_{max}, a_{min}, A_{max}, and A_{min}), and the reference phases (ϕ and Φ). The figure also shows the phase relationship (ψ) between dawn on the zeitgeber cycle and the maximum of the rhythm, but ψ can be defined between any two reference points on the zeitgeber and rhythm waveforms. Harvard University Press, Cambridge, MA].

(LD) cycle by occupying temporal niches in which they can optimize life-sustaining activities such as feeding, sleeping, and avoiding predators. It then is not surprising, perhaps, that organisms, ranging from prokaryotes to multicellular eukaryotes, have evolved an internal time-keeping system. In mammals, this internal time-keeping system, the circadian timing system (CTS), provides temporal organization for a host of behavioral, physiological, and biochemical variables. The fundamental adaptive advantage of this temporal organization is that it allows for predictive, rather than entirely reactive, homeostatic regulation of function. For example, prior to waking, body temperature, heart rate, blood pressure, and plasma cortisol increase in anticipation of increased energetic demands. In addition, the CTS, by monitoring day length and its rate and direction of change, contributes to adaptive reproductive and seasonal rhythms.

A. Discovery of Circadian Rhythms

Daily rhythms in the activities of plants and animals have been recognized from the earliest recorded times. It was not until 1729, however, that diurnal rhythmicity was empirically shown to be an endogenously generated phenomenon and not merely a passive response to a cyclic environment. That year, French astronomer Jean Jacques d'Ortous de Mairan studied the leaf movements of the heliotrope plant, *Mimosa pudica*. De Mairan observed that the leaves and pedicels of the plant continued to open during the day and close during the night even when the plant was isolated from the normal light–dark environment. De Mairan's study was not generally accepted as proof that circadian time-keeping was an innate property of the plant because other external (geophysical) oscillations (e.g., temperature or electromagnetic oscillations) had not been ruled out as time cues. Since de Mairan, other scientists have attempted to account for the potential influence of these external oscillations. For example, Hamner and co-workers showed the persistence of circadian rhythmicity in hamsters (*Mesocricetus auaratus*), fruit flies (*Drosophila*), and a fungus (*Neurospora*) when placed on a table rotating counter to the earth's rotation at the South Pole. More recently, Dr. Frank Sulzman and co-workers tested the exogenous vs endogenous hypothesis during NASA's Spacelab 1 mission. For this experiment, the mold *Neurospora crassa* was flown in the orbiting space shuttle. The specimens were maintained in constant conditions (e.g., constant dark conditions). The results showed that *Neurospora* conidiation rhythms persisted though the period of the rhythm was significantly different from the earth's 24-hr geophysical period of rotation. This finding made it clear that living organisms have internal time-keeping devices.

B. Free-Running Rhythms, Entrainment, and Masking

Persisting circadian rhythms in animals and plants isolated from environmental time cues are termed "free-running" rhythms. Every species possesses a characteristic average free-running period (τ) with individual periods distributed normally around the species mean. Most species exhibit a period close to, but not exactly, 24 hr. It was determined that the human pacemaker has an endogenous period very close to 24 hr. A true free-running circadian rhythm will persist, for the most part, indefinitely in an environment without any time cues. In an early study by Curt Richter, a blinded squirrel monkey showed a persisting circadian activity rhythm for as long as it was studied ($\sim$3 years).

If circadian clocks free-ran in the natural environment they would be of little use to the organism. Evolution has ensured that the circadian system can be synchronized to certain environmental time cues or *zeitgebers*. The process by which circadian rhythms are synchronized to periodic environmental time cues is called entrainment. The light–dark cycle is the predominant environmental entraining agent in most plants and animals, including humans. However, daily cycles of food availability, social interactions, and ambient temperature have also been shown to be effective entraining agents in *some* species. Environmental synchronization is adaptive because it confers on an organism the ability to maintain appropriate phase relationships with the external environment throughout the year. From an evolutionary perspective, the ability to perform certain behaviors at the appropriate time of day or the appropriate season confers a strong selective advantage to an organism. In effect, entrainment ensures that an organism does the right thing at the right time. Entrainment, however, is restricted to synchronizers, which cycle close to 24 hr. If the period of the zeitgeber is too short or too long, the circadian system is incapable of being entrained. This phenomenon is referred to as the "range of entrainment."

Any external signal that is capable of entraining a circadian rhythm will set the phase of the pacemaker's oscillation; however, the signal may also affect the overt (measured) rhythm in a more direct way, with or without a relationship to the process of entrainment. Such a direct effect by the signal obscures the rhythm of the oscillation and is referred to as masking. Masking may be adaptive, however. For instance, masking may augment the amplitude of a rhythm and therefore complement clock control, or, alternatively, masking may represent the reactive portion of homeostatic control with the CTS representing the predictive component. Virtually all rhythmic physiological variables can show masking and, therefore, care must be taken when evaluating circadian data.

Light is the most potent zeitgeber and the primary environmental agent for entraining the circadian timing system. Not suprisingly, then, light is typically the principal dependent variable in chronobiological studies. For the purpose of this article, the term light refers to the radiant energy detected by the physiological sensors in humans and animals. Since the late 1970s, Dr. Charles Czeisler and colleagues have performed many experiments to evaluate the ability of light to entrain and phase-shift the human circadian clock. These and other studies have demonstrated the utility of light therapy to reset rhythms in humans suffering from various circadian and sleep–wake disorders.

C. Phase Shifts and Phase Response Curves

The circadian clock is not equally sensitive to a given zeitgeber at all times of day. This fact is a conserved feature in all examined taxa and is graphically summarized in a phase response curve (PRC), shown in Fig. 3, which plots the magnitude and direction of a phase shift as a function of the circadian phase at which a stimulus is applied. The PRC models the mechanisms by which the circadian clock is entrained to environmental cycles. For example, PRCs to light stimuli illustrate the differential effects of light at different circadian phases. Light, the principal environmental zeitgeber, has its greatest effect on the circadian clock when delivered during the subjective night, the time when a species is normally exposed to darkness. Light pulses will phase-delay rhythms in the early subjective night and phase-advance rhythms in the late subjective night. Little phase shifting occurs during the subjective day—the dead zone. These features of the light PRC explain the ability of the circadian pacemaker to entrain to daily light–dark cycles (e.g., entrainment by light-inducing phase advances–delays equals the difference between the free-running period and the light–dark cycle period). In humans the PRC for light is asymmetric; delay shifts are usually larger than advance shifts. The asymmetry of the light PRC underlies the relative ease of adjusting to westward transmeridian jet travel as compared to eastward travel (jet lag).

Nonphotic cues have also been shown to have a strong resetting effect on the clock. It has been suggested that nonphotic cues may provide an additional adaptive advantage to organisms. Food availability, ambient temperature, social interaction, acute exposure to sexual odors, and exercise are all examples of factors that have been shown to phase-shift and entrain the circadian system in many animals, including humans. In general, nonphotic cues cause phase shifts when administered during the subjective day. This phase sensitivity is during a period when the clock is insensitive to light. In fact, the PRC for nonphotic cues is about 180° out of phase with the photic PRC. Nonphotic cues may help to synchronize the free-running clock in blind individuals and attenuate temporal desynchrony in shift-workers. More recent studies have further suggested that events in the environment that reliably precede the onset of light can assume the resetting function of light through conditional stimulus control.

D. Mammalian Circadian Rhythms and the Endogenous Pacemaker

At the turn of the century, any observed oscillation in mammalian physiology or behavior was dismissed as a random fluctuation of little importance. This is largely because physiologists and physicians were grounded in the developing tenet of homeostasis. Homeostasis, a term coined by Dr. Walter B. Cannon, describes the relative constancy of the internal environment or milieu de interior. Although the concept of homeostasis accounted for the presence of daily variations in physiological systems, circadian rhythmicity per se was not recognized as an important biological characteristic. This changed in 1922, however, when Dr. Carl Richter demonstrated the endogenous nature of circadian activity rhythms in rats and, furthermore, showed that the rats were synchronized by both the light–dark cycle and the time of feeding. Later in the

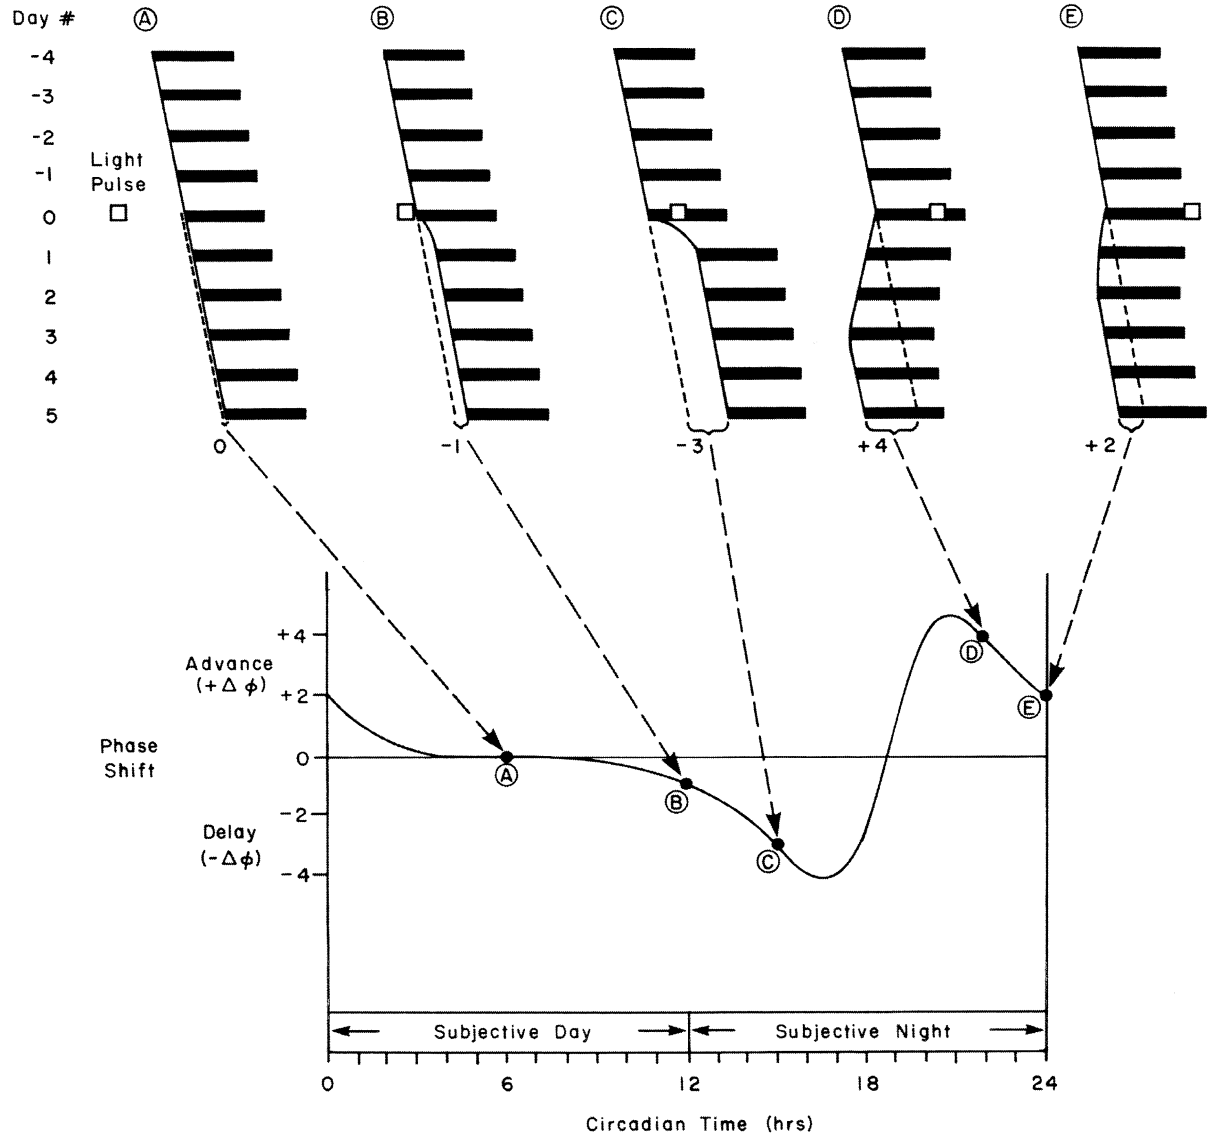

Figure 3 Derivation of a phase–response curve (PRC). (A)–(E) show five sample experiments in which a nocturnal animal, free-running in constant darkness, is exposed to a 1-hr light pulse. A free-running activity rhythm with a period of 25.0 hr is seen on days −4 to −1. On day zero, a light pulse is given at mid-subjective day (A), at late subjective day (B), at early subjective night (C), at late subjective night (D), and at early subjective day (E). The light pulses in mid-subjective day and early subjective night (B and C) produce phase delays of the activity rhythm that are complete within one cycle. The light pulses in late subjective night and early subjective day (D and E) produce phase advances with several cycles of transients before reaching a steady-state shift by day 5. *Lower panel*: Direction and magnitude of phase shifts plotted against the time of light pulses to obtain a PRC. When light pulses are given at frequent intervals throughout the subjective day and night, the waveform for the PRC follows the solid line. In mammals there is normally a gradual transition between maximum phase delay and maximum phase advance, with a point in mid-subjective night (like the one in mid-subjective day, A) where there is no phase shift. [Reproduced by permission from Moore-Ede, M. C., Sulzman, F. M., and Fuller, C. A. (1982). *The Clocks That Time Us: Physiology of the Circadian Timing System*. Harvard University Press, Cambridge, MA].

twentieth century, the endogenous nature of the human circadian timing system was confirmed, and circadian rhythms were documented in hundreds of physiological, biochemical, and behavioral variables. In fact, it became apparent that it was often more significant to find a physiological variable with no circadian rhythm.

The definition of a circadian rhythm may be straightforward; however, defining a biological clock is a bit more difficult. Any biological structure to be

considered a clock must be able to measure the passage of time independent of any periodic input from its environment as well as from timed biological events. In addition, in order to keep time reliably, a clock must have both resolution, an ability to detect the temporal order of two events closely spaced in time, and uniformity, a regularity of period and thus the ability to predict the occurrence of other regularly timed phenomena. Experimentation has revealed that a mammalian clock, which we now know resides in the suprachiasmatic nucleus (SCN) of the hypothalamus, has both relatively high resolution and uniformity. The uniformity of the clock is further augmented by the ability of an organism to "reset" its clock each day using environmental cues.

The location and function of the SCN, as a master pacemaker of the mammalian brain, have been confirmed by an impressive variety of experimental approaches. For example, lesion studies, in which the SCN was ablated, resulted in arrhythmic experimental animals. Neural transplantation of fetal SCN tissue into lesioned animals restored rhythmicity, confirming both the location and function of the circadian pacemaker. Similarly, animals with reciprocal SCN transplants have a circadian period determined by the genotype of the grafted tissue and not that of the host. The SCN also exhibits clear circadian rhythms of gene expression, metabolism, and electrophysiological activity *in vitro*.

Whereas the evidence supports the role of the SCN as a master circadian pacemaker, additional findings suggest that the circadian timing system is multioscillatory. In humans, the primary evidence for multiple pacemakers comes from temporal isolation studies in which some rhythms, such as the sleep–wake rhythm, and other rhythms, such as the body temperature rhythm, sometimes free-run with very different periods. This phenomenon is referred to as internal desynchronization.

The overall organization of the circadian timing system is thought to be hierarchical. That is, the SCN acts as a master oscillator, which in addition to receiving temporal cues from the environment drives a variety of slave oscillators. Some of these slave oscillators are thought to also generate oscillations independently, whereas others, termed passive slaves, do not. A study using fibroblasts in culture demonstrated that nonneural tissue might also possess intrinsic clocks. Serum induction of clock behavior in the fibroblast suggests that the SCN, as the principal oscillator, may simply orchestrate rather than actively drive oscillations in peripheral tissues.

Whereas the number of processes that show circadian fluctuation is large, a few physiological and behavioral rhythms (locomotor activity, body temperature, and melatonin) are commonly used to study the circadian timing system. Furthermore, several neural structures comprise the anatomical circadian timing system. Each will be discussed later in the article.

II. THE FUNCTIONAL AND ANATOMICAL CIRCADIAN TIMING SYSTEM

It is common to describe the anatomical and functional circadian timing system as consisting of three elements: input, pacemaker, and output. Though this simplification is heuristically useful, the reader should note that this descriptive paradigm belies the functional and anatomical complexity of the CTS.

A. The Pacemaker

Much is known about the anatomy and morphology of the SCN. The SCN is located in the anteroventral hypothalamus and consists of a pair of nuclei bordering the third ventricle at midline. Experimental lesions of the SCN result in the abolishment or severe disruption of most circadian rhythms, including locomotor activity, feeding, drinking, body temperature, sleep–wake, cortisol, melatonin, and growth hormone secretion. The unique functionality of the SCN is underscored by the fact that neonatal ablations of the SCN in rats permanently abolish circadian rhythms; thus, no other brain region can take over the function of the SCN. Although SCN lesions do not interfere with thermoregulation, eating, drinking, hormonal secretion, and so on, the temporal organization of homeostatic regulation is lost.

The SCN can be divided into two primary anatomical subdivisions, each with several neuronal subfields. The first subdivision, the shell, receives input from the basal forebrain, thalamus, and brain stem, whereas the second subdivision, the core, receives visual input, both direct, the retinohypothalamic tract (RHT), and indirect, intergeniculate leaflet (IGL), as well as afferents from the midbrain raphe, hypothalamus, and thalamus. The core subdivision, analogous to the ventrolateral SCN (vlSCN), projects densely to the shell, but reciprocal projections from the shell, analogous to the dorsomedial SCN (dmSCN), are sparse. Both the core and shell have commissural connections with homologous areas in the contralateral SCN.

In both the core and shell SCN, distinct subfields of SCN neurons exist. The retinorecipient zone of the vlSCN contains most of the neurons containing vasoactive intestinal peptide (VIP), gastrin-releasing peptide (GRP), and peptide histidine isoleucine (PHI). In contrast, the dmSCN contains most of the neurons containing arginine vasopressin (AVP) and somatostatin (SS). Notably, the VIP neurons form extensive connections both within the SCN and with extra-SCN targets. Photoinduction of c-Fos occurs in VIP neurons; thus, they are implicated in photic entrainment. The AVP- and SS-containing neurons are predominantly found in the dmSCN. These neurons exhibit robust circadian rhythms in peptide synthesis both in constant conditions and in hypothalamic slice preparations. More recently, it has been shown that GABA is colocalized in all neurons throughout the SCN and, thus, appears to be the principal small neurotransmitter in the mammalian SCN. A number of studies have also provided evidence for nitric oxide (NO) as an SCN neurotransmitter. Because the nitric oxide synthase-containing cells are found within VIP neurons, the putative role for NO is in mediating the effects of light.

The SCN also possesses a mechanism for generating autonomous circadian rhythms in individual pacemaker cells and the ability to synchronize these autonomous pacemaker cells. Electrophysiological evidence has strongly suggested that the generation of circadian rhythms within the SCN is by autonomous cell pacemakers and is not an emergent property of a population of cell oscillators as once thought. However, the intracellular mechanisms responsible for circadian rhythms and the mechanisms of cell–cell electrical coupling remain poorly understood.

B. Input

1. Retinohypothalamic Tract

The best characterized projection to the SCN is the retinohypothalamic tract (RHT). The RHT serves as the anatomical and physiological circadian visual system and is distinct from the visual system responsible for reflex oculomotor function and image formation. The RHT originates in a subset of specialized retinal ganglion cells, W-cells, and terminates bilaterally within the vlSCN.

Ablation of the RHT abolishes photoentrainment, suggesting that all photoreceptors responsible for entrainment of the CTS are in the retina. Retinal rod and cone photoreceptors are thought to participate in CTS entrainment. However, other putative photoreceptive elements have been implicated in entrainment, including several non-opsin-based photopigments (light-absorbing heme moieties such as hemoglobin and bilirubin), B2-based photopigments (i.e., cryptochromes), and, more recently, melanopsins. Electrophysiological and retrograde labeling studies suggest a diffuse distribution and high photic threshold for the photoreceptive cells of the RHT. The spectral sensitivity of the photoreceptive system that mediates entrainment of the hamster's circadian rhythms has a maximum sensitivity near 500 nm. Dr. Joseph Takahashi noted two unusual features of this system: the threshold of the response is high, especially for a hamster with a predominantly rod retina, and, second, the reciprocal relationship between intensity and duration holds for relatively long durations (up to 45 min). Largely on the basic of these observations, Takahashi has suggested that the clock's photoreceptive system is capable of integrating total photon exposure over a long period without becoming nonlinear in response. In addition, the unique intensity–response curve and relatively high threshold suggest that the photoreceptor system, at least in the hamster, is specialized for luminance coding in the range of light intensities occurring around dusk and dawn.

In vitro and *in vivo* electrophysiological studies have provided compelling evidence that the RHT utilizes glutamate as its primary transmitter. Both ionotropic and metabotropic glutamate receptors for glutamate have been identified in the SCN. Antagonists, which act upon ionotropic glutamate receptors, both reduce the phase-shifting effects of light on rodent locomotor rhythms and attenuate the photoinduction of c-Fos in the SCN. Additional neurotransmitters, including substance P (SP) and pituitary adenylyl cyclase-activating peptide (PACAP), are also thought to participate in retinohypothalamic transmission. Both SP and PACAP have been shown to modulate glutamate neurotransmission, though it is not currently understood how. Extensive analysis on the organization, synaptology, and morphology of the RHT projection to the SCN has revealed considerable structural plasticity in its synapses with the SCN.

2. Geniculohypothalamic Tract

The intergeniculate leaflet (IGL), a distinct lamina of neurons interposed between the dorsal and ventral lateral geniculate nuclei of the thalamus, gives rise to a dense neuropeptide-Y (NPY) containing projection that terminates bilaterally in the vlSCN. This projec-

tion is the geniculohypothalamic tract (GHT), and the termination in the vlSCN is coextensive with the retinorecipient neurons. This NPY projection is thought to subserve, in part, nonphotic entrainment of the SCN. Lesion of the IGL results in altered phase angles of entrainment consistent with a role of mediating nonphotic input to the SCN. However, some IGL cells are photically responsive. These cells are innervated by retinal afferents, which are collaterals of fibers that also innervate the SCN. Thus, the SCN can receive photic influences via the multisynaptic retina–IGL–GHT–SCN pathway. It is thought that the IGL's primary role is to integrate photic and nonphotic information in order to provide a regulatory influence on the SCN. GABA colocalizes with NPY-containing cells in the IGL and also with a subset of enkephalin-containing neurons, which give rise to a commissural projection to the contralateral IGL.

3. Raphe Afferents

The ventral and medial SCN receive dense innervation from serotonergic (5HT) fibers originating in the median raphe nuclei. The functional significance of this pathway remains unclear; however, evidence suggests that the primary role of the serotonergic innervation of the SCN is to modulate the activity of the retinal afferents (i.e., photic information). Similar to the GHT innervation of the SCN, the 5HT raphe projection to the SCN is coextensive with visual input and also synapses on VIP neurons in the vlSCN. The dorsal raphe nuclei projects to the IGL, providing another pathway to modulate the SCN. Some effects of 5HT are thought to be mediated by both the $5HT_7$ receptors in the SCN and the $5HT_{1B}$ receptors located on retinal afferents to the SCN. However, because several other 5HT receptor subtypes exist in several sites in and around the SCN, the exact mechanisms by which the serotonergic raphe acts on the SCN are unclear.

4. Other Afferents

Whereas the SCN does not appear to contain any intrinsic cholinergic neurons, it receives choline acetyltransferase-immunopositive projections from the pedunculopontine tegmental nuclei, the lateral dorsal tegmental nuclei, and the basal forebrain. These nuclei contribute to sleep and wakefulness and probably other behavioral state changes. *In vivo* administration of carbachol, a cholinergic agonist, advances the phase of the SCN at night via muscarinic acetylcholine receptor-mediated activation of guanylyl cyclase–cGMP–PKG pathways. Nicotinic acetylcholine receptors may also mediate, in part, the cholinergic influence on the circadian system; however, the extent of the mediation remains undetermined.

Many additional hypothalamic projections to the SCN have been identified and characterized both anatomically and pharmacologically. These include hypothalamic projections from the preoptic, arcuate, dorsomedial, and ventromedial nuclei, lateral hypothalamic area, posterior hypothalamus, tuberomammillary nuclei, and the bed nucleus of the stria terminalis. In addition, there are extrahypothalamic projections from the paraventricular thalamic nuclei, lateral septal nucleus, pretectum, infralimbic cortex, zona incerta, and ventral subiculum. The majority of the afferent projections are excitatory, whereas GABAergic projections from the IGL, tuberomammillary, and arcuate nuclei are inhibitory.

SCN afferents utilize a variety of neurotransmitters in addition to acetylcholine as signals, not all of which are fully characterized. In turn, different signals act through various intracellular pathways to adjust clock timing. Notably, there appear to be one or more time domains in which the SCN is refractory or shows altered responses to the different signaling compounds at different times. For example, light and the RHT transmitter glutamate cause phase delays in the early night and phase advances in the late night. Studies have shown that glutamate acts via increased intracellular Ca^{2+}, mediated by activation of ryanodine receptors in the early night and via a cGMP-mediated signaling pathway in the late night. During dusk, the SCN exhibits an increased sensitivity to the hypnogenic pineal hormone melatonin, which appears to act via a protein kinase C pathway. Other putative signal pathways include cAMP, nitric oxide, and PIP2 and suggest that the SCN may engender its temporal sensitivity at the intracellular level.

C. Output

The efferent projections of the SCN are extensive. Dr. Robert Moore has described four primary projections. These include the following: (1) projections to the anterior paraventricular thalamus, ventral lateral septum, and bed nucleus of the stria terminalis; (2) a periventricular fiber system innervating a large portion of the medial hypothalamus from the preoptic region to the premammillary region; (3) a lateral thalamic projection to the IGL; and (4) projections to the posterior paraventricular thalamus, precommisural

nucleus, and olivary pretectal nucleus. The majority of these projections exhibit vasopressin or VIP immunoreactivity. In general, this restricted subset of projections receives a particularly dense innervation from the SCN and therefore is thought to serve as relays for the distribution of SCN information to other neural structures. The subparaventricular zone (SPVZ), a region ventral to the paraventricular nucleus of the hypothalamus, is another structure receiving dense efferent SCN projections. The SPVZ has parallel projections to most of the same sites as the direct efferents of the SCN. With the exception of the SCN commissural connections, the efferents of each nucleus are ipsilateral.

The efferent projection to the preoptic hypothalamus is of particular importance because this area is involved in the regulation of sleep–wake, reproduction, fluid homeostasis, and thermoregulation. The projection to the PVN is part of a multisynaptic pathway regulating melatonin synthesis. Evidence suggests that the SCN, via the PVN, may influence the intermediate nucleus of the solitary tract (NTS), a structure that integrates gustatory, respiratory, and cardiovascular information. How efferent projections from the SCN convey time of day information to other neural networks is largely unclear.

The SCN also has a humoral output, which is known to include a daily rhythm in levels of the neuropeptide arginine vasopressin (AVP). Cerebrospinal fluid levels of AVP are high during the subjective day and low during the subjective night in both nocturnal and diurnal animals. These rhythms also persist *in vitro*. Rhythms of other neuroactive peptides synthesized in the SCN have been measured in the cerebral spinal fluid (CSF) and *in vitro* as rhythms in both mRNA and protein production.

The circadian and noncircadian visual systems may, in fact, interact. Except for the sharing of retinal photoreception, the nature of this interaction is not well-understood. Interconnections of these pathways occur between the superior colliculus and ventrolateral geniculate leaflet and the IGL.

III. MOLECULAR MECHANISMS OF THE CIRCADIAN CLOCK

A. Molecular Biology of the Pacemaker

Until the 1990s, very little was known regarding the intracellular mechanisms in the pacemaker responsible for the generation of circadian rhythms. The first indication that the circadian pacemaker had a genetic underpinning occurred during a selection experiment by Drs. Konopka and Benzer. In their classic experiment, the frequency of pupal hatching in *Drosophila* was studied, leading to the identification of the first single-gene circadian clock mutant, the *Period* (*Per*) gene. To date, three mammalian orthologs, homologs of the fly *Period* gene, have been identified (*mPer1, mPer2*, and *mPer3*). Shortly after the discovery of the *Period* gene, several other mutants exhibiting altered or eliminated circadian rhythm were discovered, including *timeless* (*tim*) in *Drosophila* and *frequency* (*frq*) in *Neurospora*. The first mammalian clock gene, *Clock*, was discovered by Joseph Takahashi using a phenotype-driven *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis screen. The *Clock* gene was identified by positional cloning followed by a functional transgenic BAC rescue, which served to confirm that the *Clock* gene was in fact responsible for the mutant phenotype. More recently, two additional mammalian *Clock* genes, the *Cryptochrome* genes (*mCry1* and *mCry2*), have been described.

The *Clock* gene regulates two properties of the circadian clock: the endogenous circadian period and the persistence of rhythmicity. The protein encoded by the *Clock* gene, CLOCK, is a basic helix–loop–helix (bHLH) PER–ARNT–SIM (PAS) protein that belongs to a family of transcription factors. Shortly after the cloning of *Clock*, a CLOCK-interacting protein, BMAL, was identified using a yeast two-hybrid system. The CLOCK–BMAL heterodimer acts in a *trans*-activating fashion on E-box elements, which contain bHLH DNA-binding domains. Notably, both *Period* and the *Cryptochromes* contain an E-box sequence in the promoter region. By using a luciferase gene reporter assay, it was shown that the CLOCK–BMAL1 heterodimer, via transactivation of the E-box enhancer, drives the positive component of *Per* and *Cry* transcriptional oscillations. In addition, the CLOCK–BMAL1 heterodimer is thought to activate transcription of arginine vasopressin, a primary output marker for the circadian clock. It is not currently known what other *Clock* output genes are controlled by CLOCK–BMAL1; however, it is likely there are many. Both PER and CRY proteins block the ability of the CLOCK–BMAL1 dimer to activate *Cry* and *Per* promoters via the E-box, and, thus, a simple negative feedback loop begins to emerge. The rhythmic expression of PER proteins is thought to constitute the output of the oscillator, leading to the expression of *Clock*-controlled genes (Fig. 4). More recently, it was shown that, in mice, the two *Cryptochrome* genes were

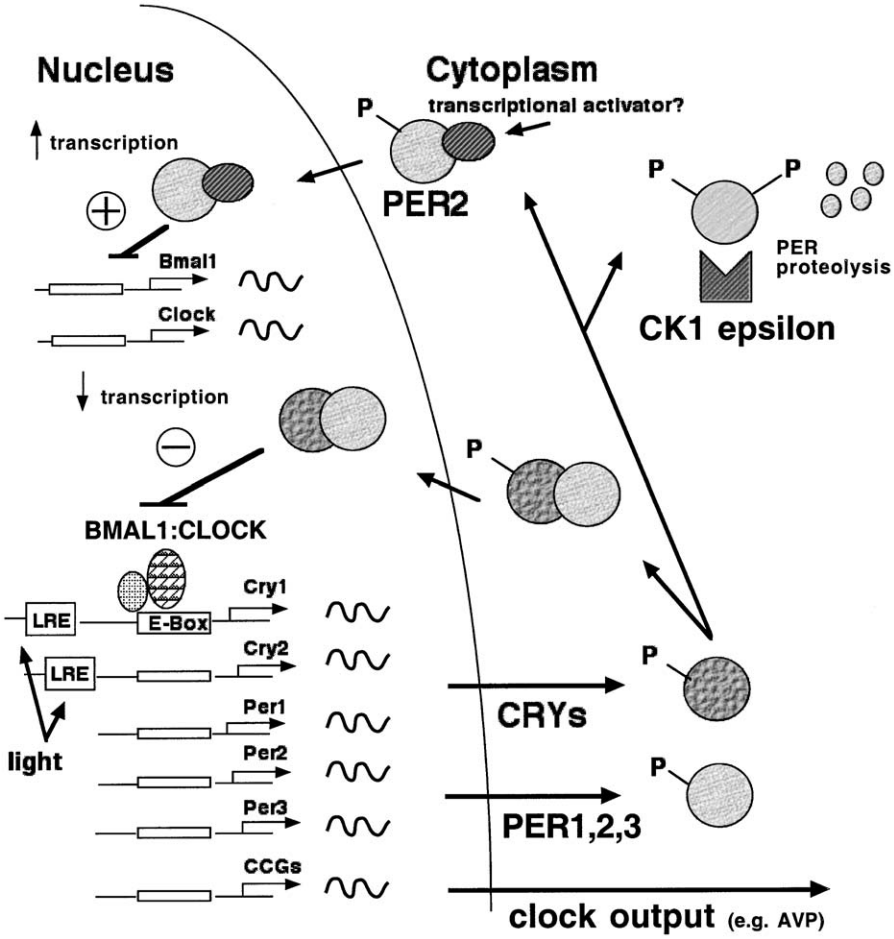

Figure 4 An illustration of the contemporary model for the autoregulatory transcriptional–translational feedback loop thought to constitute the endogenous time-keeping mechanism. The relationship between variables is described in the text. [Modified from Lowrey, P. L., Shimomura, K., Antoch, M. P., Yamazaki, S., Zemenides, P. D., Ralph, M. R., Menaker, M., and Takahashi, J. S. (2000). Positional syntenic cloning and functional characterization of the mammalian circadian mutation tau. *Science* **288,** 483–492.]

essential components of the negative limb of the circadian clock feedback loop. It now appears that the Cryptochrome proteins, CRY1 and CRY2, play an important role in the translocation of PER back to the nucleus, where PER disrupts CLOCK–BMAL1 transcriptional activity. A mammalian circadian mutant, *tau*, has been described. The *tau* mutation is a semidominant autosomal allele, which shortens the period length of circadian rhythms in Syrian hamsters. It was determined that the *tau* locus encodes casein kinase I epsilon (CKIe). CKIe phosphorylates PER proteins, which targets them for degradation. CKIe is the only enzyme identified so far in the mammalian pacemaker and, thus, may be a potential target for pharmaceutical compounds. Interestingly, the *tim* gene does not appear to have a role in mammalian circadian time-keeping.

How do light during the night and behavioral events during the day produce delays and advances? Evidence suggests that both types of shifts are mediated by changes in the levels of the state variables of the clock. For example, it now appears that PER1 protein and mRNA are rapidly down-regulated during behavioral resetting and that PER1 protein and mRNA are rapidly induced after light exposure. Whereas it is clear that much remains to be discovered about the mechanisms by which the clock loop is modulated, it is known that light appears to differentially regulate the *Per* gene. Future studies utilizing conditional transgenic and knockout mice in which genes are altered in a development- or tissue-specific manner should prove to be powerful tools for the dissection of the mammalian circadian clock mechanisms.

B. Molecular Basis of Entrainment to Light

In 1989, several groups of scientists independently reported that light could regulate the expression of the protoncogene *c-fos* in the SCN of rats and hamsters. The protein (c-Fos) belongs to the leucine zipper family of DNA-binding proteins and forms transcriptional regulatory complexes with other binding proteins. That light could physiologically regulate *c-fos* expression suggested that transcriptional control, via transcriptional regulatory proteins, was an important part of photoentrainment and might contribute to the mechanisms of circadian time-keeping. JunB appears to have a temporal pattern of expression similar to that of c-Fos and, thus, may also have an important role in light entrainment.

Following a light pulse administered during the subjective night in constant darkness, both *c-fos* mRNA and c-Fos protein are dramatically elevated in the retinorecipient areas of the SCN. This photoinduction of *c-fos* and c-Fos does not occur during the subjective day and, thus, photoinduction, like phase shifting, is phase-dependent. Circadian phase dependency of *c-fos* and c-Fos expression persists *in vitro* in SCN tissue slices. Thus, the gating of *c-fos* and c-Fos induction does not appear to require an intact retina or other neuronal structure. The mechanism that gates the photoresponsiveness of *c-fos* expression is unknown. However, phase dependency of c-Fos induction implies that the *c-fos* gene is clock-controlled. In contrast, photic stimulation of *c-fos* and c-Fos in another important CTS structure, the IGL, is not dependent on the circadian phase. The response to light in the SCN includes rapid and transient peak expression of mRNA after 30 min and peak expression of immunoreactive c-Fos protein 1–2 hr after onset of light administration.

There is a strong correlation between the photic induction of *c-fos* and the magnitude of phase shifts in behavioral rhythms. Further, the illumination threshold for gene expression is identical to the threshold for phase shifts. This correlation does not apply at high light intensities or with long photoperiods. Experimentation has indicated that about 20% of the total SCN neuron population consists of photoinducible c-Fos cells. These cells are located in the ventrolateral portion of the SCN. The exact mechanism of *c-fos* induction in the SCN remains unclear. However, it appears that an initial intracellular elevation of Ca^{2+} and cyclic AMP results from glutamanergic stimulation from the RHT. This then leads to phosphorylation of Ca^{2+}–cAMP response element-binding protein (CREB), an important transcription factor.

Only when Fos proteins are complexed as heterodimers, particularly with *jun* gene family members (c-Jun, JunB, JunD), will binding to the DNA regulatory element, AP-1, occur. AP-1-binding complexes may have constant or variable protein components, and it has been proposed that light, via c-Fos activation, alters the protein composition of the AP-1-binding complex, a regulator of transcription, altering its stability and binding affinity. The change in binding activity alters the transcription of SCN genes that have AP-1 sites on their promoters. To date, however, the *trans*-activating and *trans*-repressing activities of the various heterodimer complexes are unknown, and the identities of the AP-1-dependent genes remain to be elucidated. Exactly how the IEGs modulate *Clock* genes is not understood.

C. Molecular Basis of Pacemaker Cell Coupling

It is not understood how the activity of autonomous pacemaker cells of the SCN is synchronized to form a unified endogenous oscillator. Unfortunately, empirically distinguishing between endogenous pacemaker components and synchronizing mechanisms is very difficult. Extracellular ion fluxes, small membrane-diffusible molecules, glial regulation, and neural adhesion molecules have been examined as possible synchronizers of SCN neurons. Synaptic transmission and calcium-dependent neurotransmitter release are not essential for circadian time-keeping or pacemaker neuron synchronizing. Nitric oxide, a small membrane-diffusable molecule, is a promising candidate for a synchronizer. However, the fact that nitric oxide synthase is calcium-dependent is a confounding point. Previously, GABA was thought to underlie the generation of circadian rhythmicity via a rhythm in GABA equilibrium potential. However, it has been shown that antagonists to GABA neurotransmission do not prevent circadian rhythms in multiunit activity *in vitro*. Glial processes, gap junctions, adhesion molecules, and regions of membrane appositions have also been proposed as potential mechanisms of intercellular synchronization.

IV. MELATONIN AND BODY TEMPERATURE

Both the body temperature (T_b) and melatonin rhythms are robust and relatively easily measured in mammals. Consequently, both body temperature and

plasma melatonin are routinely utilized as indicators of the phase, amplitude, and period of the circadian clock. As such, it is instructive to examine both rhythms.

A. Melatonin

Melatonin, the "hormone of the night," has received much attention over the past few decades. Circulating melatonin levels at night are elevated by about 10-fold relative to during the day. Physiologically, melatonin acts as a humoral signal to provide a highly accurate indicator of night length. In effect, melatonin acts as an endocrine code for photoperiod information. Melatonin can also modulate the endogenous clock and influence a number of physiological functions. It is also thought to be hypnogenic. In certain vertebrates, lengthening or shortening of the nocturnal melatonin signal can alter reproduction, body weight, pelage, and seasonal behavior.

Melatonin is produced from serotonin in two enzymatic steps. Serotonin is first converted to *N*-acetylserotonin by arylalkamine *N*-acetyltransferase (AANAT), which, in turn, is converted to melatonin by hydroxyindole-*O*-methyltransferase (HIOMT). This conversion takes place in the pineal gland and is regulated by β-adrenergic receptor-mediated regulation of AANAT activity. The pineal gland is located in the epithalamus adjacent to the habenular nuclei. Pineal melatonin synthesis is driven by the SCN via a rather elaborate neural pathway. SCN efferents project to cells in the paraventricular nucleus, which in turn send projections to the intermediolateral cell column (IML) of the spinal cord. The IML projects to the superior cervical ganglia cells, which in turn send noradrenergic sympathetic projections to the pineal gland.

In mammals, the synthesis of melatonin is regulated by the SCN. In turn, melatonin can regulate the phase of the clock in a time-of-day-dependent manner via G-protein-coupled melatonin receptors in the SCN. Additional melatonin receptors are located in the pars tuberalis of the adenohypophysis. Melatonin is thought to act via the pars tuberalis to effect changes in gonadotrophin secretion and the reproductive axis. More recently, melatonin receptors have been discovered in the testis, epididymis, vas deferens, prostate, ovary, and mammary glands of various mammals, showing the multiple sites of action on the reproductive system.

Melatonin is a popular output marker for the circadian pacemaker because melatonin production and levels are not influenced by many exogenous factors. In humans, only very bright light and β-adrenergic drugs are known to suppress melatonin production. Notably, the PRC to melatonin for humans is about 12 hr out of phase with the PRC to light. Exogenous melatonin administration thus has been used clinically, both alone and in concert with bright light exposure, to shift circadian rhythms. Appropriate scheduled melatonin administration has also been used to treat circadian sleep and mood disorders, shift-work adaptation, and jet lag.

B. Body Temperature

The daily oscillation of body temperature in mammals constitutes one of the most regular and predictable of mammalian circadian rhythms. Historically, the body temperature rhythm is of unique importance in the circadian field. In addition, the T_b rhythm is also easily measured, coupled to numerous other body rhythms, and stable. Whereas the T_b rhythm integrates many other aspects of physiology, for the most part it is generated endogenously. The overt or expressed rhythm is a complex product of physiological integration among many control systems, including the thermoregulatory, cardiovascular, sleep–wake, and circadian systems. In addition, the endogenous temperature rhythm can be modified by factors such as activity, feeding, ambient temperature, and light. However, in a controlled environment, the T_b rhythm can provide an extremely accurate picture of the underlying clock activity.

The influence of the CTS on body temperature homeostasis is well-documented. The daily rhythm of body temperature is generated by the relative phasing of the heat production and heat loss rhythms in both entrained and free-running subjects. Changes in the ambient temperature produce coordinated and compensatory changes in heat production and heat loss; however, their phase relationships with the T_b rhythm are conserved. As with all circadian rhythms, the temperature rhythm is controlled by a circadian oscillator. Interestingly, this circadian oscillator may reside in another nucleus separate from the SCN. Some studies support the hypothesis that the thermoregulatory system is controlled by two or more circadian oscillators. The concept of multioscillator control of body temperature is old and is derived, in part, from studies in which the body temperature rhythm persisted following SCN lesions. However, other studies of similarly placed lesions have evidenced a highly

attenuated or absent body temperature rhythm. These findings suggest that a second (or more) oscillator would likely be found very close to the SCN, perhaps in the hypothalamic preoptic area or subparaventricular zone.

V. SLEEP–WAKE CYCLES

According to sleep researcher Alan Hobson, "Sleep is characterized by a recumbent posture, a raised threshold to sensory stimulation, decreased motor output and a unique behavior, dreaming." Sleep is, ironically, one of the least well-understood biological phenomena, yet over one third of our lives are spent in this behavioral state. Various hypotheses of sleep function and the functional significance of sleep have been proposed. These hypotheses have led to the development of a variety of sleep theories, each with evidence of varying quality to support it. For example, there is a restorative sleep theory, an energetic sleep theory, a dream and REM theory, a thermoregulatory theory, an immune theory, and a ethological theory. Whereas each theory most likely holds some truth, a unified sleep theory remains elusive.

The specific physiological processes that control sleep–wake behavior are fairly well-characterized. Collectively, these processes interact to promote and inhibit both sleeping and waking. The nature of these interactions has been described in a number of models for human sleep regulation, of which a circadian consolidation model is one of the most widely accepted at this time. In this model, sleep is timed by the CTS to provide a longer period of uninterrupted sleep. A two-process model of sleep regulation also exists that describes the interaction between a homeostatic sleep drive and a circadian rhythm of alertness. Work in sleep regulation has uncovered a role for the SCN in both the timing of the sleep–wake cycle and the regulation of the internal structure of sleep (Fig. 5). When the SCN was ablated in squirrel monkeys, a loss of sleep–wake consolidation was seen. Furthermore, circadian rhythms in sleep–wake, sleep stages, brain temperature, and drinking were eliminated, and total sleep time was significantly increased in SCN-lesioned monkeys. However, total times in deeper stages of non-rapid eye movement (non-REM; e.g., δ sleep) and REM sleep were not significantly affected by SCN lesions. It appears that the circadian timing system promotes waking and alertness while interacting with a homeostatic sleep drive to promote consolidated sleep. In effect, the interaction between the output (amplitude) of the circadian pacemaker and the homeostatic sleep drive is the primary determinant of vigilance and sleep–wake consolidation.

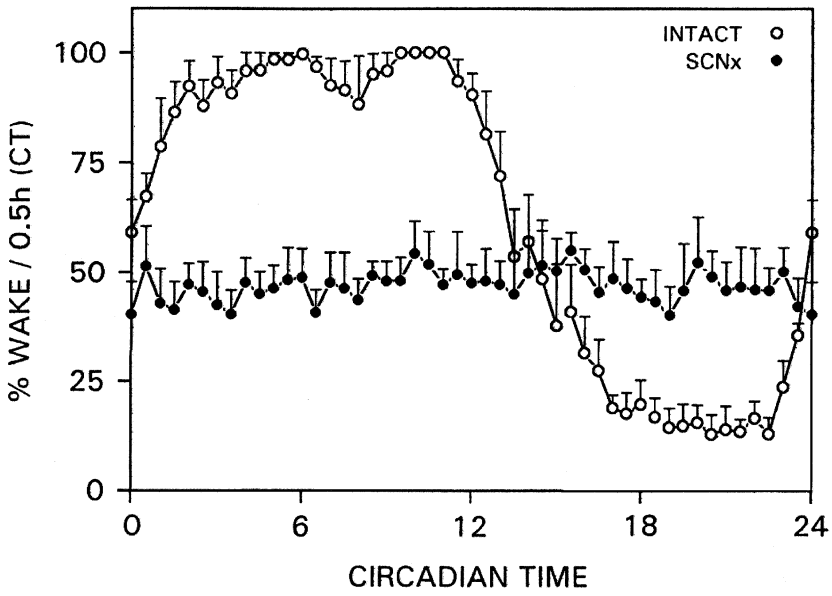

Figure 5 Effects of SCN lesion on sleep–wake behavior in the squirrel monkey. This diurnal nonhuman primate is similar to that of humans in sleep–wake consolidation pattern and sleep architecture. SCN-lesioned monkeys exhibited significantly greater wake and sleep bout counts and a loss of the daily sleep–wake cycle. [Reproduced by permission from Edgar, D. M., Dement, W. C., and Fuller, C. A. (1993). Effect of SCN lesions of sleep in squirrel monkeys: Evidence for opponent processes in sleep–wake regulation. *J. Neurosci.* **13,** 1065–1079.]

The circadian rhythm of sleep and waking is tightly coupled to the circadian rhythm of body temperature. Sleep onset occurs on the descending limb of the body temperature cycle. Notably, studies have shown that human subjects in isolation will enter long sleep episodes only at or near the minimum body temperature. In these studies, entry into sleep was not seen at other circadian phases of body temperature. Experimental paradigms utilizing different photoperiods have allowed investigators to artificially separate the sleep–wake and body temperature rhythms. This process is called forced internal desynchronization and results from the inability of one rhythm, usually that of T_b, to entrain to the LD cycle. This rhythm then becomes free-running, whereas the other remains entrained to external time.

VI. CLINICAL RELEVANCE

A. Circadian Susceptibility

Circadian rhythmicity is a significant source of variation in many important diagnostic variables (Fig. 6). Taking circadian variation into account can only improve the precision and validity of any clinical test. Furthermore, circadian rhythmicity can substantially affect both susceptibility to trauma and toxins and drug effectiveness and toxicity. Examples include cancer chemotherapy, anesthetics and analeptics, corticosteroid therapy, antiasthmatics, cardiovascular medications, antibiotics, and anabolic steroids. From a pharmacological perspective, a circadian variation in therapeutic response and efficacy is of interest. The effectiveness of a drug is largely a function of the rates of absorption, metabolism, excretion, and, finally, target susceptibility. Documented circadian variations in heart rate, acid secretion, glomerular filtration, renal plasma flow, urine production, pH, gastric emptying time, and blood pressure all, to a great extent, determine absorption, metabolism, excretion, and target susceptibility.

It is possible to increase the therapeutic efficacy and minimize the toxic side effects of drug treatments by providing treatment at a certain time of day. One medically relevant disease for chronotherapy is cancer, as many drugs used in chemotherapy affect the mitotic replication of normal and malignant cells. By treating the normal cells at times when DNA synthesis is low, higher levels of chemotherapeutic agents can be tolerated. Conversely, limitation of exposure to chemotherapy drugs during times when DNA synthesis is high can reduce the side effects. Moreover, cancer patients have been receiving adjuvant immunotherapy. Because both the humoral arm and the delayed (cellular) arm of the immune system function in a rhythmic manner, chronodiagnostics and treatments may prove to dramatically increase the efficacy of immunotherapy in cancer treatment. Figure 7A illustrates the effects of cyclophosphamide and 1-β-D-arabinofuranosylcytosine administered to mice previously given injections of L1210 leukemia cells. Mean survival time and cure rate exhibited a marked circadian phase dependency. For example, the cure rate was 94% in mice treated at one circadian phase but only 44% in those treated at another phase.

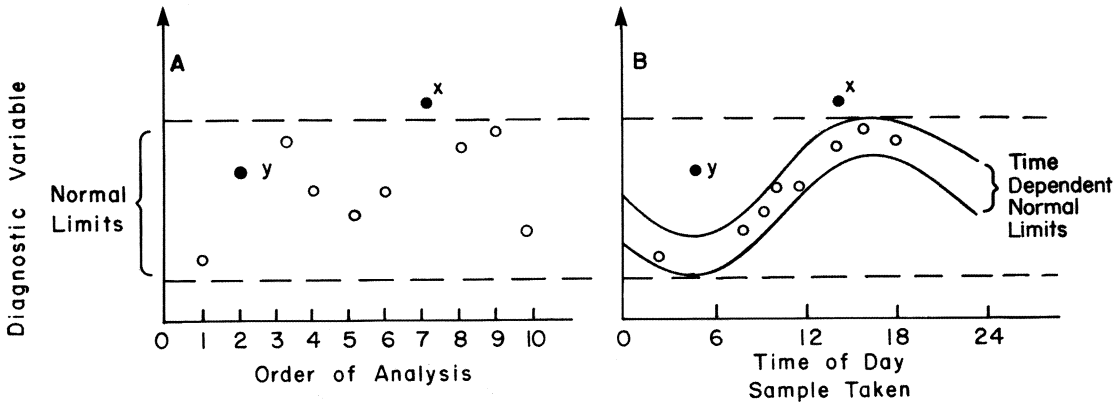

Figure 6 Normal limits for a diagnostically useful variable plotted (A) without and (B) with regard to the time of day. When the time of day is taken into account, the detection of abnormal values is improved, so that not only value *x* but also value *y* can be identified as being outside the normal range. Harvard University Press, Cambridge, MA].

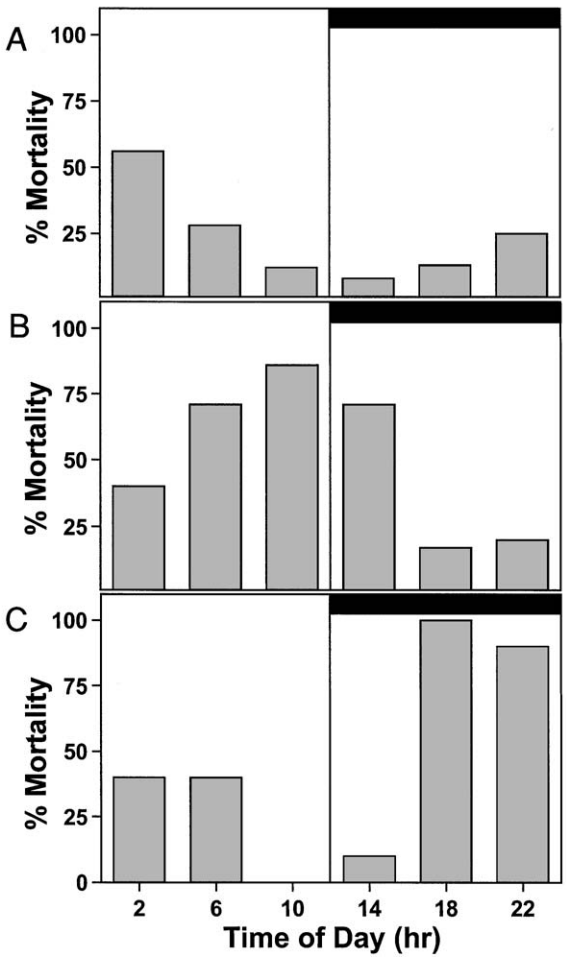

Figure 7 Circadian phase dependency for toxicity and efficacy of exogenous agents. Three different experiments demonstrate the marked circadian variation in the tolerance, susceptibility, and the rate of cure for (A) chemotherapuetic agents, (B) radiation, and (C) bacterial infection. [Modified from Moore-Ede, M. C., Sulzman, F. M., and Fuller, C. A. (1982). *The Clocks That Time Us: Physiology of the Circadian Timing System.* Harvard University Press, Cambridge, MA].

As previously mentioned, circadian variation in susceptibility has been documented for a number of exogenous challenges. Figure 7B illustrates a dramatic example of circadian susceptibility in mice injected with a bacterial endotoxin. Here, over 80% of the mice who received the toxin during the late subjective day died, whereas less than 20% of the mice who received the toxin during the mid-subjective night died. Figure 7C illustrates an even more dramatic example of circadian susceptibility with direct relevance to cancer therapy. In this study, mice were exposed to 550 R of whole-body X irradiation. Strikingly, 8 days after exposure all mice irradiated at the midpoint of the subjective night were dead, whereas all those exposed during the late subjective day were still alive. Similar studies have examined the minimum alveolar concentration (MAC) for effectiveness of inhalant anesthetics. Not surprisingly, both the concentration necessary to achieve an adequate plane of anesthesia and the lethal effects of the same drug vary widely and *predictably* over the 24-hr day. One area of clinical relevance that has not been adequately explored is homeostatic regulatory capacity, which can be severely compromised in conditions without temporal cues (Fig. 8). This condition unfortunately is very similar to the environment experienced by patients in the intensive care units (ICUs) of some hospitals.

The onset and symptoms of pathologies such as myocardial infarction, stroke, acute pulmonary embolism, sudden cardiac death, thoracic aortic rupture, and paroxysmal supraventricular tachycardia all exhibit marked circadian phase dependency. Thus, circadian time is an important parameter to be considered during the diagnosis and treatment of any patient.

B. Circadian Disorders

Disorders of the circadian timing system are more common than previously thought. Circadian dysfunction is thought to be a common contributing factor in both sleep–wake disorders and affective disorders. The etiological bases of most circadian disorders are not known. However, such problems are thought to result from either compromised pacemaker function or faulty signaling to effector systems, or from other factors. Circadian function disorders are often manifest in the elderly, the blind, and individuals with hypothalamic, pituitary, or optic tumors.

Individuals with circadian sleep disorders typically are only symptomatic when forced to conform to a societal schedule. The underlying circadian pacemaker is usually functional but either is unable to entrain or has a deficient capacity for phase delays–advances. The circadian sleep disorders include delayed and advanced sleep phase syndrome and non-24-hr sleep–wake syndrome. Certain forms of sleep–wake disorders such as irregular sleep–wake syndrome are linked to defective pacemaker function.

Shift-work sleep disorder constitutes a significant epidemiological problem. Some 8 million workers in the United States currently work a schedule that requires night, swing or rotating shifts. The night shift sleep–wake schedule is in direct opposition to the

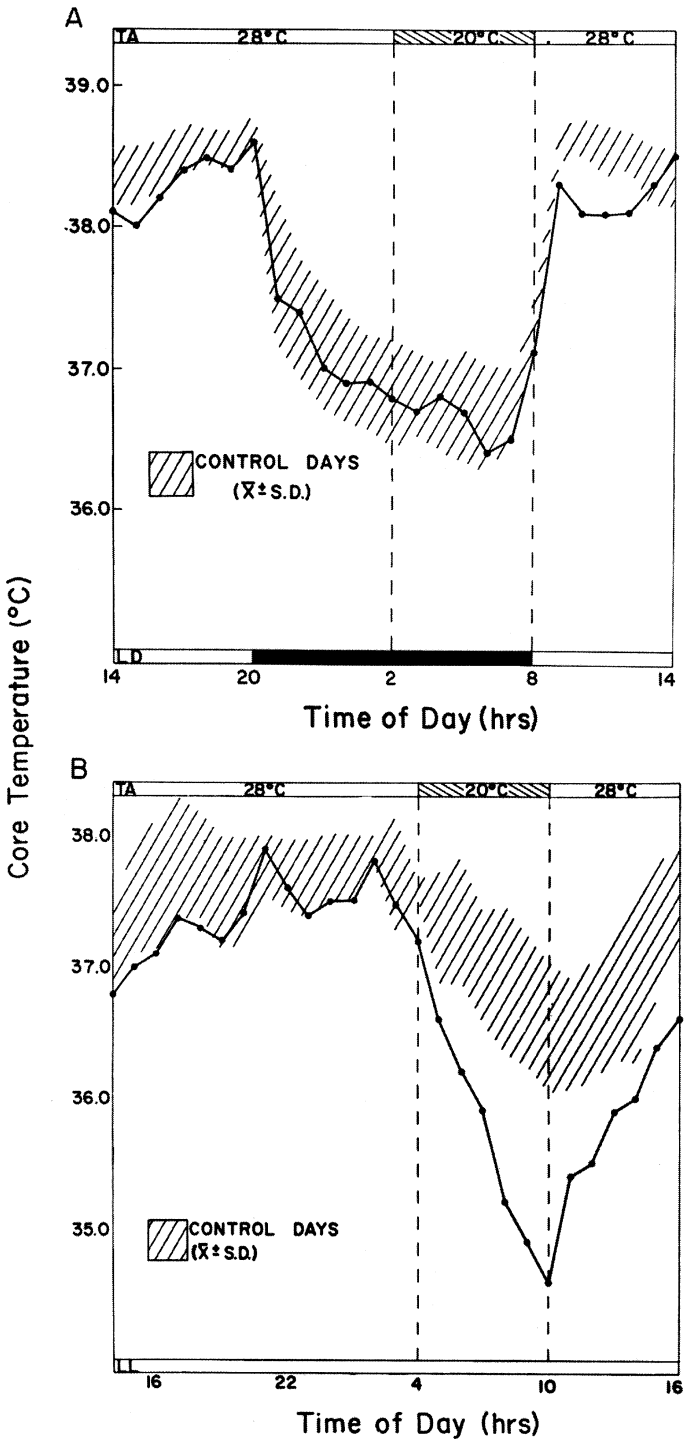

Figure 8 Thermoregulation is impaired in an environment with temporal cues. Effects of 6-hr exposures to cold (20°C ambient temperature) on body temperature in monkeys normally maintained at 28°C when (A) entrained to an LD 12:12 cycle and (B) free-running in constant light (lighting regimen indicated at the base of each graph). The shaded areas show the body temperature rhythm ($x \pm$SD) for the three previous control days, and the solid line is the body temperature on the day of the cold pulse. The cold pulse had virtually no physiological effect in LD but produced a significant fall in core body temperature when the animals were isolated from environmental time cues. [Reproduced by permission from Fuller, C. A., Sulzman, F. M., and Moore-Ede, M. C. (1978). Thermoregulation is impaired in an environment without circadian time cues. *Science* **199,** 794–796.]

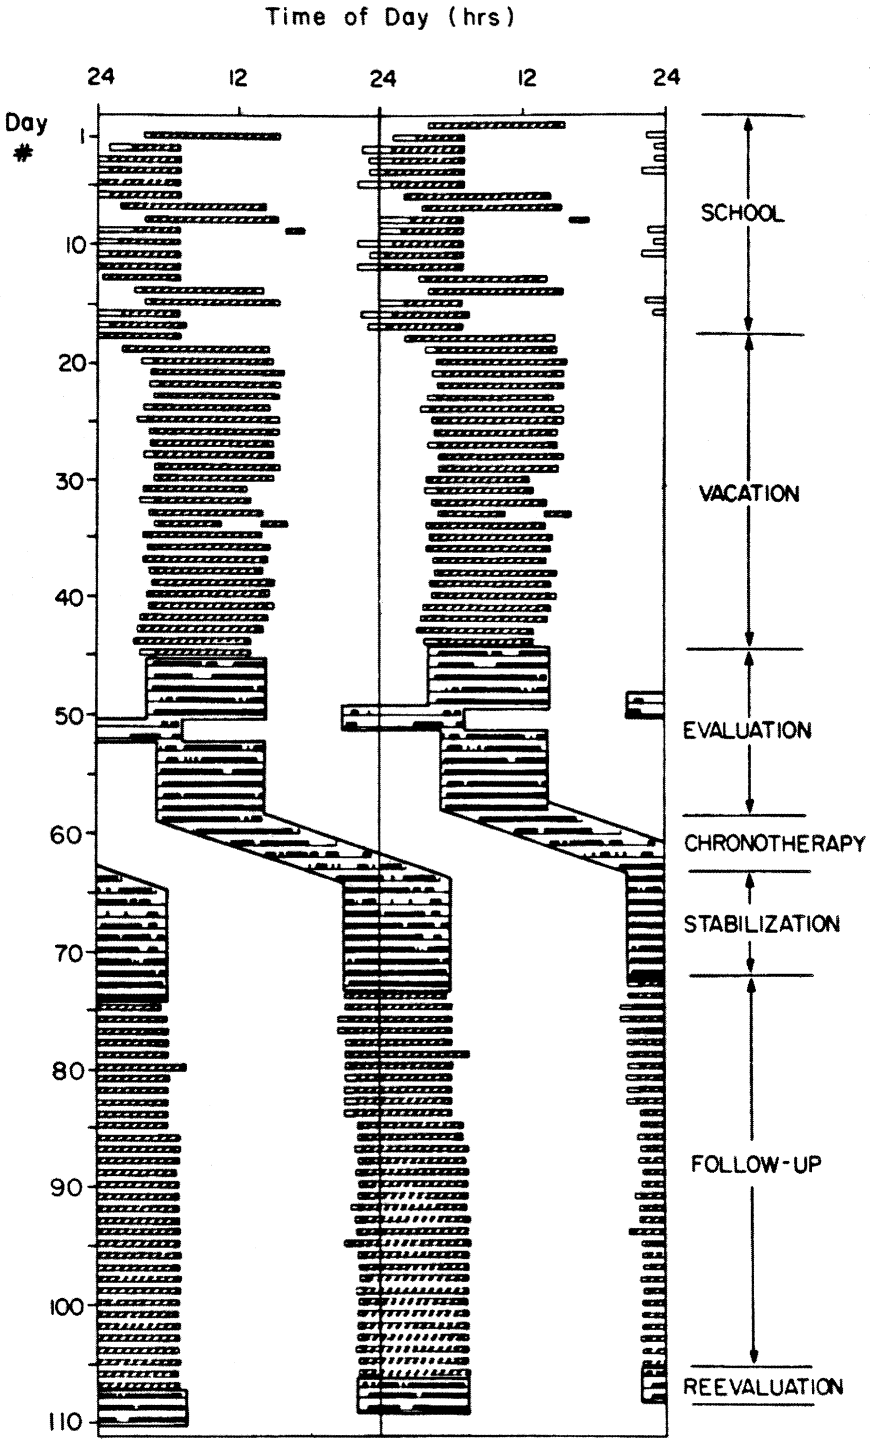

Figure 9 Sleep times as self-reported (striped horizontal bars) and via polygraphic recordings (dark horizontal bars) in an individual with delayed sleep phase insomnia. When attending school 5 days week, days 1–18, she lay awake in bed for several hours (open horizontal bars) before falling asleep but could sleep at a delayed phase with no difficulty on weekends (days 1, 7, 8, 14, and 15) and on vacation (days 19–45). On days 46–59, she was evaluated in the laboratory and on days 51 and 52 was subjected to an acute phase advance, which confirmed her inability to sleep at the desired time (2200–0600 hr). She was treated by chronotherapy on days 58–65 by phase-delaying her bedtime 3 hr each day until the desired phase relationship with the 24-hr clock was obtained. [Reproduced by permission from Moore-Ede, M. C., Sulzman, F. M., and Fuller, C. A. (1982). *The Clocks That Time Us: Physiology of the Circadian Timing System.* Harvard University Press, Cambridge, MA].

sleep–wake schedule dictated by the circadian clock. Similar to jet lag, many workers report insomnia during their off hours and hypersomnolence during their work hours. Consequently, alterness and performance suffer on the job and place the worker at greater risk for sleepiness-related accidents. Most workers also complain of additional symptoms including gastrointestinal discomfort and malaise. It is thought that the extreme work shift schedules of workers are largely responsible for two infamous disasters, the grounding of the oil tanker Exxon Valdez in 1989 and the Chernobyl nuclear plant explosion in 1986. In a similar vein, a 1992 study demonstrated that nurses on shift-work schedules were up to 3 times more likely to misdiagnose and provide improper treatment than their daytime counterparts. Furthermore, a well-documented link exists between shift-work and both gastrointestinal and cardiovascular diseases. Often confounding the treatment of shift-work disorders is the fact that shift-workers tend to implement countermeasures in the form of caffeine, nicotine, alcohol, and sedatives.

Circadian dysfunction is also implicated in a number of affective disorders. One particularly notable example is *winter depression* or seasonal affective disorder (SAD). SAD is characterized by depression, lethargy, loss of libido, hypersomnia, weight gain, carbohydrate cravings, anxiety, and an inability to concentrate and focus. Onset of SAD occurs during the late autumn or winter and occurs 6 months out of phase in the northern and southern hemispheres. SAD patients experience a spontaneous remission in late spring or early summer. SAD is set apart from nonseasonal depression by three atypical symptoms: hyperphagia, carbohydrate craving, and hypersomnia. Bright light therapy has proven extremely effective in ameliorating its symptoms. Administration of a few hours of early morning or evening bright light (>2500 lx) can frequently help to resynchronize biological rhythms. This may be primarily due to the ability of light to entrain the daily melatonin rhythm or to suppress inappropriate daytime melatonin secretion.

Figure 9 demonstrates the efficacy of chronotherapy in an individual suffering from delayed sleep phase insomnia, a common sleep disorder.

C. Aging

The circadian timing system and circadian clock are altered in senescence. Circadian rhythms of body temperature, melatonin, corticosterone, and serum testosterone all show reduced amplitude in old rats. In addition, changes in the intrinsic period and phase angle of entrainment to light–dark cycles have been observed in rhythms of old hamsters. A dramatic age-related decrease in the amplitude of circadian rhythms has also been observed in a number of animal models. Moreover, the effects of age on activity rhythms can be reversed with SCN grafts from young animals. Because mRNA synthesis in mammals has been demonstrated to decrease with age, altered production of clock proteins may contribute to age-related changes. Aging also appears to alter the response to entraining agents such as light. For example, the light-induced increase in the number of c-Fos and JunB immunoreactive SCN cells is significantly attenuated in aged animals. More recently, it has also been suggested that reductions in polysialyted neural cell adhesion molecules on the surface of SCN cells may contribute to the aging-related deficits in circadian function.

VII. SUMMARY

Circadian rhythms touch upon every aspect of human biology. The future of circadian biology will rest heavily on the use of molecular biology techniques to dissect the biological time-keeping processes. For example, we will be able to ask and answer questions such as are circadian disorders and individual variations in period linked to polymorphisms of the clock genes? In addition, advances in circadian biology will allow physicians to develop more efficacious and rational therapies through a greater understanding of temporal variances in sensitivity. Furthermore, an increase our understanding of the "clocks that time us" will aid in the treatment of circadian-related disorders such as depression, sleep–wake disorders, SAD, aging-related circadian problems, and desynchrony (e.g., jet lag).

Classical Conditioning

ROBERT E. CLARK
University of California, San Diego

GLOSSARY

alpha responses Nonassociative responses that follow the presentation of the conditioned stimulus. They are nonassociative in the same way that unconditioned responses are nonassociative in that they are innate reflexes to the presentation of a stimulus. However, unconditioned responses do not show much habituation. In other words, repeated presentations of the unconditioned stimulus will continue to induce unconditioned responses. Alpha responses quickly habituate, which means that after a few presentations of the conditioned stimulus, they no longer occur. Ideally, conditioned stimuli are chosen because they are neutral (i.e., do not initially elicit a response). However, sometimes it is preferable to use a particular conditioned stimulus even if it temporarily results in alpha responses.

amplitude The magnitude of the conditioned response or unconditioned response. For example, in eyeblink conditioning the amplitude is expressed as the distance the eyelid moves in millimeters. Accordingly, a conditioned response of 2 mm has a greater amplitude than a conditioned response of only 1 mm.

conditioned response A learned response that is elicited by the conditioned stimulus.

conditioned stimulus A stimulus that signals the unconditioned stimulus. Initially the conditioned stimulus does not cause a response, but eventually it elicits a conditioned response.

conditioned stimulus-alone test trial A conditioned stimulus-alone test trial is a trial in which the unconditioned stimulus is omitted, leaving only the conditioned stimulus presentation. Conditioned stimulus-alone test trials are sometimes used because the presentation of the unconditioned stimulus and subsequent unconditioned response can obscure or mask the conditioned response.

extinction training Extinction training can be presented following the acquisition of the conditioned response. Conditioned responses are formed by pairing a conditioned stimulus and an unconditioned stimulus. During extinction training only the conditioned stimulus is presented (i.e., the unconditioned stimulus is omitted). Extinction training will gradually result in the disappearance of the conditioned response. This is referred to as extinction "training" because the conditioned response is not forgotten but inhibited. In other words, extinction is an active process. Evidence that extinction training is different from forgetting comes from paired conditioned stimulus and unconditioned stimulus trials. This results in the rapid reinstatement of the conditioned response. The reinstatement occurs much more rapidly than the original acquisition of the conditioned

response. Therefore, the conditioned response is not forgotten but, rather, inhibited.

interstimulus interval Sometimes called the conditioned stimulus–unconditioned stimulus interval, the interstimulus interval is the amount of time between the onset of the conditioned stimulus and the onset of the unconditioned stimulus.

intertrial interval A classical conditioning trial begins with the onset of the conditioned stimulus and ends with the offset of the unconditioned stimulus. The intertrial interval is the amount of time between each individual trial and is usually an average amount of time. The exact time between trials is usually varied within a restricted range in order to prevent ''time'' from becoming a conditioned stimulus as it is in temporal conditioning.

latency The amount of time between one event and another event. For example, the latency of the conditioned response is the amount of time between the onset of the conditioned stimulus and the onset of the conditioned response. The latency of the unconditioned response is the time between the onset of the unconditioned stimulus and the onset of the unconditioned response.

pseudoconditioning Classical conditioning results in conditioned responses when an association forms between the conditioned stimulus and the unconditioned stimulus. However, sometimes responses that appear to be conditioned responses, in that they follow the presentation of a conditioned stimulus, result from experience with the unconditioned stimulus only and not because of an association between the conditioned stimulus and the unconditioned stimulus. This is known as pseudoconditioning.

spontaneous recovery Spontaneous recovery is related to the process of extinction. Extinction training will result in the disappearance of the conditioned response. However, when the subject is given further extinction training following a break, the conditioned response will initially reemerge or spontaneously recover. Continued extinction training will more quickly result in the disappearance of the conditioned response until spontaneous recovery no longer occurs.

unconditioned response An innate response that is elicited by the unconditioned stimulus.

unconditioned stimulus A stimulus that is signaled by the conditioned stimulus. The unconditioned stimulus always elicits an unconditioned response.

unconditioned stimulus-alone test trial In unconditioned stimulus-alone test trials, the conditioned stimulus is omitted, leaving only the unconditioned stimulus presentation. In many classical conditioning experiments, the amplitude of the unconditioned response is an important measure (e.g., as a test to evaluate if a manipulation such as a brain lesion affects the ability of the subject to make a completely normal response). However, in a subject that is emitting conditioned responses, it is not possible to obtain an accurate measure of the unconditioned response amplitude because of contamination from the presence of conditioned responses. Unconditioned stimulus-alone test trials allow an uncontaminated measure of unconditioned response amplitude in subjects that are emitting conditioned responses.

Classical conditioning is a basic form of associative learning in which the organism learns something about the causal fabric of the environment or, in an experimental setting, the relationship of stimuli. Stimuli can be arranged so that one stimulus provides the organism with information concerning the occurrence of another stimulus. This type of associative learning is most commonly referred to as classical conditioning, but it has also been termed Pavlovian conditioning, respondent conditioning, and conditioned reflex type I conditioning, or type S conditioning.

I. INTRODUCTION

In the most basic form of classical conditioning, the stimulus that predicts the occurrence of another stimulus is termed the conditioned stimulus (CS). The predicted stimulus is termed the unconditioned stimulus (US). The CS is a relatively neutral stimulus that can be detected by the organism but does not initially induce a reliable behavioral response. The US is a stimulus that can reliably induce a measurable response from the first presentation. The response that is elicited by the presentation of the US is termed the unconditioned response (UR). The term ''unconditioned'' is used to indicate that the response is ''not learned'' but, rather, it is an innate or reflexive response to the US. With repeated presentations of the CS followed by US (referred to as paired training) the CS begins to elicit a conditioned response (CR). Here, the term ''conditioned'' is used to indicate that the response is ''learned.''

The most well-known example of classical conditioning comes from the pioneering work of Ivan Pavlov (1849–1936) and his dogs. In this prototypical example, a bell (in reality the CS was usually a metronome or buzzer) is rung just before meat powder is placed on the dog's tongue. The meat powder causes the dog to salivate. Therefore, the meat powder acts as the US, and the salivation caused by the meat powder is the UR. Initially, the ringing bell, which serves as the CS, does not cause any salivation. With repeated pairings of the ringing bell CS and the meat powder US, the ringing bell CS causes the salivation to occur before the presentation of the meat powder US or even if the meat powder not presented. The salivation in response to the presentation of the ringing bell CS is the learned or conditioned response.

II. BRIEF HISTORY

In 1904, Ivan Pavlov was awarded the Nobel prize in medicine for his pioneering work on the physiology of

digestion. Pavlov primarily studied the process of digestion in dogs. This early research set the stage for the discovery of a learning process that would come to be known as classical conditioning. As early as 1880, Pavlov observed that sham feedings, in which food was eaten but failed to reach the stomach (being lost through a surgically implanted esophageal fistula), produced gastric secretions, just like real food did. He immediately understood that this phenomenon must involve the central nervous system and began a program to thoroughly evaluate the parametric features of this learned response.

Pavlov modified his preparation in order to simplify the forthcoming studies. Rather than measure gastric secretions, he began measuring salivation. The first of these studies involved showing the dog a piece of bread as the CS. Pavlov then noticed that in dogs with extensive training, even the act of an experimenter walking into a room could elicit salivation. This finding led to the discovery that a variety of stimuli could induce salivation if paired with meat powder. Accordingly, in a further simplification of his experimental procedures he began using the sound of a bell presented with the meat powder to elicit salivation. It is this preparation that has become synonymous with Pavlov and historical examples of classical conditioning. In fact, Pavlov has become synonymous with classical conditioning because the term Pavlovian conditioning can be used interchangeably with classical conditioning.

Initially, Pavlov referred to the conditioned response as a ''psychic secretion'' to distinguish this type of response from the unlearned physiological secretions that would later come to be known as the unconditioned response. In 1903, a student of Pavlov's published a paper that changed the term psychic secretion to conditioned reflex. The terms conditioned reflex and unconditioned reflex were used during the first two decades of the 20th century, during which time this type of learning was often referred to as ''reflexology.''

Although Pavlov is correctly credited with the discovery of classical conditioning, and with identifying and describing almost all the basic phenomena associated with this form of conditioning, it is worth noting that the phenomenon of classical conditioning was independently discovered by an American graduate student in 1902. Edwin B. Twitmyer made this discovery while finishing his dissertation work on the ''knee-jerk'' reflex. When the Patellar tendon is lightly tapped with a doctor's hammer, it results in the well-known knee-jerk reflex. Twitmyer's work required many tap-induced reflexes for each subject. Twitmyer, like Pavlov, noticed that eventually the mere sight of the doctor's hammer (the CS) could produce a knee-jerk reflex (the CR). This largely forgotten report was the first example of classical conditioning of a muscle reflex. The potential significance of this finding was not apparent to Twitmyer, and the work was never extended or cast in a theoretical framework as Pavlov had done.

Pavlov's work on classical conditioning was essentially unknown in the United States until 1906 when his lecture ''The Scientific Investigation of the Psychical Faculties or Processes in the Higher Animals'' was published in the journal *Science*. In 1909, Robert Yerkes, who would later become president of the American Psychological Association, and Sergius Morgulis published a thorough review of the methods and results obtained by Pavlov. Although these reports provided a true flavor of the potential value of classical conditioning, the method was not immediately embraced by psychologists. This changed when John B. Watson, who is widely regarded as the founder of a branch of psychology known as behaviorism, championed the use of classical conditioning as a research tool for psychological investigations. Watson's presidential address delivered in 1915 to the American Psychological Association was titled ''The Place of the Conditioned Reflex in Psychology.'' Watson was highly influential in the rapid incorporation of classical conditioning, as well as other forms of conditioning, into American psychology. In 1920, his work with classical conditioning culminated in the now infamous case of ''little Albert.''

Albert B. was an 11-month-old boy who had no natural fear of white rats. Watson and Rosalie Rayner used the white rat as a CS. The US was a loud noise that always upset the child. By pairing the white rat and the loud noise, Albert began to cry and show fear of the white rat—a CR. With successive training sessions over the course of several months, Watson and Rayner were able to demonstrate that this fear of white rats generalized to other furry objects. The plan had been to then systemically remove this fear using methods that Pavlov had shown would eliminate or extinguish the CR—in this case, fear of furry white objects. Unfortunately, little Albert, as he as historically come to be known, was removed from the study by his mother on the day these procedures were to begin. There is no known reliable account of how this experiment on classical conditioning of fear ultimately affected Albert B. Nevertheless, this example of classical conditioning may be the

most famous single case in the literature on classical conditioning.

In 1921, a popular textbook on conditioning changed the terms of conditioned and unconditioned reflex to the current terms of conditioned and unconditioned response. This broadened the concept of conditioning to include other behaviors that were not merely automatic reflexes. In 1927, the Anrep (a former student of Pavlov's) translation of Pavlov's *Conditioned Reflexes* was published, thus making all of his work available in English for the first time. The availability of 25 years worth of Pavlov's research, in vivid detail, led to increased interest in the experimental examination of classical conditioning—an interest that has continued to this day.

III. THE DISTINCTION BETWEEN CLASSICAL AND INSTRUMENTAL/OPERANT CONDITIONING

In classical conditioning, no contingency exists between the CR and the presentation or omission of the US. In other words, it does not matter if a CR is made or not; the presentation of the US still occurs and is experienced and processed by the subject. This has been termed stimulus-contingent reinforcement or the law of contiguity. In instrumental conditioning, in contrast, a contingent relationship is arranged between the subject's response and the presentation or nonpresentation of a reinforcer. In other words, instrumental conditioning involves response-contingent reinforcement or the law of effect.

The simplest forms of learning are known as nonassociative learning. Examples of nonassociative learning include habituation (a decrease in a response to repeated presentations of a stimulus) and sensitization (an increase in a response to repeated presentation of a stimulus). Associative learning is a more complex form of learning. Classical conditioning and instrumental conditioning are both examples of associative learning. In classical conditioning, an association is made between two stimuli, the CS and US. This association is manifested by the occurrence of a conditioned response. In instrumental conditioning, an association is made between a stimulus and the outcome of a response. In other words, the organism learns what responses are reinforced given a particular stimulus. Although classical conditioning and instrumental conditioning are both examples of associative learning, classical conditioning is generally viewed as the simpler form of learning. There are many reasons for considering classical condition to be a simpler form of learning. For example, classical conditioning has been demonstrated in organisms that are very low on the phylogenetic scale, such as planaria, slugs, and leeches. Second, the ability to be classically conditioned appears earlier ontogenetically than the ability to be instrumental conditioned. Successful classical conditioning has been reported for chick embryos, neonatal monkeys, goats, and dogs as well as human fetuses *in utero*.

IV. ORIGIN OF THE TERM CLASSICAL CONDITIONING

Often, it is possible to precisely identify the time and reason a new scientific term is introduced. Generally, this is possible because the author of the new term describes the reasons for introducing the term and justifies why the particular term was chosen. For example, the term instrumental conditioning was coined by Clark L. Hull to describe the type of learning in which the subject is "instrumental" in obtaining reinforcement. That is, the animal is the instrument, as in maze learning. Operant conditioning was chosen by B. F. Skinner because the subject must perform a behavioral "operation" to obtain reinforcement. In other words, the animal operates on a manipulandum in the environment, such as pressing a bar to obtain food. However, unlike instrumental and operant conditioning, there does not appear to be an instance in which a single individual coined the term classical conditioning. Therefore, only an inference can be made concerning the origin of the term classical conditioning.

Only in the most rare cases do authors comment on the origin of the term classical conditioning. Often in these cases, the term is inaccurately attributed to John B. Watson. This is understandable because Watson was largely responsible for publicizing the classical conditioning method and outlining how it could be used as a method of scientific investigation. However, Watson never actually used the term classical conditioning, instead referring to it as simply the "conditioned reflex." His 1930 edition of *Behaviorism* was his last significant scientific publication, and although the process of classical conditioning is referenced extensively, the term was never used.

Before the 1940s, the process of classical conditioning was referred to most often as the conditioned reflex, Pavlovian conditioning, or simply conditioning.

However, in the 1930s, scientists began to understand that the laws governing learning, in paradigms in which reinforcement was contingent on the organism's behavior, appeared to be fundamentally different from the laws governing the conditioned reflex. The latter type of learning would come be known as instrumental or operant conditioning. This created a need to distinguish these different forms of conditioning. It is my contention that the term classical conditioning developed as a contraction of the descriptive phase "classical Pavlovian conditioning" that was used to denote the "well-known" (i.e., classical) type of conditioning used by Pavlov (i.e., Pavlovian).

V. TYPES OF CLASSICAL CONDITIONING

Classical conditioning is a generic term that can refer to a variety of different types of classical conditioning procedures and paradigms. Two different parameters can distinguish the type of classical conditioning: (i) the temporal arrangement and spacing of the CS and the US and (ii) the type of response that is measured and conditioned. Some general comments regarding the influence that different types of conditioning have on behavior can be made, but it is impossible to make any specific comments regarding conditioning. The specifics depend on the response system being measured, the nature of the stimuli being used, and the species being conditioned.

A. Temporal Arrangement and Spacing of the CS and the US

The relationship of the CS and the US can be arranged in different ways to produce different conditioning paradigms. These arrangements can greatly influence how the CR develops. Figure 1 illustrates the major classical conditioning paradigms. The upward movement of a line represents the onset of a stimulus, and the downward movement of a line represents the offset of a stimulus.

1. Simultaneous Conditioning

In simultaneous conditioning the CS and the US are presented simultaneously. In this case, because the US always elicits a UR and the CS and US are presented together, it is not possible to determine if CRs are present. In order to determine if a CR has developed, a CS-alone trial must be presented (i.e., the US is omitted). If the CS elicits a response on the CS-alone trial, this response is a CR. This form of conditioning is not commonly used, and it generally yields only weak conditioning, if any at all.

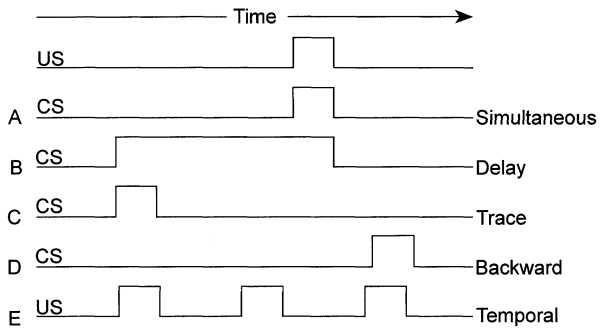

Figure 1 Temporal arrangements of the CS and the US (top trace) used in five classical conditioning paradigms. The upward movement of a line represents the onset of a stimulus, and the downward movement of a line represents the offset of a stimulus. A, simultaneous conditioning; B, delay conditioning; C, trace conditioning; D, backward conditioning; E, temporal conditioning. In the case of temporal conditioning, there is no discrete CS. The interval of time between the USs serves as the CS.

2. Delay Conditioning

In delay conditioning, the CS onset precedes the US onset. The termination of the CS occurs with the US onset, during the US, at the termination of the US, or at some point after the US. This paradigm is called delay conditioning because the onset of the US is delayed relative to the onset of the CS. Generally, responses that develop to the CS and occur before the onset of the US are CRs. This is the most common conditioning paradigm and generally results in the most robust and rapid conditioning.

3. Trace Conditioning

In trace conditioning, the CS is presented and terminated before the onset of the US. The interval separating the CS offset and the US onset is called the trace interval. This paradigm was named trace conditioning by Pavlov because in order for conditioning to occur, the subject (i.e., the subject's brain) must maintain a memory "trace" of the CS. Responses that develop in response to the CS and occur before the onset of the US are CRs. This form of conditioning is

also common and yields good conditioning but generally not as readily as delay conditioning.

4. Backward Conditioning

In the backward conditioning paradigm, the US is presented and terminated prior to the CS. A CR is a response that follows the presentation of the CS. This form of conditioning is not commonly used and in most circumstances does not result in conditioning. However, in some situations backward conditioning can occur.

5. Temporal Conditioning

In temporal conditioning there are no discrete CSs. Instead, the US is presented at regular intervals, and over time the CR will be exhibited just prior to the onset of the US. In this case, the CS is the time interval. Temporal conditioning is possible in some experimental paradigms, but in most classical conditioning paradigms it does not result in conditioning.

6. Differential Conditioning

In differential conditioning, two CSs are used. One of the CSs always precedes and predicts the US. This CS is termed the positive CS or the CS^+. The other CS is not predictive of the US and occurs alone. This CS is termed the negative CS or the CS^-. Differential conditioning is indicated by a greater number of CRs in response to the CS^+ than to the CS^-.

7. Controls for Pseudoconditioning

Classical conditioning results in CRs when an association forms between the CS and the US. However, sometimes responses that appear to be CRs, in that they follow the presentation of a CS, result from experience with US only and not because of an association between the CS and the US. This is known as pseudoconditioning. For example, if a very intense US is presented (e.g., a strong shock), the organism might respond to any subsequent stimulus presentation. The response does not occur because of an association between the CS and the US but, rather, because the US sensitizes the subject, making it more likely to respond to any stimulus presentation. To test for the possibility of pseudoconditioning, the CS and the US can be arranged so that the CS does not predict the US. This is known as unpaired training. There are two basic forms of unpaired training. Explicitly unpaired training is used to describe a situation in which the CS and the US never coincide. Random unpaired training is used to describe a situation in which the CS and the US rarely coincide but occasionally (i.e., by chance) do so. Random unpaired training is generally thought to be superior to explicitly unpaired training because during explicitly unpaired training the animal learns that the CS signals a safety period (i.e., the US will not occur).

Because the CS and the US are never paired, an association between them cannot be made. If responses nevertheless follow the presentation of the CS, it can be concluded that pseudoconditioning has occurred and not classical conditioning. If unpaired presentations do not result in responses to the CS, then any responses that subsequently develop in response to the CS, after paired training is begun, can be considered true CRs.

B. Types of Classical Conditioning Based on the Measured Response

In addition to the conditioning paradigms discussed previously, different types of classical conditioning can be characterized by the measured response. For example, in Pavlov's experiments, he measured salivation, whereas in Twitmyer's experiments, he measured the knee-jerk response. Although both of these basic experiments are examples of classical conditioning, they involve different response systems.

1. Two Fundamental Response Classes

The nervous system can be divided into the central nervous system (CNS) and the peripheral nervous system (PNS). The CNS consists of all the neural tissue that is encased in bone (i.e., the brain and spinal cord). The CNS is discussed later. Because this section focuses on responses, the PNS will be discussed. In order for a response to occur, the PNS must be engaged (excluding responses of neurons that can be recorded from the CNS). The PNS can be divided into the autonomic nervous system and the somatic nervous system. The autonomic nervous system controls the viscera, and the somatic nervous system controls muscles.

a. Autonomic Classical Conditioning Autonomic classical conditioning refers to any classical conditioning paradigm in which the measured response is under

the control of the autonomic nervous system. The autonomic nervous system consists of two divisions, the sympathetic nervous system and the parasympathetic nervous systems. These two systems work together, in opposing directions, to control bodily functions such as heart rate, breathing, dilation and constriction of the pupil, and the control of sweat glands. These systems are not generally under voluntary control but can be modified by classical conditioning. Autonomic conditioning has been used extensively because in addition to involving primarily involuntary responses, autonomic responses can also be used as an index of changes in emotion. Autonomic conditioning is sometimes referred to as conditioned emotional responses because changes in emotion are accompanied by changes in these autonomic measures. For example, many of these measures are also used in polygraph/lie-detection work. The following is a brief overview of the most common types of autonomic conditioning studies.

i. *Galvanic Skin Response/Skin Conductance Response Conditioning* This response is measured by the change in skin resistance to an electrical current. Research using this response measure dates back to the 1880s. For most of this time, the response was termed the Galvanic skin response (GSR) in honor of Luigi Galvani (1737–1798), an early pioneer in research describing the electrical nature of the body. Today, descriptive terms are commonly used, such as the electrodermal response or the skin conductance response (SCR). This response is measured by passing a small amount of electrical current between two electrodes pasted to the skin. The conductance (the reciprocal of resistance) between the two electrodes is measured. Many different stimuli can induce a SCR. For example, a mild shock, or any new stimulus of sufficient intensity as to attract the attention of the subject, can cause an autonomic response in which sweat glands pump extra sweat into sweat ducts located in the skin. The net effect of this action is an increase in skin conductance (i.e., a skin conductance response). In conditioning experiments in which, for example, a tone CS is paired with a shock or loud noise US, an association is made between the CS and the US and the CS begins to elicit a classically conditioned SCR.

ii. *Heart Rate Conditioning* Another common autonomic conditioning paradigm is the classically conditioned heart rate response. In this paradigm the change in heart rate (i.e., heartbeats per minute) is measured with electrodes pasted on the chest. For example, a tone CS can be paired with a mild shock US. Initially, the CS does not cause a change in the heart rate, but the shock will increase the heart rate. With continued pairing of the CS and the US, the CS will elicit a CR—a change in heart rate. Interestingly, the CR in this case is change in heart rate to the CS, but the direction of change (i.e., slower or faster) depends on the animal species being testing. For example, the CR with human subjects is an increase in heart rate, which is called conditioned tachycardia (heart rate increasing). However, the CR with, for example, rabbits, is a decrease in heart rate, which is called conditioned bradycardia (heart rate slowing).

iii. *Other Examples* Another example of autonomic classical conditioning is the conditioned pupillary response, which is a conditioned change in the size of the pupil. This response was first conditioned in 1922, but today it is rarely used because it is a difficult response to condition and to measure, and it is subject to a great deal of noise (i.e., spontaneous responses that are unrelated to the CS or the US). As noted previously, salivary conditioning was used by Pavlov in the initial demonstration of classical conditioning and this response was adapted for work with humans by Karl Lashley (1890–1958). Today, this paradigm is almost never used because salivation is a relatively slow response, difficult to measure, and difficult to condition in humans.

b. Somatic Classical Conditioning Somatic classical conditioning refers to any classical conditioning paradigm in which the measured response is under the control of the somatic nervous system. The somatic nervous system as it relates to classical conditioning controls striate or skeletal muscles. Accordingly, any response that requires a motor movement must be controlled by striate muscles and the somatic nervous system. The following is a brief overview of the most common types of somatic conditioning paradigms.

i. *Eyeblink Classical Conditioning* Eyeblink classical conditioning is by far the most common form of experimental conditioning paradigm with both humans and experimental animals. As early as 1922, eyeblink classical conditioning paradigms were being used. In eyeblink conditioning a CS (typically a tone or light) is paired with a US (e.g., a mild shock or puff of air to the eye). Eyeblink studies have been carried out in a variety of species, including humans, monkeys, rabbits, cats, rats, and mice. The response can be

measured with a minitorque potentiometer. A string is attached to the eyelid and any eyelid movement changes the resistance in the potentiometer, which can then be recorded. Electromyographic (EMG) measures can also be used to record the activity of the muscles controlling the eyeblink. Today, the most common method of measuring eyeblink responses in humans is the use of an infrared reflective sensor. In this method, an infrared beam is directed at the eye (usually mounted in goggles) and the amount of light reflected by the eyelid is recorded. Eyeblinks change the amount of light that is reflected and subsequently detected by an infrared sensor.

ii. *Nictitating Membrane Classical Conditioning* Closely related to eyeblink conditioning, conditioning of the nictitating membrane (NM) is the most frequently used response measure in rabbits, which are the most frequently used experimental subjects for conditioning studies. The NM is often called the "third eyelid" and it consists of a sheet of cartilage located behind the inner canthus of the eye. When the eyeball is stimulated, the eyeball retracts into the eye socket. This causes the NM to passively sweep across a portion of the eyeball. The NM response is popular because it is simple to measure (usually with a minitorque potentiometer) and because the NM cannot completely cover the eye. Thus, it prevents the subject from avoiding the airpuff US (the eyelids are prevented from closing by the experimenter during NM conditioning).

iii. *Leg Flexion Classical Conditioning* In the typical leg flexion experiment, an animal is usually restrained so that the legs hang freely, although it has also been used in freely moving subjects. A CS is paired with a mild shock US to the leg, which causes the leg to flex. With pairing of the CS and the US, a CR develops where the leg flexes in response to the CS. The response can be measured by a minitorque potentiometer or EMG.

iv. *Fear Classical Conditioning* Classical conditioning has been increasingly used to study the learning of fear. This paradigm can be considered a hybrid of autonomic and somatic classical conditioning because fear causes numerous autonomic changes, which could be measured as the CR. However, in the rat, the most common subject for studies of this type, fear can also be measured with the somatic response of freezing. In the typical paradigm, a tone CS is paired with a shock US. The shock US is delivered to the rat through an electrified floor grid. With pairing of the CS and the US, a fear CR develops in response to the CS. In this case, the fear CR is freezing (the rat holds completely still).

VI. ACQUISITION OF THE CR

As noted previously, the specifics regarding any aspect of classical conditioning must be reserved for the particular type of classical conditioning paradigm, the response that is measured, and the species that is used. However, some general features can be noted regarding the acquisition of the CR. The most fundamental element of classical conditioning is the association of the CS and the US that results in the acquisition of the CR. During the initial presentation of the CS and the US, no response to the CS is observed. With continued pairing of the CS and the US (i.e., presentation of additional training trials), CRs begin to develop in response to the CS. This development of the CR is referred to as the acquisition of the CR. It is often referred to as an increasing probability of CRs. In other words, with continued training, the probability of a CR on a given trial increases. In some conditioning paradigms (such as classical conditioning of the NM response in rabbits) this probability can approach 0.99 (i.e., CRs on almost every trial). During the early phases of CR acquisition, CRs are generally small-amplitude responses that gradually (over the course of training) grow larger until they become as large as the UR. The latency of the CR also tends to change during CR acquisition. Initially, the latency of the CR onset begins just before the onset of the US. With continued training the latency decreases so that the onset of the CR begins well before the onset of the US. Finally, the CR is acquired to the extent that the maximum amplitude of the CR (the CR peak) occurs at the time of the US onset. This is sometimes referred to as a "well-timed" CR.

A. Factors That Can Influence the Acquisition of the CR

1. Interstimulus Interval

Every type of conditioning paradigm has an optimal interstimulus interval (ISI). The optimal ISI depends on the particular paradigm, but it is clear that ISIs that are very short or very long and result in little or no CR acquisition. For example, in the rabbit classically conditioned NM response paradigm, the optimal ISI

for delay conditioning is 250 msec. An ISI of 100 msec or less results in poor conditioning, as does increasing the ISI to longer than 250 msec. In this paradigm, an ISI of 2000 msec (i.e., 2 sec) will not result in any CR acquisition.

2. Intertrial Interval

It is a general finding from many conditioning paradigms that increasing the ITI will tend to produce more rapid CR acquisition, although this influence is not robust in most cases. Reducing the ITI to less than several seconds can drastically impair acquisition of the CR. The typical ITI ranges from 30 to 60 sec.

3. Temporal Arrangement and Spacing of the CS and the US

As noted previously, delay conditioning generally results in the most rapid rate of CR acquisition followed by trace conditioning. Simultaneous conditioning generally results in much poorer CR acquisition. In many cases simultaneous conditioning (ISI=0) does not produce CRs. Backward conditioning results in CRs in only a few paradigms and generally does not produce any CR acquisition.

4. CS Intensity

It was initially believed that the CS intensity did not influence that rate of CR acquisition, but recent studies indicate that more intense CSs tend to result in slightly more rapid CR acquisition.

5. US Intensity

An increase in the acquisition rate of the CR has been a consistent finding with increases in the intensity of the US.

VII. EYEBLINK CLASSICAL CONDITIONING IN HUMANS

It was previously noted that different types of classical conditioning paradigms can be distinguished on the basis of the measures response. By the early 1930s, successful classical conditioning had been reported in 23 different response systems (e.g., eyeblink response, skin conductance response, pupillary response, leg flexion response, and salivary response). Of these numerous preparations, the majority were explored for only short periods before being, for the most part, abandoned for one reason or another. For example, the salivary preparation in humans or other experimental animals never flourished because of many methodological difficulties.

Classical conditioning of the skin conductance response has had a long history dating back to the late 19th century. However, skin conductance conditioning failed to flourish in the 1930s–1950s because the physiological basis of the response was poorly understood and difficult to measure accurately with the equipment of the day. A renewed interest occurred in the 1960s due to a better understanding of the physiology of the response and better and more readily available equipment for measuring and quantifying the response. Today, this paradigm still enjoys some popularity with researchers studying cognitive factors of classical conditioning and the neural mechanism underlying conditioned emotional responses.

By the 1940s the human eyeblink classical conditioning paradigm had surpassed all other conditioning paradigms in terms of number of articles published primarily because it was methodologically superior to all other classical conditioning paradigms. From the 1940s through the 1960s, studies of human eyeblink conditioning remained the dominant paradigm for studying the processes and variables that related to classical conditioning. During this time, methodological improvements that included precise measurement of the eyeblink response allowed investigators to explore the effects of such variables as the intertrial interval, interstimulus interval, CS intensity, US intensity, and variable reinforcement schedules. Additionally, cognitive factors were also extensively explored. For example, subjects were asked about the information they acquired during the conditioning session. This information was then compared to how well the subjects acquired the CR. Other studies explored how instruction sets affected CR acquisition rates: that is, how different verbal instructions given to subjects before conditioning affected CR acquisition rates.

VIII. PROBLEMS FOR STUDIES OF HUMAN EYEBLINK CLASSICAL CONDITIONING

In all forms of classical conditioning, the responses are considered primarily reflexive in nature. For example, the UR is an innate, automatic, ''reflexive'' reaction to

the puff of air that is delivered to the eye. With repeated pairing of a CS and a US a learned, conditioned response develops. This response is also thought to be reflexive and, as such, should not require cognitive involvement. Nevertheless, although an eyeblink response can be involuntary, clearly the eyeblink response can also be brought under voluntary control. If individuals become aware of the fact that the CS predicts the US, they are in a position to voluntarily blink their eyes to avoid the airpuff (i.e., blink on purpose). This circumstance has caused concern among experimentalists because it has been argued, at least since the 1940s, that the processes and characteristics of responses that are voluntary are very different from those that are involuntary or reflexive. That is, classical conditioning measures involuntary, automatic responses, not purposeful behavior. Therefore, some means of identifying voluntary responses needed to be developed so that they could either be discarded as contaminants or analyzed separately.

Two criteria emerged for identifying voluntary responses. The first was based on the slope of the response. Voluntary responses were believed to be more rapid and thus to have a characteristically steeper slope than a true CR. The second was based on response latency. Voluntary responses were believed to have a short onset latency (which also involved a steep slope), and eye closure was maintained until the onset of the US. Despite these improvements, there is no consensus about the most appropriate methods for detecting voluntary responses. In fact, the only large-scale study to test the validity of these two criteria (slope and latency) found that neither was fully satisfactory for discriminating voluntary responses from conditioned responses.

By the 1960s, studies of human eyeblink classical conditioning began to wane. This gradual decrease in human eyeblink classical conditioning research was likely due to a combination of at least two factors. First, researchers were never completely successful in identifying and dealing with the issue of voluntary vs conditioned responding. Second, researchers never reached a consensus on what the "standard" conditions should be for conditioning studies. Various laboratories used different CS and US intensities, different ISIs and ITIs, and different criterion for determining if responses were CRs. Consequently, there were persistent problems with obtaining reproducible results between different laboratories, which essentially prevented progress in exploring interesting variables.

IX. THE EMERGENCE OF ANIMAL STUDIES OF CLASSICAL CONDITIONING

Although human eyeblink classical conditioning studies began a steep decline in the 1960s, classical conditioning studies using animals showed rapid growth. This was in part likely due to at least two factors. First, some experimentalists moved from human conditioning research to working with animals, which served to stimulate the field of animal work. Second, although problematic, the human research on classical conditioning nevertheless revealed the potential of classical conditioning to serve as a paradigm for the systematic and thorough analysis of associative learning if it could be appropriately exploited. What was needed was the development of a "model" paradigm of classical conditioning in which all the basic features (e.g., CS and US types and intensities, measurement of the responses, and ISIs and ITIs) would be held consistent across laboratories. A model paradigm must result in robust acquisition of the CR, which is reliable across laboratories. This would allow theoretical questions about learning and memory to be addressed. Additionally, these methods must be economical and relatively easy to implement, and the characteristics of the learned response must not be unique to the experimental circumstances or to the species being tested.

In the early 1960s, Isidore Gormezano and colleagues developed a paradigm in which classical conditioning of the NM response was used with rabbits. The NM is vestigial in humans but is quite pronounced in the rabbit. It consists of a sheet of cartilage located behind the inner canthus of the eye. When the eyeball is stimulated, it retracts into the eye socket. This causes the NM to passively sweep across a portion of the eyeball. This movement is the measured response. The NM response was chosen because it is simple to measure (usually with a minitorque potentiometer) and because the NM cannot completely cover the eye. In this preparation, the rabbit's eyelids are held open with clips to prevent the subject from completely closing its eyelids and avoiding an airpuff US. Because the rabbit cannot avoid the airpuff US, the response cannot be an instrumental response but remains squarely within the domain of classical conditioning.

This paradigm remains the model classical conditioning paradigm. It has endured because it has simply proven to be an ideal paradigm. The result is that the processes and factors that influence the acquisition of the CR are now understood in detail. These details

allow learning theories to be constructed. This model system then allows the hypotheses that are derived from these theories to be rigorously tested and interpreted against an immense background of empirical data. In this respect, the importance of classical conditioning to modern learning theory cannot be overestimated.

X. EYEBLINK CLASSICAL CONDITION AS A TOOL TO STUDY BRAIN FUNCTION

In his preface to the Russian edition of his 1927 book *Conditioned Reflexes*, Ivan Pavlov wrote "At [this] time [I am] am convinced that this method of research [classical conditioning] is destined, in the hands of other workers, and with new modifications in the mode of experimentation, to play a yet more considerable part in the study of the physiology of the nervous system." Pavlov's statement can be viewed not only as prophetic but also as in fact quite understated. Until the past 25 years, Pavlov's enthusiasm for classical conditioning as a method of studying brain function had not been shared by physiologists. As a research procedure, classical conditioning had been almost the exclusive property of psychologists. However, beginning in the mid-1970s, classical conditioning became one of the most important tools for relating learning to specific brain structures.

XI. THE SEARCH FOR THE ENGRAM

The term engram is a hypothetical construct used to represent the physical processes and changes that constitute memory in the brain, and the search for the engram is the attempt to locate and identify that memory. Karl Lashley was perhaps the first person to clearly conceptualize the issue in a framework that would lend itself to experimental analysis. Lashley's primary interest was in localizing the engram to a specific region of the brain—an endeavor that would prove to be extraordinarily difficult and ultimately end in failure for Lashley. A likely reason why Lashley and others have historically had such great difficulty in locating an engram is because the behavior they typically used was an operant form of conditioning—a relatively complex form of associative learning. To make localization more tractable a simpler behavior was needed. Classical conditioning of the NM response in rabbits proved to be the solution.

For many reasons, Classical conditioning is a valuable tool for studying the physical processes of the brain that may be important for forming and storing memory. The presentation of the CS and the US is determined by the experimenter, not by the subject's behavior. This has important implications for the analysis of stimulus selection, which can be precisely manipulated by the experimenter. However, of greater importance is the fact that the CR is time locked to the CS. This allows a temporal analysis of neural events and then correlation of electrophysiological recordings with changes in the CR. The conditioning procedures provide a more adequate control for nonspecific effects of training on biological processes than do operant procedures. For example, the same kind of density of stimulation and number of unconditioned responses can be produced in both experimental and control conditions. Perhaps the greatest advantage is that the effects of experimental manipulations on "learning" rather than "performance" can be easily evaluated. This problem of learning versus performance has plagued the study of brain substrates of learning from the beginning. For example, does a brain lesion impair a learned behavior because it damages the memory trace or because it impairs the animal's ability to respond? This problem can be circumvented by simply comparing the amplitude of the learned or conditioned response to the reflex or unconditioned response amplitude. If the lesion abolishes the CR (the learned response) but leaves the UR (the ability to respond) intact, then it can be concluded that the lesion has impaired learning rather than performance.

The use of the classically conditioned NM response in rabbits offers additional advantages for studying the neural correlates of the learned behavior. Rabbits are docile animals that do not find full-body restraint aversive. They will usually sit quietly for more than 2 hr with little or no struggling. Rabbits also have a very low spontaneous blink rate, which reduces the amount of contamination caused by blinks that are unrelated to the CS and the US. The parametric features of the CR have been well characterized. The behavioral NM response is robust and discrete and the exact amplitude–time course of the response is easily measurable. The CR is acquired, at least to a significant degree, in a single training session, but not all at once. This allows for an analysis of brain substrates over a period of time as learning is proceeding (as opposed to one-trial learning or some operant tasks, which show a rapidly accelerating acquisition curve). The presentation of the CS and the US does not yield sensitization or

pseudoconditioning. That is, unpaired presentations of the CS and the US do not increase the ability of the CS to elicit a response; they also do not increase the spontaneous blink rate. These are the primary reasons that led Richard F. Thompson and associates to choose this paradigm to continue the search for the elusive engram.

Conceptually, to search for an engram, a neural circuit must be identified. No single neurobiological method or technique is sufficient in and of itself to define the characteristics of a neural circuit, including the essential site of plasticity. Therefore, numerous methods must be used to determine the roles that different brain structures play in any learned behavior. To date, the most fruitful methods have been electrophysiological recordings, permanent and reversible lesions, and electrical microstimulation of various nuclei and fiber tracts. These methods are used in combination with classical conditioning and with the assumption that there are neural pathways connecting the CS, the US, and the UR pathways. It is also assumed that it is possible to localize a specific brain region where some essential modification takes place to drive the conditioned response. All these methods have been used successfully in defining the circuit for classical eyeblink conditioning.

XII. THE BRAIN SUBSTRATES OF THE CLASSICALLY CONDITIONED NM RESPONSE IN THE RABBIT

Since the early 1970s, Thompson and many others have used a variety of methods to search for the classically conditioned NM response engram. A neuronal circuit diagram has been systematically constructed during the course of 20 years to represent all the brain structures that are essential for the acquisition and retention of the classically conditioned NM response for the delay conditioning paradigm. This circuit is the most thoroughly investigated and completely understood learning and memory circuit known for the mammalian brain. The essential site of plasticity (i.e., the location of the engram) appears to be the interpositus nucleus of the cerebellum, although the cerebellar cortex is also important.

A. Components of the Circuit

Figure 2 is a neuronal circuit diagram that represents all the brain components that are essential for the acquisition and retention of the CR.

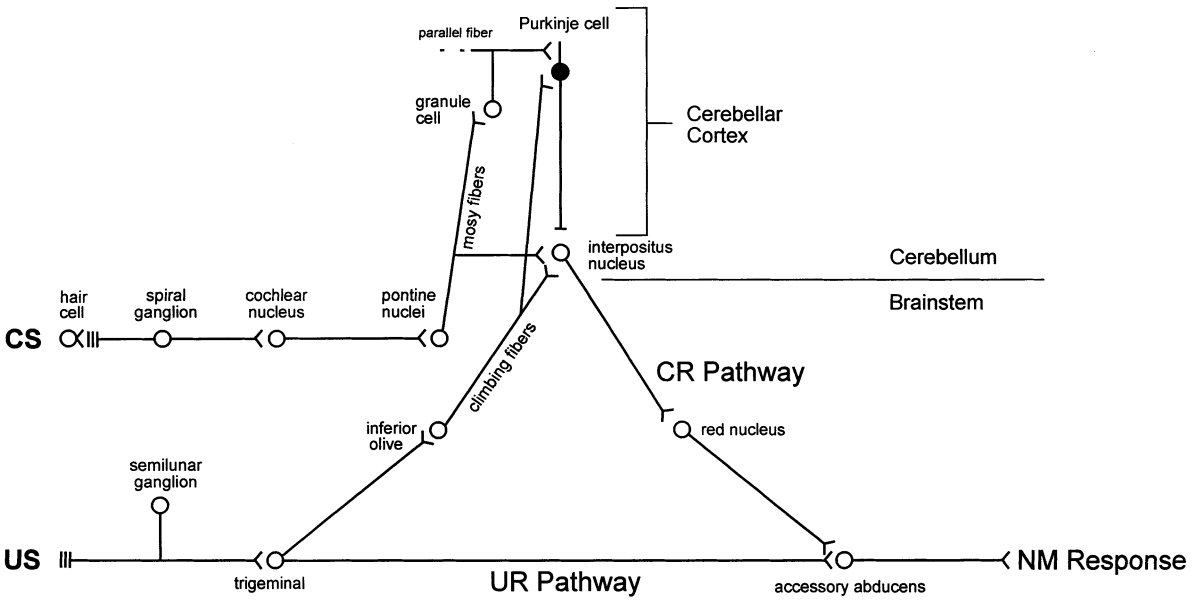

Figure 2 The cerebellar neural circuit for delay eyeblink/nictitating membrane (NM) classical conditioning. The focus of this diagram is on the relationships between the conditioned stimulus (tone CS), unconditioned stimulus (airpuff US), conditioned response (CR), unconditioned response (UR), and their connecting fiber pathways. The cerebellar cortex in the diagram consists of granule cells, parallel fibers, and Purkinje cells. Cerebellar structures in the diagram include the cerebellar cortex and interpositus nucleus. All other structures depicted are located in the brain stem. Pairing of the CS and US results in an essential plastic change in the interpositus nucleus that results in the generation of the CR.

1. The CS Pathway

The tone CS is detected by auditory hair cells, which stimulate spiral ganglion cells. These cells project to the cochlear nucleus, which then projects to the lateral pontine nuclei. The lateral pontine nuclei send mossy fibers to both interpositus nucleus and granule cells in the cerebellar cortex.

2. The US Pathway

The airpuff US is detected by similunar ganglion cells that send somatosensory information to the spinal trigeminal nucleus. This nucleus projects to the dorsal accessory olive. The olive sends climbing fibers to both the interpositus and the cerebellar cortex.

3. The UR Pathway

The sensory trigeminal projects to the abducens, accessory abducens, and facial motor nucleus, which are the motor nuclei that drive the eyeblink and NM response.

4. The CR Pathway

The interpositus nucleus, which receives convergent information concerning the CS and the US, projects to the red nucleus. The red nucleus then projects to the same motor nuclei that drive the eyeblink and NM response (i.e., the abducens, accessory abducens, and facial motor nucleus).

5. Circuit Philosophy and Function

Figure 2 focuses on the relationships of the CS, US, CR, and UR pathways rather than emphasizing the physical position of the nuclei and tracts within the brain. Initially, in a naive subject, the CS does not cause a NM response. The US stimulates the trigeminal nucleus, which then projects to motor nuclei to cause the reflexive UR from the first trial on. During training the interpositus nucleus receives convergent CS and US information. Eventually, this convergent information causes a change (i.e., learning) in the interpositus nucleus and cerebellar cortex. This change enables the CS information to activate the interpositus, which can then activate the red nucleus. The red nucleus then activates the motor nuclei, which then drive the NM response. This response occurs before the delivery of the airpuff US. This is the conditioned response.

B. Brain Structures That Are Critical for Classical Conditioning of the NM Response

1. Interpositus Nucleus

The interpositus nucleus receives convergent CS and US information from the pontine nuclei (CS information) and the inferior olive (US information). The plastic changes that occur in the interpositus as a result of this convergent information are responsible for the CR. The interpositus is considered to be the prime location of the classically conditioned NM response engram. Damage to the interpositus nucleus completely and permanently abolishes the CR without affecting the UR.

2. Cerebellar Cortex

The cerebellar cortex also receives convergent CS and US information. The output of the cerebellar cortex goes through the interpositus nucleus. It has been suggested that the cerebellar cortex might form and store the essential plasticity for the engram and that interpositus lesions only block the expression of the CR. However, large lesions of the cerebellar cortex do not abolish the CR or prevent the acquisition of the CR. The cerebellar cortex likely plays a critical modulatory role in the acquisition and expression of the CR.

3. Pontine Nuclei

The pontine nuclei receive information about the tone CS and relay this information to the interpositus nucleus and cerebellar cortex. Rabbits can be classically conditioning by electrically stimulating the pontine nuclei in place of a tone CS and pairing the stimulation with an airpuff US.

4. Inferior Olive

The inferior olive receives US information from the trigeminal nucleus located in the brain stem. The inferior olive then relays this information to the interpositus and cerebellar cortex. Rabbits can be classically conditioned by electrically stimulating the inferior olive in place of an airpuff US. Pairing a tone CS with inferior olive stimulation as the US results in the development of CRs. In fact, rabbits can be conditioned without tones or airpuffs by stimulating the pontine nuclei as the CS and the inferior olive as the US. In well-trained rabbits (i.e., rabbits showing CRs),

lesions of the inferior olive result in a gradual extinction of the CR as if the US has been removed, even though the US is still being presented. This indicates that the inferior olive sends critical US information to the interpositus and cerebellar cortex.

5. Red Nucleus

The red nucleus is a critical structure in the CR pathway. It receives input from the interpositus, which is outputting a neural signal for driving the CR. The red nucleus then relays this signal to motor nuclei for driving the learned NM response. Lesions of the red nucleus abolish the conditioned response. It is known, however, that the red nucleus is not responsible for forming the CR because reversibly inactivating the red nucleus during training prevents the expression of the CR but does not prevent the acquisition of the CR. When the lesion is reversed (i.e., restored to normal function), CRs rapidly appear. In contrast, when the interpositus is inactivated, there is no acquisition of the CR.

6. Trigeminal Nucleus

The trigeminal nucleus receives information regarding the occurrence of the US. It then sends this information to the interpositus and cerebellar cortex (via the inferior olive) so that an association between the CS and the US can be accomplished. It also sends the US signal to the motor nuclei for driving the UR.

7. Accessory Abducens

The accessory abducens is the motor nucleus that drives the NM response. It receives information from the trigeminal nucleus for driving the UR and information from the red nucleus for driving the CR.

XIII. THE HIPPOCAMPUS IS REQUIRED FOR TRACE CLASSICAL NM CONDITIONING

The circuit just described includes all the brain structures required for the successful acquisition and retention of the CR in the delay classical conditioning paradigm. For example, in a well-trained animal, all the neural tissue above the level of the midbrain can be completely removed without affecting the retention and expression of the CR. In other words, removing the entire neocortex, thalamus, basal ganglia, and limbic system, including the hippocampus, has no effect on the CR.

For trace classical conditioning, these structures are also essential; however, the hippocampus is also required. If an interval of at least 500 msec separates the offset of the CS and the onset of the US, hippocampal lesions prevent CR acquisition and retention.

XIV. THE AMYGDALA IS ESSENTIAL FOR THE ACQUISITION AND RETENTION OF THE CLASSICALLY CONDITIONED FEAR RESPONSE

Although amygdala lesions do not affect the acquisition or retention of eyeblink/NM classical conditioning, the amygdala is essential for the acquisition and retention of the classical conditioned fear response. For example, in rats, when a tone CS is paired with a shock US several times, a conditioned fear response develops. In other words, after pairing the CS will cause a fear response of freezing. The rat that has been conditioned will hold completely still when the CS is presented. Amygdala lesions completely prevent rats from learning or retaining this fear response. Thus, classical condition has revealed that the amygdala is a critical brain structure for emotional fear learning.

XV. BRAIN STRUCTURES INVOLVED IN HUMAN CLASSICAL CONDITIONING

Although studies of classical conditioning in humans began to wane in the 1960s, particularly for eyeblink classical conditioning, within the past 10 years there has been a resurgence of experimental work that can largely be attributed to the success of classical conditioning as a tool to study brain function in the experimental animal. Currently, our understanding of how different human brain structures contribute to classical condition lags far behind what is known in the animal and will likely never approach the level of precision that is possible with animal studies. Nevertheless, there has recently been much progress with relating classical conditioning to brain function in humans.

Recent findings from human studies have been remarkably consistent with previous work with animal studies of conditioning. For example, work in rats has convincingly demonstrated the importance of the amygdala in fear classical conditioning. Studies using

brain imagining methods such as positron emission tomography (PET) and functional magnetic resonance image (fMRI) have shown that fear classical conditioning activates the amygdala. Additionally, humans with bilateral degeneration of the amygdala, as a result of Urbach–Wiethe disease, show an impaired ability to acquire fear classical conditioning.

Results from human studies of eyeblink classical conditioning have also been remarkably consistent with those of studies in rabbits. For example, work with rabbits clearly indicates that the cerebellum is critical for acquisition of delay classical conditioning. Humans with cerebellar damage are also severely impaired on eyeblink classical conditioning. Humans with bilateral hippocampal damage due to anoxia are normal at acquiring CRs in the delay classical conditioning paradigm, but they are impaired when tested on trace classical conditioning. These results are entirely consistent with the animal work. Imagining studies using PET and fMRI have also consistently identified the cerebellum and hippocampus as being activated during classical conditioning of the eyeblink response.

In addition to supporting previous work in animals, human eyeblink conditioning studies have also extended our understanding of brain function in several interesting ways. For example, it has been reported that the knowledge that humans sometime acquire about the stimulus contingencies of the conditioning experiment (e.g., the CS predicts the US) is an important variable for trace conditioning but irrelevant or superfluous for delay eyeblink conditioning. Humans with hippocampal damage fail to acquire this knowledge and accordingly fail to acquire trace conditioning while being unaffected on delay conditioning.

It has repeatedly been reported that subjects with Alzheimer's disease and those with probable Alzheimer's disease are impaired on delay classical conditioning of the eyeblink response. At first, this finding did not appear to be congruent with the animal work because Alzheimer's disease does not affect the cerebellum or other brain stem structures that are critical for delay conditioning. However, work in rabbits has shown that although the hippocampus can be removed without affecting acquisition in the delay paradigm, disrupting the hippocampus by inactivating the cholinergic input to the hippocampus can disrupt delay conditioning. Alzheimer's disease disrupts the septohippocampal cholinergic system and it is this disruption that likely causes the impairment in delay eyeblink conditioning. If fact, this classical conditioning paradigm is so sensitive to the early effects of Alzheimer's disease that, it has been proposed as a simple neuropsychological test for Alzheimer's. Finally, humans with autism, a developmental disorder characterized by severe impairments in communication and social relating and by ritualistic and repetitive patterns of behavior, also show abnormalities in the cerebellum. Subjects with autism also show abnormal acquisition and extinction of the CR. This finding further supports the involvement of the cerebellum in classical eyeblink conditioning.

Cognitive Aging

NAFTALI RAZ
Wayne State University

GLOSSARY

Alzheimer's disease (AD) An age-related degenerative condition that is associated with excessive deposits of amyloid in the neurons, formation of plaques and tangles, and eventual demise of large swaths of brain tissue. As a rule, AD starts in the hippocampus and the enthorhinal cortex and gradually progresses to engulf the whole cerebral cortex. The cognitive expression of AD is dementia characterized by significant difficulties in delayed recall of information, spatial and temporal disorientation, and progressive language difficulties.

association cortex Regions of the cerebral cortex that are cytoarchitechtonically different from the sensory cortices and perform no modality-specific functions.

basal ganglia A group of subcortical nuclei extensively connected among themselves as well as with the cerebral cortex and the midbrain nuclei. The group includes the caudate nucleus, the putamen, the globus pallidus, the subthalamic nucleus, and nucleus accumbens. Sometimes referred to as the extrapyramidal motor system.

excitotoxicity A chain of biochemical and electrophysiological events that accompanies release of an excitatory neurotransmitter glutamate. Excessive release of glutamate results in the demise of the neurons in which it occurs. Excitotoxicity is believed to be the cause of cerebral damage in hypoxic and ischemic episodes and stroke.

executive functions The term "executive" is amorphous and ill defined. It encompasses a broad range of cognitive skills, such as monitoring one's recent and past performance, generating future goals, inhibiting prepotent overlearned responses, and switching behavioral patterns in response to feedback.

explicit memory A mnemonic activity that relies on effortful conscious processes. It can be considerably improved by an increase in environmental contextual support, additional elaboration of material, and reduction in uncertainty in the target stimuli. It responds negatively to an increase in attentional load. The major subtypes of explicit memory are episodic and semantic. Episodic memory refers to encoding and retrieval of information about personally experienced past events and observed objects, locations, and actions. Semantic memory represents hierarchically organized knowledge about past events common to many individuals, concepts, rules, and scripts.

implicit memory A mnemonic activity that involves retention of information without conscious awareness. Implicit memory can be inferred only from changes in performance rather than from an individual's direct report. A type of implicit memory called repetition priming occurs when a past experience, such as exposure to a stimulus, increases the likelihood of selecting this stimulus beyond the statistically expected level. Implicit memory is insensitive to distraction and cannot be improved by elaboration of encoding procedures.

ischemia The temporary or permanent interruption or significant reduction of blood supply to an organ (e.g., brain). In the brain, it is accompanied by deprivation of delivery of oxygen and glucose to neural tissue. It sets in motion a chain of biochemical events that result in necrosis of living tissue.

magnetic resonance imaging A neuroimaging technique based on recording the response of protons in the living tissue to radiofrequency waves in a strong magnetic field. By converting the values of proton relaxation in circumscribed regions of the brain into grayscale values, an anatomically faithful picture of the brain is created, thus allowing *in vivo* observation of the cerebral structures in intact humans. A variant of this technique, called functional magnetic resonance imaging, is based on measuring changes of blood oxygenation in time (a hemodynamic response) that can be triggered by an externally presented stimuli. By time-locking stimuli to the hemodynamic response sampling, brain response to specified cognitive and perceptual demands can be studies.

neurotransmitter A messenger between two neurons and a substance that is synthesized in the body of a neuron, transported to the presynaptic membrane, released into the synaptic cleft, and

delivered to the postsynaptic terminal where its molecules attach to the molecules of a receptor, thus delivering information between the two neurons. Neurotransmitters that play an important role in aging and age-related pathology include dopamine and norepinephrine (catecholamines), glutamate, and acetylcholine.

positron-emission tomography An imaging technique based on computerized reconstruction of localized brain activity inferred from decay of highly volatile radioactive probe material attached to one of the major fuels of the neurons (oxygen and glucose) or to a specific pharmaceutical ligand that binds to a receptor.

primary cortex A region in the cerebral cortex that contains neurons receiving projections from the periphery of a given sensory system (sensory cortex) or sending projection to the peripheral systems of neurons regulating the effectors (motor cortex).Within primary sensory cortices a high degree of segregation of processing (by retinal location, sound frequency, or skin patch) is observed.

procedural memory Retention of a learned skill (mental, perceptual, or motor) acquired after practice. It is independent of explicit or declarative understanding and recollection of the performed activity and of the acquisition process.

receptor A protein embedded in the membrane of a neuron. The ionotropic receptor forms a fluid-filled pore (ion channel) that allows a regulated flow of ions across the membrane. The metabotropic receptor opens ion channels indirectly through a chain of intracellular messengers. The stereochemical configuration of the receptor and the neurotransmitter determines the likelihood of binding between the former and the latter.

working memory An ability to process information while maintaining intermediate products, goals, and associated strategies of processing online.

Aging is a fundamental biological process with far-reaching cognitive consequences. Deeply rooted in the genetic makeup and metabolic workings of the organism, but sensitive to fluctuations of biological and social environment, aging brings with it complex changes in the workings of the mind. Although multiple age-related changes in brain and cognition have been described in detail, their mechanisms are still poorly understood.

I. INTRODUCTION

After decades of diligent cataloguing of neural and behavioral properties of the aging organisms, the stage is set for a union of neuroscience and cognitive psychology aimed at understanding the relationships between aging brain and cognitive performance. Although a promise of cognitive neuroscience looms large in the minds of the students of cognitive aging, its emergence created a flux of ideas and generated empirical findings that compel us to revise ostensibly well-set concepts and theories on almost a daily basis. Thus, the following article, by necessity, is a snapshot of a powerful stream in its exciting but ill-defined turbulence rather than a detailed picture of a stationary entity.

As often happens in science, the advent of new measurement techniques and invention of new instruments provided an impetus for the current neural revolution in cognitive science in general and cognitive gerontology in particular. In the past two or three decades, with the help of magnetic resonance imaging (MRI), previously inaccessible *terra incognita* of the human brain has been clearly visualized *in vivo* with relatively high anatomical precision ($<1\ mm^3$). Metabolic workings of the brain and local changes in cerebral blood flow can be gauged by positron emission tomography (PET) and functional MRI (fMRI).

II. THE AGING BRAIN

The studies of brain and cognition reveal that in both domains, age-related changes are differential as well as generalized. The results of postmortem and *in vivo* investigations of the human brain demonstrate that although advanced age is associated with reduced total brain weight, nonspecific sulcal expansion, ventricular enlargement (Fig. 1), and a decline in global brain

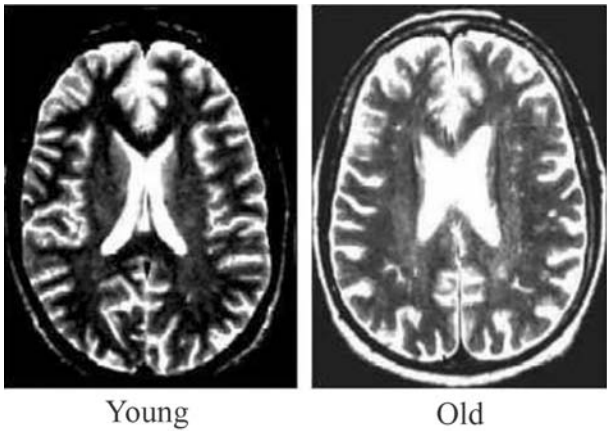

Figure 1 Examples of brain aging as seen on MR images (a 23-year-old female and a 77-year-old female). The images represent a cross section of the brain in a horizontal plane. The parameters used to acquire these images emphasize changes in brain water state and content, thus highlighting the spaces surrounding blood vessels and the cerebral sulci and ventricles filled with cerebrospinal fluid. In this type of MR scan, fluid appears white and myelinated fibers are at the darkest end of the gray scale. Note enlarged ventricles, widened sulci, and the presence of subcortical white matter hyperintensities in the aging brain.

blood flow, the greatest negative impact of aging is evidenced by the prefrontal cortex (PFC) and the neostriatum (Figs. 2A and 2B). Age-related changes in the hippocampus (Fig. 2C) are also significant, although some of them may be attributed to the early signs of age-related pathology and are more prevalent in the oldest old. The cerebellum and the primary sensory cortices show only mild age-related decline, and the lower brain regions such as the ventral pons appear insensitive to the impact of senescence.

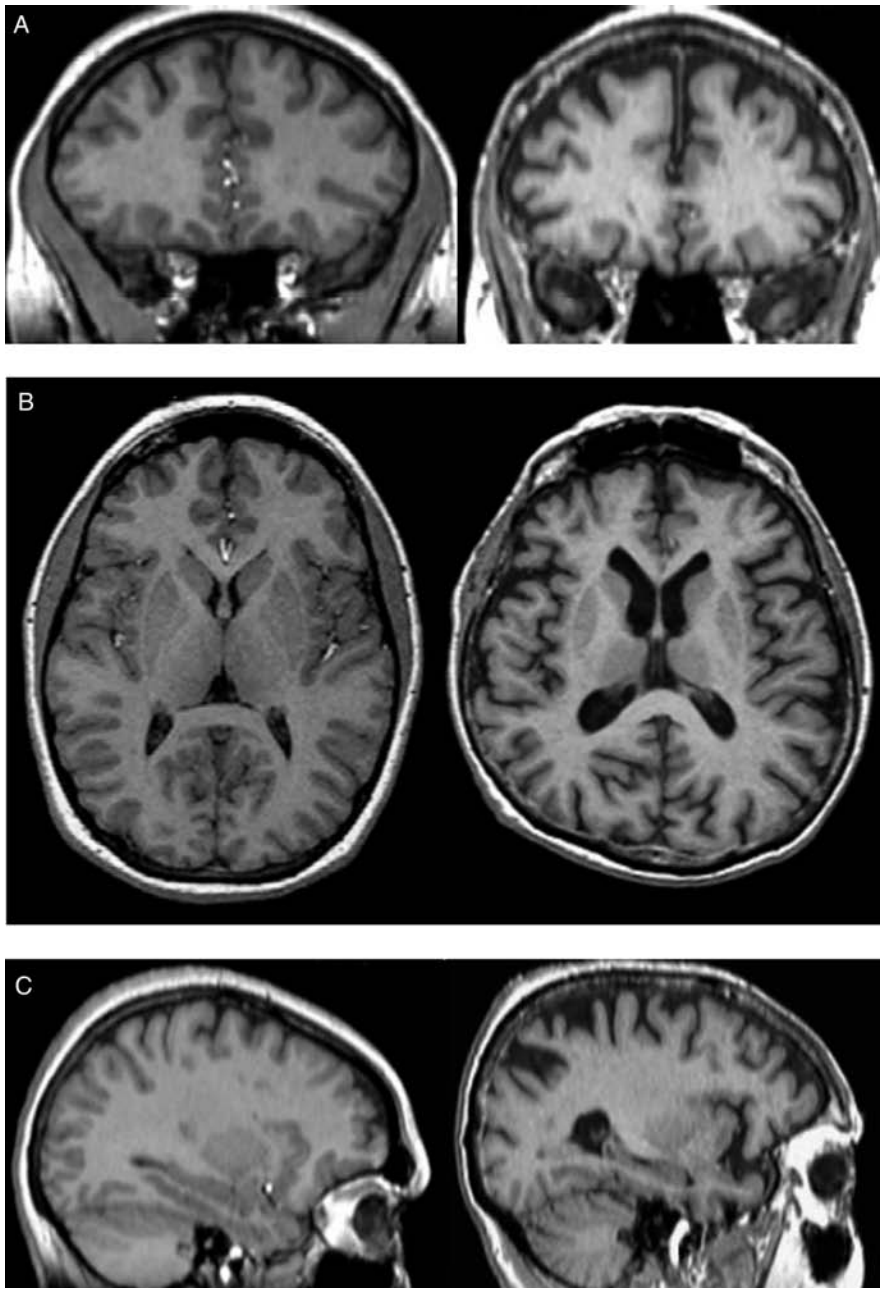

Figure 2 Regional age-related differences in the brain comparison of MR images. (A) Prefrontal cortex in a coronal plane perpendicular to the plane cutting through the anterior and posterior commissures (AC–PC). (B) Basal ganglia (striatum) in a horizontal plane approximately parallel to the AC–PC. (C) Hippocampus (HC; in a sagittal plane, perpendicular to the AC–PC). The images of a 23-year-old female are on the left, and the images of a 77-year-old female are on the right. The image acquisition parameters were selected to emphasize anatomical details and the white–gray matter differences. On these images, the white matter and blood vessels appear in high-intensity white, the gray matter is rendered in a darker end of the gray scale, and the cerebrospinal fluid is black.

The reasons for the observed differential distribution of age-related vulnerabilities are unclear. The pattern of differential brain aging reflects to some extent the outline of age-sensitive neurotransmitter systems and may be associated with age-related changes in the intracellular distribution of calcium ions. The regions and cell ensembles that have higher propensity to calcium-driven plasticity may be more vulnerable to excitotoxic events that cause age-related damage. Although there is a tendency of phylogenetically newer and ontogenetically late to mature regions to show greater negative effects of age, interspecies and even interstrain differences in brain response to aging are plentiful. Most of the age-sensitive regions are also located in the areas of the brain that are prone to suffer negative effects of subclinical ischemia. Although those are only clues, and biological mechanisms that drive differential brain aging remain to be elucidated, the connection between brain aging and cognitive changes of late adulthood is undeniable. The main challenge for cognitive neuroscience is to establish specific relations between age-related transformations of the brain circuitry and altered performance of cognitive operations that depend on those circuits.

III. COGNITIVE AGING AND ITS NEURAL SUBSTRATES

Age-related changes in cognitive performance mirror the complex picture of brain aging as it presents a pattern of selective preservation and decline against the background of generalized changes. A substantial proportion of age-related variance in cognitive performance can be explained by generalized slowing and dwindling of the general pool of cognitive resources. Age-related slowing of response and difficulties in dealing with multiple tasks are easy to spot even by untrained observers. It is difficult, however, to separate cognitive declines that are due to slowing from those that result from a reduction of resources. From the stand-point of the classic information theory, time needed for message processing, signal-to-noise ratio of the message, and the availability of processing elements (resources) are mutually dependent. In principle, deficiency in one of these properties can be compensated by excess in another. However, the process of aging affects all the information processing capabilities and such compensation may no longer be feasible. Thus, aging individuals may require increasingly longer time for processing, can tolerate less admixture of noise in the stimuli, and can deploy fewer resources. As task difficulty and complexity of processing increase, so do age-related differences in speed and accuracy of performance. The debate among scholars of cognitive aging is centered on whether such incremental slowing is proportional and uniform across the tasks or disproportional and differential. Indeed, after accounting for generalized change in speed and resource availability, examples of differential cognitive aging are not difficult to find. Functions associated with episodic memory and executive control of cognitive processes are more sensitive to aging than are semantic memory and verbal reasoning, which rely on stable knowledge structures and well-honed expert skills. The distinction between the tasks dependent on overlearned and automated skills and those that require effortful processing in the absence of environmental support extends into the age-sensitive domains as well.

Because both brain and cognition age differentially, it is plausible that age-sensitive cognitive operations are supported by age-sensitive areas of the brain, whereas age-invariant cognitive abilities are maintained by brain circuits that are not particularly prone to aging. It is also plausible that age-related deterioration of specific circuits that are crucial for normal execution of cognitive operations leads to functional reorganization of the aging brain. As a result of such reorganization, the patterns of brain–behavior relations observed in young adults may become transformed and redefined in older people, thus complicating an already daunting task of understanding brain–behavior relations in the old age. On a more positive note, an important factor in reduction of age-related deficits is expertise. The tasks that are performed repeatedly throughout the life span are less likely to show age-related deficits. Moreover, deliberate prolonged practice that characterizes experts careers acts as a protector against age-related declines even in the realms of behavior that demand considerable exertion even from younger performers. Evidence from multiple domains, such as piano playing and chess supports the notion of expertise as an antidote to aging. One must bear in mind, however, that impressive stability of expert performance shows little if any spillover to other cognitive and behavioral domains. Thus, despite some local successes, the general battle against aging is gradually lost, and determination of the neural harbingers, substrates, and correlates of that process remains the central issue in modern gerontology.

The relationship between global indices of cognitive performance and generalized age-related alterations in brain structure has been examined in several studies. The early studies that relied on neuroimaging techniques of limited resolution revealed moderate general associations between nonspecific age-related atrophy markers (ventriculomegaly and cerebral sulcal expansion) and performance on a broad range of neuropsychological tests in healthy elderly. In some samples, however, global deterioration of the white matter predicts age-related cognitive slowing and declines in executive functions whereas showing no links to other, more age-invariant functions. Although newer investigations in which brain structure and functions were assessed with more sophisticated techniques confirmed the link between the signs of generalized brain deterioration and general indices of cognitive decline, more detailed inquiries into specific relations between cognitive operations and brain structure and function became possible. The findings generated to date by this fruitful approach are summarized next.

1. Motor Functions

Age differences in cognition are inferred from observing a motor (vocal or manual) response to the task stimuli, and age-related changes in the motor system must be taken into account. Although age effects on simple reaction time are mild, aging is accompanied by multiple deficits in planning, control, and execution of movements. Only some of these changes can be attributed to age-related changes in the musculoskeletal system. *In vivo* PET studies of the dopaminergic system of healthy adults suggest that an age-related decline in availability of dopamine receptors in the caudate nucleus and putamen is linked to impaired fine motor performance. In fMRI measures of activation associated with simple motor tasks, older participants show more sluggish hemodynamic response and lower signal-to-noise ratio than their younger counterparts. Notably, some of the age-related motor deficits may be mediated by differences in aerobic fitness and cardiovascular status. Thus, the results of experimental studies of age differences in cognition should be interpreted in the context of age-related changes in the motor response system.

2. Sensory Processes

Aging is known to inflict significant selective changes on the earliest echelons of sensory systems. Thus, the information extracted from the environment reaches the cerebral cortex of an elderly individual in a partial or distorted form. Some functions, such as auditory gain control, high-frequency discrimination, and visual contrast sensitivity, are especially hard hit by age-related processes. In the context of far-reaching changes in the cerebrovascular system, it is not surprising that aging is associated with alteration of cerebral hemodynamics in response to simple sensory stimulation. Because microvascular response of brain vessels is regulated by dopamine, age-related dopaminergic deficits may dampen the hemodynamic response elicited from the aging brain, regardless of cognitive factors. On the other hand, patients with cardiovascular diseases that are common in old age display task-relevant *hyper*activation in the brain regions that are activated by the same task in normal controls. Thus, sensory changes and the health problems frequently associated with aging impose constraints on the interpretation of patterns of brain evoked by cognitively demanding tasks.

3. Perception

A substantial amount of evidence established the existence of two main streams of visual information processing in the brain. According to the two-stream model, perception of objects depends on the ventral stream, incorporating the inferior temporal and the fusiform gyri, whereas identification of spatial location is subserved by the dorsal stream anchored by the superior parietal lobule. Neuroimaging investigations of age differences in visual perception support the double dissociation of ventral and dorsal streams in both younger and older subjects. However, several important age differences have been observed. When confronted with a relatively simple perceptual task, older subjects evidenced increases in rCBF to the amodal and visual association areas, whereas their younger counterparts showed greater activation of the primary and secondary visual cortices.

4. Attention

The current view of the neural substrate of attention distinguishes between two major brain systems guiding deployment, maintenance, focusing, and division of attention: a posterior system mainly devoted to selective deployment and disengagement of visual attention and an anterior system that is responsible for division of attention among multiple cognitive processes. The anterior cortical attentional system

comprises dorsolateral prefrontal cortex (DLPFC) and anterior cingulate gyrus and is critical for executive control of attention, including control of its motivational aspects. The posterior attentional system involves a network of cortical and subcortical components, such as the superior and inferior parietal lobules, secondary association cortices in visual and auditory modalities, and the subcortical pathways guiding saccadic eye movements. A dense network of neural connections between the two systems led to an understanding that they cannot operate in isolation but act as parts of an integrated entity.

Age differences in focused and divided attention appear to stem not only from quantitative declines in the magnitude of cerebral activation but also from discrepancies in the patterns of cortical activation. The younger subjects activate the brain circuitry that subserves specific visual attention processing, whereas their older counterparts appear to increase engagement of the anterior, general attention system while failing to deactivate the regions usually not associated with attentional control.

5. Memory

Perhaps because it is widely believed that mnemonic deficits are the harbingers of dementia, the cognitive aging literature emphasizes age-related differences in memory. Consequently, most of the neuroimaging studies on aging have concentrated on a search for neural substrates of encoding and recall of information. Memory, however, is not a uniform domain, and aging as well as other brain-altering processes affect its distinct systems differentially. The contrast between age-related vulnerability of the episodic and stability of the semantic memories is clear. Moreover, within the realm of episodic memory, age differences in free recall tasks that challenge the participants to effortful retrieval are greater than in the tests of recognition memory, which involve a less demanding selection from a restricted menu of alternatives. In contrast, repetition priming, with its absence of conscious and effortful recollection requirements shows few age-related differences.

It is a matter of broad consensus that explicit (mainly episodic) memory depends on two subdivisions of the central nervous system: the medial–temporal–diencephalic structures and the prefrontal cortex. However, beyond that general accord, there is little agreement regarding the exact role played by specific limbic and anterior association structures in various memory functions.

Studies of experimental lesions in nonhuman mammals and observations on human diseases affecting the hippocampus suggest a central role for the hippocampal formation in mnemonic processes. The hippocampus and affiliated structures, such as the fornix, the entorhinal cortex, the medial dorsal thalamus, and the mammillary bodies, contribute to the consolidation and maintenance of memories. However, human neuroimaging studies suggest that the left prefrontal cortex is preferentially involved in the encoding of episodic memories, whereas its counterpart on the right is dominant in the retrieval of episodically acquired information. However, in addition to the prefrontal and limbic structures explicit memory depends on a wide network of cerebral circuits involving modality-specific association cortices, anterior cingulate gyrus, and selected thalamic nuclei, all of which are affected by normal aging to various degrees. In contrast to explicit memory, implicit memory processes require virtually no limbic–diencephalic support and depend instead on multiple cortical and subcortical systems, including the primary sensory cortices. Procedural learning such as acquisition of a motor or perceptual skill depends on the integrity of premotor, supplementary motor, and secondary visual areas, the neostriatum, the cerebellum, and the connections between them. Finally, simple Pavlovian conditioning relies on circumscribed circuits and nuclei in the brain stem and the cerebellum.

The majority of studies that have addressed the issue of neuroanatomical correlates of age-related differences in mnemonic performance have concentrated on the hippocampus and adjacent limbic structures, although in some samples global indices of brain aging such as measures of the white matter integrity are mildly predictive of declines in delayed recall. In healthy older adults, shrinkage of the hippocampal formation but not of the superior temporal gyrus is associated with poor delayed recall. In some samples, visual memory deficits correlate with reduced volume of the amygdala. Relatively short (2–6 years) longitudinal follow-up studies of healthy older adults reveal that reduction of the hippocampal size predicts the decline in performance on age-sensitive memory tests, and reduction of the whole brain volume predicts decline in verbal memory. Semiquantitative indices of hippocampal atrophy derived from MRI scans also predict poor memory performance in healthy older adults. In some samples, the association between hippocampal shrinkage and memory deficits is observed only in the oldest subjects or it is almost entirely confounded with age. Moreover, sometimes the results

point in the opposite direction, with smaller hippocampi and smaller parahippocampal gyri predicting better delayed recall.

Although structural neuroimaging studies provide insights into relations between long-term changes in the brain and cognitive declines, they cannot reveal brain mechanisms of observed age-related differences in cognition. Functional neuroimaging, with its almost real-time capabilities, is better suited for examination of the impact of age-related changes in brain work on cognitive performance. This area of research is in its inception and only a handful of activation studies of age-related differences in memory have been conducted. Although the stability of observed age differences in the patterns of activation is hampered by the small sample size of a typical study, some general trends have emerged. In neuroimaging studies of encoding, older participants either show reduced activation in the left inferior prefrontal cortex or fail to activate this area at all. In addition, in some samples, age-related reduction of activation in the anterior cingulate gyrus is observed. When encoding is studied within a semantic recognition framework, no age differences in prefrontal activation are observed, in accord with the findings of age-related stability of semantic memory. Also, as predicted on the basis of behavioral studies that reveal no age-related declines in priming, repetition priming produces equivalent deactivation in the occipital cortices of older and younger adults.

The evidence is less consistent in regard to the role of medial temporal activation in age-related memory changes. Although in some samples older subjects evidenced a significantly reduced activation in the hippocampus and the parahippocampal gyrus, this finding has not been consistently observed in other groups of older adults. To complicate the picture further, a recent fMRI study of verbal cued recall suggested that task-relevant medial temporal activation is more widespread in healthy older adults who possess a genetic risk for Alzheimer's disease than in risk-free controls. Thus, one cannot conclude that aging brings with it a decrease in task-related brain work. Older people in general and those predisposed to age-related pathology may use medial temporal and prefrontal structures in ways that are different from how younger people use them.

In the young participants engaged in retrieval of episodic information, activation of the prefrontal cortex predicts the speed of information processing across tasks, whereas in the older people the same region is also associated with task-specific decision processes. Thus, it appears that older brains have to recruit additional resources to manage the executive overhead of the task. It is unclear whether such an adjustment is of compensatory value because it relies on the very circuitry (prefrontal association cortex) that is most affected by the adverse influences of aging.

6. Executive Functions

A growing body of research has revealed that many age-related deficits in memory may stem from declines in the means of strategic management of mnemonic resources. Multiple studies have demonstrated that a significant proportion of age-related declines in cognitive performance can be traced to deterioration of working memory (WM). Specifically, the more prominent the strategic or executive component of the WM task, the greater the negative effect of age on WM performance. Earlier models of WM derived from laboratory experiments in nonhuman primates and human activation studies emphasized its almost exclusive dependence on amodal prefrontal association areas. However, recent data suggest that modality-specific secondary association cortices play an important role in supporting this resource, and coactivation of anterior and posterior association cortices may be critical for maintaining performance during increased load on WM.

In light of the central role played by WM in cognitive aging, the literature on cortical activation patterns associated with performance on WM tasks is surprisingly sparse. Structural MRI investigations of the neural substrates of age-related declines in WM revealed significant but weak links between verbal working memory and the volume of the prefrontal cortex. Functional neuroimaging studies of WM in young and older adults revealed that whereas task-relevant activation in secondary association cortices is equivalent across the age range, greater prefrontal (amodal) cortex activation is observed in the elderly. A typical WM task results in activation of ventral and dorsal prefrontal, anterior cingulate, and posterior parietal cortices as well as the neostriatum in both young and older adults. However, when the mnemonic demands increased, activation extended into a larger region (posterior DLPFC) in young but not old. The latter seemingly fail to respond adequately when the task calls for recruiting additional executive resources. Thus, different aspects of the delayed response task appear to be reflected in activation patterns of young and older people. Whereas at younger ages they may

reflect greater investment in stimulus-related aspects of the tasks, in older people activation may signify recruitment of resources for maintaining general attentional demands.

If the central executive component of WM is preferentially affected by aging, greater emphasis on that aspect of WM in future neuroimaging studies may help to bring more coherence to this field of research. Age-related deficits in WM may stem from declining function of the dopaminergic system and specifically the prefrontal dopamine receptors that are affected by aging. Such an association is especially plausible because activity of the dopaminergic receptors plays an important role in executive functions subserved by the prefrontal cortex. In aging monkeys, administration of low doses of dopamine agonists improves working memory. Furthermore, it has been suggested that optimal catecholaminergic and cholinergic activity in the prefrontal cortex may be the key to superior performance on executive and working memory tasks. Thus, impaired interaction between dopaminergic and noradrenergic systems rather than a deficit in either of them may cause age-related declines in WM and more complex cognitive activities that depend on it. This impairment may or may not be more acute in individuals who experience greater shrinkage of the prefrontal cortex and who show less efficient metabolism of glucose in the affected areas.

Executive tasks that engage WM and additional strategic components, such as planning, feedback-contingent switching, goal management, inhibition, and response selection, are sensitive to aging. Humans as well as nonhuman primates exhibit an age-related increase in perseverative errors (i.e., they demonstrate a propensity not to abandon a familiar response even after receiving information indicating that the response is incorrect). Empirical evidence and formal models suggest that executive functions disproportionately depend on the integrity of the prefrontal cortex.

Structural neuroimaging investigations of age-related differences in executive functions have yielded inconclusive results. A reduction in the volume of prefrontal gray matter is associated with an increase in perseverative behavior, and age-related increases in perseverative errors and other executive deficits are linked to elevated burden of white matter abnormalities in the frontal lobes.

Because prefrontal cortex is extensively connected to the basal ganglia, it is plausible that age-related declines in executive functions stem from age-related neurochemical changes in the neostriatum. In accordance with this hypothesis, a reduction in the availability of dopamine receptors predicts difficulties in inhibiting a prepotent response.

When young and older adults perform a task with a significant executive component, they demonstrate significant activation in the DLPFC and the posterior association cortices in their left hemispheres. In addition, only the young subjects show significant left-side activation of the premotor and the posterior parietal cortices, as well as the left fusiform gyrus and the left cerebellum. Notably, in the areas of activation that were common to both age groups, the elderly subjects evidenced lower magnitudes of activation than their younger counterparts, even after adjustment for individual differences in global CBF. Moreover, the magnitude of activation in the left DLPFC, right parahippocampal gyrus, and left prestriate cortex was negatively correlated with the number of perseverative errors.

Inhibition has been considered one of the key notions in discussions of age-related differences in working memory and higher cognitive functions, and the prefrontal (mainly the orbitofrontal) cortex has been widely considered the substrate of inhibitory control. The results of a PET investigation suggest that although young people respond to the introduction of a task switching requirement by an increase in prefrontal activation, their older counterparts show an equivalent activation boost when the tasks are preformed in a blocked order, without switching.

In summary, age-related shrinkage and reduced task-specific activation and increased nonspecific activation of the prefrontal cortical circuits are associated with a variety of errors in executive control of cognitive performance. The mechanisms underlying these deficits and the relationship among executive functions, working memory, and their cortical substrates are yet to be elucidated.

7. Language

Verbal skills assessed by tests of word knowledge and verbal reasoning are considered virtually age invariant, although age-related differences have been reported in more subtle aspects of language processing. A possible explanation of relative stability of some linguistic skills throughout the life-span lies in the fact that hours of sustained practice in reading and oral expression fill our day. Thus, superior vocabulary skills frequently noticed in older adults can be attributed to their extensive practice in that domain. In addition, natural languages are characterized by such a high degree of redundancy that many linguistic

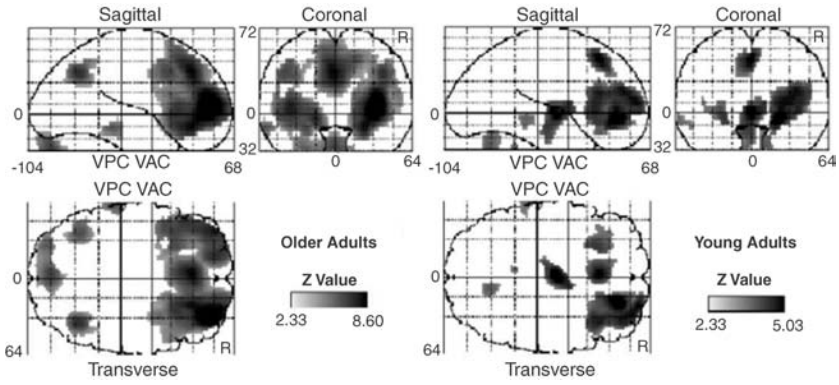

Figure 3 An example of a $^{15}H_2O$ PET activation map in a recognition memory task. (Left) A composite of 12 younger subjects. (Right) A composite of 12 older subjects. The labels VAC and VPC indicate a standard vertical reference plane passing through the anterior and posterior ommissures (AC and PC), respectively. The activation values (z scores) are mapped onto a coordinate grid (Talairach space) anchored at the AC–PC line. Note a substantially broader activation in older adults that in their younger counterparts [images courtesy of D. J. Madden, and first appeared in N. Raz (2000), in *Handbook of Aging and Cognition—II*, (F. I. M. Craik and T. A. Salthouse, Eds.), pp. 1–90. Erlbaum, Mahwah, NJ].

operations can be performed literally with half of the information deleted. However, when a task calls for higher than usual demands on the working memory or speed of processing, age-related declines in linguistic performance become apparent.

Very little is known about neural substrates of age-related differences in linguistic functions. It is unclear whether declines in performance in a given language function reflect changes in general resources such as speed and WM, or specific deterioration of brain circuitry responsible for language processing. An optimistic belief in the lack of age effects on language may be responsible for the dearth of neuroimaging studies of age differences in that domain, although the results of recent investigations that did employ measures of linguistic competence may temper that optimism. For instance, a longitudinal study of a small sample of healthy middle-aged adults showed that reduction of temporal lobe volumes may be associated with mild but statistically significant worsening of performance on language tests.

Neuroimaging findings suggest that although neural mechanisms responsible for semantic processing and filtering of verbal information are unaffected by age, older adults may experience difficulty in recruiting cortical resources for processing of novel pseudolinguistic stimuli.

IV. CONCLUSIONS

Aging is associated with slowing of information processing, reduction in cognitive resources, moderate declines in episodic memory, and increased likelihood of failure of executive or strategic control over cognitive operations. Extensive practice in a specific cognitive domain ameliorates and delays these age-related changes within the restricted domain of practice. Performance on the tasks that depend on overlearned and well-practiced skills such as reading, use of lexicon, and engagement of semantic knowledge network are stable across most of the life span. Brain mechanisms of selective age-related changes in cognition are unclear. A small but steadily growing number of neuroimaging studies indicate that older adults evidence reduced brain activity in the task-relevant and modality-specific cortical areas while increasing the magnitude of activation and broadening the activation regions in the areas that are amodal and irrelevant to the task. An illustration of such dedifferentiation of cortical activation with age is shown in Fig. 3. In an apparent paradox, the brain regions recruited by older people are located in cortical structures that are differentially vulnerable to the effects of aging.

A contrasting interpretation of age-related differences in brain activation patterns has been offered by researchers who proposed to view it as a sign of compensation. One way to decide whether the observed pattern reflects compensation or dedifferentiation is examination of associations between activation and performance. Although the data are still sparse, several studies of healthy adults revealed that more bilateral, wide spread activation patterns is associated with better performance. Clarifying the relationships between structural and functional neuroanatomy and

cognitive performance remains one of the central questions in cognitive aging research.

GLOSSARY

counterfactual emotions Counterfactual arguments involve reasoning that makes assumptions contrary to the facts in evidence (e.g., "If I were king, I'd make everyone rich"). Counterfactual emotions are feeling states, such as regret and disappointment, that require a comparison between some state of affairs and what might have been.

dichotic listening A technique in which different auditory messages are presented over separate earphones; the subject is instructed to repeat (shadow) one message but ignore the other.

dissociation A statistical outcome in which one variable, either a subject characteristic (such as the presence of brain damage) or an experimental manipulation (such as the direction of attention), has different effects on two dependent measures (such as free recall or priming).

functional magnetic resonance imaging A brain-imaging technique using magnets to measure the changes in the ratios of deoxygenated to oxygenated hemoglobin due to brain activity.

gambler's fallacy The idea that prior outcomes, such as a string of "red" numbers in roulette, can influence the outcome of some future outcome, such as a "black" number; it is a fallacy because in a truly random game each outcome is independent of the others.

magnetoencephalography A brain-imaging technique using superconducting quantum interference devices to measure changes in weak magnetic fields caused by the brain's electrical activity.

positron emission tomography A brain-imaging technique that uses positrons (positively charged electrons) to measure blood flow, metabolic rate, and biochemical changes in the brain.

priming The facilitation (or, in the negative case, inhibition) of perceptual–cognitive processing of a target stimulus by prior presentation of a priming stimulus.

schemata Organized knowledge structures representing a person's beliefs and expectations, permitting the person to make inferences and predictions.

sensory thresholds In psychophysics, the minimum amount of energy required for an observer to detect the presence of a stimulus (the "absolute" threshold) or a change in a stimulus (the "relative" threshold).

tabula rasa Latin meaning "blank slate"; refers to the empiricist view that there are no innate ideas, and that all knowledge is gained through experience.

Cognition has to do with knowledge, and cognitive psychology seeks to understand how human beings acquire knowledge about themselves and the world, how this knowledge is represented in the mind and brain, and how they use this knowledge to guide behavior.

I. A SHORT HISTORY

Psychology was cognitive at its origins in the mid- to late 19th century. Structuralists such as Wilhelm Wundt and E. B. Titchener attempted to decompose conscious experience into its constituent sensations, images, and feelings. On the very first page of the *Principles of Psychology* (1890), the discipline's founding text, William James asserted that "the first fact for us, then, as psychologists, is that thinking of some sort goes on," and the functionalist tradition that he and John Dewey established sought to understand the role of thinking and other aspects of mental life in our adaptation to the environment. In

the early 20th century, however, John B. Watson attempted to remake psychology as a science of behavior rather than, as James had defined it, a science of mental life.

For Watson, public observation was the key to making psychology a viable, progressive science. Because consciousness (not to mention "the unconscious") was essentially private, Watson argued that psychology should abandon any interest in mental life and instead confine its interest to what could be publicly observed: behavior and the circumstances in which it occurred. In Watson's view, thoughts and other mental states did not cause behavior; rather, behavior was elicited by environmental stimuli. Thus began the behaviorist program, pursued most famously by B. F. Skinner, of tracing the relations between environmental events and the organism's response to them. Psychology, in the words of one wag, lost its mind.

The behaviorist program dominated psychology between the two world wars and well into the 1950s, as manifested especially by the field's focus on learning in nonhuman animals, such as rats and pigeons. Gradually, however, psychologists came to realize that they could not understand behavior solely in terms of the correlation between stimulus inputs and response outputs. E. C. Tolman discovered that rats learned in the absence of reinforcement, whereas Harry Harlow discovered that monkeys acquired general "sets" through learning as well as specific responses. Noam Chomsky famously showed that Skinner's version of behaviorism could not account for language learning or performance, completely reinventing the discipline of linguistics in the process, and George Miller applied Chomsky's insights in psychology. Leo Kamin, Robert Rescorla, and others demonstrated that conditioned responses, even in rats, rabbits, and dogs, were mediated by expectations of predictability and controllability rather than associations based on spatiotemporal contiguity. These and other findings convinced psychologists that they could not understand the behavior of organisms without understanding the internal cognitive structures that mediated between stimulus and response.

The "cognitive revolution" in psychology, which was really more of a counterrevolution against the revolution of behaviorism, was stimulated by the introduction of the high-speed computer. With input devices analogous to sensory and perceptual mechanisms, memory structures for storing information, control processes for passing information among them, transforming it along the way, and output devices analogous to behavior, the computer provided a tangible model for human thought. Perceiving, learning, remembering, and thinking were reconstrued in terms of "human information processing," performed by the software of the mind on the hardware of the brain. Artificial intelligence, simulated by the computer, became both a model and a challenge for human intelligence.

Jerome Bruner and George Miller founded the Center for Cognitive Studies at Harvard University in 1960, intending to bring the insights of information theory and the Chomskian approach to language to bear on psychology. Miller's book, *Plans and the Structure of Behavior* (1960; written with Karl Pribram and Eugene Galanter) replaced the reflex arc of behaviorism with the feedback loops of cybernetics. The cognitive (counter)revolution was consolidated by the publication of Neisser's *Cognitive Psychology* in 1967 and the founding of a scientific journal by the same name in 1970. With the availability of a comprehensive textbook on which undergraduate courses could be based, psychology regained its mind.

II. THE DOMAIN OF COGNITION

Although some philosophers (including Plato, Descartes, and Kant) have asserted that some knowledge is innate, most also agree that at least some knowledge is acquired through experience. Accordingly, theories of human cognition must include some account of the sensory and perceptual processes by which the person forms internal, mental representations of the external world; the learning processes by which the person acquires knowledge through experience; the means by which these representations of knowledge and experience are stored more or less permanently in memory; the manner in which knowledge is used in the course of judgment, decision making, reasoning, problem solving, and other manifestations of human intelligence; and how one's thoughts and other mental states are communicated to others through language. We cannot hope to give a comprehensive analysis of these processes in this article. Detailed treatment is provided by the textbooks listed under Suggested Reading and also in the multivolume *Handbook of Perception and Cognition*, which has appeared serially since 1994. Instead, we seek only to orient the reader to the general thrust of work in this field and to the problems and controversies that occupy its practitioners.

A. Sensation

Philosophers of mind have debated two views about the origins of knowledge: nativism and empiricism. Cognitive psychology, while acknowledging the possibility that some knowledge is innate, favors the empiricist view that most knowledge is acquired through the senses, including our reflections on sensory experience. Therefore, cognitive psychology begins with an analysis of the sensory mechanisms by which physical energies arising from a stimulus are transformed into neural impulses.

Research on sensation is dominated by the definition of the various sensory modalities (vision, audition, etc.), the determination of thresholds for sensory experience, the physical basis of various qualities of sensation (e.g., blue, C-sharp, and sour), and the search for *psychophysical laws* that would relate the physical properties of a stimulus to the psychological properties of the corresponding sensory experience. The most general psychophysical law, Stevens' law ($S=kI^n$), holds that there is some exponent that will relate any physical property of a stimulus to the psychological property of its corresponding sensory experience. The analysis of sensation is so closely tied to the physical and biological sciences that it is often omitted from cognitive psychology textbooks. However, even such "lower" mental processes as sensation and perception do not escape the influence of "higher" mental processes of judgment and decision making.

For example, the early psychophysicists assumed that the detection of an object in the environment was simply a matter of the physical intensity of the stimulus and the sensitivity of the corresponding receptor organs. If a light were of sufficient intensity, given the modality and species in question, it would be detected (a "hit"); otherwise, it would be missed. However, it is also the case that observers will miss stimuli that are clearly above threshold and make false alarms by "detecting" stimuli that are not actually present. Experiments based on signal detection theory use the pattern of hits and false alarms to decompose performance into two parameters: Sensitivity, presumably closely tied to the biology of the sensory system, and bias, or the perceiver's willingness to report the presence of a stimulus under conditions of uncertainty. Interest in most signal detection experiments focuses on sensitivity; bias is a nuisance to be evaluated and statistically controlled. However, the fact that bias occurs at all shows that the perceiver's expectations, motives, and biases influence performance even in the simplest sensory task. Thus, processes involved in reasoning, judgment, choice, and decision making percolate down to even the lowest levels of the information processing system, and they are grist for the cognitive psychologist's mill.

B. Perception

While sensation has to do with detecting the presence of stimuli and changes in the stimulus field, perception has to do with forming mental representations of the objects that give rise to sensory experiences. Much perceptual research focuses on the process by which individuals determine the size, shape, distance, and motion of objects in the environment.

For most of its history, the study of perception has been dominated by the constructivist/phenomenalist tradition associated with Hermann von Helmholtz, Richard Gregory, Julian Hochberg, and Irvin Rock (among many others). The constructivist view assumes that the proximal stimulation impinging on sensory receptors is inherently ambiguous, and that there is an infinite array of distal configurations compatible with any momentary state of proximal stimulation. For example, consider the relationship between the size and distance of an object, on the one hand, and the size of the retinal image of that object, on the other hand. Holding distance constant, the size of the retinal image is directly proportional to the size of the stimulus; however, holding size constant, the size of the retinal image is inversely proportional to the distance between the object and the perceiver. Thus, given the size of a retinal image, the perceiver does not know whether he or she is viewing a large object far away or a small object close at hand.

According to the constructivist view, stimulation of this sort must be disambiguated by inference-like rules that compare the size of the object with the size of its background or make some comparison of the stimulus input with an a priori model of the world that tells us the size of various objects. In either case, perceiving entails thinking and problem solving. Sometimes, the solution can be wrong, such as when the perceptual system overcompensates for distance cues to generate the illusion that the moon on the horizon is larger than the moon at zenith. Helmholtz famously argued that the inferential rules that guide perception are part of our tacit knowledge: They can be discovered by the scientist but cannot be articulated by the perceiver. Because the thoughts that give rise to our percepts are unconscious, perception lacks the phenomenal quality

of thought. However, it remains the case that the final product of perception is a mental representation of the stimulus world, constructed by cognitive operations such as computations and symbolic transformations. We are not aware of the world itself but only of our mental representation of it, which is projected onto the world so that the objects of perception and the objects of the world are coreferential. Even more than sensation, perception from the constructivist/phenomenalist view has cognitive underpinnings that cannot be denied.

Nevertheless, a contrary, noncognitive view of direct realism was proposed by J. J. Gibson in his ecological theory of perception (interestingly, Neisser took a constructivist approach to perception in Cognitive Psychology, but has since embraced a version of direct realism). According to the ecological view, stimulation is ambiguous only at very elementary levels, but there is no ambiguity at higher levels. Therefore, for example, in determining an object's size, the perceptual system extracts information about the ratio of the size of an object to the size of its background; this ratio determines perceived size, not the size of the retinal image of the object alone. Thus, the perceived size of an object remains constant even as its distance from the viewer (and thus the size of its corresponding retinal image) varies. However, this requires no computations, inferences, or a priori models of the world on the part of the perceiver; size is perceived directly from information available in the environment about the ratio of the figure to ground, without need of any mediating cognitive operations. Because perceptual systems evolved in order to support adaptive behavior, Gibson further proposed that we perceive objects in terms of their affordances, or the actions that we can take with respect to them. Thus, in the same way that the ecological view of perception argues that all the information required for perception is "in the light," an ecological view of semantics argues that the meanings of words are "in the world," available to be perceived directly.

The ecological theory of perception proposes that the perception of form, distance, motion, and other stimulus properties is no different from perceiving the hue of a light or the pitch of a sound. In each case, phenomenal experience occurs by virtue of the transduction of stimulation into perception, accomplished in a single step by specialized neuronal structures that have evolved to be selectively sensitive to higher order variables of stimulation available in an organism's environmental niche. The contrast between the constructivist/phenomenalist and direct/realist views dominates much of contemporary perception research, with proponents of the ecological approach conducting clever experiments showing that percepts commonly attributed to computations, inferences, or world models are actually given directly by higher-order variables of stimulation. However, it is one thing to demonstrate that such information is available and quite another to demonstrate that such information actually contributes to perception. The occurrence of visual illusions strongly suggests that we do not always see the world as it really is, and that the perceiver must, in Bruner's famous phrase, go "beyond the information given" by the environment in order to form mental representations of the world.

C. Attention

In many theories, attention is the link between perception and memory: The amount of attention devoted to an event at the time it occurs (i.e., at encoding) is a good predictor of the likelihood that it will be consciously remembered later (i.e., at retrieval). Early cognitive theories considered attention to be a kind of bottleneck determining whether incoming sensory information would reach short-term memory and thus enter into "higher level" information processing. In early attention research there was a major controversy between early selection theories, which held that preattentive processing was limited to "low-level" analyses of physical features, and late selection theories which allowed preattentive processing to include at least some degree of "high-level" semantic analysis. Early selection was favored by experiments showing that subjects had poor memory for information presented over the unattended channel in dichotic listening experiments. Late selection was favored by evidence that such subjects were responsive to the presentation of their own names over the unattended channel.

Definitive tests of early versus late selection proved difficult to come by, and beginning in the 1970s the problem of attention was reformulated in terms of mental capacity: According to capacity theories, individuals possess a fixed amount of processing capacity, which they can deploy freely in the service of various cognitive activities. Various information processing tasks, in turn, differ in terms of the amount of attentional capacity they require. Some tasks may be performed automatically, without requiring any attentional capacity at all; such tasks do not interfere

with each other or with effortful tasks that do make demands on cognitive resources. When the total attentional capacity required by effortful tasks exceeds the individual's capacity, they will begin to interfere with each other. Some automatic processes are innate; however, other processes, initially performed effortfully, may be automatized by extensive practice. Thus, skilled readers automatically and effortlessly decode letters and words, even while they are doing something else, whereas unskilled readers must expend considerable mental effort performing the same task at great cost to other, ongoing activities.

According to one prominent view, automatic processes are almost reflexive in nature (although the "reflexes" in nature are cognitive, not behavioral, and they are acquired, not innate). That is, they are inevitably engaged by the appearance of certain stimuli, and once invoked they proceed inevitably to their conclusion. Because their execution consumes no attentional resources, they do not interfere with other ongoing processes, and they leave no traces of themselves in memory. This "attention-based" notion of automaticity plays a central role in many cognitive theories. According to a revisionist "memory-based" view, however, automaticity has nothing to do with attention but, rather, depends on the way in which skill underlying task performance is represented in memory. Automatization occurs when performance is controlled by procedural rather than declarative knowledge representations. From either point of view, automatic processes are strictly unconscious: We have no direct introspective awareness of them, and we know them only by inference from task performance.

D. Memory

Perceptual activity leaves traces in memory, freeing behavior from dominance by stimuli in the immediate present. The knowledge stored in memory consists of two broad forms: declarative knowledge, which can be either true or false, and procedural knowledge of how certain goals are to be accomplished. Procedural knowledge can be further classified into cognitive and motor skills, such as one's knowledge of arithmetic or grammar, how to tie one's shoes, or how to drive a standard-shift car. Similarly, declarative knowledge can be subdivided into episodic memories of specific experiences that occurred at a particular point in space and time, such as one's memory of eating sushi for dinner at home last Thursday, and semantic memories that are more generic in nature, such as one's knowledge that sushi is a Japanese dish made of rice, vegetables, and fish. In theory, many semantic memories are formed by abstraction from related episodic memories, and much procedural knowledge represents a transformation of declarative knowledge.

Most research on memory has focused on episodic memories for specific events and is based on an analysis of memory into three stages of encoding, storage, and retrieval. Early views of memory that made a structural distinction between short- and long-term stores have now been replaced by a unitary view in which "short-term" (or "working") memory refers to those items that are actively engaged in processing at any moment. Earlier views of forgetting as a product of the loss of memories from storage have been replaced by the view that retention is a function of the extent of processing received by an item at the time of encoding and the amount of cue information available at the time of retrieval. The relations between encoding and retrieval processes are effectively captured by a general principle of encoding specificity (also known as transfer-appropriate processing), which states that the likelihood that an event will be remembered depends on the match between the information processed at the time of encoding and the information available at the time of retrieval.

Most research on memory has employed experimental tasks requiring conscious recollection, or the ability of subjects to recall or recognize past events. However, episodic memory may also be expressed implicitly in tasks that do not require conscious recollection in any form. For example, a subject who has recently read the word "veneer" will be more likely to complete the stem "ven" with this word than with the more common word "vendor." A great deal of experimental research shows that such priming effects can occur regardless of whether the study word is consciously remembered; in fact, they can occur in amnesic patients who have forgotten the study session in its entirety. Similarly, amnesic patients can learn new concepts without remembering any of the instances they have encountered, and they can acquire new cognitive and motor skills while failing to remember the learning trials. Along with the concept of automaticity, the dissociations observed between explicit and implicit expressions of memory have given new life to the notion of the psychological unconscious.

The dissociations observed between explicit and implicit expressions of episodic memory, between

semantic and episodic memories, and between procedural and declarative knowledge are subject to a variety of interpretations. According to the multiple systems view, explicit (conscious) and implicit (unconscious) memories are served by different memory systems in the brain. The multiple systems view, in turn, is compatible with the neuroscientific view of the brain as a collection of modules, each specialized for a particular information-processing task. In contrast, researchers who prefer a processing view, while accepting that there is some degree of specialization in the brain, explain these same dissociations as generated by different processes that operate in the context of a single memory system. For example, according to one processing view, implicit memories are the product of automatic, attention-free processes, whereas explicit memories are the product of effortful, attention-demanding ones. In general, processing views are compatible with computational theories of memory, which typically assume that different memory tasks require the processing of different features of memories stored in a single memory system. One of the interesting features of the debate over explicit and implicit memory is how little contact there has been between neuroscientific and computational views of memory.

E. Categorization

Memory also stores conceptual knowledge about things in general as well as representations of specific objects and events. Bruner noted that this conceptual knowledge plays an important role in perception: In fact, every act of perception is an act of categorization. A great deal of research in cognitive psychology has sought to understand the way in which conceptual knowledge is organized in the mind.

According to the classical view handed down by Aristotle, concepts are represented by a list of features that are singly necessary and jointly sufficient to define the category in question. For example, in geometry, all triangles are closed two-dimensional figures with three sides and three angles, and a sharp boundary divides all triangles from all quadrilaterals. However, in the 1970s it became clear that however satisfying such a definition might be philosophically, it did not reflect how concepts are represented in human minds. When perceivers judge equilateral and right triangles to be ''better'' triangles than isosceles triangles, they are referring to something other than a list of defining features. According to the classical view, all members of a category are equally good representatives of that category. For this and other reasons, the classical view of concepts as proper sets has been replaced with a revisionist probabilistic view of concepts as fuzzy sets. According to the fuzzy set view, features are only imperfectly correlated with category membership, and concepts themselves are represented by prototypes (real or imagined) that possess many features that are characteristic of category members. The probabilistic view permits some instances (e.g., robin) of a category (bird) to be better than others (e.g., emu), even though all possess the same set of defining features. Moreover, it permits the boundaries between categories to be somewhat blurred (is a tomato a fruit or a vegetable?).

Both the classical and the probabilistic view regard concepts as summary descriptions of category members. However, an alternative exemplar view holds that concepts are represented as collections of instances rather than as summary descriptions. Thus, when we seek to determine whether an object is a bird, we compare it to other birds we know rather than to some abstract notion of what a bird is. Just as there is empirical evidence allowing us to firmly reject the classical view of conceptual structure as inadequate, so too there are studies showing that objects are slotted into categories if they resemble particular instances of the category in question, even if they do not resemble the category prototype. Perhaps novices in a domain categorize with respect to abstract prototypes, whereas experts categorize with respect to specific exemplars.

Regardless of whether concepts are represented by prototypes or exemplars, categorization is a special case of similarity judgment: The perceiver assigns an object to a category by matching its features to those of his or her category representation, prototype or exemplar. There is no absolute threshold for similarity, however: Categorization, like signal detection, is always a matter of judgment.

Although categorization seems to be special case of similarity judgment, and the most recent development in theories of concepts has been stimulated by evidence of certain anomalies of similarity. For example, subjects judge gray clouds to be similar to black clouds and different from white clouds, but they judge gray hair to be similar to white hair but different from black hair. The brightness of the color patches is identical, so the judgment must be based on something other than perceptual similarity, such as the perceiver's theory about how hair changes with age or how clouds change with the weather. According to the theory-based view of categorization, concepts are not represented by lists

of features or instances, and categorization does not proceed by feature matching. Instead, concepts are represented by theories that make certain features and instances relevant and that explain how features and instances are related to each other, and categorization proceeds by applying the theory to the case at hand. It remains to be seen, however, whether the theory-based view of concepts and categorization will supplant, or merely supplement, the similarity-based view.

F. Learning

Behaviorism was dominated by an emphasis on learning, but cognitive psychology has not abandoned the question of how knowledge is acquired. After all, although knowledge of such basic categories as time and space may be innate, most knowledge is derived from experience. Learning, then, is the process of knowledge acquisition. In fact, some of the earliest cognitive challenges to behaviorism came through alternative accounts of learning. Even such basic processes as classical and instrumental conditioning are now interpreted in terms of the organism's developing ability to predict and control environmental events. Pavlov's dogs did not salivate to the bell because it occurred in close spatiotemporal contiguity with meat powder, and Skinner's pigeons did not peck at the key because it was reinforced by the delivery of food in the presence of a certain light. Rather, they did so because they expected food to follow the bell and the keypeck. Learning occurs in the absence of reinforcement; reinforcement controls only performance, the organism's display of what it has learned.

The importance of expectancies, and the limited role played by contingencies of reinforcement, is underscored by the development of theories of social learning by Julian Rotter, Albert Bandura, Walter Mischel, and others, who argued that human learning rarely involved the direct experience of rewards and punishments. Rather, most human learning is vicarious in nature: It occurs by precept, in the sense of sponsored teaching, or by example, as in observational modeling. In either case, we learn by watching and listening to other people. Bandura argued that behavior was controlled not by environmental stimuli but by expectancies concerning the outcomes of events and behaviors and also by self-efficacy expectations (i.e., people's belief that they can engage in the behaviors that produce desired outcomes). Some clinical states of anxiety may be attributed to a (perceived) lack of predictability in the environment, whereas some instances of depression may be attributed to a perceived lack of controllability. Interestingly, a capacity for observational learning has been uncovered in nonhuman animals, such as rhesus monkeys, and has been implicated in the genesis of animal "cultures."

Learning processes are obviously implicated in analyses of the encoding stage of memory processing, in the acquisition of procedural knowledge, and in concept formation. At the same time, cognitive psychologists have generally avoided the topic of learning itself. This may partially reflect an overreaction to the excessive interest in learning on the part of behaviorists, and it may partially reflect the influence of Chomsky, who discounted the role of learning in the development of language. Recently, this situation has changed due to the rise of parallel distributed processing, interactive activation, neural network, or connectionist models as alternatives to traditional symbolic processing models of human information processing. In symbolic models, each individual piece of knowledge is represented by a node, and discrete nodes are connected to each other to form a network of associative links. Thus, a node representing the concept *doctor* is linked to semantically related nodes representing concepts such as *nurse* and *hospital*. Such models are very powerful, but they leave open the question of how the knowledge represented by nodes is acquired in the first place. Connectionist models assume that individual concepts are represented by a pattern of activation existing across a large network of interconnected nodes approximately analogous to the synaptic connections among individual neurons (hence, the alternative label). No individual node corresponds to any concept; every concept is represented by a pattern of widely distributed nodes. Instead of one node activating another one in turn, all nodes are activated in parallel, and each passes activation to each of the others. In connectionist systems, learning occurs as the pattern of connections among nodes is adjusted (sometimes through a learning algorithm called backpropagation) so that stimulus inputs to the system result in the appropriate response outputs. Although the link between connectionism and stimulus–response behaviorism is obvious, connectionist theories are cognitive theories because they are concerned with the internal mental structures and processes that mediate between stimulus and response. Compared to traditional symbolic models, they are extremely powerful and efficient learning devices. Unfortunately, they also display a

disconcerting tendency to forget what they have learned as soon as they are asked to learn something new—a phenomenon known as catastrophic interference. Moreover, although connectionist models seem to reflect the neural substrates of learning, it has proved difficult to demonstrate the biological plausibility of specific features such as backpropagation. Accordingly, the future of connectionist models of information processing remains uncertain.

G. Language and Communication

Language is both a tool for human thought and a means of human communication. The ability of people to generate and understand sentences that have never been spoken before is the hallmark of human creative intelligence and arguably the basis for human culture. Also, language permits us to convey complex information about our thoughts, feelings, and goals to other people, and it provides a highly efficient mechanism for social learning.

Language was one of the first domains in which cognitive psychology broke with behaviorism. Early cognitive approaches to language were couched in terms of information theory, but a real breakthrough came in the late 1950s and early 1960s with the work of Chomsky. In his early work, Chomsky distinguished between the surface structure of a sentence, viewed simply as a sequence of words, its phrase structure in terms of noun phrases and verb phrases, and its deep structure or underlying meaning. He also argued that transformational grammar mediated between deep structure and phrase structure. Transformational grammar is universal and innate. Language acquisition consists of learning the specific rules that govern the formation of surface structures in a particular language.

The field of psycholinguistics largely arose out of attempts to test Chomsky's early views. For example, it was shown that clicks presented while sentences were being read were displaced from their actual location to the boundaries between phrases, and that the time it took to understand a sentence was determined by the number of transformations it employed. Nevertheless, over the ensuing years this theory has been substantially altered by Chomsky and colleagues, and in some quarters it has even been discarded. In any event, it is clear that other aspects of language are important besides grammatical syntax. Languages also have phonological rules, which indicate what sounds are permitted and how they can be combined, and morphological rules, which constrain how new words can be formed. Moreover, research on the pragmatics of language use shows how such aspects of nonverbal communication as tone of voice, gesture, facial expressions, posture, and context are employed in both the production and the understanding of language.

A major controversy in the psychology of language concerns speech perception. According to the motor theory of speech perception proposed by Alvin Liberman and colleagues, speech is special in the sense that it is processed by mechanisms that are part of a specifically human cognitive endowment; no other species has this capacity. According to a rival auditory theory of speech perception, understanding speech is simply a special case of auditory perception, and requires no special capacities that are unique to humans. Tests of these theories often revolve around categorical perception, or the ability to distinguish between related sounds such as [b] and [p]. Evidence that there are sharp boundaries between such speech categories is often attributed to innate, specifically human, mechanisms for producing speech, thus favoring the motor theory. On the other hand, evidence of categorical perception in nonhuman species that do not have a capacity for speech favors the auditory theory.

A common theme in the Chomskian approach to language is that language use is mediated by innate rules that cannot be acquired by general-purpose systems that learn solely by virtue of associations among environmental events. Chomsky claims that support for the role of innate rules comes from the errors children and other language learners make in forming the past tenses of irregular verbs; for example, "goed" instead of "went" or "eated" instead of "ate." Because children have never heard such words (the adults they listen to do not speak them), the words cannot have been acquired through experience; rather, they must be produced by a rule that the child has abstracted in the course of learning his or her native tongue. If computers are to have a language capacity, they must be programmed with these kinds of rules; they will never learn language without some rule-based cognitive structure. Recently, however, connectionist models of language have been developed that have no rules of syntax and operate solely by associationistic principles but that make precisely the errors that are traditionally attributed to the operation of grammatical rules. If so, the implication may be that human language is special after all: It is something that can be

done by any associationistic learning system that possesses sufficient computational power. Proponents of rules have criticized these demonstrations as misleading and unrepresentative of people's actual language use. For example, the model makes mistakes that children do not make, and it learns by virtue of inputs that do not resemble children's actual learning environments. Because the capacity for language is so central to our traditional conception of what it means to be human, the debate between rules and connections is likely to be vigorous and protracted.

H. Judgment, Reasoning, and Problem Solving

Thinking played a prominent role in early psychology. The structuralist school of Wundt and Titchener was almost consumed by a fruitless debate over imageless thought, whereas Oswald Kulpe's act psychology attempted to characterize the process of thinking rather than the static elements of thoughts. Like other mentalistic topics, thinking dropped out of sight with the rise of behaviorism, but interest in the topic was preserved by Gestalt psychologists such as Kohler, who worked on problem solving in chimpanzees. Whereas behaviorists construed thinking as a matter of gradual trial-and-error learning, the Gestaltists emphasized sudden insights produced by a cognitive restructuring of the problem at hand. In England, Frederick C. Bartlett argued that perception and memory were essentially exercises in problem solving—the problem being to construct mental representations of the present and to reconstruct mental representations of the past. After World War II, the cognitive revolution was heralded by Bruner's work on concept learning, Jean Piaget's research on the development of thought in children, and the work of Herbert Simon and Allan Newell on computer simulations of human problem solving.

Much early research on thinking was guided, at least tacitly, by a normative model of human rationality that held that people reason according to a logical calculus and make rational choices based on principles of optimality and utility. According to the classical view of concept structure, for example, people categorize objects according to lists of defining features that are singly necessary and jointly sufficient to define category membership. In classical decision theory, individuals calculate the costs and benefits to themselves of various options and then make choices that maximize their gains and minimize their losses as efficiently as possible. Much work on reasoning was dominated by the search for algorithms: Logical, systematic rules, analogous to recipes, that specify how information should be combined to yield the correct solution to whatever problem is at hand.

Although normative rationality provided a reasonable starting point for developing theories of human reasoning and problem solving, many human judgments must be made under conditions of uncertainty, where there is no algorithm applicable or where the information needed to apply an algorithm is unavailable. Other judgments must be made under conditions of complexity, where there are simply too many choices available, or too many factors entering into each choice, to permit evaluation according to some judgment algorithm. Under such conditions, people tend to rely on judgment heuristics, which are shortcut "rules of thumb" that bypass normative rules of logical inference and thus permit judgments without recourse to algorithms. One such heuristic, associated with the work of Herbert Simon on organizational decision making, is satisficing: Instead of conducting an exhaustive search for the optimal choice, a judge may terminate search as soon as the first satisfactory option is encountered. Prototype or exemplar matching constitute heuristics for categorization: Instead of consulting a list of defining features that are singly necessarily and jointly sufficient to assign an object to some category, people compare the object at hand to a "typical" instance, or indeed to any instance at all.

Although appropriate algorithms are guaranteed to deliver the correct solution to whatever problem is at hand, use of heuristics incurs some risk of making an error in reasoning or judgment. Analysis of common judgment errors, such as the "gambler's fallacy" described by Daniel Kahneman, Amos Tversky, and others, has documented many other commonly used judgment heuristics. Representativeness permits judgments of category membership, similarity, probability, and causality to be based on the degree to which an event resembles the population of events from which it has been drawn. Availability permits judgments of frequency and probability to be based on the ease with which relevant examples can be brought to mind, whereas simulation bases judgments on the ease with which plausible scenarios can be constructed. In anchoring and adjustment, initial estimates are taken as reasonable approximations to the final result of some calculation.

These and other effects show that the principles of cognitive functioning cannot simply be inferred from abstract logical considerations; rather, they must be

inferred from empirical data showing how people actually perform. Research shows that people commonly depart from the principles of normative rationality, but what should be made of these departures? Although Aristotle defined humans as rational animals, one possible conclusion from empirical studies is that people are fundamentally irrational—that human judgment, reasoning, choice, and problem solving are overwhelmed by many fallacies, illusions, biases, and other shortcomings. At best, according to this argument, most people are "cognitive misers" who use as little information, and as little cognitive effort, as possible in their lives; at worst, people are just plain stupid—incapable, without extensive instruction (and perhaps not even then), of conforming themselves to the principles of logic and rationality.

This pessimistic conclusion about human nature is reminiscent of Sigmund Freud's argument at the turn of the 20th century that human rationality is derailed by unconscious affects and drives. On the other hand, it is possible that the case for human irrationality has been overstated. For example, the philosopher Jonathan Cohen questioned whether the formal laws of deductive and probabilistic reasoning are properly applied to the problems that people actually encounter in the ordinary course of everyday living. Herbert Simon concluded that human rationality is bounded by limitations on human information-processing capacity (as demonstrated, for example, by George Miller's famous essay on "the magical number seven, plus or minus two"). From this perspective, it is simply unreasonable to hold humans up to an impossible standard of unbounded rationality of a sort that might characterize a computer, which has the capacity to search and calculate for as long as it takes to deliver a "logical" result. Relatedly, Gerd Gigerenzer and colleagues argued that "fast and frugal" judgment heuristics succeed more often than they fail because they are appropriately tuned to the structure of the environments in which people actually operate. From this perspective, most "fallacies" in human reasoning emerge in performance on laboratory tasks that do not adequately reflect the real world in which judgment heuristics work. On the other hand, some evolutionary psychologists have argued that judgment heuristics are part of an "adaptive toolbox" of domain-specific cognitive devices (or modules) that evolved in the "environment of evolutionary adaptedness"—namely, the African savanna of the late Pleistocene era, approximately 500,000 years ago—to help our hominid ancestors solve fundamental problems of survival and reproduction.

III. COGNITIVE DEVELOPMENT

Compared to other mammals, human beings are born with relatively immature brains; moreover, physical development continues even after brain development has essentially completed. These facts raise the question of how the intellectual functions characteristic of the human adult arise in the first place (and, from a life span perspective, whether, how, and to what extent cognitive skills are lost through aging).

A. The Ontogenetic View

From an ontogenetic point of view, tracing the growth of cognition in the individual organism, cognitive development has recapitulated the debate between nativism and empiricism that has dominated cognitive psychology at large. From the empiricist perspective, the child is a *tabula rasa* who acquires knowledge and skills with learning and experience. From the nativist perspective, even neonates possess at least primitive cognitive faculties, which develop further from interaction with the environment. The tension between nativism and empiricism can be clearly seen in the debate, discussed earlier, regarding whether language acquisition is mediated by innate grammatical rules or by a general-purpose associative learning mechanism.

A new perspective on cognitive development, combining elements of both nativism and empiricism, was offered by Jean Piaget, who proposed that children enter the world with a rudimentary set of reflex-like cognitive structures, called sensory motor schemata, through which they interact with the world. Environmental events are interpreted through prevailing cognitive schemata, but they also force these schemata to change in order to cope with an increasingly complicated stimulus environment. Through the cycle of assimilation and accommodation, the child moves through many qualitatively different stages, each highlighted by a particular cognitive achievement. The milestone marking the end of the sensory motor stage, at about 18 months of age, is object permanence—the ability to deal with objects that are not present in the immediate physical environment. The end of the preoperational stage, at about age 7, is marked by conservation—the ability to appreciate that quantities remain constant despite changes in physical appearance. The transition from concrete operations to formal operations, at about age 12, is marked by the

child's ability to comprehend abstract concepts and formal logical relations.

According to Piaget, the child proceeds through these stages of cognitive growth in a strict sequence: Some tasks, requiring abilities characteristic of later stages, are simply impossible for a child who is still at an earlier stage. Such a proposal was bound to be challenged, and indeed later experiments employing extremely subtle measures often showed that, as a 1993 cover story in Life magazine stated, "Babies are smarter than you think." For example, 7-month-old infants may not reach for the spot where a toy has been hidden, but they do stare at it, indicating that they have some sense of object permanence. Similarly, when a mouse hidden behind a screen is joined by a second mouse, 5-month-olds show surprise when the screen is removed to reveal only one mouse, suggesting that they have some ability to conserve number.

Results such as these suggest to some theorists that infants enter the world with a surprisingly sophisticated fund of innate knowledge about the world that is refined and elaborated through experience. What develops, then, is expertise: The infant starts out as a novice with respect to objects, numbers, and so on. Development proceeds with continuous increases in motor control and information-processing capacity and also with increased opportunities for learning through experience. Infants reach for the hidden toy not because they have acquired object permanence but because they have acquired the ability to coordinate their actions with their thoughts. Recent experiments, however, indicate that infants' appreciation of object permanence is incomplete. Developing children acquire new knowledge and skills, not just the ability to use innate knowledge and skills more efficiently and effectively.

Development also entails the acquisition of metacognition—one's knowledge of what one knows, how one's own mind works, and how this knowledge can be deployed strategically in the service of adaptive behavior. Metacognitive knowledge is sometimes characterized as a theory of mind, a phrase that recalls Piaget's argument that children, no less than adults, function as naïve scientists. From the first moments of life, children are constantly trying to understand themselves and the world around them, including other people, by generating hypotheses, testing them empirically, and refining their theories accordingly. The "theory" theory, as it is sometimes called, makes clear that cognitive development is not just something that happens passively to the child by virtue of maturation, learning, and the activities of adults. Rather, the child takes an active role in his or her own development, instigating the very interactions that promote cognitive growth.

B. Language, Culture, and Thought

Cognitive development can also be viewed in cultural terms. Cognitive anthropology had its origins in the efforts of Lucien Levy-Bruhl, Franz Boas, W. H. R. Rivers, and others to determine whether there were differences in the thought patterns characteristic of members of "primitive" and "advanced" cultures. Some early Soviet psychologists, such as Lev Vygotsky and Alexander Luria, attempted to trace the effects of economic development on how people think. In view of the central role of language in culture, considerable effort has been devoted to the question, initially raised by the American anthropologists Edward Sapir and Benjamin Whorf, whether there are cognitive differences between speakers of different languages. This is not a matter of "development" per se because all languages are equally complex: It is merely a matter of language and culture.

The Sapir–Whorf hypothesis takes two forms: That language determines thought or that language influences thought. The former is a much stronger view because it states that one is incapable of understanding a concept for which the language has no name (it also implies that there is no thought without language). There is no empirical evidence supporting the strong version and considerable evidence that thought can proceed without benefit of language. However, the weak version plausibly suggests that different languages can "carve up" the world into different ways or, in other words, that conceptual thinking can be shaped and constrained by available linguistic categories. As Whorf stated,

> *We cut nature up, organize it into concepts, ascribe significance as we do, largely because we are parties to an agreement to organize it in this way—an agreement that holds throughout our speech community and is codified in the patterns of our language.*

There are actually two aspects to the Sapir–Whorf hypothesis: Linguistic relativity and linguistic determinism. Relativity refers to the claim that speakers are required to pay attention to different aspects of the world that are grammatically marked (e.g., shape classifiers in Japanese or verb tenses to indicate time).

Determinism claims that our cognitive processes are influenced by the differences that are found in languages. The most famous example of the Whorf hypothesis, and the most erroneous, is Whorf's observation that Eskimos have many words for snow, implying that because they live in a snowy environment they need to make finer distinctions for the different types of snow. However, American skiers also have different words for snow, so the example is not as remarkable as it first may appear because expertise leads to larger vocabularies for certain domains.

In a classic test of the Sapir–Whorf hypothesis, Paul Kay and colleagues compared English speakers with Tarahumara speakers. Tarahumara is an Uto-Aztecan language of Mexico that does not have a separate color term for blue and green. In the first experiment, the subjects were presented with a blue color chip, a green color chip, and another color chip that was intermediate to blue and green. English speakers sharply distinguished the intermediate color chip into either blue or green by using a naming strategy, whereas the Tarahumara speakers chose randomly. In the second experiment, English speakers were first presented with two color chips and shown that one (intermediate) was greener than the other color chip (blue), and then they were shown that the same intermediate chip was bluer than the other color chip (green). By making the subjects call the intermediate color chip both green and blue, the bias that was demonstrated in the first experiment was removed and the English speakers performed similarly to the Tarahumara speakers.

The influence of language on how we think about the events that happen in our world can be demonstrated in experiments other than those designed to confirm or disconfirm the Whorf hypothesis. Classic work by Leonard Carmichael and colleagues demonstrated that subjects had different systematic distortions in their recall of ambiguous line drawings depending on which verbal label they were given (e.g., dumbbells or eyeglasses). Experiments on eyewitness testimony by Elizabeth Loftus and others showed that by varying the verb (e.g., ''crashed'' or ''hit'') one can manipulate the estimated speed of the traveling car given by the subjects. Whorf became interested in language when he noticed that behavior around gasoline drums changed when the drums were called ''empty'' even though they contained dangerous vapors. Because the word *empty* connotes ''lack of hazard,'' careless behavior from the workers resulted in fires from the tossing of cigarette stubs or smoking by the workers.

Beyond the influence of language on categories, the linguist George Lakoff's work on metaphors offers another way of testing the Sapir–Whorf hypothesis without depending on the idea that language carves the world into different pieces and, as he stated, ''cultures differ only in the way they have their meat cut up.'' Though some metaphors are universal (e.g., love is warmth), not all cultures share the same metaphors. Future research on the Sapir–Whorf hypothesis should be less reliant on the differences between ''exotic'' and ''nonexotic'' languages, a paradigmatic focus which sometimes implies that speakers of the exotic language are cognitively deficient.

C. The Phylogenetic View

Cognitive development can also be approached from a phylogenetic perspective, tracing the relations between the intellectual functions of human children and adults and those of other animals, especially the great apes, whose genetic endowment is similar to our own. There is a vigorous debate over whether chimpanzees and gorillas have anything like the human capacity for language, but it is clear that these and other animals do have the ability to acquire symbolic representations of objects, events, and concepts—similar to semantics, if not syntax as well. Pigeons can be taught to categorize a wide variety of objects, including trees, people (and their emotional expressions), fish, flowers, and automobiles. Studies of mirror recognition indicate that chimpanzees possess a rudimentary concept of self, and the notion of a ''theory of mind'' initially arose from observations that chimpanzees had the ability to attribute mental states to others of their kind. Setting aside the question of whether other species have a capacity for language, it is clear that the behavior of nonhuman animals, especially those who are closest to us in the evolutionary scheme of things, is not just a matter of innate and conditioned responses; some of them, at least, have cognitive capacities not unlike our own.

IV. COGNITION BEYOND PSYCHOLOGY

The cognitive revolution in psychology was paralleled by the development of the field of cognitive science, whose practitioners included philosophers, linguists, computer scientists, neuroscientists, behavioral biologists, sociologists, anthropologists, and psychologists. In some sense, the rise of cognitive science may have been a reaction to the dominance of behaviorism

within psychology: Many who wished to pursue a science of mental life may have believed that they would have to go outside psychology to do so. By the same token, it seems reasonable to hope that the combined efforts of many different disciplines are more likely to yield a better understanding of cognitive processes than any one working in isolation.

Whereas some early cognitive psychologists viewed the computer as a model of the human mind, some early cognitive scientists believed that it offered the prospect of implementing the "mechanical mind" debated by philosophers at least since the time of Descartes. In the formulation of the philosopher John Searle, work on artificial intelligence (AI) takes two broad forms. In "weak" AI, the computer provides a vehicle for writing formal theories of the mind, which can be tested by pitting the results of a computer simulation against the data of actual human performance. In terms of formal precision of its theories, weak AI is cognitive psychology at its best. In contrast, "strong" AI entails the notion that computer programs can, in principle, really think just as humans do. The program of strong AI has its origins in the proposal by Alan Turing that appropriately programmed computers are capable of performing any explicitly stated cognitive task: A machine would pass the Turing test if its responses were indistinguishable from those of a human being. Searle believes that the program of strong AI is seriously misguided—a position that is opposed with equal vigor by other philosophers such as Daniel Dennett.

Recently, research in AI has shifted from an effort to make machines think the way humans do to an effort to allow machines to "think" however they are capable of doing so, regardless of how humans might accomplish the same task. Thus, in May 1997 Deep Blue, a supercomputer programmed by IBM, was able to beat the world champion Gary Kasparov at chess, but nobody claimed that Deep Blue played chess the way Kasparov (or any other human) did. Cognitive psychology remains an important component of cognitive science. However, to the extent that it seeks to develop intelligent machines on their own terms, without reference to human intelligence, cognitive science departs from cognitive psychology.

Cognitive science, which once was dominated by behavioral experiments and computational models, has recently reached "down" to strengthen its connections to neuroscience. At the same time, neuroscience, which once was preoccupied with events at the molecular and cellular levels, has reached "up" to take an interest in the organismal level of experience, thought, and action. Both trends have been aided by the development of brain imaging techniques, such as positron emission tomography, functional magnetic resonance imaging (fMRI), and magnetoencephalography (MEG), which open windows to the brain as it is engaged in complex cognitive activities such as perceiving, remembering, imaging, and thinking. Particularly promising is the combination of the high spatial resolution of fMRI with the high temporal resolution of MEG. Just as earlier investigators discovered specific cortical areas specialized for vision, hearing, and so on, a new generation of brain researchers have uncovered specific areas activated in such activities as language comprehension, mathematical computation, analytical reasoning, and working memory.

The advent of new brain imaging techniques promises to solve the ancient mind–body problem, but they also present the danger of lapsing into a kind of high-technology revival of phrenology. In the final analysis, brain imaging can only reveal which areas of the brain are activated when experimental subjects engage in particular tasks, such as lexical decision and mental arithmetic. Discovering what these areas do requires a careful analysis of the experimental tasks employed in the imaging study, and this is a matter for cognitive psychology. If researchers do not have a correct description of the components of the task at the cognitive and behavioral level, they will reach erroneous conclusions concerning the cognitive functions of various parts of the brain. Solving the mind–body problem is not just a matter of building bigger magnets, resolving the details of neurochemistry, and ruling out physiological artifacts. Genuine advances in cognitive neuroscience depend on continued progress in cognitive psychology so that brain researchers can work with tasks that are well understood.

Even within the social sciences, it is clear that cognition is not just for psychologists anymore (if it ever was). Linguistics, traditionally concerned with the discovery of linguistic regularities and the origins of words, has increasingly worked to understand language as a tool of thought and means of sharing ideas. Economics, once concerned solely with the abstract description of economic systems, has recently turned its attention to individual economic decision making (and, in the process, drawing on the insights of psychologists such as Tversky and Kahneman). For cognitive sociologists, social conventions and norms create a framework in which individuals think their thoughts. By the same token, cognitive anthropologists are willing to entertain (and test) the hypothesis that cultural differences entail differences in modes of

thought as well as differences in beliefs and behavior. Sociology and anthropology have challenged the doctrines of individualism and universalism, which have traditionally dominated psychological approaches to human thought.

V. BEYOND COGNITION: EMOTION AND MOTIVATION

Cognitive psychology is about knowing, but knowing is not all that the mind does. In his Critique of Pure Reason (1791), the philosopher Immanuel Kant proposed that there are three "faculties of mind," knowledge, feeling, and desire. Each of these enters into a causal relationship with behavior, and none is reducible to any other. If Kant is right, then cognitive psychology cannot be all there is to psychology: The principles of cognition must be supplemented by principles of emotion and motivation. In fact, some cognitive psychologists have argued that Kant is wrong, and that our emotional and motivational states are the by-products of cognitive activity. For example, prominent cognitive theories of emotion hold that our emotional states are essentially beliefs about our feelings. In other words, cognitive theories of emotion hold that our emotional states depend on our interpretation of environmental events and our own behaviors. As William James famously stated, we do not run from the bear because we are afraid; we are afraid because we run from the bear. In response, some theorists have argued that emotions are not dependent on cognitive processing but, rather, are governed by their own independent systems. To some degree, such proposals reflect a reaction to the hegemony of the cognitive point of view within psychology. At the same time, the question of the independence of emotion and motivation from cognition is a legitimate one, and has given rise to a new interdisciplinary field, affective neuroscience, proceeding in parallel with cognitive neuroscience.

Regardless of how the independence issue is resolved, it is clear that cognitive processes can influence emotions and motives. Emotions can be induced by remembering past events, and they can be altered by construing events differently. Certain "counterfactual" emotions, such as disappointment and regret, require that the person construct a mental representation of what might have been. Although some emotional reactions may be innate and reflex-like, others are acquired through conditioning and social learning. As noted earlier, there is evidence that some emotional states, such as anxiety and depression, result from the perception that environmental events are unpredictable or uncontrollable; they may disappear when such beliefs are corrected. Surgical patients' fears can be allayed (and the outcome of treatment improved) if their doctors carefully explain what is going to happen to them and why it is necessary. The ability to use cognitive processes to regulate one's own feelings and desires is an important component of emotional intelligence.

On the other hand, it is clear that emotional and motivational states can have an impact on cognition. In an important sense, the "affective revolution" in psychology was initiated by studies of the effects of mood on memory; these led psychologists to become more interested in the nature of the moods. Five such effects have been well documented: The affective intensity effect (better memory for positive or negative events compared to neutral events), the affective valence effect (better memory for positive than for negative events), mood-congruent memory (better memory for material whose affective valence matches the mood in which it is encoded or retrieved), resource allocation effects (depression impairs performance on effortful, but not automatic, aspects of memory function), and mood-dependent memory (memory is better when there is congruence between the emotional state present at the time of encoding and the state present at the time of retrieval). Although clinical lore holds that emotional trauma can render people amnesic, the overwhelming finding in both the clinical and the experimental literature is that traumatic experiences are remembered all too well.

There is also a growing literature on the emotional effects of other cognitive processes, such as perception and judgment. Signal-detection theory has demonstrated that goals and motives can percolate down to affect the most elementary psychological functions. Common metaphors speak of happy people viewing the world through rose-colored glasses and that things look dark when we are unhappy; in fact, mood and emotion do seem to serve as filters on perception, just as they do on memory. Similarly, emotions have a considerable effect on judgment and decision making. Prospect theory, proposed by Kahneman and Tversky as an alternative to rational choice, holds that decisions are affected by the way in which choices are framed, and emotions and motives form an important element in these frames. Happy people are more likely to take risks than are unhappy people. Even if feelings and desires prove to be largely independent of knowledge and belief, the interest of cognitive psychologists

in our emotional and motivational lives gives eloquent testimony to the breadth of the field as it approaches its second half-century.

Cognitive Rehabilitation

STEPHANIE A. KOLAKOWSKY-HAYNER and JEFFREY S. KREUTZER
Virginia Commonwealth University

GLOSSARY

cognition The process of understanding and functioning within the world, including complex skills such as orientation, initiation, attention, concentration, learning, memory, perception, communication, comprehension, self-monitoring, problem solving, and reasoning.

compensatory strategies Skill- and strength-focused rehabilitation technique including the use of external aids to offset cognitive and psychomotor impairments and improve daily living activities.

generalization The ability to apply previously learned material to a variety of novel contexts.

prosthetic device An external aid used to offset cognitive problems arising from neurological impairment; includes use of microcomputer organizers, filing systems, and lists.

supported employment A functional approach to cognitive rehabilitation incorporating a variety of rehabilitation strategies, characterized by the presence of an employment specialist working directly at the job site.

transfer The ability to apply previously learned material to similar contexts; it is *positive* when learning in one context is applied to another context, and it is *negative* when learning in one context, and it is hinders learning in another context.

Cognitive rehabilitation is a comprehensive, holistic approach to improving and restoring impaired mental, psychomotor, and behavioral functioning. Cognitive rehabilitation is most frequently used after postconcussion syndrome, head injury, and other neurological conditions. Clients are made aware of changes in their cognitive abilities and taught to recognize impairments. Cognitive rehabilitation enhances a client's ability to compensate for lasting impairments.

I. INTRODUCTION

Ongoing advances in medical care and medical management, following an insult to the brain (e.g., brain injury, tumor, and stroke), have increased clients' likelihood of survival. Although more clients are surviving, they are faced with numerous enduring physical, cognitive, and behavioral difficulties. Often, life quality is also diminished due to impaired functional skills. Most survivors are unable to return to work or school, live independently, support themselves financially, or participate in social activities. In order to ameliorate functional problems, and increase the likelihood of return to productive living, many clients participate in a program of cognitive rehabilitation.

Cognitive rehabilitation includes a variety of approaches and techniques, including computer training, memory retraining, social skills training, life skills training, use of prosthetic devices, stimulation therapy, process training, attention and concentration training, stimulus response conditioning, strategy training, domain-specific training, cognitive cycle techniques, enhancement of physical and emotional health and social functioning, and nutrient and drug treatment. However, given the numerous approaches, development of a standard treatment protocol has

been unsuccessful. No consensus exists regarding which approaches or techniques should be used.

There are few research studies regarding cognitive rehabilitation techniques, and these have limited generalizability. For example, studies often used single-subject designs, selectively enrolled clients, and showed therapy benefits in terms of only paper-and-pencil tests. Studies have not been consistent regarding efficacy, do not provide long-term outcome information, and do not adequately describe therapy candidate characteristics. Furthermore, most prior research has failed to recognize and control for the factors influencing cognitive rehabilitation, including a person's physiological state, perceptual skills, emotional status, level of motivation, and social states (e.g., marital status, education level, and socioeconomic status).

II. NEUROBEHAVIORAL PROBLEMS

Persons with brain injury and other neurological conditions often experience lasting neurobehavioral problems. Cognitive deficits may include impairments in orientation, initiation, attention, concentration, discrimination, perception, learning, memory, and reasoning. Behavioral problems may include lack of motivation, inhibition, poor self-monitoring, irritability, apathy, aggressiveness, depression, lack of awareness, restlessness, unusual sexual behavior, and substance abuse. Physical difficulties may include fatigue, motor slowness, and diminished coordination.

Neurobehavioral sequelae are a consequence of both the client's reaction to loss of ability and neurophysiological changes in the brain. Researchers have found that behavioral and emotional problems cause greater impairments in family and emotional functioning than neuropsychological and physical disabilities. Behavioral problems related to depression, anxiety, and social withdrawal have been shown to be predominant.

Although some problems are resolved relatively early postinjury, deficits have been known to persist for a decade or more. The most common long-term difficulties include lack of social contact, personality change, slowness, decreased initiation, poor memory, restlessness, irritability, and bad temper. Persons injured before age 20 tend to have significantly more long-term difficulties. Persistent cognitive, behavioral, and physical problems impede employment and productive living after injury or neurologic insult.

III. COGNITIVE REHABILITATION TECHNIQUES

Cognitive rehabilitation techniques are often geared to three broad categories: restore, substitute, or restructure. Techniques for restoring cognitive functions include cognitive training and exercises directed toward strengthening and the reestablishment of impaired abilities. Substitute techniques commonly include external prosthetic devices and compensatory strategies utilized in place of impairments, which do not attempt to ameliorate impairments. Lastly, restructure techniques reorganize the client's environment in order to compensate for impairments. The following are examples of the most common cognitive rehabilitation techniques and approaches:

- ***Computer training*** utilizes multipurpose software for assessment, treatment planning, treatment, data analysis, progress recording, and reporting. Multimedia applications are also used for education and simulation.
- ***Memory retraining*** often involves teaching a client to use rehearsal techniques to maintain information within memory.
- ***Social skills training*** primarily involves training conversation tracking skills, eye contact, initiation, attention, and appropriate behavioral skills.
- ***Use of prosthetic devices*** involves using external aids rather than retraining the cognitive deficit (e.g., memory watch, calculator, tape recorder, pill organizer, and voice recognition software).
- ***Stimulation therapy*** is the oldest type of cognitive rehabilitation. It involves direct retraining through paper-and-pencil exercises and computer programs that require one or more mental skills.
- ***Process training*** is similar to stimulation therapy but is designed to improve only one specific aspect of cognition.
- ***Attention and concentration training*** is designed to improve one's ability to focus attention, maintain vigilance, resist distraction, and perform mental manipulations quickly and efficiently.
- ***Stimulus–response conditioning*** involves the identification of rewards and punishments and then either providing or withholding these in order to affect some desired change.
- ***Strategy training*** involves the teaching of mental sets that are applicable in other situations (e.g., mnemonics, conversation skills, and problem-solving skills).
- ***Domain-specific training*** provides guidance with the use of simulated life experiences or within a specific

functional domain (e.g., computer-simulated driving).

- ***The cognitive cycle technique*** is a five-step process for retraining complex executive functioning skills. The five steps include having the client identify goals, determine methods of achieving the goals, act to achieve goals based on chosen method, assess progress, and, if necessary, repeat the process until the desired goal is achieved.
- ***Enhancement of physical and emotional health and social functioning*** is an indirect approach that focuses on changes to one's overall lifestyle (e.g., stress reduction, better nutrition, exercising regularly, and getting enough sleep and relaxation).
- ***Nutrient and drug treatment*** is a relatively new approach involving the use of various drugs and nutrients believed to improve brain functioning to treat cognitive deficits (e.g., nootropics, vasodilators, mechanism-based drugs, nutrients, herbs, minerals, antioxidants, and vitamins).

IV. PRACTICAL ISSUES

A. Who Provides Therapy?

To date, there are few education programs specializing in cognitive rehabilitation. Persons qualified to provide cognitive rehabilitation include psychologists, rehabilitation counselors, speech pathologists, occupational therapists, neuropsychologists, recreational therapists, rehabilitation nurses, psychiatrists, physical therapists, and other rehabilitation providers. Each specialty provides its own treatment approaches and diverse resources. Deciding which practitioner is best suited to help each client is a matter of personal judgment.

B. Generalization Issues

Generalization can be characterized into three distinct levels. Level 1 involves basic learning over trials, in which performance improves as training continues. The client should demonstrate the ability to transfer learning from one task to another similar task. The second level involves the transfer of learning to performance on psychometric tests measuring similar functional areas. For example, a client is trained to use maintenance rehearsal techniques (simple repetition of information) for memory and then incorporates similar behaviors while completing a verbal memory test. Lastly, level 3 includes transferring learning to general activities of daily living. For example, the client taught to use maintenance rehearsal techniques calls directory assistance for the phone number of a pizza place. He proceeds to repeat the number until he finishes dialing.

Cognitive rehabilitation has been shown to provide adequate training such that clients are able to transfer previously learned material to similar contexts. However, the most controversial issue regarding the efficacy of cognitive rehabilitation is level 3 generalization, the ability to apply previously learned material to a variety of novel contexts. For example, outcome studies often use paper-and-pencil tests to measure the benefits of cognitive rehabilitation, and it has been difficult to determine whether such test results translate into meaningful functional abilities. Furthermore, difficulty arises when trying to measure real-life contexts. Vocational rehabilitation settings provide potential real-world assessment arenas; however, obtaining a truly randomized and controlled sample would be nearly impossible.

C. Assessing Rehabilitation Potential

Who should be a candidate for cognitive rehabilitation? Clinicians often confront a series of questions. For example, is the client out of a coma? Is he or she medically stable and out of crisis? What was his or her preinjury level of functioning? What is his or her current level of functioning? Are his or her perceptual skills intact? Will he or she be able to attend to a therapist for any length of time and, if so, for how long? Is the client combative, apathetic, depressed, or aggressive? Are there any secondary gain issues (e.g., settlement, worker's compensation, and retirement secondary to disability)? What social supports does the client have? Is the client likely to improve with rehabilitation?

Most of these questions are easily answered via medical record review, neuropsychological testing, and client/informant interview. However, there is no clear-cut, standardized method for determining who will benefit from cognitive rehabilitation and who will not. When making such a decision, a clinician must consider the following: First, when improvement is demonstrated, improvement is likely with intervention. For example, if a client performs progressively better on the second and third trials of a task but is still exhibiting impairment relative to preinjury levels, this

area will likely benefit from training. Second, when improvement is not demonstrated, intervention will most likely be ineffective and frustrating. For example, when the client has difficulty learning across multiple trials, additional trials will most likely not improve functioning but will probably diminish enthusiasm and increase aggravation. Alternate training approaches should be taken. Third, start rehabilitating stronger areas, and increase difficulty of tasks with progress. A clinician should determine the client's strengths and weaknesses. Rehabilitation of a semi-intact skill will prove easier than rehabilitation of a completely impaired skill. Fourth, concentrate on steep learning curves, not high performance levels. A steep learning curve exists when a client gradually learns a little more information at each training session or across each trial (Fig. 1). Such a curve suggests the client has a high learning potential and will likely benefit from intervention. Conversely, high performance levels are evident when the client makes a proverbial leap from learning almost nothing to knowing a great deal more and performs relatively consistently over time (Fig. 2). No more and no less learning occurs between trials.

D. Center-Based vs Community-Based Programs

Cognitive rehabilitation has been provided in a variety of settings, including acute hospitals, rehabilitation hospitals, skilled nursing facilities, outpatient rehabilitation clinics, and at clients' homes. Within the past 10 years, the scope of cognitive rehabilitation has grown tremendously. In the past, cognitive rehabilitation was provided primarily through center-based computer training of rote memory tasks. Recently, there has been a shift to real-world community-based programming with a more holistic approach. Currently, the ideal is to provide cognitive rehabilitation sessions along a continuum of care from the acute setting to outpatient and homebound settings.

Both center-based and community-based programs have advantages and disadvantages. Center-based cognitive rehabilitation programs often provide comprehensive, multidisciplinary assessment, treatment, and follow-up. However, they often provide canned programming and computer-based rehabilitation tasks and the programs are often artificial (e.g., clients performing office tasks in a hospital room). Community-based cognitive rehabilitation programs often occur in real-world settings, alleviating the problems with generalizability. However, real-world settings are highly variable and often unpredictable, challenging the effectiveness of therapy.

V. FUNCTIONAL APPROACHES

The main goal of cognitive rehabilitation is to enhance productive living by improving impaired daily living skills. Although the approaches and techniques previously discussed affect overall cognitive functioning,

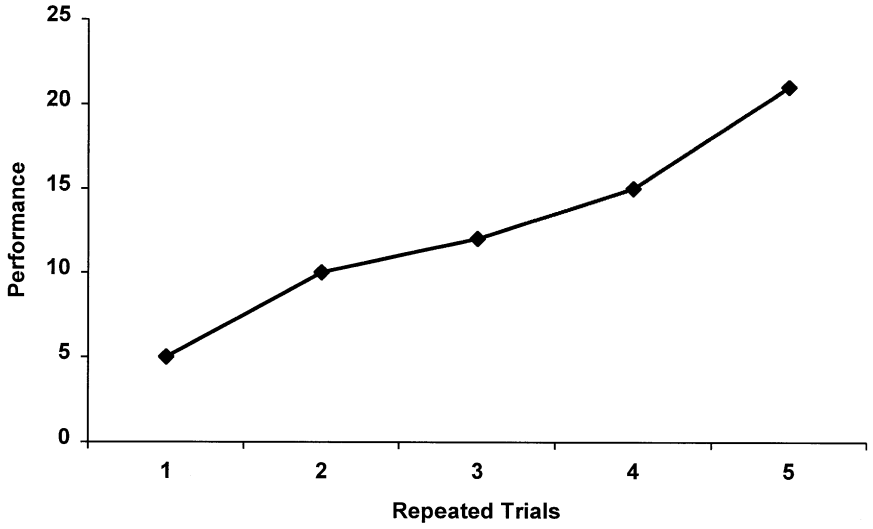

Figure 1 Example of a steep learning curve across learning trials.

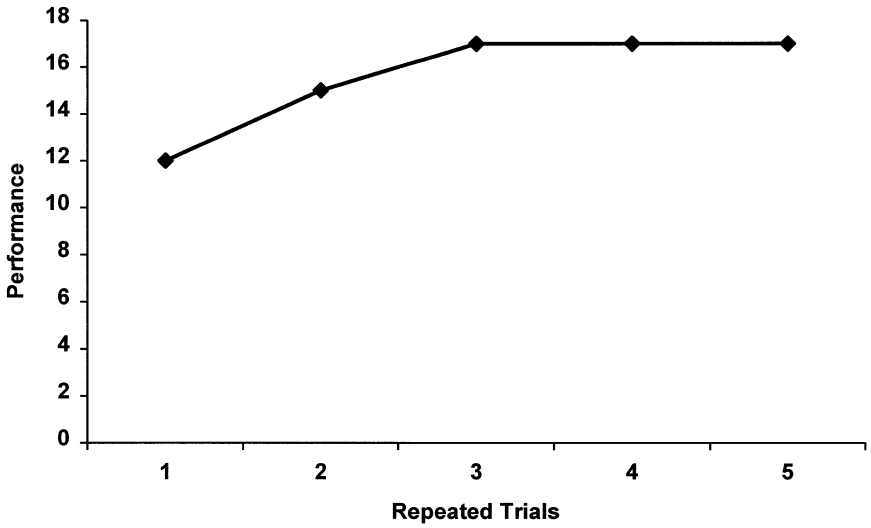

Figure 2 Example of high performance across learning trials.

the generalizability of such training is uncertain. Functional strategies have begun to be developed to assuage the generalizability issue. Within the past 10 years, clinicians and researchers have attempted to design new methods of training to counteract the most problematic issues faced by persons with neurological disorders—living and working independently.

A. Compensatory Strategy Training

Memory and psychomotor problems are extensive following brain injury and neurological impairment. Compensatory strategy training was developed to help persons with brain-related disabilities overcome impairments in daily living skills. People with brain dysfunction are trained to utilize external aids to compensate for impairment rather than working to improve the impaired skill. Compensatory strategy training is often used when clients' cognitive limitations and environmental barriers impede alternative types of treatment.

Compensatory strategy training utilizes and focuses on existing strengths to compensate for what the client cannot do. Clinicians often maximize client involvement in the development and use of strategies because less involvement results in hesitancy and reduces chances of success. For the client, understanding the utility of the strategy is helpful but not necessary. Selection and use of strategies will change over time and strategies are developed along a continuum of intrusiveness and complexity (e.g., the number of external cues is reduced over time following internalization). Clinicians are often cautious to ensure that the client is not taught too many strategies, resulting in inefficiency and confusion.

Compensatory strategy training typically provides rapid improvement in daily living skills, providing clients with increased self-esteem and feelings of accomplishment. The training is cost-effective given that only a limited number of sessions are needed for mastery of skills. Additionally, the minimal number of sessions makes it easier for clients with transportation problems to participate. Since training involves real-world activities, there are minimal assumptions about lack of generalization. Furthermore, client participation in the treatment process is increased and resistance is reduced because benefits are apparent.

As with any type of cognitive rehabilitation technique, clinicians must consider many factors prior to initiating compensatory strategy training. Specifically, one must consider motivation issues; cognitive and neurobehavioral impairments, especially memory dysfunction and adynamia (the inability to complete tasks), often due to lack of energy or interest; the number of environments in which behavior is expected to occur and similarity among environments; relevance to real-world requirements; and need for generalization from training environment. Failure to implement strategies may be due to the fact that the strategy was not matched to client's needs. The client

may not be convinced of the value or may hope that the problem will resolve quickly without intervention. Clients may go from a supportive training session to an unsupportive environment. Additionally, failure may be due to the client's unwillingness to practice the compensatory technique.

Many compensatory strategies are relatively simple and are often used by persons without disabilities. Examples of common compensatory strategies include the use of memory books, "wake up" services, pocket memo recorders, word processors, spell checkers, calculators, phone message pads, schedule books, financial management software, pill minder boxes with daily compartments, "to do" lists, alarm watches, shopping lists, and autodial phones.

B. Supported Employment

Supported employment is an individualized rehabilitation approach developed as a means of addressing the inadequacies of traditional employment methods. Originally developed to assist persons with psychiatric and intellectual disabilities, supported employment was adapted in the early 1980s for use with persons with brain dysfunction. Supported employment has become the standard of practice for many vocational rehabilitation professionals. The approach to vocational rehabilitation is well suited to illustrate the benefits of real-world cognitive rehabilitation efforts and the use of compensatory strategies. Despite progress in rehabilitation program development, return to work remains a formidable challenge, especially for persons with severe cognitive impairments. In many societies, employment is the basis of an adult's personal identity, with higher paying and more prestigious occupations affording higher levels of social recognition. Consequently, many unemployed persons with brain dysfunction view their recovery as incomplete or insignificant.

There are many variations of supported employment. Services are provided by job coaches or employment specialists. In contrast to traditional programs, which focus on job acquisition, emphasis is placed on helping people maintain jobs. Characteristics of the successful model include the following:

- ***Community placement and integration:*** Clients are helped to find and keep jobs in their home community by working in local businesses. In an effort to avoid segregation and promote widespread community integration, one to four clients work alongside nondisabled coworkers.
- ***Competitive hiring, wages, and benefits:*** Clients are hired through the same competitive process as other employees, such as by completing the employer's standard application form and attending an interview. Often, employment specialists help clients complete job applications, provide transportation, or prepare the client for an interview using role-playing techniques. Furthermore, workers with disabilities receive the same pay and benefits as coworkers.
- ***Emphasis on inclusion:*** Rather than excluding clients on the basis of mental health or behavioral or medical problems, an interdisciplinary team follows the client to meet needs for rehabilitation, medical care, and mental health services before and after placement.
- ***Holistic assessment of the client, home environment, and workplace:*** Assessment often includes a series of questionnaires completed by the client and family members; center-based and community-based interviews with clients, family, employers, and coworkers; and a comprehensive neuropsychological evaluation. Additionally, a job analysis is conducted in which the job coach visits each potential employment site and evaluates the characteristics of the workplace. A special effort is made to understand the exact nature of job responsibilities, the degree of interpersonal interaction with customers and coworkers, safety risks, and level of available supervision.
- ***Emphasis on choice and job matching:*** People, regardless of disability, are less likely to succeed at a job that is demeaning, meaningless, or boring. Although the client has the final choice regarding which job to apply for, the job coaches strive to match clients' goals, interests, and abilities with appropriate employment settings based on job analysis.
- ***Emphasis on intervention after placement:*** On average, 32–36 hr of intervention time occur prior to placement, whereas 240–260 hr occur within the first 6 months following placement. Ongoing behavioral and cognitive rehabilitation techniques are utilized within the workplace. Problems with memory are common after brain injury and severely limit generalization from preplacement training. Strategies such as self-monitoring, rehearsal, and reinforcement are used to teach and help generalize skills.
- ***Coworker and employer education:*** To alleviate negative attitudes, prior to placement the job coach provides the employer and coworkers with educational materials regarding the effects of brain injury and information concerning the client's positive

attributes. After placement, the job coach acts as a liaison between clients, coworkers, and employers, maintaining communication between all parties.

- ***Long-term follow-up:*** After placement, the client may face many difficult situations that all people face during employment. For example, there may be changes in personnel or job responsibilities. External life stresses may interfere with productivity. Job support and intervention fluctuate as new problems are encountered and resolved. Feedback from the client, supervisor, and rehabilitation team is considered in the determination of follow-up intensity. Early on, the employment specialist may spend the entire workday with the client to identify problems, develop methods of resolution, provide direct feedback, and reduce the client's stresses. With job mastery, the employment specialist "fades," reducing direct intervention time. After employment stabilization (e.g., 6 months following placement), follow-up may require 2 or 3 hr per month.
- ***Job completion guarantee:*** Prior to employment, job coaches assert that clients will meet work responsibilities. A system of checks and balances is employed by the coach, including having the job coach work alongside the client to make certain job goals are met.
- ***Intensive ongoing analysis of program outcome:*** To ensure efficacious supported employment programming, ongoing data collection and analysis are essential. Program data include typical information such as injury severity, age, time elapsed since injury, employment status, and wages. In addition, the following information is collected: hours and types of intervention, employers' and clients' performance and satisfaction ratings, reasons for job separation, factors promoting successful work outcome, and level of employment stability.

C. Supported Living

The success of supported employment inspired the development of supported living programs. Instead of relying on job coaches, clients are afforded the help of a life skills trainer or specialist. The life skills trainer uses cognitive rehabilitation techniques to teach living skills, which may include cooking, cleaning, financial management, personal hygiene, use of public transportation, time management, first aid, driving, shopping, laundry skills, medication management, and appliance safety. Supported living programs are often centered in apartment buildings or homes that can accommodate 4–10 clients and several life skills trainers. Successful clients are gradually transitioned to greater independence, and many ultimately live on their own.

Color Processing and Color Processing Disorders

PETER GOURAS
Columbia University College of Physicians and Surgeons

GLOSSARY

achromatic contrast Gradients of energy in an image resulting in black–white vision.

achromats Subjects who have either only short-wave-sensitive or no cones; they have no color vision.

chromatic contrast Gradients of wavelength in an image responsible for color vision.

color opponency Colors that cancel each other when mixed, such as red and green or blue and yellow.

cone opponency Signals from two spectrally different cones that have opposite effects on the same neuron (i.e., one cone signal excites and the other inhibits the neuron).

deuteranopes Subjects who lack middle-wave-sensitive cones; their color vision is also divariant (about 1% of males).

opsins Proteins in photoreceptors that absorb light and trigger a neural response.

protanopes Subjects who lack longwave sensitive cones; their color vision depends on two variables and is divariant (about 1% of males).

successive color contrast Enhancement of a color appearing just after another color disappears (i.e., red is redder when it appears just after green goes off).

simultaneous color contrast Enhancement of a color when next to another color (i.e., reds are redder when surrounded by green).

tritanopes Subjects who lack short-wave-sensitive cones; they are also divariant but extremely rare.

trivariance The fact that normal human color depends on only three variable—the three different types of cones.

Color vision is a neural process occurring in our brain that depends on a comparison of responses of at least two, but normally three, spectrally different cone photoreceptors. The brain uses these cone systems to detect achromatic and chromatic contrasts. Achromatic contrasts depend on light energy gradients across an image; chromatic contrasts depend on wavelength gradients of light across an image. Achromatic contrast is detected by the two longer but not by the short-wave-sensitive cones; in the fovea, achromatic contrast can resolve the dimensions of neighboring cones (about 1 μm on the retina). Chromatic contrasts are detected using all three types of cones and is done by comparing their responses to the same object. From an evolutionary perspective, the first comparison was between the short- and the longer wavelength-sensitive cones creating blue/yellow color vision. This still occurs in most mammals and in about 2% of human males. In this case, if an object affects the short-wave more than long-wave cones, it appears blue. The converse appears yellow. If the object affects both cone

systems equally, it appears white, gray, or black. In the Land color vision model this comparison between cone signals occurs after each cone system's response is normalized over visual space. The second comparison evolved in primates when the longer wave cones were split into long- and middle-wave cones; this created red/green color vision. If an object affects the long-wave more than the middle wave-sensitive cones, it appears red. The converse appears green. If an object affects both of these cones equally, it appears yellow, white, or bluish depending on the former comparison. Color vision compares responses of groups of cones rather than single neighboring cones; it has a lower spatial resolution than achromatic vision. The neural processing responsible for color perception occurs in visual cortex. The retina and the lateral geniculate nucleus provide the signals from each cone mechanism in a form that allows the comparisons necessary for color vision. Our brain combines cues from both chromatic and achromatic contrast to perceive a particular color. There are several different mechanisms involved. One depends on the blue/yellow and red/green comparison signals and is most related to the hue of a color, reflected by the words red, green, etc. The second is related to the amount of white, gray, or black that is mixed with the previous signal. This confers a quality called saturation of a color; it distinguishes pinks from reds. The third depends on the achromatic system to establish the lightness or darkness of a color. Together these separate operations provide us with about 1 million different colors. All these operations, which involve both achromatic and chromatic contrast detection, provide cues to the form of an object. Although we can mentally separate the form of an object from its color, it is not known where in cerebral cortex this separation of form from color occurs.

I. COLOR VISION

Light has several independent properties, including its energy and its wavelength or frequency of vibration. Color vision takes advantage of both of these properties, allowing us to detect objects and navigate in the external world. Wavelength and energy contrasts vary independently in a visual image and therefore require different neural circuits for their analysis. The secret of color vision is to understand how the brain distinguishes wavelength from energy contrasts. The addition of wavelength contrasts to energy contrasts greatly increases the potential cues to the visual universe. In addition, energy contrasts depend on both the surface properties of an object and its position relative to its illuminant, sunlight for our past evolutionary history. Positional variations can lead to highlights and shading that can obscure the identity or existence of objects. The wavelength reflectance of an object is relatively independent of such effects and therefore a more reliable identifier. For this reason, wavelength contrast and derivative, color vision, have been important to survival. In man it has added an aesthetic dimension that far exceeds the value for survival in modern society.

Figure 1 shows a colorful Renaissance painting, which has been decomposed into its wavelength (chromatic) and achromatic (black-and-white) contrasts. When these two operations are combined in our brain, the picture is seen in color. Energy contrast leads to the perception of achromatic forms of different brightness (white, gray, or black). Wavelength contrast leads to the perception of forms that have a new dimension (color). Energy contrast provides finer detail than wavelength contrast, but the latter adds a new dimension to vision. The combination of both forms of contrast is what we normally experience as color vision.

II. NEURAL BASIS OF COLOR VISION

A. The Photoreceptors

Vision starts in the photoreceptor cells of the retina and their outermost organelle that contains specialized protein molecules, called opsins (from the Greek word "to see"), which absorb and amplify light energy. In the human retina, there are four types of photoreceptors, defined primarily by the opsin they contain. Usually one type of cone contains only one type of opsin. Each type of opsin absorbs a particular waveband of light in the visible spectrum. The wavelength selectivity, defined by an absorption spectrum, is related to the opsin's amino acid sequence interacting with a specific isomer of vitamin A.

One set of photoreceptors, called rods because of the shape of their long outer segments, function only at dim light levels. Their extraordinarily high sensitivity to light drives them into saturation at daylight levels. Rods are very sensitive and numerous in our retina but only work well in moonlight and play little to no role in

Figure 1 A segment of a painting by Jan van Eyck (1434) in which the luminance information has been removed (left) rendering an image based on chromatic contrasts alone. (Right) The chromatic contrast has been removed, rendering an achromatic black-and-white image of the same scene; the latter has more fine detail. In the middle and fusion of these two different forms of contrast produces color vision. (See color insert in Volume 1).

color vision. Rod vision is without color and has become vestigial in modern society.

Color vision is mediated by the other three photoreceptors called cones, which require broad daylight to work well. Figure 2 shows the absorption spectra of the three cones of human vision. Cones are much more important to human vision than rods because if they are lost or fail to function, one is legally blind. The absence of rod function, on the other hand, is only a minor inconvenience. Cones' tolerance of high levels of illumination depends in great part on their ability to adapt to light. As light levels increase, cones reduce their sensitivity and speed up their responses, making them almost impossible to saturate. For color vision, the responses of the three types of cones are compared. Figure 2 shows the spectral colors that result from these comparisons. The colors we see in the spectrum are not near the peak absorption of the cone opsins because they depend on sophisticated neural comparisons.

B. Long-Wavelength Cone System

Long-wavelength-sensitive cones dominate the primate retina, comprising 90% of all the cones. The short-wavelength-sensitive or S cones comprise only 10% of the cones and are absent from the central fovea, the area of highest visual resolution. The long-wave cones are composed of two types of cones, with similar opsins. Both absorb best in the long wave or yellow half of the spectrum. One type, M or "green" cones, absorbs slightly better in the middle or green part of the spectrum, and the other, L or "red" cones, absorbs slightly better in the long or red part of the spectrum (Fig. 2). These L and M cones seem to be

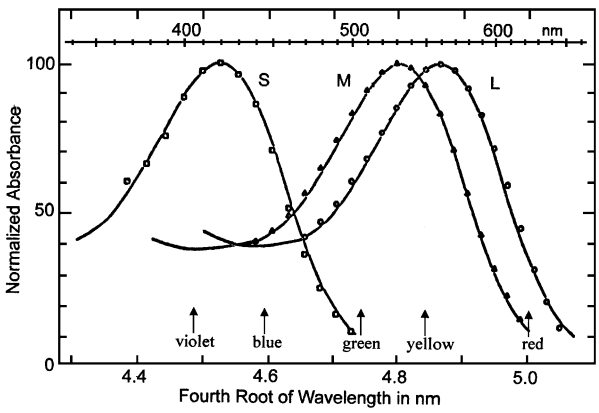

Figure 2 Normalized absorption spectra of the three cone mechanisms of human vision plotted against the fourth root of wavelength, which tends to make these curves independent of their position on the abscissa. An equivalent wavelength abscissa is shown above. Short-wave- (S), middle (M), and long-wavelength (L)-sensitive cones. The colors perceived at different points in the spectrum are shown below.

organized in an identical way, although there may be slightly more L than M cones. The central fovea contains only L and M and no S cones. L and M cones in the fovea are slender, optimizing their ability to sample small areas of visual space.

Each L and M cone synapses with at least two different bipolar cells. One is an on bipolar that is excited (depolarized) whenever its cone or cones absorb light; the other is an off bipolar, which is excited (depolarized) whenever light absorption by its cone or cones decreases (Fig. 3). This is a push–pull system that provides excitatory signals for increments (lightness) in one channel and excitatory signals for decrements (darkness) of light energy in a parallel channel. These signals are used in visual cortex to sense both energy (achromatic) and wavelength (chromatic) contrasts.

In the fovea, each L and M cone on and off bipolar synapses with a single cone (Fig. 3, left). Each single bipolar cell synapses with a single on or off ganglion cell. This is the so-called "midget cell" system discovered by Stephen Polyak. The signals from single L or M cones are transmitted by relay cells in the parvo cellular layers of the lateral geniculate nucleus of the thalamus to striate cortex mediating the high visual resolution of the fovea.

Away from the fovea, the midget arrangement ceases and several L and/or M cones synapse with single on or off bipolar cells. The breakdown of the midget system creates a problem for transmitting information about both energy and wavelength contrast in the same neural channel. For energy contrast, it is best to minimize the area within which the cones are selected. Therefore, selecting both L and M cones would be preferable (Fig. 3, right). For wavelength contrast it is best to select only L or only M cones in any one area. This tends to expand the area from which cones were selected and therefore decrease spatial resolution. It is not clear how this situation is handled.

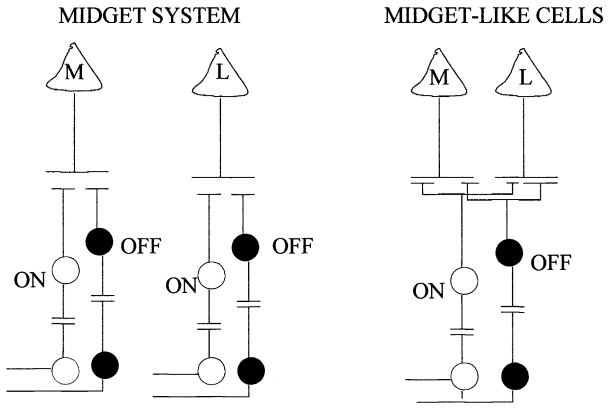

Figure 3 The retinal circuitry of the parvocellular L and M cone system. The midget system on the left is characteristic of the fovea, where each L and M cone has a private on and off bipolar and ganglion cell. Away from the fovea, this private line breaks down. Some cells, midget-like, are thought to preserve the selectivity for only one type of cone, a prerequisite for chromatic contrast.

1. The Parvo System: L and M Cone Antagonism

The selectivity for either an L or M cone input (Fig. 3) exposes antagonistic cone interaction in these retinal ganglion cells that depends on the wavelength of stimulation and is mediated by amacrine and horizontal cell interneurons. Ganglion cells transmitting signals of L cones are antagonized by stimuli that affect M cones and vice versa. This antagonism enhances both achromatic and chromatic contrast.

It enhances achromatic spatial contrast by reducing a ganglion cell's response to large but not small stimuli covering the center of the receptive field of the ganglion cell. It enhances chromatic contrast by reducing a ganglion cell's spectral response to green light if it is transmitting signals of L cones or reducing the cell's response to red light if it is transmitting the signals of M cones. It also enhances successive chromatic contrast, which occurs when a stimulus moves over the retina. The removal of green (antagonizing) light as red light enters the receptive field of an on ganglion cell transmitting the signals of L cones will enhance its response to the following red light. The removal of red (antagonizing) light as green light enters the receptive field of an on ganglion cell transmitting the signals of M cones will enhance its response to the green light. Off cells will also exhibit successive color contrast in the opposite way.

Retinal ganglion cells showing this behavior, called "cone or color opponency," are a system of small cells relatively concentrated at the fovea, including the "midget system." These cells transmit their signals to the parvocellular layers of the lateral geniculate nucleus of the thalamus. This system seems to be involved in both achromatic and chromatic contrast and is responsible for the high spatial resolution of the fovea. These cells receive no input from S cones.

2. The Magno System: L and M Cone Synergism

There is a parallel system of on- and off-bipolars and ganglion cells transmitting signals from L and M cones to striate cortex via relay cells in the magnocellular

layers of the lateral geniculate nucleus. These are larger cells, which have faster conduction velocities and respond phasically to maintained stimuli. They mix synergistic signals of L and M cones. They are only involved in achromatic contrast, showing no color opponency (Fig. 4). This phasic magnocellular system is relayed to layer 4C alpha of striate cortex. The system is not as foveally oriented as the parvosystem. It is not involved in high spatial resolution and color vision; it receives no input from S cones. It seems to play a role in the detection of movement and body orientation and perhaps brightness perception.

C. Short-Wavelength Cone System

The S cones are only involved in chromatic contrast, which has a lower spatial resolution than achromatic contrast. Chromatic aberration makes the short wavelength image out of focus when the image that the long-wave cone system sees is in focus. Therefore, the S cones have been excluded from high-resolution achromatic vision and the central fovea. S cones transmit their signals to the brain by a unique system of retinal ganglion cells. S cones synapse on S cone-specific on bipolars, which excite a bistratified ganglion cell that is also excited by L and M cone off bipolars (Fig. 5). Such a ganglion cell cannot mediate energy contrasts, being excited by both increments and decrements of light energy. It is designed for successive chromatic contrast, being excited when short wavelengths enter and long wavelengths leave its receptive field. The S cone channel is transmitted by relay cells in the parvo and/

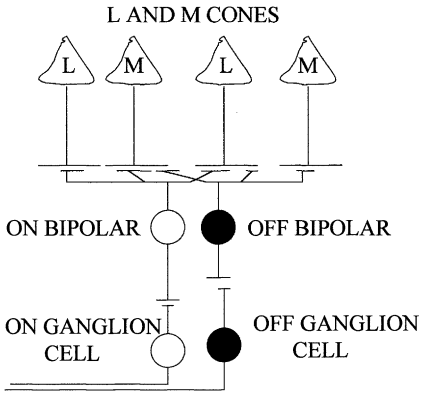

Figure 4 The retinal circuitry of the magnocellular L and M cone system. Here, the L and M cone act synergistically on both on and off channels.

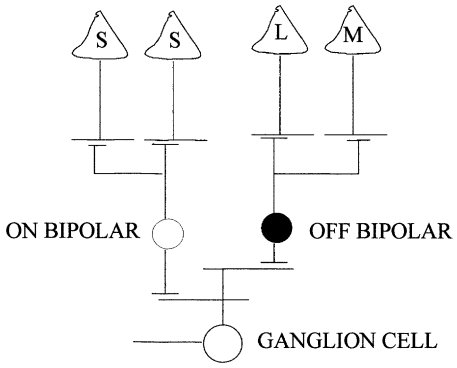

Figure 5 The retinal circuitry of the S cone channel. There are two inputs to a bistratified retinal ganglion cell. One is from on bipolars from S cones and the other is from off bipolars from L and M cones. Both bipolars excite the ganglion cell. The S cones excite their bipolars when there is an increment and the L and M cones excite their bipolar when there is a decrement of light absorption in the corresponding cone. The existence of an antagonistic amacrine cell that interacts off with on bipolars can explain transient tritanopia, a phenomenon of S cone vision.

or the intercalated layers of the lateral geniculate nucleus of the thalamus to striate cortex, layer 4C beta, where it is used to distinguish chromatic contrasts.

There is agreement that this S cone channel, consisting of an on–off ganglion cell, is a major route, possibly the only route for information from S cones to reach striate cortex and visual perception. This channel exhibits relatively little cone opponent behavior. Both white and blue lights excite this cell. Long wavelengths excite the cell when they go off, producing strong responses to successive color contrast. It responds best to white or blue after yellow. This cell informs the brain that the S cone system is or is not absorbing significant light in a particular area of visual space.

Whether there is also an S cone off channel is unclear. Few investigators have detected it. The strongest evidence for its existence comes from measurements with stimuli changing along the tritanopic axis of color space. It is possible that some of the more numerous tonic L and M cone opponent cells could also respond uniquely to such a stimulus. Because S cones are not involved in achromatic contrast, an off channel may not be necessary. Evidence suggesting the absence of an S cone off channel is the subjective phenomenon of transient titanopia, which involves a brief weakening of the appearance of blue whenever a long-wavelength field is turned off. There is no corresponding weakening of yellow when a

short-wavelength field is turned off. S cones appear to lack the ability to antagonize the other cone channels at the retinal level, presumably because their image is so out of focus that it would interfere with achromatic vision.

III. ACHROMATIC VERSUS CHROMATIC CONTRAST

Achromatic contrast detects spatial differences, which depend on the distribution of light energy in the retinal image. For daylight vision, it is mediated by the two longer wavelength-sensitive cones. It is well developed in the fovea, mediating our highest spatial resolution, and represented in relatively large areas of visual cortex. The foveal area of striate cortex is about 36 times larger than that of striate cortex serving peripheral vision. In the fovea, the responses of neighboring cones are compared for achromatic contrast (Fig. 6). Extrafoveally, spatial resolution is reduced because ganglion cells collect synergistic signals from more than one cone. Achromatic contrasts establish local lightness and darkness, which input orientation-selective neurons in striate cortex and undoubtedly contribute to form perception. Lightness or darkness is determined entirely by simultaneous contrast. Absolute values of light energy are discarded by antagonistic interactions between neurons representing different areas of visual space. An object is light or dark depending entirely on its background.

Chromatic (wavelength) contrast is established by eliminating the effects of energy contrast. It compares the responses of one set of cones to those of another in the same area of space (Fig. 6) and then compares this with comparisons obtained in neighboring areas of space (Fig. 7). Chromatic contrast depends on the difference between cone responses in a unit area of chromatic visual space and not on the absolute responses of the cones. Chromatic contrast does not resolve the detail offered by a single cone because a cone cannot provide an unambiguous clue to wavelength contrast as it can to energy contrast.

A cone's response depends on the energy absorbed, regardless of wavelength. Wavelength determines the probability with which a quantum is absorbed. A response to any wavelength can be reproduced by any other wavelength by varying energy. A mosaic of at least two different types of cones must be sampled to distinguish wavelength contrast. Wavelength contrast needs a double comparison. First, the responses of two different sets of cones in one area of visual space must be compared, and then this comparison must be compared with other areas of visual space to establish spatial contrast based on gradients of wavelength. If one compared only two neighboring cones, a gradient of energy contrast would create an ambiguous signal. For this reason, a unit area of chromatic space is larger than that of achromatic space. The lower spatial resolution of chromatic contrast has been demonstrated psychophysically. The spatial resolution of chromatic contrast for all three cone mechanisms appears to be identical. Figure 8 shows the difference between the spatial resolution of chromatic and achromatic

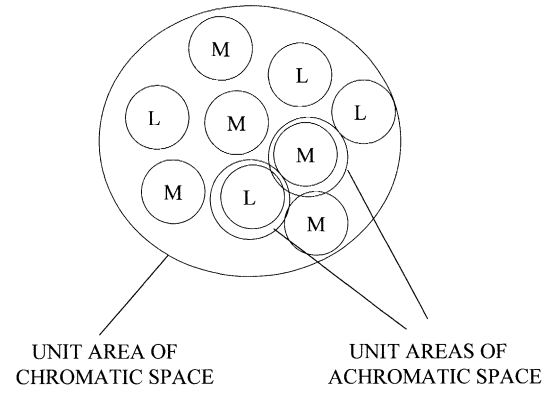

Figure 6 This figure illustrates that the unit areas of chromatic and achromatic space differ because of the nature of the neural comparison. For chromatic contrast, the responses of a group of L cones must be compared with the responses of a neighboring group of M cones in the same area of visual space. For achromatic contrast a single cone can be compared with a neighboring L or M cone.

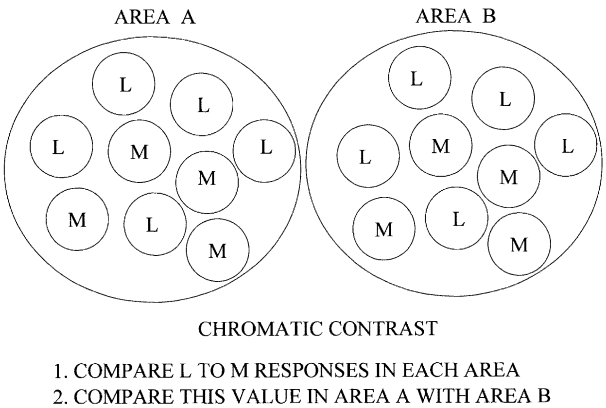

Figure 7 In order to establish chromatic contrast, a unit area of chromatic space must be compared with a neighboring area of chromatic space. Two neighboring L and M cones cannot be compared because a border of any wavelength could create ambiguity.

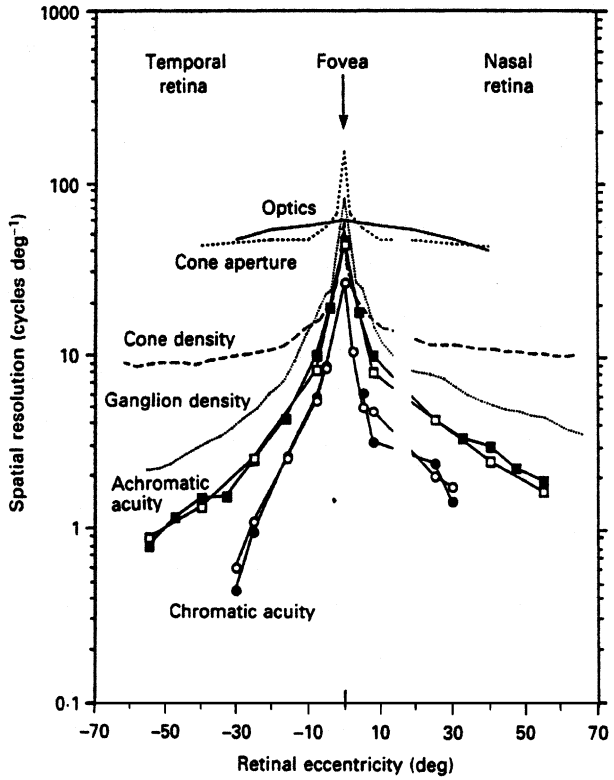

Figure 8 The degree of spatial resolution of the achromatic and chromatic systems of human vision and their distribution across the retina. The symbols represent the data of two normal subjects. They are shown in relationship to the optical properties of the eye and the filtering characteristics of the cones and ganglion cells of the retina (reprinted with permission of Cambridge University Press).

contrast across the human retina. Everywhere the former is lower than the latter, and this increases with eccentricity. Chromatic vision is relatively more developed centrally than achromatic vision.

IV. PSYCHOLOGY OF COLOR VISION

A. Trivariance

In the 1850s, Maxwell in England demonstrated that all human color perception depends on three variables, which he assumed reflected three different types of cones. In Germany, Helmholtz was arriving at a similar conclusion, led by the intuitive insights of Grassmann. The ability to define color by measured amounts of three physically defined variables led to colorimetry. Any color can now be defined by three international standards. The spectral properties of the three-cone mechanisms of human color vision were first derived psychophysically by Stiles in England in the 1950s. Subsequently, microspectrophotometry of single human cones confirmed these measurements. Defining the absorption spectra of the cones is the starting point for understanding human color vision (Fig. 2).

B. Hering Theory of Color Vision

Ewald Hering, a German physiologist, proposed a unique theory of color vision that went beyond trivariance in its insights into how the nervous system compares cone signals to perceive color. He proposed the existence of antagonism between certain pairs of colors, such as blue and yellow and red and green. The brain could not perceive a blue–yellow or a red–green color, whereas it could perceive red–yellow, green–yellow, red–blue, or green–blue colors. Blue and yellow cancel each other so that one cannot perceive bluish-yellow. Similarly, red and green cancel each other so that one cannot perceive reddish-green. This cancellation of one color impression by another was thought to represent neural antagonism. This was a major insight into how the brain compares the three cones in two pairs in order to perceive color.

Hering's theory was based on subjective experience. The discovery of antagonism between cone responses in single neurons of fish retina led to a renaissance of his theory. Linking the physiology of retinal neurons with subjective colors has proven to be difficult, however. The major reason for the difficulty is that color does not appear to be determined at the retinal or geniculate level but depends on additional operations that occur in visual cortex. Antagonism between cones, which occurs in the retina, is not equivalent to antagonism between colors, which occurs in the cortex.

1. Blue–Yellow Opponency

A scheme that combines physiology and Hering's color opponency is shown in Fig. 9. The operations occurring at the retinal and geniculate level are separated from those thought to be occurring in visual cortex. For blue–yellow color vision, the brain combines excitatory signals from S cone on bipolars with excitatory signals from long-wave cone off bipolars at the retinal level. This on–off–S cone channel excites a cell in the cortex that signals blue; this cell also receives antagonistic (inhibitory) signal from L and M

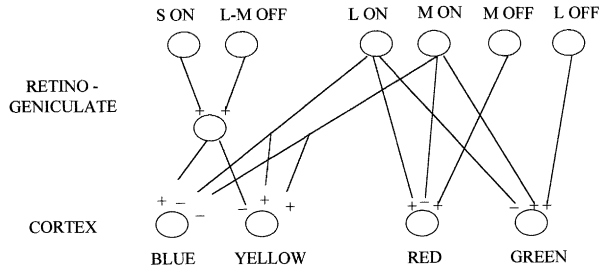

Figure 9 Circuitry that logically organizes the retinogeniculate inputs from the parvocellular system to establish cells responsive to opponent colors in local areas of visual space. (Right) The circuitry of blue–yellow opponent colors in which two different cortical cells receive inputs from the retinal S cone channel, on the one hand, and the long-wavelength tonic system, on the otherhand. The latter excites and the former inhibits the cell detecting "yellow." The converse arrangement affects the cell detecting "blue." If neither cell is excited, achromatic vision determines the color as white, gray, or black. (Left) The circuitry of red–green opponent colors. L cone on and M cone off signals excite and L cone off and M cone on signals inhibit a cell detecting "red"; the converse arrangement detects "green."

cones. This on–off–S cone channel also antagonizes (inhibits) a cell in cortex that signals yellow; this same cell receives an excitatory signal from the L and M cone on-system. These two cells form a blue–yellow opponent system.

If the S cone on-system and the L–M cone on system are excited, the blue and yellow cells are both silent (inhibited) and the system defaults to black-and-white (achromatic) vision. If the S cone on system is excited and the L–M cone on system is not excited (its off system is excited), the color is blue (and dark). If the S cone on system is not excited and the L–M cone on system is, the color is yellow. If both the S cone and the L–M cone on systems are not excited, the color is black (and dark). Whether white and yellow are dark (i.e., gray or brown) is determined by achromatic simultaneous brightness contrast. Humans share this prototypical blue–yellow color vision system, with many other mammals.

The scheme as it stands, however, is deficient in not addressing simultaneous color contrast and in disregarding a fundamental principle in the Land model of color vision, which requires that each cone's system's response be normalized over the visual scene before a comparsion is made for color.

2. Red–Green Opponency

In primates, a second comparison arose with the evolution of two different long-wavelength-sensitive opsins, which split the bright and yellow part of the visible spectrum in two. This provided a new dimension of chromatic contrast (i.e., red–green) (Figs. 9 and 10). The M on and L off channels are not brought together in the same retinal neuron as is the case for the S cone system, presumably because the L and M systems mediate achromatic as well as chromatic contrast. At the cortical level, where many more neurons are available, these systems are brought together in an opponent manner to form cells that respond uniquely to color (i.e., red or green). Again, this scheme disregards simultaneous chromatic contrast as well as the requirement required in the Land model of color vision for normalization of the responses of each cone mechanism over space before color is determined.

This model has another weakness in disregarding a role for the S cone system in determining redness. There is evidence for trivariant interactions in the perception of red–green opponent colors, and this has not been incorporated into this scheme.

There is another controversy in neural modeling of the red–green opponent system. There are two competing models that have been proposed to mediate red–green opponent responses as depicted in Fig. 9. One theory employs all the midget cells of the fovea as well as hypothetical midget-like cells in the parafovea. This is attractive because these cells are very numerous and they possess an essential requirement for transmitting signals for color to the brain. They isolate in one neural channel the signals of one spectral type of cone. However, they have an inappropriate retinal receptive field for a cell mediating color vision. These cells receive excitatory signals from one cone mechanism in

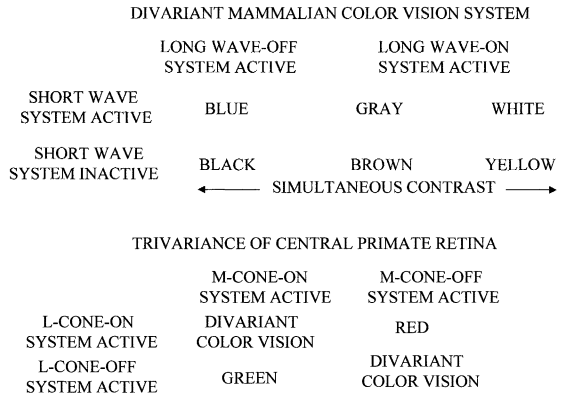

Figure 10 A comparison of the divariant color vision of most mammals and about 2% of human males with that of trivariant color vision.

the center and antagonistic signals from the opponent cone mechanism in the surrounding receptive field. It would be more appropriate to receive the antagonism from the same area of visual space (i.e., its receptive field center rather than from surrounding retina). Nevertheless, this drawback has been disregarded in most models of color vision, which routinely employ this variety of retinal cell. It has been intuitively assumed that visual cortex can correct this deficiency by assembling groups of these cells that subserve coextensive areas of visual space.

A second complexity involved in using the midget system to transmit information about color is that it is also transmitting information about achromatic contrast. Therefore, the brain needs two different detectors to extract the achromatic from the chromatic information from the same neural channel. A scheme suggesting how chromatic and achromatic information, "multiplexed," in a single neural channel is demultiplexed by the brain is shown in Fig. 11. In this scheme synergistic signals from L on and M off channels become logical ways to facilitate the perception of red; similar ones from M on and L off channels are logical to facilitate the perception of green. On the other hand, neurons receiving synergistic inputs from either L on or M on would lose their advantage for chromatic contrast detection but could function to detect achromatic lightness. Similarly, L off and M off channels could function to detect achromatic darkness. By disregarding the source of the cone input achromatic contrast can exploit the fine pixel grain of the fovea. This model does not solve how midget cells with concentric cone opponent fields compare cone responses over coextensive areas of visual space.

A different model has been proposed by Rodieck, who assumes that the midget system does not mediate chromatic contrast. Instead, he postulates a much smaller group of retinal ganglion cells that receive coextensive inputs from L and M cones. These cells would be similar to the S cone retinal channel and perhaps also involve bistratified retinal ganglion cells. There is no anatomical evidence that such retinal cells exist; however, there is physiological evidence that such cells do exist. Further research is required to distinguish which of these two models is correct.

3. Simultaneous Color Contrast

Simultaneous chromatic contrast is not as strong as simultaneous brightness contrast, probably because the comparison of cones in the same area of visual space provides a unique local signal not present in achromatic contrast. Cells sensitive to simultaneous chromatic contrast are first found in visual cortex. Such cells respond best to a red area surrounded by green or the converse. The logical way to establish such cells is to have similar color comparison in one area of space inhibit a similar comparison in neighboring areas or have dissimilar comparisons excite each other (Fig. 12). Cells organized in this manner are first encountered in striate cortex but have also been detected in higher visual areas.

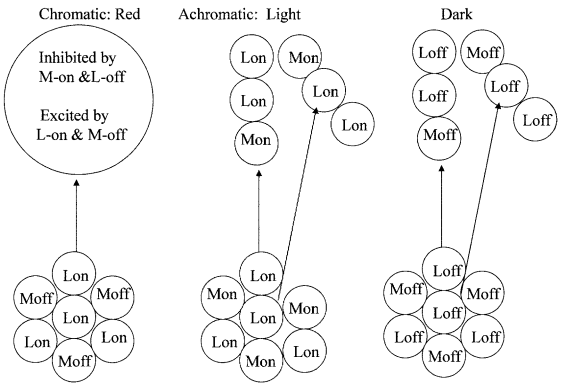

Figure 11 A scheme showing how the same signals from the midget cell system are processed by different sets of parallel circuits, which extract a chromatic signal on the left and an achromatic signal on the right. The chromatic detector mixes synergistic signals from L-on and M-off cells. The achromatic detectors mix only on or only off signals but from either L or M cones.

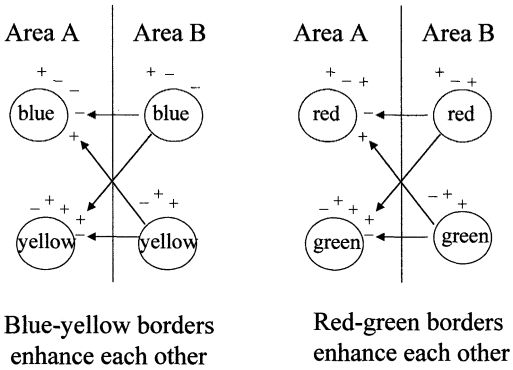

Figure 12 For simultaneous color contrast, the logical arrangement is to have cells responsive to a particular color (in this case "red" or "green" in one area of space) inhibit the same type of neuron in a neighboring area of space. In addition, a cell detecting one color should excite cells detecting the opponent color in neighboring areas of space. In this way, red/green or yellow/blue borders can be enhanced.

C. Land's Retinex Model

Edwin Land emphasized the importance of global influences in color vision. He demonstrated that objects stimulating the retina identically could have totally different colors depending on their surrounding spectral illumination. He proposed a model to handle such global effects called the Retinex model, implying that it depended on both the retina and the cerebral cortex. The model corrects for changes in the spectral characteristics of the illuminant and therefore facilitates color constancy. Color constancy allows us to see a green plant as green in sunlight or artificial light, usually tungsten light, which emits many more long wavelengths than sunlight. The key element in his model is that the signals from each cone mechanism have to be normalized across the visual scene before being compared with another cone mechanism to establish color. It implies that Hering's paired comparisons occur after a stage in which each cone mechanism's response is normalized over a large part of the visual field. Such wide field interactions are quite possible in visual cortex as or before the paired comparisons of cone signals occur.

V. FORM AND COLOR

The most difficult problem in color vision and vision as a whole is to understand how form perception occurs and how once an object's form is determined its color is appended. A reasonable explanation for form perception is Marr's idea of arrays of orientation-selective detectors coding for an object's configuration based on a retinotopic order. The initial detectors of contrast are retinogeniculate neurons with a center-surround receptive field organization based on energy contrast. The mathematical descriptions of such detectors are best represented by a difference of two-dimensional Gaussian-shaped fields. The central field is smaller and overlapped by a larger antagonistic field. The interaction of such detectors can lead to orientation-selective units that detect edges of contrast based on achromatic contrast. The neural machinery for doing this is highly developed in areas of visual cortex serving the fovea. Most of the neurons encountered in striate cortex of primates are sensitive to achromatic (energy) contrast and not selective for color. A smaller amount of neural machinery appears to be devoted to chromatic contrast and color vision in any one area of visual cortex, probably due to its lower spatial resolution.

It is reasonable to assume that chromatic detectors of contrast contribute to form perception in a similar way as achromatic detectors but as a parallel system. Here, wavelength rather than energy contrast determines the activation of the detectors established by cone opponent interactions as independent systems. One system detects blue–yellow chromatic contrasts and the other red–green contrasts. In general, the cues produced by energy contrasts are reinforced by chromatic contrast in detecting the same object. If there are ambiguities, the brain must make a decision favoring one or the other, perhaps favoring chromatic contrast because of its relative independence from shading. Other properties of an object, such as well-defined borders or texture, would be better determined by the achromatic system. In this scheme, three parallel systems for contrast detection are envisaged—one for achromatic (black–white–gray), one for blue–yellow, and one for red–green chromatic contrasts, each arranged with its own retinotopic order. Whether all three systems converge on a single neuron to determine the fused sense of color is unclear. For colors such as magenta, such interactions may occur. In addition, there seem to be neurons that respond to both chromatic and achromatic signals to perform neural functions but are not involved in the perception of color.

A clue to the cortical processing of vision comes from observations of multiple areas of prestriate cortex where the entire visual field is re-represented. These areas send and receive signals from each other. Working together they create a unified and presumably richer impression of the visual world. The actual role of each subarea is poorly understood.

Zeki proposed that one of these subareas, visual area 4, is unique for color processing. He argued that in this area cells correct for color constancy and respond to true color. At earlier stages cells may respond to wavelength contrast but not to color. It has been difficult to prove this hypothesis. Single neuron recordings from most visual areas reveal cells selective for chromatic contrast and color vision but usually in the minority. Visual area 4 has been reported to have a larger proportion of color-selective cells but there is no universal agreement about this.

There is little doubt that the cortex works by dividing different aspects of visual function into anatomically distinct areas and that perception of a unified image depends on the multiple physiological linking of these separate subareas. A critical element in this reasoning is the question of retinotopic order, which seems to be the backbone of form perception.

The integration of form must be based on linking inputs labeled by retinal coordinates. Chromatic contrasts must be handled in a similar way as achromatic contrasts, each with its own retinal coordinates. Does the lower spatial resolving chromatic contrast system get funneled into a separate cortical area for color vision even though color vision depends as much on achromatic contrast as on chromatic contrast? It seems more likely that chromatic and achromatic processing occurs in all the areas to which the parvocellular system projects, and color discrimination as well as color constancy improve as increasingly more visual areas are involved in the processing.

Color discrimination continues to improve with the size of the object being judged. Surfaces subtending 20° and more of visual angle significantly improve color discrimination when compared with those subtending only a few degrees. Color discrimination can integrate over very large areas of visual space and consequently striate cortex. One of the characteristics of neurons in higher visual areas is the relatively large size of their receptive fields. They require inputs from large areas of the retina before deciding to respond. The larger size of visual stimuli activates more antagonistic interactions and therefore could increase the variety of experience. If one is judging a small object, he or she may not be using as much of his or her brain. If the object is enlarged, it begins to activate more cells in higher visual areas and its recognition is improved. This operation may depend on all subareas working in concert through feedback rather than a serial progression from lower to higher areas.

Table I
Classification and Incidence of Color Vision Defects

Type	% Males
Congenital	
Trivariants (three cones present)	
Normal	91.2
Anomalous	
Protanomaly (L cone opsin abnormal)	1.3
Deuteranomaly (M cone opsin abnormal)	5
Tritanomaly (S cone opsin abnormal)	0.001
Divariants (Two cones present)	
Protanopia (L cones absent)	1.3
Deuteranopia (M cones absent)	1.2
Tritanopia (S cones absent)	0.001
Achromats	
Complete achromat (all cones absent)	0.00001
S cone achromat (L and M cones absent)	0.000001
Acquired	
Tritanopia (outer or peripheral retinal disease)	0.01
Protan deuteranopia (inner or central retinal disease)	0.01
Cerebral achromatopsia (brain disease)	0.0000001

VI. DISORDERS OF COLOR PROCESSING

A. Genetic Defects

The major abnormalities of color vision are due to genetic defects (Table I). The most common involve red–green color vision and are due to defects in the genes for L and M cone opsins located on the X chromosome. Therefore, they occur mainly in males. In the most severe cases, both genes fail to function. This leads to achromatopsia, loss of all color vision. Such subjects have only S cones and rods and are called S cone achromats. With only one class of cones, color vision is impossible. Such subjects may experience a primitive form of color vision that depends on a comparison between S cones and rods. Without L and M cones, they also lack high spatial resolution and are legally blind. A second form of achromatopsia is due to a gene defect on chromosome 2 for an ion channel exclusive to cones. These subjects only have functional rods.

In less severe defects, only an L or an M cone gene is functional. Such subjects have blue–yellow color vision obtained by comparing S cones with the remaining long-wave cone mechanism. Subjects who lack L cones are called protanopes. They are insensitive to the long wave end of the spectrum (the red end). Subjects who lack M cones are called deuteranopes. They are sensitive to the entire spectrum. Both protanopes and deuteranopes cannot distinguish reds from greens and have only blue–yellow color vision. They all have high spatial resolution.

In milder defects, both L and M cone opsins are transcribed but the absorption spectrum of one is shifted closer to the other, diminishing the potential for chromatic contrast. Such subjects are called deuteranomalous if the M cone opsin is abnormal and protanomalous if the L cone opsin is abnormal. They have reduced red–green but normal blue–yellow color vision. They all have high spatial resolution. The similarities of colors vary in different ways for each color deficiency (Fig. 13).

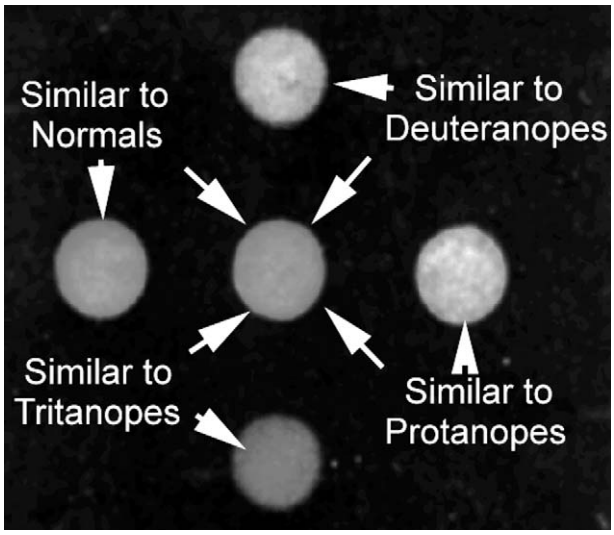

Figure 13 These spots of color appear different to subjects with color deficiencies. Normal subjects see the spot on the left most similar to the central spot. Deuteranopes see the upper, protanopes the right, and tritanopes the lower spot as most similar to the central spot.

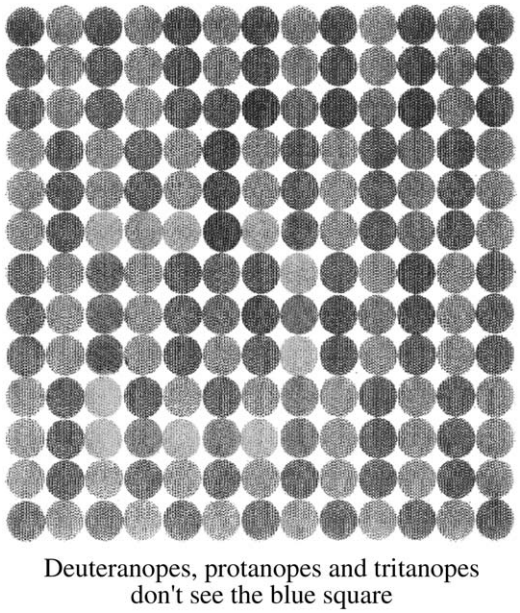

Figure 14 A pseudoisochromatic plate that detects protanopes, deuteranopes, and tritanopes, who fail to see the blue square at the upper right side. (See color insert in Volume 1).

Such color deficiences can also be detected by the use of plates in which spots of different colors that confuse defective subjects are arranged in different sizes so that a figure can be seen by normal subjects but not by defective ones and sometimes vice versa. One that detects both red–green and blue–yellow defective vision is shown in Fig. 14.

Defects in the S cone opsin located on chromosome 7 are rare. They are usually autosomal-dominant mutations. Such subjects are called tritanopes and have only red–green color vision. They retain high spatial resolution. A pseudoisochromatic plate that detects tritanopia is shown in Fig. 15.

Interestingly, there is no gene defect that produces achromatopsia without decreasing acuity, but the converse frequently occurs, including virtually all disorders of the macula.

B. Color Vision Defects Associated with Other Diseases

There is a group of retinal degenerations, primarily genetic in origin such as retinitis pigmentosa, that destroy peripheral vision first and in general slowly progress toward the fovea. These diseases tend to produce tritanopia. This may reflect the possibility that blue–yellow color vision extends further into peripheral retina and therefore is more vulnerable to this disease process. It may also reflect the possibility that S cones are more susceptible to the degeneration than L and M cones.

There is a second class of diseases that tend to affect central vision and are due to defects in either the optic nerve or the macula area of the retina. These can be

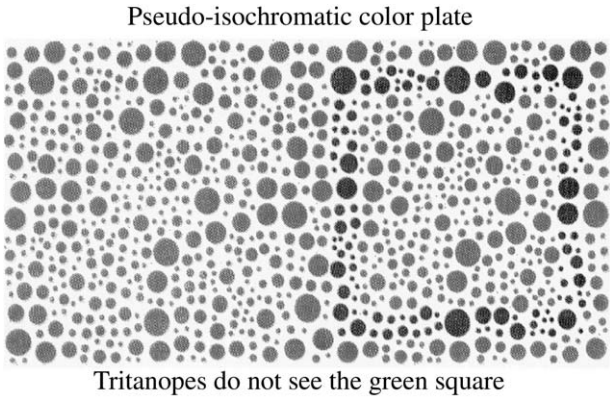

Figure 15 A pseudoisochromatic plate that detects tritanopes, who fail to see the pattern on the right.

associated with red–green color vision defects but they are always accompanied by a diminution in acuity. The vulnerability of red–green defects in these diseases may reflect the possibility that red–green color vision is more developed centrally than blue–yellow vision.

There is a class of autoimmune diseases that arise from cancers that express antigens, which are also expressed by photoreceptors. The immune system detects these antigens and reacts to them both on the cancer cells and on the photoreceptors. This class of diseases has been called cancer-related retinopathies. Some of these diseases are highly specific, involving only cones and not rods. Such subjects can lose all cone vision and consequently color vision. Recently, we found a subject who lost only L and M cones but not S cones or rods. These are examples of acquired achromatopsia.

C. Abnormalities of Acuity and Color Vision

In general, abnormalities of central vision, such as those involving the macula, reduce spatial resolution but have little or no effect on color vision. A remarkable example is ''oligocone trichromasy.'' These subjects have very few cones and greatly reduced acuity but retain normal color vision. This must reflect the fact that color vision integrates over larger areas of the visual field and is disconnected from the high spatial resolution discrimination mediated by achromatic contrast and the ''midget'' system. This does not mean that the midget system does not mediate chromatic contrast and consequently color vision; it must mean that there is considerable overlap in the integration of these midget cell signals that are used for chromatic contrast. There is an alternative view that there are specific ganglion cells divorced entirely from the midget system.

D. Cerebral Achromatopsia

There are rare exceptions-to the tolerance of color discrimination despite large losses in acuity. An occasional subject loses color vision but maintains normal visual acuity after acquired damage of visual cortex. The cases that have been studied most completely with the entire gamut of color testing methods confirm major but not complete loss of color discrimination. They appear to be able to use wavelength contrast to detect objects but are unable to perceive colors from these cues. Such a subject can distinguish the shape and achromatic brightness differences of traffic lights but cannot see them as red, green, or yellow. They appear as washed-out objects of white and gray. Testing reveals a greater tendency for a blue–yellow (tritanopic) than a red–green deficiency. In general, the recovery from damage to visual cortex will usually include a stage in which white and grays are seen first before colors return. The first color to return is usually red. Increasing the size of the stimulus also tends to improve color perception. Nevertheless, such subjects are indeed very deficient in color vision and retain normal acuity.

These clinical findings imply that there is a significant anatomical separation of chromatic and achromatic contrast processing in the cerebral cortex. This is consistent with a cortical area devoted exclusively to the perception of color, but it is not proof. All of these patients invariably have prosopagnosia, the inability to recognize faces, and a scotomatous area, usually in their superior visual field. There are no reports of isolated acquired achromatopsia without other concurrent visual deficits. It is possible that the perception of color requires feedback from prestriate to striate cortex that facilitates the fusion of chromatic contrast with achromatic contrast perception. This feedback may be more important for incorporating the relatively sparse chromatic processing centers in striate cortex into visual perception.

VII. THE FUTURE OF COLOR VISION

Color vision offers a valuable insight into how the cerebral cortex works because it is a well-defined process that depends on three retinal variables serving each area of visual space and is intimately associated with form vision. Many of the logical operations necessary for color vision, which are performed by circuits of nerve cells, are relatively well understood. The major impasse in our understanding of the process is how its clues to contrast are unified into the recognition of form. It is our poor understanding of form vision that makes the final stage of understanding color vision difficult. Understanding how nature interweaves clues from chromatic and achromatic contrast into those for form perception using arrays of neurons and neuronal interactions should lead to a better understanding of not only color vision but also the cerebral cortex in general. The problem of

researching this topic, however, has been that the tools to study it have been and still are too crude. It is necessary to monitor large numbers of single neurons performing their operations within a fraction of a second and to continue doing so during long-term experiments. Such techniques are just beginning to evolve.

GLOSSARY

cones The retinal receptor cells that underlie vision for daylight conditions; there are three classes of cone in retinas of individuals having normal color vision.

metamers Lights of different wavelength compositions that appear identical.

opponent colors Pairs of colors that are perceptually mutually exclusive (e.g., red–green and yellow–blue).

opsin genes Genes specifying the protein component of photopigment molecules; variations in these genes can be mapped directly into variations in color vision.

photopigments Molecules located in photoreceptors that absorb energy from light and initiate the visual process.

principle of univariance Encompasses the observation that the responses of photoreceptors are proportional to the number of photons absorbed by the photopigment they contain independent of the wavelength of the light.

spectrally opponent cells Nerve cells that transmit information useful for the production of color vision; these cells combine excitatory and inhibitory inputs reflecting the activation of different classes of cone.

trichromatic The formal characterization of normal human color vision; derived from the results of experiments in which it is shown that three primary lights can be combined to match the appearance of any other spectral light.

Color vision is the neural process that provides one of the important and dramatic aspects of the brain's interpretation of the visual world. This process is initiated by variation in the spectral distribution of light reaching the eye and culminates in the rich range of human color experience. Fundamental features of color vision are described in this article, including a summary of human capacities to perceive and discriminate color, an outline of the principal biological mechanisms underlying color vision, and a description of variations in color vision among people.

I. THE PERCEPTION AND DISCRIMINATION OF COLOR

At least for simple viewing situations, color experience has been traditionally ordered along three principal perceptual dimensions—brightness, hue, and saturation. The first is considered to be part of both achromatic and chromatic features of color, whereas the latter two are chromatic features. In terms of everyday experience, brightness is that aspect of a percept most closely associated with changes in the intensity of a light yielding visual experience along a dimension that encompasses verbal descriptions running from dim to bright to dazzling. Hue is primarily correlated with the wavelength of light and is typically designated through the use of common color terms—red, green, blue, and so on. Saturation is the degree to which a chromatic sensation differs from an achromatic sensation of the same brightness—for example, yielding sensory experiences that are situated on a continuum changing from white (achromatic) to light pink and to a deep red.

Many aspects of color have been conveniently summarized in geometric configurations. The three

perceptual dimensions of color just described are often represented in a so-called color solid. In this color solid, hues are positioned around the circumference of a circle where they are placed in the order in which they are perceived in a spectrum. The ends of the spectrum (reds and blues) are connected through a series of purple hues. White is located at the center of the hue circle and saturation is then represented as increasing along lines drawn from the center to the various hues located on the circle circumference. The plane surface thus formed encompasses chromatic variation at a single brightness level; increases and decreases in brightness from this level are plotted along a third dimension that runs perpendicular to the plane. Within this color solid any particular color experience can be conceived as representing a location in the three-dimensional space.

A. Environmental Signals

A basic problem for students of color vision is to relate the perceptual dimensions of color to physical features of the environment. Common experience suggests that color is an inherent property of objects: Apples are red; grass is green, and so on. However, is that the case, or is it rather that color is produced by active processes in a perceiver that are initiated by light? Philosophers and others have long debated these alternatives and their arguments continue to reverberate today. Most vision scientists, however, incline to some version of the second alternative and, in so doing, follow the lead of Isaac Newton, the great English scientist whose 16th-century observations caused him to conclude that "the Rays to speak properly are not coloured. In them there is nothing else than a certain Power and Disposition to stir up a Sensation of this or that Colour."

Light reaching the eye from any location in space can vary in intensity (number of photons per unit time) and wavelength. People are sensitive to a narrow band of wavelengths, extending from about 400 to 700 nm (1 nm=10^{-9} m). For most ordinary viewing, the distribution of wavelengths and intensities reaching a viewer depends jointly on characteristics of the source of illumination, on the surface reflectance properties of an illuminated object, and on the geometric relationship between the object and the viewer (Fig. 1). For instance, a snowfield seen in full sunlight yields a very

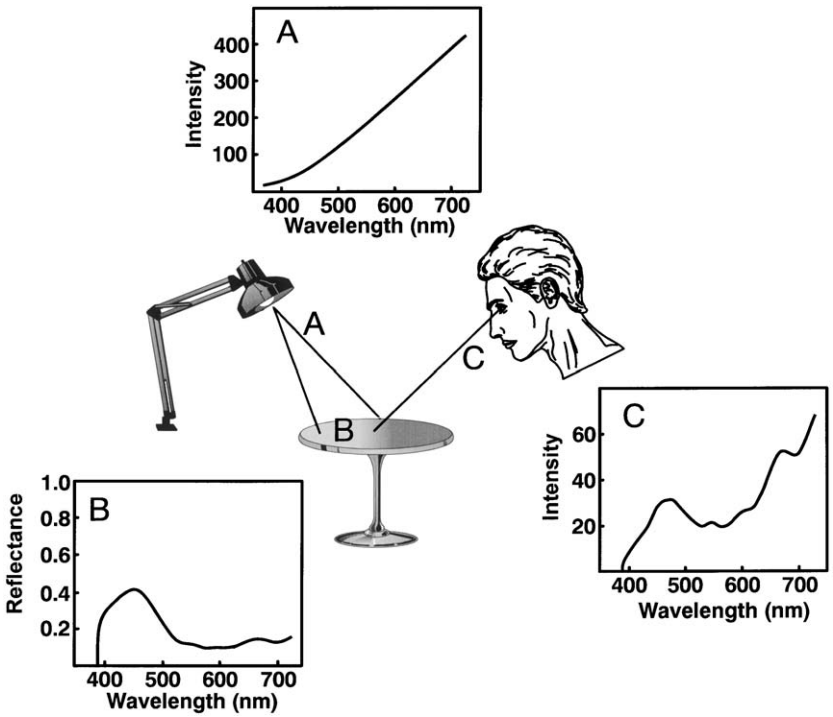

Figure 1 Light reaching a viewer is dependent on the nature of the light source and on the reflectance properties of the object being viewed. In this illustration the spectral distribution of energy emerging from a light source (A) is indicated at the top. The spectral reflectance properties of the surface of the table (B) are given on the left. The spectral distribution of light reaching the viewer (C) that is shown on the right is the product of the spectral distribution of the illuminant and the reflectance property of the object.

different array of wavelengths and intensities for analysis from that provided by an expanse of lawn seen at twilight. Viewed across natural scenes there are usually substantial local variations in the wavelength and the intensity of light, and the number of possible combinations of the two is virtually infinite. All species with sight can exploit intensity variations as an aid to the discrimination of the form, location, and movement of objects. However, only those that also have a capacity for color vision can disentangle the effects of joint variations in wavelength and intensity and in so doing yield the experience of color.

B. The Dimensionality of Color Vision

Color vision has been frequently studied in laboratories by asking observers to judge whether pairs of stimuli—typically viewed as the respective halves of a small, illuminated circle (Fig. 2)—appear the same ("match") or are different. If the two halves are identical in wavelength and intensity content, they of course match. Differences in color appearance may be introduced by changing the intensity or wavelength content of one half or by changing both these features. A change in the intensity of the light in one half of the circle yields a mainly achromatic difference between the two; one side becomes brighter than the other. Changes in the wavelength content of one half may yield a complex of change, in hue and saturation principally but also possibly in brightness. If the observer is then allowed to adjust the relative intensity so as to remove any brightness difference, the two sides will have a pure chromatic difference. It is from this basis that color vision is often studied.

Special cases of this viewing arrangement are those in which the two sides of the small circle differ in wavelength content but have identical color appearances. Pairs of stimuli that differ physically but appear the same are said to be metameric. The occurrence of such metameric matches defines a fundamental feature of human color vision—its limited dimensionality. To better understand this feature, consider color matches obtained when separate lights having fixed spectral content are superimposed on one half of the matching field (Fig. 2). Each of these separate lights is called a primary (P), and the task given to a viewer is to adjust the relative intensity (e) of each of the primaries so as to make that half of the field appear identical to the other half (in turn, traditionally called the test light). The test light can be composed of any fixed combination of wavelengths and intensities. The important result is that most human observers can match the appearance of all test lights by simply adjusting the relative intensities of only three primary lights. Some matches are possible with only one or two primaries, and more than three will work, but three is the minimum needed to complete all matches. Humans are thus said to have trichromatic color vision. There are some qualifications to this conclusion; (i) there are restrictions on the wavelengths that can be employed as primaries, and (ii) for some test lights one of the primaries must be added to the side containing the test light. In any case, the ability of humans to complete matches using only three independent variables means that any color can be represented in a three-dimensional space where the location in that space is specified by the proportions of the three primaries required to capture the appearance of the color. Such spaces are highly useful in the many practical uses of color (e.g., the specification of colored

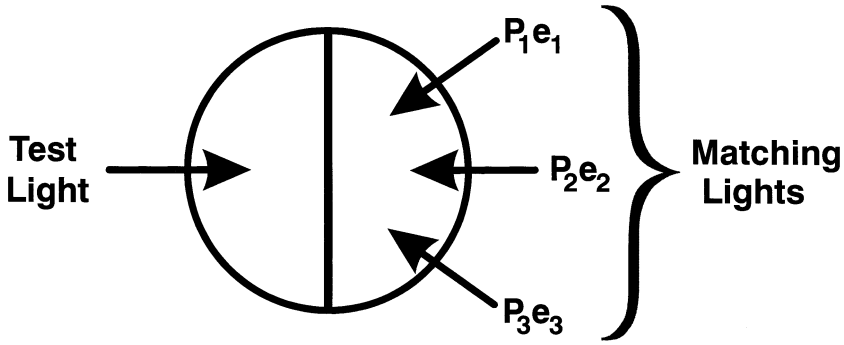

Figure 2 Schematic representation of the color matching test. In this test a subject views a small circular field. The two halves of the field are independently illuminated from different light sources. As shown here, a light of some fixed wavelength and intensity content (a test light) is projected onto the left half of the field. Lights from three separate sources are superimposed on the left. These are primary lights (P_1–P_3) that differ in wavelength. The task of the subject is to adjust the intensities of the three lights (e_1–e_3) until the two halves of the field appear identical. Illustrated is a trichromatic match where combinations of three primary lights are required to complete the match.

signal lights or of the color of a commercial logo) and so have been intensively evaluated.

The mixing of lights reveals another surprising feature of color perception. Many pairs of lights can be added together to yield an achromatic percept. Such pairs are called complementary colors and their occurrence is counterintuitive in that the perceived colors associated with the two wavelengths viewed separately utterly disappear when they are mixed together. In the color solid described previously, complementary colors are placed on opposite sides of the hue circle such that a line drawn between them passes through the location of white. The facts of color mixing make clear that the visual system is not a simple wavelength analyzer. From the viewpoint of the biology of color vision, the fact that people are trichromatic has long been taken to predict the nature of the transformations occurring in the visual system. Indeed, more than two centuries ago it was hypothesized that the fundamental facts of human color perception imply that there must be three kinds of physiological mechanisms in the eye responsible for processing those aspects of light that lead to color. This turned out to be an inspired prediction.

C. Color Discrimination Indices

One way to characterize human color vision is to ask how good we are at making color discriminations. Figure 3 summarizes results from four different tests of human color vision. Just as it does for all other animals, the sensitivity of humans to light varies as a function of the wavelength of the light. The results shown in Fig. 3A illustrate this point. The continuous line is called a spectral sensitivity function and it plots

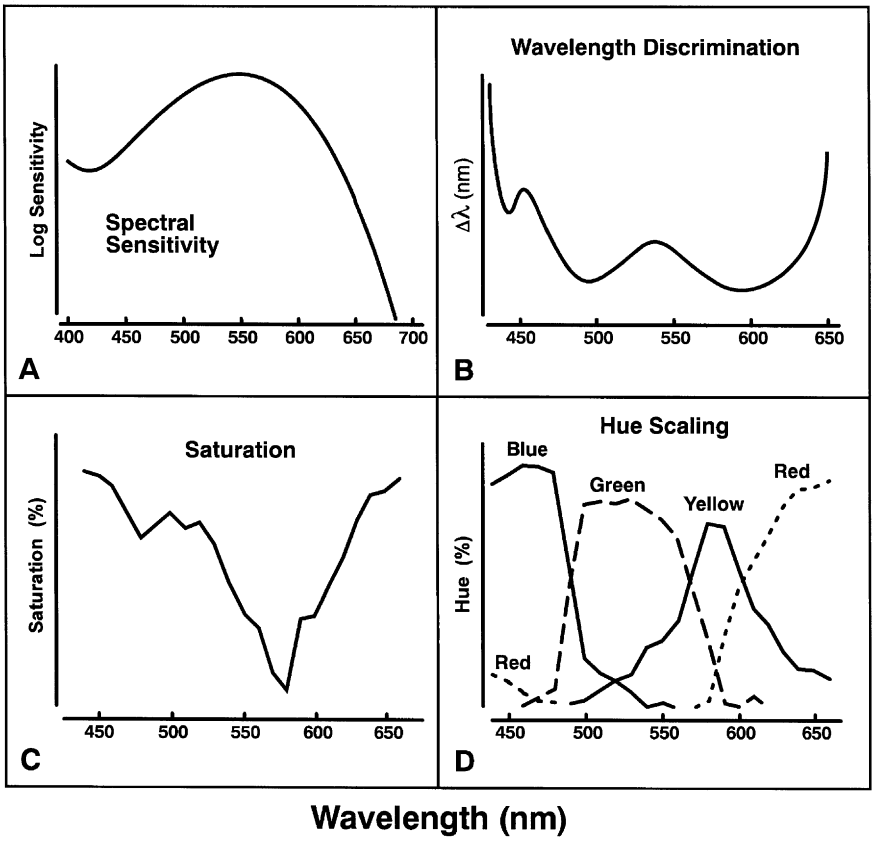

Figure 3 Four measurements of human color discrimination abilities. (A) Spectral sensitivity function. The continuous line plots the reciprocal of the intensity of spectral lights required for detection under daylight test conditions. (B) Wavelength discrimination function. Plotted is a measure of how much wavelength has to be changed in nanometers at each spectral location in order to yield a perceptible color difference. Higher values indicate poorer discrimination. (C) Spectral saturation. The continuous line shows the variation in the saturation of spectral lights as a function of the wavelength of the light. High values indicate greater degrees of saturation. (D) Spectral hues. Plotted as a function of spectral wavelength are the percentages of cases in which each of four separate hue categories (blue, green, yellow, and red) was employed to describe the colors of various lights.

the inverse of the intensity of light required for detection under daylight test conditions. This is a measure of the degree of achromatic variation across the spectrum. The sensitivity variations shown in Fig. 3A predict that colors produced by lights of different wavelengths but equal intensities vary greatly in brightness, and so they do. This characteristic feature of the visual system is so important that a standard spectral sensitivity curve representing the averaged values for many subjects has been derived. This curve has come to be used to provide another specification of the brightness dimension—a metric referred to as luminance. Because luminance has formal properties that brightness does not possess (e.g., luminance units can be additively combined, whereas units of brightness cannot), vision scientists typically prefer luminance as a means of specifying the visual effectiveness of lights.

As noted previously, color depends centrally on the wavelength of light. Figure 3B illustrates how sensitive humans are to changes in wavelength. Plotted is a measure of the size of the wavelength difference ($\Delta\lambda$) required to yield a discriminable change in the appearance of a light for all locations across the spectrum. This result is sometimes called a hue discrimination function, although in fact wavelength change may induce both hue and saturation differences. Note that people are exquisitely sensitive to wavelength changes in two parts of the spectrum. Indeed, under stringent test conditions humans can reliably discriminate some wavelength differences that amount to no more than fractions of a single nanometer. Saturation can be measured in several ways, but they all indicate that spectral lights differ greatly in the degree to which they yield a saturated color. As illustrated in Fig. 3C, lights of both long and short wavelength (usually having an appearance of red and blue, respectively) are seen as highly saturated; lights of about 570–580 nm (seen as yellow) are very unsaturated. The results shown in Figs. 3A–3C imply that people are acutely attuned to detecting differences in several color dimensions when these dimensions are probed separately. However, how good are we at detecting differences when all three perceptual dimensions can vary as they do in normal viewing? One way to appreciate human color vision is to ask how many different colors people can see. A recent estimate suggests that those of us with normal color vision can discern in excess of 2 million different surface colors. Clearly, the human color palette is very extensive.

The results of Figs. 3A–3C are discrimination measures in which people were asked to operate as instruments solely designed to detect differences, entirely ignoring how these lights actually appear. In our ordinary experience with color the rich medium of language is most often employed to give objects color names. It turns out that people can apply color names to lights varying in wavelength and intensity in a sufficiently systematic fashion to generate very reliable indications of color appearance. Figure 3D shows the results from a so-called hue-scaling experiment in which people were asked to name the colors of lights varying in wavelength. They were allowed to use only four different color names (red, yellow, green, and blue), either singly or in pairs; the latter being the case in which one of the four names could be used to modify another (e.g., yellowish red). Not only can people do this reliably but also, perhaps surprising, there is very high consistency of the use of hue names among individuals. There are two important aspects of these results. First, note that in some parts of the spectrum hue changes rapidly with changes in wavelength (i.e., there are well-defined transitions between the color names used by the subjects). Not surprisingly, these regions are those where wavelength discrimination is most acute. Therefore, for example, at approximately 580 nm there are abrupt changes in the hue names given to lights of different wavelengths and this coincides with one of the locations where wavelength discrimination is most acute (compare Fig. 3D with Fig. 3B). Second, there are apparently mutually exclusive categories of hue appearance: A light may be seen to yield both red and yellow components (i.e., reddish yellow or yellowish red) or green and yellow components, but people almost never describe lights as containing both red and green components. The same conclusion holds for yellow and blue. This mutually exclusive pairing of color sensations has long been known and traditionally interpreted as reflecting mutually antagonistic interactions between color processing mechanisms somewhere in the visual system. The antagonistic hue pairs (red/green and yellow/blue) are usually called opponent colors.

The utilization of names to group colors into coherent categories seems universal across all human populations. Results from a survey conducted by Berlin and Kay in 1969, involving an analysis of more than 100 languages, indicated that there are only 11 basic color terms (the English equivalents are white, black, red, yellow, green, brown, purple, pink, orange, and gray). The survey further suggested that these basic color terms have "evolved" among human populations in a reasonably predictable sequence in the sense that rules can be established to specify which

names are present in languages that do not contain the full set of color terms. For example, languages that contain only two basic color terms have black and white, and those with three color terms have black, white, and red. These observations have been taken to imply that basic color terms could reflect universal properties of the organization of the human nervous system. This conclusion has not escaped criticism, particularly from professional linguists, and although attempts have been made to connect these universal color categories to features of visual system physiology, no completely compelling linkages have been established.

D. Context and Constancy

Those aspects of color vision summarized previously were measured with small illuminated spots of specified wavelength and intensity presented in otherwise featureless, usually achromatic, visual fields or with small, carefully calibrated colored papers viewed against an achromatic background. Although ideal for examining human color vision in rigidly controlled circumstances, these conditions are quite unlike everyday visual worlds that are most often rich with both spatial and temporal variegation. From many laboratory studies of the influence of spatial and temporal variables it is clear that perceived color depends not only on the wavelength and intensity of the light reaching the eye from some point in a scene but also on a host of contextual features.

Color context effects have long been appreciated and often exploited for visual effect by painters, tapestry makers, and dyers. For example, the reddishness of a region in a visual scene can be much enhanced if adjoined by a region that appears green. Similarly, surrounding a yellow spot with an expanse of blue can increase the perceived yellowness significantly. These are examples of simultaneous color contrast. Analogous effects on perceived color operate along a timescale. Thus, exposing the eye to a red surface causes a subsequently viewed white surface to take on a greenish cast. Note that these successive contrast effects are similar to the spatial effects in that they tend to enhance the perception of colors that are complementary to those inducing the effect: Yellows enhance blueness; greens enhance redness, and so on. In this sense, they support the idea of a mutual exclusivity of some color sensations similar to that noted previously for the naming of colors.

Seemingly opposed to such contrast effects are instances of what has been called color assimilation. Assimilation occurs when a background color and an interlaced region tend to take on the same color rather than that of a contrast color. For example, consider a white hatched pattern that periodically interrupts a continuous red field. On the grounds of simultaneous color contrast one might expect the white region to take on a greenish appearance, but instead it looks red. It is as if the predominant color has spread into these neighboring regions. The conditions that determine whether contrast or assimilation occurs are incompletely understood, but the relative sizes and configurations of the spatially opposed regions are certainly factors. In any case, both contrast and assimilation effects make it clear that the visual system constructs a color world that is not solely based on the array of wavelengths and intensities coming from each individual region in the scene.

As Fig. 1 illustrated, light reaching the eye from an object depends jointly on surface reflectance of the object and on the nature of the illumination. Surface reflectance is an intrinsic property of objects, but the nature of the illumination is changeable and, consequently, the light reflected from any particular object can vary significantly. For example, the spectral distribution of light reflected from a clump of grass will change drastically as the sun moves from its overhead position to one on the horizon. If color depended solely on the distribution of wavelengths and intensity reaching the eye, one might expect the color of the grass would also change during this period of time. In fact, for the most part, the grass appears to remain resolutely green in appearance. The ability of the visual system to maintain a reasonably consistent object color in the face of these variations in illumination is called color constancy. The occurrence of color constancy implies that somehow the visual system is able to register the nature of the changes in illumination and then to substantially discount these changes. Although the mechanisms in the nervous system that allow this are not well understood, color constancy is supremely important in enhancing stability in our perceptual representations of the color world.

II. COLOR VISION AND THE RETINA

The processing of information that leads to color vision begins in the retina. The retina is an exquisitely organized portion of the nervous system lining the

interior of the back surface of the eye. Each human retina is made up of approximately 115 million cells that act in concert to extract information from the optical image formed on the retinal surface. Our understanding of the processing of color information in the retina and the rest of the visual nervous system is drawn mainly from studies of humans and from our close relatives, the Old World monkeys.

A. Cone Photopigments

There are two classes of photoreceptor—rods and cones. Rods are involved in supporting vision under low-light conditions (technically called scotopic vision). Cones subserve color vision and other characteristic features of daylight vision (photopic vision), such as high spatial and temporal sensitivity. The conversion of energy from light into nerve signals is accomplished in the photoreceptors. The initial step in this transduction process involves the absorption of photon energy by photopigments. Molecules of cone pigment are densely packed in a series of parallel membranes making up one end of the photoreceptor, a physical arrangement that is particularly effective in trapping incoming light. The pigment molecule has two essential components—a protein called opsin and a covalently linked chromophore, the latter being a derivative of vitamin A. Absorption of energy from a photon of light causes the chromophore to undergo a conformational change, an isomerization. This change is virtually instantaneous, complete in no more than 200 fsec (fsec=10^{-15} sec). It serves as a first step in a cascade of molecular changes that produce a modulation in the flow of ionic current across the photoreceptor membrane. This induced electrical change spreads along the length of the photoreceptor and in turn alters the rate of release of neurotransmitter to second-order cells in the retina and thereby communicates a signal onward into the retinal network.

The efficiency with which photopigments absorb light varies continuously as a function of the wavelength of the light. Figure 4 illustrates the absorption spectra for the three classes of cone pigment found in the retinas of people with normal color vision. When properly scaled the shapes of absorption spectra for all photopigments are similar, and thus they can be economically specified by using one number, the wavelength to which they are maximally sensitivity (λ_{max}). The human cone pigments have λ_{max} values at about 420, 530, and 560 nm. The shape and width of the absorption spectrum for the photopigment are dependent on features of the chromophore, whereas the spectral positioning of the pigment along the wavelength axis depends on structural features of the opsin. Note that there is a significant amount of overlap in the wavelengths of light absorbed by these pigments. This is important because it is the comparison of the amount of light absorbed by different pigments that constitutes the basis for the nerve signals that lead to color vision. Among vision scientists, the receptors containing these three pigments are usually termed S, M, and L cones, respectively (shorthand for short-, middle-, and long-wavelength sensitive). The three classes of cone are unequally represented in the retina, having an overall ratio of 1S:3M:6L, with some significant individual variations. As discussed later, this fact is important in understanding some features of human color vision.

A fundamental feature of the operation of pigments is that their response to light is proportional to the number of photons they absorb independent of the wavelength of these photons so that, once absorbed, each photon contributes equally to any generated signal. This means that the signal provided by a given type of receptor contains no information about the wavelength of the light that was absorbed. The blindness of a single type of photopigment to wavelength differences is formally called the principle of univariance. An important functional consequence of pigment univariance is that a retina having only a single type of photopigment could not support any color vision capacity. This is one reason why colors disappear under scotopic conditions when only a single (rod) pigment is operational.

Color matching behavior can be traced directly to the univariant property of the cone pigments. Thus, in a color match of the sort described previously, the subject is actually adjusting the amounts of the primary lights so that the three types of cone will absorb equal numbers of photons from the primary lights and from the test light. A consequence is that color matches are very sensitive to the relative spectral positions of the cone pigments. Indeed, other things being equal, the retinas of two individuals who set different color matches must contain photopigments that differ in their spectral positioning. This single fact constitutes one of the earliest and still most persuasive examples of a compulsive linkage between behavior and nervous system organization. Most humans have trichromatic color vision because their retinas contain three classes of cone pigment, each of which behaves univariantly. It is obvious from the absorption spectra

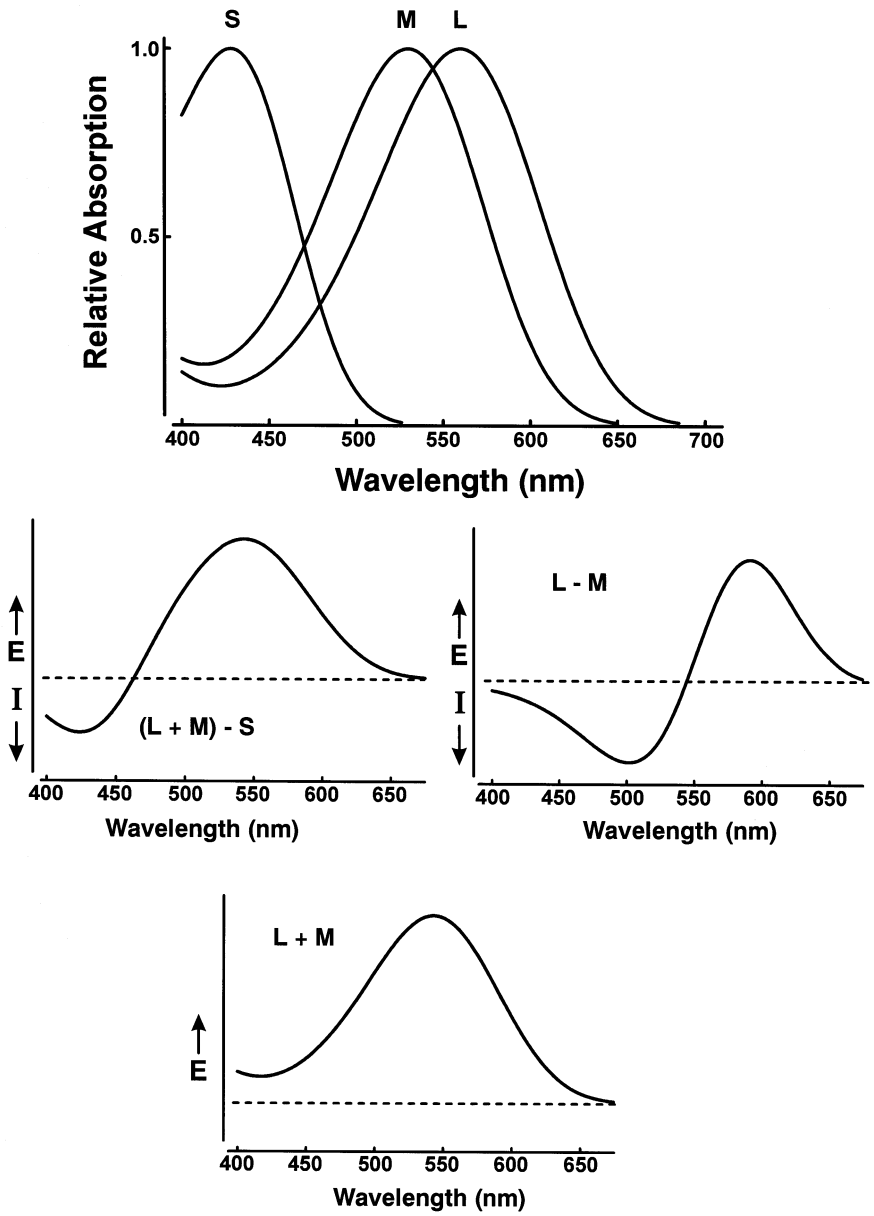

Figure 4 Response properties of photopigments and nerve cells. (Top) The absorption curves for the three classes of cone found in the eyes of people with normal color vision. The peak sensitivities of the three cone types are at 430 nm (S), 530 nm (M), and 560 nm (L). The three graphs at the bottom illustrate the responses of nerves cells in the visual pathway that combine inputs from the three cone types. (Middle) Spectrally opponent cells that show additive and subtractive combinations of cone signals. The inputs are indicated. E, excitation; I, inhibition. (Bottom) Response property of a nonopponent cell that additively combines signals from M and L cones.

of Fig. 4 that S cones absorb very little light from the middle- to long-wavelength portion of the spectrum. A consequence of this is that only two primary lights are required to complete color matches in this part of the spectrum (i.e., over those wavelengths, three-variable, trichromatic color vision gives way to two-variable, dichromatic color vision).

B. Genes and Photopigments

Single genes specify the opsins of each of the types of cone pigment. The human opsin genes were first isolated and sequenced in 1986. As long predicted from observations about the inheritance of color vision defects, the genes for the M and L pigments are located

on the q-arm of the X chromosome where they lie in a head-to-tail tandem array. Each of the X chromosome genes specifies an opsin composed of 364 amino acids, and the two are so similar in structure that the amino acid sequences for M and L pigments are 96% identical. Most individuals (at least 75% of the population) have more than one copy of the M cone pigment gene, although the functional significance of these ''extra'' genes remains debatable. The S cone opsin gene is autosomal, located on chromosome 7. It specifies a photopigment opsin containing 348 amino acids. The sequence of this gene differs from the other two enough to produce an S cone opsin that is 40–45% identical to that of the M and L cone pigments.

The close physical proximity on the X chromosome of the M and L opsin genes and their great sequence similarities makes them particularly susceptible to unequal recombination during meiosis. Such recombination events can result in the loss or the gain of complete copies of the opsin genes, or they can produce novel genes through recombination of partial sequences drawn from the original M and L genes. All of these changes will have an impact on the nature of the photopigments that get produced and hence they will alter significantly the details of color vision in that individual. For example, a loss of either the M or the L pigment gene reduces the retina so that it contains two, not three, types of cone pigment and consequently limits the individual to a dichromatic form of color vision.

C. Evolution of Human Color Vision

In recent years, the study of color vision in nonhuman species has expanded greatly, as has our view of the nature of opsin genes and photopigments in a host of different species. This has begun to allow an understanding of the evolution of human color vision. Comparison of opsin gene sequences indicates that visual pigments have an ancient origin and that there is evidence for the presence of two separate cone pigments very early in vertebrate history (perhaps as long as 400 million years ago). This arrangement would have provided the necessary basis for a dichromatic color vision system, although there is currently no way of knowing if that potential was actually realized. The nature of color vision and the physiology that allows for color vision vary significantly among present-day vertebrates. As previously mentioned, humans normally have three classes of cone pigment and trichromatic color vision. The retinas of many fishes, reptiles, and birds contain at least four classes of cone pigment, and there is evidence to support the conclusion that these may well provide a four-variable form of color vision—a tetrachromacy. On the other hand, the retinas of most mammals (e.g., domestic dogs and cats) contain only two types of cone pigment allowing a basic dichromacy. This difference has led to the hypothesis that the potential for a sophisticated form of color vision was lost sometime early in mammalian history. Among mammals, the presence of three types of cone pigment and trichromatic color vision is restricted to primates. From this fact, it can be concluded that our exceptional color vision sense appeared during the evolution of primates.

Comparison of opsin genes and color vision in Old World primates (in particular, Old World monkeys, apes, and humans) and in New World monkeys indicates that the essential change from a basically dichromatic form of color vision to uniform trichromatic color vision occurred shortly after the divergence of Old World and New World primates approximately 30–40 million years ago. The means for accomplishing this was an X chromosome opsin gene duplication that yielded two separate M and L genes. Whether that duplication arose from identical X chromosome genes that eventually diverged in structure or whether it was built from the baseline of a polymorphism at a single gene site is not clear. In any case, the origins of human trichromacy can be traced to changes that first appeared in the retinas of our early primate ancestors. An important consequence of this is that human color vision is very similar in its detail to the color vision enjoyed by all contemporary Old World monkeys and apes.

D. Neural Mechanisms for Color Vision in the Retina

As noted previously, the human retina contains multiple types of cone photopigment. Multiple cone types are a necessary but not sufficient basis to support a color vision capacity. In addition, there must also be an appropriately organized nervous system. The extraction of information that allows for color vision begins in the neural networks of the retina.

In addition to the photoreceptors, there are four other major classes of nerve cell in the retina: bipolar, ganglion, horizontal, and amacrine cells. These form intricately organized vertical and horizontal

possessing networks arrayed through the thickness of the retina with bipolar and ganglion cells serving as the principal vertical pathway and the other two types providing a rich array of horizontally organized connections. Each of the four types of cell in turn consists of discrete subtypes. Currently, a majority of the latter are poorly defined, both structurally and functionally, but it is believed that it will eventually be possible to characterize as many as 50 distinct types of cells in the primate retina. The main business of the networks formed by these cells is to perform the first stages in the processing of the retinal image. These tasks include the analysis of local spatial and temporal variations and the regulation of visual sensitivity. The processing of color information proceeds in the context of all these other analyses.

Because each cone type behaves univariantly, the extraction of color information requires the comparison of the signals from cone types containing different photopigments. There are two principal ways in which cone signal information is combined in the nervous system: additively (spectrally nonopponent) or subtractively (spectrally opponent). Cells of the former type sum signals from the L and M cone types (L + M). Because they do not respond differentially to wavelength differences irrespective of the relative intensity, cells so wired cannot transmit information useful for the production of color vision. The response properties of spectrally opponent cells are produced by convergence of excitatory and inhibitory signals onto recipient nerve cells. The cone signal combinations are classified into two main groups: L−M and (L + M)−S (for each of these types the signs can be reversed, i.e., there are both L−M and M−L types). Response profiles for opponent and nonopponent cells are shown in Fig. 4. It can be seen that, unlike the nonopponent cells, spectrally opponent cells will yield different responses to different wavelengths of light irrespective of the relative intensities of those lights. They thus can transmit information that may be useful for supporting color vision. With regard to color information, the output cells of the retina (the ganglion cells) are classified into three groups: those that transmit nonopponent information into the central nervous system, those carrying M−L information, and those whose response patterns are (M + L)−S (Fig. 4). Much is known about the anatomy of such cells and the input pathways that yield these different response patterns.

Several structural and functional properties of the retina map are directly mapped into the quality of human color vision. For example, S cones are sparsely distributed across the retina and are absent entirely from its very central portion (the fovea). A consequence is that the color information contributed from S cone signal pathways is lost for stimuli that are very small (i.e., trichromacy gives way to dichromacy under such viewing conditions). The connection pathways from the L and M cones also vary across the retina. Although the picture is still somewhat controversial, in general there is an observed decrease in the relative potency of L/M spectrally opponent signals toward the peripheral parts of the retina. This decrease is presumed to be a factor in the gradual decline in sensitivity of red/green color vision for stimuli located away from the direction of gaze. Finally, due to variations in the neural circuitry, there are significant differences in the spatial and temporal sensitivities of the different types of retinal cells. One consequence of this is that our color vision becomes progressively more restricted for regions in the visual scene that are very small and/or are changing very rapidly. Thus, human color vision is trichromatic only for relatively large and slowly changing stimuli, giving way to dichromatic color vision as the space/time components of the stimulus are increased and, eventually, one can lose color vision entirely (i.e., become monochromatic) for very small and/or very rapidly changing stimuli.

III. THE CENTRAL VISUAL SYSTEM AND COLOR

Behavioral studies of vision have led to a consensus view that the facts of human color vision can best be understood as reflecting the operation of three separate mechanisms. These mechanisms are conceived as implying the presence of three parallel channels of information in the central visual system. Two of these are opponent channels reflecting, respectively, the mutual antagonisms of red and green and of yellow and blue. The third is a nonopponent channel that provides achromatic information (the luminance mechanism). The spectrally opponent and nonopponent cells of the type described previously were first recorded approximately 40 years ago not in the retina but in the lateral geniculate nucleus (LGN), which is a large thalamic structure that serves as a relay site situated in the central visual pathway between the retina and the visual cortex. Following the discovery of these cells it was immediately recognized that there is a compelling analogy between the physiological results and the behavioral conception of the color mechanisms. Thus, the L−M cells and the (L + M)−S cells

(Fig. 4) have many characteristic features that appear to be like those of the behaviorally defined red/green and yellow/blue color channels. Similarly, the L + M cells have the appropriate spectral sensitivity as well as many other features that appear to make them ideal candidates to serve as the luminance mechanism.

Over time, however, closer examination of the relationships between the standard behavioral model and the physiological results has revealed a lack of complete correspondence between the two, and this forced a reevaluation of the idea that the spectrally opponent cells of the retina and LGN directly represent the color mechanisms documented in behavioral experiments. To note just one problem, consider the perceptual observation that the spectrum takes on a distinctly reddish appearance in the short wavelengths (this can be seen in the hue naming results of Fig. 3C). Among color vision theorists, the conventional explanation for this fact is that the red/green color mechanism must receive some signals from the S cones. However, electrophysiological studies indicate that the L−M cells do not have an S cone input so they cannot directly account for this feature of red/green color vision. Many other disparities between the behavioral aspects of human color vision and the physiology of cells located early in the visual pathway have also been enumerated. The inevitable conclusion is that although the spectrally opponent cells clearly transmit the information necessary for color vision, the response properties of these cells cannot directly account for many features of human color vision. This means that there must be some further transformations of the signals provided by spectrally opponent cells and those transformations are assumed to take place somewhere in the visual cortex.

The picture of how color information is processed and elaborated in the visual cortex is still very sketchy. Researchers have tried to understand how color information is encoded by cortical neurons, and they have pursued the hypothesis that color processing might be localized to particular component regions of the cortex. Analysis of the response properties of single cortical cells has been avidly pursued. Unfortunately, the results have led to conflicting views as to how cortical cells encode color information. This is understandable since the task is far from simple. Much of the difficulty arises from the fact that although the responses of cells in the retina and in the LGN are only modestly dependent on the spatial and temporal features of the stimulus, the responses of cortical cells are very much conditioned by these properties. The consequence is that studies utilizing differing spatio-temporal stimulus features have often reached quite different conclusions about the nature of cortical color coding. What is known, both from single cell studies conducted on monkeys and imaging studies of human brains, is that color-selective responses can indeed be recorded in primary visual cortex (area V-1) and at other locations in the extrastriate cortex. Studies also make clear that transformations of the spectrally opponent responses of LGN cells do occur in V-1 and that such transformations arise, at least in part, from dynamic interactions between cortical cells. For example, neural feedback circuits may significantly amplify contributions from signals originating in S cones relative to those S cone signals recorded at more peripheral locations. Such a change brings the physiological picture more in line with behavioral measures of color vision. Similarly, at least some cells in V-1 are known to combine signals from the two classes of LGN spectrally opponent cells. This too brings the physiology closer to the coding scheme inferred from behavioral studies of color vision. Although the relationships between cortical codes for color and psychophysical models of color coding are not clear, significant progress is being made toward their rationalization.

For years it has been argued that the processing of color information can be localized in the extrastriate visual cortex. From studies of both monkey and human brains, regions in the lingual and fusiform gyrus (sometimes characterized as area V-4) have been identified as particularly important for color. In humans this area responds robustly to the presentation of stimuli designed to specifically probe color vision, and it has been reported that cells in monkey area V-4 exhibit some forms of color constancy. Providing additional support for the idea of localized cortical representation of color are clinical descriptions of patients who have suffered a loss of color vision as a result of cortical damage (cerebral achromatopsia). The nature of the color vision loss in cerebral achromatopsia is complex and beyond the scope of this article. For our purposes, the important fact is that although the locus of damage that results in cerebral achromatopsia varies significantly among described cases, it most often does include area V-4.

IV. VARIATIONS IN HUMAN COLOR VISION

In 1794, John Dalton, the celebrated chemist, offered a series of astute observations about his own color

perceptions. He noted, for instance, that the spectrum appeared to him to contain just three colors (yellow, blue, and purple) and that flowers that appeared pink to others seemed to him "an exact sky blue." Dalton eventually discovered that many other individuals shared his atypical color perceptions and he was led to offer a hypothesis to explain the condition based on the presumed presence of some unusual intraocular filter. Retrospective analysis shows that Dalton suffered from deuteranopia, a common congenital color vision defect that affects about 1% of all males. Dalton was not the first to learn of defective color vision among humans, and his explanation of the source of the defect was wrong, but his detailed descriptions were very instrumental in initiating a long series of examinations of color defect that continue to the present day. Studies of color vision defects, and of other individual variations in color vision, have provided significant insights into the biology of color vision. In addition to the congenital color vision defects, color vision change may be acquired through a wide variety of visual system pathologies as well as senescent changes occurring in the visual system.

A. Congenital Color Vision Defects

There are many distinct types of congenital color defect and each yields a characteristic pattern of results on behavioral tests of color vision (these include both laboratory tests of the kinds described previously and the familiar plate tests used for the clinical screening of color vision). Those most severely impacted have dichromatic color vision, like that of John Dalton. When tested in color matching experiments of the sort described previously, such individuals require only two primary lights to complete all the color matches. The number of discrete color discriminations that can be made is also severely reduced. For instance, in the wavelength discrimination test (Fig. 3B), dichromats basically fail to discriminate among wavelengths in the middle to long wavelengths while retaining an ability to discriminate wavelengths shorter than approximately 490–500 nm from wavelengths longer than that value. As a result, they are commonly characterized as "red/green color blind." This is a somewhat misleading description since dichromats are not blind to color in this part of the spectrum: Rather, they simply fail to discriminate among these colors. The full gamut of saturations that dichromats see is also significantly smaller than that seen by people with normal trichromatic color vision. There are two major types of congenital dichromacy, protanopia and deuteranopia. Individuals of the two types differ both in the details of color discriminations they can make and in their spectral sensitivity.

In addition to the dichromacies, there are also trichromatic individuals whose color vision nevertheless differs significantly from normal trichromacy. These people are said to have anomalous trichromatic color vision and, like the dichromats, their color vision defects can be detected by color discrimination tests. Anomalous trichromats are of major two types: protanomalous and deuteranomalous. An essential difference between the two types emerges from a simple color matching task in which an individual is asked to complete a color match by adding green and red lights in proportion to match a yellow test light. Dichromats so tested fail to set a reliable match since they cannot discriminate among colors in this part of the spectrum. All trichromatic individuals can make such matches. Relative to the normal, the protanomalous observer will require additional red light to complete the match, whereas the deuteranomalous individual needs additional green light. A wide range of other discrimination tests can be similarly used to distinguish among the trichromatic subtypes. Although the trichromatic anomalies are usually classified as color vision defects, it is important to note that in fact many anomalous trichromats have quite acute color vision.

Individuals with these congenital defects thus differ significantly from those with normal color vision in their discrimination abilities. What do they actually see? This intriguing question has not been easy to answer. Growing up as a minority in a color-coded world, most color defectives acquire a rich vocabulary of color names that they learn to use in a discerning fashion. They can do this because there are many secondary cues to allow one to apply color names in accord with the majority view (e.g., familiar objects are often characteristically colored and objects of different color often have systematic brightness differences). It is only when these secondary cues become scarce or disappear entirely (as they do in formal tests of color vision) that color defect become readily apparent. Some insights into the color world of the color defective come from examination of the occasional individual who has defective color vision in one eye and normal color vision in the other. Similarly, inferences can be drawn from comparison of the discrimination abilities of the normal and the color defective. These pieces of evidence suggest that the two

major types of dichromat view the world in what to the normal would be varying shades of only two hues—blues and yellows. Furthermore, there are significant losses in the saturation of lights so that the perceptual world of the dichromat is distinctly pallid relative to that of the normal. Recently, computer algorithms have been developed that allow one to transform a digitized colored image to obtain a perceptual prediction of the dichromatic world. Although defective color vision is often treated as a benign condition, there is documented evidence to indicate that those who have defective color vision find that it provides a real barrier in many aspects of normal life—from things as mundane as making judgments about the ripeness of a piece of fruit to issues as far reaching as a choice of a profession.

A vast majority of those with defective color vision are male. The incidence of defective color vision among males is given in Table I. In total, approximately 8% of the in Western Europe and in the United States can be classified into one or another of these diagnostic categories with 5% of all males having deuteranomalous color vision. The incidence of red/green defective color vision is low in females, being approximately the square of the frequency of the corresponding male color vision defects.

There are also rare congenital color vision defects that arise from change or alteration in the ability to discriminate among short-wavelength lights (tritanopia and tritanomaly). The incidences of these defects do not differ for male and females. Finally, in addition to dichromats and anomalous trichromats, a relatively few individuals lack color vision completely (are monochromatic) or only show an ability to discriminate color in very restricted test circumstances.

Table I
Incidence of Congenital Defective Color Vision among Caucasian Males[a]

Diagnostic category	%
Protanopia	1.0
Deuteranopia	1.1
Tritanopia	0.001
Protanomaly	1.0
Deuteranomaly	4.9
Monochromacy	0.003

[a]The incidence values are based on large-scale surveys of defective color vision and should be considered approximate.

B. The Biology of Congenital Color Defects

Protanopia, deuteranopia, protanomaly, and deuteranomaly all arise from changes in the X chromosome opsin genes. As noted previously, unequal recombination events that occur during meiosis can lead to additions and losses of genes from the X chromosome as well as to the production of novel genes (Fig. 5). Thus, a loss of the L cone opsin produces a protanopic dichromacy; loss of the M opsin yields deuteranopia. On the other hand, the anomalous trichromacies reflect the genomic presence of atypical opsin genes. In these cases, a new pigment replaces either the normal M pigment (in cases of deuteranomaly) or the normal L pigment (in protanomaly). The spectrum of this new pigment is shifted so as to be closer to that of the other (normal) M or L pigment. Depending on which of several atypical genes is present, the spectral separation of the M and L pigments is made either greater or smaller and severity of the color vision defect is correspondingly more or less. Only females that are homozygous for these defective X chromosome opsin genes show classical indications of these red/green color defects, thus explaining why the frequency of defective color vision in females is low. Pedigrees of color vision defects have long indicated that in the usual case sons inherit a color defect from mothers who carry a defective gene but who have normal color vision. The tritan defects similarly result from changes in S opsin genes. Since these represent changes in autosomal genes, the incidences of these defects do not differ for males and females. The biology underlying the complete loss of color vision is not straightforward and, in different cases, is apparently traceable to either photopigment or nervous system alterations.

Surveys indicate that the incidence of defective color vision varies significantly among different population groups. The highest frequencies are found in the United States and Western Europe, where approximately 7–9% of all males show a form of red/green color vision defect. Elsewhere, the incidence is often lower. For instance, several populations have been reported to show comparable defects in only about 1% of the males. These regional/ethnic differences have received various interpretations, perhaps the most popular being that the higher rates of defect are found in those populations in which there has been a relaxation of natural selection pressure against color vision defects. According to this view, those societies that are least altered from their hunter/gatherer origins should have the lowest incidences of defective color

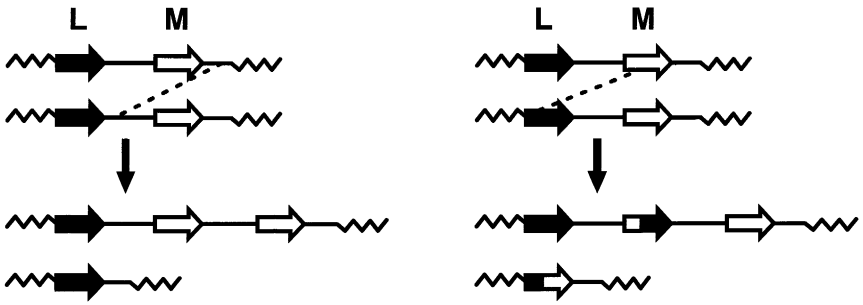

Figure 5 X chromosome gene combinations leading to defective color vision. Arrows represent genes for M and L cone opsins. Illustrated are two examples of unequal recombinations that yield new gene arrays. The dashed lines indicate where crossing over occurs during meiosis. (Left) The unequal crossover yields two new gene arrays, one with an L opsin gene and two copies of the M opsin gene. This genotype is common in individuals having normal color vision. The second result is a deletion of the M cone opsin gene. A male with this genotype would have dichromatic color vision. (Right) The crossovers occur within the gene. This produces new genes whose pigment products will differ from those of the normal M and L opsin genes, and depending on the resultant combination of genes the effects on color vision can be subtle or drastic.

vision. There is no compelling evidence to support this idea, but neither can it be flatly rejected.

C. Subtle Variations in Human Color Vision

The differences in color vision between normal trichromats and various color defectives are major and dramatic, but there are also reliable differences in color vision among individuals within each of these groups and study of these small variations can provide a useful tool for understanding the biological basis of color vision. One particular example comes from the study of variations in the color matching among normal trichromats. In a standard version of the color-matching task, people are asked to adjust the proportions of red and green primaries to match a yellow test light (with lights drawn from this part of the spectrum, trichromats make dichromatic matches). Color discrimination is particularly acute for lights from this part of the spectrum and, consequently, subjects make extremely reliable matches. It has long been known that individual matches may differ in that some people consistently require relatively more red light to complete the match, and others need relatively more green light. As previously explained, differences in color matches mostly arise from differences in the spectral positioning of the retinal photopigments, so an implication is that individuals who make different color matches must have different photopigments.

In recent years, the biological basis of this small variation in color matching has been uncovered. As predicted, it reflects the fact that normal human trichromats show small variations in the spectral positioning of their photopigments. Unexpectedly however, the variation is not continuously distributed in the population but rather appears to have a discrete character. This variation has been shown to result principally from a polymorphism in the gene specifying the L cone opsin. This polymorphism, involving a difference of only a single nucleotide, in turn causes a variation in a single amino acid in the photopigment molecule and thus there are two forms of the L cone pigment. This variation allows the L cone pigment to occupy either one of two spectral positions, with the two varying in their λ_{max} values by about 4 nm. A male who has the longer of the two pigment versions will require systematically less red light in the color match than will a male who has the shorter of the two pigments. These two polymorphic variants of the L cone opsin gene are nearly equally represented in the population. It is remarkable that this very small genetic variation sorts individuals of normal color vision into groups that go through life experiencing the colors of the world as biased to appear either slightly redder or slightly greener.

Consciousness

MICHAEL S. GAZZANIGA
Dartmouth College

Just what is consciousness? The answer, I believe, is that consciousness is an instinct—a built-in property of brains. Like all instincts, it is just there. You do not learn to be conscious and you cannot unlearn the reality of conscious experience. Someday we will achieve a more mechanistic understanding of its operation, but I warn you now: That won't be especially fulfilling on a personal level. We have to shed our expectation that a scientific understanding of consciousness will sweep away our sense of strangeness, like finding out how ships get in bottles. Take our reproductive instinct. Does it help our sense of desire to understand the role of testosterone when we see a shapely figure across the room? Or take the human instinct for language. Does it help us to enjoy language if we understand that grammar is a universal built-in reflex but that our lexicon is learned? Understanding the problem of consciousness may be essential to our ultimate ability to deal with some mental disorders. Disorders of conscious experience, whether autism or schizophrenia or dementia, will be illuminated by a mechanistic understanding of personal conscious experience.

My own thinking on this topic started early, in Roger Sperry's laboratory at the California Institute of Technology on an afternoon almost 40 years ago, when I first tested a split-brain patient. It seemed that, whatever consciousness was, you could have two of them after the surgical severy of the corpus callosum connecting the two cerebral hemispheres. Mind Left did not appear to know about Mind Right and vice versa. Those first impressions, which still endure, nevertheless left much to be desired as a sophisticated perspective on the question of consciousness. My plight as a researcher echoed Tom Wolfe's admonition to practice writing for 20 years before you seek a publisher.

Classic split-brain research highlighted how the left brain and the right brain serve distinctive functions and led us to believe that the brain is a collection of modules. The left brain (or hemisphere) is specialized not only for language and speech but also for intelligent behavior. After the human cerebral hemispheres are disconnected, the patient's verbal IQ remains intact and his problem-solving capacity (as observed in hypothesis formation tasks) remains unchanged for the left hemisphere. Indeed, that hemisphere seems to remain unchanged from its presurgical capacity. Yet the largely disconnected right hemisphere, which is the same size as the left, becomes seriously impoverished for many cognitive tasks. While it remains superior to the left hemisphere in certain activities (in recognizing upright faces, having better skills in paying attention, and perhaps in expressing emotions), it is poorer after separation at problem solving and many other mental activities.

Apparently the left brain has modules specialized for higher cognitive functions, while the right has modules specialized for other functions. Visuospatial function, for example, is generally more acute in the right hemisphere, but left hemisphere integration may be needed to perform higher order tasks. The use of

This article is reproduced from Gazzaniga, M. S. (1999). The interpreter within: The glue of conscious experience. *Cerebrum* **1**(1). with permission of the Dana Foundation.

tactile information to build spatial representations of abstract shapes appears to be better developed in the right hemisphere, but tasks such as the Block Design test, which are typically associated with the right parietal lobe, appear to require integration between the hemispheres in some patients. Furthermore, even though the right hemisphere is better able to analyze unfamiliar facial information than is the left hemisphere, and the left is better able to generate voluntary facial expressions, both hemispheres can generate facial expression when spontaneous emotions are expressed.

In addition to the skills named previously, our big human brains have hundreds if not thousands more individual capacities. Our uniquely human skills may well be produced by minute, circumscribed neuronal networks, sometimes referred to as ''modules,'' but our highly modularized brain generates a feeling in all of us that we are integrated and unified. If we are merely a collection of specialized modules, how does that powerful, almost self-evident feeling come about?

I. THE ''INTERPRETER''

The answer appears to be that we have a specialized left hemisphere system that my colleagues and I call the ''interpreter.'' This interpreter is a device (or system or mechanism) that seeks explanations for why events occur. The advantage of having such a system is obvious. By going beyond simply observing contiguous events to asking why they happened, a brain can cope with such events more effectively should they happen again.

We revealed the interpreter in an experiment using a ''simultaneous concept test.'' The split-brain patient is shown two pictures, one presented exclusively to his left hemisphere, one exclusively to his right. He is then asked to choose from an array of pictures the ones he associates with the pictures that were presented (or ''lateralized'') to his left brain and his right brain. In one example of this, a picture of a chicken claw was flashed to the left hemisphere and a picture of a snow scene to the right. Of the array of pictures then placed in front of the subject, the obviously correct association was a chicken for the chicken claw and a shovel for the snow scene. Split-brain subject case 1 did respond by choosing the shovel with his left hand and the chicken with his right. Thus each hemisphere picked the correct answer.

Now the experimenter asked the left-speaking hemisphere why those objects were picked. (Remember, it would only know why the left hemisphere had picked the shovel; it would not know why the disconnected right brain had picked the shovel.) His left hemisphere replied, ''Oh, that's simple. The chicken claw goes with the chicken, and you need a shovel to clean out the chicken shed.'' In other words, the left brain, observing the left hand's response, interprets the response in a context consistent with its own sphere of knowledge —one that does not include information about the snow scene presented to the other side of the brain.

One can influence the left-brain interpreter in many ways. As I mentioned, we wanted to know whether the emotional response to stimuli presented to half of the brain would influence the emotional tone of the other half. Using an optical computer system that detects the slightest eye movement, we projected an emotion-laden movie to the right hemisphere. (If the patient tried to cheat and move the eye toward the movie, it was electronically shut off.)

When we did this experiment with case 2, the movie that her right hemisphere saw was about a vicious man pushing another off a balcony and then throwing a firebomb on top of him. The movie then showed other men trying to put the fire out. When V. P. was first tested on this problem, she could not access speech from her right hemisphere. She was able to speak only out of her left brain. When asked what she had seen, her left brain (the half brain that had not actually seen the movie) replied, ''I don't really know what I saw. I think just a white flash.'' When I asked, ''Were there people in it?'' case 2, replied, ''I don't think so. Maybe just some trees, red trees like in the fall.'' I asked, ''Did it make you feel any emotion?'' and V. P. answered, ''I don't really know why, but I'm kind of scared. I feel jumpy. I think maybe I don't like this room, or maybe it's you; you're getting me nervous.'' She turned to one of the research assistants and said, ''I know I like Dr. Gazzaniga, but right now I'm scared of him for some reason.''

This kind of effect is common to all of us. A mental system that is operating outside the conscious realm of the left hemisphere's interpreter generates a mood that alters the general physiology of the brain. Because the alteration in brain physiology is general, the interpreter is able to note the mood and immediately attributes some cause to it. This is a powerful mechanism; once clearly seen, it makes one wonder how often we are victims of spurious emotional/cognitive correlations.

Our recent investigations have looked further at the properties of the interpreter and how it influences mental skills. For example, there are

hemisphere-specific changes in the accuracy of memory processes. Specifically, the predilection of the left hemisphere to interpret events has an impact on the accuracy of memory. When subjects are presented with pictures representing common events (e.g., getting up in the morning or making cookies) and several hours later asked to say if pictures in another series appeared in the first, both hemispheres are equally accurate in recognizing the previously viewed pictures and rejecting the unrelated ones. Only the right hemisphere, however, correctly rejects pictures in the second set that were not previously viewed but were related to pictures previously viewed. The left hemisphere incorrectly "recalls" significantly more of these related pictures as having occurred in the first set, presumably because they fit into the schema it has constructed. This finding is consistent with the hypothesis that a left hemisphere interpreter constructs theories to assimilate perceived information into a comprehensible whole. In doing so, however, the process of elaborating (story making) has a deleterious effect on the accuracy of perceptual recognition. This result has been shown with verbal as well as visual material.

A recent example of the interpreter can be found in studies of case 3, a split-brain patient who can speak out of his right hemisphere as well as his left. His naming of stimuli in the left field seems to be increasing at a rapid rate. Although there is no convincing evidence of any genuine visual transfer between the hemispheres, during trials when J. W. was certain of the name of the stimulus, he maintained that he saw it well. On trials when he was not certain of the name of the stimulus, he maintained that he did not see it well. This is consistent with the view that the left hemisphere interpreter actively constructs a mental portrait of past experience, even though that experience did not directly occur in that hemisphere. This experience was probably caused by the left hemisphere's interpreter giving meaning to right hemisphere spoken responses, possibly by activating the left hemisphere mental imagery systems.

The left hemisphere's capacity for continual interpretation may mean that it is always looking for order and reason, even where there is none. This came out dramatically in a study by George Wolford and me. On a simple test that requires one to guess if a light is going to appear on the top or the bottom of a computer screen, we humans perform in an inventive way. The experiment manipulates the stimulus to appear on the top 80% of the time. While it quickly becomes evident that the top button is being illuminated more often, we keep trying to figure out the whole sequence—and deeply believe that we can. We persist even if, by adopting this strategy, we are rewarded only 68% of the time (whereas if we guessed "top" repeatedly, by rote, we would be rewarded 80% of the time). Rats and other animals are more likely to learn to maximize their score by pressing only the top button! Our right hemisphere behaves more like the rats. It does not try to interpret its experience to find the deeper meaning; it lives only in the thin moment of the present. But when the left brain is asked to explain why it is attempting to psych out the whole sequence, it always comes up with a theory, however spurious.

II. ANOSAGNOSIA AND PARAMNESIA

Neurology yields weird examples of how the interpreter can work, and understanding the interpreter increases our insight into some bizarre syndromes. Take, for example, a malady called "anosagnosia," in which a person denies awareness of a problem he has. People who suffer from right parietal lesions that render them hemiplegic and blind on their left side frequently deny that they have any problem. The left half of their body, they insist, is simply not theirs. They see their paralyzed left hand but maintain that it has nothing to do with them. How could this be?

Consider what may happen as a result of a lesion in a person's optic tract. If the lesion is in a nerve that carries information about vision to the visual cortex, the damaged nerve ceases to carry that information; the patient complains that he is blind in part of his visual field. For example, such a patient might have a huge blind spot to the left of the center of his visual field. He rightly complains. If another patient, however, has a lesion not in the optic tract but in the visual cortex, creating a blind spot of the same size and in the same place, he does not complain at all. The reason is that the cortical lesion is in the place in his brain that represents that exact part of the visual world, the place that ordinarily would ask, "What is going on to the left of visual center?" In the case of the lesion on the optic nerve, this brain area was functioning; when it could not get any information from the nerve, it put up a squawk—something is wrong. When that same brain area is itself lesioned, the patient's brain no longer cares about what is going on in that part of the visual field; there is no squawk at all. The patient with the central lesion does not have a complaint because the part of the brain that might complain has been incapacitated, and no other can take over.

As we move farther into the brain's processing centers, we see the same pattern, but now the problem is with the interpretive function. The parietal cortex is where the brain represents how an arm is functioning, constantly seeking information on the arm's whereabouts, its position in three-dimensional space. The parietal cortex monitors the arm's existence in relation to everything else. If there is a lesion to sensory nerves that bring information to the brain about where the arm is, what is in its hand, or whether it is in pain or feels hot or cold, the brain communicates that something is wrong: "I am not getting input." But if the lesion is in the parietal cortex, that monitoring function is gone and no squawk is raised, though the squawker is damaged.

Now let us consider our case of anosagnosia, and the disowned left hand. A patient with a right parietal lesion suffers damage to the area that represents the left half of the body. The brain area cannot feel the state of the left hand. When a neurologist holds a patient's left hand up to the patient's face, the patient gives a reasonable response: "That's not my hand, pal." The interpreter, which is intact and working, cannot get news from the parietal lobe since the flow of information has been disrupted by the lesion. For the interpreter, the left hand simply does not exist anymore, just as seeing behind the head is not something the interpreter is supposed to worry about. It is true, then, that the hand held in front of him cannot be his. What is the mystery?

An even more fascinating syndrome is called "reduplicative paramnesia." In one such case studied by the author, the patient was a women who, although she was being examined in my office at New York Hospital, claimed we were in her home in Freeport, Maine. The standard interpretation of this syndrome is that the patient has made a duplicate copy of a place (or person) and insists that there are two.

This woman was intelligent; before the interview she was biding her time reading the *New York Times*. I started with the "so, where are you?" question. "I am in Freeport, Maine. I know you don't believe it. Dr. Posner told me this morning when he came to see me that I was in Memorial Sloan–Kettering Hospital and that when the residents come on rounds to say that to them. Well, that is fine, but I know I am in my house on Main Street in Freeport, Maine!" I asked, "Well, if you are in Freeport and in your house, how come there are elevators outside the door here?" The grand lady peered at me and calmly responded, "Doctor, do you know how much it cost me to have those put in?"

This patient has a perfectly fine interpreter working away trying to make sense of what she knows and feels and does. Because of her lesion, the part of the brain that represents locality is overactive and sending out an erroneous message about her location. The interpreter is only as good as the information it receives, and in this instance it is getting a wacky piece of information. Yet the interpreter still has to field questions and make sense of other incoming information—information that to the interpreter is self-evident. The result? It creates a lot of imaginative stories.

III. CREATING OUR AUTOBIOGRAPHY

The interpreter's talents can be viewed on a larger canvas. I began this article by observing our deep belief that we can attain not only a neuroscience of consciousness but also a neuroscience of human consciousness. It is as if something wonderfully new and complex happens as the brain enlarges to its full human form. Whatever happens (and I think it is the emergence of the interpreter module), it triggers our capacity for self-reflection and all that goes with it. How do we account for this?

I would like to make a simple, three-step suggestion. First, focus on what we mean when we talk about "conscious experience." I believe this is merely the awareness we have of our capacities as a species—awareness not of the capacities themselves but of our experience of exercising them and our feelings about them. The brain is clearly not a general-purpose computing device; it is a collection of circuits devoted to these specific capacities. This is true for all brains, but what is amazing about the human brain is the sheer number of capacities. We have more than the chimp, which has more than the monkey, which has more than the cat, which runs circles around the rat. Because we have so many specialized systems, and because they may sometimes operate in ways that are difficult to assign to a given system or group of them, it may seem as though our brains have a single, general computing device. But they do not. Step one is to recognize that we are a collection of adaptive brain systems and, further, to recognize the distinction between a species' capacities and how it experiences them.

Now consider step two. Can there be any doubt that a rat at the moment of copulation is as sensorially fulfilled as a human? Of course it is. Do you think a cat does not enjoy a good piece of cod? Of course it does.

Or a monkey does not enjoy a spectacular swing? Again, it has to be true. Each species is aware of its special capacities. So what is human consciousness? It is awareness of the very same kind, except that we can be aware of so much more, so many wonderful things. A circuit, perhaps a single system or one duplicated again and again, is associated with each brain capacity. The more systems a brain possesses, the greater our awareness of capacities.

Think of the variations in capacity within our own species; they are not unlike the vast differences between species. Years of split-brain research have shown that the left hemisphere has many more mental capacities than the right. The left is capable of logical feats that the right cannot manage. Even with both our hemispheres, however, the limits to human capacity are everywhere in the population. No one need be offended to realize that some people with normal intelligence can understand Ohm's law, while others, such as yours truly, are clueless about hundreds of mathematical concepts. I do not understand them and never will; the circuits that would enable me to understand them are not in my brain.

When we realize that specialized brain circuits arose through natural selection, we understand that the brain is not a unified neural net that supports a general problem-solving device. If we accept this, we can concentrate on the possibility that smaller, more manageable circuits produce awareness of a species' capacities. By contrast, holding fast to the notion of a unified neural net forces us to try to understand human conscious experience by figuring out the interactions of billions of neurons. That task is hopeless. My scheme is not.

Hence step three. The same split-brain research that exposed startling differences between the two hemispheres revealed as well that the human left hemisphere harbors our interpreter. Its job is to interpret our responses—cognitive or emotional—to what we encounter in our environment. The interpreter sustains a running narrative of our actions, emotions, thoughts, and dreams. The interpreter is the glue that keeps our story unified and creates our sense of being a coherent, rational agent. To our bag of individual instincts, it brings theories about our life.

These narratives of our past behavior seep into our awareness; they give us an autobiography. Insertion of an interpreter into an otherwise functioning brain creates many by-products. A device that begins by asking how one thing relates to another, a device that asks about an infinite number of things, in fact, and that can get productive answers to its questions, cannot help giving birth to the concept of self. Surely one question the device would ask is "Who is solving all these problems?" "Let's call it me"—and away it goes! A device with rules for figuring out how one thing relates to another will quickly be reinforced for having that capacity, just as an ant's solving where to have its evening meal reinforces the ant's food-seeking devices. In other words, once mutational events in the history of our species had brought the interpreter into existence, there would be no getting rid of it.

Our brains are automatic because physical tissue carries out what we do. How could it be otherwise? Our brains are operating before our conceptual self knows it. But the conceptual self emerges and grows until it is able to find interesting—but not disheartening—the biological fact that our brain does things before we are consciously aware of them. The interpretation of things that we encounter has liberated us from a sense of being determined by our environment; it has created the wonderful sense that our self is in charge of our destiny. All of our everyday success at reasoning through life's data convinces us of this. And because of the interpreter within us, we can drive our automatic brains to greater accomplishment and enjoyment of life.

Conversion Disorders and Somatoform Disorders

RICHARD J. BROWN and MARIA A. RON
Institute of Neurology and National Hospital for Neurology and Neurosurgery, United Kingdom

GLOSSARY

conversion Putative psychological process whereby emotional distress is converted into physical symptoms to resolve internal conflict.

conversion disorder Disorder characterized by the presence of at least one unexplained neurological symptom thought to be caused by the process of conversion.

dissociation Putative psychological process whereby normally integrated aspects of memory become separated.

dissociative disorder Disorder characterized by at least one unexplained neurological symptom thought to be caused by the process of dissociation.

factitious illness Deliberate simulation of physical symptoms and/or signs to obtain medical attention.

hysteria Label traditionally used to describe either a condition characterized by unexplained physical symptoms or a type of personality characterized by overdramatic expression (i.e., hysterical personality disorder).

malingering Deliberate simulation of physical symptoms for personal gain.

somatization Tendency to experience or express psychological distress as physical symptoms.

somatization disorder A severe, chronic form of somatoform disorder involving multiple unexplained physical symptoms across several bodily systems.

somatoform disorder A group of disorders characterized by the presence of disabling unexplained physical symptoms for which there is no medical explanation.

Individuals who report physical symptoms for which no organic explanation can be found are commonly encountered by medical practice. Such symptoms are often associated with high levels of disability, distress, and medical resource utilization and are attributed to psychological factors. This article addresses the nature of ''unexplained'' physical symptoms, how they are diagnosed and treated, and current ideas concerning the mechanisms involved in their pathogenesis.

I. NOSOLOGY

Attempts to identify the mechanisms involved in the pathogenesis of unexplained physical symptoms extend as far back as ancient Egyptian times, when the prevailing view attributed their origin to a ''hysterical'' process involving abnormal movements of the uterus within the sufferer's body (the ancient Greek *hysteron*=''uterus''). Although the so-called ''wandering

womb'' hypothesis lost favor almost 2000 years ago, the term *hysteria* continued to be used as a generic label for the occurrence of medically unexplained symptoms until 1980, when the terms *hysteria* and *hysterical* were eliminated from the third edition of the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-III*) and two new superordinate categories, subsequently refined in *DSM-IV*, were created to capture the basic elements of the hysteria concept (Table I). The *somatoform disorders* category encompasses a range of complaints characterized by the symptoms of somatic illness (e.g., pain, fatigue, and nausea) in the absence of underlying physical pathology. Broadly speaking, *DSM-IV* categorizes somatoform complaints according to the nature, number, and duration of the unexplained symptoms in question. The *somatization disorder* category corresponds to the traditional conception of hysteria as a syndrome characterized by large numbers of unexplained symptoms across multiple bodily systems (also known as *Briquet's syndrome*). A *DSM-IV* diagnosis of somatization disorder (onset before the age of 30) requires a history of unexplained pain in at least four different bodily sites, at least two unexplained gastrointestinal symptoms, at least one unexplained sexual or reproductive symptom, and at least one unexplained neurological symptom. The *undifferentiated somatoform disorder* category includes less severe cases, in which unexplained symptoms have persisted for at least 6 months but are fewer in number and may be less disabling. Similar unexplained symptoms of a shorter duration are categorized as instances of *somatoform disorder not otherwise specified*. Each of the latter categories encompasses all possible physical symptoms, with the exception of unexplained neurological phenomena, which are categorized separately as *conversion disorders*. In addition, the term *pain disorder* is reserved for syndromes specifically characterized by the occurrence of persistent unexplained pain. In all cases, symptoms are classified as unexplained if adequate medical investigation has failed to identify a plausible physical cause for their occurrence; they must also cause clinically significant functional disability or distress to meet diagnostic criteria. Moreover, the symptoms should not be attributable to hypochondriasis or other forms of overt psychopathology, such as anxiety, depression, or psychosis. In addition, *DSM-IV* assumes that somatoform symptoms are not produced intentionally by the person. Rather, ''unexplained'' symptoms that are intentionally produced in order to obtain medical attention (e.g., as in Münchausen's disorder) are classified within the *factitious illness* category; symptoms that are intentionally produced for personal gain (e.g., in the context of a litigation claim or to avoid military service) are labeled as instances of *malingering*.

Table I
Classification of Somatoform and Dissociative Disorders in *DSM-IV*

Somatoform disorders	Dissociative disorders
Somatization disorder	Dissociative amnesia
Undifferentiated somatoform disorder	Dissociative fugue
Conversion disorder	Dissociative identity disorder
Pain disorder	Depersonalization disorder
Somatoform disorder not otherwise specified	Dissociative disorder not otherwise specified
Hypochondriasis	
Body dysmorphic disorder	

The *DSM-IV dissociative disorders* category includes unexplained symptoms involving an apparent disruption of consciousness, such as instances of amnesia and the alteration of personal identity (encompassing *dissociative amnesia, dissociative fugue*, and *dissociative identity disorder*). *Depersonalization disorder*, characterized by persistent and unpleasant feelings of detachment from the self or the world, is also placed within this category. Although, strictly speaking, the dissociative disorders should be viewed as one dimension of the hysteria concept, they are not typically regarded as medically unexplained symptoms and we will not consider them in detail in this article.

The nosological status of medically unexplained symptoms continues to provoke controversy. First, there is very little evidence to suggest that there are natural boundaries between the different categories of somatoform illness. Indeed, evidence suggests that the different somatoform categories should be regarded as points on a continuum of severity, with somatization disorder at the pathological extreme. Second, the persistence and stability of many cases of somatoform illness suggest that these conditions could be more appropriately viewed as a form of personality disorder rather than an acute psychiatric condition in their own right.

II. TERMINOLOGY

Despite being abandoned as a nosological entity, hysteria is still commonly used as a generic label for the

occurrence of medically unexplained symptoms. The continuing popularity of the term is viewed with regret by many. First, it implies that medically unexplained symptoms are an exclusively female phenomenon, despite the fact that somatoform illness is observed in both men and women (although much more commonly in the latter). Second, the terms *hysteria* and *hysterical* have acquired different and pejorative meanings in popular parlance that no longer apply to medically unexplained symptoms. Not surprisingly, many individuals suffering from such symptoms strongly object to the use of the hysterical label.

In addition to hysteria and the diagnostic labels provided in *DSM*, many other terms have been used in relation to medically unexplained symptoms, including *functional*, *nonorganic*, *psychosomatic*, and *psychogenic*, each of which is ambiguous or has unfortunate connotations. For the sake of neutrality and descriptive ease, we use *somatoform illness* and *unexplained medical symptoms* as labels encompassing the range of phenomena described in the somatoform disorder category; we use *unexplained neurological symptoms* as a label for those phenomena specifically included in the conversion disorder category. We use the term *somatization* to refer to the process underlying the generation of unexplained medical symptoms.

III. PRESENTATION

A. Clinical Features

Unexplained symptoms may be related to any bodily system. Indeed, every branch of medicine has its own syndrome characterized by the presence of such symptoms. Pain, fatigue, dizziness, shortness of breath, and general malaise are the most commonly observed symptoms in primary care, although gastrointestinal and sexual/reproductive symptoms are frequently found. Within the neurological domain, the most common symptoms are limb weakness, gait disturbances, abnormal movements, sensory disturbances, amnesia, and cognitive impairment. Contrary to popular belief, somatoform symptoms are subjectively real to the patient—that is, their experience is "as if" they have the symptoms of organic illness.

In some cases, a somatoform diagnosis may be suspected on the basis of the inconsistency or medical implausibility of the symptoms in question, although in other cases they may closely resemble symptoms of organic disease. Symptoms are often internally inconsistent. For example, a patient may have a preserved ability to cough (requiring intact vocal chord function) despite being unable to speak or whisper, or a patient may display weakness for some movements and not others involving the same muscle groups. Other symptoms may not fit with recognized disease patterns (e.g., asynchronous generalized tonic–clonic seizures) and may even be physiologically impossible (e.g., triplopia). Often, symptoms correspond more closely to what the patient believes about the body and illness than to actual physical processes. Indeed, the role of beliefs in determining the nature of somatoform phenomena has been widely recognized since the time of Charcot. It is well evidenced by the fact that individuals prone to the development of somatoform illness often develop symptoms that mirror those observed in others. It is also reflected in the varying prevalence of different unexplained symptoms across cultures. Burning hands or feet, for example, are more common in African and Asian cultures than in North America, reflecting local concerns about health and illness. A core set of somatoform symptoms is nevertheless observed across all cultures (e.g., pain, fatigue, pseudoseizures, and paralysis). A history of other unexplained medical symptoms is also frequently found in these patients.

B. Comorbidity

Comorbid psychopathology is extremely common in somatoform illness, with as many as 75% of these patients meeting criteria for an additional psychiatric disorder. Almost all forms of psychiatric illness are more prevalent in these patients compared to primary care patient averages, with elevated levels of depression and anxiety being particularly common. Psychiatric comorbidity studies suggest that between 40 and 80% of patients with somatoform illness meet diagnostic criteria for an affective disorder, whereas between 15 and 90% meet criteria for an anxiety disorder (particularly panic, phobic, and obsessive–compulsive disorders). Such variations in comorbidity estimates are a function of several factors, including the study sample used and somatoform illness severity. Studies conducted on psychiatric populations, for example, are likely to yield disproportionately high rates of psychiatric comorbidity compared to community, primary care, or other specialist samples. Similarly, patients meeting criteria for somatization disorder are considerably more likely to report psychiatric symptoms than are patients with fewer unexplained symptoms.

The comorbidity between somatoform illness and personality disorders is also much higher than that in patients with other psychiatric diagnoses. About 60% of patients with somatoform illness meet criteria for at least one personality disorder; of these, a significant proportion are likely to meet criteria for two or more such diagnoses. Contrary to historical belief, there is no particular association between medically unexplained symptoms and histrionic (i.e., hysterical) personality disorder. Indeed, evidence suggests that the most common personality disturbances in these patients are of the avoidant, dependent, paranoid, and obsessive–compulsive types. Similarly, there is little evidence in support of the traditional view that antisocial personality disorder is a common concomitant of unexplained medical symptoms.

Somatoform illness is also commonly found in the context of physical illness. In such cases, a somatoform diagnosis is made on the grounds that identifiable pathology is unable to account for the range of symptoms and degree of disability exhibited by the patient. In the neurological setting, as many as 60% of patients diagnosed with somatoform illness have comorbid organic diagnoses, although there is no consistent pattern to the type of neurological pathology found in these patients. In contrast, physical comorbidity is often less than 5% within the general psychiatric setting. Such findings indicate that neurological dysfunction plays an important role in the development of somatoform illness. However, many of these patients have extracerebral comorbid neurological disease, which contradicts the view that altered cerebral function provides a fertile soil for the development of conversion disorder. Rather, it is more likely that exposure to neurological illness provides a model for the development of symptoms and an environment in which illness behavior is rewarded.

IV. DIAGNOSTIC ISSUES

Diagnosing somatoform illness is important in order to offer relevant psychiatric treatment and to avoid unnecessary medical intervention. A much-quoted study by Eliot Slater in the 1960s suggested that the rate of misdiagnosis was very high and questioned the validity of hysteria as a diagnostic entity. Recently, the advent of noninvasive investigative techniques (e.g., brain imaging and video telemetry) and the better characterization of neurological disease patterns have made the exclusion of organic pathology easier and more reliable. Indeed, recent studies of patients with both acute and chronic unexplained symptoms suggest that neurological illness is rarely missed in these patients.

Currently, the gold standard for the diagnosis of somatoform illness involves a combination of careful history taking, the judicious use of investigations to rule out significant organic disease, and the assessment of psychiatric morbidity. The exclusion of organic pathology is essential, although it is often difficult to establish the right balance between the benefits and dangers of further investigations. Moreover, the presence of organic disease does not exclude the possibility of somatization; it is therefore important to assess all patients for unexplained symptoms or disability. The clinical history may reveal many features that support a positive diagnosis of somatoform illness, including the inconsistency and implausibility of symptoms, a previous history of unexplained symptoms, and psychosocial stressors preceding the development of symptoms. The successful alleviation of symptoms in response to placebo, suggestions, or psychological treatment also supports a positive somatoform diagnosis.

In some cases, symptoms are consistent and plausible and there may be few or no additional diagnostic features in evidence. For example, although *DSM-IV* explicitly requires the presence of psychosocial stressors for a firm diagnosis of both conversion and somatoform pain disorder, obvious stressors are absent in many cases. Even when present, establishing a causal link between such stressors and physical symptoms can be extremely difficult and involves considerable subjectivity. Other clinical features previously thought to be characteristic of somatoform illness have been found to have little or no diagnostic validity. For example, historically it has been thought that patients suffering from unexplained symptoms display an unusual lack of concern over the condition, so-called *la belle indifférence*. However, research indicates that patients with somatoform illness show no more indifference to their physical condition than do patients with organic illness. The traditional notion that unexplained medical symptoms are exclusive to individuals of low socioeconomic status has also been disputed.

Even in cases in which positive somatoform features are present, many physicians are reluctant to diagnose somatoform illness for fear of missing an underlying physical illness. However, in the clear absence of pathology following appropriate investigation, and particularly if positive signs are present, a diagnosis of somatoform illness can be safely made. In cases in which somatoform illness is suspected but an organic

explanation cannot be ruled out unequivocally, careful follow-up is often the best diagnostic tool.

V. EPIDEMIOLOGY

Somatoform illness is a ubiquitous phenomenon, representing one of the most common categories of illness encountered within the health care system. Precise prevalence estimates vary enormously due to the different diagnostic criteria employed across studies. In general, prevalence estimates decrease as symptoms become more severe, chronic, and greater in number. Recent evidence suggests that approximately 25% of patients attending primary care have a history of four or more unexplained symptoms. In contrast, studies have estimated the prevalence of *DSM-IV* somatization disorder (defined as a history of eight symptoms across multiple bodily sites) to be between 3 and 5% of primary care attenders. Within the neurological domain, evidence suggests that between 20 and 60% of new inpatient admissions have symptoms that cannot be fully accounted for by organic factors.

The understandable reluctance of many physicians to make formal somatoform diagnoses suggests that current data may underestimate the true prevalence of unexplained medical symptoms. In addition, many patients with diagnoses such as chronic fatigue syndrome, fibromyalgia, and noncardiac chest pain may be more appropriately viewed as having somatoform illness.

VI. RESOURCE UTILIZATION

The health service costs associated with somatoform illness are considerable and are not simply attributable to the ubiquity of these conditions. Rather, patients with somatoform illness often consume a disproportionate amount of resources compared to other service users. Indeed, it has been estimated that the health care costs of patients meeting criteria for somatization disorder are nine times the U.S. national average. The bulk of resource utilization by these patients is on diagnostic tests rather than psychiatric services. The frequency of general practitioner and emergency room visits, as well as the number and length of hospital admissions, also tends to be elevated in these patients. In general, the level of resource use increases with the severity and chronicity of unexplained symptoms. Improved physician recognition of these conditions and the limitation of needless investigations could significantly reduce the health care costs of this group of patients.

VII. MANAGEMENT AND TREATMENT

A. Presenting the Diagnosis

The way in which a diagnosis of conversion or somatoform illness is presented can have a considerable effect on the doctor–patient relationship; it may also be an important factor in whether the patient cooperates with the management plan. Coming to terms with a diagnosis of conversion or somatization is difficult for many patients, who often believe that their suffering is being dismissed as "all in the mind" or, worse, deliberately faked. Understandably, many patients find it difficult to accept that their debilitating symptoms may be caused by psychological rather than physical processes, particularly if they have no obvious psychological symptoms, such as anxiety or depression.

Where somatoform illness is suspected, considerable effort should be made to establish a strong therapeutic alliance between physician and patient while necessary physical investigations are being conducted. This prepares the groundwork for the later exploration of possible psychological factors that may be contributing to the presentation of unexplained symptoms and reduces resistance if a formal somatoform diagnosis is being considered. At all times, it is essential to explicitly acknowledge that the patient's symptoms are subjectively real and that they cause significant distress and disability. Such an approach allows the patient to feel that he or she is taken seriously, thereby reducing the likelihood of subsequent doctor shopping. At the appropriate point, the patient should be reassured that all necessary investigations have been done, that no sinister cause for their symptoms has been identified, and that they are not suffering from a serious physical illness. It should be emphasized that further physical investigation would be of no benefit, that certain physical treatments will not be prescribed, and that current medications might need to be withdrawn. Patients may then be gently introduced to the notion that psychological factors may be important in causing their symptoms. It should be emphasized that such an interpretation does not mean that their symptoms are faked or all in the mind and that they are not insane or crazy; the words hysteria and

hysterical should be avoided. It is also common to introduce the idea that their symptoms may be caused by psychological events of which they are unaware, giving everyday examples demonstrating the close link between psychological processes (e.g., anxiety) and physical symptoms (e.g., tremor and dizziness).

Many practitioners believe that it is unnecessary to label patients with a formal diagnosis of conversion or somatoform illness, preferring to describe their symptoms simply as "medically unexplained." Indeed, if it is possible to make therapeutic progress without psychological referral, the use of an explicit diagnosis may be unnecessary and potentially damaging to the doctor–patient relationship. Many patients with acute symptoms respond to simple measures, such as reassurance and physiotherapy; a greater therapeutic challenge is presented by patients with chronic symptoms, where an explicit diagnosis can help ensure patient cooperation with the management plan. The development of new symptoms, a refusal to accept reassurance, and/or demands for further physical investigation may also necessitate the use of a formal diagnosis. To many people, a diagnosis of "medically unexplained symptoms" implies that further physical investigation could eventually yield a medical explanation for their suffering—a belief that ultimately undermines the appropriate management of somatoform conditions. Indeed, without a firm diagnosis, many patients persist in the belief that "the doctor couldn't find what was wrong with me"—a belief that simply serves to intensify their perceived need for further physical investigation. In contrast, use of the somatoform or conversion label serves to legitimize the patient's complaint, firmly identifying it as a recognizable condition that is commonly encountered within medical care. Where psychological referral is indicated, it may be more appropriate to leave diagnostic labeling to the psychiatrist or psychologist.

B. General Management Principles

The general practitioner plays a central role in the management of somatoform illness, with the often difficult task of controlling the patient's access to further investigation and hospitalization. Referrals should only be made when clearly indicated by the clinical picture, paying particular attention to the signs rather than the symptoms of illness. It is important to remember, however, that individuals with somatoform disorders are no less likely to suffer from physical illness than are other patients; it should not be assumed, therefore, that any new complaints are necessarily somatoform. When further investigations are indicated, their purpose and results should be clearly explained to the patient.

Investigating and treating physicians should liaise with the general practitioner and make him or her aware of any explanation and advice given to the patient. A consistent approach should be adopted where possible, aimed at ensuring that the patient does not receive mixed messages. For this reason, the patient should be strongly discouraged from doctor shopping. One useful approach within primary practice is to schedule regular, time-limited appointments for the patient every 4–6 weeks. Such an approach allows the patient to feel that he or she is being taken seriously and that his or her physical health is being monitored; this is particularly useful for patients who are reluctant to accept a psychological interpretation of their symptoms. It is also preferable to a "return-as-needed" approach, which can encourage the development of new symptoms in order for the patient to obtain physician contact.

It is also important to screen for psychiatric problems such as anxiety and depression, which can prove difficult with this patient group. Often, the patient will deny being anxious or depressed, despite exhibiting clear physiological indicators to the contrary (e.g., sleep and appetite disturbance in depression and palpitations and dizziness in anxiety). Rather than directly asking the patient whether he or she is anxious or depressed, it is useful to question the patient about his or her psychological reaction to his or her symptoms. Such an indirect approach often elicits useful information concerning the patient's mental state while maintaining a strong therapeutic alliance.

C. Treatment

The way in which somatoform illness is treated depends largely on the nature of the individual and his or her symptoms. Where appropriate, efforts are made to resolve any psychosocial problems that may have provoked the presenting symptoms. Symptomatic treatments, such as physiotherapy, orthopedic treatment, occupational therapy, and speech therapy, are often used to reduce loss of function and disability and to prevent secondary damage. Other approaches, such as pain management techniques, are used to ameliorate the distress caused by symptoms. Where appropriate, depression and anxiety are treated using

medication. Often, the use of these and other techniques, combined with a careful management approach, is sufficient to provide the patient with lasting symptomatic relief. In some cases, however, more specific psychological treatment is necessary. In such cases, cognitive-behavioral therapy is most commonly used, typically targeting maladaptive beliefs about health and illness, behavioral patterns that maintain symptoms, and social factors that reinforce them. Cognitive-educational therapy, typically aimed at informing patients about the relationship between symptoms and psychological processes, is also sometimes used, often in a group context. Insight-oriented psychotherapy may be used in cases in which emotional issues appear to be a significant pathogenic factor. In terms of efficacy, evidence suggests that a cognitive approach is often effective in the treatment of somatoform illness; however, very few data exist on the efficacy of psychotherapy in these conditions.

In cases in which symptomatic and psychological interventions fail to provide complete resolution of the patients' symptoms, it may be necessary to adjust the therapeutic goal from curing the patients to simply caring for them. Accordingly, management should aim to contain the patients' symptoms and distress, limit their health care utilization, and prevent iatrogenic damage.

VIII. OUTCOME

The majority of studies addressing outcome in somatoform illness have concentrated either on conversion disorder or on somatization disorder, and research explicitly addressing other forms of somatoform illness is rare. It is nevertheless likely that studies investigating the outcome of conditions such as chronic fatigue syndrome, fibromyalgia, irritable bowel syndrome, and chronic pain conditions are implicitly addressing other aspects of somatoform illness. A review of the substantial literature concerning these conditions is beyond the scope of this article.

One of the earliest follow-up studies of unexplained symptoms was conducted in the mid-19th century by Paul Briquet, who studied 430 patients with a variety of symptoms over a period of 10 years. In about half of these patients, symptoms followed a course of progressive, chronic deterioration and recurrent episodes were common; in other cases, recovery occurred after 3–6 months. Briquet identified many factors associated with outcome in these patients. For example, onset during adolescence carried a poor prognosis, whereas a favorable change in social circumstances was associated with a positive outcome.

Several recent studies have provided information concerning outcome in adult patients with unexplained neurological symptoms and identified many prognostic indicators. Given the heterogeneity of the samples studied, it is not surprising that reported remission rates vary considerably; that notwithstanding, a relatively good prognosis has been found in most studies. On average, complete recovery of the index symptom is observed in about two-thirds of acute cases, whereas little or no improvement is observed in up to 20%. The chances of recovery in acute patients are increased in cases in which symptoms have been precipitated by traumatic events. Evidence suggests that between one-fourth and one-third of patients with chronic neurological symptoms receiving inpatient treatment show complete remission of the index symptom; moreover, between 20 and 60% show some improvement at follow-up. Evidence suggests that patients are most likely to recover during the period of hospital admission; after this time, recovery is much less likely. The findings of such outcome studies should be interpreted with caution, however. Most studies conducted in this domain report improvement for the index symptom only; information concerning other symptoms and subsequent referral patterns is rarely provided.

Younger patients tend to have a better prognosis than older patients; indeed, children with unexplained neurological symptoms of recent onset have a particularly favorable outcome. Other factors predicting outcome include the presence of comorbid psychopathology and personality disorders. The presence of comorbid personality disorder typically carries a poor prognosis, although there is no apparent association between outcome and any specific personality type. Conversely, the presence of comorbid anxiety and depression are associated with a good prognosis.

Outcome is broadly similar across the range of unexplained symptoms; the same prognostic factors (e.g., duration of symptoms) are relevant in all cases.

IX. PSYCHOPATHOLOGICAL MECHANISMS

Current theorizing concerning the psychopathological mechanisms of somatoform illness is dominated by the concepts of dissociation, conversion, and somatization; these models, and the evidence cited in their

support, are described here. Currently, no one model provides a completely satisfactory explanation of how it is possible for the symptoms of illness to be experienced in the absence of organic pathology. Although current models have shed light on many aspects of somatoform illness, they are conceptually underspecified and, in certain respects, not well supported by empirical research. Although it is likely that a complete account of unexplained medical symptoms will incorporate aspects of the dissociation, conversion, and somatization models, the development of such an account ultimately requires a more detailed examination of psychological and neuroscientific concepts not currently considered in this domain.

A. Dissociation and Conversion

The term *dissociation* originated in the 19th-century work of Pierre Janet, who proposed one of the earliest systematic accounts of the psychopathological mechanisms underlying somatoform phenomena. Although more than a century old, many of Janet's ideas concerning the organization of mental processes remain popular (albeit implicitly) within contemporary cognitive psychology. According to Janet, personal knowledge is represented by an integrated network of associated memories, which are accessible to consciousness through the operation of attention. This process of attentional selection is responsible for synthesizing the contents of conscious experience by which the execution of volitional actions is coordinated (Fig. 1). In this view, the synthetic functions of attention are disrupted in hysterical patients, rendering them susceptible to a breakdown in psychological integration in the face of extreme trauma. Traumatic experience initiates the separation or *dissociation* of memories from the main body of knowledge by an amnesic barrier. Although these dissociated memories or "fixed ideas" are prevented from entering consciousness by the amnesic barrier, they may be automatically activated by external events. The activation of dissociated memories in this way is responsible for the generation of hysterical symptoms (Fig. 2) that, because they are produced without conscious control, are essentially nonvolitional phenomena. According to Janet, this automatic activation of fixed ideas is a process of suggestion, with the underlying deficit in attention being akin to a state of hypnosis.

Shortly after the publication of Janet's account of hysteria, the dissociation model was extended by Josef Breuer and Sigmund Freud with the introduction of the *conversion* concept. According to Breuer and Freud, the process of dissociation occurs when the subject attempts to regulate his or her experience of negative affect by defensively suppressing (or *repressing*) the conscious recall of memories associated with personal trauma. In the conversion model, this repression of negative affect serves as the primary determining factor in the generation of hysterical symptoms rather than the dissociation of memories *per se*. According to Breuer and Freud, emotions are associated with high levels of neural energy that must be discharged if the energetic balance of the brain is to be preserved. By avoiding negative affect through the repression of traumatic memories, however, this discharge of neural energy is prevented. In order for it to occur, negative affect is transformed or "converted" into a somatic (i.e., hysterical) symptom, which allows the individual to discharge emotional energy without recalling the traumatic memories

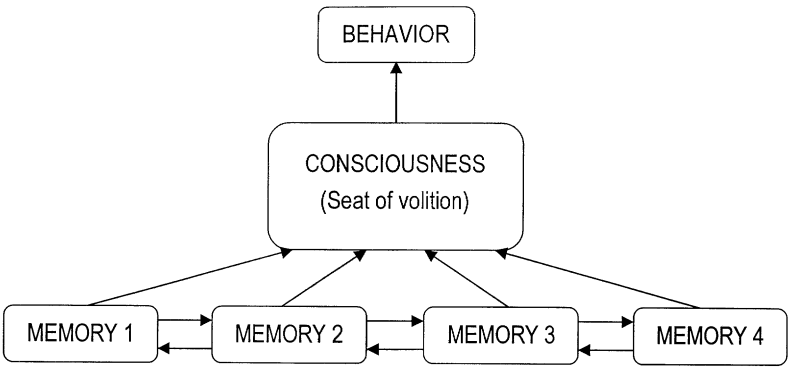

Figure 1 Organization of the cognitive system as described by Janet (1924).

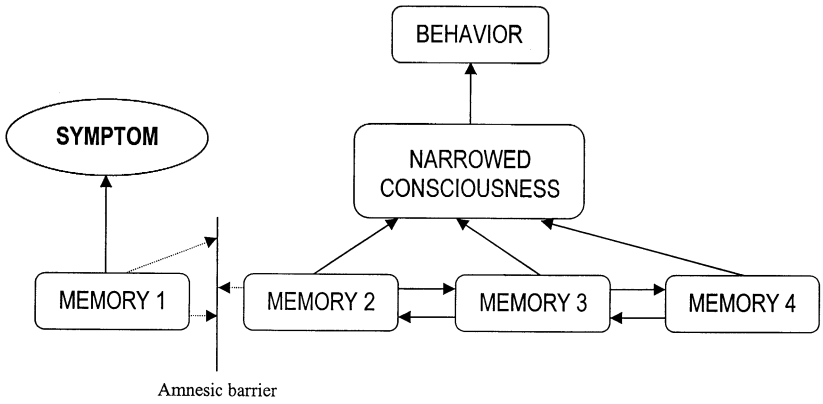

Figure 2 Generation of an unexplained symptom through the dissociation of a memory from consciousness.

giving rise to it. By this account, therefore, hysterical symptoms serve an important psychological purpose (i.e., defense), with the discharge of emotional energy representing the *primary gain* from symptoms. In this model, symptoms generated by the process of conversion correspond to sensations present at the time of the underlying trauma, or they are a symbolic representation of it.

Although more than a century old, the theoretical analyses of hysteria offered by Janet, Breuer, and Freud continue to influence nosology, theory, and clinical practice concerning medically unexplained symptoms. Several lines of evidence provide information concerning the validity of the dissociation and conversion models.

1. Attention

Many theoretical models have endorsed Janet's idea that somatoform illness involves an alteration in attention that prevents processed information from entering conscious awareness. Recent electrophysiological research indicating that conversion disorder is associated with normal early evoked potentials but a deficit in the later P300 component provides strong support for such a view. Several cognitive and psychophysiological studies have also found evidence for a diffuse attentional deficit in individuals with conversion symptoms, with patients showing decrements on tasks assessing vigilance, habituation, cognitive flexibility, set shifting, and mental transformation. However, the precise nature of the attentional deficit underlying conversion remains unclear; further research is required if it is to be described in greater detail.

2. Hypnosis

Janet's proposal that hysterical and hypnotic phenomena share similar psychological mechanisms also continues to attract support. In line with this hypothesis, many studies have shown that individuals with somatoform and conversion illness tend to exhibit high levels of suggestibility. Moreover, recent imaging studies using positron emission tomography have provided limited evidence indicating that similar neuroanatomical substrates may be involved in both conversion and hypnotic paralysis. Currently, however, the link between hypnosis and somatoform illness is still largely theoretical; further empirical evidence based on larger sample sizes is required before firm conclusions can be drawn in this regard.

3. Psychological Trauma

The view that unexplained symptoms are related to traumatic experiences, central to both the dissociation and the conversion models, has also been widely adopted. Indeed, current diagnostic criteria require that clear psychosocial precipitants be present for a diagnosis of conversion disorder or somatoform pain disorder. Although there is substantial evidence to suggest that many instances of somatoform illness are either preceded by psychosocial precipitants or associated with significant early trauma, it is clear that traumatic precipitants are absent in many cases. Moreover, many traumatized individuals with somatoform illness have not experienced amnesia for their trauma, and symptom resolution is not guaranteed by the recovery of previously forgotten traumatic memories. As such, trauma cannot play the primary

pathogenic role in the generation of medically unexplained symptoms suggested by Janet, Breuer, and Freud, although it is clearly relevant in many instances.

4. Alexithymia

Although the concept of emotionally derived neural energies has long since been abandoned, the work of Freud and Breuer still remains influential. The notion that a reduction in anxiety is the primary gain associated with unexplained symptoms is largely responsible for the continuing popularity of *la belle indifférence* as a diagnostic indicator of somatoform illness. As noted previously, however, patients with somatoform illness show no more indifference to their condition than do patients with comparable physical illnesses. Moreover, it is clear that many individuals with somatoform illness show high levels of anxiety, demonstrating that any conversion process that is occurring is far from effective in controlling this emotion. However, there is evidence that somatoform illness is associated with an inability to identify and report on one's emotional states (so-called *alexithymia*). Such evidence could be interpreted as indicating that the process of conversion occurs as a means of discharging unexpressed emotion. These findings must be interpreted with caution, however, because there is evidence that existing measures of alexithymia are confounded by psychopathology in general.

5. Symptom Laterality

The Freudian view that unexplained symptoms are the expression of unconscious emotional conflict has led many to conclude that the right cerebral hemisphere (traditionally viewed as one of the neural sites responsible for emotion) plays an important role in the pathogenesis of unexplained symptoms. Several studies have provided evidence suggesting that unexplained symptoms are more common on the left than the right, apparently providing support for this hypothesis. However, recent research has shown that left- and right-sided symptoms are equally common; bilateral symptoms are also frequently found.

B. Somatization

Dissociation and conversion represent the main theoretical precursors to contemporary accounts of the somatoform disorders based on the concept of *somatization*. The term somatization originated in the psychoanalytic literature of the early 19th century as a label for the hypothetical process whereby bodily dysfunction (i.e., unexplained symptoms) was generated by "unconscious neurosis." Since the 1960s, however, the work of Zbigniew Lipowski has encouraged many within the field to adopt a more descriptive usage of the term. According to this approach, somatization may be broadly defined as the tendency to experience or express psychological distress as the symptoms of physical illness. Unlike previous approaches, which attempted to identify neuropsychological processes underlying the occurrence of medically unexplained symptoms, the somatization model places explanatory emphasis on the entire biopsychosocial context surrounding the experience of physical and mental illness. In this respect, the somatization model is influenced by the concept of "illness behavior"—that is, the way in which we perceive, evaluate, and react to our physical and psychological states in relation to socially sanctioned models of health and illness (the so-called "sick role"). According to this model, individuals suffering from somatoform illness are said to display *abnormal* illness behavior—that is, a tendency to adopt the sick role that is inappropriate given the absence of identifiable physical pathology. Many features of somatoform illness have been identified as instances of abnormal illness behavior. For example, many somatoform disorder patients dispute the diagnoses they have been given, refuse to accept that they have been investigated adequately, or fail to comply with treatment. Indeed, many such patients are perceived as "difficult" by the treating physician, and the doctor–patient relationship is often less than satisfactory.

The somatization model views the development of abnormal illness behavior as a multifactorial process in which social, cultural, cognitive, perceptual, personality, and physiological factors are all implicated.

1. Sociocultural Factors

Research and theory suggest that abnormal illness behaviors may pass from generation to generation through early social learning within the familial context. Disproportionate parental concern over a child's physical symptoms, the misattribution of normal sensations to pathological causes, and inappropriate help-seeking behavior have all been linked to subsequent bodily preoccupation, which may serve as a risk factor for the development of somatoform

illness. Moreover, some studies have shown that children exposed to abnormally high amounts of family illness are more likely to experience somatoform illness as adults. Early exposure to pathology may reinforce illness behavior and provide a model for the subsequent development of symptoms. In addition, repeated exposure to illness provides misleading information concerning illness base rates, leading those that are exposed to overestimate the likelihood of certain forms of pathology.

The dynamic relationship between illness behavior and culture in general may also play an important role in the development of somatization. In most cultures, there is a stigma attached to mental illness that is not associated with physical forms of infirmity; as such, expressing emotional distress somatically offers a socially acceptable way of gaining support via the sick role. Cultural factors pertaining to the health care system are also likely to be influential in shaping the nature and occurrence of somatization. Some studies, for example, have implicated iatrogenic factors in the maintenance of many medically unexplained symptoms, often involving physical misdiagnoses that could serve to perpetuate symptoms by legitimizing the individual's somatic interpretation of their condition. Moreover, the biological emphasis of modern health care systems encourages individuals to communicate nonspecific distress somatically rather than psychologically.

2. Perceptual and Cognitive Factors

What we know and believe about bodily states is inextricably bound with our experience of physical sensations as well as our behavioral response to them. For example, some studies have suggested that the acquisition of maladaptive beliefs about health and illness may be related to the development of somatization. Thus, the somatizing individual may hold the mistaken belief that health is a state devoid of physical symptoms, and that symptoms necessarily imply the presence of disease. Recently, Arthur Barsky and colleagues argued that such beliefs lead the somatizing individual to develop a preoccupation with his or her bodily states and a tendency to misinterpret them as pathological. Once symptoms are attributed to illness, further attention may be directed toward the body, with subsequent physical events being perceived as evidence in support of a pathological interpretation. Evidence demonstrating that hypochondriasis is associated with body-focused attention provides support for this model, as do several studies indicating that self-focused attention is positively related to somatic symptom reports in nonclinical populations. Clinical experience strongly suggests that body-focused attention is also a central aspect of somatoform illness.

3. Personality Factors

It is likely that cognitive and perceptual factors precipitate and maintain somatization by maximizing the degree to which physical states are experienced as aversive. Research suggests that the tendency to experience physical and psychological states as aversive is also related to the personality dimension of negative affectivity (NA), characterized by a negative self-concept and a trait-like tendency to experience distress and dissatisfaction. Indeed, subjective symptom reports consistently correlate with NA, despite there being no correlation between NA and objective health markers. Individuals high in trait NA are hypervigilant about their bodies and have a lower threshold for perceiving physical sensations, so-called somatic amplification. Such individuals are also more likely to interpret physical symptoms as the signs of serious disease and seek medical attention accordingly.

4. Physiological Factors

Unlike previous theories, the somatization model embraces the idea that normal physical processes (e.g., the physical component of an emotional state) and minor pathological events may contribute to the development of unexplained symptoms. For example, anxiety is typically associated with increased autonomic arousal that may result in physical changes such as shaking, sweating, and tachycardia; moreover, fear-related hyperventilation can produce symptoms such as breathlessness, chest pain, and fatigue. Similarly, the sleep problems and physical inactivity often associated with depression may give rise to fatigue, pain, and the feeling that increased effort is required to execute everyday tasks. Other physical processes unrelated to emotional states may also contribute to the development of medically unexplained symptoms. For example, muscle wasting resulting from illness-related inactivity may produce fatigue that perpetuates itself by preventing the resumption of physical exercise after illness remission.

A recent model of the interaction between these different factors has been described by Lawrence Kirmayer and colleagues (Fig. 3). According to this model, illness, emotional arousal, and everyday physiological processes produce bodily sensations that

capture the individual's attention to varying degrees. These sensations may be interpreted as indicators of disease, an attribution that can serve to generate illness worry, catastrophizing, and demoralization. As a result, individual may adopt the sick role by pursuing assessment and treatment for his or her putative condition, thereby exposing himself or herself to social forces that may reinforce their illness behavior and experience. This process may be moderated by many situational and dispositional factors, including previous illness experience, environmental contingencies that reward illness behavior, the response of significant others to illness worry, and individual differences in personality, attentional set, coping behavior, and autonomic reactivity.

Despite their obvious explanatory power, there are certain problems with models based on the concept of somatization. First, such models obscure potentially important differences between the various forms of medically unexplained symptoms, such as those that are the physical concomitants of conditions such as anxiety and depression, normal physical sensations or minor pathological events that are mistakenly attributed to serious illness through hypochondriacal misinterpretation, and those characteristic of the conversion and somatoform disorders. Although there is considerable overlap between these conditions in clinical practice, these different forms of somatization can be distinguished both conceptually and empirically. Although the somatization model offers a powerful account of the medically unexplained symptoms associated with depression, anxiety, and hypochondriasis, it fails to provide an adequate account of the mechanisms underlying conversion and somatoform symptoms. Arguably, a proper understanding of somatoform illness requires a theoretical approach that is specific to this form of somatization—an approach that is inherent to dissociation and conversion models.

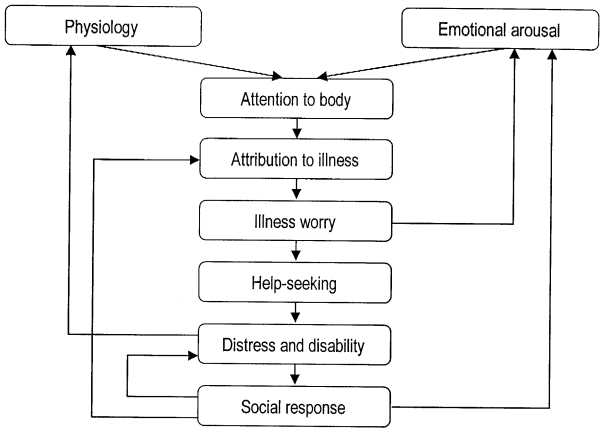

Figure 3 A multifactorial model of somatization (based on Kirmayer and Taillefer (1997)).

Second, the model of somatization described here assumes that medically unexplained symptoms are necessarily the product of physiological processes, such as the physical components of emotional states, and minor pathological events. Although such processes might play an important role in the generation of certain somatoform symptoms, it is difficult to understand how unexplained neurological (i.e., conversion) symptoms can be explained in this way.

Third, as with theories based on the concepts of conversion and dissociation, the somatization model assumes that unexplained symptoms are necessarily the expression of psychological distress. Although this may be true in many cases, particularly those associated with anxiety, depression, or hypochondriasis, it is apparent that such an assumption may be inappropriate in many other cases.

Finally, it may be misleading (and, indeed, pejorative) to identify somatoform illness as necessarily involving "abnormal" illness behavior. In our view, seeking help for subjectively compelling and debilitating symptoms is more appropriately regarded as *normal* illness behavior, regardless of whether an underlying pathophysiological basis for those symptoms can be found. Similarly, it is unclear what constitutes a "normal" illness response to repeatedly negative physical investigations despite the persistence of symptoms, particularly when disability is high (e.g., as in paralysis). As such, it may be more appropriate to reserve the concept of abnormal illness behavior for those cases in which the problem appears to involve more than just a poor doctor–patient relationship or the presentation of unexplained symptoms *per se*.

X. SUMMARY

In summary, the following points should be noted:

1. Somatoform illness is one of the most common forms of psychiatric disorder encountered within the health care system and is associated with high levels of resource utilization.
2. Almost every symptom of organic illness has an "unexplained" (i.e., somatoform or conversion) counterpart.
3. In some cases, unexplained medical symptoms have positive features (e.g., internal inconsistency) that

are indicative of a somatoform diagnosis; however, other somatoform symptoms closely resemble the symptoms of organic disease.
4. Comorbid psychopathology, particularly depression, anxiety, and personality disorders, is extremely common in patients with unexplained medical symptoms; comorbid organic pathology is also common in these patients.
5. The diagnosis of somatoform illness involves careful history taking, the exclusion of physical illness through appropriate investigation, and the assessment of psychiatric morbidity.
6. Management of somatoform illness involves containing the patient's symptoms and distress, limiting their access to investigations and hospitalizations, and preventing iatrogenic damage; careful consideration must be given to whether a formal diagnosis of somatoform illness should be used and, if so, how such a diagnosis should be presented.
7. A typical therapeutic approach involves the use of reassurance, symptomatic treatments and, where necessary, psychological intervention; the prognosis of somatoform illness is quite good, with acute symptoms being more responsive to treatment than chronic symptoms.
8. Current theorizing concerning unexplained medical symptoms is dominated by the concepts of dissociation, conversion, and somatization. Although there is limited evidence in support of these concepts, they fail to provide a complete account of the psychopathological mechanisms underlying these conditions.

Corpus Callosum

KATHLEEN BAYNES
University of California, Davis

GLOSSARY

agenesis of the corpus callosum A chronic condition in which the corpus callosum fails to develop. The condition has been increasingly recognized due to the widespread use of imaging techniques that reveal the distinctive ventricular pattern that occurs when this major fiber tract fails to develop. Persons with this condition may be cognitively normal but show increased interhemispheric transfer times on a variety of tests.

alien (anarchic) hand sign A condition in which one hand performs complex motor acts outside of the person's conscious control. It can occur in either the dominant or nondominant hand. One form of anarchic hand is thought to occur following a callosal lesion. The other type occurs after disruption of the motor system due to medial frontal lobe damage. Both types are usually intermittent and transitory.

anterior commissure A fiber bundle that connects the two hemispheres. It is inferior to the corpus callosum, near the rostrum. It is thought to connect the anterior temporal lobes, but in humans it may carry fibers from more widely distributed areas.

body of the corpus callosum The central fibers of the corpus callosum. The fibers lie between the genu and the isthmus.

callosotomy The surgical section of the corpus callosum. It is usually accomplished in two stages. The anterior two-thirds of the callosum is sectioned first, followed by the section of the splenium if satisfactory seizure control has not been achieved. In humans, this procedure is only used in the treatment of intractable epilepsy.

commissurotomy The surgical section of the corpus callosum, the anterior commissure, and the hippocampal commissure. This more radical procedure was introduced when the first callosotomies appeared to be ineffective. It remains an alternative to the callosotomy.

contralateral This term refers to the hand, visual field, etc. that is on the opposite side from the structure under discussion. The left hemisphere controls the right or contralateral hand.

fiber tract A group of axons that follows the same path through the brain.

genu The anterior fibers of the corpus callosum that appear to bend like a knee in sagittal section before becoming the more horizontal body of the corpus callosum.

hippocampal commissure One of the fiber tracts inferior and dorsal to the callosum that is usually cut during the posterior section of the callosum. It carries fibers from the hippocampus, a structure important in forming new memories.

homonomous hemianopsia Cortical blindness in one complete visual field. It commonly results from destruction of the right or left occipital lobe, causing blindness in the contralateral visual field.

ipsilateral This term refers to the hand, visual field, etc. that is on the same side as the structure under discussion. The left hemisphere does not control the left or ipsilateral fingers well, although it can participate in ipsilateral limb movement.

isthmus The portion of the corpus callosum just anterior to the splenium.

laterality This term refers to the tendency for one hemisphere to perform a particular cognitive or motor task better than the other.

rostrum The most anterior portion of the corpus callosum.

splenium The most posterior portion of the corpus callosum. It conveys visual information between the hemispheres.

split-brain A term used to refer to a person who has undergone either commissurotomy or callosotomy for the treatment of intractable epilepsy.

The corpus callosum is one of the most anatomically prominent structures in the human brain. It is composed of approximately 200 million fibers that course across the brain's midline to connect the two cerebral hemispheres. Despite its structural prominence, which led early investigators to believe it played an important role in cognition and behavior, identifying the role of callosal connections in modifying behavior has proven difficult. This article discusses the anatomy of the callosum, the changing view of its role in behavior, the effects of surgical and other lesions on different aspects of behavior, studies of callosal transfer times, and theories of the role of the callosum in human laterality, cognition, and consciousness.

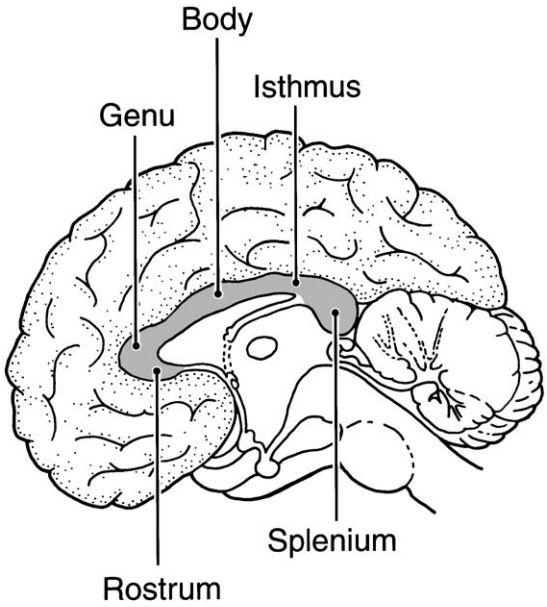

Figure 1 Sagittal section of the brain with major divisions of the corpus callosum labeled.

I. ANATOMY

The corpus callosum is composed of millions of nerve fibers that connect the two halves of the brain. These fibers traveling together from one cerebral hemisphere to the other form a brain structure easily visible to the beginning student of neuroanatomy. Figure 1 shows a saggital section of the brain, which is a slice that runs from front to back on a vertical plane. This slice passes through the midline. The large curved structure in the middle of the brain is the corpus callosum.

Although there is considerable variability in the size and shape of the corpus callosum in humans, it is known that it contains approximately 200 million fibers that carry neural signals from one side of the brain to the other. Although most of these fibers are thought to be excitatory, their effect may be inhibitory due to the activity of inhibitory interneurons. Approximately half of these fibers are small and unmyelinated. These fibers transmit information more slowly than the larger myelinated axons, which are capable of extremely rapid transmission of information. Some of the fibers connect to similar areas in the right and left hemispheres; other fibers go to areas in the contralateral hemisphere that are analogous to areas that have dense ipsilateral connections with their area of origin. A final group of fibers are diffusely connected to the contralateral hemisphere. If there is an analogy in the human brain with findings reported in the animal literature, some neurons may cross the callosum and descend to the subcortical structures before terminating.

Fibers from different areas of the cortex cross the callosum in discrete locations. To understand this phenomenon, it is necessary to examine the divisions of the corpus callosum (Fig. 1). The most anterior part of the callosum is the rostrum. Just behind the rostrum, the callosum bends to form the genu (or knee) and then extends posteriorly in the body. The body constricts slightly to become the isthmus and finally terminates in the slightly bulbous splenium. There is a great deal of individual variation in the shape and thickness of the different parts of the callosum. There have been attempts to understand differences in the anatomy of the right and left hemispheres and in the lateralization of function with regard to the morphology of the corpus callosum. As behavioral claims regarding the contributions of different areas of the callosum become more precise, it will become more crucial to be able to carefully define the areas of the callosum in which particular fibers cross. Currently, however, the areas are conventionally defined as proportions of the length of the callosum. There seems to be minimal difference whether the curvature of the callosum is taken into account or simply maximum anterior and posterior extension is used for the partition. The anterior one-fourth of the callosum is considered the genu. The rostral body begins directly behind the genu, extending back to include the anterior one-third of the callosum. The center one-third of the callosum is split into two equal sections, the anterior and posterior midbody. The isthmus extends from the posterior one-third to the posterior one-fifth of the callosum. Finally, the most posterior one-fifth is considered the splenium.

Because these definitions are arbitrary, they may differ in detail from investigator to investigator, depending on the investigator's emphasis.

Generally, however, it is believed that the fibers that pass through the different regions of the corpus callosum represent the anterior-to-posterior organization of the cerebral cortex (Fig. 2). Deepak Pandya and Benjamin Seltzer demonstrated an anterior-to-posterior organization of the callosal fibers of passage in the rhesus monkey. Prefrontal cortex and premotor cortex axons cross in the rostrum and genu. Motor and somatosensory axons are found primarily in the body. Auditory and association areas are represented in the isthmus and visual areas in the splenium. Stephen Lomber and colleagues document a similar arrangement in the corpus callosum of the cat, although auditory fibers are found throughout the body and dorsal splenium, largely overlapping with limbic and visual fibers except in the very ventral sections of the splenium, which are entirely visual. The same anterior-to-posterior organization has been demonstrated by Marie Christine de Lacoste and colleagues in the human brain. That is, the right and left prefrontal, orbital–frontal, and frontal language areas are connected in the rostrum and the genu. The anterior part of the body carries fibers from the sensory and motor regions that abut the central sulcus. It appears that fibers from the area around the Sylvian fissure, associated with language function in the left hemisphere, cross in the posterior part of the body or isthmus. Finally, the splenium carries fibers connecting the visual areas of the occipital lobe.

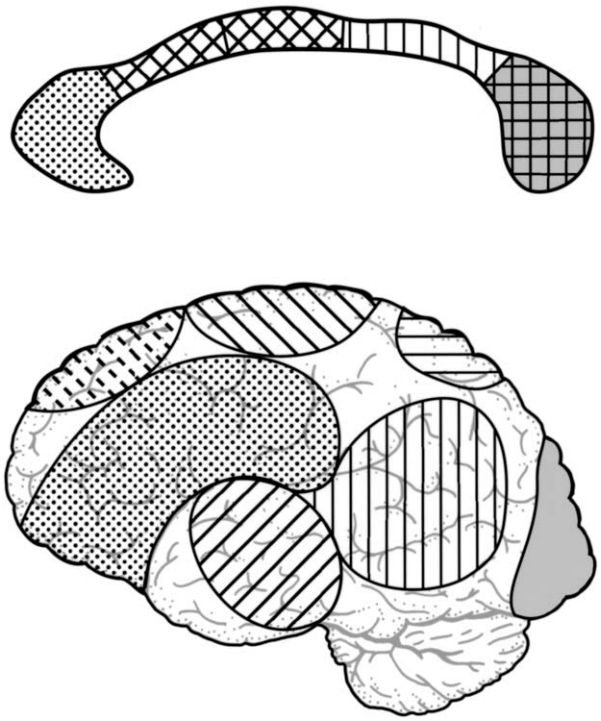

Figure 2 Areas of the cortex where fibers of the corpus callosum originate are coded to match the section of the corpus callosum where those fibers cross to the other hemisphere (adapted from M. C. DeLacoste, J. B. Kirkpatrick, and A. D. Ross, Topography of the human corpus callosum, *J. Neuropathol. Exp. Neurol.* **44,** 578–591, 1985).

Although it is now known that there are distinctive behavioral deficits associated with lesions to some regions of the callosum, contributions of the corpus callosum to behavior have not been easy to observe and understand. Some scientists have argued that evolutionary evidence suggests that the corpus callosum plays a distinctive role in human behavior. The callosum is not present in some primitive marsupials and takes on greatly increased prominence in the human species. The prominence of the corpus callosum appears to increase as lateralization increases, but this relationship is currently very speculative. In fact, James Rilling and Thomas Insel argue that, based on studies of 11 primate species, only the size of the splenium increases in proportion to increasing brain size, whereas the size of the corpus callosum as well as that of the anterior commissure are actually reduced relative to the size of other structures in higher primates. This observation suggests that any changes in the callosum related to human evolution are specific to particular areas of the callosum such as the splenium.

Developmentally, the callosum is a small structure in the neonatal brain that increases in size and prominence as the fibers myelinate (Fig. 3). At approximately 7 weeks of gestation, the lamina terminalis begins to thicken forming the commissural plate. By approximately 9 weeks cells begin to form the massa commissurelis, which supports the growth of the first commissural fibers at approximately 12 weeks. The basic structure of the callosum is present by 20 weeks and it continues to thicken and develop until birth, with development of the genu and body occurring before that of the splenium and rostrum. The myelinization of the corpus callosum is not believed to be complete until puberty, and recent evidence suggests that it reaches its maximum size at approximately age 25. It has been argued that the distinctive evolutionary and developmental patterns suggest a special role for the callosum in human behavior. Sandra Witelson has argued strongly that the anatomy of the callosum may be key to

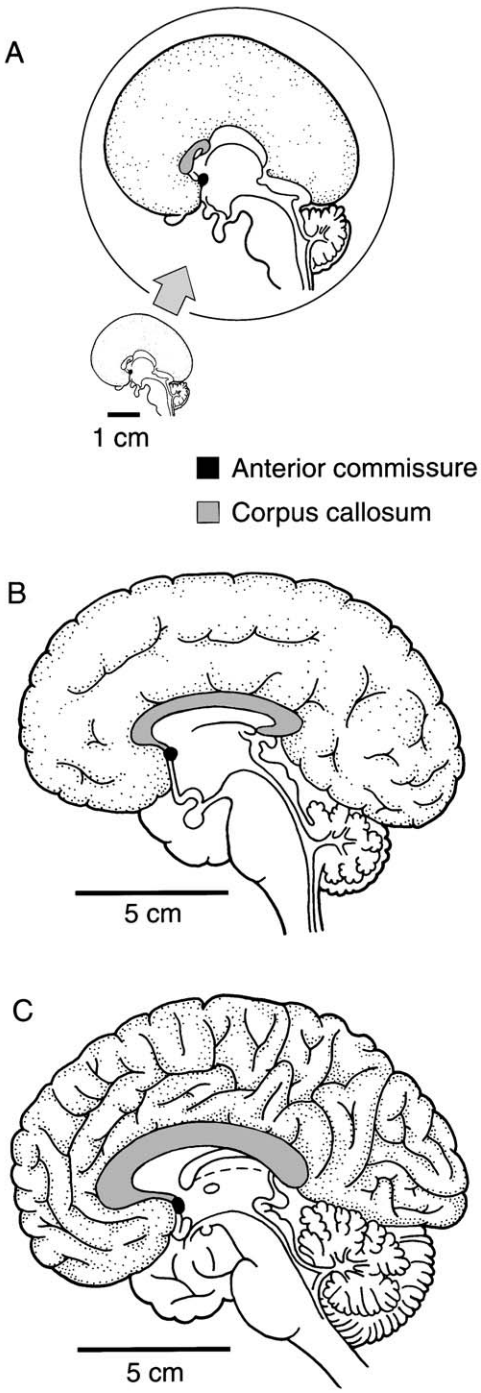

Figure 3 Relative size of the corpus callosum is seen in at 16 weeks (A), 40 weeks (B), and at adulthood (C) (adapted from S. P. Springer and G. Deutsch, *Left Brain, Right Brain: Perspectives from Cognitive Neuroscience*. p. 260. Freeman, New York, 1997).

understanding developmental issues of lateralization and hemispheric specialization. Deliniating that role has proven difficult.

II. HISTORY

The previously mentioned observations, specifically that of the sheer size of the fiber tract and its position as a unique midline structure, were important in suggesting to early scientists that it would be crucial to understand the callosum's role in behavior to fully understand the organization of the brain. In the early literature, it even competed with the pineal gland as a potential seat of the soul. Responding to an increasing belief that the corpus callosum played a major role in the integration of brain activities, Thomas Huxley called the corpus callosum "the greatest leap forward anywhere made by Nature in her brain work."

However, in the 20th century, studies of the callosum suggested that it was of much less interest than its prominent anatomy might indicate. Work in Pavlov's laboratory by Konstantin Bykov and Aleksei Speransky demonstrated that the transfer of conditioned learning from one side of the body to the other in dogs was abolished after section of the corpus callosum. However, this interesting work failed to gain significant recognition and was overshadowed by other animal work that did not document an important role for the corpus callosum in behavior. In the 1940s, William Van Wagenen and Robert Herren resected the callosum in a series of patients as treatment for epilepsy. These patients were extensively tested for psychological and behavioral changes. Although some patients improved, there did not appear to be consistent benefits in control of epilepsy nor consistent changes in their cognitive ability as a result of the severing of this enormous band of fibers. This series of surgeries did not continue and the interest in callosal function waned. Psychologist Karl Lashley was so unimpressed with the effect of severing the corpus callosum that he concluded that the corpus callosum played only a minimal role in psychological function.

It was the remarkable developments in animal research in the 1950s that paved the way for a greater understanding of the function of the corpus callosum in humans. Roger Sperry and Ronald Meyers, after splitting both the corpus callosum and the optic chiasm in the cat, showed that if one eye of the cat was covered while it learned a task, when that eye was covered and the other eye uncovered the animal acted as if it had no knowledge of the task. When exposed to the same learning trials, it had to learn again from scratch with no significant benefit from the prior exposure. In this case, the hemisphere of the brain that had not been able to see the task being learned had to

complete the task and showed no evidence of having learned it previously. The important principle that their approach uncovered was that care had to be taken to introduce information only to one hemisphere of the brain and to test that hemisphere independently as well. For the first time, the discovery that learning of a task could occur independently in the separate hemispheres of the brain was widely appreciated.

In the 1960s, Norman Geschwind published his influential review of disconnection syndromes. Disconnection syndromes are patterns of behavior that occur when the fibers that connect areas of the brain responsible for different aspects of a task are damaged, preventing communication needed to complete complex behaviors. Perhaps the most striking of these syndromes is alexia without agraphia—that is, the ability to write in the absence of the ability to read. Patients with this striking disorder can write words and sentences spontaneously or to dictation, but they are unable to read what they have written. All reading is severely impaired in this group due to a disruption of the fibers that carry visual information to the area of the left hemisphere that decodes words into sound and meaning. However, that decoding area is intact and, hence, the ability to write and spell is intact. The existence of such syndromes suggested that a complete section of the corpus callosum should produce other dramatic behavioral changes.

Geshwind's comprehensive review of the animal and human literature emphasized the importance of the corpus callosum and other fiber tracts in producing complex behaviors. The corpus callosum was obviously the largest of the known fiber tracts and Geshwind's review suggested that it played an important role in transmitting information between the two hemispheres of the brain, despite the discouraging results from the series of split-brain surgeries performed by Van Wagenen. Pursuing this idea, Geschwind and colleague Edith Kaplan were among the first to observe disconnection symptoms in a patient with a naturally occurring lesion of the corpus callosum.

Meanwhile, physicians continued to consider a possible role for the corpus callosum in the spread of epileptic seizures. After a careful review of the Van Wagenen series and with the new observations of Geschwind in mind, Philip Vogel and Joseph Bogen decided once again to attempt to resect the corpus callosum as a treatment for epilepsy, but with some differences in procedure. The corpus callosum is not the only fiber tract that connects the left and right hemispheres. Many smaller tracts, the anterior commissure in particular, that were not severed in the Van Wagenen series also cross the midline and could serve as an alternative route to spread seizure activity. Bogen and Vogel suspected that some of the original surgeries had not alleviated the epilepsy because these alternate tracts served to spread the seizure activity in the absence of the callosum. Hence, they initiated a new series of surgeries that resected not just the corpus callosum but also additional tracts, including the anterior commissure.

Guided by the exciting observations made in the Sperry laboratory with cats and by the renewed interest in disconnection syndromes, plans were made for a more intensive study of the disconnection effects in humans after commissurotomy. A team consisting of Joseph Bogen, Roger Sperry, and Michael Gazzaniga assembled the tasks and methods of response they thought would be necessary to demonstrate the effect of split-brain surgery in humans. To understand their approach and observations, some knowledge of functional anatomy is necessary.

The most crucial problem the researchers faced was that the left hemisphere in most people is the only one that controls speech. Hence, if only a verbal response to a task is accepted, the mute right hemisphere will not be able to respond and may appear unable to do simple tasks. They realized that if right hemisphere skills were to be probed, a manual response was required. Tasks had to be designed to allow a button press response or some other tactile response.

Second, because there is some ipsilateral control of motor output, knowledge being tested had to somehow be isolated in one hemisphere or the other to prevent interference between the two hemispheres in controlling a tactile response. Because of the unique anatomy of the visual system in humans, it was possible to isolate visual words and pictures to one hemisphere but only under very special conditions. Figure 4 shows the organization of the visual system. Information from the right side of space first reaches the cortex in the back of the left side of the brain or occipital lobe and vice versa. Unlike in the cat in the earlier Sperry experiments, covering one eye does not isolate information to one hemisphere, so more elaborate procedures are necessary. In most people, the information about the two sides of space is quickly woven together into a seamless visual world through the neural transmission across the callosum. Once these fibers are severed, information in one visual field is isolated in the contralateral hemisphere. This only holds true, however, if the eyes remain focussed on a single central location or fixation point. In everyday life, though, our eyes are always in motion and are

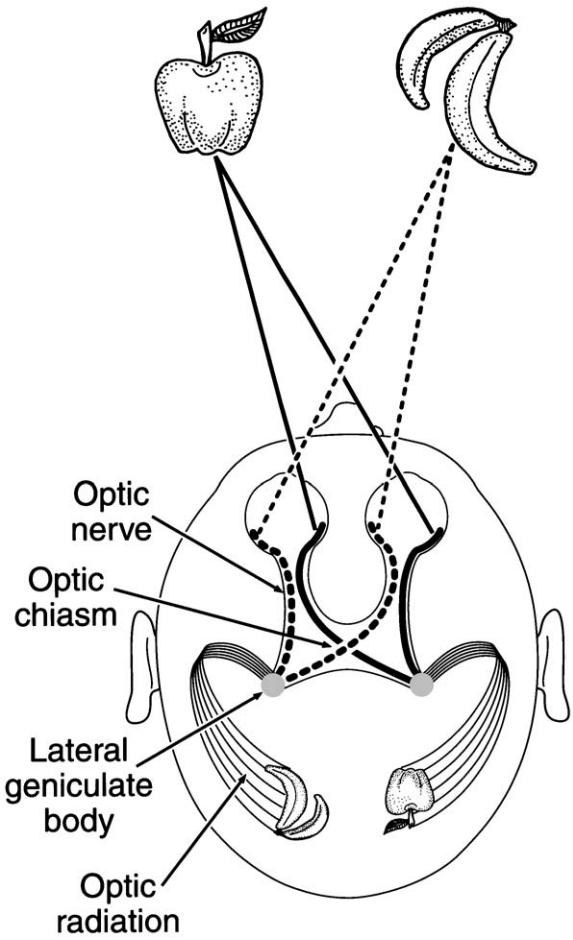

Figure 4 After the corpus callosum is cut, the unique anatomy of the human visual system displays material presented on one side of space only to the contralateral hemisphere. When the callosum is intact, this visual information is shared between the hemispheres via the fibers of the splenium.

drawn quickly to changes in the visual environment. Hence, to an investigator who wishes to have visual information presented in the left visual field seen only in the right hemisphere, this reflexive orienting movement presents a challenge. To prevent eye motion from interfering with lateralization, words or pictures had to be presented for 150 msec or less so that there was not time for the eyes to move from the fixation point to the stimulus display. The early devise used to ensure brief presentations was known as a tachistoscope, but today many investigators control the length of the stimulus display with a computer.

Although the visual system provides clean lateralization of information in a split-brain subject, the auditory system does not. Fibers from the auditory system of one ear reach both hemispheres of the brain, with about 60% of the pathway arriving in the contralateral hemisphere and 40% in the ipsilateral hemisphere. In order to test auditory comprehension separately in the left and right hemispheres, an auditory stimulus had to be compared with some completely lateralized visual stimulus.

One other neural pathway, although it has some ipsilateral representation, provides relative isolation of information to the contralateral hemisphere. Somatosensory information from the hands is predominently transferred to the contralateral hemisphere. Hence, when real objects are placed in the hands and palpated to aid in identification, the somatosensory information about the object remains in one hemisphere. The ipsilateral fibers do provide the ipsilateral hemisphere with some basic perceptual information but do not generally provide enough cues for identification of the object.

Bogen, Sperry, and Gazzaniga used these basic facts about the anatomy of the nervous system to guide their investigations of the changes that follow section of the corpus callosum. By carefully isolating the hemispheres via these methods, they were able for the first time to map the profound changes that do occur after callosotomy. They examined the subjects in this new series before and after surgery and were able to confirm one of the early observations: These patients appear quite normal after surgery. To the casual observer, there appears to be very little difference in the presentation of the person before and after surgery. After the initial few weeks following surgery in which there may be symptoms such as mutism and intermanual conflict, the split-brain subjects experience the world as unified and converse and interact normally. The subjective response to what might be expected to be a radical and frightening change in one's inner world appears to be minimal. Gazzaniga observed, "Indeed, one would miss the departure of a good friend more, apparently, than the left hemisphere misses the right."

However, when observations were made under conditions that allowed only one hemisphere access to information and gave the mute right hemisphere a means of response, the now well-known hemispheric disconnection syndrome was elicited. The researchers gave patients objects to palpate in one hand at a laboratory table that screened the hand and the item from the subject's view. When an item was palpated by the right hand, there was no difference from normal behavior. The patient was easily able to name the item because all the tactile information from the right hand was available to the speaking left hemisphere. In contrast, when the same common objects were placed

in the left hand (and kept out of view), the talking left hemisphere was not able to identify the item and could not name it. The subject appeared to be anomic. However, despite being unable to name the object being grasped, the left hand of the subject could often demonstrate how the object was used or identify it from a group of objects. The somatosensory information from the left hand allowed the right hemisphere to identify but not to name the object. Because the information about the object could not be transmitted across the callosum, the talking left hemisphere could not help and supply the spoken name of the item. This was a vivid demonstration of what is now generally accepted about lateralization of function in right-handed people. The right hemisphere may possess knowledge about objects and their use in the world, but it lacks knowledge of how to produce the spoken name. This information is represented only in the left hemisphere, and once the callosum is cut the right hemisphere is left mute.

Another way to demonstrate the inability to transfer somatosensory information between the hemispheres in the absence of the callosum is to lightly touch different points on the patient's hand when it is out of view. If the right hand is touched in different positions, the right thumb can accurately point to each of the stimulated positions, but if the patient is asked to respond to the right-sided touch on the homologous area of the left hand, the task is impossible. This is equally true in reverse. The left hand can point to stimulated areas on the left hand but cannot transfer this information to the right hand. This task is trivial for people with an intact callosum, and if you are in doubt, try it. With your eyes closed, have a friend tap different areas on the palm and fingers of each hand. You will be able to respond easily with either the ipsilateral or the contralateral hand to the light touches.

Perhaps the most striking change demonstrated by Gazzaniga and Sperry was the inability to transfer visual information between the hemispheres. When two visual stimuli, either words or pictures, were lateralized one to each hemisphere, simple same/different judgments were performed at chance levels. That is, the patients could not accurately decide if the two words or pictures were identical or different when one was seen by the right hemisphere and one by the left hemisphere. However, within a hemisphere, both the right and the left hemispheres not only were able to decide if two stimuli were identical but also to match words and pictures. The ability to match words and pictures within the right hemisphere was particularly exciting because it showed that the isolated right hemisphere was able to read for meaning at least at the single word level (although it could not say the words out loud).

These basic observations ignited a period of rapid and productive investigation of the capacities of the two hemispheres. In the following sections, only the work that bears on a closer examination of the functional significance of the callosum will be presented.

III. ANATOMY AND BEHAVIOR

As the resurgence of interest in the results of callosotomy helped to elucidate the functional capacities of each hemisphere, questions arose regarding the specificity of callosal function. In an early review of the literature on callosal organization, Georgio Innocenti offered some general principles regarding the topography of callosal fibers. He considered the organization of the callosum in humans to be an interesting question because of the demonstration by Sidtis, Gazzaniga, and colleagues in the human split-brain subject that semantic and sensory aspects of visual stimuli were transferred in different parts of the callosum. The Gazzaniga laboratory and others have continued to report very specific limitations on transfer after partial lesions to the callosum.

Nonetheless, Francisco Abolitz and Eran Zaidel argue that there is great equipotentiality across the callosum. There is other anatomical support for this view. The de Lacoste work demonstrates substantial overlap between temporal lobe and superior frontal lobe fibers in the body of the callosum. The superior parietal lobe, temporal parietal junction, and occipital lobe all have some fibers passing in the splenium. Behaviorally, inconsistencies reported later suggest minimally that there may be notable individual differences.

One factor that can make the specific role of the callosum difficult to isolate is the myriad of additional interhemispheric tracts and other interactions that occur in the midbrain and brain stem. There are numerous other commissures not routinely part of split-brain surgery in humans, including the posterior commissure, the habenular commissure, the commissures of the inferior and superior colliculi and the massa intermedia, and the thalamic commissure (which is not present in all brains). As fibers descend into the brain stem, there is much less segregation and many pathways may share information across the

midline. These commissures are so deep in the brain that they are never severed during split-brain surgery in humans because of the devastating effects this would have on life-sustaining behavior. Hence, when an unexpected transfer of information occurs, the possibility that there is some subcortical communication that accounts for it is often raised.

Nonetheless, there are consistent deficits after complete section of the corpus callosum. Joseph Bogen outlined the principal deficits associated with lesions of the corpus callosum. He enumerated 10 symptoms that should be tested to confirm cases of callosal disconnection in normally lateralized right-handed subjects. In all cases, information is isolated in one hemisphere due to the loss of callosal fibers, resulting in the following symptoms:

1. Unilateral "verbal anosia": If an odor is presented unilaterally to the right nostril, it cannot be named, although the left hand can pick out the item associated with the odor.
2. Double hemianopsia: If responses are permitted from one hand at the time, the patient will appear to have a homonomous hemianopsia (i.e., an apparent blindness for one-half of space) in the field ipsilateral to the response hand. When responses are required from the opposite hand, the side of the "blind" field will change.
3. Hemialexia: If words are presented rapidly in one visual field, the ipsilateral hemisphere cannot give any sign that it has read or even seen the words.
4. Auditory suppression: Information presented from one ear is suppressed or extinguished by the ipsilateral hemisphere.
5. Unilateral (left) ideomotor apraxia: Because the left hemisphere is dominant not just for language but also generally for motor planning, the left hand is unable to carry out actions to command. It is essential to demonstrate that the deficit is not due to weakness or problems with coordination or ataxia.
6. Unilateral (left) agraphia: Most right-handed people have some ability to write with their left hand, although the letters may be less fluent and well formed than those made by their dominant hand. After callosal disconnection, the left hand loses this ability.
7. Unilateral (left) tactile anomia: Objects placed in the left hand but not seen cannot be named. Often, the function of the object can be demonstrated or a related object can be selected.
8. Unilateral (right) constructional apraxia: Because the right hemisphere is better at visual–spatial problems, the right hand will have difficulty executing complex drawings or manipulating three-dimensional objects or puzzles. However, it should be noted that the Gazzaniga laboratory has observed bilateral constructional apraxia in several patients. Gazzaniga has argued that these skills depend on interhemispheric integration in some patients, and therefore can be observed to decline for either hand after callosal section in these patients.
9. Spatial acalculia: The degree of visual–spatial impairment may be sufficiently great that patients are more successful at solving verbal arithmetic problems mentally than at writing them down with paper and pencil due to the distortion introduced by the act of writing. However, observation of this symptom may vary in the same way that it does for constructional apraxia.
10. Inability to transfer somesthetic information: As discussed previously, sensory and position information cannot be passed from hand to hand after callosotomy.

These distinctive sequelae of the disruption of cortical fibers had been noticed in part by the great 19th-century neurologists who laid the groundwork for our modern understanding of brain function. Sadly, many of their insights were lost or obscured by later experiments that failed due to shortcomings in observational techniques.

IV. SPECIFICITY

Here, we examine evidence from partial split-brain surgery, agenesis of the corpus callosum, and callosal lesions caused by stroke to better understand if different portions of the corpus callosum can be associated with different symptoms. After complete callosotomy, the whole range of symptoms discussed by Bogen should be found, with exceptions due to individual differences in lateralization. However, partial lesions may result in a subset of symptoms occurring, and these natural lesions provide another window into callosal function.

The discoveries of the Sperry, Gazzaniga, and Bogen group led to the identification of a new syndrome, alien (or anarchic) hand syndrome, by the French neurologists Serge Brion and C. P. Jedynak. They recognized that the unusual behaviors of a series of patients were related to naturally occurring callosal lesions. These lesions were the result of cerebrovascular disease or tumor. The patients shared a partial

lesion of the corpus callosum and the experience of a left or nondominant hand that appeared to be completing complex motor behaviors outside of the control of the dominant left hemisphere. Although Gary Goldberg subsequently showed that medial frontal lobe damage can result in anarchic hand sign that has both a dominant and a nondominant form, patients with no evidence of frontal damage represent what Todd Feinberg terms the callosal type of anarchic hand syndrome. Comparison of the symptoms and lesion location of patients with callosal anarchic hand sign provides another window into the location of the information that transfers in the callosum.

First, we review the observations made based on partial callosotomies, and then we use reports from patients with natural lesions of the callosum to refine these observations regarding specific transfer of information. We know from the differences observed in spilt-brain patients who had either anterior or posterior section of the callosum first that the splenium or posterior callosum is important in the transfer of visual information. This is expected given the function of the occipital lobes and the preservation of the anterior/posterior cortical organization of the cortex in the position of the callosal fibers.

Gail Risse and colleagues examined the transfer of visual, somatosensory, kinesthetic, auditory, and motor information in seven patients with section of the anterior callosum sparing the splenium and varying amounts of the posterior section of the body. By comparing transfer ability across these patients, they were able to confirm that intact splenial fibers permitted transfer of visual information for both naming and same/different judgments. However, patients that had only splenial fibers intact were unable to name objects palpated by the left hand. This suggests that the information transferred in the splenium is specifically visual and does not include higher order information synthesized from sensory information in another modality (i.e., it is generally observed that the right hemisphere is able to identify objects palpated by the left hand). If palpated objects cannot be identified by name in subjects with an intact splenium, it suggests that the tactile information necessary to build a semantic representation cannot cross to the left hemisphere in the splenium and neither can higher order information representing the semantic identification. In contrast, patients with the posterior one-third to one-fifth of the body of the callosum intact were able to name these objects relatively well. Generally, this patient group could also match limb position across hemispheres and could complete tests of apraxia with both the right and the left hand. Some difficulty with intermanual point localization was observed. A suppression of left ear auditory stimuli under dichotic conditions was noted for all but one subject. Although prior work indicates a role for the anterior callosum in praxis (due most likely to an interruption in the pathway necessary to carry the left hemisphere to ''translation'' of verbal commands for the right hemisphere to perform), there was little evidence of limb apraxia in this study except in the patients with sections that extended to the splenium. Another point made by Risse is that the left suppression on dichotic listening tasks in patients with good somatosensory function suggests that auditory fibers may be crossing anterior to somatosensory fibers, contrary to the results of Deepak Pandya and Benjamin Seltzer.

Although many sources confirm the importance of the splenium in the transfer of visual information, there may be even more specific function within the splenium. One of the patients investigated by the Gazzaniga laboratory, V.P., has shown some very specific transfer abilities. Margaret Funnell, Paul Corballis, and Michael Gazzaniga demonstrated that although V.P. is unable to transfer information about color, size, or shape across these spared fibers, she does show evidence of some access to words displayed to either hemisphere in the other, despite MRI confirmation of her status as a ''complete'' split. This remarkable specificity is supported by the work of Kyoko Suzuki and colleagues, who studied a young man with a small ventroposterior lesion to the callosum who could not read words in the left visual field. He could name pictures, however, suggesting that the anterior to middle section transfers picture information and the ventroposterior region is specific to letter transfer. Such precise lesions are rare but are revealing when carefully investigated. Of course, further work to confirm these observations is required, but they suggest that we are moving toward a much more specific understanding of the nature and location of the information transmitted in the callosum.

There remains disagreement regarding the relation between somatosensory and auditory fibers. A patient with a very discrete callosal lesion following a head injury showed increased suppression of left ear stimuli in dichotic testing when investigated by Michael Alexander and colleagues. His lesion appears to coincide with the posterior one-third to one-fourth of the body observed to be intact in some of Risse's patients. However, Risse found no auditory suppression in patients with good somatosensory function, suggesting auditory fibers were crossing anteriorly.

This was not true of Alexander's patient, who showed mildly impaired praxis and somatosensory function. (Unfortunately, transfer could not be tested because there were too many errors within a single hand to make it possible to observe decline in transfer.)

Early dichotic studies were in agreement that the portion of the callosum that caused greater left ear suppression was anterior to the splenium and was made up of the posterior one-half or one-third of the body of the callosum or was in the area of the isthmus. This was consistent with anatomical observations that indicated superior temporal lobe fibers crossed the callosum in this position. However, Sugushita and colleagues' careful examination of six patients with varied abnormalities of the corpus callosum suggested that damage to the splenium and posterior trunk leads to chronic left ear suppression. The patients in this study often had tumors that resulted in partial callosal resections, so there may have been some reorganization of function in response to tumor growth.

Given the individual differences in gyri, it may be that splenial fibers might better be defined by a common point of origin or by functional criteria rather than by a mathematically defined proportion. One paradox is that although some very precise disruptions in callosal transfer have been documented, there is significant variation in the areas where this transfer occurs. If this represents individual differences in the organization of the callosum, mathematical precision in separating the sections may not be helpful. In the meantime, the Risse observation remains difficult to reconcile with our current understanding of anatomy, and further observations will be necessary to understand the nature of the differences.

Another important function of the callosum is the transfer of information about an item identified either visually or tactilely in the right hemisphere to the left for oral naming. In a systematic investigation of the clinical signs associated with callosal transfer during a 12-month review of 282 new cases of cerebral infarction, Giroud and Dumas noted only 1 case of tactile anomia, and this patient had the most posterior callosal lesion, including the anterior one-third of the splenium. A patient investigated by Kathleen Baynes, Mark Tramo, and Michael Gazzaniga corroborates the observation that the anterior one-third of the splenium may be crucial for naming of items palpated by the left hand. This may represent transfer of word information as in the patient V.P., discussed previously.

However, all these observations await a better method for defining the regions of the callosum and tracing the origin and destination of fiber tracts than is currently available in order to be adequately confirmed or denied. It is also necessary to consider differences between right-to-left and left-to-right transmission because there are consistent behavioral advantages associated with direction of transfer.

V. CALLOSAL TRANSFER

Many research groups have been predominantly concerned with the speed and direction of callosal transfer or interhemispheric transfer time (IHTT). Perhaps the oldest method of estimation was developed by Albert Poffenberger in the early 19th century. He used lateralized visual displays to compare reaction time to material in the fields ipsilateral and contralateral to each response hand. Material in the contralateral field should be processed in the same hemisphere that initiates the manual response without need for callosal transfer. In contrast, ipsilateral displays must be processed in the opposite hemisphere and the signal must be transferred into the responding hemisphere. He subtracted crossed from uncrossed reaction times to yield a crossed–uncrossed difference as an estimate of how much time was required for this transfer. His results yielded an estimate of 2 or 3 msec for healthy adults. Such short transfer times are thought to implicate the large myelinated fibers of the callosum.

The advent of averaged evoked potentials to measure electrophysiological responses of populations of neurons provided another way of measuring IHTT. By comparing the time course of ipsilateral and contralateral peaks to lateralized visual or somatosensory stimulation, another estimate of IHTT has been obtained. Clifford Saron and Richard Davidson found about a 12-msec IHTT to visual stimuli. In contrast, somatosensory stimulation yielded estimates from 8 to 26 msec. The differences in even these simple stimulus-response IHTTs suggest to some that there is more than one route of callosal transfer, which would be expected if different sources of information indeed cross in different sections of the callosum. However, anatomical evidence of widespread callosal distribution of fibers from particular cortical loci also presents the possibility of multiple routes of crossing for specific types of information.

There have been many studies of callosal transfer that suggest that this transfer of information may not be symmetric. Carlo Marzi performed a meta-analysis that indicated that for right-handed people, responses

to displays in the left visual field with the right hand are faster than the converse. One implication of this finding is that the right hemisphere transfers information to the left hemisphere more rapidly than the left hemisphere transfers it to the right hemisphere. Because this advantage does not appear in left-handed people (although determination of hemispheric dominance is more problematic in this population), it may not mark a consistent or important principle of brain organization. It is nonetheless interesting to note that the nondominant hemisphere appears to be more adept at "reporting" to the dominant hemisphere, at least in simple reaction time tasks.

VI. CORPUS CALLOSUM AND COGNITION

Despite the remarkably normal presentation of split-brain subjects, profound changes can be observed when the appropriate experimental controls are in place to observe them. However, there remain many claims regarding the role of the corpus callosum in normal and abnormal behavior that are intriguing but require further study to determine if they have merit. Such diverse mental characteristics as lateralization of language, disposition of attention, mnemonic processing, conscious behavior, disorders of learning, and schizophrenia have all been linked to callosal changes.

The relatively large size of the corpus callosum in humans compared with other primates and the prominent cerebral lateralization in humans suggest that corpus callosum may play a role in the development or maintenance of lateralized behaviors. The first premise has been challenged, but despite increasing evidence of some lateralization of function in other species, it remains true that the lateralization of language in the human is one of the most striking examples of cerebral specialization. In a twist on this logic, Sandra Witelson suggested that within the human species, greater lateralization of function may lead to decreased callosal size because fewer fibers are necessary to connect bilateral areas with similar functions. Therefore, if right-handed people are more clearly lateralized than left-handed people, as data from examinations to determine lateralization of language and memory prior to brain surgery indicate, one would expect to see greater relative size of the corpus callosum in left-handed people. Likewise, there have been claims that males are more clearly lateralized than females, so females should as a group have larger callosums. Moreover, because language is the most clearly lateralized cognitive skill, and the axons from the language areas cross the midline primarily in the isthmus of the callosum, that structure is most likely to vary with relatively strong and weak lateralization.

With the advent of magnetic resonance imaging (MRI), visualization of the corpus callosum and measurement of its relative size in the living brain have become more straightforward. This has stimulated many attempts to test hypotheses regarding relative callosal size in right- and left-handed people, males and females, etc. The conclusions remain far from clear, although Witelson's work found a strong relationship between the site of the isthmus and handedness in men. Jeffrey Clark and Eran Zaidel, among others, have reported greater isthmus size in right-handed males compared to left-handed males. This effect is not found in females, although it is not known why handedness should have a different effect on lateralization and isthmus size in females. The Clark and Zaidel laboratories have performed many studies attempting to link behavioral measures to the size of the isthmus, with some success.

Although split-brain patients do not display the profound memory deficits associated with amnestic disorders, there do appear to be changes in the ability to integrate new memories in both laboratory and real-life settings. Most researchers with a long history of investigating these patients would agree that they exhibit a stereotypical conversational pattern that repeatedly returns to the same stories and episodes. This repertoire can expand to include information about things that happened postsurgically (unlike the dense memory deficits associated with hippocampal damage), but there is a lack of richness in the quality of reminiscence. These are, of course, subjective observations, and a more systematic evaluation of the clarity and accuracy of the pre- and postsurgical memory for life events in this population has yet to be completed.

There is evidence that clinical measures of memory show declines in some patients. Dahlia Zaidel observed declines on memory scales postsurgery, but this does not appear to be the case for all of the split-brain patients examined by the Gazzaniga laboratory. Elizabeth Phelps observed that memory scores decline after the posterior but not the anterior section of the corpus callosum, suggesting that perhaps inadvertent damage to the hippocampal commissure during surgery may contribute to the decline in memory skills. Amishi Jha and colleagues found that split-brain patients have difficulty "binding" both visual and verbal memory traces perhaps due to the dependence of some lateralized aspects of the memory trace

formation on interhemispheric communication. Hence, it seems likely that some combination of extracallosal damage as well as the resection may result in some decline in memory function that implicates the callosum in the formation of a complete memory trace.

Work in the laboratories of Marie Banich and Jacqueline Liederman has indicated that greater task difficulty leads to a greater advantage for bilateral presentations. The conclusion is that for tasks that are easy, one hemisphere is able to accomplish them with the same speed and accuracy as two. When tasks become more difficult, bilateral presentations can be more advantageous. Banich employed many cleverly designed and careful experiments to demonstrate the complexity of such interactions, with the corpus callosum providing a crucial mechanism for the division of labor across the hemispheres. Essentially, attention is a resource that depends at least partially on the corpus callosum for allocation. Since most tasks can be accomplished by either hemisphere, there must be a flexible neural mechanism for determining whether a single hemisphere or both are necessary under different task demands. Liederman stressed the corpus callosum as a mechanism to "shield" incompatible neural processes. Although it is clear that the corpus callosum plays some role in attentional processing because deficits in both selective and sustained attention have been observed in split-brain subjects, a detailed model for this role remains a goal for the future.

A theoretical model that depends heavily on callosal inhibition as a mechanism for some aspects of lateralized behavior has been proposed by Norman Cook. Although it is generally agreed that most callosal fibers are excitatory, their effect can be inhibitory via interneurons. Cook stresses the inhibitory processes in describing the process of homotopic callosal inhibition. Excitation of an area in one hemisphere leads to inhibition of the analogous area in the other hemisphere and excitation of immediately surrounding areas in a sort of center-surround arrangement. He also posits a bilateral neural semantic net such that when an item such as "farm" is excited in one hemisphere, the analogous item in the opposite hemisphere is inhibited. Immediately related items (tractor, pig, cow, sheep, and plow in one of his examples) are excited via center-surround mechanisms. This arrangement is the underlying cause of the denotative language capacity of the left hemisphere and the connotative language of the right hemisphere. He presumes this mirror-symmetric activation pattern to be a general mechanism, applicable to more than semantics. As Joseph Hellige rightly points out, the best evidence for interhemispheric inhibition is at the cellular level, whereas Cook often appears to be talking about a more functional role. Moreover, as his model stands, it would seem as if the hemispheric activation patterns could be easily reversed. This does not appear to be the case, at least for language functions. Despite the current lack of empirical support, this remains an interesting model of callosal function.

Despite many attempts to link morphological callosal differences to sex differences in lateralization, learning disabilities, and schizophrenia, definitive work in these areas remains elusive, and they will not be discussed here. The possibilities are intriguing, but the problems at this point contain too many degrees of freedom. The callosum appears to be a lever that could unlock our knowledge of brain function, but choosing the correct place to stand to use that leverage remains a problem.

VII. CORPUS CALLOSUM AND CONSCIOUSNESS

The study of split-brain patients during the past 40 years has helped change our understanding of the nature of consciousness. It has offered a prime example of the modularization of cognitive processes and documented the distinctions between a dominant and nondominant hemisphere. It has raised the question of whether the callosum may have played a unique role in the development of human consciousness. One of the key observations made regarding the Vogel and Bogen series of commissurotomies was that severing the callosum seemed to yield two separate conscious entities with the ability to respond independently. The idea of a "dual consciousness" was embraced by some scientists such as Pucetti, who hypothesized that the human condition was always made up of dual-consciousnesses that were only revealed after the section of the callosum. Others rejected the status of the right hemisphere as conscious. Daniel Dennett concluded that the right hemisphere had, at best, a "rudimentary self."

Michael Gazzaniga, Paul Corballis, and Margaret Funnell, recently proposed a new role for the corpus callosum as "the prime enabler for the human condition." They suggest the corpus callosum allows the brain to be more efficient, allowing hemispheric specialization but permitting integration of specialized functions as needed. In their view, lateral

specialization reflects the emergence of new skills and the retention of others. An advantageous mutation that changes the function of one hemisphere can be maintained and flourish while established functions continue without disruption. The callosum permits a reduction of redundant function and the easier acquisition of new skills. They suggest that the corpus callosum facilitated the development of a ''theory of mind,'' the skills that support the ability to understand the point of view of another creature, by permitting ''this extended capacity [to arise] within a limited cortical space.''

The best examples of behavior that appear to represent a separate consciousness in the right hemisphere come from split-brain patients with at least some language capacity. The newest completely split patient with normal intelligence, V.J., is anomalous in that she controls written and spoken output with different hemispheres. She is also unique in another way. She is the first split in my experience who is frequently dismayed by the independent performance of her right and left hands. She is discomforted by the fluent writing of her left hand to unseen stimuli and distressed by the inability of her right hand to write words she can read out loud and spell. In the myriad of articles discussing duality of consciousness, consciousness is sometimes considered as arising from the need for a single serial channel for motor output. In normally lateralized persons, the left hemisphere maintains control of output of both speech and writing. In V.J., there are two centers of control of the motor output of language, one partially disabled but still functional. One problem of this view point is that some split-brain patients, notably J.W. and V.P., also have some control of motor speech from either hemisphere. However, in both of these cases, the control of spoken language developed after the surgical intervention and this sequence of events may have different consequences for the conscious experience of it. If serial control of output is an important determinant of the function experienced as consciousness and the fluent shifting of control of output from one system to another is a part of that function, we may still have a good deal to learn from the split-brain model.

VIII. FUTURE DIRECTIONS

Giorgio Innocenti suggests that the complexity of callosal connections promises that these functional problems will remain fascinating but frustrating for some time. He points out that there is not yet an adequate understanding of the neural parameters that contribute to differences in size and shape of the callosum, including the number and size of axons that make up the callosum, the proportion of those axons that are myelinated, the thickness of the myelin sheath, and the number and size of blood vessels and other supporting elements. Although work in numerous laboratories is focused on answering some of these questions, until they are answered, studies correlating the size of the callosum or any of its sections to behavior are likely to continue to be frustrating.

Many of the fascinating but unproven hypotheses discussed previously could be more clearly addressed or ruled out if we had a better understanding of the neurophysiology of the human corpus callosum. Relatively little work has been done on the human callosum, although there is a large body of correlative data on differences in the morphology of the callosum derived from MRI and various aspects of behavior. However, there is still a very limited understanding of the anatomy of the callosum, where the crossing fibers originate and terminate, and the differences in the proportion of large and small fibers in different areas. Little is known about the connectivity of interneurons and how it affects the nature of the information transferred.

The advent of MRI led to a major increase in the number of studies examining gross correlations between anatomy and behavior, but the lack of a better understanding of the anatomy of callosal fibers and the basic mechanisms of transmission allowed too much freedom of interpretation. Hence, many of these studies reached inconsistent or conflicting conclusions.

A new method of image analysis known as diffusion tensor weighting is allowing researchers to examine the direction of movement in individual fiber tracts during different cognitive tasks. As this method is refined, and if it can be combined with a more explicit knowledge of callosal anatomy, the plethora of theories regarding the function of the callosum and its contribution to cognition may at last be open to more satisfying investigation.

Cranial Nerves

ANN B. BUTLER
George Mason University

GLOSSARY

branchial arches The third and several additional visceral arches (usually five in all), which in fishes are in the region of the gills.

epimere The dorsal portion of the mesodermal layer in the developing body wall and head; also called paraxial mesoderm. It forms a segmental, rostrocaudal series of mesodermal masses called somites in the body and the caudal part of the developing head. Further rostrally in the head, it forms incompletely divided, segmental masses called somitomeres.

hypomere The ventral portion of the mesodermal layer in the developing body wall; also called lateral plate mesoderm. It gives rise to the smooth muscle of the gut and to the cardiac muscle of the heart.

mesomere The middle portion of the mesodermal layer in the developing body wall; also called the nephric ridge. It gives rise to the kidneys and gonads.

neural crest Ectodermally derived cells initially located at the lateral edge of the invaginating neural tube that subsequently migrate and contribute to numerous parts of the developing nervous system and body, including some of the bipolar neurons that lie in the ganglia of most sensory cranial nerves, all of the bipolar neurons of the sensory spinal nerve ganglia, the postganglionic neurons of the autonomic nervous system, most of the cranium, and the visceral arches.

neurogenic placodes Thickened regions of the epidermis that give rise to many of the bipolar neurons that lie in the ganglia of most of the sensory cranial nerves. Placodes occur only in the developing head region.

somites The segmental, mesodermal masses of the developing body wall and caudal head that are derived from epimere. In the body, somites give rise to the striated skeletal muscle of the body wall and limbs. In the caudal head, the somites give rise to most of the branchial arch muscles of the palate, pharynx, and larynx (innervated by cranial nerve X) and to the hypobranchial muscles of the tongue (innervated by cranial nerve XII).

somitomeres The incompletely divided, mesodermal masses of the developing head that are derived from epimere. They give rise to the striated muscles of the eyes (innervated by cranial nerves III, IV, and VI) and of the first three visceral arches (innervated by cranial nerves V, VII, and IX).

visceral arches A series of skeletal arches that occur in the region of the jaw and throat (pharynx) in mammals; they include the mandibular arch that forms the jaw, the hyoid arch, and the branchial arches. Most of the tissues of these arches are in fact somatic rather than visceral in developmental origin and function.

The cranial nerves provide the sensory and motor interfaces between the brain and the structures of the head. They supply the sensory inputs from our more than five senses and the motor (effector) innervation of muscles and glands. Like spinal nerves, the cranial nerves have sensory, or afferent, components that innervate structures in the head as well as the viscera of the thorax and abdomen and motor, or efferent, components that innervate muscles and glands in the head and the viscera. Three additional "special" components of cranial nerves are commonly recognized that spinal nerves lack; however, insights into the embryological derivation of sensory structures and muscles in the head allow us to discard this special category. Considering the sensory cranial nerves, humans arguably have at least 13 different senses, but even so we lack some additional senses that are present in other vertebrates. Some tetrapods, including most mammals, have an accessory olfactory (vomeronasal) system, for example, that is present in humans only

transiently during embryological development, and humans (along with other mammals) entirely lack the lateral line mechanoreceptive and electroreceptive systems of most aquatic vertebrates. We do not possess the infrared-receptive system of snakes or the independently evolved electroreceptive and mechanoreceptive systems via the trigeminal nerve that platypuses have. With regard to these other systems, we are, as William Wordsworth wrote, "creature[s] moving about in worlds not realized." Nevertheless, our set of sensory and motor, cranial and spinal nerves is the essential and only connection that the human central nervous system has with the external world. Via these nerves, all the sensory stimuli that one can detect are brought into the brain, and all the motor actions that one makes are commanded.

I. INTRODUCTION

Some of the cranial nerves are purely sensory, others are purely motor, and the rest have both sensory and motor components. Twelve cranial nerves have traditionally been recognized in humans, which are designated by Roman numerals as well as by descriptive names (Table I). The first two cranial nerves, the olfactory nerve (I) and the optic nerve (II), are purely sensory and innervate the nasal mucosa for the sense of smell (olfaction) and the eye for the sense of sight (vision), respectively. The 10 cranial nerves of the midbrain and hindbrain collectively comprise 23 individual, traditionally recognized components.

Table I
Traditional 12 Cranial Nerves

Nerve	Name
I	Olfactory
II	Optic
III	Oculomotor
IV	Trochlear
V	Trigeminal
VI	Abducens
VII	Facial
VIII	Vestibulocochlear (or statoacoustic)
IX	Glossopharyngeal
X	Vagus
XI	Spinal accessory
XII	Hypoglossal

Three purely motor nerves that innervate the muscles of the eye are collectively called oculomotor nerves and comprise the oculomotor nerve (III), the trochlear nerve (IV), and the abducens nerve (VI). The 4 nerves with both sensory and motor components that innervate the jaws, face, throat, and the thoracic and abdominal viscera are the trigeminal nerve (V), the facial nerve (VII), the glossopharyngeal nerve (IX), and the vagus nerve (X). Cranial nerve VIII, the vestibulocochlear (or statoacoustic) nerve, innervates the inner ear organs for the auditory and vestibular senses. Cranial nerves XI, the spinal accessory nerve, and XII, the hypoglossal nerve, are purely motor and innervate the muscles of the neck that are used to turn the head (the sternocleidomastoid and upper part of the trapezius) and the muscles of the tongue, respectively.

Most of the sensory cranial nerves are formed by the processes of bipolar (or pseudounipolar) neurons whose cell bodies lie within one or two sensory ganglia located on the nerve in the peripheral part of the nervous system. The sensory neurons each have a distal portion that either innervates a separate receptor cell or has a modified ending that itself is the receptor. Sensory transduction—the translation of the sensory stimulus into neuronal activity—involves a variety of physical and chemical mechanisms. The proximal portions of the bipolar sensory neurons project to a group of multipolar neurons that lie within nuclei in the central nervous system and in turn project to other groups of multipolar neurons in the sensory pathway. For each sensory system pathway, the bipolar-receptive, multipolar neurons are referred to here as first-order multipolar neurons since they are the first of several groups of multipolar neurons in the pathway. The sensory nuclei that contain the first-order multipolar neurons are named for the name of their major cranial nerve input (vestibular, cochlear, and trigeminal nuclei), the particular sensory system (gustatory nucleus), or for their appearance (solitary nucleus).

The motor cranial nerves innervate either muscles or glands. Most of the nerves that innervate muscles have cell bodies within their respective nuclei in the brain stem; their axons exit the brain in the cranial nerve and terminate directly on the particular muscle. Most of the nuclei of these nerve components have the same name as the nerve (oculomotor, trochlear, trigeminal motor, abducens, facial motor, and hypoglossal nuclei) or arise from a nucleus named for its indistinct appearance (nucleus ambiguus). Glands are innervated via a two-neuron chain of neurons that belong to the parasympathetic division of the autonomic

nervous system. The cell bodies of the first neurons in the chain, called preganglionic parasympathetic neurons, lie within nuclei in the brain stem, and their axons exit the brain in the cranial nerve. These axons terminate on a second set of neurons that lie in a ganglion located close to the target organ and are called postganglionic parasympathetic neurons in reference to their axons, which exit the ganglion and innervate the gland. Three small muscles within the eye are also innervated by the autonomic nervous system. Two of these intraocular muscles (for pupillary constriction and control of the shape of the lens) are innervated by the axons of postganglionic parasympathetic neurons, whereas the third (for pupillary dilation) is innervated by postganglionic axons that are part of the sympathetic division of the autonomic nervous system, which arises from neurons located within thoracic and upper lumbar spinal cord segments. The parasympathetic cell groups of the brain stem have a variety of names, including the eponymic Edinger–Westphal nucleus, the superior and inferior salivatory nuclei, the dorsal motor nucleus of X, and some of the neurons in nucleus ambiguus.

The motor nuclei of the brain stem all receive a variety of inputs from other neuron cell groups in the brain. These inputs include relatively local connections with reticular formation neurons and long, descending projections from motor regions of neocortex. Since the latter connections arise from neurons located above (rostral to) the cranial nerve nuclei, they are referred to as supranuclear connections. The majority of supranuclear inputs to cranial nerve nuclei are bilateral.

II. TRADITIONAL FUNCTIONAL COMPONENTS

Each of the various components of most of the cranial nerves has traditionally been classified as somatic (referring to body wall structures) or visceral (referring to internal organs), afferent (sensory) or efferent (motor), and general or special. The latter pair of terms are used in reference to earlier beliefs concerning the embryological derivation of some of the sensory structures and muscles in the head. Recent new information will allow us to discard these categories later in this article, but their current widespread use necessitates discussing them here.

The first two pairs of classification terms for cranial nerves correspond to the four components of spinal nerves. Sensory nerve components are thus either somatic afferent or visceral afferent, and motor components are likewise either somatic efferent or visceral efferent. Spinal nerve components and some cranial nerve components are additionally classified as general, so they are designated general somatic afferent (GSA), general visceral afferent (GVA), general somatic efferent (GSE), and general visceral efferent (GVE). The sensory GSA components innervate the skin of the face and position sense (proprioception) receptors in head musculature, whereas GVA components innervate the viscera of the thorax and abdomen and a few structures in the head and neck, such as the mucous membranes of the oral cavity. The motor GSE components innervate extraocular eye muscles and the muscles of the tongue, whereas GVE components supply parasympathetic innervation to the thoracic and abdominal viscera and to glands and intraocular muscles in the head.

Two sensory cranial nerve components are categorized as special and thus designated special somatic afferent (SSA) and special visceral afferent (SVA). The SSA category is applied to the auditory and vestibular senses, whereas the SVA category is applied to the sense of taste (gustation). The two most rostral cranial nerves of the traditional 12, for olfaction and vision, are frequently not categorized at all. One cranial nerve motor category is also designated as special—the special visceral efferent (SVE) components of cranial nerves V, VII, IX, and X. Cranial nerve XI is sometimes not categorized but can be included in this traditional SVE category as well. SVE components of cranial nerves innervate muscles of the face, the mandibular and hyoid arches, the throat, and the neck, which all develop embryologically from muscles of the visceral arches that include the mandibular arch for the jaw, the hyoid arch, and a series of branchial arches. The latter give rise to the gill region in fishes and to components of the throat in tetrapods. The variously recognized traditional components of the midbrain and hindbrain cranial nerves are summarized in Table II, whereas the newer, revised classification is presented in Table III.

In the spinal cord, the two sensory afferent and two motor efferent components of the spinal nerves have their central cell groups organized in a dorsal to ventral order of GSA, GVA, GVE, and GSE. These rostrocaudally running functional columns extend into the brain stem so that the central cell groups of the cranial nerves in the hindbrain and midbrain lie in a similar topographic order. Due to the geometry of the brain's ventricular system, these cell columns lie in a lateral to medial order of GSA, GVA, GVE, and GSE. The two additional "special" sensory components of the cranial

Table II
Traditionally Recognized Components of Midbrain and Hindbrain Cranial Nerves[a]

Cranial nerve	Component	Sensory ganglion or motor ganglion and/or nucleus
Oculomotor (III)	GSE	Oculomotor nucleus
	GVE	Edinger–Westphal and anterior medial nuclei/ciliary ganglion
Trochlear (IV)	GSE	Trochlear nucleus
Trigeminal (V)	GSA	Trigeminal ganglion
	SVE	Trigeminal motor nucleus
Abducens (VI)	GSE	Abducens nucleus
Facial (VII)	GSA	Geniculate ganglion
	SVA	Geniculate ganglion
	GVE	Superior salivatory nucleus/pterygopalatine and submandibular ganglia
	SVE	Facial motor nucleus
Vestibulocochlear (VIII)	SSA	Spiral and vestibular ganglia
Glossopharyngeal (IX)	GSA	Superior (jugular) ganglion
	GVA	Inferior (petrosal) ganglion
	SVA	Inferior (petrosal) ganglion
	GVE	Inferior salivatory nucleus/otic ganglion
	SVE	Nucleus ambiguus
Vagus (X)	GSA	Superior (jugular) ganglion
	GVA	Inferior (nodose) ganglion
	SVA	Inferior (nodose) ganglion
	GVE	Dorsal motor nucleus of X and nucleus ambiguus/parasympathetic ganglia of thoracic and abdominal viscera and heart
	SVE	Nucleus ambiguus
Spinal accessory (XI)	SVE	Cervical anterior horn cells
Hypoglossal (XII)	GSE	Hypoglossal nucleus

[a]Abbreviations used: GSA, general somatic afferent; GVA, general visceral afferent; SSA, special somatic afferent; SVA, special visceral afferent; GSE, general somatic efferent; GVE, general visceral efferent; SVE, special visceral efferent.

nerves (SSA and SVA) have central cell groups that lie near the GSA nuclei. The SVE cell column lies in a more displaced, ventrolateral position, which is a legacy of its early evolutionary origin. The SVE cranial nerves and the visceral arch muscles that they supply evolved in the earliest vertebrates before the GSE column and its associated set of muscles were gained.

A. Cranial Nerves of the Medulla

Four of the cranial nerves are present in the medulla: the hypoglossal nerve (XII), the spinal accessory nerve (XI), the vagus nerve (X), and the glossopharyngeal nerve (IX). Cranial nerves XII and XI are simple nerves that have only a single component, which is motor. Cranial nerves X and IX are the two most complex cranial nerves, each with five traditional functional components.

1. Hypoglossal Nerve

Cranial nerve XII innervates the muscles of the tongue. A fleshy tongue and thus a distinct hypoglossal nucleus and nerve are present only in tetrapods. The tongue develops embryologically from hypobranchial musculature that lies ventral to the visceral arches of the pharyngeal region. The only component present in the hypoglossal nerve is the GSE. The nerve arises from motor neurons in the hypoglossal nucleus, which lies in a medial position in the dorsal part of the medulla and is the caudalmost portion of the GSE column in the brain stem. Hypoglossal nerve fibers run ventrally from the hypoglossal nucleus and exit the medulla on its ventral surface between the medially lying pyramidal (corticospinal) tract and the more laterally lying inferior olivary nucleus. Hypoglossal innervation of the tongue is ipsilateral.

Damage to the ventromedial medulla may thus result in the syndrome called inferior alternating hemiplegia, which is motor impairment on the contralateral side of the body (due to damage to the pyramidal tract) combined with weakness of tongue muscles on the ipsilateral (i.e., alternate) side due to a lower motor neuron lesion of the nerve. When protruded, the tongue deviates toward the side of the lesion. Supranuclear innervation of the hypoglossal nucleus is bilateral, so lesions that interrupt this input result only in mild weakness of the tongue musculature on the side opposite to the lesion. During normal usage, the pattern of tongue movements is modulated by inputs to the hypoglossal nucleus relayed from other cranial nerve nuclei, including those of V for

Table III
New Classification of Cranial Nerve Components in Humans[a]

Cranial nerve	Traditional classification	New classification	Embryological derivation or site of innervation
Terminal	—	SA	Olfactory placode
I	—	SA	Olfactory placode
II	—	NTA	Neural tube
Epiphyseal	—	NTA	Neural tube
III	GSE	SE	Epimeric muscles
	GVE	VE	Ciliary ganglion
IV	GSE	SE	Epimeric muscle
V	GSA	SA	Neural crest and trigeminal placode
	SVE	SE: branchial motor	Epimeric muscle
VI	GSE	SE	Epimeric muscle
VII	GSA	SA	Neural crest and/or ventrolateral placode
	SVA	VA	Neural crest and/or ventrolateral placode
	GVE	VE	Neural crest
	SVE	SE: branchial motor	Epimeric muscles
VIII	SSA	SA	Dorsolateral placode
IX	GSA	SA	Neural crest and/or ventrolateral placode
	GVA	VA	Neural crest and/or ventrolateral placode
	SVA	VA	Neural crest and/or ventrolateral placode
	GVE	VE	Neural crest
	SVE	SE: branchial motor	Epimeric muscle
X	GSA	SA	Neural crest and/or ventrolateral placode
	GVA	VA	Neural crest and/or ventrolateral placode
	SVA	VA	Neural crest and/or ventrolateral placode
	GVE	VE	Neural crest
	SVE	SE: branchial motor	Epimeric muscles
XI	SVE	SE: branchial motor	Epimeric muscles
XII	GSE	SE	Epimeric muscles

[a]Abbreviations used: GSA, general somatic afferent; GVA, general visceral afferent; SSA, special somatic afferent; SVA, special visceral afferent; GSE, general somatic efferent; GVE, general visceral efferent; NTA, neural tube afferent; SVE, special visceral efferent; SA, somatic afferent; VA, visceral afferent; SE, somatic efferent; VE, visceral efferent.

proprioception and IX and X for stimuli from the mucosal lining of the oral cavity.

2. Spinal Accessory Nerve

Cranial nerve XI (the accessory nerve) has traditionally been considered to comprise two parts, a cranial part that arises from neuron cell bodies in the caudal part of nucleus ambiguus (which lies in the lateral region of the medulla) and a spinal part that arises from neuron cell bodies located in the lateral part of the gray matter within upper segments of the cervical spinal cord. The laterally displaced position of the latter cell group is similar to that of the corresponding cell column in the brain stem. The so-called cranial part of XI (not included in Table II) is in fact merely the more caudal part of the vagus nerve. It supplies innervation to the intrinsic muscles of the larynx on the ipsilateral side. The spinal part of XI innervates the ipsilateral sternocleidomastoid muscle and the upper parts of the trapezius muscle. Contraction of the sternocleidomastoid muscle on one side causes the mastoid process (which lies behind the ear) to approach the sternum and medial part of the clavicle

(''cleido''), thus causing the head to turn toward the contralateral side. Innervation of the spinal nucleus of XI from motor cortex appears to be predominantly ipsilateral. Damage to the spinal accessory nerve results in weakness of the ipsilateral muscles, which is revealed when trying to turn the head toward the opposite side against resistance.

The accessory nerve is sometimes unclassified, but it is a branchial motor nerve and belongs in the traditional category of SVE. The sternocleidomastoid and trapezius muscles evolved from the levator muscles of the branchial arches.

3. Vagus Nerve

Cranial nerve X has five components and by this measure joins cranial nerve IX in the distinction of being most complex. It has three sensory components GSA, SVA, and GVA and two motor components GVE and SVE. The GSA component is a minor one; its fibers innervate the region of the external auditory meatus and the tympanic membrane. These GSA fibers have cell bodies located in the superior (jugular) ganglion of X and enter the brain stem via the vagus nerve. They terminate in a rostrocaudally elongated group of first-order multipolar neurons that receive most of their input from GSA fibers of the trigeminal nerve. This group of neurons is called the spinal, or descending, nucleus of V since it extends from the pontine levels caudally into the upper part of the spinal cord, ending at the level of the second cervical segment. The ascending sensory pathway that arises from the spinal nucleus of V is discussed later.

The GVA and SVA sensory components of the vagus nerve are more substantial than the GSA component. The GVA component has its bipolar neurons located in the inferior (nodose) ganglion of X and provides sensory innervation to the viscera of the thorax and abdomen as well as to mucous membranes lining the pharynx, larynx, trachea, and esophagus. In the brain stem, these GVA axons enter a fiber bundle that is surrounded by its nucleus and thereby appears to be isolated from neighboring structures. This bundle is called tractus solitarius, and its nucleus, which contains the first-order multipolar neurons that receive the visceral sensory input, is called nucleus solitarius (the nucleus of the solitary tract). Nucleus solitarius projects to multiple brain stem sites, including the dorsal motor nucleus of X and nucleus ambiguus.

Additional visceral sensory innervation is via afferent fibers that traverse sympathetic and parasympathetic nerves and then terminate on spinal cord dorsal horn neurons, which in turn project to the dorsal thalamus (ventral posterolateral and intralaminar nuclei). This information is then relayed to the neocortex. This ascending system accounts for most of the sensations from thoracic, abdominal, and pelvic viscera that are consciously experienced. Since the same pool of dorsal horn neurons also receives inputs from the somatic part of the body at each segmental level, this pattern of innervation is responsible for the phenomenon of ''referred pain,'' in which visceral sensations are perceived as originating from the body wall.

The SVA component of the vagus nerve has bipolar neurons located in the inferior (nodose) ganglion of X. The cell group that receives taste afferents via this SVA component of the vagus nerve (and the SVA components of the glossopharyngeal and facial nerves as well) has previously been viewed as the rostral part of nucleus solitarius but is now recognized as a distinct and separate entity, the gustatory nucleus. The first-order multipolar neurons located in this nucleus receive taste sensation via the superior laryngeal branch of the vagus nerve from taste buds located on the epiglottis and esophagus. An ascending pathway originates from the gustatory nucleus and projects to a nucleus in the dorsal thalamus, specifically the parvicellular portion of the ventral posteromedial nucleus (VPMpc), which in turn projects to two neocortical gustatory regions, one in the insular region and the other in parietal opercular cortex. The gustatory nucleus has other projections, including those to nucleus ambiguus and to the hypoglossal and salivatory nuclei for throat, lingual, and secretory reflexes.

The two motor components of the vagus nerve are both traditionally classified as visceral components. The GVE component provides innervation to the parasympathetic ganglia that supply the viscera of the thorax and abdomen. (The parasympathetic ganglia for pelvic viscera receive their parasympathetic innervation from preganglionic neurons located in the sacral spinal cord.) Preganglionic parasympathetic GVE neurons are mostly located in the dorsal motor nucleus of X, which lies immediately dorsolateral to the hypoglossal nucleus. Some GVE neurons also lie within nucleus ambiguus and specifically supply additional parasympathetic innervation to the heart. The vagus nerve exits the lateral surface of the medulla, and its GVE fibers distribute to parasympathetic ganglia for the esophagus, trachea and lungs, heart, and most of the abdominal viscera. Parasympathetic activity results in decreased heart rate, bronchial

constriction, increased blood flow to the gut, and increased peristalsis and secretion.

The SVE, branchial motor component of the vagus nerve arises from neurons in nucleus ambiguus and innervates muscles of the palate, pharynx, and larynx. These muscles are embryologically derived from muscles associated with the branchial arches. Nucleus ambiguus receives bilateral corticobulbar input and input from other cranial nerve nuclei for coordination of movements involved in reflex actions (such as coughing or vomiting) and for phonation and swallowing. The latter, for example, is a complex action that also involves motor neurons of the trigeminal (V), facial (VII), and hypoglossal (XII) nerves.

Damage to nucleus ambiguus or to the fibers of the vagus nerve results in reduction of the arch of the palate on the ipsilateral side, difficulty in swallowing, and hoarseness. Hoarseness is one of the manifestations of Parkinson's disease. It is due to supranuclear effects on the function of SVE vagal neurons. Hoarseness can also result from a lung tumor on the left side that involves the left recurrent laryngeal nerve; the latter arises from the vagus nerve in the upper part of the thorax, an anatomical relationship that does not occur on the right due to a higher origin of the recurrent nerve.

4. Glossopharyngeal Nerve

Like the vagus nerve, cranial nerve IX has five components, three of which are sensory and two of which are motor. The GSA component is a minor one, which innervates a small region of skin behind the ear. The GSA fibers of the glossopharyngeal nerve have cell bodies located in the superior (jugular) ganglion of IX, and they traverse the spinal tract of V to terminate in the spinal nucleus of V with similar GSA afferents from cranial nerves X, VII, and V. The GVA component of IX has a much more restricted distribution than the GVA component of X. Glossopharyngeal GVA fibers innervate the mucosal membranes that line the internal surface of the middle ear and cover the posterior third of the tongue, the tonsils, the posterior and upper surfaces of the pharynx, and the Eustachian tube. These GVA fibers have cell bodies in the inferior (petrosal) ganglion of IX. They enter the tractus solitarius and terminate in its nucleus. The latter projects to sites that include nucleus ambiguus (for throat reflexes), the dorsal motor nucleus of X, and the reticular formation. The carotid sinus reflex depends on some additional glossopharyngeal GVA fibers that innervate the carotid sinus (which is located at the bifurcation of the internal and external carotid arteries) and are stimulated by increases in arterial blood pressure. These fibers terminate on solitary nucleus neurons that project to the dorsal motor nucleus of X, which, via its projection to the parasympathetic ganglia of the heart, decreases heart rate and the arterial blood pressure. The SVA component of IX innervates taste buds located on the posterior third of the tongue. These fibers have cell bodies located in the inferior (petrosal) ganglion of IX and project to first-order multipolar neurons in the gustatory nucleus, which, as discussed previously, projects to VPMpc in the dorsal thalamus for relay to gustatory cortical areas.

The glossopharyngeal nerve has two efferent components, GVE and SVE. In the latter, branchial motor fibers arise from neurons in nucleus ambiguus and innervate the stylopharyngeus muscle (which arises from part of the styloid process on the inferior surface of the temporal bone of the skull and inserts along the side of the pharynx and part of the thyroid cartilage). The stylopharyngeus muscle is embryologically derived from the muscles of the branchial arches. The GVE component of IX arises from a nucleus that lies rostral to the dorsal motor nucleus of X but is displaced laterally away from the ventricular surface; it is called the inferior salivatory nucleus. As its name implies, its neurons give rise to preganglionic parasympathetic fibers that project via the tympanic and lesser superficial petrosal nerves to the otic ganglion, which in turn gives rise to postganglionic parasympathetic fibers that innervate the largest of the salivary glands—the parotid gland. Parasympathetic stimulation increases the secretory activity of the parotid gland. The glossopharyngeal nerve is rarely involved clinically in isolation, and deficits are predominantly sensory. Damage to cranial nerve IX results in loss of the pharyngeal (gag) reflex due to loss of the sensory input, a similar loss of the carotid sinus reflex for blood pressure regulation, and loss of taste to the posterior third of the tongue. Loss of salivatory activity by the parotid gland results from damage to the glossopharyngeal GVE component.

B. Cranial Nerves of the Pons

Four cranial nerves are present at pontine levels: the vestibulocochlear nerve (VIII), the facial nerve (VII), the abducens nerve (VI), and the trigeminal nerve (V). Cranial nerve VIII has a single sensory component that

comprises two divisions, and cranial nerve VI has only a single motor component. Cranial nerve VII is second in complexity only to the vagus and glossopharyngeal nerves, with four traditionally recognized functional components, whereas cranial nerve V is a mixed nerve with two components, one sensory and one motor.

1. Vestibulocochlear Nerve

The eighth cranial nerve traditionally has been classified in one of the special categories, SSA. It comprises the two senses of audition and the relative position and motion of the head in space. The eighth nerve innervates the inner ear organs—the spiral-shaped cochlea, which transduces auditory stimuli via vibration of its perilymphatic fluid, and the vestibular labyrinth, which transduces the effects of gravity and acceleration on its receptor apparatus.

a. Cochlear Division The bipolar neurons of the cochlear division of VIII innervate the hair cells of the cochlear organ of Corti. The apical surfaces of the hair cells are studded with stereocilia and border the inner chamber of the cochlea, the scala media, which is filled with endolymph. A tectorial membrane overlies the stereocilia. An outer chamber, formed by the scala vestibuli and scala tympani, contains perilymph, and the scala tympani portion is separated from the organ of Corti by a basilar membrane. Sound waves cause vibration of the perilymph and resultant displacement of the basilar membrane, which in turn pushes the stereocilia against the tectorial membrane, bending them and opening ion channels. Influx of potassium from the endolymph through the opened channels causes depolarization of the receptor cell. The frequency of the auditory stimuli is tonotopically mapped along the length of the cochlear spiral, with best responses to high frequencies occurring at its base and those to lower frequencies at more apical locations. The bipolar neurons preserve the tonotopic map for relay to the cochlear nuclei and then throughout the ascending auditory pathway. They also encode intensity by their discharge rate.

Cell bodies of cochlear bipolar neurons lie within the spiral ganglion, named for the shape of the cochlea. Their central processes enter the lateral aspect of the brain stem at a caudal pontine level and terminate in the dorsal and ventral cochlear nuclei. The cochlear nuclei project to multiple sites, including the superior olivary nuclear complex in the pons and the inferior colliculus in the midbrain roof. The superior olivary complex (SO) receives bilateral input mainly from the so-called bushy cells of the ventral cochlear nucleus; SO neurons are coincidence detectors that utilize the time delay between the inputs from the two sides in order to compute the location in space of the sound source. The ascending auditory projections predominantly originate from pyramidal neurons within the dorsal cochlear nucleus and from the superior olivary complex and pass via the lateral lemniscus to the inferior colliculus, which in turn projects to the medial geniculate body of the dorsal thalamus. The latter projects to auditory cortex in the temporal lobe. Damage to the cochlear division of VIII results in dysfunction (such as experiencing a buzzing sound) and/or deafness.

b. Vestibular Division The bipolar neurons of the vestibular division of VIII innervate hair cells within several parts of the vestibular labyrinth. The fluid-filled labyrinth consists of three semicircular canals that transduce rotational movements (angular acceleration) of the head and two chambers, the saccule and utricle, that constitute the otolith organ and transduce linear acceleration and gravitational force. The three semicircular canals are arranged at right angles to each other for responses in the various planes of space, and each contains a dilated area, the ampulla, that contains a ridge, the crista ampullaris. Vestibular hair cells on the surface of the crista have stereocilia and a longer kinocillium that are displaced by movement of an overlying gelatinous cupula, which moves due to fluid displacement within the canal caused by rotational motion. Similarly, the saccule and utricle contain hair cells in an area called the macula. The cilia of these hair cells are displaced by movement of an overlying gelatinous mass, the otolith membrane, that contains the otoliths (or otoconia), which are small particles of calcium carbonate that are denser than the surrounding fluid and are displaced by gravity when the head is tilted or during linear acceleration.

Cell bodies of vestibular bipolar neurons lie within the vestibular (Scarpa's) ganglion. The central processes of these neurons enter the lateral aspect of the pons along with the cochlear nerve fibers; most terminate in the superior, inferior, medial, and lateral vestibular nuclei, which lie in the floor of the fourth ventricle. A small number of vestibular afferent fibers bypass the vestibular nuclei and project directly to the cerebellar cortex, particularly within its flocculonodular lobe, which is concerned with the maintenance of

posture, balance, and equilibrium. The vestibular nuclei also receive a substantial input from the cerebellum via its deep nuclei.

Descending projections from the vestibular nuclei form the medial and lateral vestibulospinal tracts that innervate spinal cord neurons for extensor muscles involved in postural maintenance and related reflexes. Unlike other brain stem nuclei that give rise to descending spinal projections, the vestibular nuclei do not receive any direct input from the cerebral cortex. Other major vestibular connections are with the oculomotor nuclei of cranial nerves III, IV, and VI via the medial longitudinal fasciculus for the vestibuloocular reflex—the stabilization of eye fixation on a target while the head is moving—and other vestibular–oculomotor interactions. The ascending pathway for conscious perception of vestibular stimuli arises from neurons in the superior, lateral, and inferior vestibular nuclei and terminates in several dorsal thalamic nuclei, including part of the ventral posterolateral (VPLc) nucleus and the ventral posteroinferior (VPI) nucleus. Thalamocortical vestibular projections are to ventrally lying parietal cortical areas (designated 2v and 3a), which are adjacent to the head representation of somatosensory and motor cortices, respectively. Damage to the vestibular division of VIII results in dizziness, pathologic nystagmus (an involuntary, repeated eye movement pattern consisting of conjugate movement of the eyes to one side followed by a rapid return to the original position), nausea and vomiting, vertigo (the sensation of rotation in the absence of actual movement), and other related symptoms.

2. Facial Nerve

Cranial nerve VII contains four of the five components present in the vagal and glossopharyngeal nerves, namely, GSA, SVA, GVE, and SVE. The seventh nerve can be divided into two parts—the intermediate nerve (of Wrisberg), which comprises the GSA, SVA, and GVE components, and the facial branchial motor nerve, which is the SVE component. The two sensory components of VII both have cell bodies located in the geniculate ganglion. As is also the case for cranial nerves IX and X, the GSA component of VII is minor, innervating a small area of skin behind the ear and the external auditory meatus. The GSA fibers terminate in the spinal nucleus of V, for which the ascending sensory pathway is discussed later. Facial SVA fibers innervate taste buds that lie on the anterior two-thirds of the tongue via the chorda tympani nerve. These neurons project to the gustatory nucleus, which, as discussed previously, projects to VPMpc in the dorsal thalamus for relay to gustatory cortical areas.

Special visceral efferent fibers arise in the branchial motor nucleus of VII, which lies ventrolateral to the abducens (VI) nucleus in the pons. The axons of motor VII initially follow a dorsomedial course within the pons and then turn laterally and curve over the dorsal surface of the abducens nucleus, forming the internal genu of the nerve. This course is due to ventrolateral migration of the neuron cell bodies during embryological development. The facial motor fibers then traverse the pons in a ventrolateral direction to exit on its lateral surface near the junction of the pons with the medulla. The facial branchial motor nerve innervates muscles embryologically derived from the muscles of the branchial arches, including the platysma (a superficial muscle of the skin of the neck), buccinator (which forms the cheek), stapedius (which inserts on the stapes bone within the middle ear), auricular and occipital muscles, and the muscles of facial expression. An additional component supplies efferent innervation to the inner ear. The branchial motor nucleus of VII receives afferent input from structures that include the spinal nucleus of V for corneal and other trigeminofacial reflexes, auditory input from the superior olivary complex for facial reflexes to loud noise (including closing the eyes and the stapedius reflex to damp sound transmission through the middle ear ossicles), and corticobulbar input, which is bilateral to the facial motor neurons for the forehead and upper face but predominantly contralateral for the lower face and mouth region.

The GVE component of the facial nerve arises from neurons in the superior salivatory nucleus. Some preganglionic parasympathetic fibers project via the greater petrosal nerve to the pterygopalatine ganglion for innervation of the lacrimal gland. Other preganglionic fibers project via the chorda tympani nerve to the submandibular ganglion for innervation of the sublingual and submandibular salivary glands. Damage to cranial nerve VII results in deficits according to the location of the lesion and the components involved. Sensory loss of taste to the anterior two-thirds of the tongue occurs with involvement of the SVA component, and loss of production of tears from the lacrimal gland and saliva from the sublingual and submandibular salivary glands occurs with involvement of the GVE component. Damage to the nucleus or nerve for the SVE motor VII component results in paralysis of all the muscles of the ipsilateral face,

whereas a supranuclear lesion affecting corticobulbar input results in paralysis of only the lower part of the face on the contralateral side. Motor VII damage also results in sounds being abnormally loud due to loss of the stapedius reflex.

3. Abducens Nerve

Cranial nerve VI is one of the set of three ocular motor (oculomotor) nerves (III, IV, and VI) and innervates one of the six extraocular muscles of the eye, the lateral rectus muscle. The abducens nerve is a purely motor nerve with only a GSE component. The nerve arises from motor neurons in the abducens nucleus, which lies in a medial position in the dorsal pons and, along with the other oculomotor nuclei and the hypoglossal nucleus, forms the GSE column of the brain stem. Abducens nerve fibers run ventrally from the nucleus and exit the brain stem on its ventral surface at the junction of the pons with the medulla. The abducens nerve runs forward along the side of the brain stem, traverses the cavernous sinus, and passes through the superior orbital fissure (along with the other oculomotor nerves) to innervate the ipsilateral lateral rectus muscle. Contraction of the lateral rectus causes abduction (lateral movement) of the eye. Damage to the ventral region of the brain stem at the level of the abducens nerve may result in the syndrome called middle alternating hemiplegia, which is motor impairment on the contralateral side of the body (due to damage to the corticospinal tract) combined with medial deviation of the eye on the ipislateral (i.e., alternate) side due to a lower motor neuron lesion of the abducens nerve. In this situation, the eye deviates medially due to the unopposed contraction of the medial rectus muscle, which is innervated by cranial nerve III. Supranuclear innervation of the oculomotor nuclei derives from the superior colliculus and from cortical eye fields in the frontal and parietal lobes, and it is relayed to the oculomotor nuclei via gaze centers in the brain stem.

Connections from the gaze centers and vestibular nuclei and among the oculomotor nuclei via the medial longitudinal fasciculus serve to coordinate the actions of the extraocular muscles so that, for example, when a person moves both eyes to the right, the right lateral rectus contracts to move the right eye laterally, the right medial rectus does not oppose the action, and the actions of the medial and lateral recti of the left eye are similarly coordinated to produce the conjugate movement. Damage to the medial longitudinal fasciculus results in internuclear ophthalmoplegia; this condition is characterized by weakness in adduction of the eye on the side ipsilateral to the lesion during attempted conjugate eye movements toward the opposite side accompanied by nystagmus in the contralateral, abducting eye. Bilateral internuclear ophthalmoplegia can occur due to multiple sclerosis.

4. Trigeminal Nerve

Cranial nerve V has only two components, GSA and SVE. The trigeminal nerve is named for its three divisions: The ophthalmic division provides sensory innervation to the upper face, including the forehead, upper eyelid, and cornea; the maxillary division to the region of the upper jaw, including the upper lip, jaw, and cheek, parts of the nose, and upper teeth; and the mandibular division to the region of the lower jaw, including the lower lip, jaw, cheek, lower teeth, and anterior two-thirds of the tongue. The mandibular division also provides motor innervation to the muscles of the jaw used for mastication (chewing). The trigeminal nerve emerges from the lateral aspect of the brain stem at a midpontine level.

The GSA fibers of the trigeminal nerve have most of their cell bodies located within the trigeminal ganglion and innervate the face and upper head region for fine (discriminative) touch, position sense, vibratory sense, pain, and temperature. GSA fibers for the modalities of fine touch, vibration, and position enter the brain stem and terminate in the principal sensory nucleus of V in the lateral part of the pons, which in turn projects to the ventral posteromedial nucleus (VPM) in the dorsal thalamus. The latter projects to the face representation within somatosensory cortex. GSA fibers for pain and temperature enter the brain stem and distribute to the spinal (or descending) nucleus of V, which also receives inputs from the GSA components of the facial (VII), glossopharyngeal (IX), and vagus (X) nerves. Like the principal sensory nucleus of V, the spinal nucleus projects to VPM for relay of its inputs to somatosensory cortex. (Trigeminal innervation of the mucous membranes of the nose and anterior tongue region has traditionally been lumped with the GSA components, but since these membranes are embryologically derived from endoderm, this component is technically general visceral afferent.)

A third trigeminal sensory nucleus, the mesencephalic nucleus of V, is present along the lateral border of the central gray matter encircling the upper part of the fourth ventricle and the cerebral aqueduct of the midbrain. This nucleus comprises bipolar neurons that

lie within the central nervous system rather than in the cranial nerve ganglion. The neurons' peripheral processes form the mesencephalic tract of V and carry pressure and position information from structures including the teeth, the palate, and the muscles of mastication. The mesencephalic V neurons project to multiple sites, including the motor nucleus of V for reflexive control of jaw position.

SVE, branchial motor fibers arise in the motor nucleus of V, which lies medial to the principal sensory nucleus and receives bilateral corticobulbar input. The axons exit the brain stem on its lateral surface in the trigeminal nerve head and distribute via the mandibular division to the jaw muscles used in mastication—the temporalis and masseter muscles and the medial and lateral pterygoids, which are embryologically derived from the muscles of the branchial arches. Additional branchial arch-derived muscles innervated by the branchial motor component of V are the tensor veli palatini muscle of the palate, the tensor tympani muscle of the middle ear (which inserts on the malleus), and two suprahyoid muscles, the anterior belly of the digastric and mylohyoid.

Damage to the GSA components of cranial nerve V results in sensory loss to the face and loss of many reflexes due to lack of the sensory part of the reflex arc, including the corneal reflex (closing the eyes in response to light touch to the cornea) via the facial motor nucleus (via the reticular formation), the tearing reflex via the superior salivatory nucleus, the sneezing reflex via nucleus ambiguus, the vomiting reflex via vagal nuclei, salivatory reflexes via the superior and inferior salivatory nuclei, and the jaw-jerk reflex via the mesencephalic nucleus of V. The sensation for hot pepper (capseisin) on the anterior two-thirds of the tongue is also lost. Damage to the SVE component of V results in paralysis of the jaw muscles on the ipsilateral side, whereas a supranuclear lesion produces only moderate weakness due to the bilaterality of the supranuclear input. Changes in the loudness of sounds can also result from loss of innervation to the tensor tympani muscle.

C. Cranial Nerves of the Midbrain

Only two cranial nerves are present in the midbrain: the trochlear nerve (IV) and the oculomotor nerve (III). Cranial nerve IV has only a single component, which is motor. Cranial nerve III has two motor components.

1. Trochlear Nerve

Cranial nerve IV is one of the set of three oculomotor nerves (III, IV, and VI) and innervates one of the six extraocular muscles of the eye, the superior oblique muscle. The trochlear nerve is a purely motor nerve with only a GSE component. The nerve arises from motor neurons in the trochlear nucleus, which lies in a medial position in the dorsal part of the caudal half of the midbrain tegmentum. The trochlear nerve is unique among cranial nerves in that it decussates to the contralateral side (through the superior medullary velum that forms the roof of the fourth ventricle), and its point of exit is through the dorsal surface of the brain. The trochlear nerve thus innervates the superior oblique muscle of the contralateral eye.

The superior oblique muscle arises from the dorsomedial surface of the orbit and ends in a tendon that bends through a connective tissue pulley and then passes laterally to insert on the dorsal part of the eye bulb lateral to its center. Contraction of the superior oblique muscle causes intorsion (rotation of the eyeball around a horizontal, anteroposterior axis through the pupil such that the top moves medially), depression, and abduction. Deviation of the eye due to isolated damage to the trochlear nucleus or nerve is not readily apparent due to the actions of the other extraocular muscles, which mask most of the deficit. Supranuclear innervation of the trochlear nucleus is via the gaze centers in the brain stem, and the gaze centers, the three oculomotor nuclei, and vestibular nuclei are interconnected via the medial longitudinal fasciculus.

2. Oculomotor Nerve

Cranial nerve III innervates four of the six extraocular muscles of the eye as well as the levator palpebrae superioris muscle of the eyelid and, via projections to the ciliary ganglion, the small intraocular muscles that control the constriction of the pupil and the shape of the lens. Unlike the other two oculomotor nerves—the abducens nerve, which innervates the lateral rectus muscle, and the trochlear nerve, which innervates the superior oblique muscle—the oculomotor nerve has more than one functional component. It contains a GSE component for innervation of the extraocular and levator palpebrae superioris muscles and a GVE

parasympathetic component for innervation of the ganglion that in turn innervates the intraocular muscles. The oculomotor nerve fibers traverse the tegmentum and exit the brain in the interpeduncular fossa medial to the crus cerebri and then pass rostrally to the orbit with the other oculomotor nerves.

The GSE component of cranial nerve III arises from motor neurons in the oculomotor nucleus proper, which lies in the dorsomedial part of the rostral half of the midbrain tegmentum. This component innervates four muscles that insert on the globe of the eye: the inferior oblique muscle, which extorts, elevates, and abducts the eye; the medial rectus muscle, which adducts the eye; the inferior rectus muscle, which depresses, extorts, and adducts the eye; and the superior rectus muscle, which elevates, intorts, and adducts the eye. (Extorsion is rotation of the eyeball around a horizontal, anteroposterior axis through the pupil such that the bottom moves medially; intorsion is rotation in the opposite direction.)

The oculomotor nuclear complex comprises several nuclei in addition to the GSE main nucleus, including the Edinger–Westphal nucleus and several accessory oculomotor nuclei—the nucleus of Darkschewitsch, the interstitial nucleus of Cajal, and the nuclei of the posterior commissure. These accessory nuclei receive inputs from a variety of visual- and vestibular-related sources and contribute to vertical and smooth-pursuit movements of the eyes directed by the GSE component. The Edinger–Westphal nucleus and a more rostral anterior median nucleus contain preganglionic parasympathetic neurons (GVE) that project via the oculomotor nerve to the ipsilateral ciliary ganglion, which lies deep to the posterior boundary of the eye. Postganglionic parasympathetic fibers from the ciliary ganglion supply the ciliary muscle, which affects the shape of the lens for focusing on near objects, and the sphincter (or constrictor) pupillae muscle. The consensual pupillary light reflex of evoking bilateral constriction of the pupils when light is shined in one eye depends on a pathway from the retina to the olivary pretectal nucleus, which in turn projects bilaterally via the posterior commissure to the anterior median and Edinger–Westphal parasympathetic nuclei. In this context, it should be noted that dilation of the pupil is accomplished by the action of sympathetic innervation that arises from preganglionic neurons in the intermediolateral column of the spinal cord and affects the dilator pupillae muscle fibers via postganglionic neurons of the superior cervical ganglion.

Damage to the ventral region of the midbrain may result in the syndrome called superior alternating hemiplegia, which is motor impairment on the contralateral side of the body (due to damage to the corticospinal fibers in the crus cerebri) combined with lateral and downward deviation of the eye on the ipsilateral (i.e., alternate) side due to a lower motor neuron lesion of the oculomotor nerve. In this situation, the eye deviates laterally due to the unopposed contraction of the lateral rectus muscle, which is innervated by cranial nerve VI. Supranuclear innervation of the oculomotor nuclei is mediated by cortical eye fields and the superior colliculus via gaze centers in the brain stem and is coordinated among the oculomotor, trochlear, and abducens nuclei and the vestibular system via the medial longitudinal fasciculus. Damage to the oculomotor nuclear complex or nerve also results in drooping of the eyelid (ptosis) and pupillary dilation.

D. Cranial Nerves of the Forebrain

Two of the traditionally recognized cranial nerves are present in the forebrain: the optic nerve (II) and the olfactory nerve (I). Both of these nerves are purely sensory, but they are usually left unclassified according to the traditional scheme.

1. Optic Nerve

Cranial nerve II is composed of the distal parts of the axonal processes of retinal ganglion cells. These axons course caudally and medially from the retina to the optic chiasm, where some decussate (cross over) to the opposite side. The proximal parts of these same axons are then called the optic tract as they continue caudally and laterally from the chiasm to sites in the diencephalon and midbrain.

The retinal ganglion cells receive input from retinal bipolar cells, which in turn receive input from the receptor cells of the retina (rods and cones). Rods are predominantly located in the peripheral parts of the retina, whereas cones are densely packed in the central part of the retina, particularly within the fovea. Rods transduce light stimuli of a broad range of wavelengths, whereas cones are of three types for color vision, each transducing a different part of the spectrum. The transduction process is a complex series of biochemical events initiated by the absorption of a photon by pigment within the receptor cells. The visual

world topologically maps in precise order onto the retina, and this map is preserved throughout the system.

The retinal bipolar neurons correspond to the bipolar neurons that lie within the ganglia of other sensory cranial nerve components in terms of their relative position in the sensory pathway. The retinal ganglion cells are the first-order multipolar neurons of the pathway. At the optic chiasm, optic nerve fibers that arise from retinal ganglion cells in the nasal (medial) retina decussate, whereas axons from retinal ganglion cells in the temporal (lateral) retina do not. The net result is that the axons in the optic tract on the right side, for example, receive input that initiates from stimuli in the left half of the visual world. Thus, the right brain ''sees'' the left visual world and vice versa.

The optic tract projects to multiple sites in the diencephalon and midbrain. The major visual pathway for conscious vision is to neocortex via the dorsal lateral geniculate nucleus in the dorsal thalamus. This nucleus contains two large-celled (magnocellular) layers; they receive input relayed from rods via ganglion cells in the peripheral parts of the retina that conveys the general location of stimuli and their motion. It also contains four small-celled (parvicellular) layers that receive fine form and color input from cones. The dorsal lateral geniculate nucleus projects to primary (striate) cortex, which lies in the caudal and medial part of the occipital lobe. The spatial information from retinal ganglion cells via the magnocellular layers of the dorsal lateral geniculate nucleus is relayed from striate cortex via multiple synapses predominantly to posterior parietal cortex, which is involved in spatial cortical functions, whereas the form and color information via the parvicellular geniculate layers is likewise relayed predominantly to inferotemporal cortex, which is involved in numerous complex functions including the visual recognition of objects and individuals.

Midbrain visual projections are to the superficial layers of the rostral part of the midbrain roof, the superior colliculus, in which visual information is mapped in register with similar maps of somatosensory and auditory space that are projected into its deeper layers. The superior colliculus visual input is relayed to part of the pulvinar in the dorsal thalamus, which in turn projects to extrastriate visual cortical areas, which border the primary visual cortex in the occipital lobe. The midbrain visual pathway is concerned with the spatial orientation of the visual world.

Damage to the retina or optic pathway causes loss of vision in part or all of visual space (the visual field) depending on the location and extent of the lesion. Although damage to the retina or optic nerve results in blindness for the eye on the same side, damage located in the thalamocortical part of the pathway causes a deficit for the visual field on the opposite side. Damage to the central part of the optic chiasm, as can occur with a pituitary gland tumor in that region, causes ''tunnel vision''—loss of the peripheral parts of the visual field on both sides.

2. Olfactory Nerve

Cranial nerve I is composed of the set of axonal processes that arise from the olfactory bipolar cells that lie within the nasal mucosa. These sensory cells lie in a sheet-like formation across the mucosal surface rather than being condensed into a ganglion as is the case for other peripheral nerves. Unlike the situation with the visual, vestibulocochlear, and gustatory systems, there are no separate receptor cells for the olfactory system. The distal ends of the olfactory bipolar cells have the molecular machinery to bind oderant molecules and transduce the signal via various complex biochemical events. These bipolar neurons terminate on first-order multipolar neurons called mitral cells that are located within the olfactory bulbs, which lie ventral to the frontal lobes.

The bipolar cell axons form complex synaptic contacts with the mitral cell processes in a series of spherical structures called glomeruli. The glomeruli form a layer superficial to the layer of mitral cell bodies in the olfactory bulb. Different oderant molecules stimulate different sets of glomeruli, but a simple oderant ''map'' across the region of different oderant molecules has not been found. The mitral cells project via the olfactory tract to multiple sites in the ventral region of the telencephalon collectively referred to as the olfactory cortex. An olfactory pathway to part of neocortex is via a relay from olfactory cortex to the mediodorsal nucleus of the dorsal thalamus and then to prefrontal cortex, which occupies a large portion of the frontal lobe and is concerned with a multitude of complex, higher cognitive functions.

Damage to the olfactory system results in the loss of the sense of smell. The appreciation of the sensation of the flavors of food is also impaired since flavor is a complex sensation based on olfactory and gustatory interactions at the cortical level. In some cases of epilepsy caused by lesions involving the ventral, olfactory-related regions of the cerebral hemispheres (particularly a structure called the uncus), an aura

involving an olfactory hallucination may preceed seizure activity.

III. NEW INSIGHTS FROM EMBRYOLOGY AND NEW CLASSIFICATION OF THE CRANIAL NERVE COMPONENTS

Studies of embryological development, most within the past decade and including the work of LeDouarin, Gilland and Baker, Noden and colleagues, Northcutt, Gans, and others, require several changes to our treatment of cranial nerves. Two additional cranial nerves need to be recognized in humans—a terminal nerve (T) and an epiphyseal nerve (E)—and the two diencephalic cranial nerves (E and II) can be classified as neural tube afferent (NTA). The traditional classification of cranial nerve components needs to be revised and simplified. The distinctions between the "general" and "special" categories can now be eliminated, and the components of spinal nerves and most cranial nerves can be reduced to the four simple categories of somatic afferent (SA), visceral afferent (VA), somatic efferent (SE), and visceral efferent (VE). The branchial motor nerves form a subset of the SE column since the branchial muscles are derived from the same mesodermal source as are the extraocular muscles and the muscles of the tongue.

A. Terminal Nerve

The terminal nerve is arguably the most rostral cranial nerve. Its bipolar neurons have free nerve endings that are located in the nasal mucosa, but their modality (possibly chemosensory) has not been established. These neurons project to several sites in the ventral and medial regions of the forebrain, including the septum, olfactory tubercle, and preoptic area. The terminal nerve neurons contain the reproductive hormone, luteinizing hormone-releasing hormone, and may be involved in the regulation of reproductive behavior.

B. Sensory Cranial Nerves Derived from the Neural Tube

The optic nerve (II) and neural retina develop as an outgrowth from the diencephalon. The optic nerve is thus in fact not a true cranial nerve but rather a tract of the central nervous system. Unlike most sensory cranial nerves that have receptors and/or bipolar neurons in the peripheral nervous system, the receptor rods and cones of the retina and the retinal bipolar cells are within the central nervous system. Nevertheless, the optic nerve is so firmly and universally considered to be a cranial nerve that eliminating it from the list is not an option. A second, similar tract of the central nervous system that innervates a diencephalic outgrowth, the epiphyseal nerve, thus also needs to be included in the list of cranial nerves for completeness.

The epiphysis forms from the roof plate of the diencephalon and comprises a variety of structures in various vertebrates, including a frontal organ and pineal gland in frogs, a parietal eye and pineal gland in lizards, and a pineal gland in mammals. The pineal gland does not receive light directly, as do the neural retina and the parietal eye, but it is influenced by light via a pathway from the suprachiasmatic nucleus of the hypothalamus to the sympathetic intermediolateral column of the spinal cord and then via postganglionic sympathetic fibers that arise from the superior cervical ganglion and travel on branches of the internal carotid artery to reach the pineal gland, where the sympathetic input inhibits the conversion of serotonin to melatonin. In mammals, the pineal gland contains neurons that project to the medial habenular nucleus and part of the pretectum. Pineal projections to other brain sites are minor in humans, but recognition of an epiphyseal cranial nerve is justified based on its similarities of development and organization with the optic nerve. Neither the optic nerve nor the epiphyseal nerve can be categorized as somatic or visceral sensory, however. Since both derive from the neural tube, they can be classified as NTA. They are unique among the cranial nerves in this regard.

C. Afferent Components

Components of six cranial nerves could arguably be assigned to the traditional category of special afferent. The facial (VII), glossopharyngeal (IX), and vagus (X) nerves have SVA components for taste sensation. The olfactory nerve (I) is sometimes classified as SVA, and the terminal nerve could be provisionally included in this category as well. The vestibulocochlear nerve (VIII) is traditionally classified as SSA. Of the nondiencephalic sensory cranial nerves, only the trigeminal nerve (V) and small components of VII, IX, and X have been classified as GSA. The fourth traditional afferent category of GVA has been

assigned to the neurons of the glossopharyngeal and vagus nerves that predominantly innervate the visceral structures of the body cavities. What all these sensory cranial nerve components have in common is that their bipolar neurons are embryologically derived from the same two tissues: neural crest and/or placodes.

1. Neural Crest and Placodes

During embryological development, the neural tube forms by a process of invagination of the ectoderm along the dorsal midline of the body and the head. At the edges of the invaginating neural tube tissue, a population of neural crest cells arises from the dorsomedial wall of the neural folds and migrates laterally and ventrally to contribute to many different structures of the adult, including the dorsal root ganglion cells (bipolar neurons) for all the spinal cord sensory nerves. In the head region, neural crest cells likewise migrate away from the region of the neural tube and give rise to multiple structures. A second tissue present only in the head region is a set of neurogenic placodes, which are thickened patches of ectodermal cells. The bipolar sensory neurons for all the cranial nerves except II and the epiphyseal are derived from the neurogenic placodes and/or neural crest tissues.

In the region of the nose, an olfactory placode forms that gives rise to the bipolar neurons of the olfactory and terminal nerves, and additional sets of placodes form along the sides of the head. Neural crest and/or placodally derived cells give rise to the bipolar neurons for the sensory ganglia of the trigeminal (V), facial (VII), vestibulocochlear (VIII), glossopharyngeal (IX), and vagus (X) nerves. A trigeminal placode contributes neurons to the trigeminal ganglion. The sensory neurons within the vestibular and spiral ganglia for the vestibulocochlear nerve arise from a dorsolateral, otic placode; this is a much simpler situation than in fishes, in which a series of dorsolateral placodes gives rise to the vestibulocochlear nerve and to the set of mechanoreceptive and electroreceptive lateral line nerves. The receptor hair cells for the vestibulocochlear system likewise are derived from this dorsolateral placode.

The gustatory system is more variable across vertebrates in terms of both its peripheral and its central components. Mammals have a relatively limited gustatory system. A set of ventrolateral, or epibranchial, placodes contributes sensory neurons to ganglia of cranial nerves VII, IX, and X, but, unlike the situation in the vestibulocochlear system, the taste receptor cells of the taste buds are all derived locally from the pharyngeal endoderm in the oral cavity. This system thus is classified here as visceral. Fishes, in comparison, have much more elaborate taste systems than mammals, and in some groups, such as catfishes, the taste receptor cells are distributed over the entire body surface. The gustatory afferent fibers project into elaborate, laminated lobes in the brain stem and preserve a topographic map of the inputs.

2. Somatic Afferent and Visceral Afferent Cranial Nerve Components

Due to these recent findings on the embryological derivation of these cranial nerve components, their former classification into four separate categories of SVA (I the terminal nerve, and the components of VII, IX, and X for taste sensation), SSA (VIII), GSA (V, VII, IX, and X), and GVA (IX and X) can be revised (Table III). Since the bipolar sensory neurons for all these nerves are derived from the same embryonic source (i.e., neural crest and/or placodes), the "special" versus "general" distinction is not warrented. We are thus left with the resolution of classifying most of the cranial nerve sensory components (i.e., the traditional GSA and SSA components plus I and the terminal nerve) simply as somatic afferent (SA). Due to the derivation of the receptor cells from endoderm, the taste components of VII, IX, and X are assigned to the simple category of visceral afferent (VA). The remaining sensory category of GVA for innervation of the thoracic and abdominal viscera and pharyngeal region by the vagus nerve and of the tongue and pharyngeal region by the glossopharyngeal nerve can likewise be revised to the VA category.

D. Efferent Components

Some of the motor components of four cranial nerves have traditionally been assigned to the category of SVE—the trigeminal (V), facial (VII), glossopharyngeal (IX), vagus (X), and spinal accessory (XI) nerve components that innervate muscles derived from the branchial arches. Four purely motor cranial nerves classified as GSE—III, IV, VI, and XII—innervate eye and tongue muscles. Recent embryological findings, particularly from the work of Noden and collaborators, have shown that the nerve components of the SVE and GSE categories both innervate striated skeletal muscles that are all derived from the same

embryonic muscle masses in the developing head and neck regions. Components of the third efferent category, GVE, are present in cranial nerves III, VII, IX, and X and give rise to preganglionic parasympathetic fibers for innervation of the ganglia that supply glands in the head and the viscera of the thorax and abdomen.

1. Epimere versus Hypomere and the Development of Striated Muscles in the Head

To appreciate the resolution of the problem of head musculature and its innervation, one must consider it in the context of the pattern of development of the muscular components of the body. The body is essentially a tube with three layers—an outer layer of ectoderm that forms the central nervous system, the neural crest, the epidermis, and other tissues; an inner layer of endoderm that forms the lining of the gut and related organs; and an intermediate layer of mesoderm that forms the bones, muscles, blood vessels, dermis, and other structures of the body. The mesoderm has three dorsal-to-ventral components. The epimere (or paraxial mesoderm), the most dorsal component, forms somites, which are segmental mesodermal masses that give rise to the striated, skeletal muscles of the body wall and the limbs. The intermediate component, mesomere (or nephric ridge), gives rise to the kidneys and gonads, whereas the ventral component, hypomere (or lateral plate mesoderm), gives rise to the smooth, visceral muscles of the gut as well as to the cardiac muscle of the heart.

In the head, the embryological derivation of the various groups of muscles was until recently incorrectly understood, particularly concerning the pharyngeal region. In addition to giving rise to multiple components of the peripheral nervous system and to most of the skull, neural crest cells give rise to mesenchymal tissue that forms the so-called ''visceral'' arches of the pharynx. The muscles of this region were long thought to arise from a rostral continuation of hypomeric muscle—the ventral part of the mesodermal tissue that in the body gives rise to the smooth muscle of the gut. Muscles derived from the visceral arch region, which in mammals are the muscles of the mandibular arch (lower jaw muscles innervated by the trigeminal nerve), hyoid arch (facial and other muscles innervated by the facial nerve), and the several branchial arches (throat and larynx muscles innervated by the glossopharyngeal and vagus nerves), were thus presumed to be visceral muscles. In conflict with this view was the resemblance of the visceral arch muscles to the striated, skeletal muscle of the body wall and of the tongue and extraocular muscles. The histological structure of the visceral arch muscles and their single-motor neuron innervation pattern are both markedly different from the histological structure and two-neuron chain, parasympathetic innervation pattern of the smooth muscle of the gut. The designation of ''special'' acknowledged these differences.

Recent work by Gilland, Noden, Northcutt, and others has revealed a different embryological source for the muscles of the visceral arches and has resolved the previous confusion. Rather than being derived from hypomere, the muscles of the visceral arches are in fact derived from the epimeric muscle of the head, the caudal continuation of which gives rise to the striated, skeletal muscles of the body wall. Somites and somitomeres, which are incompletely separated somites, form in the head region and give rise to the extraocular muscles, the muscles of the visceral arches, and the muscles of the tongue. Thus, none of the visceral arch muscles are actually visceral, and there is nothing special about them. They are embryologically derived and innervated in the same manner (by neural tube-derived motor neurons) as the extraocular and tongue muscles. The visceral arch muscles probably evolved before the extraocular muscles were acquired by early vertebrates, however, and long before the muscular tongue was gained by tetrapods, and this difference in history may account for the different position within the brain stem of the two columns of motor neurons that innervate them.

2. Somatic Efferent and Visceral Efferent Cranial Nerve Components

Due to these recent findings on the embryological derivation of the visceral arch muscles, the former classification of their motor cranial nerve components of SVE can be revised. These components can be classified as somatic, just like those that supply the extraocular muscles and the tongue. Since the classification of visceral is invalid, the distinction of special (for V, VII, IX, X, and XI) versus general (for III, IV, VI, and XII) is also moot. All these motor components are simply somatic efferents (Table III). For the remaining motor category, GVE, the parasympathetic components of cranial nerves III, VII, IX, and X are indeed visceral efferents, and with the elimination of the special visceral category the use of the term general is not needed here. These parasympathetic components can simply be classified as visceral efferents.

GLOSSARY

alexithemia Lack of affect; low emotionality. This often characterizes the individual with a "split brain" and seems to inhibit his or her creativity.

creativity complex Influences on creativity reflect personality, attitude, affect, cognition, and metacognition. Creativity is not unidimensional or tied to a single domain.

divergent thinking Problem solving and ideation which moves in different directions rather than converging on one correct or conventional idea or answer.

intrinsic motivation The personal interests that often lead to creative work and are independent of extrinsic influences, such as rewards and incentives.

range of reaction Genetic potential delimits the range of potential; environmental influences determine where within that range the individual performs.

split brain Lay term for the result of a commisurotomy, which surgically separates the two hemispheres of the brain.

Creativity is important, and probably vital, for innovation, technological progress, and societal evolution. It may be more important now than ever before because it plays a role in adaptations. Creativity also benefits the individual, providing coping skills and a means for self-expression. Very likely the creativity of individuals determines the creative potential of society. Just as likely, the creative potentials of individuals is dependent on brain structure and process.

I. INTRODUCTION

The brain and creativity are typically studied from very different perspectives. Simplifying, the human brain is a topic for the hard sciences, including neurology and medicine. Creativity, on the other hand, is traditionally studied by social and behavioral scientists. This makes it more difficult to bring the two topics together and may explain why there is not more literature on the brain and creativity. Efforts are being made, especially very recently, to bridge the two topics. In fact, researchers are discovering advantages to this kind of cross-disciplinary investigation.

One advantage is conceptual. Useful concepts and ideas can be borrowed from one field and applied to the other. Consider the concept of a range of reaction. This was originally proposed in the hard sciences (genetics) but is vital for our understanding of virtually all behavior (psychology), including creative behavior. As is the case with the biological contributions to other human characteristics, biology contributes to creativity by providing a range of possible expressions. This range delimits our potential, but it guarantees nothing. The environment determines how much of that potential we fulfill. Family experiences seem to influence the fulfillment of creative potentials, just to name one example of how experience interacts with biology.

The range of potential delimits the levels of performance in simple terms, the amount of creative talent the individual will express but also the domain of expression. This is an important point because creativity in the visual arts is very different from musical creativity, and both of these are very different from mathematical creative talent. There are many domains and possible areas of expression, and each very likely has particular biological underpinnings. An individual may inherit the potential to excel in music but not mathematics or to excel in languages but not the performing arts. It is quite possible that the different domains of creative expression are associated with different brain structures.

Such domain specificity further complicates matters, especially for investigations focused on creativity. This is because creativity is often a kind of self-expression, and it is frequently maximal when the individual is intrinsically motivated. This simply means that the individual is expressing himself or herself in an original fashion or putting the effort into solving a problem in a creative manner, not because of incentive or reward (both of which are extrinsic) but because of personal interests. However, what if those interests do not fit well with the biological potentials? What if the individual is intrinsically motivated to study music but biologically predisposed to excel in a field that involves very different talents, such as science? We can hope that most persons inherent a potential to be interested in the same domain in which they have inherited the potential for relevant skills, but we should also accept the strong likelihood that some persons have unfulfilled creative potentials. This is all the more reason to examine the brain and creativity.

Creativity is multifaceted. There are cognitive skills involved in all creative acts, but these are also attitudes that can facilitate or inhibit creative performance. Personality has long been recognized as an important determinant, and increasingly more is being done with the emotions that play significant roles in creative work. Creativity is often operationalized for research or practice (e.g., education or organizational efficacy) in a fairly simplistic fashion, with an emphasis on divergent thinking or the production of original ideas. However, definitions that focus on one or two traits or abilities do not do justice to the creative efforts that have literally changed each of our lives through technological innovation or the artistic perspective. Often, in the research creativity is called a syndrome or complex because of its multifaceted nature. We must keep this in mind as we discuss the specific research findings on the brain and creativity. Most of the research focuses on one kind of creativity or one of the relevant skills. I previously noted that biological potentials do not guarantee that the talent will be expressed, and the same thing must be said about any connection we discover between the brain and a particular facet of the creativity complex: That is no guarantee of actual creative performance.

The creativity complex comprises cognitive, attitudinal, and emotional components. These are described in this article and tied to brain structure and function.

II. SPLIT BRAIN

Probably the best known research on the brain and creativity is that of Roger Sperry. He was awarded the Nobel prize for his research with individuals who had commisurotomies (i.e., the corpus callosum is cut, thereby functionally disconnecting the two hemispheres of the brain). Sperry did not administer any tests of creativity per se to the commisurotomy patients, but his research is very relevant because he found that certain important alogical and simultaneous processes tended to be controlled by the right hemisphere. Logical and linguistic processes seemed to be controlled by the left hemisphere. This is quite telling, although we must be careful not to make the mistake that is made in the popular press.

Sperry studied more than two dozen individuals, and not all of them demonstrated the dramatic differences between the right and left hemispheres. Additionally, Sperry worked with epileptic individuals who had the surgery because of this disease. It was an attempt to reduce the number of grand mal seizures. Surely epileptic persons have atypical nervous systems. They also had commissurotomies, further precluding generalizations from Sperry's research. Finally, it is simplistic and inappropriate to view creativity as a solely right hemisphere function. Clearly, individuals cannot use one hemisphere or the other. None of us can do that, unless of course you are one of Sperry's patients and have had a commissurotomy. Nor should we try to rely on one hemisphere: Creativity involves both logic and imagination, divergent and convergent thinking.

Sperry's patients have been studied many times. Klaus Hoppe, for example, reported what may be some of the most relevant findings about individuals with split brains—namely, that they often have

trouble understanding their own emotional reactions, if they have them. In "Dual Brain, Creativity, and Health," he and Neville Kyle referred to this as alexithymia. It is especially significant because creativity so often involves enthusiasm, excitement, and the like.

Hoppe and Kyle's interpretation focuses on the corpus callosum. They described how

> *commisurotomy patients, in comparison with normal controls, use significantly fewer affect laden words, a higher percentage of auxiliary verbs, and applied adjectives sparsely revealing a speech that was dull, uninvolved, flat, and lacking color and expressiveness. … Commissurotomy patients tended not to fantasize about, imagine, or interpret the symbols, and they tended to describe the circumstances surrounding events, as opposed to describing their own feelings about these events. … Commisurotomy patients, in comparison with normal controls, symbolized in a discursive, logically articulate structure, using mainly a secondary process, as opposed to a presentational structure as an expression of a predominantly prominent process. They also showed a concreteness of symbolization, emphasizing low rather than creative capacity… showed a relatively impoverish fantasy life, and tended not to be able and convey symbolic meanings.*

III. ELECTROENCEPHALOGRAM PATTERNS

Electroencephalogram (EEG) data were also collected. These indicated that the subjects had low activity in the right temporal area (T4) when listening to music and viewing an emotionally stimulating film. They also had low levels of activity in the left hemisphere, particularly in Broca and Wernickes' areas (F3 and T3). Hoppe and Kyle believed that this suggested a lack of inner speech. The same patients had high levels of activity in the left parietal area (P3).

Perhaps most important was the fact that the patients had what Hoppe called a high coherence between the left parietal area (P3) and the right frontal area (F4). This was interpreted as "a possible interhemispheric aspect of inhibition of expression." The control subjects who were more emotional and expressive, in contrast, had coherence between the left temporal (T3) and the right frontal (F4) areas, which suggested "a possible mechanism facilitating the transformation of the effective understanding in the right hemisphere into verbal expression of the lower left hemisphere."

Hoppe and Kyle believe strongly that communication between the hemispheres is necessary for creative thinking. Earlier, Salvatore Arieti described "a magic synthesis," the title of his 1976 book, and Arthur Koestler proposed in his book *The Art of Creation* that creativity could be understood as bisociation. Both of them were pointing to the need for communication between and collaboration by the two hemispheres of the brain. There are other relevant data. Most, however, involve indirect measurement.

For example, there are studies of handedness, which is supposedly an indication of hemispheric dominance and preference. Yet other studies use dichotic listening tasks wherein particular messages are played to one ear or the other, and thereby presented to one hemisphere or the other. In a 1999 review of this research, Albert Katz indicated that the findings were not all that convincing, although they were in the direction in what would be expected with a right hemisphere contribution to creative thinking. It is very likely that such indirect measures will not be used very frequently or very much longer, given new technologies for brain imaging and the like. Importantly, Katz, like Hoppe and others, concluded that

> *creative activity cannot be localized as a special function unique to one to the cerebral hemispheres. Rather, productive thought involves the integration coordination of processes subserved by both hemispheres. … There appears to be privileged role in creativity to the cognitive functions associated with the right hemisphere. … There is some evidence that different creative tasks may differentially call on cognitive resources for which the two hemispheres were specialized. … Finally, there is some evidence that creativity related hemispheric asymmetries can be found both online (as the person performs a task) and as a consequence of habitual patterns of behavior.*

IV. STAGES OF THE CREATIVE PROCESS

Colin Martindale, like Hoppe, employed EEGs. Martindale examined particular brain wave patterns and their association with specific stages within the problem-solving process. Findings indicated that EEG patterns vary as a function of stage of the creative process, at least in creative individuals. These phases are usually labeled preparation, incubation,

illumination (or inspiration), and verification. Creative individuals have higher alpha during the inspirational phase of creative work than during elaboration phases. There are no differences in basal alpha. EEG was measured at right posterior temporal areas.

Another technique for the study of the biology of creativity involves individuals who have had accidental trauma to the nervous system. In his 1982 book, *Art*, *Mind*, *and Brain*, Howard Gardner tells how through use of this technique he was able to infer much about processes that are very important for creativity, such as the use of metaphor. This kind of research is useful because it identifies particular parts of the brain. However, the locations studied are not chosen by the researchers but of course are the result of various unfortunate accidents.

V. MAGNETIC IMAGING

We probably need not look to accidents much longer. We now have systematic techniques, such as magnetic imaging. In a 1995 investigation, Thomas Albert, Christo Pantey, Christian Wiendruch, Bridget Rockstroh, and Edward Taub found that the cortical representation of the digits of the left hand of string players was larger than that in controls. The effect was smallest for the left thumb and no such differences were observed for representations of the right hand digits. The amount of cortical reorganization in the representation of the fingering digits was correlated with the age at which the person had begun to play. These results suggested that the representation of different parts of the body and the primary somatosensory cortex of humans depends on use and changes to conform to the current needs and experiences of the individual.

Recall the idea introduced earlier in this article, that performance often reflects both biological potential and experience. Note also the fact that this research focused on individuals within a very specific domain of performance (stringed instruments). Generalizations cannot be applied to other instruments, let alone other kinds of musical creativity or other kinds of art. Finally, it is critical to keep in mind that although the participants of this study were musicians, their actual creativity was not assessed. Music may be an unambiguously creative domain, but it would be interesting to know the actual level of creative skill of the individuals and to correlate that with the size of the cortical representations.

VI. EINSTEIN'S BRAIN

Given the complexity of creativity and the diversity of definitions that have been proposed, some scholars prefer to focus on unambiguously creative persons. The advantage of this approach is that the creativity of the research subjects (e.g., Darwin, Picasso, and Einstein) is beyond question.

This approach is often used in the psychological research but has also been employed in physiological research, such as the 1985 study of the brain of Albert Einstein by Marian Diamond, Arnold Scheibel, Greer Murphy, and Thomas Harvey. These authors found that Einstein's brain had a significantly smaller mean ratio of neuron to glial cells (connections) in "area 39" of the left hemisphere than did control scientists. This was not the case in three other areas. It was not true of the right hemisphere. The interpretation focused on the "metabolic need" of Einstein's cortex and the role of the cortex in associative thinking. Diamond and his colleagues concluded that the exceptionality of Einstein's brain may have given him outstanding "conceptual power."

VII. CONCLUSIONS

One area of the brain may be involved in creativity but has received little attention. More than one theorist has pointed to the prefontal lobes. Salvatore Arieti did so long ago, and others have echoed it, often citing tendencies involved in creativity and controlled by the prefrontal lobes. Elliott, for example, argued that creative behavior is a product of the human capacity to will. He believed that this implies that the prefrontal lobe must be engaged, "thereby facilitating the harmonious functioning of the entire brain (left–right, top–bottom, front–back) and thus regulating all psychological functions associated with the creative process." In 2000, Torsten Norlander came to a similar conclusion but drew from what is known about the prefrontal dysfunction and hypofrontality of schizophrenic patients. (Data include the cerebral regional blood flow of schizophrenic patients.) Although largely inferential, this line of thought is noteworthy in part because it is consistent with the idea of balanced processes contributing to creative thinking. The balance may require communication between the left and right hemispheres of the brain, and between logic and imagination (the magic synthesis), but it may also benefit from collaboration with the prefrontal lobes.

Empirical research on the prefrontal lobes and their role in creative thinking is needed. Fortunately, we can

expect a great deal of progress to be made in the very near future. There are two reasons for this. First, the field of creative studies in growing explosively. The implications of creativity for health and learning are now widely recognized, as is the role of creativity in innovation, business, and technological advancement. Even more important may be the technological advances that are being made in medicine. These provide sophisticated methods for studying the brain. Soon, we should understand how the different parts and processes of the human brain correspond to the various components of the creativity complex.

Dementia

ALFRED W. KASZNIAK
University of Arizona

GLOSSARY

aphasia Impairment in the expression and/or comprehension of language.

cognitive functions Distinct domains of intellectual ability, including memory, language, visuospatial ability, judgment, and abstraction, among others.

depression A clinical disorder characterized by at least five of the following nine symptoms present during at least a 2-week period: depressed mood, markedly diminished interest in activities, significant weight loss or gain, difficulty sleeping or excessive sleeping, agitation or slowing of thought and action, fatigue or loss of energy, feelings of worthlessness or guilt, diminished ability to think or concentrate, and suicidal ideation.

executive functions That subgroup of cognitive functions necessary to plan and carry out complex, goal-oriented behavior. Executive functions include planning, organizing, sequencing, and abstracting abilities.

neuroimaging Technologies available for the detailed visualization of brain structure and/or function. These technologies include computerized tomography (CT), magnetic resonance imaging (MRI), functional magnetic resonance imaging (fMRI), positron emission tomography (PET), and single photon emission computed tomography (SPECT).

neuropsychological assessment An approach to the evaluation of dementia and other neurobehavioral disorders involving structured interviewing, behavioral observation, and the administration of standardized tests of cognitive and emotional functions.

perseveration Persistence in a particular action or thought after task demands have changed and the action or thought is no longer appropriate.

prosopagnosia Deficit in the ability to recognize familiar faces.

verbal fluency Ability to quickly generate words from within a particular semantic category (e.g., animal names, items that can be found in a grocery store) or beginning with a particular letter of the alphabet.

The clinical syndrome of dementia is characterized by impairment of multiple cognitive functions (e.g., memory, language, visuospatial abilities, judgment), typically due to chronic or progressive brain disease. The cognitive impairments are frequently accompanied by personality changes, including deficits in motivation and emotional control. Several different illnesses can cause the dementia syndrome, and the pattern of cognitive deficits and personality changes may differ by the type of illness as well as by the specific brain structures and systems most affected. This article will present an overview of the more common dementia syndromes, emphasizing their epidemiology, clinical presentation, and pattern of neuropsychological deficits. Neuropathological characteristics and neurobiological research concerning causes and treatments are mentioned only briefly because these aspects are specifically reviewed in other articles (e.g., Alzheimer's Disease) within this volume.

I. CHARACTERISTICS AND EPIDEMIOLOGY OF DEMENTIA

Most diagnostic criteria for the dementia syndrome stipulate that two or more cognitive functions must be sufficiently impaired so as to interfere with social and/or occupational functioning and that there must not be clouding of consciousness. Clouding of consciousness, particularly in the context of a sudden onset of confusion, disorientation, hallucinations, disturbance in attention, or marked behavior change, is typically indicative of delirium (also termed acute confusional state). Delirium may be caused by an acute or chronic systemic illness (e.g., bacterial infection, hypoglycemia), adverse effects of medication, or serious neurological event requiring immediate medical attention. Untreated, these illnesses may result in death or irreversible impairment.

The risk of developing dementia increases markedly with age in later adulthood and is the single most prevalent category of mental illness for older persons. Worldwide, between 10 and 15% of persons over the age of 65 show at least mild dementia and approximately 6% show severe dementia. After age 65, dementia prevalence doubles approximately every 5 years. Overall, dementia is somewhat more common among women and may be more common in community-dwelling older black Americans. Prevalence for other nonwhite ethnic and racial groups is difficult to estimate due to the small number of adequate epidemiological studies. Annual incidence of new cases of dementia is also age-related, estimated to steadily increase from 0.33% at age 65 to 8.68% for those 95 years of age and older. A family history is a risk factor for dementia, increasing with the number of first-degree relatives similarly affected. Low educational background or low lifetime occupational attainment also increases the risk of dementia diagnosis. Studies have suggested that higher levels of education and higher levels of linguistic ability in early adulthood may be protective against the development of dementia, although controversy concerning this conclusion still remains.

A. Prevalence of Specific Dementia Types

More than 50 different illnesses can produce the symptoms of dementia. Available studies indicate that, on average, 5% of all causes of dementia are reversible and 11% have some specific treatment available, although not typically resulting in symptom reversal. Among the more common potentially reversible causes are those due to prescription and nonprescription drug toxicity, metabolic disorder, brain tumors, subdural hematoma (a collection of blood under the outermost meningeal covering of the brain), and depression. The more common dementia types that are presently irreversible include Alzheimer's disease, Parkinson's disease, dementia with Lewy bodies, Huntington's disease, frontotemporal dementias, vascular dementia, and traumatic brain injury.

Autopsy studies have varied in their estimates of the relative proportion of all dementia cases accounted for by each of these causes or types, although all agree that Alzheimer's disease (AD) is the most common. The neuropathological characteristics of AD consist primarily of neuritic plaques and neurofibrillary tangles, as well as neuronal loss. The neuropathology appears to be focused in the medial temporal lobe regions (including the hippocampus, entorhinal cortex, and subiculum) early in the illness course, with progression to the frontal, temporal, and parietal association cortices. Neuronal loss is also seen within the subcortical neurons of the nucleus basalis of Meynert (a major source of cholinergic neurotransmitter input to widespread cortical areas) and in the locus ceruleus (a major source of widespread noradrenergic neurotransmitter projections). Eventually, diffuse neuronal loss results in gross cerebral atrophy, which can easily be seen in autopsied brains, and in structural neuroimaging evidence of ventricular and sulcal enlargement, such as that provided by computerized tomography (CT) and magnetic resonance imaging (MRI; see Fig. 1). Across several studies, AD alone has been found to account for between 53 and 66% of total dementia cases and may be present in combination with the neuropathology of other diseases in as many as 87%. Vascular disease, typically in the form of multiple infarctions of blood vessels (blockages, with resultant tissue death in the area supplied by the vessel), had previously been thought to be the second most frequent cause. However, more recent studies suggest that multiple infarctions alone may account for less than 2% of all dementias, although contributing to dementia severity, along with coexistent AD, in approximately 13%.

Lewy body disease has only relatively recently been recognized as a significant cause of dementia, and earlier autopsy studies typically did not include it. Lewy bodies are microscopic intracellular abnormalities seen in the brain stem structures of patients with Parkinson's disease but are also found distributed

Figure 1 Magnetic resonance image (MRI) showing the greatly enlarged lateral ventricles characteristic of cerebral atrophy in later stage Alzheimer's disease.

diffusely throughout the cortex and subcortex when associated with dementia. Autopsy studies have suggested that dementia with Lewy bodies (DLB) might account for 15–30% of all cases of dementia, which would make it the second largest subgroup after AD.

The frontotemporal dementias (FTD) include both Pick's disease and non-Pick's neuropathology and account for about 3.5% of all dementia cases. Pick's disease is characterized by Pick's cells (enlarged neurons with displaced nuclei) and Pick's inclusion bodies (round inclusions within the neuron cell body) in frontal and temporal cortical areas. Non-Pick's neuropathology of FTD includes microvacuolation (small holes or vacuoles) or spongiosus (spongelike softening), predominantly in the frontal cortex.

Other causes, including Huntington's disease, Parkinson's disease, corticobasal degeneration (all considered among the frontal–subcortical dementias), depression, and several very rare causes, account for the remaining percentage of dementia cases. Within the following sections, the clinical and neuropsychological features characterizing the major dementia types will be described.

II. ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is a chronic, progressive degenerative brain disease. The most striking behavioral changes of AD include increasing difficulty in learning and retaining new information, handling complex tasks, reasoning, spatial ability and orientation, language, and social behavior. In 1984, a task force assembled by the United States Department of Health and Human Services developed the diagnostic criteria for AD shown in Table I. These criteria now form the basis for standard AD diagnosis in research and have been incorporated into widely used clinical diagnostic criteria (e.g., those of the *American Psychiatric Association Diagnostic and Statistical Manual of Mental Disorders*, 4th ed.). These criteria have been shown to achieve good sensitivity (against the criterion of neuropathological confirmation), although more limited specificity, in the clinical diagnosis of AD.

Early in the course of AD, the most sensitive indicators of cognitive impairment are standardized tests of memory (particularly delayed recall) for recently presented verbal or nonverbal information. This is not surprising given that neuropathology in hippocampal and entorhinal cortices appears early in the illness course and that rapid forgetting is the hallmark of focal damage to these structures in both human and nonhuman animal studies. Several studies now provide evidence that AD has a long, preclinical (i.e., prior to the time when the patient meets standard diagnostic criteria) course, during which subtle memory changes occur. Mild memory impairments, measurable with sensitive neuropsychological tests, thus have been documented in apparently well-functioning persons several years prior to their diagnosis of AD. Similar memory impairments are seen in those presently healthy persons at genetic risk (i.e., showing the apolipoprotein e4 gene allele, a known risk for AD). Of persons demonstrating mild cognitive impairment (MCI), typically defined as standardized memory test performance that is one standard deviation below age- and education-specific normative expectations, between 6 and 25% per year progress to meet diagnostic criteria for dementia (most typically AD). However, preclinical AD is not the only cause, because those with MCI also show higher rates of overall poorer health, cerebrovascular disease, and disability and are more often depressed than those with normal memory functioning.

Also relatively early in the course of AD, individuals tend to show decreased verbal fluency, best documented by an ability to produce words within a given

Table I
Alzheimer's Disease (AD) Diagnostic Criteria

A clinical diagnosis of *probable* AD is made when:

(1) Dementia is established by clinical examination and documented by performance on a standardized mental status examination, *and*

(2) confirmed by neuropsychological testing, documenting deficits in two or more areas of cognition, *and*

(3) characterized by a history of progressive worsening of memory and other cognitive deficits, *with*

(4) no disturbance in level of consciousness, *and*

(5) symptom onset between the ages of 40 and 90 years, most typically after age 65, *and*

(6) there is an absence of systemic disorders or other brain diseases that of themselves could account for the progressive deficits.

The diagnosis of probable AD is further supported by evidence (i.e., from neuropsychological reexamination) of progressive deterioration of specific cognitive functions, impairment in activities of daily living (ADLs), a family history of similar disorders, and results of particular laboratory tests (e.g., a normal lumbar puncture, normal pattern or nonspecific changes in the electroencephalogram, and evidence of cerebral atrophy on structural neuroimaging).

The clinical diagnosis of *possible* AD is made when:

(1) the syndrome of dementia is present, *and*

(2) there is an absence of other neurologic, psychiatric, or systemic disorders sufficient to cause the dementia, *but*

(3) variations are present from criteria for probable AD in the onset, presentation, or clinical course. Possible AD may also be diagnosed when a systemic brain disease sufficient to produce a dementia is present but (for various reasons) is not considered to be the cause of the patient's dementia.

semantic category (e.g., names of animals or items that can be found in a supermarket) that is significantly below normative expectation. With disease progression, difficulties in spatial orientation and visuospatial abilities (e.g., ability to accurately draw a clock face), facial recognition, and language comprehension all occur. These impairments appear to reflect increasing neurofibrillary tangle and neuritic plaque involvement of the parietal and temporal association cortices. In addition, increasing problems with focusing and shifting attention and "executive functions" are seen with disease progression. Executive functions refer to those various abilities (including volition, planning, organizing, sequencing, abstracting, and performance self-monitoring) that contribute to the capacity to plan and carry out complex, goal-oriented behavior. Apathy, difficulty in shifting behavioral set to accommodate new task demands, impaired abstract reasoning, difficulty in the correct sequencing of behavior, and poor awareness of cognitive deficits are all aspects of executive dysfunction and are also correlated with the degree of behavioral disinhibition and agitation among AD patients. The increasing difficulties in attention and executive functioning appear to reflect the frontal cortex neuritic plaque and neurofibrillary tangle density increase that occurs with AD progression.

Apathy and other aspects of executive dysfunction have been found to correlate with functional neuroimaging measures (see Fig. 2) documenting decreased blood flow in the anterior cingulate, dorsolateral frontal, orbitofrontal, and anterior temporal cortical regions. In general, functional neuroimaging [e.g., positron emission tomography (PET)] studies have shown that, in AD patients with mild dementia (relatively early in the illness course), cerebral metabolism is decreased in temporal and parietal cortices, with progression to metabolic decreases in the frontal cortex as dementia severity worsens. There is also evidence for heterogeneity in the relative severity of various cognitive deficits among persons with AD. If we equate for overall severity of dementia, those who show the greatest visuospatial impairments demonstrate the lowest right-hemispheric metabolism, and those with the greatest language impairments have the lowest left-hemispheric metabolism. By the late stage of severe dementia in AD, only sensory and motor cortical areas show preserved metabolic rates.

III. FRONTAL–SUBCORTICAL DEMENTIAS

The most common clinical features of the frontal–subcortical dementias are bradyphrenia (a slowing of thought processes and information processing speed), memory problems, impairment of executive functions, mood changes, and sometimes visuospatial deficits.

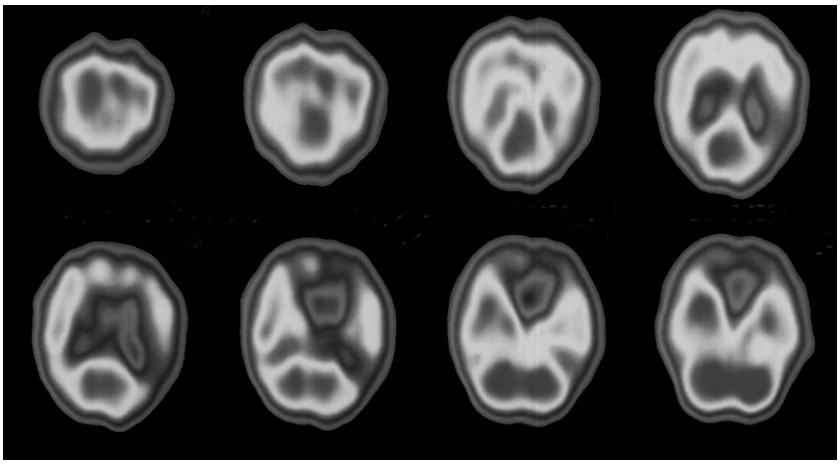

Figure 2 Single photon emission computed tomographic (SPECT) image of the brain of an individual with Alzheimer's disease, showing decreased blood flow (darker areas) in frontal regions as well as in temporal–parietal association cortices.

Those diseases that can cause this dementia syndrome include progressive supranuclear palsy (PSP), Huntington's disease (HD), Parkinson's disease (PD), dementia with Lewy bodies (DLB), and corticobasal degeneration (CBD). Damage to the rostral brain stem, thalamus, basal ganglia, and/or reciprocal connections between these subcortical regions and frontal cortical areas appears to be the common factor in these dementias. These structures all participate in several distinct, semi-closed-loop-circuits that subserve particular motor, cognitive executive, and emotional functions.

A. Progressive Supranuclear Palsy (PSP)

PSP is also known as Steele–Richardson–Olszewski syndrome. It is a degenerative disorder of subcortical nuclei, including the subthalamic nucleus, substantia nigra, globus pallidus, caudate, putamen, and periaqueductal gray. Clinically, persons with PSP show paralysis involving motor neurons of the eye, leading to impaired downward ocular gaze and other ocular symptoms. Clinical diagnosis requires documentation of at least two of the following signs: axial dystonia (abnormal pattern of muscle tonus in the axial musculature) and rigidity (especially of the neck), pseudobulbar palsy (manifested as sudden crying or laughing without apparent cause or accompanying experienced emotion), bradykinesia (slowness in the initiation of movement), signs of frontal lobe dysfunction (e.g., motor perseveration, difficulty in behavioral set-shifting in response to changing task demands), postural instability with backward falling, and sometimes dysarthria (difficulty in the motor aspects of speech). Cognitive deficits, documented by neuropsychological testing, include memory loss, slowed information processing speed, apathy and depression, irritability, and executive function deficits.

B. Huntington's Disease (HD)

HD is an autosomal-dominant genetic disorder marked by initial abnormal choreiform (dancelike) movements, slowed voluntary movements, depressive and manic emotional disturbances, and eventual dementia. HD manifests in an insidious onset, usually in young to middle adulthood. The dementia of HD is characterized neuropsychologically by impaired attention and concentration, executive function deficits, and impaired encoding and retrieval of new information. However, if care is taken to make sure that the person with HD adequately encodes the information (e.g., by having the individual semantically categorize it) and procedures are used that do not require effortful retrieval strategies (e.g., recognition memory rather than a free recall task), then it can be shown that the retention of new information is more intact in HD than in AD patients with comparable overall dementia severity. The neuropathology of HD includes cell loss and atrophy that begins in the medial caudate nucleus and eventually includes the entire caudate and putamen. Some degree of cortical atrophy is also

typically seen in the brains of persons with HD at autopsy.

C. Parkinson's Disease (PD)

PD is primarily a progressive, extrapyramidal (involving motor systems of the basal ganglia rather than the pyramidal tract) disorder with clinical motor features of stooped posture, bradykinesia (slowing of movement initiation), tremor (when the affected limb is at rest, but typically not during movement), cogwheel rigidity (i.e., rigidity that seems to catch and release, much like a cogwheel, when the clinician attempts to passively move the patient's limb), and festinating gait. Dementia has been estimated to occur in approximately 35–40% of persons with PD. The neuropsychological impairments manifested in the dementia of PD include psychomotor slowing, impaired cognitive tracking and set-shifting flexibility, visuospatial deficits, diminished learning and retrieval (although, as with HD, often there is evidence of more intact information retention shown by recognition memory tasks), decreased verbal fluency, and abstract reasoning impairment. Neuronal degeneration (with Lewy bodies; see later discussion) occurs primarily in pigmented cells of the substantia nigra (particularly the pars compacta region) and other brain stem structures (e.g., locus ceruleus, dorsal vagal nucleus). The substantia nigra degeneration causes a severe reduction in dopamine neurotransmitter projections to the striatum, responsible for the observed extrapyramidal motor disorder and contributing to the cognitive impairments.

D. Dementia with Lewy Bodies (DLB)

In addition to occurring in brain stem structures in persons with PD, Lewy bodies are the neuropathological characteristic of DLB, where they appear diffusely distributed throughout the neocortex, diencephalon, brain stem, and basal ganglia. Because of the brain structures involved, DLB is sometimes considered to be among the frontal–subcortical dementias. The core clinical features of DLB are the presence of dementia, gait–balance disorder, prominent hallucinations and delusions, sensitivity to neuroleptic antipsychotic drugs, and fluctuating alertness. A consensus has been reached concerning the clinical criteria for diagnosing DLB (see Table II). These criteria have demonstrated high specificity, although relatively low sensitivity, against neuropathological findings.

Illness progression in DLB is often rapid, with severe dementia and the motor features of PD present

Table II
Criteria for Dementia with Lewy Bodies (DLB)

The central required feature is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function.
(1) Prominent or persistent memory impairment may not necessarily occur in early stages but usually is evident with progression.
(2) Deficits on tests of attention, frontal–subcortical functions, and visuospatial abilities may be especially prominent.
Core features (two required for probable DLB and one for possible):
(3) Fluctuating cognition with pronounced variations in attention and alertness.
(4) Recurrent visual hallucinations that are typically well-formed and detailed.
(5) Spontaneous motor features of parkinsonism.
Features supportive of the diagnosis:
(6) Repeated falls
(7) Syncope
(8) Transient loss of consciousness
(9) Neuroleptic drug sensitivity
(10) Systematized delusions
(11) Hallucinations in other modalities
Diagnosis of DLB is less likely in the presence of:
(12) Evidence of stroke from focal neurological signs or brain imaging.
(13) Evidence of any physical illness or other brain disorder sufficient to account for the clinical features.

within 1–5 years of diagnosis. It has been suggested that a diagnosis of DLB should require that cognitive dysfunction occur within 12 months of the onset of parkinsonian motor features. Patients with PD who develop dementia more than 12 months after the onset of their motor signs are diagnosed as having PD with dementia. The neuropsychological test profiles of persons with DLB show marked deficits in attention and visual–constructive skills (e.g., ability to copy a geometric pattern with blocks), frequently with relative sparing of memory. However, neuropsychological testing has not been able to reliably differentiate DLB from either AD or vascular dementia, given the clinical variability and overlap of the cognitive impairments in these dementia types. Structural neuroimaging (CT or MRI) also has not been successful in differentiating DLB from AD.

E. Lewy Body Variant (LBV) of AD

The Lewy body variant of AD (sometimes also referred to as ''common'' DLB, in contrast to ''pure'' DLB) is characterized by the typical neuritic plaques and neurofibrillary tangles of AD, the subcortical changes of PD, and the presence of diffusely distributed cortical Lewy bodies. Persons with the LBV of AD, compared to persons with ''pure'' AD, show a greater proportion of mild parkinsonian or other extrapyramidal motor findings, a typically fluctuating cognitive impairment, visual or auditory hallucinations, and frequent unexplained falls.

F. Corticobasal Degeneration (CBD)

CBD is a rare disorder that presents clinically as an asymmetric, akinetic rigid syndrome with apraxia (impaired voluntary execution of symbolic movements and gestures), myoclonus, and sometimes dementia. When dementia is present, the pattern of neuropsychological test performance resembles that of PSP, except that apraxia is typically more severe in CBD. Symptoms of cortical sensory loss (e.g., impaired visual or tactile discrimination) are also common early in CBD. Persons with CBD often show the ''alien limb'' syndrome, in which the individual reports that their limb is moving without their volitional control, and often are mildly depressed. CBD is associated with markedly asymmetric patterns of cortical metabolism alteration (as measured by PET). Cortical metabolism contralateral to the affected limb is typically lower in inferior parietal, lateral temporal, and sensory motor cortices than that seen in PSP.

IV. FRONTOTEMPORAL DEMENTIAS

FTD includes both Pick's disease and non-Pick's frontotemporal dementia (also called frontal lobe dementia, FLD), motor neuron disease, and progressive subcortical gliosis. Although estimates of the prevalence of FTD remain somewhat controversial, some investigators think that these disorders have been underestimated and could account for 10–19% of all demented cases. The usual age of onset is between 45 and 65 years, with equal sex incidence. A family history of the illness is present in approximately 50% of persons with FTD. FTD includes subtypes of semantic dementia, primary progressive aphasia, and progressive prosopagnosia, as described later.

Pick's disease is characterized by Pick's cells (enlarged neurons with displaced nuclei) and Pick's inclusion bodies (round intraneuronal cellular inclusions) in frontal and temporal cortical areas. In Pick's disease, marked atrophy (termed ''knife edge'' due to the extreme thinning of the cortical gyri) is found in the frontal and anterior temporal lobes, with some patients also showing atrophy in the basal ganglia and caudate nucleus. The gross neuropathology of non-Pick's FTD is similar to that of Pick's, with atrophy primarily affecting the frontal lobes. However, those with non-Pick's FTD do not typically show Pick's cells and bodies. Some show microvacuolation or spongiosus (often termed the frontal lobe dementia type, FLD). Degeneration of bulbar cranial nerve nuclei and anterior horn cells may also be present in some persons with FTD. Chromosome 17 abnormality with τ protein aggregation and decreased τ binding to neuronal cell microtubules has been found in the brains of persons who died with FTD.

Personality and behavioral changes, executive dysfunction, and language disturbances are predominant early signs of FTD. Language deficits are progressive in nature and may eventually lead to mutism. Neurological signs including akinesia, rigidity, masked facies (markedly decreased spontaneous facial expression), gait disturbance, dysarthria, dysphagia (swallowing difficulty), and tremor are present throughout the disease for some patients and only in advanced disease for others.

A. Behavioral and Emotional Characteristics of FTD

The most common behavioral changes that accompany FTD are loss of social awareness and insight, personal neglect, disinhibition, impulsivity, impersistence, inertia, aspontaneity, mental rigidity and inflexibility, motor and verbal perseveration, stereotyped activities and rituals, utilization behavior (tendency to compulsively use whatever object is placed before the individual), and hyperorality (tendency to frequently mouth objects). Emotional changes of FTD include unconcern, apathy, emotional shallowness and lability, loss of empathy and sympathy, and a fatuous jocularity. Consensus clinical criteria, based on these behavioral and emotional characteristics, have been developed for FTD (see Table III). However, as yet there is insufficient research comparing these criteria to neuropathological findings, preventing adequate assessment of sensitivity and specificity.

Neuropsychological testing of persons with FTD typically reveals deficits in verbal fluency, abstraction ability, and other areas of executive functioning. However, because some AD patients also demonstrate substantial executive function deficits, this pattern of neuropsychological test performance cannot be considered specific to FTD.

B. Semantic Dementia

Semantic dementia is a subtype of FTD characterized by fluent, anomic aphasia (marked difficulty with word-finding and naming), with impaired verbal comprehension and loss of semantic knowledge. The neuropathology in semantic dementia is typically most marked in the left (or bilateral) temporal pole and inferolateral cortex.

C. Progressive Nonfluent Aphasia

Another subtype of FTD, known as progressive nonfluent aphasia, is characterized by nonfluent, hesitant, distorted speech with preserved verbal comprehension. The neuropathology is typically most marked in the left perisylvian cortical area.

D. Progressive Prosopagnosia

The progressive prosopagnosia subtype of FTD is characterized by impaired identification of familiar faces, followed by loss of person knowledge. The neuropathology is typically most marked in the right temporal pole and inferolateral cortex.

V. VASCULAR DEMENTIA

In the presence of cerebrovascular disease, dementia may be observed when there are multiple infarctions within both cerebral hemispheres. The clinical features that accompany multiple infarctions of relatively large cerebral blood vessels (termed multi-infarct dementia, MID) depend upon the particular brain regions

Table III
Criteria for Frontotemporal Dementia (FTD)

Core diagnostic features:

(1) Insidious onset with gradual progression

(2) Early decline in interpersonal conduct

(3) Early impairment in the regulation of personal conduct

(4) Early emotional blunting

(5) Early loss of insight

Supportive diagnostic features:

(6) Behavioral disorder, including decline in personal hygiene and grooming; mental rigidity and inflexibility; distractibility and impersistence; hyperorality and dietary changes; perseverative and stereotyped behavior; and/or utilization behavior.

(7) Speech impairment, including altered speech output (either aspontaneity and economy of speech or press of speech); stereotype of speech; echolalia; perseveration; and/or mutism.

(8) Physical signs, including primitive reflexes; incontinence; akinesia, rigidity, and tremor; and/or low and labile blood pressure.

(9) Investigations, including significant impairment on neuropsychological tests of executive functioning in the absence of severe amnesia, aphasia, or visuospatial disorder; normal electroencephalogram despite clinically evident dementia; and brain imaging (structural and/or functional) showing predominant frontal and/or anterior temporal abnormality.

affected. Dementia may also be the result of multiple small subcortical (termed lacunar) infarctions. As previously noted in this article, although vascular disease was earlier thought to be the second most frequent cause of dementia, more recent autopsy studies have indicated that dementia most typically occurs when both multiple infarctions and the neuropathology of AD or Lewy bodies are present. Consensus criteria for the diagnosis of VAD have been proposed (see Table IV). Evaluation of these criteria against neuropathological findings has shown relatively high specificity, but low sensitivity.

In studies of neuropsychological test performance, persons with pure VAD (i.e., those without coexistent AD pathology or Lewy bodies) show less memory impairment than persons with AD matched for overall dementia severity. In contrast, persons with VAD may be relatively more impaired that those with AD on tests of executive functioning. However, the considerable variability of the neuropsychological test performance in both VAD and AD limits the specificity of these features for differential diagnosis.

VI. DEMENTIA ASSOCIATED WITH DEPRESSION

Depression in older age has been given increasing clinical and research attention. Although the prevalence of depression (according to standard diagnostic criteria) is not higher for older than for younger adults, older persons with depressive symptoms have health care costs about 50% higher than those without depressive symptoms. These increased costs are not accounted for by mental health service utilization. Depression frequently coexists with neurological disorders among older adults (e.g., stroke, AD, PD) and is often underdiagnosed in older persons, especially when physical illness is present.

Further complicating both accurate diagnosis and treatment is the fact that various prescription and nonprescription medications (and their interactions) can cause, aggravate, or mimic depression symptoms. In addition, persons with depression show impairment on a range of neuropsychological measures of cognitive functioning, particularly on speeded tasks, vigilance tasks, and tasks with pleasant or neutral (in contrast with unpleasant) content. The magnitude of cognitive impairment tends to increase with older age, severity of depression, and history of electroconvulsive treatment (ECT). Previously, the term "pseudo-dementia" was often used to describe persons with depression and cognitive impairment, reflecting the expectation that the cognitive deficits would reverse along with effective treatment of the depression. However, this term is no longer used because several

Table IV
Criteria for Vascular Dementia (VAD)

The clinical diagnosis of *probable* VAD is made when:

(1) Dementia is present, defined by (a) cognitive decline from a previously higher level of functioning; (b) impairment of memory and two or more other cognitive domains (preferably established by clinical examination and documented by neuropsychological testing); (c) sufficient severity as to interfere with activities of daily living; and (d) not due to the sensorimotor effects of stroke alone, *and*

(2) the patient does *not* show disturbance of consciousness, delirium, psychosis, severe aphasia, sensorimotor impairment sufficient to preclude neuropsychological testing, systemic disorders, or other brain diseases (e.g., AD) that could account for the cognitive deficits, *and*

(3) cerebrovascular disease is present, defined by (a) the presence of focal neurologic signs (e.g., hemiparesis, sensory deficit, hemianopsia, Babinski sign, etc.); (b) evidence of relevant features consistent with cerebrovascular disease on brain imaging (CT or MRI), *and*

(4) a relationship is established between the dementia and the cerebrovascular disease inferred by one or more of the following: (a) onset of dementia within 3 months following a recognized stroke; (b) abrupt deterioration in cognitive functioning; or (c) fluctuating, stepwise progression of cognitive deficits.

The diagnosis of probable VAD is further supported by (a) the early presence of a gait disturbance; (b) a history of unsteadiness and frequent falls; (c) early urinary urgency, frequency, and other urinary symptoms not explained by urologic disease; (d) pseudobulbar palsy; and (e) mood and personality changes, psychomotor retardation, and abnormal executive function.

The clinical diagnosis of *possible* VAD is made when:

(1) The patient meets criteria for dementia with focal neurologic signs, *but*

(2) brain imaging studies to confirm cerebrovascular disease are missing, *or*

(3) when there is absence of a clear temporal relationship between dementia and stroke, *or*

(4) in patients with subtle onset and variable course (improvement or plateau) of cognitive deficits and evidence of relevant cerebrovascular disease.

studies have indicated that substantial numbers of these individuals show progressive dementia that does not reverse with depression treatment. Such studies have indicated the need for both caution and persistent follow-up in any attempts to clinically differentiate dementia associated with depression from that due to AD or other dementia syndromes.

Although the severity of cognitive impairment in depression is typically less than that in dementia syndromes such as AD or VAD, differential diagnosis can sometimes be difficult. Depression can coexist with AD, VAD, and other dementia types, complicating differential diagnosis when dementia severity in these disorders is relatively mild. Further, research has shown that those with a first onset of depression in older age (in contrast to older persons with depression onset earlier in life) often show clinical and/or structural neuroimaging evidence of cerebrovascular damage. Persons with later-age-of-onset depression and MRI evidence consistent with relatively large areas of cerebrovascular damage in the subcortical white matter are also more likely to show executive function deficits on neuropsychological testing and are less responsive to antidepressant pharmacotherapy than older adults with depression onset in younger adulthood.

Research comparing the neuropsychological test performance of persons with depression to those with AD has suggested that the following features can be helpful in differential diagnosis. First, as already noted, the cognitive deficits of depression tend to be less severe and extensive than in AD. Second, consistent impairment across various memory tests (particularly involving delayed recall and recognition memory) is more consistent with AD than with depression. Persons with depression are also less likely than those with AD to show impaired naming ability, verbal fluency, and visuospatial ability. Finally, those with depression may appear to exert less effort than those with AD in the performance of various neuropsychological tests and may complain more about their cognitive difficulties (even when testing does not document significant deficits).

VII. NEUROPSYCHOLOGICAL ASSESSMENT IN DEMENTIA DIAGNOSIS

Accurate diagnosis of dementing illness often necessitates the efforts of multidisciplinary teams of physicians (particularly neurologists and psychiatrists), neuropsychologists, and other mental health professionals (e.g., social workers). As noted throughout the previous sections, neuropsychological assessment, utilizing standardized tests of cognitive and emotional functioning, makes an important contribution to the clinical identification of the dementia syndrome and the differentiation of various dementia types.

Brief mental status questionnaires can provide a quick and valid documentation of the presence of dementia. However, such questionnaires generally are not sufficiently sensitive to detect very mild dementia, particularly in persons with high premorbid intellectual functioning. This limitation in sensitivity reflects the fact that these questionnaires are composed of relatively easy questions and memory items. In addition, they lack the specificity to assist in differential diagnosis of dementia types. In comparison, standardized neuropsychological tests typically contain a range of task difficulty, so that test scores approximate a normal distribution when administered to individuals in the general population. This can provide for greater sensitivity to mild or subtle cognitive deficits than what is possible through the use of mental status questionnaires, for which normative performance distributions are markedly skewed due to most individuals achieving near-perfect scores.

Appropriate neuropsychological tests thus may reveal subtle and circumscribed cognitive impairments in patients who show no evidence of cognitive deficit on commonly employed mental status questionnaires. The ability of neuropsychological test batteries to examine the pattern of performance across different, reliably measured domains of cognitive functioning may be particularly important in assessing persons with high premorbid intellectual functioning. This is due to the fact that the different dementia types do not manifest with equivalent impairment across all cognitive functions. Thus, performance on those cognitive tests that are likely to be affected can be compared to those that are likely to remain intact as an aid in improving detection of relatively circumscribed cognitive decline.

In selecting, administering, and interpreting neuropsychological tests, several factors need to be considered. First, specific tests should be selected on the basis of adequate standardization, including demonstrated reliability and normative data appropriate to the age, educational background, and other demographic characteristics of the person being examined. In addition, the tests should have demonstrated sensitivity and specificity for the diagnostic

possibilities to be differentiated. Fortunately, there is a growing empirical literature that allows for a comparison of the expected test performance of persons with differing dementia types. In addition to test standardization, sensitivity, and specificity, the impact of various patient characteristics must be considered. Age-related sensory acuity changes and response slowing can influence test performance, as can the physical limitations of such prevalent illnesses as arthritis.

In addition to a diagnostic role, neuropsychological assessment provides a foundation for the accurate provision of information to patients, family members, and health care providers concerning specific strengths and deficits. Accurate information can reduce ambiguity and anxiety (for both patients and their caregivers), and the identification of relatively intact areas of functioning facilitates the maximizing of patient independence. Identification of intact functioning helps in developing plans for sharing daily responsibilities between the patient and others in his or her environment, directing caregivers to areas in which the patient will require additional supervision or assistance. Early identification of dementia and accurate feedback to the patient and family members allows time for them to make future plans (e.g., disposition of estate, medical and long-term care wishes) while the patient is still able to communicate his or her wishes. Neuropsychological tests are also a critical component in the assessment of treatment effects or disease progression, and they provide guidance for treatment and management of cognitive and behavior problems. Tracking of disease progression, through periodic reexamination, is important for guiding caregivers and adjusting the goals of clinical management. Research has also shown that feedback to patients, based on neuropsychological test performance, results in the improved utilization of coping strategies in persons with preserved awareness of their cognitive deficits.

Evaluation of behavior problems, utilizing standardized and validated informant questionnaire and behavioral observation instruments, can be particularly helpful in efforts to assist the caregivers of dementia patients. Apathy, agitation, depression, delusions, and diurnal rhythm disturbance (e.g., wandering and agitation at night and somnolence during the day) are common in persons with AD and other dementias. These behavior problems are associated with increased caregiver distress, higher rate of nursing home placement, and more rapid disease progression. Once identified and accurately described by careful assessment, family members and other caregivers can be instructed in approaches to minimizing the occurrence and frequency of these behavior problems.

VIII. TREATMENT AND CLINICAL MANAGEMENT OF DEMENTIA

Pharmacological treatment options for the dementias presently are limited, although numerous experimental treatments are being evaluated. The one well-validated approach to symptomatic treatment of AD is based upon the documented deficit in acetylcholine neurotransmitter levels, due to the loss of cholinergic projecting neurons within the nucleus basalis of Meynert. It has been shown that this deficit can be partially compensated for by interfering with the action of that enzyme (cholinesterase), which breaks down acetylcholine after it enters the synaptic junction, allowing the constituent molecules to be taken back into the presynaptic neuron to synthesize additional acetylcholine. There are four such cholinesterase inhibitors that have been approved by the U.S. Food and Drug Administration: Tacrine, Donepezil, Rivastigmine, and Galantamine. These drugs have all been shown to result in some temporary improvement of function in at least some AD patients. However, none of these drugs interrupts the progression of the illness, and the search continues for treatments that can alter the fundamental neuropathological processes of AD. Vitamin E (α-tocopherol) has been shown to delay the time to institutionalization and the loss of ability in common activities of daily living in moderately severe AD patients; thus, it is often prescribed along with cholinesterase inhibitors.

Some of the behavioral problems of dementia (e.g., aggression) may be treated with antipsychotic drugs (e.g., Risperidone, Haloperidol). However, caution must be exercised because those with DLB may be excessively sensitive to such neuroleptic drugs, and several deaths have been reported within weeks of starting such drugs in these patients. Antidepressant drugs (e.g., tricyclics, monoamine oxidase inhibitors, selective serotonin re-uptake inhibitors) may also be useful in the treatment of depression in persons with dementia.

In addition to pharmacological treatment, behavior management strategies can assist in minimizing the consequences of cognitive deficits and managing the behavior problems of dementia. Memory aids and household memory cues (e.g., reminders posted on the

refrigerator or above the toilet) can partially compensate for memory deficits. There are also interventions available to reduce behavioral problems in dementia. Small-scale empirical studies of various behavior management procedures have shown some efficacy in reducing select behavior problems (e.g., aggressiveness, agitation, incontinence). A larger scale study has documented the effectiveness of a behavioral therapy taught to caregivers in reducing coexistent depression in AD. Other research has shown that intensive, long-term education and support services for caregivers can delay the time to nursing home placement for AD patients. Even short-term programs that educate family caregivers about AD may improve caregiver morale and satisfaction. Finally, education about AD and other dementias for the staff of nursing homes and other long-term care facilities may help to reduce the use of unnecessary antipsychotic medications.

Thus, although there is no available treatment capable of reversing or arresting the progression of dementia, both symptomatic treatment and interventions to reduce behavior problems are available. The vigor with which experimental treatments are being evaluated creates hope for a future in which the dementias can be more effectively treated, and someday perhaps even cured.

Depression

ESTEBAN V. CARDEMIL
Brown University School of Medicine and Rhode Island Hospital

GLOSSARY

anhedonia One of the core symptoms of depression; defined as the loss of interest in, and inability to derive pleasure from, activities that were previously considered interesting and pleasurable.

catecholamine A group of neurotransmitters that includes norepinephrine, epinephrine, and dopamine.

concordance rates The proportion of twins in a sample that both possess the disorder of interest.

heritability The proportion of the variance of a disorder in the population that is due to genetic factors.

indoleamines A group of neurotransmitters that includes serotonin and histamine.

lifetime prevalence The proportion of individuals in an epidemiological sample that have ever experienced a disorder at some point in their lives.

Depression is a psychiatric disorder with emotional, cognitive, physiological, and behavioral symptoms. This article presents both biological and psychological theories and treatments of depression.

I. SYMPTOMS OF DEPRESSION

Depression is a disorder characterized by emotional, cognitive, physiological, and behavioral symptoms. The primary emotional symptom is a profound sense of sadness and low mood. Irritability, frustration, and anger often accompany this low mood. Cognitive symptoms include a sense of hopelessness and helplessness, worthlessness, and guilt. Depressed individuals often have difficulty concentrating or making simple decisions. Physiological symptoms include changes in appetite and sleep, fatigue, and concerns about aches and pains. Diminished sexual interest is also commonly reported in depressed individuals. Behavioral symptoms include decreased activity, often the result of anhedonia, which is the loss of interest in and an inability to derive pleasure from activities that previously were interesting and pleasurable.

Depression tends to be classified into two major categories: major depressive disorder and dysthymic disorder. The principal differences between major depressive disorder and dysthymic disorder are severity and chronicity. Major depressive disorder is more severe and characterized by discrete major depressive episodes, whereas dysthymic disorder is less severe and characterized by a more chronic course. These disorders are not mutually exclusive; a major depressive episode superimposed on a chronic course of dysthymic disorder is conceptualized as double depression.

The American Psychiatric Association, in its *Diagnostic and Statistical Manual of Mental Disorders (DSM-IV)*, defined the symptomatic criteria for a major depressive episode (Table I). Once the criteria for a major depressive episode have been met, and the appropriate diagnostic rule-outs have been made (e.g., other psychiatric disorder and general medical condition causing the depressive episode), a diagnosis of major depressive disorder can be made.

Table I
***DSM-IV* Criteria of a Major Depressive Episode**

Five or more of the following symptoms must be present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms must be either depressed mood or loss of interest or pleasure.

1. Depressed mood most of the day, nearly every day
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (anhedonia)
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in 1 month) or decrease or increase in appetite nearly every day
4. Insomnia or hypersomnia nearly every day
5. Psychomotor agitation or retardation nearly every day (noticeable by others)
6. Fatigue or loss of energy nearly every day
7. Feelings of worthlessness or retardation nearly every day (noticeable by others)
8. Diminished ability to think or concentration, or indecisiveness, nearly every day
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt, or a specific plan for committing suicide

A. Subtypes of Depression

DSM-IV distinguishes among several subtypes of depression in order to capture some of the different patterns of depressive symptoms with which individuals present. Melancholic depression is characterized by a loss of interest or pleasure in all, or almost all, activities. Individuals with melancholic depression do not show reactivity to normally pleasurable stimuli and do not show even temporary improvements in mood following good events. In addition, at least three of the following symptoms are present: the sensation that depression is worse in the morning than in the evening, significant weight loss or loss of appetite, insomnia characterized by early morning awakening, psychomotor agitation, and excessive or inappropriate guilt.

In contrast, individuals with atypical depression show mood changes in response to actual life events. Their mood might temporarily brighten with the development of good news, for example. In addition, individuals also demonstrate two or more of the following symptoms: significant weight gain or appetite increase, hypersomnia, feelings of heaviness in the limbs, and a long-standing pattern of sensitivity to interpersonal rejection.

Individuals who display a characteristic onset and remission of depressive episodes at specific times of the year are given the specifier "with seasonal pattern." Most cases of depression with seasonal pattern occur in the winter months and tend to be found in locations where winter seasons are long and accompanied by days with short exposure to sun. The symptoms include increased fatigue, hypersomnia, weight gain, and a craving for carbohydrates.

Women who develop a major depressive episode within 4 weeks of giving birth are given the specifier "with postpartum onset." The symptoms do not seem to differ from nonpostpartum depressive episodes but may be more fluctuating in course. Often, the focus of the depression is related to the newborn and can be accompanied by obsessional thoughts of harming the child, suicidal ideation, and psychomotor agitation. Researchers currently disagree about the extent to which depression with postpartum onset is actually distinctive enough to warrant a separate category.

II. EPIDEMIOLOGY OF DEPRESSION

Up to 17% of the general population in the United States will meet criteria for a major depressive episode at some time. The lifetime prevalence for dysthymia is approximately 6%, and that of depression with a seasonal pattern is approximately 0.4%. Also, many more people will have some experience with lower, subclinical levels of depressive symptoms. Children and adolescents also experience depression and its associated symptoms: Estimates of the number of children who will experience a depressive episode by the end of high school range as high as 20%.

The annual economic consequences of depression in the United States have been estimated at $44 billion (e.g., medical expenses and lost work hours). In addition to the financial burdens to society associated with depression, there are tremendous psychological

and emotional consequences of depression. Almost 75% of individuals who reported a lifetime history of depression also reported experience with one or more other psychiatric disorders, including anxiety disorders (58%) and substance use disorders (39%). Up to 15% of individuals with severe major depressive disorder will attempt to commit suicide.

A. Demographic Risk Factors for Depression

The prevalence rates of depression are approximately twice as high in women as in men. At some point during their lives, as many as 20% of women will experience a major depressive episode. Prevalence rates of depression range from 0.4 to 2.5% in children and are between 0.4 and 8.3% in adolescents. Epidemiological studies in the United States have consistently found lower lifetime prevalence rates of major depression among African Americans than among Caucasians and similar lifetime prevalence rates between Latinos and Caucasians. Although comparable rates of depression have been found in many non-Western cultures, there is evidence that depression may be more prevalent in Western societies. In particular, it appears that the increased prevalence of depression in women may be more characteristic of Western cultures.

Other demographic risk factors that have been consistently associated with depression include a family history of depression, low socioeconomic status, and specific stressful life events (including assaults and robberies, serious marital problems, divorce, loss of employment, serious illness, and significant financial problems). Research on the role of stressful life events has also found that specific buffers may protect against the development of depression. Some of the buffers include the existence of supportive relationships, the presence of three or fewer children, employment, self-identification with a religion, and the possession of clear roles in life.

B. Course of Depression

Major depression can begin at almost any age, but the average age of onset is in the mid-20s, although data are emerging that suggest that the average age of onset is steadily dropping. Once they begin, depressive symptoms can develop over the course of days or weeks. An untreated depressive episode usually lasts between 6 and 10 months and is often followed by a return to normal functioning with the complete absence of symptoms. However, in a significant minority of cases (20–30%), depression either does not abate at all or significant symptoms persist that continue to interfere with normal functioning. After 2 years, approximately 20% of patients will continue to meet criteria for depression, 12% will meet criteria at 5 years, and 7% will continue to meet criteria 10 years after the onset of the episode. Currently, there are few diagnostic predictors that can distinguish among individuals who return to functioning and those who experience a more chronic course of depression.

Depression is also a recurring disorder: Recent estimates have found that approximately 50–85% of individuals who meet criteria for a depressive episode will experience multiple episodes, and between 25 and 40% of patients will have a second depressive episode within 2 years of their first. Moreover, the risk for relapse appears to increase as time goes on; in some studies the rate increases to 60% and higher after 5 years. Given this high risk for relapse, depression is now more commonly understood as a recurrent and potentially lifelong disorder.

III. BIOLOGICAL THEORIES OF DEPRESSION

Depression can be caused by specific biological conditions, including strokes, nutritional deficiencies, and infections. In these cases, the diagnosis mood disorder due to a general medical condition is given. Depression can also be the result of alcohol or substance abuse, often associated with the symptoms of withdrawal and intoxication. In these cases, the diagnosis substance-induced mood disorder is appropriate. Apart from these two categories, however, the role of biological causes in the development of depression is less definitive. Researchers view the role of biology as contributing one important element to the development of depression.

A. Genetic Theories

To date, researchers have been unable to identify specific genes, acting singly or in combination, that account for the expression of depression. As such, the evidence that has supported the proposition that depression is a heritable disorder comes from family studies, twin studies, and adoption studies. Unfortunately, this research has been unable to definitively

separate the respective contribution of genetics and environment.

For example, depression is up to three times more common in first-degree biological relatives of persons with the disorder than among the general population, and it is almost twice as common in first-degree biological relatives of persons with bipolar disorder. Moreover, children of parents with other psychiatric disorders, including anxiety and substance use disorders, are more than twice as likely to develop depression than are children of parents without psychiatric disorders. However, this support for a genetic contribution to depression is confounded with the increased likelihood of shared environment of first-degree biological relatives.

Twin studies have found mixed evidence for heritability in depression. Concordance rates of depression in identical twins tend to be up to twice as high as the concordance rates in fraternal twins, suggesting a genetic component. However, with heritability estimates only reaching 50%, the genetic contribution must also be considered in the context of environmental factors. Adoption studies have yielded similarly equivocal findings with respect to the heritability of depression. One large-scale study reported that biological relatives of individuals with depression have up to eight times the risk of adoptive relatives, but two other studies did not replicate these findings.

Taken together, the evidence suggests that genetic factors play a contributory role in the etiology of depression, but nowhere near as primary a role as in some other psychiatric disorders (e.g., bipolar disorder and schizophrenia).

B. Neuroanatomical Theories

Early neuroanatomical conceptualizations of depression focused on the limbic system, given its predominant role in normal mood and affect regulation. These early conceptualizations have been bolstered by recent functional imaging studies, which are conducted while depressed patients perform a variety of cognitive tasks. The functional imaging research has generally found abnormal patterns of limbic activity in depressed patients when compared to normal controls, although no coherent pattern has emerged across studies. For instance, some research has noted decreased activation in the midcingulate gyrus; other studies have found reduced activity in the inferior frontal gyrus. Researchers have also reported decreased cerebral blood flow in brain structures other than the limbic system, including the frontal and prefrontal lobes, the cerebrum, and the cerebellum. This hypometabolism is often in direct proportion to the severity of the depressive symptoms.

Given both the correlational nature of this neuroanatomical research and the fact that it is still in its relative infancy, researchers have been unable to determine the extent to which these neuroanatomical dysfunctions are the result or the cause of depression. One recent study found intriguing similarities between depressed and remitted (previously depressed) patients in that both groups displayed decreased prefrontal and limbic activation compared with normal controls. This finding raises the possibility that a neuroanatomical dysregulation may produce a vulnerability to depression and/or relapse.

Taken as a whole, neuroanatomical theories of depression have yet to produce reliable and specific insights into the causes and treatment of depression. However, given the power of functional imaging research, it is likely only a matter of time before researchers begin to clarify the neuroanatomical substrates of depression.

C. Neurotransmitter Theories

Most of the biological research on depression has focused on the role of dysregulation of neurotransmitters and has progressed in step with the development of antidepressant medications that affect these neurotransmitters. The two primary classes of neurotransmitters that have been implicated in depression are the catecholamines (primarily norepinephrine) and the indoleamines (primarily serotonin).

The observation that medications with depressive side effects depleted norepinephrine (NE) in the brain led researchers to hypothesize that catecholamines played a primary role in depression. Reserpine, a medication prescribed for hypertension in the 1950s, was found to produce depression in a significant minority of cases and subsequently found to reduce NE levels in the brain. Moreover, medications that increased the availability of NE, including amphetamines, produced antidepressant effects. These discoveries led to the catecholamine theory of depression, which posits that deficits in NE are the cause of depression. This theory led to the development of antidepressant medications that increased the availability of NE in the brain: the tricyclic antidepressants (TCAs) and the monoamine oxidase inhibitors (MAOIs).

Researchers soon noted that in addition to affecting NE, both TCAs and MAOIs appeared to also increase the availability of serotonin (5-HT) in the brain. This discovery led to the indoleamine theory of depression, which hypothesized that deficits in 5-HT were the root cause of depression. As a result, researchers soon developed a class of drugs that primarily increased the availability of 5-HT: the selective serotonin reuptake inhibitors (SSRIs). More than 14 subtypes of 5-HT receptors have been subsequently identified, and evidence is emerging that has linked 5-HT_{1A} and 5-HT_2 receptors with mood. Given that the definition of depression includes a combination of cognitive, physiological, and behavioral symptoms, future research is likely to identify more 5-HT receptor subtypes that play a significant role in depression.

Neither the catecholamine nor the indoleamine theories of depression account for some important clinical observations, however. For example, the biochemical action of antidepressant medication (in particular the TCAs) occurs quickly, whereas the clinical response takes several weeks to develop. That is, the increased availability of both NE and 5-HT precedes the amelioration of depressive symptoms by several weeks. In addition, TCAs vary in their ability to increase the availability of NE and 5-HT, and SSRIs vary in the extent to which they increase the availability of 5-HT, but all antidepressants have generally the same effectiveness. These observations, among others, have led researchers to doubt that simple deficits in either NE or 5-HT can explain the development of depressive symptoms. Instead, researchers are considering more complicated models that involve the dysregulation of one or more neurotransmitter systems and the various interactions across neurotransmitter systems to explain the development of depression.

D. Neuroendocrine Theories

Approximately 40–60% of depressed individuals produce and secrete excessive amounts of cortisol, primarily during the afternoon and evening. In these patients, cortisol secretion returns to normal levels after the depressive episode remits. This excessive cortisol is thought to be due to the overproduction by the hypothalamus of corticotropin-releasing hormone (CTRH), a compound that is stimulated by norepinephrine and acetylcholine, leading some to believe that CTRH and the noradrenergic system may be interconnected. Administration of dexamethasone, a chemical that temporarily suppresses the production of cortisol in nondepressed adults, was at one point believed to be a useful tool in the diagnosis of depression since many depressed individuals did not demonstrate this cortisol suppression. Recent evidence has indicated that many nondepressed psychiatric patients also fail to display a response to the dexamethasone suppression test, thus limiting its utility in the diagnosis of depression.

IV. PSYCHOLOGICAL THEORIES OF DEPRESSION

Despite the prominent role of biological theories of depression, psychological theories continue to play a significant role in understanding depression. There exist many different psychological approaches to understanding depression that can be considered to emerge from three primary theoretical orientations. Psychoanalytic and psychodynamic theories postulate that depression is the result of unconscious developmental processes that lead to anger being turned inwards. Behavioral theories maintain that depression is the result of excessive behaviors and activities that contribute to low mood. Cognitive theories of depression posit that maladaptive thinking puts individuals at greater risk for developing a depressive episode when faced with negative life events.

A. Psychoanalytic and Psychodynamic Theories

Sigmund Freud and his followers developed the first psychological theories of depression. According to Freud, depression (or melancholia) was comparable to normal grief following the loss of a loved one. Depression, however, would occur in certain people who experienced a loss or disappointment at an early age. These individuals would actually feel rage at the lost loved object, but since part of their personality had become identified with this lost loved object, the individuals would then direct this rage at the self. Often, this redirected self-hatred was safer than rage at the lost loved object. Thus, according to the psychoanalytic model, depression is actually anger turned inwards toward the self. This ''anger turned inwards'' is the source of low self-esteem, feelings of guilt and worthlessness, and sense of deserving punishment, and it may ultimately lead to suicide.

The psychoanalytic model was not originally developed to explain the development of discrete psychological disorders. Rather, it was developed as a comprehensive model of human personality and

development. As such, until recently its relationship to the development of depression was not the subject of much empirical investigation; therefore, few data exist to support its perspective.

Modern psychodynamic theories of depression, while tied to the original psychoanalytic theories, tend to emphasize the role of maladaptive social relationships in the development of depression. In general, these maladaptive relationships mirror significant early childhood relationships. Some theorists, including John Bowlby and Harry Stack Sullivan, have argued that the quality of young children's attachments to their mothers will influence the development of future relationships. Some empirical evidence exists, including some animal data, to support the role of maladaptive relationships in depression. The extent to which these early maladaptive relationships play a primary causal role is disputed, however.

B. Behavioral Theories

Behavioral theories of depression focus on the links between behaviors and mood. These dysfunctional connections lead to an excess of behaviors and activities that produce depressed mood and a deficit in behaviors and activities that produce positive mood. This disconnect between behavior and positive mood can occur because of insufficient engagement in pleasurable activities (e.g., living in an impoverished environment) and/or deficiencies in interpersonal skills (e.g., excessive shyness). Depressed individuals thus find themselves engaging in fewer activities and relationships that promote positive mood. This withdrawal and avoidance of pleasurable activities results in increased depressed mood, which then contributes to a cycle of continued lack of engagement and skill deficits.

C. Cognitive Theories

Cognitive theories of depression emphasize the role of accessible cognitive processes in the development and maintenance of depression. Maladaptive cognitions contribute to the etiology of depression by making individuals susceptible to depression in the face of significant negative life events. Moreover, these maladaptive cognitions and behaviors play a critical role in the maintenance of the depressive state by preventing depressed individuals from considering any alternatives to the pervasive hopelessness that dominates their thinking.

Two influential cognitive theories of depression are Aaron T. Beck's negative cognitive triad and Martin E. P. Seligman's learned helplessness theory.

1. Beck's Negative Cognitive Triad

In his 1967 book, *Depression: Causes and Treatments*, Beck first proposed that depression was the result of the activation of overly negative views (or schemas) of oneself, one's world, and one's future. A negative view of oneself would produce low self-esteem, a negative view of the world could produce helplessness, and a negative view of the future would lead to hopelessness. These depressive schemas begin to develop in childhood as individuals begin to form beliefs about their place in the world. They are maintained and reinforced through a system of cognitive distortions, whereby individuals lend excessive credence to evidence that supports their negative beliefs and selectively ignore evidence that contradicts these beliefs.

Extensive research supports the presence of negative schemas and cognitive distortions in depressed individuals. The extent to which these negative cognitions precede and cause the development of depression is less clear. Some researchers argue that negative cognitions should be considered symptoms of depression rather than causes.

2. Seligman's Learned Helplessness Model

The learned helplessness model posits that individuals become depressed and helpless if they experienced a disconnect between their behavior and life outcomes. This experience with uncontrollable outcomes leads to expected noncontingencies between future responses and outcomes. This theoretical model evolved from animal research in which dogs that were exposed to inescapable shock demonstrated helplessness deficits when they were later exposed to escapable shock. This learned helplessness, which included motivational and emotional symptoms, appeared to mimic many of the motivational, emotional, and cognitive deficits found in individuals experiencing depression.

In 1978, Lyn Abramson, Martin Seligman, and John Teasdale reformulated the original learned helplessness model because the theory was unable to explain why not everyone who was exposed to uncontrollable negative life events would become helpless and depressed. The reformulated learned helplessness model proposed that individuals have habitual ways of explaining the stressors that occur in their lives. This tendency to explain stressors in a characteristic

manner was termed attributional or explanatory style. There are three dimensions along which explanatory style can be measured: internality, stability, and globality. Internality refers to the extent to which the cause of an event is due to something about the individual or something outside of the individual (e.g., other people or luck). Stability refers to the extent to which the cause of the event will remain stable over time or is more transient in nature. Globality refers to the extent to which the cause of the event affects many different life domains or those most immediately related to the stressor. A pessimistic explanatory style is the tendency to explain negative life events with internal, stable, and global causes, and according to the reformulated learned helplessness model it puts individuals at risk for developing depression when exposed to uncontrollable life events.

Considerable evidence exists to support the role of a pessimistic explanatory style in depression, both in children and in adults. In particular, the role of a pessimistic explanatory style as a psychological risk factor for depression in the face of negative life events has received much support.

V. BIOLOGICAL TREATMENTS FOR DEPRESSION

The primary forms of biological treatments for depression are the antidepressant medications. Electroconvulsive therapy (ECT) is generally used with only severely depressed individuals. Alternative biological treatments (e.g., herbal supplements) are also discussed.

A. Antidepressant Medication

Given the emphasis on neurotransmitter theories of depression, the primary biological treatments of depression are antidepressant medications, all of which appear to effectively treat depression in approximately 60–70% of individuals. Antidepressants typically improve mood, energy, and sleep and reduce anhedonia, and they generally accomplish these changes by increasing the availability to the brain of norepinephrine and serotonin. More recent antidepressants also increase dopamine levels in the brain. Because research has not been able to definitively identify the relationship between antidepressant chemical structure and function, antidepressants tend to be classified by their action on neurotransmitters. As such, antidepressants can be categorized into three primary classes: those that inhibit the reuptake of neurotransmitter, those that inhibit the degradation of neurotransmitter, and those that act at specific receptor sites to induce greater production of neurotransmitter (Table II).

1. Reuptake Inhibitors

There exist four types of reuptake inhibitors. The first antidepressants to be identified were the tricyclic antidepressants that inhibited the reuptake of both serotonin and norepinephrine (serotonin–norepinephrine reuptake inhibitors). A second generation of tricyclic antidepressants was developed that predominately inhibited the reuptake of norepinephrine (selective norepinephrine reuptake inhibitors). By interfering with the normal reuptake process by which the synapse cleanses itself of excess neurotransmitter, the tricyclic antidepressants increased the availability of norepinephrine and serotonin in the synapse. Both sets of tricyclic antidepressants interact with other neurotransmitter system receptor sites, including histamine, acetylcholine, and epinephrine, producing a wide range of unwanted side effects (e.g., dry mouth, dizziness, blurred vision, constipation, orthostatic hypotension, and cardiovascular effects). In addition, given tricyclics' high solubility in lipid tissue, and subsequent difficult extraction in emergency, risk of death from overdose remains a serious concern.

The effort to develop effective antidepressants that produced fewer and less serious side effects than the tricyclics led researchers to those that selectively inhibit the reuptake of serotonin (e.g., the SSRIs). SSRIs are well tolerated, provide safety from overdose, and do not appear to increase the risk for seizures. The most common side effects associated with SSRIs include some anxiety and agitation, nausea, sleep disruption, sexual dysfunction, gastrointestinal cramps, diarrhea, and headache. SSRIs are currently the most commonly prescribed antidepressant medication.

Recently, researchers have developed several new classes of antidepressants. Venlafaxine is a serotonin–norepinephrine reuptake inhibitor, similar to the first generation of tricyclic antidepressants, but it does not affect the other neurotransmitter systems and thus has significantly fewer side effects. Buproprion is a novel antidepressant that inhibits the reuptake of norepinephrine and dopamine while having no effect on

Table II
Antidepressant Medications

Class	Mechanism of action	Example drugs	Common side effects
Tricyclic antidepressants I	Block reuptake of both norepinephrine and serotonin	Amitryptaline (Elavil), doxepin (Sinequan), imipramine (Tofranil)	Dry mouth, dizziness, blurred vision, constipation, orthostatic
Tricyclic antidepressants II	Selectively block reuptake of norepinephrine	Desipramine (Norpramin), nortryptaline (Pamelor), protriptyline (Vivactil)	Hypotension and cardiovascular effects
Monoamine oxidase inhibitors	Inhibit degradation of norepinephrine, serotonin, and dopamine	Phenelzine (Nardil), tranylcypromine (Parnate)	Dizziness, sleep disturbances, sedation, fatigue, general weakness, hyperreflexia, dry mouth, and gastrointestinal disturbances; important to avoid food rich in tyramine to avoid hypertensive crises or seizures
Selective serotonin reuptake inhibitors	Block reuptake of serotonin by interfering with the serotonin transport system	Citaprolam (Celexa), fluoxetine (Prozac), fluvoxamine (Luvox), paroxetine (Paxil), sertraline (Zolaft)	Some anxiety and agitation, nausea, sleep disruption, sexual dysfunction, GI cramps, diarrhea, headache
Non-tricyclic serotonin–norepinephrine reuptake inhibitor	Block reputake of serotonin and norepinephrine	Venlafaxine (Effexor)	Nausea, dizziness, drowsiness, possible sexual dysfunction; at high doses, risk for hypertension, sweating, and tremors
Norepinephrine–dopamine reuptake inhibitor	Block reputake of norepinephrine and some dopamine	Buproprion (Wellbutrin)	Dry mouth, dizziness, constipation, nausea/vomiting, blurred vision, agitation, seizure risk at high doses (0.4%)
Serotonin antagonist and reuptake inhibitors	Block 5-HT2a receptor and block reuptake of serotonin	Trazodone (Desyrel), nefazodone (Serzone)	Dry mouth, drowsiness, dizziness or lightheadedness, nausea/vomiting, constipation, blurred vision, priapism (1 in 15,000) with Trazodone
Norepinephrine antagonist and serotonin antagonist	Block α_2-adrenoreceptor and 5-HT_2 and 5-HT_3 receptors which leads to increased norepinephrine and specific serotonin production	Mirtazapine (Remeron)	Drowsiness, increased appetite, weight gain

serotonin. Our current understanding of the role of dopamine in depression is poor.

2. Monoamine Oxidase Inhibitors

The antidepressants that inhibit the degradation of neurotransmitter act by interfering with the enzyme monoamine oxidase, which destroys excess norepinephrine, serotonin, and dopamine in the synapse and the presynaptic terminal. Like the tricyclics, MAOIs have unpleasant side effects, including dizziness, sleep disturbances, sedation, fatigue, general weakness, hyperreflexia, dry mouth, and gastrointestinal disturbances. More serious is the fact that MAOIs can interact with tyramine (a protein building block for norepinephrine that is found in many common foods) and produce lethal hypertension. As such, individuals taking MAOIs must adhere to a tyramine-free diet, avoiding such foods as cheese, smoked meats, wine and beer, and yeast.

3. Serotonin and Norepinephrine Antagonists

Mirtazapine (Remeron) is a novel antidepressant that appears to produce antidepressant effects by blocking both the α_2-adrenoreceptor and two postsynaptic serotonin receptors, 5-HT2 and 5-HT3, which increases norepinephrine activity and specific serotonin activity in the brain. Common side effects of mirtazapine include drowsiness, increased appetite, and weight gain.

Currently, practice guidelines recommend SSRIs and some of the newer antidepressants (e.g., buproprion, nefazodone, and venlafaxine) as first choice antidepressants given their relatively modest side effect profile. For nonresponders to the first choice antidepressant, current guidelines suggest consideration of tricyclic antidepressants followed by MAOIs.

B. Electroconvulsive Treatment

ECT is the second form of biological treatment for depression and is currently used predominately with individuals experiencing severe and/or intractable depression that has not responded to antidepressant medications and psychotherapy. ECT involves the induction of a general seizure via the application of a brief electrical stimulus through electrodes that are placed on the scalp. Individuals are placed under general anesthesia and given a muscle relaxant in order to prevent discomfort and injury resulting from the seizure.

It is the seizure that is believed to produce the antidepressant effect, although the mechanism of action remains unclear. Animal studies suggest that ECT exerts its effects via the enhancement of norepinephrine and serotonin systems, paralleling the effects of antidepressant medications. In addition, ECT appears to affect the dopaminergic, cholinergic, GABA, and opioid systems.

Considerable research has supported the short-term efficacy of ECT in alleviating depressive symptoms, particularly those that are accompanied by psychotic symptoms: ECT produces significant improvement in approximately 80–90% of individuals with severe depression. Research has shown that both the dosage of the electrical current and the placement of the electrodes (unilateral or bilateral) are related to the alleviation of depressive symptoms and the production of unwanted side effects (mostly short-term memory loss and other cognitive impairments, including mild disorientation). Bilateral stimulation produces greater and more rapid improvement from depressive symptoms than does unilateral stimulation; however, bilateral stimulation also produces greater short-term disorientation and retrograde amnesia. High-dose unilateral stimulation, while producing fewer side effects than bilateral stimulation, appears to improve depressive symptoms more than low-dose unilateral stimulation, although not to the extent of bilateral stimulation.

C. Alternative Treatments

Little research exists to support the efficacy or mechanism of action of alternative biological treatments, generally in the form of herbal supplements. For example, St. John's Wort, a popular herbal supplement, appears to inhibit the reuptake of serotonin, norepinephrine, and dopamine. Several studies have shown it to be relatively effective in alleviating mild to moderate depression; however, given the significant methodological flaws present in these studies, no general consensus currently exists regarding the effectiveness of this or any other particular supplement.

D. Limitations of Biological Treatments

Although considerable evidence exists demonstrating the effectiveness of antidepressant medication in the alleviation of depressive symptoms, antidepressant medications are not a panacea. Approximately 30–40% of individuals with depression will not respond to antidepressants. In addition, no empirical data exist to guide practitioners in the selection of specific antidepressants, or even classes of antidepressants, over another. Practice guidelines suggest that failure to respond to an antidepressant in one class will likely predict failure to respond to other antidepressants of the same class, but no empirical data exist to conclusively support this proposition.

Furthermore, the relapse rates are very high for individuals who have been treated exclusively with biological treatments. Approximately 40–60% of individuals will relapse if antidepressant medication is discontinued within the first few months of a response. Up to 60% of individuals treated with ECT will relapse in the following year, particularly if they do not continue on antidepressant medication after the ECT regimen. Given the increasingly accepted conception of depression as a chronic, relapsing disorder, practitioners have begun moving toward

prescribing biological treatments over many years, often beyond the length of the original depressive episode.

Research on the use of antidepressant medication with children and adolescents remains sparse, and the few well-designed experiments that have been conducted have not shown that antidepressants are more effective than placebo. There also exists little research that has investigated the safety of these medications with pregnant women or women who are breast-feeding.

VI. PSYCHOLOGICAL TREATMENTS FOR DEPRESSION

There currently exist many different psychological treatments with varying levels of empirical support for their efficacy in treating depression in adults and a few that have been evaluated with children and adolescents. Although each has been developed and studied in its pure form, most psychotherapy available in the community incorporates some elements from more than one theoretical orientation.

A. Psychodynamic Psychotherapy

Psychodynamic psychotherapies evolved from psychoanalytic therapies, and as such they were originally designed to assist patients in the modification of their personality. This task occurs via the uncovering and bringing to awareness of unconscious conflicts that interfere with functioning. Recent adaptations of psychodynamic psychotherapies that have focused on depression emphasize more active approaches while continuing to uncover unconscious conflicts. Psychodynamic psychotherapies tend to emphasize the development of a therapeutic alliance that can increase patients' self-efficacy with respect to problem solving. Once the therapeutic alliance is developed, patients are then better able to gain insight into their problems by learning more about their relationship patterns, which then leads to increased potential for change. Some of this insight is developed via an exploration of the therapist–patient relationship and an examination of the ways in which this relationship mirrors the patients' real-world relationships.

When compared with other forms of psychotherapy for adults, psychodynamic psychotherapy tends to perform equivalently. Unfortunately, few studies have successfully compared psychodynamic psychotherapy with placebo conditions; therefore, the extent to which psychodynamic psychotherapy offers benefits that are particular to the psychoanalytic orientation remains in dispute.

B. Interpersonal Therapy

Interpersonal therapy (IPT) attempts to reduce depressive symptoms by focusing on current interpersonal problems. Specifically, IPT examines grief, role conflicts in relationships, role transitions, and social deficits, all in the context of problematic relationships. Depressed individuals are asked to pay close attention to all of their social interactions and social disappointments. By carefully examining their own role, patients become better able to reconstruct (or construct new) relationships more productively.

Empirical support exists for the efficacy of IPT in the treatment of depression in adults, and preliminary evidence suggests that it may be useful with adolescents. Several studies have found that it consistently outperforms control conditions and produces results at least equivalent to those of cognitive therapy and antidepressant medication.

C. Behavior Therapy

The primary goal of most behavior therapies is to increase the amount of pleasurable activity in patients' lives. Patients learn to monitor the fluctuations in their mood over the course of the week. They are taught to note what events produce positive changes in mood and what events bring about negative changes in mood. The therapist and patient then attempt to institute changes in the patient's life that would bring about more positive mood states. In situations in which the patient lacks the skills necessary to bring about changes in behavior, the therapist and the patient work together to enhance these skill deficits. Social skill training, relaxation skills, and assertiveness training are all examples of skill-building exercises in which patients may engage.

Empirical support exists for the effectiveness of behavior therapy in the treatment of depression in adults, although it has not been as extensively evaluated in clinical populations. Several studies have found results equal to those of other forms of psychotherapy, and one study found that behavior therapy produced comparable results to those of the antidepressant amitriptyline.

D. Cognitive Therapy

Cognitive therapy reduces depressive symptoms by addressing the maladaptive and pessimistic thinking in which depressed individuals engage. Working collaboratively, the individual and therapist attempt to identify and then change those elements of a patient's thinking and behavior that are contributing to the depressive symptoms. Once patients learn about the relationships among life events, thinking, and mood, they are taught to recognize the presence of "negative automatic thoughts" and pessimistic thinking that contribute to the maintenance of their depressed mood. These pessimistic thinking styles are examined together by the therapist and patient in order to consider their validity and utility. Patients learn how to generate alternative explanations for events, search for relevant information, and then decide on the most realistic explanation. Often, the most realistic explanation is less hopeless than the original belief and can lead to behavior change. When the most realistic explanation continues to be depressive, the patient and therapist work together to generate realistic solutions to the problems.

Considerable evidence exists to support the efficacy of cognitive therapy in the treatment of depression in both adults and adolescents, and many researchers consider cognitive therapy to be superior to many other forms of therapy for depression. Researchers are currently investigating the extent to which cognitive therapy can produce results equivalent to or better than those produced by antidepressant medication. Long-term data suggest that cognitive therapy is effective in the prevention of relapse, even more effective than that afforded by antidepressant medication.

E. Alternative Models of Therapy

Although different psychological orientations have led to the development of discrete psychological treatments, alternative models of psychotherapy complement these existing theoretical orientations. For example, cognitive and behavioral therapy techniques are often consolidated into an overarching cognitive–behavioral therapy. Moreover, modern cognitive therapy approaches are beginning to focus more on the therapist–patient relationship in ways that were originally developed by psychodynamic psychotherapies.

In addition to developments in individual-based psychotherapy, alternative models of therapy have also effectively expanded this focus to include multiple participants. For example, research suggests that group psychotherapy for depression can be as effective in treating depression as individual psychotherapy, particularly those group therapies that utilize a cognitive or behavioral approach. Family and marital treatments for depression also have considerable support for their effectiveness in treating depression in adults. In general, both group and family-based approaches work within their respective theoretical orientations to enhance the social support of the participants. Group therapy accomplishes this task by providing a novel social support system, and family-based approaches attempt to modify existing social networks.

F. Limitations of Psychological Treatments

One of the primary limitations of psychological treatments is the difficulty that researchers have in identifying the specific ingredients of the treatment that are most responsible for the alleviation of depressive symptoms. Very few psychological treatments have been compared against "placebo" psychological treatments. This limitation, coupled with the fact that placebo psychological treatments tend to produce some reduction in depressive symptoms, prevents researchers from definitively knowing what aspects of their treatment are acting to reduce depressive symptoms. A second important limitation lies in the differences that exist between the treatment providers in the community and those utilized in treatment studies. The treatment providers in depression treatment research are rigorously trained and supervised while providing the treatment. As such, it is plausible that their skill level is not representative of the skill level of the average community treatment provider, for whom there currently exists a wide range of formal training. A third limitation is the dearth of rigorous, controlled studies evaluating the effectiveness of psychotherapy with children. Although evidence supports the efficacy of cognitive–behavioral treatment with adolescents, less is known about the efficacy of other forms of treatment with adolescents and younger children.

VII. COMBINED BIOLOGICAL AND PSYCHOLOGICAL TREATMENTS

Given the strengths of both the biological and the psychological perspectives on depression, many

clinicians and researchers have assumed that combining different forms of treatments would provide individuals with the most benefit. Antidepressant medications could reduce many of the physiological symptoms of depression (e.g., sleep and appetite dysregulation) while psychotherapy could reduce the maladaptive cognitions and behaviors. However, the research evidence supporting the efficacy of combined treatment for depression has produced mixed results. Adding psychological treatments to biological treatments has been shown to reduce relapse rates; however, various studies examining the combination of antidepressant and psychotherapy from the outset of treatment have not found significant advantages of using either antidepressant medication or psychotherapy alone.

At this point, it is unclear to what to attribute this lack of a consistent effect, although some have argued that the modest advantages produced by combined treatment may not yield statistically significant effects in single research studies, and thus more sophisticated research investigations are warranted. For example, analyses that combine results from single studies into a larger meta-analytic study have demonstrated the advantages of combined treatment for depression, particularly for patients with more severe levels.

Thus, researchers have begun to more closely examine patient variables that might contribute to improved response from combined treatment. For example, a recent large-scale study conducted by Martin Keller and associates clearly demonstrated the advantages of combined treatment over single modality treatment for chronic depression. In this study, the researchers examined the efficacy of combining nefazodone and a variant of cognitive–behavioral treatment for patients with chronic depression (defined as having significant depressive symptoms for more than 2 years). Results showed that the combination of treatments was significantly more effective than either treatment alone. Among the 519 subjects who completed the study, the rates of response after 12 weeks (as defined by either a complete remission or a significant reduction in depressive symptoms) were 55% in the nefazodone group, 52% in the cognitive–behavioral group, and 85% in the combined treatment group.

Currently, the evidence is strongest for the proposition that combined treatment is more effective for individuals with more severe and chronic levels of depression. However, there remain considerable gaps in our knowledge of the effects of combined treatment on depression.

VIII. SUMMARY AND FUTURE DIRECTIONS

Depression is a serious disorder with significant economic and social consequences that appears to be increasing in prevalence. Attempts to understand the causes of depression must encompass both biological and psychological perspectives. Treatments of depression offer significant hope: Up to 70% of individuals will respond to antidepressant medication; specific forms of psychotherapy produce similar rates of symptom alleviation. ECT is even more effective: Up to 90% of people will respond to treatment. However, depression appears to be a chronic, relapsing disorder. The risk for relapse remains high in both treated and untreated individuals.

Future research will likely continue to link the biological and psychological nature of depression. Linkage of specific receptor sites with specific symptoms of depression, imaging studies that examine the extent to which psychotherapies produce noticeable biological changes, and more studies that explore the potential for joint biological and psychological treatments are all on the horizon. In addition, more research is needed to better understand the extent to which current theories of depression apply to children and adolescents.

Dopamine

LISA A. TAYLOR and IAN CREESE
Rutgers University

GLOSSARY

avoidance learning A behavioral test in which subjects can avoid a noxious stimulus if a correct response is elicited.

G protein A guanine nucleotide-binding regulatory protein that mediates the interaction between extracellular receptors and intracellular effector molecules. The Gi protein is the inhibitory G protein that reduces subsequent intracellular effects. The Gs protein is the stimulatory G protein that increases subsequent intracellular effects.

intracranial self-stimulation A task in which subjects are rewarded with electrical stimulation to brain areas such as the medial forebrain bundle.

operant task A task in which an animal is rewarded for making a particular motor response such as a bar press.

Dopamine (3-Hydroxytyramine) was initially characterized as a neurotransmitter in the central and peripheral nervous system during the 1950s. Although comprising less than 1% of the neurons in the brain, dopamine mediates a variety of physiological functions and modulates many behavioral states. Given the paucity of noninvasive techniques to study dopamine in the central nervous system (CNS) of humans, most studies characterizing the role of dopamine in the brain have been carried out in experimental animals or tissue culture expression systems or by extrapolation from human responses to dopaminergic drugs. With the relatively recent development of more sophisticated neuroimaging techniques, however, studies of dopamine function in the human brain are increasing. Since the focus of this encyclopedia is the human brain, studies using humans are emphasized. Data from animal studies or tissue culture expression systems are presented when there is a lack of data from human subjects or when specific examples illuminate the human literature.

I. ANATOMICAL DISTRIBUTION IN THE CENTRAL NERVOUS SYSTEM

There are several dopamine-containing pathways in the CNS. The nigrostriatal dopamine pathway accounts for approximately 70% of the dopamine in the brain. Cells bodies in this pathway are located in the substantia nigra pars compacta and project to the caudate, putamen, and the globus pallidus (Fig. 1). An interesting characteristic of these dopamine neurons is that they contain extensive dendritic trees, which extend ventrally into the substantia nigra pars reticulata. Dopamine release occurs from these dendrites in addition to the axon terminals. Deterioration of the nigrostriatal pathway underlies Parkinson's disease (PD).

The mesocorticolimbic dopaminergic pathway originates in the ventrotegmental area (VTA) and innervates the olfactory tubercle, nucleus accumbens, septum, amygdala, and adjacent cortical structures (medial frontal, anterior cingulate, entorhinal, perirhinal, and piriform cortet pallidus) (Fig. 1).

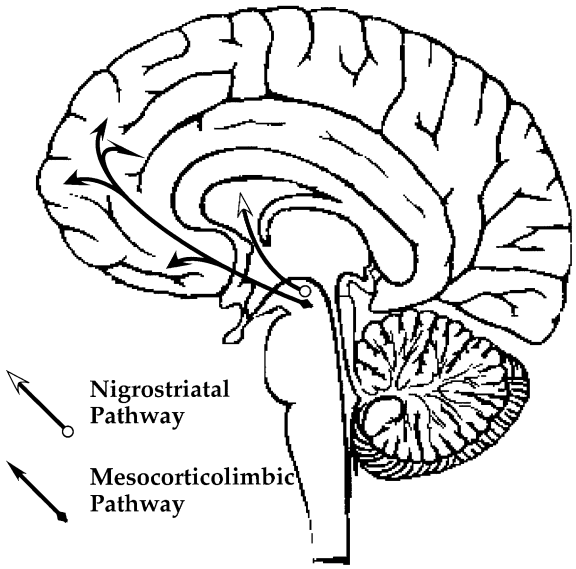

Figure 1 The nigrostriatal and mesocorticolimbic dopamine pathways.

The substantia nigra and VTA dopamine cell bodies are often referred to as the A-9 and A-10 nuclear groups, respectively, following the original designation of Dahlsstrom and Fuxe from their pioneering rodent studies using a novel technique that made dopamine neurons fluorescent. However, more detailed immunohistochemical studies suggest that the A-9 and A-10 nuclear groups are a continuum, with laterally situated cells innervating the striatum and medial cells innervating mesolimbic and mesocortical areas.

The tuberoinfundibular dopamine pathway originates in the arcuate and periventricular nuclei of the hypothalamus and projects to the intermediate lobe of the pituitary and the median eminence. Dopamine released from these neurons is secreted into the hypophysed and portal blood regulates prolactin secretion from the pituitary through inhibitory D_2 receptor on nanotrophic cells.

Other pathways containing dopamine include (i) the incertohypothalamic neurons, which connect the dorsal and posterior hypothalamus with the dorsal anterior hypothalamus and lateral septal nuclei; (ii) the medullary periventricular group, which includes dopamine cells of the dorsal motor nucleus of the vagus nerve, the nucleus tractus solitarius, and the tegmentum radiation in the periaqueductal gray matter; (iii) the interplexiform amacrine-like neurons, which link the inner and outer plexiform layers of the retina; and (iv) the periglomerular dopamine cells in the olfactory bulb, which link mitral cell dendrites in adjacent glomeruli.

II. SYNAPTIC DOPAMINE

A. Synthesis

In dopamine-secreting cells, the first step in dopamine synthesis is the conversion of dietary tyrosine into L-3,4-dihydroxyphenylalanine (L-DOPA) (Fig. 2). This reaction is catalyzed by the rate-limiting enzyme tyrosine hydroxylase (TH). L-DOPA is then converted to dopamine via the enzyme L-aromatic amino acid decarboxylase.

TH is composed of four identical subunits and contains iron ions, which are required for its activity. The cofactors oxygen and tetrahydrobiopterin are also required for its activity. A single gene encodes TH, although in humans four isoforms have been shown to result from alternative splicing of the primary transcript. TH is present in both soluble (cytoplasmic) and membrane-bound forms.

Under basal conditions TH is nearly saturated by tyrosine. The observation that pharmacological agents

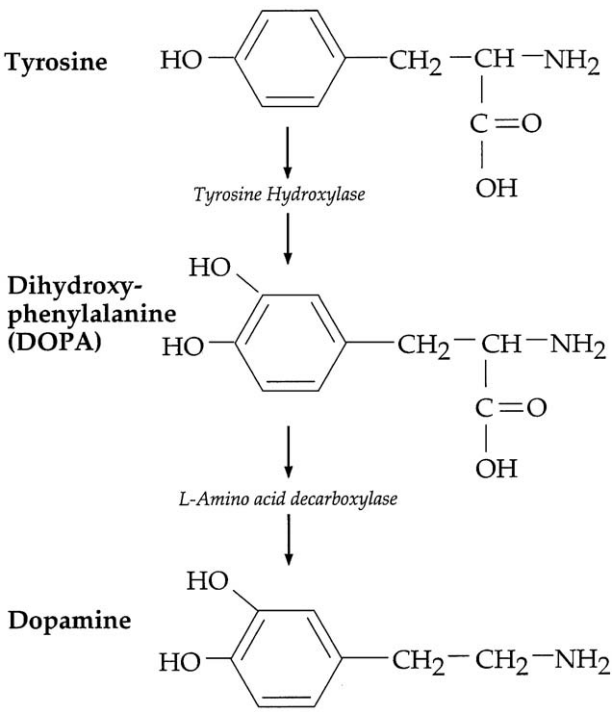

Figure 2 The dopamine synthesis pathway.

known to block TH activity have greater effects on extracellular dopamine levels than agents that block dopa-decarboxylase indicates that the rate-limiting step for dopamine synthesis is tyrosine hydroxylation of tyrosine to L-DOPA by TH. Thus, increasing levels of tyrosine by dietary modifications may also regulate dopamine synthesis.

The conversion of L-DOPA to dopamine by dopamine β-hydroxylase results from the removal of a hydroxyl group and requires pyridoxal 5-phosphate (vitamin B_6) as a cofactor.

Dopamine synthesis is regulated in a variety of ways. End product inhibition is the major regulator when dopamine neuronal activity and release are low. In contrast, when dopaminergic fibers are electrically stimulated, TH activity is increased. This increase appears to be a function of enhanced enzyme substrate kinetics, in part caused by TH phosphorylation. This results in a net decrease in affinity of TH for dopamine, which overrides end product inhibition.

B. Storage and Release

There are two release mechanisms for dopamine. The first is calcium-dependent, tetrodotoxin (TTX)-sensitive, vesicular release at the axon terminal that occurs following an action potential. The second is calcium and TTX independent and occurs following the administration of stimulant drugs that reverse the direction of the dopamine transporter (DAT). Under normal, nondrug conditions the DAT carries released dopamine from the extrasynaptic space back into the terminal region.

Pharmacological studies indicate that dopamine exists in three pools or compartments within the axon terminal. Two of these are vesicular dopamine stores, one containing newly synthesized dopamine and the second containing a longer term store of dopamine. A cytoplasmic pool has also been identified, and it consists of dopamine newly taken up by the dopamine transporter.

C. Inactivation

Dopamine inactivation is accomplished by a combination of reuptake and enzymatic catabolism. Dopamine uptake is an energy-dependent process that requires sodium and chloride. Catabolism occurs through two enzymatic pathways (Fig. 3). Although it is not clear how much dopamine is catabolized in each of these

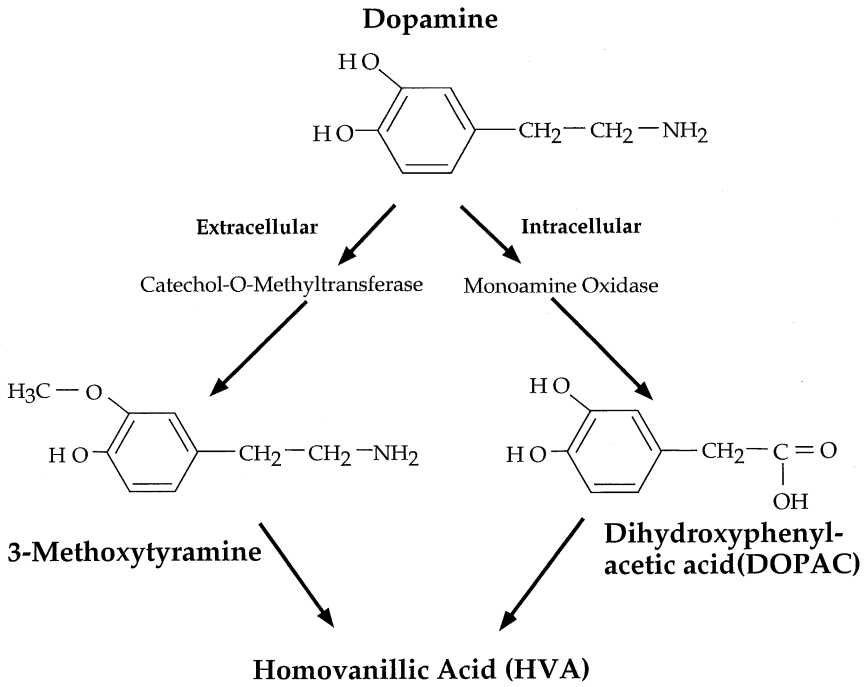

Figure 3 The dopamine metabolic pathway.

pathways in the human brain, almost 90% of catabolism in the rat striatum takes place via the monoamine oxidase (MAO) pathway. In the rat, the level of 3,4-dihydroxylphenylacetic acid is thought to reflect catabolism of intraneuronal dopamine, which includes dopamine that is taken back up by the dopamine transporter, whereas 3-methoxytyramine levels are thought to reflect metabolism of extracellular dopamine. Cerebrospinal fluid (CSF) levels of homovanillic acid (HVA) are often used as an indicator of dopaminergic activity in humans.

III. DOPAMINE RECEPTORS

A. Subtypes

Initial biochemical and pharmacological studies indicated the presence of two dopamine receptor subtypes with differential coupling to G proteins: D1 receptors stimulate adenylate cyclase through Gs protein, and D2 receptors inhibit adenylate cyclase through Gi protein. The recent application of molecular cloning techniques has revealed the existence of five dopamine receptor genes, each encoding a distinct seven-transmembrane spanning receptor. These receptors have been classified according to their structures and divided into two subfamilies, the D2-like receptors (D_2–D_4) and the D1-like receptors (D_1 and D_5). In the case of the D_2 receptor, two isoforms (D_{2L} and D_{2S}), generated by alternative splicing of the primary transcript, have been identified. Given their structural similarity, members of each subfamily exhibit similar pharmacological characteristics.

B. Distribution

The distribution of messenger RNA (mRNA) encoding all five dopamine receptors has been determined in the rat and human brain by *in situ* hybridization. High levels of D_1 mRNA are found in the caudate–putamen, nucleus accumbens, and olfactory tubercle; lower levels are found in lateral septum, olfactory bulb, hypothalamus, and cortex. In contrast, D_5 mRNA is predominantly localized to the hippocampus and the parafascicular nucleus of the thalamus.

The highest concentration of D_2 mRNA is present in the neostriatum, olfactory tubercle, substantia nigra, ventral tegmental area, and the nucleus accumbens. The levels of D_3 and D_4 receptor mRNAs are much lower in the brain relative to the level of D_2 mRNA. D_3 receptor mRNA is predominantly expressed in limbic areas, such as the nucleus accumbens, Islands of Calleja, bed nucleus of the stria terminalis, hippocampus, mammillary nuclei, and the substantia nigra. The areas with the highest levels of D_4 mRNA include the olfactory bulb, hypothalamus, and thalamus, with lower levels present in the hippocampus, cortex, and basal ganglia.

There is evidence in the rat that D_1 and D_2 receptor expression is segregated at the level of the striatum (caudate and putamen in the human). *In situ* hybridization analysis has reported two distinct post synaptic populations of striatal neurons that express D_1 or D_2 receptors: the enkephalinergic striatopallidal neurons, which express D_2 receptors, and the substance P, dynorphin-positive, striatonigral neurons, which express D_1 receptors. However, other groups using different methodologies have reported considerably more overlap in the expression of D_1 and D_2 mRNA in the striatum. They found significant coexpression of D_1 and D_2 mRNAs in the same striatal neurons. These studies suggest that at least a portion of D_1 and D_2 receptors is colocalized in the striatum.

Electrophysiological and neurochemical data suggest that a portion of dopamine receptors are located presynaptically on the axon terminals of striatal dopaminergic neurons where they serve as autoreceptors. These terminal autoreceptors modulate the synthesis and release of dopamine. These activation inhibits production and release of dopamine. These autoreceptors were originally classified as D_2 receptors. However, since D_2 and D_3 mRNA are present in nigral neurons D_3 as well as D_2 receptors are implicated as autoreceptors. Somatodendritic autoreceptors, responding to dendritically released dopamine, have also been observed. Activation of these receptors reduces the firing rate of dopamine neurons.

C. Signal Transduction Pathways

Like other G protein-coupled receptors, dopamine receptors transduce their signals through second messengers regulated by G proteins. In general, D1-like receptors stimulate adenylate cyclase via the Gs, and the D2-like receptors inhibit adenylate cyclase through the Gi. The signaling cascade is initiated by dopamine binding to the extracellular portion of the receptor. The binding of dopamine alters the receptor so that it activates a G protein present on the intracellular face of the neuron cell membrane. Once activated, G proteins modulate adenylate cyclase

activity. G proteins bind guanosine triphosphate (GTP) or guanosine diphosphate (GDP). Dopamine binding to its receptor causes GDP to be replaced with GTP. Then, in the case of the D1-like receptors, a GTP–Gs complex is formed and associates with the catalytic subunit of adenylate cyclase, stimulating the conversion of ATP to cyclic (AMP) adenosine monophosphate. The GTP–Gs protein and the catalytic subunit of adenylate cyclase together constitute the active form of adenylate cyclase. The association of the G protein with the catalytic subunit of the cyclase also results in the hydrolysis of GTP to GDP. This hydrolysis causes the G protein to dissociate from the catalytic subunit and to reassociate with the receptor. This reaction terminates the synthesis of cyclic AMP. Therefore, the duration of cyclic AMP synthesis is regulated by GTPase activity. In the case of the D2-like receptors, receptor activation causes GTP binding to Gi, and this complex inhibits cyclase activity.

It should also be noted that several other second messenger systems are involved in D2-like receptor-mediated signal transduction, such as the stimulation of aracadonic acid metabolism and the activation of potassium channels.

D. Regulation

Most studies concerned with the regulation of CNS dopamine receptors *in vivo* have examined the effects of long-term treatment with receptor agonists, antagonists, or denervation induced by 6-hydroxydopamine, a selective neurotoxin for catecholaminergic neurons, on striatal D2-like dopamine receptors.

Studies examining chronic agonist exposure have yielded mixed results. Repeated treatment with amphetamine, which increases synaptic levels of dopamine, both increased and had no effect on the density of D2-like receptors in the striatum, probably depending on dose and timing. Treatment with systemic L-DOPA, which also increases synaptic levels of dopamine, has been reported to decrease the density of D2-like receptors in the striatum.

Treatment with D1-like or D2-like antagonists has been shown to increase the density of D1-like and D2-like receptors, respectively, without changing the affinity of these receptors for dopamine. Similarly, denervation following 6-hydroxydopamine administration also leads to an increased dopamine D2-like, but not D1-like, receptor density as well as an enhanced behavioral responsiveness to dopamine. Thus, it appears that dopamine D2-like receptors upregulate in response to reduced levels of dopamine. It is not clear, however, if the molecular mechanism responsible for lesion-induced upregulation of dopamine receptors is the same as that underlying the upregulation observed after long-term antagonist treatment. The fact that D1-like receptors upregulate after long-term antagonist treatment, but not after denervation, suggests that the mechanisms must be different, at least for D1-like receptors. In the case of long-term antagonist treatment, it is also possible that the intrinsic properties of the antagonist may play a role in the upregulation of dopamine receptors.

The pathway of protein synthesis, from the initial stage of gene transcription to mRNA splicing, translation, protein processing, and insertion into the membrane, provides a number of potential points of control for the regulation of dopamine receptor number. The rate of receptor removal from the membrane and the recycling or degradation rates are also factors that contribute to the number of receptors available for binding.

It should be noted that the molecular mechanisms underlying dopamine receptor trafficking (another mechanism regulating dopamine receptor expression) are only beginning to be studied.

IV. DOPAMINE AND NEUROPSYCHIATRIC DISORDERS

Many lines of evidence suggest a role for dopamine in neuropsychiatric disorders such as PD, schizophrenia, attention deficit hyperactivity disorder (ADHD), and drug abuse. The first evidence for dopamine's involvement in these disorders came from either postmortem histological/neurochemical studies or the observation that the drugs used to treat these disorders either increased or blocked dopamine neurotransmission in the brain. Since the advent of neuroimaging techniques such as positron emission topography (PET), a majority of the current human studies use this technique to further define the role of dopamine in these disorders.

PET enables the direct measurement of components of dopamine neurotransmission in the living human brain by using radiotracers, which label dopamine receptors, dopamine transporters, and precursors of dopamine or compounds that have specificity for the enzymes that degrade dopamine. Certain types of PET

studies also provide information on regional brain metabolism or blood flow, thus, PET can be used to assess the functional consequences of changes in brain dopamine activity.

A. Parkinson's Disease

PD is a neurodegenerative disorder of unknown etiology that is associated with the degeneration of dopamine neurons primarily in the substantia nigra and manifested by disturbances in the motor system. There is evidence for genetic and environmental causes. The symptoms of PD can be classified as positive or negative. The positive symptoms of PD consist of tremor, muscular rigidity, and involuntary movements. Negative symptoms include bradykinesia, postural disturbances, and cognitive impairments. During the early course of the disease, unilateral symptoms may initially appear. Often, the disease begins with a mild tremor and some muscular rigidity. As the disease progresses, the symptoms present bilaterally, the tremor is exacerbated, and bradykinesia appears. During the later stages of the disease patients are incapacitated and are usually confined to a wheelchair.

L-DOPA is probably the single most effective medication for controlling the early symptoms of Parkinson's disease. L-DOPA is transported to the brain and taken up by the remaining dopaminergic cells, where it is converted into dopamine and increases its synaptic availability. L-DOPA therapy is effective in most patients for several years. However, as the loss of nigrostriatal neurons increases, symptoms continue to worsen and the dose of L-DOPA must be increased. As the dose is increased, it is not uncommon for patients to develop adverse effects, which may not be tolerable. In such cases, a MAO inhibitor is sometimes coadministered with a lower dose of L-DOPA to prolong the actions of dopamine at the synapse. Alternatively, direct-acting dopamine agonists, such as bromocriptine and pergolide, can be used to treat PD.

B. Schizophrenia

Schizophrenia is a serious psychiatric disorder affecting approximately 1% of the world population. Symptoms usually appear in late adolescence or early adulthood. This disease has a devastating impact on the lives of patients as well as their families. Positive symptoms include hallucinations and delusions, whereas negative symptoms consist of flattened affect social withdrawal and cognitive deficits. Several lines of evidence emerged in the 1970s that suggested alterations in dopamine transmission might constitute the pathophysiological basis for schizophrenia. Amphetamine and cocaine, which enhance dopamine transmission in the brain, can produce paranoid psychosis similar to that observed in patients with paranoid schizophrenia and exacerbated symptoms in schizophrenics. Also, a significant positive correlation between the clinical potency of neuroleptic drugs and their ability to block D2-like dopamine receptors has been consistently observed.

Although early studies suggested a postsynaptic locus for the disease because increased D2-Like receptors were observed in postmortem studies evaluating dopamine receptors, it seems likely that these results may have been caused by prior neuroleptic drug treatment. Neuroimaging studies also indicate that increased dopaminergic neurotransmission is involved in schizophrenia and is associated with activation of psychotic symptoms. Furthermore, enhanced dopamine transmission is detected in drug-naïve patients experiencing their first episode of the illness and is not detected in patients during remission, suggesting that the hyperdopaminergic state associated with schizophrenia fluctuates over time.

With respect to the negative symptoms of schizophrenia, PET studies evaluating regional brain glucose metabolism in untreated schizophrenic patients have reported reduced rates of glucose metabolism in neocortical areas, although these differences did not always reach statistical significance. Importantly, there may be a tendency toward a more pronounced reduction in metabolism in patients exhibiting negative symptoms. Since the premise underlying these studies is that glucose consumption in nerve cells is directly proportional to the impulse activity of neurons, it was postulated that decreased dopamine transmission in the mesocortical dopaminergic pathway, which is known to modulate the activity of prefrontal cortical neurons, might underlie the negative symptoms observed in schizophrenia. Support for this hypothesis has been obtained from a variety of studies. For example, animal studies have demonstrated that lesions of the prefrontal cortex in nonhuman primates lead to cognitive disturbances and poor social skills that resemble some of the negative symptoms observed in schizophrenic patients. In addition, many patients with primarily negative symptoms exhibit ventricular enlargement suggesting a loss of neurophil.

C. Attention Deficit Hyperactivity Disorder

A role for altered dopamine neurotransmission as the underlying cause of ADHD has been suggested by several observations. First, drugs used to treat ADHD, such as methylphenidate (Ritalin) and amphetamine (Adderal), increase synaptic levels of dopamine in experimental animals and in human subjects. In patients with ADHD, the maximal therapeutic effects of these drugs occur during the absorption phase of the kinetic curve, which parallels the acute release of dopamine into the synaptic cleft. These drugs are said to have "paradoxical" effects in ADHD children because they cause hyperactivity in normal children but have a "calming" or cognitive-focusing effect on ADHD children. Second, molecular genetic studies have identified genes that encode proteins involved in dopamine neurotransmission as candidate genes for ADHD. Third, neuroimaging studies have shown reduced activation in the striatum and frontal cortex of ADHD patients that is reversed by the administration of methylphenidate at least in a subset of children. Recently, functional magnetic resonance imaging studies have demonstrated differences between children with ADHD and normal controls in the degree of corticostriatal activation during a stimulus-controlled go/no-go task and its modulation by methylphenidate. Off drug, ADHD children showed impaired inhibitory control on this task and reduced striatal activation relative to the control subjects. Administration of methylphenidate significantly increased inhibitory control and frontostriatal activation in ADHD patients. These observations indicate that an optimal level of corticostriatal activation is necessary for subjects to display normal inhibitory control. Since methylphenidate increased both corticostriatal activation and inhibitory control, it follows that decreased corticostriatal activation and the poor inhibitory control may be due to reduced dopamine tone in the brain, perhaps in the striatum. However, it is equally likely that the mesolimbic dopamine system may mediate these effects by virtue of its afferent projections to the prefrontal cortex.

D. Psychostimulant Drug Abuse

Amphetamine and cocaine are psychostimulant drugs that are abused by humans because they produce feelings of euphoria. Both of these drugs increase extracellular levels of dopamine. Cocaine blocks the dopamine transporter and amphetamine primarily reverses it. Studies indicate these drugs are also primary reinforcers in animals because they will self-administer these drugs, and their propensity to do so is an excellent predictor of abuse liability in humans.

Many animal studies using a variety of different paradigms to study the role of dopamine in the rewarding properties of the psychostimulant drugs have suggested that dopamine is critically involved in this process in experimental animals. In the case of cocaine, studies carried out in human subjects have also supported the idea that enhanced dopamine transmission is responsible for the euphoric effects of this drug in humans. Dopamine appears to be a critical mediator of reward in the brain.

Dopamine also appears to play a role in craving, which often leads to relapse in abstinent human substance abusers. Brain imaging studies have identified the amygdala and the dopamine-rich nucleus accumbens as putative neuroanatomical substrates for cue-induced craving. Nucleus accumbens dopamine levels increased withdrawn from cocaine when they were exposed to cues that were previously associated with cocaine intake. Studies in humans examining the level of the dopamine metabolite HVA have reported that craving during abstinence is associated with increased HVA.

It also appears that the dopamine D_3 receptor may be involved in cocaine craving. Animal models of cocaine craving have shown that the D_3 selective partial agonist, BP 897, attenuates craving while lacking any intrinsic, primary rewarding effects.

A very interesting aspect of repeated amphetamine or cocaine administration is behavioral sensitization. Behavioral sensitization or reverse tolerance refers to the progressive augmentation of drug affects that are elicited by repeated administration of the drug. Sensitization to psychostimulants was characterized in experimental animals as early as 1932 and in humans in the 1950s. Behavioral sensitization develops when psychostimulant administration is intermittent. Tolerance develops during continuous administration.

V. DOPAMINE AND LEARNING

Animal research shows that dopamine is involved in the acquisition of operant tasks, avoidance learning, and intracranial self-stimulation. It is thought that dopamine in mesolimbic regions (most notably the nucleus accumbens) is involved in both the acquisition

and the maintenance of these behaviors. This conclusion was based primarily on results from studies using dopamine-depleting agents and dopaminergic drugs to evaluate their effects on acquisition or maintenance of reinforced behaviors. The results of acquisition studies showed that administration of dopamine antagonists or the dopamine-depleting agent, 6-hydroxydopamine, prevented the acquisition of these tasks. Reinterpretation of studies evaluating the effects of these agents on the maintenance of such behaviors has not been so clear-cut. For example, the acute administration of a dopaminergic antagonist after acquisition of an operant task often has no effect or increases the level of operant responding. This has been interpreted to be the result of a decrease in the perceived "salience" of the reward, whereas chronic administration of these agents blocks these behaviors. Recent *in vivo* voltammetry studies, which directly measure fast changes in dopamine release at the level of the synapse, carried out by Garris, Wightman, and colleagues have shown that evoked dopamine release in the nucleus accumbens is associated with the acquisition but not the maintenance of reinforced behavior, at least in the case of intracranial stimulation.

VI. DOPAMINE AND WORKING MEMORY

The prefrontal cortex receives elaborate dopamine inputs from the VTA and an optimal level of dopamine in the prefrontal cortex appears necessary for cognitive performance in experimental animals. Significant increases in dopamine levels in the dorsolateral prefrontal cortex have been observed in monkeys performing a delayed alternation task. In addition, reduced levels of dopamine in the prefrontal cortex have detrimental effects on spatial working memory tasks. It has also been reported that very large increases in dopamine levels in the prefrontal cortex can cause deficits on spatial working memory tasks. These deficits are ameliorated by the administration of dopamine D1-like drugs. Taken together, the previously mentioned observations support the idea that an optimal level of dopamine is required to perform spatial working memory tasks. If that level is reduced or increased, performance will be negatively affected.

Behavioral studies conducted in humans also indicate a role for prefrontal D1 receptors in working memory modulation in humans, although one study has also shown that the administration of the D2-like antagonist sulpride produced a dose-dependent impairment in spatial working memory.

Studies examining the performance of PD patients on working memory tasks also support the idea that dopamine may be involved in working memory in humans as well as in experimental animals. Imaging studies in PD patients have shown reduced fluorodopa uptake in the caudate nucleus and frontal cortex, which correlates with deficits in working memory as well as attention.

Some studies have also evaluated the effects of dopamine receptors in the ventral hippocampus on working memory tasks in rats. These studies suggest that D2-like but not D1-like receptors in the ventral hippocampus modulate spatial working memory.

Dreaming

MARIO BERTINI
University of Rome

GLOSSARY

bizarreness The presence of highly unlikely elements in the dream narrative. Improbable events are usually associated with discontinuities of time, place, person, object, and action as well as incongruities of these features.

REM sleep The stage of sleep defined by the concomitant appearance of relatively low-voltage, mixed frequency electroencephalograph activity with episodic rapid eye movement (REM) and low-amplitude electromyogram.

Dreaming is a term interchangeably used to indicate both the function of generating a dream and the dream itself. That is a special kind of sleep mentation usually characterized by visual imagery, bizarreness, and hallucinatory and story-like quality.

I. HISTORICAL BACKGROUND

Dreaming is a complex psychobiological function, that eludes a precise and universally shared definition. Research into this important dimension of the human mind is continually evolving, and despite the fact that much progress has been made, we are still a long way from a satisfactory understanding of its biological and psychological implications.

Given the peculiar methodological limitations of the research in this area, it is worth presenting an overview of our current knowledge in a historical perspective. I hope it will allow the reader to better judge the validity and the possible lines of development of the field.

In the antiquity, sleep had a dual significance. On the one hand, it symbolized death, in the abandonment of the limbs and in shutting oneself away from the experience of the senses (Hesiod's Theogony depicted Sleep and Death as two brothers); on the other hand, sleep was like a door that, through the secret pathways of dreams, led to a dimension beyond intelligence and enabled humans to come into contact with the supernatural.

Even on a philosophical level, there were two somewhat opposite orientations that can still be recognized in some of today's scientific views. Some thinkers viewed sleep as a passive withdrawal from consciousness and dreaming was thus an illusion or a nonsense; according to others, sleep represented the theater of a different form of mental activity and dreams bore meanings.

In *Sleep and Wake* (453 BC), Aristotle defined sleep, and what takes place in it, as a "privation of wakefulness," i.e., as a purely negative concept—a pause in human sensory experience and intellectual functioning. During sleep, either intelligence is silent and everything is dark or it is deceived by a flow of disconnected fleeting images that give rise to dreams.

In *Republic*, Plato discussed the obscure depths of the psyche that are revealed through nocturnal dreams. Not only may the gods reveal themselves to man through dreams but also in the same way man reveals himself to himself. Even Heraclitus seems to hint at a different orientation of the psyche in the transition from wakefulness to sleep: "He who is awake lives in a single world common to all; he who is asleep retires to his own particular world."

Over the centuries, dreaming aroused more the curiosity than the systematic interest of researchers. The views of 19th-century neurophysiologists, strongly influenced by positivistic thought, essentially adhered to the original Aristotelian lines.

As a matter of fact, until recently, states of consciousness were believed to vary along one continuous dimension in parallel with behavioral performance, from deep coma to the opposite extreme of manic excitement. In this view, rational thought appeared as a form of mental activity exclusively belonging to waking states, whereas dreaming was simply the expression of the fragmentation and dissolution of thought, in close relationship with the lowering of vigilance and the deepening of sleep.

Only toward the end of the 19th century were some contributions made that considered dreaming an event deserving direct attention. The observations of two French scholars, the Marquis d'Hervey de Saint-Denis and Alfred Maury, are worth mentioning here, along with those of the initiator of experimental psychology, the German Wilhelm Wundt. However, the contribution that truly catalyzed the attention of contemporary culture was the brainchild of a scholar, Sigmund Freud, who had no real connection with the emerging experimental psychology approaches. Freud pointed out a methodological flaw in the way those who considered dreaming a completely meaningless activity examined the oneiric content. Researchers were trying to understand dreams according to the same register that was used for comprehending "normal" language instead of searching for the appropriate key to decrypt a language that is quite peculiar. According to Freud, this was like expecting to understand a rebus, with its apparently bizarre compositions, by reading it as a common rational message.

Freud's book on the interpretation of dreams, which was published in 1900, is a cornerstone in psychoanalytical theory and a significant historical event in contemporary culture. However, it is well-known that Freudian studies mainly focused on the contents of the phenomenon, whereas the proposed functional explanations suffered from the poor knowledge at the time of the central nervous system's physiology and of the organization of the mind in general, matters brought to the forefront of research by modern neuroscience.

In order to probe the functional basis of dreaming, it was necessary to shed light on objective, measurable aspects, such as the frequency and periodicity of dreaming, its universality, episodic and total duration throughout the night, and especially its neurophysiological regulation. The first step in solving these and other general problems was the discovery of some objective indicators that could reveal the presence of the dream itself.

As sometimes happens in science, the first curtain protecting the mystery of dreaming was lifted almost by chance by a young student working on his doctoral thesis in the early 1950s. Studying attention in children, under the supervision of Nathaniel Kleitman at the University of Chicago, Eugene Aserinsky observed that sometime after the onset of sleep, the subjects' eyes could be observed, under the closed eyelids, moving left and right and up and down while all the major body movements ceased. After several minutes, these eye movements would stop altogether, only to resume again with the same characteristics at more or less regular intervals throughout the night. Since the pattern of eye movements resembled that of an awake subject exploring a visual scene with his or her gaze, the hypothesis was put forward that dreaming occurs in these periods.

To test the hypothesis, the experimenters set out to awaken and question subjects at various times during the night. In most cases, subjects were able to report dream content when awakened during periods of eye movements, whereas they could rarely recall dreams if awakened while their eyes did not move. The results seemed to clearly confirm the conjecture, and Aserinsky's accidental observation took on the proportions of a profound scientific discovery.

II. THE SLEEP AND DREAMING LABORATORIES

Further confirmation of such association was obtained in the Chicago sleep laboratory. By the end of the 1950s, William Dement and Nathaniel Kleitman had obtained vivid, detailed reports of dreams with an incidence of 80% when awakenings occurred during periods of sleep characterized by rapid eye movements (REM sleep), whereas dreams could be reported in only 7% of the cases when subjects were awakened

while no rapid eye movements could be observed (non-REM sleep). Various demonstrations of proportionality between objective duration of REM sleep periods and subjective length of dreaming further confirmed the relation between the two events and prompted the hypothesis that dream activity continuously progresses throughout the length of a REM phase.

Beginning in the 1960s, many other sleep and dreaming laboratories were set up throughout the world in which subjects were monitored with electroencephalographic (EEG) and polygraphic recordings throughout their sleep. The observations made in these laboratories offered a convincing picture of the physiological processes accompanying the REM stage of sleep. The term REM soon came to represent a particular sleep stage that appeared to be the privileged place for dreams. Besides rapid eye movements, this phase is characterized by fast EEG activity, resembling that of the wake alert state, contrasted by muscle tone so relaxed that the sleeper is virtually paralyzed. Heart and breathing rate are higher and more irregular than in the other sleep stages. Penis erection in males and vaginal moistening in females have also been highlighted in connection with the REM stage of sleep.

Continuous laboratory monitoring has shown that in adult humans REM phases last, on average, 20–30 min each and reoccur regularly at intervals of approximately 90–100 min throughout sleep. Thus, each subject has an average of four or five REM episodes a night that recur cyclically. These episodes, on the whole, comprise approximately 20–25% of an adult's sleep.

In the words of William Dement, "the discovery of REM sleep was the breakthrough, the discovery that changed the course of sleep research." As a matter of fact, the emphasis attributed to the REM stage has been such that the other four stages of sleep are often defined simply as non-REM sleep. As discussed later, this extreme simplification, including the exclusive attribution of dreaming to REM sleep, was later criticized in various ways.

III. PSYCHOPHYSIOLOGICAL FEATURES OF DREAMING

A. Eye Movements and Dream Imagery

The discovery of characteristic bursts of eye movements in sleep led to the hypothesis of a direct relationship with the oneiric imagery, as some anecdotal reports seem to suggest. For example, one subject—who was awakened after a period 15 min of eye inactivity followed by some large shifts from right to left—reported having dreamed of driving a car while staring at the road ahead of him until, coming to a crossroads, he was struck by the sudden appearance of another car approaching quickly from the left. Some empirical studies, albeit not completely exemplary on a methodological level, seemed to support the hypothesis of a close connection between eye movements and dream images. According to some researchers, rapid eye movements are indeed the result of the actual scanning of the dreamed "scene."

According to other researchers, however, eye movements represent random, inevitable bursts of motor activity. Eye movements could merely be one of a variety of physiological signs of the peculiar pattern of activation processes of the organism that coexist with dreaming. If a correlation between REMs and dream content were to be verified, it would still be unclear whether chaotically generated eye movements forced appropriate dream content or dream content forced appropriate eye movements; correlation is not causation. The study of subjects blind since birth soon appeared to be the most logical approach to test the "scanning hypothesis."

B. Dreaming in the Blind

Blind people do have dreams that include visual imagery, but only if blindness occurs later than 6 or 7 years of age. It has been known, however, that dreams in congenitally blind people are nonvisual, and that their content is mostly linked to other sensory modalities. If the scanning hypothesis were true, then one might argue that subjects who have never had the opportunity to gaze upon their surroundings should not show rapid eye movements while dreaming. Sleep laboratory studies, however, have demonstrated quite the opposite (i.e., the presence of eye movements in the REM sleep of congenitally blind subjects). An even greater difficulty in accepting the hypothesis that eye movements follow dream scenes arises when we consider the dreaming of newborn babies or even animals deprived of the cerebral cortex.

As discussed later, newborn infants (and even prematurely born infants) show the presence of all those physiological features that accompany the subjective phenomenon of dreaming in adults,

including eye movements. Furthermore, a persistence of eye movement bursts, although more disorganized, has been found even in decorticated cats and humans. It would certainly be difficult in these cases to postulate their relation to any kind of imaginative activity.

A different interpretation of the phenomenon, which takes into account the apparently contrasting findings, may be considered within a developmental view. Eye movement may be considered as a physiological mechanism included since birth in the constellation of functional characteristics of the REM stage. The overall and experiential maturation of the organism involves a change in these automatic movement bursts along the lines established by the interaction with psychic phenomena as they occur in dreaming processes. After all, the relationships between eye movement and dream imagery may be another example of various physiological functions controlled by lower brain centers that are coordinated in the area of higher brain processes as they mature.

C. Dream Recall

Dreaming in the course of a night takes up a considerably longer amount of time than was previously supposed. Each one of us has 1 or 2 hr per night of REM sleep; however, even those who remember dreams best generally recall only one or at most two fragments per night, and most people remember much less. Even the few dreams that are well remembered after awakening normally fade from memory after a few minutes or a few hours unless special effort is made to keep them in mind. These considerations give rise the following questions: Is it really true that everyone dreams in the proportions reported by the studies carried out in the sleep laboratories? Why are dreams so much more difficult to remember with respect to wake experiences?

An answer to the first question was provided by a study conducted in 1959 at the Downstate Medical Center in New York. Donald Goodenough and coworkers used the EEG technique to record the pattern of brain activity during sleep in two groups of subjects. The first group was composed of people claiming to dream at least once a night, whereas subjects in the second group claimed they dreamed less than once a month or even not at all. These researchers showed that (i) REM periods occurred with the same frequency in both groups; (ii) all subjects, even those who claimed they had never dreamed before, were able to report at least one dream during the nights spent in the laboratory when awakened during REM sleep; (iii) the so-called "dreamers" reported a significantly higher number of dreams than did "non-dreamers". These findings, widely confirmed in later studies, led to the conclusion that, albeit with considerable individual differences, everyone dreams. The distinction between dreamers and nondreamers should therefore be reformulated as those who remember dreams and those who do not.

This brings to the forefront the question of why there is widespread forgetting of nocturnal dreaming experiences. Even "good dreamers" do not normally remember as many dreams as they do if awakened toward the end of a REM phase. Thus, even taking into account individual differences, the basis for this forgetting should be searched for in some ubiquitous physiological factors. The reasons for the failure of transferring sleep mentation from short- to long-term memory are still not completely clear, and the most popular hypotheses present differences that depend on the stress placed on biological vs psychological factors.

One repeatedly put forward hypothesis, which has little credibility today, maintains that the periods of non-REM sleep that follow REM are responsible for forgetting, as if non-REM sleep contained conditions that were somehow incompatible with the long-term consolidation of dreams. Another biologically oriented theory, which finds greater support, considers the particular biochemical substratum underlying the REM phase as responsible for forgetting. According to Allan Hobson and Robert McCarley of Harvard University, dream amnesia depends on the cutoff during REM sleep of a special class of neurotransmitters (namely, the monoamines noradrenaline and serotonin) that are needed to convert our immediate- or short-term memories into long-term storage. According to this hypothesis, when we awaken from a dream the noradrenergic and serotonergic neurons, located in many subcortical centers and widely projecting to the cerebral cortex, turn on and give our brain a shot of these transmitters. If a dream experience is still encoded in activated networks of neurons, it can be reported, recorded, and remembered.

Researchers oriented more toward analyzing the psychological factors tend to minimize or even to deny a substantial subcortical influence on the production and forgetting of dreams. While rejecting Freud's original censorship theory, most dream scientists in the modern cognitive research area would probably accept the general idea of a relationship between the specific

process of dream construction and the easiness of dream forgetting. David Foulkes, for instance, believes that it is the very nature of the dream production process (i.e., the limited presence of the self and the quality of the encoding competence) to make remembering difficult: "When we are dreaming we are not deliberately selecting and organizing the contents of our conscious thoughts and we are not able to reflect on them in a self-conscious way."

Allan Rechtschaffen, another outstanding researcher in the field, has described this peculiarity of our dreaming state as "single-mindedness." While dreaming, there are no alternative lines of thought as in wake, when we are self-reflective and contextually aware; in a sense, our consciousness, functions as a "single channel." A connection can be seen between the tendency to forget and the absence of simultaneous channels to monitor the oneiric mentation and to put it in the more general context of our previous knowledge.

A satisfactory clarification of the reasons why dreams are so easily forgettable will have to wait for a deeper understanding of both the psychological and the biological correlates of sleep and, above all, of their dynamic integrative constraints and interactions.

IV. DEVELOPMENTAL ASPECTS OF DREAMING

A. REM Sleep at the Beginning of Life

The discovery of a sleep stage accompanied by dreaming and characterized by distinct physiological correlates had scientific implications of undoubted significance. It inaugurated investigation of the neurophysiological substratum and functional significance of REM sleep as well its ontogenetic and phylogenetic features.

The developmental aspects of sleep could certainly not be ignored and very soon the sleep and dreaming laboratories started to study newborns and even premature infants. Sleep in these subjects was monitored using the classical polygraphic recording techniques. With some surprise, it was found that the REM phenomenon is clearly present from the beginning of life. However, at variance with what is observed in older children and in adults, REM sleep in the neonate is characterized by the presence of a variety of body movements. In particular, a surprising range of facial expressions can be observed that are not present in the other sleep and wake states. In fact, in the REM state almost all the typical motor components of adult emotional face expressions have been observed since the first days of life. Because of the characteristic presence of facial and body motility, the immature REM sleep of the infant is generally called "active sleep," whereas the rest is known as "quiet sleep." Another characteristic difference from the adult is that the REM phase in the newborn is usually the first stage of sleep. However, perhaps the most relevant difference from adult REM is a quantitative one: whereas adults spend about 20–25% of their total sleep time in the REM stage, and this is reduced to about 15% in people older than 60 years of age, in newborn babies this percentage is about 50%, and it is even higher in prematurity. In various recording experiments, it was found that the proportion of REM to total sleep time reaches 70% in 7-month premature babies. These values are even more impressive if one considers the absolute amount of sleep time of children in the months following birth with respect to that of adults.

B. Do Infants Dream?

The physiological signs that accompany the dreaming experience in the adult are also present in the early months after birth; indeed, they are present in higher proportions. The question of whether infants dream, however, still cannot be answered directly. With regard to subjective characteristics and content, we can make inferences on the basis of indirect evidence whose interpretations, however, vary in relation to the theoretical assumptions and the definition of dreaming adopted by various researchers.

According to David Foulkes, a dream is not a mere analog and pictorial representation of the outside world as perceived by the subject but, rather, a product of psycholinguistic processes that are largely similar to those used in the normal waking state. The peculiar quality of the dream mentation stems from the fact that the cognitive organizing processes are applied to uninhibited memory stores, rather than to the events of the outside world and that such processes occur in the particular situation of loss of voluntary control and of self-regulation induced by sleep, particulary in the REM stage. Thus, dream would be the product of a complex symbolic activity that is not possessed at birth but acquired, in parallel with the development of cognitive–linguistic development. Supported by a longitudinal study conducted in the sleep laboratory, Foulkes claims that "young children may fail to report

dreams because they are not having them, rather than because they have forgotten them or are unable to verbalize their contents.''

This view is considerably influenced by cognitive approaches oriented more toward studying the mind as an organ of pure cognition. Other researchers place greater emphasis on ''sentient'' aspects of the mind, and in any case believe it more parsimonious to postulate the ability of dreaming also in the first stages of life. Following this line of reasoning, the researcher is prompted to consider different levels of development of dreaming ''skills'' and to accept the idea that an infant can experience emotions and fictive visual and kinesthetic sensations. At any rate, the use of narrative as the largely prevalent method to report experiences that may have multimodal origins, though understandable, poses a strong limitation to the interpretation of the data available in the literature.

V. DREAMING IN ANIMALS

Is the REM stage something peculiar to human beings or does it exist in other animal species? After the first successful study carried out in the 1950s by William Dement on cats, research on animals spread rapidly; studies have been carried out on dogs, rats, rabbits, sheep, goats, monkeys, donkeys, chimpanzees, elephants, and even on the opossum (one of the most primitive mammals). Practically all the studied mammals have shown the presence of the REM stage, and its cyclical occurrence is now considered a fundamental feature of sleep in mammals. Apart from mammals, studies seem to indicate the existence of a REM stage, at least in a rudimentary form, in birds but not in reptiles. However, it has been found that at least one reptile, the chameleon, has periods of rapid eye movements when asleep. Phylogenetic considerations therefore lead us to hypothesize that the REM stage appeared for the first time on our planet more than 150 million years ago.

Since it is certain that many animals have recurring periods of REM sleep, is it also reasonable to assume that they dream in the sense that humans do? Anyone with a pet dog, cat, or other animal would swear that their pets dream, judging by the muscle twitches of their limbs, head, and ears that occur ocassionally when asleep. Even Lucretius, in the second century BC, having observed this kind of muscle activity in horses, suggested the possibility that it was linked to their dreaming. According to some, from the developmental evidence in children we must assume that animals do not dream; according to others, this competence cannot be excluded.

Bearing in mind that, in any case, there is no direct evidence for what takes place in animals' minds, the problem cannot merely imply a straight yes or no answer; even at the purely speculative level, hypotheses for and against dreaming in animals must first specify what is meant by dreaming within the context of the animal species under consideration.

VI. NEUROPHYSIOLOGICAL AND NEUROCHEMICAL MECHANISMS OF DREAMING

The discovery of a REM stage in animals opened up new possibilities of experimental research obviously unfeasible in humans. In the early 1960s, transection studies in cats conducted by the French sleep scientist Michel Jouvet and coworkers pointed to structures in the brain stem as the source of REM sleep. More precisely, these researchers discovered the presence of both a trigger mechanism and a REM sleep clock in the pons. Investigating the pontine reticular formation through the recording microelectrode technique, McCarley and Hobson reported a series of findings that led to the formulation of a ''neurochemical'' model of the rhythmic appearance of REM sleep. They called this hypothesis the reciprocal interaction model because of its central concept: During REM sleep, aminergic subsets of neurons (the so-called REM-off cells) were inhibited, while cholinergic (REM-on) cells actively discharged. The opposite pattern of neuronal activity was observed during wake.

The relevance of the pontine brain stem in REM sleep generation has been recently confirmed using neuroimaging techniques. Studies based on positron emission tomography (PET), for example, have shown activation of the pontine tegmentum during REM sleep. Significant activations, however, were also seen in many other brain areas, including limbic and paralimbic forebrain regions that are thought to mediate emotion, an important aspect of dreaming. Finally, PET studies have found, during REM sleep, an increase in the activation of unimodal associative visual (Brodmann areas 19 and 37) and auditory (Brodmann area 22) cortices, whereas heteromodal association areas in the frontal and parietal cortex were deactivated. The frontal deactivation could be responsible for another important aspect of dreaming—the bizarreness of dream content. Despite the

general deactivation in much of the parietal cortex, an activation of the right parietal operculum, a neural structure that is important for spatial imagery construction, has been reported.

Although in REM sleep the global cerebral metabolism tends to be equal to or greater than that of waking, on the whole these findings suggest that the regional activation during dream mentation is very different from that of waking mentation. In particular, the reduced involvement of the cortical areas devoted to processing sensory information in the waking state, as reported in recent imaging studies, appears to further confirm what was already known—that is, a block against external sensory inputs during REM state and the resorting to systems connected to the internal sphere of emotions and memories.

Having recognized that REM sleep originates in neural structures located in the hindbrain, and not in the forebrain, the following was next question to address: To what extent do these centers control dreaming as well? Evidence in this respect could in theory be gained by studying brain-damaged patients. In fact, if dreaming is caused by neural activity in the brain stem, then brain stem lesions should eliminate both REM and dreaming. The available evidence in this respect is not conclusive, mostly because brain stem lesions that are extensive enough to prevent REM render the patients unconscious. Researchers who do not believe in the causal link between the brain stem and dreaming find indirect support to their claim from evidence in the literature that shows that dreaming is eliminated by forebrain lesions that completely spare the pontine brain stem. However, arguments of this sort rely on an unjustified assumption: They equate the process of dream generation to the process of dream recall and report. Cessation or reduction of dream recall after brain damage may indicate an impairment in any of the processes allowing the production of the dream experience, its recall, and its report and should not be attributed exclusively to the process underlying its production.

The question therefore remains largely unanswered despite major effort. Trying to trace the origin of dreaming to one specific brain area or another may represent too simplistic an approach that does not take into account the complex relationships between higher and lower brain centers. A highly rigid separation between the different sleep and wake phases and between rational thought and the oneiric experience is another source of bias that may have a negative impact on the progress of research. The complex psychophysiological nature of dreaming is increasingly evident, to the point that it has been questioned whether dreaming is a mental experience that can only be linked to sleep.

VII. DOES DREAMING BELONG TO SLEEP?

At the beginning of the 1960s, the interest evoked by the discovery of the REM stage was such that a proposal for calling it ''the third state of consciousness'' was often advanced. Instead of ''wake'' and ''sleep,'' it was popular at that time to speak of ''wake,'' ''dreaming,'' and ''nondreaming'' stages. Meanwhile, the occasional reports of dreaming outside of REM sleep were attributed either to recall of REM material or to the subject's waking confabulations.

Later, however, on the basis of consistent empirical findings of dream-like mentation in non-REM sleep, the notion that thought modalities are completely segregated within the different physiological states was seriously questioned. It was shown that non-REM reports could not be safely ascribed to recall of mental events taking place during REM. A considerable amount of mental activity often indistinguishable from REM dreams was found even at sleep onset (i.e., *before* the first occurrence of a REM phase). The debate between those favoring and those rejecting the hypothesis that dreaming is an exclusive production of REM is ongoing.

It seems clear that some form of mental activity is present in non-REM sleep, although in the past, there was substantial agreement on the fact that REM reports are more frequent, longer, bizarre, and more visually animated and emotional compared to non-REM reports, which appear substantially more mundane and thought-like. Later, however, some researchers challenged this notion, claiming that the special quality of REM imagery largely depends on the greater length of reports due to the stronger and more widespread brain activation present in the REM state; when data are statistically checked for report length, qualitative differences would tend to diminish and often disappear. These findings support the so-called ''single dreaming generator'' hypothesis—that all sleep mentation derives from a common imagery source that is driven by different levels of brain activation.

Those who oppose such a hypothesis maintain that qualitative differences are not the result of longer report length. On the contrary, report length would depend on the characteristic features of dreaming

experiences, which require a greater number of words to explain them, as demonstrated especially by Hunt. If we consider the relations between REM and non-REM stage phenomenology and the neurochemical substrates underlying them, we can see how the debate is not a purely academic one but is quite important in the context of a general psychophysiological theory of dreaming.

On the whole, there is substantial agreement on the fact that when a subject is awakened during the REM stage of sleep, chances of obtaining a more precise report on dream-like mentation are highest. This appears to be the main stage for dreaming activity, but not the exclusive one. Indeed, nobody today would claim that dreaming is absolutely unique to REM sleep. Dream-like mentation, in fact, can be reported in every phase of sleep.

Dream-like mentation has been demonstrated even in certain waking situations. Several years ago, a series of experiments conducted at McGill University in Canada showed that subjects placed in conditions of isolation and sensory deprivation begin, after a certain time, to experience quite vivid pseudohallucinatory-type imagery. An abundance of dream-like mentation was elicited through a so-called "reverie technique" derived from the McGill studies and developed by Mario Bertini, Helen Lewis, and Herman Witkin at the Downstate Medical Center in New York. When put in a particularly monotonous and perceptually destructured environment, awake subjects often experience scattered images and even articulated scenes with a clear dream-like character. Such images, often as complex and bizarre as dreams, seem to appear spontaneously to the subject, sometimes beyond any voluntary effort or control.

Furthermore, this type of imagery can be experienced and reported during wakefulness even without using techniques aimed at facilitating its onset. David Foulkes had subjects lie in laboratory beds during the day and at regular intervals asked them to describe their experience. Most subjects seemed to forget their surroundings and reported vivid and bizarre episodes described as "hallucinatory daydreams" that were so compelling that they were briefly experienced as real. These and other empirical observations justify a growing interest in cutting across the traditional divisions between sleep and waking states and devoting more attention to understanding the functional unifying principles, and organizational coherence, of similar experiences in different states and, specifically, of dream-like experiences through REM, non-REM, and wake states.

VIII. THE FUNCTIONS AND THE MEANING OF DREAMING

Dreaming researchers are usually asked the following fundamental questions: What is the purpose of dreaming? Do dreams have any meaning?

A. The Functions of Dreaming

In answering the first question, today's dream researchers can take advantage of a wealth of precious information available on the physiological characteristics of the stage in which dreaming mainly takes place. This is important information, if only for the opportunity offered from a methodological standpoint, for anyone studying dreaming in a laboratory and from the perspective of one's own specific level of analysis. A problem arises when considering the usefulness of findings at a biological level for understanding the nature and function of dreaming at the mental level. If, as it obviously seems, an accurate description of the psychological sphere of dreaming cannot explain the underlying REM physiology, then the opposite must also be considered true: Finding a physiological basis for dreaming is not the same as explaining it.

While greatly respecting the separate levels of analysis and avoiding any dangerous reductionism toward one side or the other, I believe that a specific analysis of the interface between levels may be useful both for a flexible reformulating of the respective theories and for proposing a general theory of dreaming.

1. Dreaming and Memory Systems

The consistent presence in most dream reports of past memories intermixed with what Freud named "day residues" prompts the commonsense idea that dreaming plays a role in the organization and consolidation of what is experienced during waking.

The hypothesis that memories are consolidated during sleep is a long-standing one. In particular, the diffuse brain activation that characterizes REM sleep could provide the appropriate context for the modifications of synaptic strength within the circuits activated during the wake experience. Such changes are thought to represent the neural basis of memory consolidation.

The evidence in favor of this hypothesis, based mostly on animal experimental models, has been methodologically criticized and is countered by some negative findings. In particular, no damage to memory and learning has occurred after the use of major antidepressant drugs that cause a marked suppression of REM sleep. However, functional brain imaging studies have recently shown that the waking experience influences regional brain activity during subsequent sleep. Specifically, several brain areas that are activated during the execution of a task during wakefulness were significantly more active during REM sleep in subjects previously trained on the task than in nontrained subjects. These results support the hypothesis that memory traces are processed during REM sleep in humans.

Thus, the relation between memory and REM is probably more complex than indicated by the idea of a consolidation function. Special attention to REM state ontogenetic development may offer a first guideline to a better understanding of dreaming function.

2. The Relevance of REM Sleep in the Beginning of Life

As already mentioned, the quantity of REM is particularly high in the early stages of life, in which it is accompanied by the appearance of new behaviors (e.g., facial emotional expressions such as smiling, anger, or fear). The fact that this pattern manifests itself at a time of maximum development of the learning processes leads to a reflection on the role of REM sleep in the structural development of behaviors that are essential for survival.

Howard Roffwarg, Joseph Muzio, and William Dement first proposed that neonate REM sleep provides endogenous nervous system stimulation, which facilitates the maturation and differentiation of sensory and motor brain areas in the absence of external stimuli. Although not above criticism, this view has found credit with many scholars who, albeit with some variations, consider REM sleep to be functional to the general processing and adaptive reprocessing of learning and memory systems.

According to Jouvet, REM sleep would serve the maturation of species-specific basic behavioral patterns at the beginning of life, when there is the highest need for brain programming, as well as the modification and continuous revision of the programs after a certain age, when plasticity in interacting with environment is increasingly required. The shift from the substantial amount of REM sleep in the prenatal and early neonatal period to a sharp downward trend, observed between the second and third postnatal months, should constitute a critical period in the development of interaction between the infant and the environment.

The exchange between what is genetically preordained and rooted in the species' history and what is epigenetic and belonging to the subject's recent and distant past appears to be a suggestive hypothesis for the function of dreaming.

3. REM as a Paradoxical Event

It is possible to deeper into this field of complexity by reflecting on the physiologically peculiar characteristics of the REM stage that have suggested the adjective "paradoxical" for this phase (in fact, this phase appears to be a specific psychophysiological condition in which elevated EEG activity paradoxically coexists with deep muscle atonia and high threshold awakening).

If we monitor an adult human subject's nocturnal sleep by using polygraph recordings, we will find the following sequence of events: Before falling asleep, the EEG signal is mostly composed of low-amplitude, high-frequency waves that are typical of a state of alert activity of the cerebral cortex. Upon sleep onset the signal tends to become increasingly more ample and slower in frequency in direct relation to sleep depth and, therefore, to reduced vigilance. However, with the onset of the REM stage (after approximately 90–100 min) and for the whole duration of it, the EEG trace looks flatter and faster again, with characteristics similar to those of the waking state, even though the subject remains in a state of complete nonresponsiveness.

The paradoxical aspect of the transition from non-REM to REM sleep is that, in parallel with EEG signs of a generalized cortical reactivation, a further "detachment" from the outside world can be clearly observed. A mechanism of presynaptic inhibition originating in the brain stem reduces the input of sensory information from the environment (hence, the heightened awaking thresholds). Furthermore, with the exception of the oculomotor and middle ear muscles, a descending mechanism of postsynaptic inhibition causes a generalized tonic paralysis. Thus, during REM sleep the human organism appears disconnected from the outside world, but brain activity is quite intense, especially in certain regions.

Some researchers view paradoxical sleep and wakefulness as almost identical intrinsic functional states,

both able to generate subjective awareness. The difference is in the orientation of the attention. According to Rodolfo Llinas, REM sleep can be considered as a modified attentive state in which attention is turned away from the sensory input and toward memories. The idea of an attentive state of REM sleep receives further support from the similarities between some physiological features of this phase and the classic physiological counterparts of the wake Pavlovian orientation reflex.

Thus, the brain in REM sleep appears to shift to an off-line status where inhibition of the sensory and motor systems corresponds to an activation of limbic and paralimbic regions that neuroimaging studies have shown to be connected with memories and emotions. The subjective experience of dream imagery characteristic of this phase could be the result of such a shift.

The idea of a duality between executive control (i.e., the waking state) oriented toward the outside and a state that favors internal reprocessing (i.e., the sleep state) has prompted several researchers to use the metaphor of the computer, which at times is in the state of executing programs and at other times undergoes reprogramming. To a certain extent, the same concept can be found, in a less prosaic style, in Heraclitus' thinking: ''He who is awake lives in a single world common to all; he who is asleep retires to his own particular world.''

Some experiments in animals may provide further insight into the processes that take place in the REM phase. Michael Jouvet and subsequently Adrian Morrison obtained some interesting results when certain pontine nuclei known to be responsible for motor paralysis during REM sleep were lesioned in cats. Each time the animal entered REM sleep, it showed an astonishing pattern of highly organized but entirely automatic motor behaviors, such as orienting and exploring its territory, using the cat litter, licking itself, attacking an imaginary prey, and having a fit of rage. The animal seemed to act out basic instinctive and highly species-specific behavioral patterns. These experimental observations reinforced the previously mentioned hypothesis of a role of REM sleep in programming such patterns.

On the whole, psychophysiological data on the ontogenetic development and phenomenological characteristics of REM sleep have opened interpretational scenarios centered on the idea of a privileged function of the REM phase with respect to the adaptive organizing and reorganizing of memory systems. This function does not necessarily imply the subjective experience of dreaming; in principle, it is not necessary for the dream to be recalled in order to accomplish it.

B. Does Dreaming Have Any Meaning?

Everything that has been said so far about the REM stage (i.e., the long philogenetic history and the presence of a physiological mechanism guaranteeing its regular ultradian cycle) amply justifies the recognition of the important biological value attributed to a sleep stage that is also called dreaming stage because of its strong links with dream mentation. Moreover, the hypothesis that this biological function may be linked to processes that are crucial for the development and adaptive functioning of the mind is a reasonable one, even though not all researchers agree with it.

Even the most compelling evidence in favor of a primary role for the REM stage in mammalian physiology would not in itself justify the attribution of meaning to the subjective experience of dreaming. In principle, dreaming could be a mere by-product of a fundamental but still largely unknown biological function.

There is no doubt that all cultures throughout history have posited the meaningfulness of dreams. Modern neurophysiology as well as cognitive neuroscience have focused more on the dreaming process than on its content. In the most entrenched positions of these approaches, a question such as ''Is it possible to recognize the presence of a message or the intention to communicate in dreaming?'' would normally receive a negative answer.

The activation–synthesis theory supported by Hobson and McCarley, for example, maintains that dreaming is the result of a ''bad job'' carried out by the cerebral cortex when, intensely activated by random stimulation coming from the brain stem, it tries to provide a plausible narrative context for the stimulation. For more cognitiveley oriented scholars such as Foulkes, the precondition of dreaming is the relinquishment of the voluntary self-regulation and the consequent diffuse activation of mnemonic systems; the organization imposed by a dream production system on the mnemonic units is syntactic in nature, not semantic.

According to both views, dreaming is devoid of any meaningful intention. At the formal level of dream mentation, however, the interpretations differ. Hobson and MacCarley, more anchored to the biological side, believe that the formal aspects of dreams are

isomorphic expressions of the peculiar physiological state of REM sleep. According to Foulkes dream mentation is substantially independent from the REM physiology and under the direct control of the same narrative-linguistic generator that controls cognitive processes during wakefulness. In both cases, we are evidently a long way from the Freudian view, whereby the manifest content of dreams conveys a censored deeper latent message to be decoded that strongly points to the dreamer's unconscious problems.

It must be stressed, however, that even in modern neuroscientific literature, there is wide agreement that dreams do convey some sort of meaning and reveal something about the dreamer. The information may be of two types. The first kind concerns the peculiar characteristics of the processes with which the dreamer constructs the dream. This aspect is particularly meaningful for cognitive sciences. Authoritative scholars hold that, applying the same cognitive–linguistic methods of analysis used in waking or stimulus-dependent narrations, the study of self-organizational mechanisms of dreaming may yield information of great value not only concerning dreaming but also on all those forms of stimulus-independent thought occurring spontaneously over the 24-h period. In this sense, although it is true that the application of the cognitive approaches is certainly useful for the study of dreaming, we should not overlook the importance of studying the mind's involuntary organizing system, in REM as well as in other sleep and wake conditions, in order to broaden our knowledge of the overall mental functioning.

A second, generally accepted notion concerns dreams as sources of information on the dreamer's personality. For example, the fact that some people may experience more frequent dreams of certain expressive or conflictual contents rather than others may, with suitable care and attention to context, provide indirect indications of the dreamer's personality. In this view, which implies the possibility of diverse clinical applications, the dream is "informative" and not "intentional" in nature.

Other perspectives that are worth considering view dream not as "random nonsense" but as a different form of intelligence with respect to that expressed in the rational, logical forms more typical of wakefulness (i.e., not alternative but complementary to it). In line with certain anticipatory views expressed by Jung, Harry Hunt summarizes this concept as follows:

A host of contemporary "dream-workers" holds that the emergent sources of dreaming, at least much of the time, are not "primitive" or "disruptive" at all. Rather, they constitute the spontaneous expressions of a symbolic intelligence alternative to standard representational thought and variously termed "imagistic," "affective," or "presentational". … I would not want … to imply an adherence to rigid dual code models of human intelligence, which tend to distinguish an abstract verbal capacity from a more rudimentary imagistic one. Not only is the latter fully capable of its own line of abstract development, as seen in certain dreams, alterations of consciousness, and aesthetics, but each of these "frames" seems capable of endlessly, complex interactions at all levels of their potential unfolding.

IX. CONCLUDING REMARKS

Studies carried out during the past 50 years, particularly those using recent neuroimaging techniques, show that the areas of the central nervous system that seem more active in REM sleep are found in the brain stem, in the limbic system, and in secondary, associative cortical areas, at variance with the alert waking state, during which the frontal lobes and the primary sensory and motor cortices are privileged. Thus, the stage of sleep in which dreaming has its greatest expression appears to be characterized by a prevalent orientation toward the inner world of memories and emotions. In line with this view, the adjective "paradoxical," as applied to the REM stage, may sound improper. Its physiological characteristics, in fact, appear perfectly orthodox if considered as an expression of a positive and qualitative shifting toward a greater resonance of the inner world—a shifting, however, that although paradigmatic for the REM state, may be available throughout the sleep and wake cycle.

As discussed earlier, a variety of findings encourage stepping beyond the Manichean barriers separating the states of wakefulness, REM sleep, and non-REM sleep in order to appreciate the continuity of the mind across these states. For instance, although it may be true that mentation during REM is largely bizarre, systematic demonstrations indicate that REM dream content also shows a heavy reliance on representations of familiar elements from the waking environment. By the same token, if it is true that during the awake state resources are usually employed in relating to the external environment, there are still opportunities for coding operations and processing of internal material. Consider, for instance, the fantasy activity conceived

as ongoing information processing. As Jerome Singer states, "the popular notion of a daydream represents only one manifestation of a more general class of phenomena perhaps best described as internally generated diversion from an ongoing motor or cognitive task." There is evidence that some type of coding and restructuring of long-term stored material goes on a great deal of the time while the organism is awake.

The critical point that needs further examination is the psychophysiological significance of this shifting. The first question is whether accessing and activating the previously mentioned brain areas in the REM stage—besides serving a possible, although not yet known, biological function—involves any direct functional value for the mind. Second, the problem arises of the semantic meaning of dream and dream-like mentation; as stated earlier, dreaming activity could in principle produce some objective organizational benefit to the mind, independently from the subjective experiencing of dreaming and from the content of the experienced dream, and that organizational benefit may be augmented by dream recall and interpretation.

An overview of the different positions on these issues shows that scholars in the broader field of dreaming can be divided into approximately two groups. On the one hand are those who, although not rejecting the adaptive hypothesis, from various angles and with different reasoning tend to characterize dream mentation as a degradation of the self-conscious, self-controlled thought of wakefulness. For example, sleep physiologist Giuseppe Moruzzi, while maintaining that sleep has a function coherent with the need to restore the myriad of cerebral neural networks, also believed dreaming to be the expression of an "impoverished conscience." Taking into account the intense activity of the brain in REM sleep, he stated that "the plastic debt accumulated during wakefulness could be paid while the cortical neurons continued to discharge impulses, even if in a different way than usual." Loss of consciousness could thus be the result not of a silence but of the temporary loss of a meaningful dialogue between nerve cells.

On the other hand, there are scholars who view REM sleep as a privileged theater for the type of plastic revision on which the adaptive flexibility of our central nervous system is based. In their view, accessing memory stores may set the potential for creating new associations, rearranging past patterns, and reformulating future plans in accord with experiences of the day. Rather than "temporary loss of a meaningful dialogue," dreaming represents the "temporary emergence of a differently meaningful dialogue." In such a perspective, at least some dreaming would be the expression of an alternative form of "intelligence," common to a variety of thinking modalities leaning toward the imagery and metaphoric side of the human vast symbolic capacity. A "symbolic–presentational" form of intelligence (Susanne Langer's terminology), although semantic and communicative, resists a complete narrative formulation when compared to the "symbolic–representational" intelligence that prevails in the vigilant waking state.

In 1890, William James stated: "Our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, whilst all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different." Thus, even though the age-old dilemma of dreaming has been engaged by modern science, we still remain within the interpretational dualism that has characterized the history of thought on dreaming. The work carried out during the past 50 years, however, seems to justify a certain optimism with respect to a converging of views in the near future.

Dyslexia

H. BRANCH COSLETT
University of Pennsylvania School of Medicine

GLOSSARY

central dyslexia A reading disorder caused by impairment of the "deeper" or "higher" reading functions by which letter strings mediate access to meaning or speech production mechanisms.

deep dyslexia A disorder characterized by semantic errors (e.g., "king" read as "prince"), poor reading of abstract compared to concrete words (e.g., "idea" vs "desk"), and an inability to "sound out" words.

peripheral dyslexia A reading disorder attributable to a disruption of the processing of visual aspects of the stimulus that prevents the patient from reliably processing a letter string.

phonologic dyslexia A disorder characterized by a largely preserved ability to read familiar words but an inability to read unfamiliar words or nonword letter strings (e.g., "flig") because of an inability to use a "sounding out" strategy.

surface dyslexia A disorder characterized by reliance on a "sounding out" strategy with the result that words that have atypical print-to-sound correspondences are read incorrectly (e.g., "yacht" read as "yatchet").

Unlike the ability to speak, which has presumably evolved over tens of thousands of years, the ability to read is a relatively recent development that is dependent on both the capacity to process complex visual stimuli and the ability to link the visual stimulus to phonologic, syntactic, and other language capacities. Perhaps as a consequence of the wide range of cognitive operations involved, reading is compromised in many patients with cerebral lesions, particularly those involving the left hemisphere. The resultant reading impairments, or acquired dyslexias, take many different forms, reflecting the breakdown of specific components of the reading process. In this article, I briefly review the history of the study of acquired dyslexia and introduce a model of the processes involved in normal reading. Specific syndromes of acquired dyslexia are discussed. I also briefly discuss connectionist accounts of reading and the anatomic basis of reading as revealed by recent functional imaging studies.

I. HISTORICAL OVERVIEW

Perhaps the most influential early contributions to the understanding of dyslexia were provided in the 1890s by Dejerine, who described two patients with quite different patterns of reading impairment. Dejerine's first patient manifested impaired reading and writing subsequent to an infarction involving the left parietal lobe. Dejerine termed this disorder "alexia with agraphia" and attributed the disturbance to a disruption of the "optical image of words" that he thought to be supported by the left angular gyrus. In an account that in some respects presages contemporary psychological accounts, Dejerine concluded that reading and writing required the activation of these optical images

and that the loss of the images resulted in the inability to recognize or write even familiar words.

Dejerine's second patient was quite different. This patient exhibited a right homonymous hemianopia and was unable to read aloud or for comprehension but could write. This disorder, designated "alexia without agraphia" (also known as agnosic alexia and pure alexia), was attributed by Dejerine to a "disconnection" between visual information presented to the right hemisphere and the left angular gyrus that he assumed to be critical for the recognition of words.

After the seminal contributions of Dejerine, the study of acquired dyslexia languished for decades, during which time the relatively few investigations that were reported focused primarily on the anatomic underpinnings of the disorders. The field was revitalized by the elegant and detailed analysis by Marshall and Newcombe that demonstrated that by virtue of a careful investigation of the pattern of reading deficits exhibited by dyslexic subjects, distinctly different and reproducible types of reading deficits could be elucidated. The insights provided by Marshall and Newcombe provided much of the basis for the "dual-route" model of word reading.

II. READING MECHANISMS AND THE CLASSIFICATION OF DYSLEXIAS

Reading is a complicated process that involves many different procedures, including low-level visual processing, accessing meaning and phonology, and motor aspects of speech production. Figure 1 provides a graphic depiction of the relationship between these procedures. This "information processing" model will serve as the basis for the discussion of the mechanisms involved in reading and the specific forms of acquired dyslexia. It must be noted, however, that the dual-route model of reading that will be employed for purposes of exposition is not uncontested. Alternatives to the information processing accounts, such as the triangle model of Plaut, Seidenberg, McClelland, and colleagues, will also be discussed.

Reading requires that the visual system efficiently process a complicated stimulus that, at least for alphabet-based languages, is composed of smaller meaningful units—letters. In part because the number of letters is small in relation to the number of words, there is often a considerable visual similarity between words (e.g., "structure" vs "stricture"). Additionally, the position of letters within the letter string is also critical to word identification (consider "mast" vs "mats"). In light of these factors, it is perhaps not surprising that reading places a substantial burden on the visual system and that disorders of visual processing or visual attention may substantially disrupt reading.

Normal readers recognize written words so rapidly and seemingly effortlessly that one might suspect that the word is identified as a unit, much as we identify an object from its visual form. At least for normal readers under standard conditions, this does not appear to be the case. Instead, analyses of normal reading suggest that word recognition requires that letters be identified as alphabetic symbols. Support for this claim comes from demonstrations that presenting words in an unfamiliar form—for example, by alternating the case of the letters (e.g., wOrD) or introducing spaces between words (e.g., f o o d)—does not substantially influence reading speed or accuracy. These data argue for a stage of letter identification in which the graphic form (whether printed or written) is transformed into a string of alphabetic characters (W-O-R-D), sometimes referred to as abstract letter identities.

The mechanism by which the position of letters within the stimulus is determined and maintained is not clear. Possibilities include associating the letter in position 1 to the letter in position 2, and so on; binding each letter to a frame that specifies letter position; or labeling each letter with its position in the word. Finally, it should be noted that in normal circumstances letters are not processed in a strictly serial fashion but letter strings are processed in parallel (provided they are not too long). Disorders of reading resulting from impairment in the processing of the visual stimulus or the failure of this visual information to contact stored knowledge appropriate to a letter string are designated as peripheral dyslexias.

In dual-route models of reading, the identity of a letter string may be determined by many distinct procedures. The first is a "lexical" procedure by which the letter string is identified by means of matching the letter string to an entry in a stored catalog of familiar words, or visual word form system. As indicated in Fig. 1 and discussed later, this procedure, which in some respects is similar to looking up a word in a dictionary, provides access to the meaning, phonologic form, and at least some of the syntactic properties of the word. Dual-route models of reading also assume that the letter string can be converted directly to a phonological form by means of the application of a set of learned correspondences between orthography and phonology. On this account, meaning may then be accessed from the phonologic form of the word.

Support for dual-route models of reading comes from a variety of sources. For present purposes, perhaps the most relevant evidence was provided by Marshall and Newcombe's groundbreaking description of "deep" and "surface" dyslexia. These investigators described a patient (GR) who read approximately 50% of concrete nouns (e.g., "table" and "doughnut") but was severely impaired in the reading of abstract nouns (e.g., "destiny" and "truth") and all other parts of speech. The most striking aspect of GR's performance, however, was his tendency to produce errors that appeared to be semantically related to the target word (e.g., "speak" read as "talk"). Marshall and Newcombe designated this disorder deep dyslexia. These investigators also described two patients whose primary deficit appeared to be an inability to reliably apply grapheme–phoneme correspondences. Thus, JC, for example, rarely applied the rule of "e" (which lengthens the preceding vowel in words such as "like") and experienced great difficulties in deriving the appropriate phonology for consonant clusters and vowel digraphs. The disorder characterized by impaired application of print-to-sound correspondences was termed surface dyslexia.

On the basis of these observations, Marshall and Newcombe argued that the meaning of written words could be accessed by two distinct procedures. The first was a direct procedure whereby familiar words activated the appropriate stored representation (or visual word form), which in turn activated meaning directly; reading in deep dyslexia, which was characterized by semantically based errors (of which the patient was often unaware), was assumed to involve this procedure. The second procedure was assumed to be a phonologically based process in which grapheme-to-phoneme or print-to-sound correspondences were employed to derive the appropriate phonology (or "sound out" the word); the reading of surface dyslexics was assumed to be mediated by this nonlexical procedure. Although many of Marshall and Newcombe's specific hypotheses have subsequently been criticized, their argument that reading may be mediated by two distinct procedures has received considerable empirical support.

The information processing model of reading depicted in Fig. 1 provides three distinct procedures for oral reading. Two of these procedures correspond to those described by Marshall and Newcombe. The first (Fig. 1A), involves the activation of a stored entry in the visual word form system and the subsequent access to semantic information and ultimately activation of the stored sound of the word at the level of the phonologic output lexicon. The second (Fig. 1B), involves the nonlexical grapheme-to-phoneme or print-to-sound translation process; this procedure does not entail access to any stored information about words but, rather, is assumed to be mediated by access to a catalog of correspondences stipulating the pronunciation of phonemes. Many information processing accounts of the language mechanisms subserving reading incorporate a third procedure. This mechanism (Fig. 1C), is lexically based in that it is assumed to involve the activation of the visual word form system and the phonologic output lexicon. The procedure differs from the lexical procedure described previously, however, in that there is no intervening activation of semantic information. This procedure has been called the direct reading mechanism or route. Support for the direct lexical mechanism comes from many sources, including observations that some subjects read aloud words that they do not appear to comprehend. For example, Coslett reported a patient whose inability to read aloud nonwords (e.g., "flig") suggested that she was unable to employ print-to-sound conversion procedures. Additionally, she exhibited semantic errors in writing and repetition and performed poorly on a synonymy judgment task with low imageability words, suggesting that semantic representations were imprecise. Semantic errors and imageability effects were not observed in reading; additionally, she read aloud low imageability words as well as many other words that she appeared to be unable to comprehend. Both observations suggest that her oral reading was not mediated by semantics. We argued that these data provided evidence for a reading mechanism that is independent of semantic representations and does not entail print-to-sound conversion—that is, a direct route from visual word forms to the phonological output representations.

III. PERIPHERAL DYSLEXIAS

A useful starting point in the discussion of acquired dyslexia is the distinction made by Shallice and Warrington between "peripheral" and "central" dyslexias. The former are conditions characterized by a deficit in the processing of visual aspects of the stimulus that prevents the patient from reliably matching a familiar word to its stored visual form or visual word form. In contrast, central dyslexias reflect impairment to the "deeper" or "higher" reading functions by which visual word forms mediate access to meaning to speech production mechanisms. In the

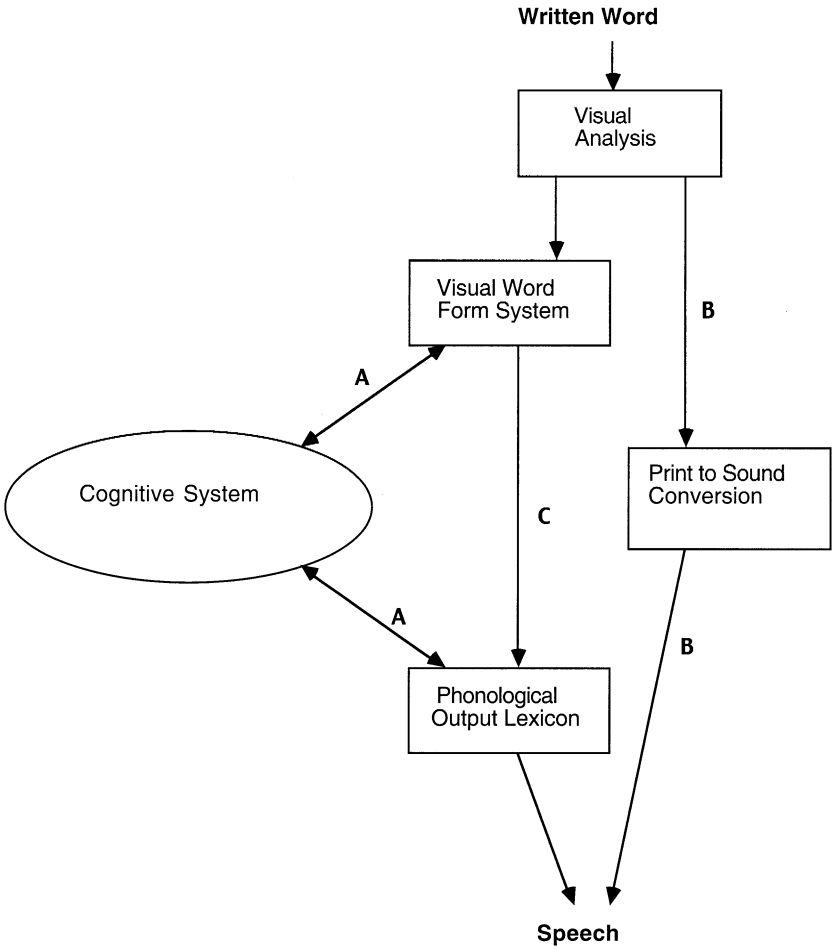

Figure 1 The relationship between the procedures involved in reading.

following sections, I discuss the major types of peripheral dyslexia.

A. Alexia without Agraphia (Pure Alexia; Letter-by-Letter Reading)

This disorder is among the most common of the peripheral reading disturbances. It is associated with a left hemisphere lesion affecting left occipital cortex (responsible for the analysis of visual stimuli on the right side of space) and/or the structures (left lateral geniculate nucleus of the thalamus and white matter, including callosal fibers from the intact right visual cortex) that provide input to this region of the brain. It is likely that the lesion either blocks direct visual input to the mechanisms that process printed words in the left hemisphere or disrupts the visual word form system. Some of these patients seem to be unable to read at all, whereas others do so slowly and laboriously by means of a process that involves serial letter identification (often termed "letter-by-letter" reading). At first, letter-by-letter readers often pronounce the letter names aloud; in some cases, they misidentify letters, usually on the basis of visual similarity, as in the case of N → M. Their reading is also abnormally slow.

It was long thought that patients with pure alexia were unable to read except letter by letter. There is now evidence that some of them do retain the ability to recognize letter strings, although this does not guarantee that they will be able to read aloud. Several different paradigms have demonstrated the preservation of word recognition. Some patients demonstrate a word superiority effect of superior letter recognition when the letter is part of a word (e.g., the "R" in "WORD") than when it occurs in a string of unrelated

letters (e.g., "WKRD"). Second, some of them have been able to perform lexical decision tasks (determining whether a letter string constitutes a real word or not) and semantic categorization tasks (indicating whether or not a word belongs to a category, such as foods or animals) at above chance levels when words are presented too rapidly to support letter-by-letter reading. Brevity of presentation is critical in that longer exposure to the letter string seems to engage the letter-by-letter strategy, which appears to interfere with the ability to perform the covert reading task. In fact, the patient may show better performance on lexical decision at shorter (e.g., 250 msec) than at longer presentations (e.g., 2 sec) that engage the letter-by-letter strategy but do not allow it to proceed to completion. A compelling example comes from a previously reported patient who was given 2 sec to scan the card containing the stimulus. The patient did not take advantage of the full inspection time when he was performing lexical decision and categorization tasks; instead, he glanced at the card briefly and looked away, perhaps to avoid letter-by-letter reading. The capacity for covert reading has also been demonstrated in two pure alexics who were completely unable to employ the letter-by-letter reading strategy. These patients appeared to recognize words but were rarely able to report them, although they sometimes generated descriptions that were related to the word's meaning (e.g., "cookies" → "candy, a cake"). In some cases, patients have shown some recovery of oral reading over time, although this capacity appears to be limited to concrete words.

The mechanisms that underlie implicit or covert reading remain controversial. Dejerine, who provided the first description of pure alexia, suggested that the analysis of visual input in these patients is performed by the right hemisphere as a result of the damage to the visual cortex on the left. It should be noted, however, that not all lesions to the left visual cortex give rise to alexia. A critical feature that supports continued left hemisphere processing is the preservation of callosal input from the visual processing on the right. One possible account is that covert reading reflects printed word recognition on the part of the right hemisphere, which is unable either to articulate the word or (in most cases) to adequately communicate its identity to the language area of the left hemisphere. By this account, letter-by-letter reading is carried out by the left hemisphere using letter information transferred serially and inefficiently from the right. Furthermore, this assumes that when the letter-by-letter strategy is implemented, it may be difficult for the patient to attend to the products of word processing in the right hemisphere. Consequently, performance on lexical decision and categorization tasks declines. Additional evidence supporting the right hemisphere account of reading in pure alexia is presented later.

Alternative accounts of pure alexia have also been proposed. Behrmann and colleagues, for example, proposed that the disorder is attributable to impaired activation of orthographic representations. By this account, reading is assumed to reflect the residual functioning of the same interactive system that supported normal reading premorbidly.

Other investigators have attributed pure dyslexia to a visual impairment that precludes activation of orthographic representations. Chialant and Caramazza, for example, reported a patient, MJ, who processed single, visually presented letters normally and performed well on a variety of tasks assessing the orthographic lexicon with auditorily presented stimuli. In contrast, MJ exhibited significant impairments in the processing of letter strings. The investigators suggest that MJ was unable to transfer information from the intact visual processing system in the right hemisphere to the intact language processing mechanisms of the left hemisphere.

B. Neglect Dyslexia

Parietal lobe lesions can result in a deficit that involves neglect of stimuli on the side of space contralateral to the lesion, a disorder referred to as hemispatial. In most cases, this disturbance arises with damage to the right parietal lobe; therefore, attention to the left side of space is most often affected. The severity of neglect is generally greater when there are stimuli on the right as well as on the left; attention is drawn to the right-sided stimuli at the expense of those on the left—a phenomenon known as "extinction." Typical clinical manifestations include bumping into objects on the left, failure to dress the left side of the body, drawing objects that are incomplete on the left, and reading problems that involve neglect of the left portions of words (i.e., neglect dyslexia).

With respect to neglect dyslexia, it has been found that such patients are more likely to ignore letters in nonwords (e.g., the first two letters in "bruggle") than letters in real words (compare with "snuggle"). This suggests that the problem does not reflect a total failure to process letter information but, rather, an attentional impairment that affects conscious recognition of the letters. Performance often improves when words are

presented vertically or spelled aloud. In addition, there is evidence that semantic information can be processed in neglect dyslexia, and that the ability to read words aloud improves when oral reading follows a semantic task.

Neglect dyslexia has also been reported in patients with left hemisphere lesions. In these patients, the deficiency involves the right side of words. Here, visual neglect is usually confined to words and is not ameliorated by presenting words vertically or spelling them aloud. This disorder has therefore been termed a "positional dyslexia," whereas the right hemisphere deficit has been termed a "spatial neglect dyslexia."

C. Attentional Dyslexia

Attentional dyslexia is a disorder characterized by at least relatively preserved reading of single words but impaired reading of words in the context of other words or letters. This infrequently reported disorder was first described by Shallice and Warrington, who reported two patients with brain tumors involving (at least) the left parietal lobe. Both patients exhibited relatively good performance with single letters or words but were significantly impaired in the recognition of the same stimuli when presented as part of an array. For example, both patients read single letters accurately but made significantly more errors naming letters when presented as part of 3×3 or 5×5 arrays. Similarly, both patients correctly read more than 90% of single words but read only approximately 80% of words when presented in the context of three additional words. Although not fully investigated, it is worth noting that the patients were also impaired in recognizing line drawings and silhouettes when presented in an array.

Two additional observations from these patients warrant attention. First, Shallice and Warrington demonstrated that for both patients naming of single black letters was adversely affected by the simultaneous presentation of red flanking stimuli and that flanking letters were more disruptive than numbers. For example, both subjects were more likely to correctly name the black (middle) letter when presented "37L82" compared to "ajGyr." Second, the investigators examined the errors produced in the tasks in which patients were asked to report letters and words in rows of two to four items. They found different error patterns with letters and words. Whereas both patients tended to err in the letter report task by naming letters that appeared in a different location in the array, patients often named words that were not present in the array. Interestingly, many of these errors were interpretable as letter transpositions between words. Citing the differential effects of letter versus number flankers as well as the absence of findings suggesting a deficit in response selection, these investigators attributed the disorder to a failure of transmission of information from a nonsemantic perceptual stage to a semantic processing stage. Another patient, BAL, was also reported by Warrington and colleagues. BAL was able to read single words but exhibited a substantial impairment in the reading of letters and words in an array. BAL exhibited no evidence of visual disorientation and was able to identify a target letter in an array of "X"s or "O"s. He was impaired, however, in the naming of letters or words when these stimuli were flanked by other members of the same stimulus category. This patient's attentional dyslexia was attributed to an impairment arising after words and letters had processed as units.

Recently, Saffran and Coslett reported a patient, NY, with biopsy-proven Alzheimer's disease that appeared to selectively involve posterior cortical regions who exhibited attentional dyslexia. NY scored within the normal range on verbal subtests of the WAIS-R but was unable to perform any of the performance subtests. He performed normally on the Boston Naming Test but performed quite poorly on a variety of experimental tasks assessing visuospatial processing and visual attention. Despite his visuoperceptual deficits, NY's reading of single words was essentially normal. He read 96% of 200 words presented for 100 msec (unmasked). Like previously reported patients with this disorder, NY exhibited a substantial decline in performance when asked to read two words presented simultaneoulsy. He read both words correctly in only 50% of 385 trials with a 250-msec stimulus exposure. Most errors were omissions of one word. Of greatest interest, however, was the fact that NY produced a substantial number of "blend" errors in which letters from the two words were combined to generate a response that was not present in the display. For example, when shown "flip shot," NY responded "ship." Like the blend errors produced by normal subjects with brief stimulus presentation. NY's blend errors were characterized by the preservation of letter position information; thus, in the preceding example, the letters in the blend response ("ship") retained the same serial position in the incorrect response. NY produced significantly more blend errors than did five controls whose overall level of performance had been matched to NY's by virtue of

brief stimulus exposure (range, 17–83 msec). A subsequent experiment demonstrated that for NY, but not for controls, blend errors were encountered significantly less often when the target words differed in case (''desk FEAR'').

Saffran and Coslett considered the central deficit in attentional dyslexia to be impaired control of a filtering mechanism that normally serves to suppress input from unattended words or letters in the display. Specifically, they suggested that as a consequence of the patient's inability to effectively deploy the ''spotlight'' of attention to a particular region of interest (e.g., a single word or a single letter), multiple stimuli fall within the attentional spotlight. Because visual attention may serve to integrate visual feature information, impaired modulation of the spotlight of attention would be expected to generate word blends and other errors reflecting the incorrect concatenation of letters.

Saffran and Coslett also argued that loss of location information also contributed to NY's reading deficit. Several lines of evidence support such a conclusion. First, NY was impaired relative to controls with respect to both accuracy and reaction time on a task in which he was required to indicate if a line was inside or outside a circle. Second, NY exhibited a clear tendency to omit one member of a double-letter pair (e.g., ''reed'' → ''red''). This phenomenon, also demonstrated in normal subjects, has been attributed to the loss of location information that normally helps to differentiate two tokens of the same object. Finally, it should be noted that the well-documented observation that the blend errors of normal subjects and attentional dyslexics preserve letter position is not inconsistent with the claim that impaired location information contributes to attentional dyslexia. Migration or blend errors reflect a failure to link words or letters to a location in space, whereas the letter position constraint reflects the properties of the word processing system. The latter, which is assumed to be at least relatively intact in patients with attentional dyslexia, specifies letter location with respect to the word form rather than space.

D. Other Peripheral Dyslexias

Peripheral dyslexias may be observed in a variety of conditions involving visuoperceptual or attentional deficits. Patients with simultanagnosia, a disorder characterized by an inability to ''see'' more than one object in an array, are often able to read single words but are incapable of reading text. Other patients with simultanagnosia exhibit substantial problems in reading even single words.

Patients with degenerative conditions involving the posterior cortical regions may also exhibit profound deficits in reading as part of their more general impairment in visuospatial processing. Several patterns of impairment may be observed in these patients. Some patients exhibit attentional dyslexia with letter migration and blend errors, whereas other patients exhibiting deficits that are in certain respects similar do not produce migration or blend errors in reading or illusory conjuctions in visual search tasks. It has been suggested that at least some patients with these disorders suffer from a progressive restriction in the domain to which they can allocate visual attention. As a consequence of this impairment, these patients may exhibit an effect of stimulus size such that they are able to read a word in small print but when shown the same word in large print see only a single letter.

IV. CENTRAL DYSLEXIAS

A. Deep Dyslexia

Deep dyslexia, initially described by Marshall and Newcombe in 1973, is the most extensively investigated of the central dyslexias and, in many respects, the most compelling. Interest in deep dyslexia is due in large part to the intrinsically interesting hallmark of the syndrome—the production of semantic errors. Shown the word ''castle,'' a deep dyslexic may respond ''knight''; shown the word ''bird,'' the patient may respond ''canary.'' At least for some deep dyslexics, it is clear that these errors are not circumlocutions. Semantic errors may represent the most frequent error type in some deep dyslexics, whereas in other patients they comprise a small proportion of reading errors. Deep dyslexics also typically produce frequent ''visual'' errors (e.g., ''skate'' read as ''scale'') and morphological errors in which a prefix or suffix is added, deleted, or substituted (e.g., ''scolded'' read as ''scolds'' and ''governor'' read as ''government'').

Additional features of the syndrome include a greater success in reading words of high compared to low imageability. Thus, words such as ''table,'' ''chair,'' ''ceiling,'' and ''buttercup,'' the referent of which is concrete or imageable, are read more successfully than words such as ''fate,'' ''destiny,'' ''wish,'' and ''universal,'' which denote abstract concepts.

Another characteristic feature of deep dyslexia is a part of speech effect such that nouns are typically read more reliably than modifiers (adjectives and adverbs), which are in turn read more accurately than verbs. Deep dyslexics manifest particular difficulty in the reading of functors (a class of words that includes pronouns, prepositions, conjunctions, and interrogatives including "that," "which," "they," "because," and "under"). The striking nature of the part of speech effect may be illustrated by the patient who correctly read the word "chrysanthemum" but was unable to read the word "the." Most errors to functors involve the substitution of a different functor ("that" read as "which") rather than the production of words of a different class, such as nouns or verbs. Because functors are in general less imageable than nouns, some investigators have claimed that the apparent effect of part of speech is in reality a manifestation of the pervasive imageability effect. There is no consensus on this point because other investigators have suggested that the part of speech effect is observed even if stimuli are matched for imageability.

All deep dyslexics exhibit a substantial impairment in the reading of nonwords. When confronted with letter strings such as "flig" or "churt," deep dyslexics are typically unable to employ print-to-sound correspondences to derive phonology; nonwords frequently elicit "lexicalization" errors (e.g., "flig" read as "flag"), perhaps reflecting a reliance on lexical reading in the absence of access to reliable print-to-sound correspondences.

Finally, it should be noted that the accuracy of oral reading may be determined by context. This is illustrated by the fact that a patient was able to read aloud the word "car" when it was a noun but not when the same letter string was a conjunction. Thus, when presented the sentence "Le car ralentit car le moteur chauffe" ("The car slowed down because the motor overheated"), the patient correctly pronounced only the first instance of "car." Recently, three deep dyslexics were demonstrated to read function and content words better in a sentence context than when presented alone.

How can deep dyslexia be accommodated by the information processing model of reading illustrated in Fig. 1? Several alternative explanations have been proposed. Some investigators have argued that the reading of deep dyslexics is mediated by a damaged form of the left hemisphere-based system employed in normal reading. In such a hypothesis, multiple processing deficits must be hypothesized to accommodate the full range of symptoms characteristic of deep dyslexia. First, the strikingly impaired performance in reading nonwords and other tasks assessing phonologic function suggests that the print-to-sound conversion procedure is disrupted. Second, the presence of semantic errors and the effects of imageability (a variable thought to influence processing at the level of semantics) suggest that these patients also suffer from a semantic impairment. Lastly, the production of visual errors suggests that these patients suffer from impairment in the visual word form system or in the processes mediating access to the visual word form system.

Other investigators have argued that deep dyslexics' reading is mediated by a system not normally used in reading (i.e., the right hemisphere). Finally, citing evidence from functional imaging studies demonstrating that deep dyslexic subjects exhibit increased activation in both the right hemisphere and nonperisylvian areas of the left hemisphere, other investigators have suggested that deep dyslexia reflects the recruitment of both right and left hemisphere processes.

B. Phonological Dyslexia: Reading without Print-to-Sound Correspondences

First described in 1979, phonologic dyslexia is perhaps the "purest" of the central dyslexias in that, at least by some accounts, the syndrome is attributable to a selective deficit in the procedure mediating the translation from print to sound. Thus, although in many respects less arresting than deep dyslexia, phonological dyslexia is of considerable theoretical interest.

Phonologic dyslexia is a disorder in which reading of real words may be nearly intact or only mildly impaired. Patients with this disorder, for example, correctly read 85–95% of real words. Some patients read all different types of words with equal facility, whereas other patients are relatively impaired in the reading of functors (or "little words"). Unlike patients with surface dyslexia described later, the regularity of print-to-sound correspondences is not relevant to their performance; thus, phonologic dyslexics are as likely to correctly pronounce orthographically irregular words such as "colonel" as words with standard print-to-sound correspondences such as "administer." Most errors in response to real words bear a visual similarity to the target word (e.g., "topple" read as "table").

The striking and theoretically relevant aspect of the performance of phonologic dyslexics is a substantial impairment in the oral reading of nonword letter

strings. We have examined patients with this disorder, for example, who read >90% of real words of all types but correctly pronounce only approximately 10% of nonwords. Most errors to nonwords involve the substitution of a visually similar real word (e.g., ''phope'' read as ''phone'') or the incorrect application of print-to-sound correspondences [e.g., ''stime'' read as ''stim'' (to rhyme with ''him'')].

Within the context of the reading model depicted in Fig. 1, the account for this disorder is relatively straightforward. Good performance with real words suggests that the processes involved in normal lexical reading (i.e., visual analysis, the visual word form system, semantics, and the phonological output lexicon) are at least relatively preserved. The impairment in nonword reading suggests that the print-to-sound translation procedure is disrupted.

Recent explorations of the processes involved in nonword reading have identified many distinct procedures involved in this task. If these distinct procedures may be selectively impaired by brain injury, one might expect to observe different subtypes of phonologic dyslexia. Although the details are beyond the scope of this article, there is evidence suggesting that different subtypes of phonologic dyslexia may be observed.

Lastly, it should be noted that several investigators have suggested that phonologic dyslexia is not attributable to a disruption of a reading-specific component of the cognitive architecture but, rather, to a more general phonologic deficit. Support for this assertion comes from the observation that the vast majority of phonologic dyslexics are impaired on a wide variety of nonreading tasks assessing phonology.

In certain respects, phonologic dyslexia is similar to deep dyslexia, the critical difference being that semantic errors are not observed in phonologic dyslexia. Citing the similarity of reading performance and the fact that deep dyslexics may evolve into phonologic dyslexics as they improve, it has been argued that deep and phonologic dyslexia are on a continuum of severity.

C. Surface Dyslexia: Reading without Lexical Access

Surface dyslexia, first described by Marshall and Newcombe, is a disorder characterized by the relatively preserved ability to read words with regular or predictable grapheme-to-phoneme correspondences but substantially impaired reading of words with ''irregular'' or exceptional print-to-sound correspondences. Thus, patients with surface dyslexia typically are able to read words such as ''state,'' ''hand,'' ''mosquito,'' and ''abdominal'' quite well, whereas they exhibit substantial problems reading words such as ''colonel,'' ''yacht,'' ''island,'' and ''borough,'' the pronunciation of which cannot be derived by sounding out strategies. Errors to irregular words usually consist of ''regularizations''; for example, surface dyslexics may read ''colonel'' as ''kollonel.'' These patients read nonwords (e.g., ''blape'') quite well. Finally, it should be noted that all surface dyslexics reported to date read at least some irregular words correctly; patients will often read high-frequency irregular words (e.g., ''have'' and ''some'') but some surface dyslexics have been reported to read such low-frequency and highly irregular words as ''sieve'' and ''isle.''

As noted previously, some accounts of normal reading postulate that familiar words are read aloud by matching the letter string to a stored representation of the word and retrieving the pronunciation by means of a mechanism linked to semantics or by means of a ''direct'' route. A critical point to note is that because reading involves stored associations of letter strings and sounds, the pronunciation of the word is not computed by rules but is retrieved, and therefore whether the word contains regular or irregular correspondences does not appear to play a major role in performance.

The fact that the nature of the print-to-sound correspondences significantly influences performance in surface dyslexia suggests that the deficit in this syndrome is in the mechanisms mediating lexical reading—that is, in the semantically mediated and ''direct'' reading mechanisms. Similarly, the preserved ability to read words and nonwords demonstrates that the procedures by which words are sounded out are at least relatively preserved.

In the context of the information processing discussed previously, how would one account for surface dyslexia? Scrutiny of the model depicted in Fig. 1 suggests that at least three different deficits may result in surface dyslexia. First, this disorder may arise from a deficit at the level of the visual word form system that disrupts the processing of words as units. As a consequence of this deficit, subjects may identify ''sublexical'' units (e.g., graphemes or clusters of graphemes) and identify words on the basis of print-to-sound correspondences. Note that semantics and output processes would be expected to be preserved. The patient JC described by Marshall and Newcombe exhibited at least some of the features of this type of surface dyslexia. For example, in response to the word

"listen," JC said "Liston" (a former heavyweight champion boxer) and added "that's the boxer," demonstrating that he was able to derive phonology from print and subsequently access meaning.

In the model depicted in Fig. 1, one might also expect to encounter surface dyslexia with deficits at the level of the output lexicon. Support for such an account comes from patients who comprehend irregular words but regularize these words when asked to read aloud. For example, MK read the word "steak" as "steek" (as in seek) before adding, "nice beef." In this instance, the demonstration that MK was able to provide appropriate semantic information indicates that he was able to access meaning directly from the written word and suggests that the visual word form system and semantics are at least relatively preserved.

In the model depicted in Fig. 1, one might also expect to observe semantic dementia in patients exhibiting semantic loss. Indeed, most patients with surface dyslexia (often in association with surface dysgraphia) exhibit a significant semantic deficit. Surface dyslexia is most frequently observed in the context of semantic dementia, a progressive degenerative condition characterized by a gradual loss of knowledge in the absence of deficits in motor, perceptual, and, in some instances, executive function.

Note, however, that the information processing account of reading depicted in Fig. 1 also incorporates a lexical but nonsemantic reading mechanism by means of which patients with semantic loss would be expected to be able to read even irregular words not accommodated by the grapheme-to-phoneme procedure. Surface dyslexia is assumed to reflect impairment in both the semantic and the lexical but nonsemantic mechanisms. It should be noted that in this context the triangle model of reading developed by Seidenberg and McClelland provides an alternative account of surface dyslexia. In this account, to which I briefly return later, surface dyslexia is assumed to reflect the disruption of semantically mediated reading.

V. READING AND THE RIGHT HEMISPHERE

One important and controversial issue regarding reading concerns the putative reading capacity of the right hemisphere. For many years investigators argued that the right hemisphere was "word blind." In recent years, however, several lines of evidence have suggested that the right hemisphere may possess the capacity to read. Indeed, as previously noted, many investigators have argued that the reading of deep dyslexics is mediated at least in part by the right hemisphere.

One seemingly incontrovertible finding demonstrating that at least some right hemispheres possess the capacity to read comes from the performance of a patient who underwent a left hemispherectomy at age 15 for treatment of seizures caused by Rasmussen's encephalitis. After the hemispherectomy the patient was able to read approximately 30% of single words and exhibited an effect of part of speech; she was unable to use a grapheme-to-phoneme conversion process. Thus, as noted by the authors, this patient's performance was similar in many respects to that of patients with deep dyslexia, a pattern of reading impairment that has been hypothesized to reflect the performance of the right hemisphere.

The performance of some split-brain patients is also consistent with the claim that the right hemisphere is literate. For example, these patients may be able to match printed words presented to the right hemisphere with an appropriate object. Interestingly, the patients are apparently unable to derive sound from the words presented to the right hemisphere; thus, they are unable to determine if a word presented to the right hemisphere rhymes with an auditorally presented word.

Another line of evidence supporting the claim that the right hemisphere is literate comes from the evaluation of the reading of patients with pure alexia and optic aphasia. We reported data, for example, from four patients with pure alexia who performed well above chance on many lexical decision and semantic categorization tasks with briefly presented words that they could not explicitly identify. Three of the patients who regained the ability to explicitly identify rapidly presented words exhibited a pattern of performance consistent with the right hemisphere reading hypothesis. These patients read nouns better than functors and words of high imageability (e.g., "chair") better than words of low imageability (e.g., "destiny"). Additionally, both patients for whom data are available demonstrated a deficit in the reading of suffixed (e.g., "flower") compared to pseudosuffixed (e.g., "flowed") words. These data are consistent with a version of the right hemisphere reading hypothesis postulating that the right hemisphere lexical–semantic system primarily represents high imageability nouns. By this account, functors, affixed words, and low imageability words are not adequately represented in the right hemisphere. An important additional finding is that magnetic stimulation applied to the skull, which disrupts electrical activity in the brain, interfered with

the reading performance of a partially recovered pure alexic when it affected the parietooccipital area of the right hemisphere. The same stimulation had no effect when it was applied to the homologous area on the left. Additional data supporting the right hemisphere hypothesis come from the demonstration that the limited whole-word reading of a pure alexic was abolished after a right occipitotemporal stroke.

Although a consensus has not been achieved, there is mounting evidence that, at least for some people, the right hemisphere is not word blind but may support the reading of some types of words. The full extent of this reading capacity and whether it is relevant to normal reading, however, remains unclear.

VI. THE ANATOMIC BASIS OF DYSLEXIA

A variety of experimental techniques, including position emission tomography, functional magnetic resonance imaging (fMRI), and evoked potentials, have been employed to investigate the anatomic basis of reading in normal subjects. Although differences in experimental technique and design inevitably lead to variability in reported sites of activation, there appears to be at least relative agreement regarding the anatomic basis of several components of the reading system.

As previously noted, most accounts of reading postulate that after initial visual processing, familiar words are recognized by comparison to a catalog of stored representations that is often termed the visual word form system. A variety of recent investigations involving visual lexical decision with fMRI, viewing of letter, and direct recording of cortical electrical activity suggests that the visual word form system is supported by inferior occipital or inferior temporooccipital cortex.

Additional evidence for this localization comes from a recent investigation by Cohen *et al.* of five normal subjects and two patients with posterior callosal lesions. These investigators presented words and nonwords for lexical decision or oral reading to either the right or the left visual fields. They found initial unilateral activation in what was thought to be V4 in the hemisphere to which the stimulus was projected. More importantly, however, for normal subjects activation in the left fusiform gyrus (Talairach coordinates −42, −57, and −6) that was independent of the hemisphere to which the stimulus was presented was observed. The two patients with posterior callosal lesions were impaired in the processing of letter strings presented to the right compared to the left hemisphere; fMRI in these subjects demonstrated that the region of the fusiform gyrus described previously was activated in the callosal patients only by left hemisphere stimulus presentation. As noted by the investigators, these findings are consistent with the hypothesis that the hemialexia demonstrated by the callosal patients is attributable to a failure to access the visual word form system in the left fusiform gyrus.

Deriving meaning from visually presented words requires access to stored knowledge or semantics. Although the architecture and anatomic bases of semantic knowledge remain controversial, investigations involving semantic access for written words implicate cortex at the junction of the superior and middle temporal gyrus (Brodman areas 21, 22, and 37).

VII. ALTERNATIVE MODELS OF READING

Our discussion has focused on a "box and arrow" information processing account of reading disorders. This account not only has proven useful in terms of explaining data from normal and brain-injured subjects but also has predicted syndromes of acquired dyslexia. One weakness of these models, however, is the fact that the accounts are largely descriptive and underspecified.

In recent years, many investigators have developed models of reading in which the architecture and procedures are fully specified and implemented in a manner that permits an empirical assessment of their performance. One computational account of reading has been developed by Coltheart and colleagues. Their dual-route cascaded model represents a computationally instantiated version of dual-route theory similar to that presented in Fig. 1. This account incorporates a lexical route (similar to C in Fig. 1) as well as a nonlexical route by which the pronunciation of graphemes is computed on the basis of position-specific correspondence rules. The model accommodates a wide range of findings from the literature on normal reading.

A fundamentally different type of reading model was developed by Seidenberg and McClelland and subsequently elaborated by Plaut, Seidenberg, and colleagues. This model belongs to the general class of parallel distributed processing or connectionist models. Sometimes referred to as the triangle model, this approach differs from information processing models in that it does not incorporate word-specific representations (e.g., visual word forms and output phonologic representations). In this approach, subjects are assumed to learn how written words map onto spoken

words through repeated exposure to familiar and unfamiliar words. Learning of word pronunciations is achieved by means of the development of a mapping between letters and sounds generated on the basis of experience with many different letter strings. The probabilistic mapping between letters and sounds is assumed to provide the means by which both familiar and unfamiliar words are pronounced. This model not only accommodates an impressive array of the classic findings in the literature on normal reading but also has been "lesioned" in an attempt to reproduce the patterns of reading characteristic of dyslexia. For example, Patterson *et al*. attempted to accommodate surface dyslexia by disrupting the semantically mediated reading, and Plaut and Shallice generated a pattern of performance similar to that of deep dyslexia by lesioning a somewhat different connectionist model.

A full discussion of the relative merits of these models as well as approaches to the understanding of reading and acquired dyslexia is beyond the scope of this article. It appears likely, however, that investigations of acquired dyslexia will help to adjudicate between competing accounts of reading and also that these models will continue to offer critical insights into the interpretation of data from brain-injured subjects.

GLOSSARY

alpha rhythms Electroencephalogram (EEG)/magnetoencephalogram (MEG) rhythmic activity at 8–13 Hz occurring during wakefulness, mainly over the posterior regions of the head. It is predominant when the subject has closed eyes and is in a state of relaxation. It is attenuated by attention, especially visual, and by mental effort. There are other rhythmic activities within the same frequency range, such as the mu rhythm and the tau or temporal alphoid rhythm, that in MEG recordings have been associated with cortical auditory function, but these are less clear in EEG recordings.

beta/gamma rhythms These rhythmic activities represent frequencies higher than 13 Hz; typically, the beta rhythmic activity ranges from 13 to approximately 30–40 Hz and the gamma extends beyond the latter frequency. Rhythmical beta/gamma activities are encountered mainly over the frontal and central regions and are not uniform phenomena. These rhythmic activities can occur in relation to different behaviors, such as during movements or relaxation after a movement.

desynchronization A state in which neurons are randomly active. Desynchronization is reflected in the absence of a preferred EEG/MEG frequency component. Event-related desynchronization of ongoing EEG/MEG is a state characterized by a decrease in the power of spectral peaks at specific frequency components, elicited by an event.

electroencephalogram, magnetoencephalogram Electrical potentials or magnetic fields recorded from the brain, directly or through overlying tissues.

excitatory synaptic potential or current An active electrical response of the postsynaptic membrane of a neuron to the release of a neurotransmitter that consists of a local, graded depolarization or of the corresponding ionic current.

event-related potential or field A change in electrical or magnetic activity related to an event, either sensory or motor. The event may precede or follow the event-related potential or field.

evoked potentials or fields A change in electrical or magnetic activity in response to a stimulus. Typically, these transients last tens or hundreds of milliseconds.

inhibitory postsynaptic potential/current Consists of a local, graded hyperpolarization or the corresponding ionic current.

mu or rolandic (central) rhythm Rhythmic activity within the same frequency range as the posterior alpha rhythm but with a topographic distribution that is predominant over the central sensorimotor areas. It is attenuated or blocked by movements.

nonlinear dynamics and brain oscillations Systems with nonlinear elements, such as neuronal networks, may exhibit complex dynamics. Typically, these systems may have different kinds of evolution in time and may switch from one oscillatory mode to another. A qualitative change in the dynamics that occurs as a system's parameter varies is called a bifurcation. Some brain oscillations appear to be generated by systems of this kind, with complex nonlinear dynamics.

sleep or sigma spindles Waxing and waning spindle-like waves occurring during the early stage of sleep at 7–14 Hz within sequences lasting 1 or 2 sec. Sleep spindles typically recur at a slow rhythm of about 0.2–0.5 Hz.

synchronization State in which neurons oscillate in phase as a result of a common input and/or of mutual influences. Event-related synchronization of the ongoing EEG/MEG signals is a state characterized by an increase in power of specific frequency components.

theta rhythms or rhythmical slow activity This term denotes rhythmic activity in the frequency range from 4 to 7 Hz in humans, although macro-osmatic animals show a powerful limbic, and especially hippocampi, rhythm from 3 to 12 Hz that is activated by arousal and motor activity.

The recording of the electrical activity of the brain [i.e., the electroencephalogram (EEG)], either the ongoing activity or the changes of activity related to a given sensory or motor event [the event-related potentials (ERPs)], provides the possibility of studying brain functions with a high time resolution but with a relatively modest spatial resolution. The latter, however, has been improved recently with the development of the magnetoencephalogram (MEG) and more sophisticated source imaging techniques. These new methods allow an analysis of the dynamics of brain activities not only of global brain functions, such as sleep and arousal, but also of cognitive processes, such as perception, motor preparation, and higher cognitive functions. Furthermore, these methods are essential for the characterization of pathophysiological processes, particularly those with a paroxysmal character such as epilepsy. In this article, the possibilities offered by EEG/MEG recordings to analyze brain functions, and particularly the neural basis of cognitive processes, are discussed. In this respect, special attention is given to the basic mechanisms underlying the generation of functional neuronal assemblies (i.e., the processes of synchronization and desynchronization of neuronal activity) and their modulation by exogenous and endogenous factors. Therefore, a brief overview of the neurophysiology of the dynamics of neuronal networks and of the generation of brain oscillations, an account of the phenomenology of EEG/MEG activities, and a discussion of the main aspects of ERPs and/or magnetic fields are presented. The article concludes with a short discussion of the roles that brain oscillations may play in the processing of neural information. In this respect, the need to understand what happens at the level of neuronal elements within brain systems in relation to different types of oscillations is emphasized. Only in this way is it possible to obtain insight into the functional processes that occur in the brain, at the level of information transfer or processing, during the occurrence of brain oscillations and the transition between different states. The relevance of electrophysiological studies of the human brain regarding neurocognitive investigations is also discussed in light of recent advances in brain imaging techniques.

I. THE ELECTROPHYSIOLOGICAL APPROACH VERSUS OTHER APPROACHES OF STUDYING BRAIN FUNCTIONS

In the past decade, the emergence of brain imaging techniques, such as positron emission tomography and functional magnetic resonance (fMRI), has made important contributions to our understanding of basic brain processes underlying neurocognitive functions. Notwithstanding the fact that, in particular, fMRI can provide maps of brain activity with millimeter spatial resolution, its temporal resolution is limited. Indeed, this resolution is on the order of seconds, whereas neurocognitive phenomena may take place within tens of milliseconds. Therefore, it is important to use electrophysiological techniques to achieve the desired temporal resolution in this kind of investigation, although this is done at the cost of spatial resolution. The essential problem of electro/magnetoencephalography is that the sources of neuronal activity cannot be derived in a unique way from the distribution of EEG or MEG activity at the scalp; thus, the inverse problem is an ill-posed problem. However, new possibilities are emerging to solve this problem. A promising solution is to solve the inverse problem by imposing spatial constraints based on anatomical information provided by MRI and additional physiological information from metabolic or hemodynamic signals, derived from fMRI, that are associated with the neuronal activity. The precise nature of this association, however, is not trivial and it is a matter of current investigation. This implies that we may expect that in the near future technical advances in combining fMRI and EEG/MEG measures of brain activity will contribute to a better understanding of neurocognitive and other brain functions.

II. HISTORY OF THE ELECTROPHYSIOLOGY OF THE BRAIN

The existence of the electrical activity of the brain (i.e., the EEG) was discovered more than a century ago by Caton. After the demonstration that the EEG could be recorded from the human scalp by Berger in the 1920s, it was slowly accepted as a method of analysis of brain functions in health and disease. It is interesting to note that acceptance came only after the demonstration by Adrian and Mathews in the 1930s that the EEG, namely the alpha rhythm, was likely generated in the occipital lobes in man. The responsible neuronal

sources, however, remained undefined until the 1970s, when it was demonstrated in dog that the alpha rhythm is generated by a dipole layer centered on layers IV and V of the visual cortex. It is not surprising that the mechanisms of generation and the functional significance of the EEG remained controversial for a relatively long time, considering the complexity of the underlying systems of neuronal generators and the involved transfer of signals from the cortical surface to the scalp due to the geometric and electrical properties of the volume conductor (brain, cerebrospinal fluid, skull, and scalp).

The EEG consists essentially of the summed electrical activity of populations of neurons, with a modest contribution of glial cells. Considering that neurons are excitable cells with characteristic intrinsic electrical properties and that interneuronal communication is essentially mediated by electrochemical processes at synapses, it follows that these cells can produce electrical and magnetic fields that may be recorded at a distance from the sources. Thus, these fields may be recorded a short distance from the sources [i.e., the local EEG or local field potentials (LFPs)], from the cortical surface (the electrocorticogram), or even from the scalp (i.e., the EEG in its most common form). The associated MEG is recorded usually by way of sensors placed at a short distance around the scalp.

In order to understand how the electrical and magnetic signals of the brain are generated, it is necessary to examine how the activity of assemblies of neurons is organized both in time and in space and which biophysical laws govern the generation of extracellular field potentials or magnetic fields.

III. THE GENERATION OF ELECTRIC AND MAGNETIC EXTRACELLULAR FIELDS

It is generally assumed that the neuronal events that cause the generation of electric and/or magnetic fields in a neural mass consist of ionic currents that have mainly postsynaptic sources. For these fields to be measurable at a distance from the sources, it is important that the underlying neuronal currents are well organized both in space and in time. The ionic currents in the brain obey Maxwell's and Ohm's laws.

The most important ionic current sources in the brain consist of changes in membrane conductances caused by intrinsic membrane processes and/or by synaptic actions. The net membrane current that results from changes in membrane conductances, either synaptic or intrinsic, can be either a positive or a negative ionic current directed to the inside of the neuron. These currents are compensated by currents flowing in the surrounding medium since there is no accumulation of electrical charge. Consider as the simplest case that of synaptic activity caused by excitatory postsynaptic currents (EPSCs) or inhibitory postsynaptic currents (IPSCs). Because the direction of the current is defined by the direction along which positive charges are transported, at the level of the synapse there is a net positive inward current in the case of an EPSC and a negative one in the case of an IPSC. Therefore, extracellularly an active current sink is caused by an EPSC and an active current source by an IPSC. Most neurons are elongated cells; thus, along the passive parts of the membrane (i.e., at a distance from the active synapses) a distributed passive source is created in the case of an EPSC and a distributed passive sink in the case of an IPSC. In this way, a dipole configuration is created (Fig. 1). At the macroscopic level, the activation of a set of neurons organized in parallel is capable of creating dipole layers. The following are important conditions that have to be satisfied for this to occur: (i) The neurons should be spatially organized with the dendrites aligned in parallel, forming palisades, and (ii) the synaptic activation of the neuronal population should occur in synchrony.

Lorente de Nó named the type of electric field created in this way an "open field," in contrast to the field generated by neurons with dendrites radially distributed around the soma which form a "closed field." In any case, as a result of synaptic activation, extracellular currents will flow. These may consist of longitudinal or transversal components, the former being those that flow parallel to the main axis of a neuron and the latter flow perpendicular to this axis. In the case of an open field, the longitudinal components will add, whereas the transversal components tend to cancel out. In the case of a closed field, all components will tend to cancel, such that the net result at a distance is zero.

The importance of the spatial organization of neuronal current sources for the generation of electric and/or magnetic fields measurable at a distance can be stated in a paradigmatic way for the cortex. Indeed, the pyramidal neurons of the cortex are lined up perpendicular to the cortical surface, forming layers of neurons in palissade. Their synaptic activation can occur within well-defined layers and in a synchronized way. The resulting electric fields may be quite large if the activity within a population of cells forms a

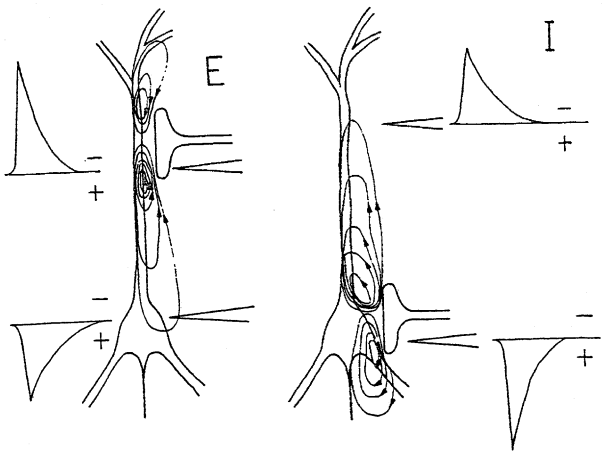

Figure 1 Model cortical pyramidal cell showing the patterns of current flow caused by two modes of synaptic activation at an excitatory (E) and an inhibitory (I) synapse. Typically, the apical dendrites of these cells are oriented toward the cortical surface. E, current flow caused by the activation of an excitatory synapse at the level of the apical dendrite. This causes a depolarization of the postsynaptic membrane (i.e., an EPSP), and the flow of a net positive current (i.e., EPSC). This current flow creates a current sink in the extracellular medium next to the synapse. The extracellularly recorded EPSP is shown on the left. It has a negative polarity at the level of the synapse. At the soma there exists a distributed passive current source resulting in an extracellular potential of positive polarity. I, current flow caused by activation of an inhibitory synapse at the level of the soma. This results in a hyperpolarization of the postsynaptic membrane and in the flow of a negative current. Thus, an active source is created extracellularly at the level of the soma and in passive sinks at the basal and apical dendrites. The extracellularly recorded IPSP at the level of the soma and of the apical dendrites is shown. Note that both cases show a dipolar source–sink configuration, with the same polarity, notwithstanding the fact that the postsynaptic potentials are of opposite polarity (EPSP vs IPSP). This illustrates the fact that not only does the nature of the synaptic potential determine the polarity of the potentials at the cortical surface but also the position of the synaptic sources within the cortex is important (adapted with permission from Niedermeyer and Lopes da Silva, 1999).

coherent domain (i.e., if the activity of the neuronal sources is phase locked). In general, the electric potential generated by a population of neurons represents a spatial and temporal average of the potentials generated by the single neurons within a macrocolumn.

A basic problem in electroencephalography/magnetoencephalography is how to estimate the neuronal sources corresponding to a certain distribution of electrical potentials or of magnetic fields recorded at the scalp. As noted previously, this is called the inverse problem of EEG/MEG. It is an ill-posed problem that has no unique solution. Therefore, one must assume specific models of the sources and of the volume conductor. The simplest source model is a current dipole. However, it should not be considered that such a model means that somewhere in the brain there exists a discrete dipolar source. It simply means that the best representation of the EEG/MEG scalp distribution is by way of an equivalent dipolar source. In the sense of a best statistical fit, the latter describes the centroid of the dipole layers that are active at a certain moment. The estimation of equivalent dipole models is only meaningful if the scalp field has a focal character and the number of possible active areas can be anticipated with reasonable accuracy. An increase in the number of dipoles can easily lead to complex and ambiguous interpretations. Nevertheless, methods have been developed to obtain estimates of multiple dipoles with only the a priori information that they must be located on the surface of the cortex. An algorithm that performs such an analysis is multiple signal classification (MUSIC), which is illustrated in Fig. 2 for the case of the cortical sources of the alpha rhythm. An alternative approach is to use linear estimation methods applying the minimum norm constraint to estimate the sources within a given surface or volume of the brain. Currently, new approaches are being explored that use combined fMRI and EEG/MEG recordings in order to create more specific spatial constraints to reduce the solution space for the estimation of the underlying neuronal sources. In general, the problems created by the complexity of the volume conductor, including the scalp, skull, layer of cerebrospinal fluid, and brain, are easier to solve in the case of MEG than EEG since these media have conductivities that affect the EEG much more than the MEG. The major advantage of MEG over EEG is the relative ease of source localization with the former. This means that when a dipole source algorithm is used on the basis of MEG recordings, a simple homogeneous sphere model of the volume conductor is usually sufficient to obtain a satisfactory solution. The position of the sources can be integrated in MRI scans of the brain using appropriate algorithms.

IV. DYNAMICS OF NEURONAL ELEMENTS: LOCAL CIRCUITS AND MECHANISMS OF OSCILLATIONS

Here, I discuss the dynamics of the electrical and magnetic fields of the brain, i.e., their time-dependent properties. These properties are determined to a large extent by the dynamical properties of ionic currents.

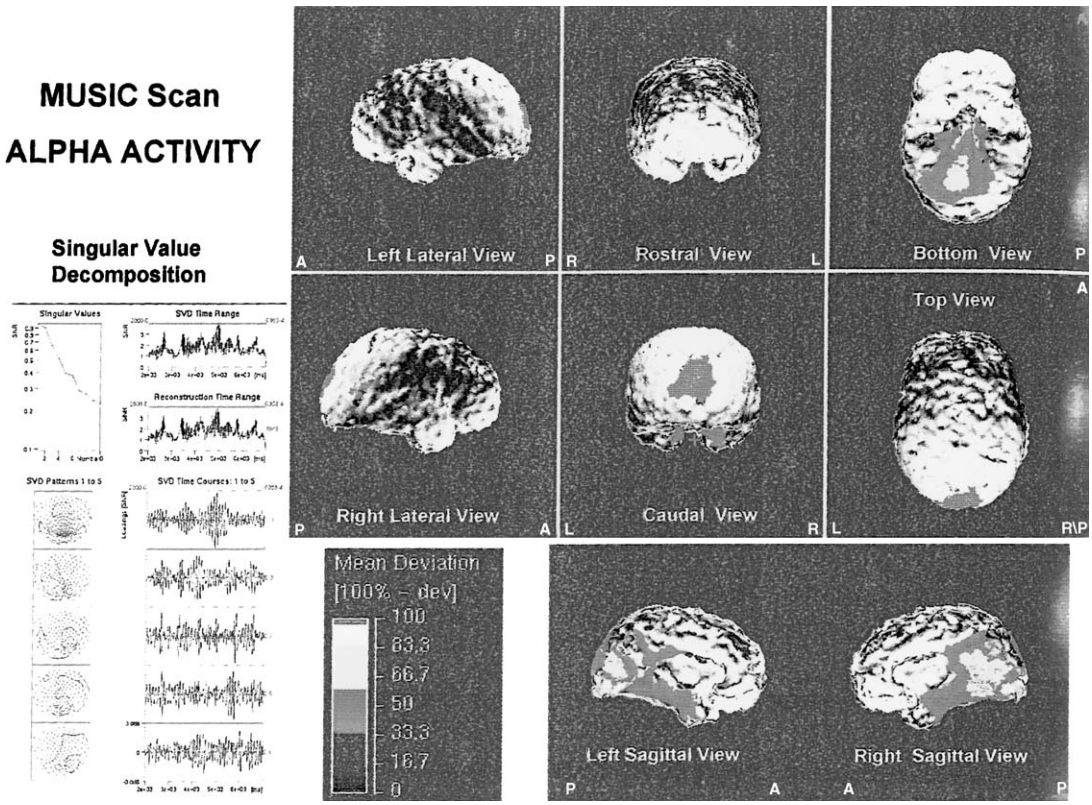

Figure 2 Results of a multiple signal classification analysis (MUSIC) scan of a 5-sec-long epoch of alpha activity recorded using a whole-head 151 MEG system during the eyes-closed condition. A singular value decomposition of the MEG signals yielded four factors. The scale indicates the cortical areas where the most significant sources were estimated (reproduced with permission from Parra *et al.*, *J. Clin. Neurophysiol.* **17,** 212–224, 2000).

The most elementary phenomenon to be taken into account is the passive time constant of the neuronal membrane. This is typically about 5 msec for most cortical pyramidal neurons. Therefore, the activation of a synapse causing an ionic current to flow will generate a postsynaptic potential change that decays passively with such a time constant. However, there are other membrane phenomena that have much longer time constants. Some of these are intrinsic membrane processes, whereas others are postsynaptic. Among the intrinsic membrane phenomena, a multitude of ionic conductances, distributed along both soma and dendrites, enable neurons to display a variety of modes of activity. Among the synaptic phenomena, some present much longer time constants than the membrane passive time constant. This is the case, for example, for the $GABA_B$-mediated inhibition that consists of a K^+ current with slow dynamics. The synaptic actions of amines and neuropeptides, in contrast with those of amino acids such as glutamate and GABA, also have slow dynamics. The effect of acetylcholine (ACh) is mixed since fast and slow actions occur, depending on the type of receptors to which ACh binds. Furthermore, note that the dendrites do not consist of simple passive membranes, as in the classical view; rather, the dendrites also have voltage-gated ion conductances that can contribute actively to the electrical behavior of the whole neuron. Thus, a neuron must be considered as a system of functional nodes, where each node represents a chemical synapse, an active ionic conductance, a metabolic modulated ion channel, or, in some cases, a gap junction (i.e., a direct electrical coupling between adjacent cells through a low-resistance pathway).

The sequence of hyperpolarizations and depolarizations caused by inhibitory and excitatory synaptic activity, respectively, can induce the activation or the removal of inactivation of intrinsic membrane currents. This aspect is difficult to analyze in detail under natural conditions in intact neuronal populations. However, much was learned about this kind of phenomena from studies carried out *in vitro* both in

isolated cells and in brain slices. To illustrate this, consider the typical behavior of thalamic neurons that participate in the thalamocortical circuits with feed-forward and feedback connections (Fig. 3). Even in isolation, these cells may show intrinsic oscillatory modes of activity, either in the alpha range of activity (namely, in the form of spindles at 7–14 Hz) or in the delta frequency range (0.5–4 Hz). To understand how

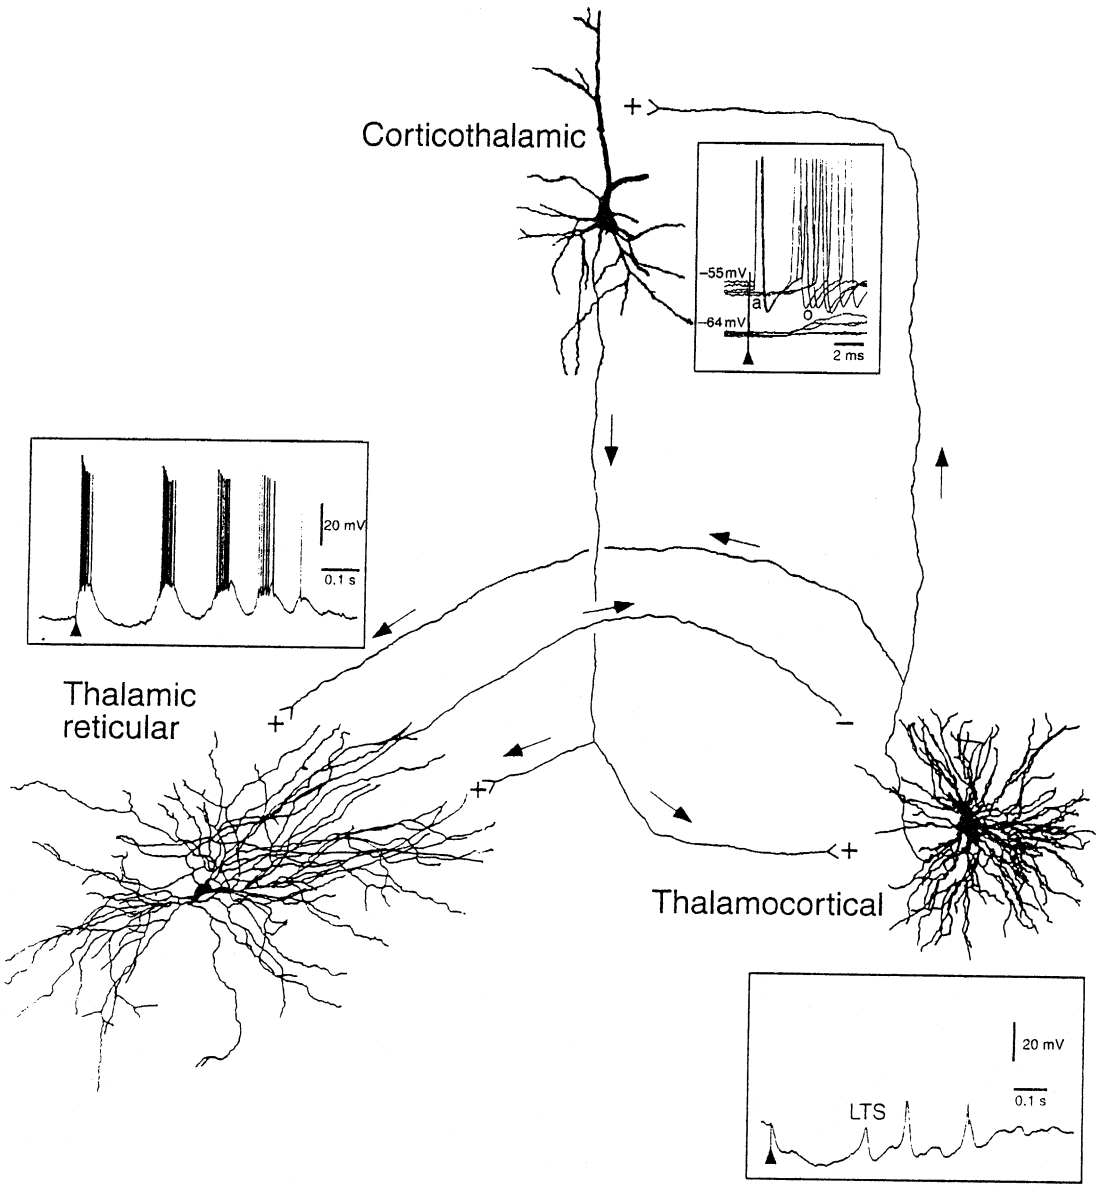

Figure 3 Corticothalamic circuits and different types of neuronal activities. A thalamocortical relay cell is shown on the lower right-hand side, a neuron of the reticular nucleus (GABAergic) is shown on the left, and a cortical pyramidal cell is shown on top. The direction of the flow of action potentials along the axons is indicated by arrows. Positive signs indicate excitatory synapses and negative signs indicate inhibitory synapses. The insets show cellular responses obtained intracellularly. In this case, the activity of the cortical neuron was obtained by electrical stimulation of the intralaminar nucleus of the thalamus. At the membrane potential of −55 mV the response consisted of an antidromic spike (a) followed by a bursts of orthodromic spikes (o). At a more hyperpolarized level (−64 mV), the antidromic response failed but the orthodromic response consisted of a subthreshold EPSP. The responses of the two thalamic neurons were obtained by stimulation of the cortex. The response of the neuron of the reticular nucleus consists of a high-frequency burst of spikes followed by a series of spindle waves on a depolarizing envelope. The response of the thalamocortical neuron consists of a biphasic IPSP that leads to a low-threshold calcium spike (LTS) and a sequence of hyperpolarizing spindle waves (reproduced with permission from Steriade, 1999).

oscillations can take place in these circuits it is important to realize that these cells have, among other kinds of ionic currents, a low-threshold Ca^{2+} conductance (I_T) that contributes to the low-threshold spike. This I_T conductance is de-inactivated by a previous membrane hyperpolarization and causes sufficient depolarization of the cell for the activation of a persistent (non-inactivating) Na+ conductance. These cells also have a nonspecific cation "sag" current (I_h) that has much slower kinetics than I_T and is activated by hyperpolarization. The alpha range oscillatory mode depends essentially on the low-threshold Ca^{2+} current I_T. In addition, other currents contribute to the oscillatory behavior—namely, a fast transient potassium current (I_A) that has a voltage dependence that is similar to that of I_T, a slowly inactivating potassium current, and calcium-dependent potassium currents that need increased intracellular Ca^{2+} concentration for activation—and are mainly responsible for after-hyperpolarizations. In this way, a sequence of hyperpolarizations followed by depolarizations tends to develop. This could be sufficient for such cells to behave as neuronal "pacemakers." Under the *in vitro* conditions in which these basic properties have been studied, the initial hyperpolarization that is necessary for the removal of the inactivation of the Ca^{2+} current is provided artificially by an intracellular injection of current. However, under natural conditions in the intact brain, the oscillatory behavior cannot occur spontaneously (i.e., it is not autonomous). For the de-inactivation of the low-threshold Ca^{2+} current to occur, initially the cell has to be hyperpolarized by a synaptic action mediated by GABAergic synapses that impinge on these cells and stem from the GABAergic neurons of the reticular nucleus of the thalamus. Therefore, the notion that these thalamo-cortical relay cells behave as pacemakers, in the sense of generating pure autonomous oscillations, *in vivo* is only a relative one. Indeed, they need a specific input from outside to set the conditions under which they may oscillate. Thus, *in vivo* the alpha spindle and delta waves result from network interactions. Nevertheless, the intrinsic membrane properties are of importance in setting the frequency response of the cells and of the network to which they belong.

In general terms, it must be considered that neurons, as integrative units, interact with other neurons through local circuits, excitatory as well as inhibitory. In a neuronal circuit feedforward and feedback elements have to be distinguished. In particular, the existence of feedback loops can shape the dynamics of a neuronal network affecting its frequency response and even creating the conditions for the occurrence of resonance phenomena and other forms of oscillatory behavior. Furthermore, note that the transfer of signals in a neuronal network involves time delays and essential nonlinearities. This may lead to the appearance of nonlinear oscillations and possibly even to what is in mathematical terms called chaotic behavior.

In recent years, much has been learned about these issues with the advent of the theory of nonlinear dynamics. This has resulted in the application of nonlinear time series analysis to EEG signals, with the aim of estimating several nonlinear measures to characterize different kinds of EEG signals. This matter is the object of recent interesting studies reported in specialized publications in which the question "chaos in brain?" is discussed. I stress here only that a theoretical framework based on the mathematical notions of complex nonlinear dynamics can be most useful to understanding the dynamics of EEG phenomena. In this context, insight may be obtained into how different types of oscillations may be generated within the same neuronal population and how such a system may switch from one type of oscillatory behavior to another. This occurs, for example, when an EEG/MEG characterized by alpha rhythmic activity suddenly changes into a 3-Hz spike and wave pattern during an absence seizure in epileptic patients. Based on the use of mathematical nonlinear models of neuronal networks, it is possible to formulate hypotheses concerning the mechanisms by means of which a given neuronal network can switch between these qualitatively different types of oscillations. This switching behavior depends on input conditions and on modulating parameters. Accordingly, such a switch can take place depending on subtle changes in one or more parameters. In the theory of complex nonlinear dynamics, this is called a bifurcation. In this respect, the most sensitive parameter is the neuronal membrane potential that in the intact brain is modulated by various synaptic inputs. Typically, the change of oscillation mode may be spectacular, whereas the initial change of a parameter may be minimal.

The frequency of a brain oscillation depends both on the intrinsic membrane properties of the neuronal elements and on the properties of the networks to which they belong. Considerations regarding the membrane conditions that determine which ionic currents can be active at a given time lead to the conclusion that the modulating systems mediated by several neurochemical systems are of utmost importance in setting the initial conditions that determine the

activity mode of the network (i.e., whether it will display oscillations or not and at which frequency). Different behavioral states are characterized by the interplay of different chemical neurotransmitter and neuromodulator systems.

A fundamental property of a neuronal network is the capacity of the neurons to work in synchrony. This depends essentially on the way the inputs are organized and on the network interconnectivity. Thus, groups of neurons may work synchronously as a population due to mutual interactions. The experimental and theoretical work of Ad Aetsen and Moshe Abeles showed the existence of precise (within 5 msec) synchrony of individual action potentials among selected groups of neurons in the cortex. These synchronous patterns of activity were associated with the planning and execution of voluntary movements. These researchers noted that during cognitive processes the neurons tend to synchronize their firing without changing the firing rates, whereas in response to external events they synchronize firing rates and modulate the frequency at the same time. In addition, they also showed that the synchronization dynamics are strongly influenced by the level of background activity. This indicates the importance that the ongoing electrical activity can have in setting the activity climate in a given brain system.

A fundamental feature of the cortex is that groups of neurons tend to form local circuits organized in modules with the geometry of cortical columns. The basic cortical spatial module is a vertical cylinder with a 200–300 μm cross-section. There exist different systems of connecting fibers between cortical columns, namely, (i) the collaterals of axons of pyramidal neurons that may spread over distances of approximately 3 mm and are mostly excitatory; (ii) the ramifications of incoming terminal axons that may extend over distances of 6–8 mm along the cortical surface; and (iii) the collaterals of interneurons, an important part of which are inhibitory, that may branch horizontally over 0.5–1 mm within the cortex. These systems range over distances on the order of magnitude of hundreds of micrometers, and this determines the characteristic length of intracortical interactions.

It is not simple to directly relate the dynamic behavior of a neuronal network to the basic parameters of neurons and synapses. In order to construct such relationships, basic physiological and histological data have to be combined like pieces of a puzzle. However, the available knowledge of most neuronal networks in terms of detailed physiological and even histological information is still incomplete. To supplement this lack of specific knowledge, a synthetic approach can be useful. This implies the construction of connectionist models of neuronal networks using all available and relevant data. Such models can be of practical use to obtain a better understanding of the main properties of a network. Indeed, a model offers the possibility of studying the influence of different parameters on the dynamic behavior of the network and of making predictions of unexplored properties of the system, which may lead to new experiments. In this way, EEG signals, particularly local field potentials (LFPs), can also be modeled. Thus, hypotheses concerning the relevance of given neuronal properties to the generation of special EEG features may be tested.

V. MAIN TYPES OF EEG/MEG ACTIVITIES: PHENOMENOLOGY AND FUNCTIONAL SIGNIFICANCE

A. Sleep EEG Phenomena

In the neurophysiology of sleep two classic EEG phenomena have been established: the spindles or waves between 7 and 14 Hz, also called sleep or sigma spindles, which appear at sleep onset, and the delta waves (1–4 Hz), which are paradigmatic of deeper stages of sleep. Recently, the work of Mircea Steriade and coworkers in Quebec described in animals another very slow oscillation (0.6–1 Hz) that is able to modulate the occurrence of different typical EEG sleep events, such as delta waves, sleep spindles, and even short high-frequency bursts. This very slow oscillation was recently revealed in the human EEG by Peter Acherman and A. Borbély and in the MEG by our group.

The basic membrane events that are responsible for the occurrence of sleep spindles and delta waves were described previously. The sleep spindles are generated in the thalamocortical circuits and result from the interplay between intrinsic membrane properties of the thalamocortical relay neurons (TCR) and the GABAergic neurons of the reticular nucleus, and the properties of the circuits to which these neurons belong. It is clear that the spindles are a collective property of the neuronal populations. Experimental evidence has demonstrated that the sleep spindle oscillations are generated in the thalamus since they can be recorded in this brain area after decortication

and high brain stem transection. The very slow rhythm (0.6–1 Hz), on the contrary, is generated intracortically since it survives thalamic lesions, but it is disrupted by intracortical lesions. Interestingly, note that the rhythmicity of the very slow oscillation appears to be reflected in that of the typical K complexes of human EEG during non-REM sleep.

How are these oscillations controlled by modulating systems? It is well-known that sleep spindles are under brain stem control. It is a classic neurophysiological phenomenon that electrical stimulation of the brain stem can block thalamocortical oscillations causing the so-called "EEG desynchronization," as shown in studies by Moruzzi and Magoun. This desynchronization is caused by the activation of cholinergic inputs (Fig. 4) arising from the mesopontine cholinergic nuclei, namely, the pedunculopontine tegmental and the laterodorsal tegmental areas. Indeed, both the reticular nucleus and the TCR neurons receive cholinergic muscarinic synapses. Cholinergic activation of the reticular nucleus neurons elicits hyperpolarization with a K^+ conductance increase that is mediated by an increase in a muscarinic-activated potassium current. In contrast, it causes depolarization of TCR neurons.

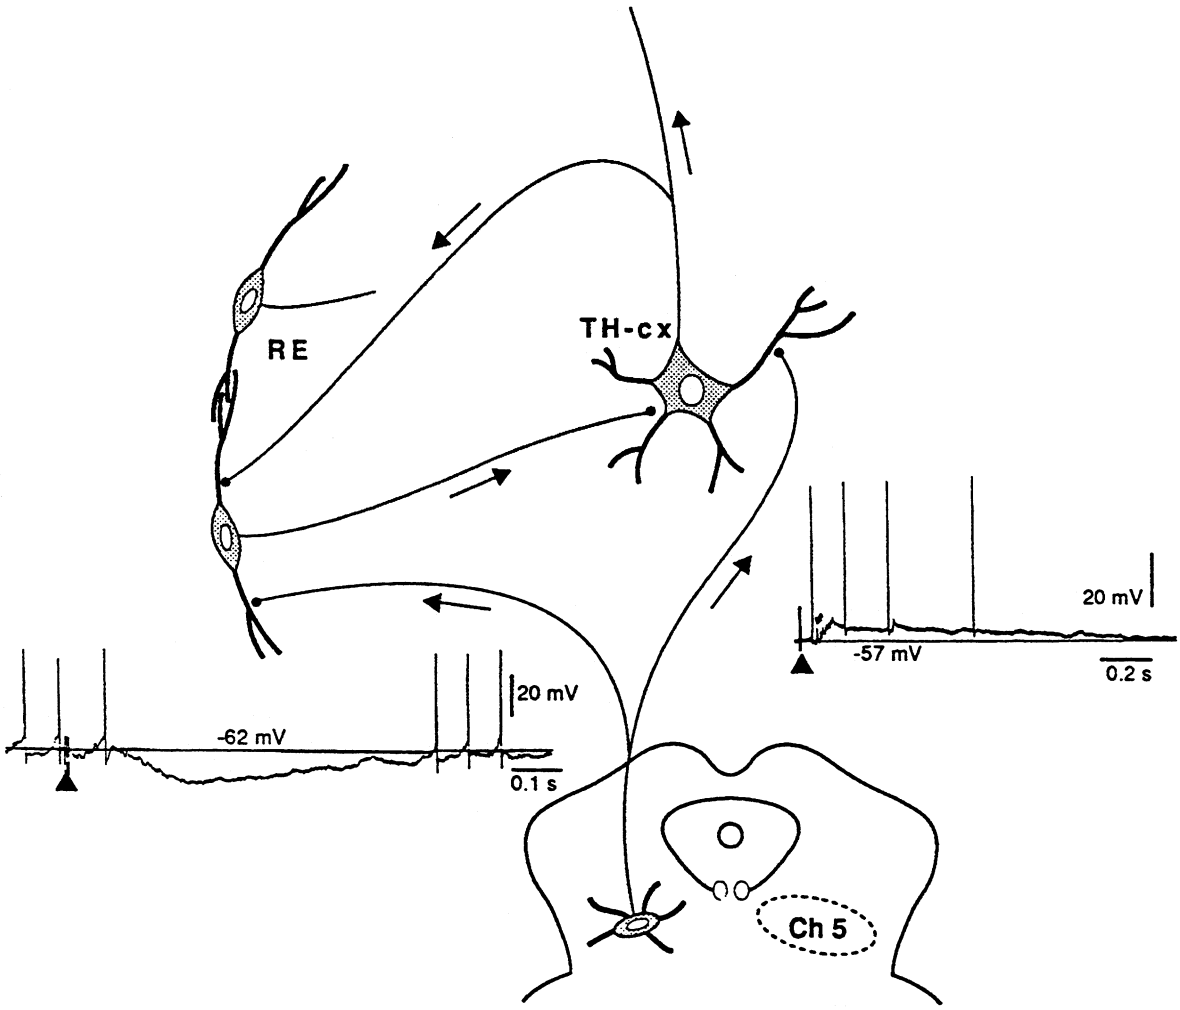

Figure 4 Basic thalamic network responsible for the generation of spindles at 7–14 Hz. A thalamocortical (TH-cx) neuron and two neurons of the reticular nucleus (RE), which are interconnected by mutual inhibitory synapses, are shown. This network is under the modulating influence of mesopontine afferents arising from the cholinergic (Ch5) neurons of the pedunculopontine tegmental nucleus. The stimulation of Ch5 neurons causes depolarization of TH-cx neurons and hyperpolarization of RE neurons. In this way, the occurrence of spindles is blocked (i.e., desynchronization of the corresponding oscillation takes place) (reproduced with permission from Steriade *et al.*, *Electroencephalogr. Clin. Neurophysiol.* **76,** 481–508, 1990).

Furthermore, the reticular nucleus receives inputs from the basal forebrain that may be GABAergic and can also exert a strong inhibition of the reticular neurons leading to the subsequent suppression of spindle oscillations. In addition, monoaminergic inputs from the brain stem, namely those arising at the mesopontine junction (i.e., from the noradrenergic neurons of the locus coeruleus and the serotoninergic neurons of the dorsal raphe nuclei), also modulate the rhythmic activities of the forebrain. These neuronal systems have only a weak thalamic projection but have a diffuse projection to the cortex. Metabotropic glutamate receptors also appear to exert a modulating influence on the activation of thalamic circuits by descending corticothalamic systems.

Because this point is often misunderstood, it is emphasized that slow-wave sleep, characterized by typical EEG delta activity, does not correspond to a state in which cortical neurons are inactive. On the contrary, in this sleep state cortical neurons can display mean rates of firing similar to those during wakefulness and/or REM sleep. Regarding the neuronal firing patterns, the main difference between delta sleep and wakefulness and REM sleep is that in the former the neurons tend to display long bursts of spikes with relatively prolonged interburst periods of silence, whereas in the latter the firing pattern is more continuous. The functional meaning of these peculiar firing pattern of delta sleep has not been determined.

In general, EEG signals covary strongly with different levels of arousal and consciousness. The changes of EEG with increasing levels of anesthesia are typical examples of this property.

B. Alpha Rhythms of Thalamus and Neocortex

Alpha rhythms recorded from the occipital areas occur in relaxed awake animals and show a typical reactivity to eye closure. Although the frequency range of alpha rhythms overlaps that of sleep spindles, these two phenomena differ in many aspects. Namely, the behavioral state in which both types of oscillations occur is quite different, and their distribution over the cortex and thalamus also differs considerably. The basic mechanisms responsible for alpha oscillations at the cellular level have not been described in detail due to the inherent difficulty in studying a phenomenon that by definition occurs in the state of relaxed wakefulness under conditions that allow measuring the underlying membrane currents under anesthesia, or, optimally, in slice preparations *in vitro*. To overcome this difficulty, some researchers assumed that spindles occurring under barbiturate anesthesia were analogous to alpha rhythms. However, this analogy was challenged on experimental grounds because a comparative investigation of alpha rhythms, obtained during restful awakeness at eye closure, and spindles induced by barbiturates, recorded from the same sites over the visual cortex and lateral geniculate nuclei in dog, presented differences in frequency, spindle duration, topographic distribution, and amount of coherence among different cortical and thalamic sites. Investigations using multiple electrode arrays placed on the cortical surface, depth intracortical profiles, and intrathalamic recordings from several thalamic nuclei elucidated many elementary properties of alpha rhythms:

- In the visual cortex, alpha waves are generated by a current dipole layer centered at the level of the somata and basal dendrites of the pyramidal neurons of layers IV and V.
- The coherence between alpha waves recorded from neighboring cortical sites is greater than any thalamocortical coherence.
- The influence of alpha signals recorded from the pulvinar on cortical rhythms can be conspicuously large, depending on cortical area, but intercortical factors play a significant role in establishing cortical domains of alpha activity.

These experimental findings led to the conclusion that in addition to the influence of some thalamic nuclei, mainly the pulvinar, on the generation of alpha rhythms in the visual cortex, there are systems of surface-parallel intracortical connections responsible for the propagation of alpha rhythms over the cortex. These oscillations appear to be generated in small patches of cortex that behave as epicenters, from which they propagate at relatively slow velocities (approximately 0.3 cm/sec). This type of spatial propagation has been confirmed, in general terms, by experimental and model studies. A comprehensive study of alpha rhythms in the visual cortex of the cat showed characteristics corresponding closely to those of alpha in man and dog. It was found that this rhythmic activity was localized to a limited part of the primary visual cortex area 18 and at the border between areas 17 and 18. In this context, additional insight into the sources of alpha rhythms in man has been obtained using MEGs integrated with anatomical information obtained from MRI. Different sources of alpha rhythms, the so-called "alphons," were found

concentrated mainly in the region around the calcarine fissure, with most sources located within 2 cm of the midline. A typical distribution of sources of alpha rhythmic activity over the human cortex was recently obtained using whole-head MEG and analyzed using the MUSIC algorithm as shown in Fig. 2.

In addition to the alpha rhythms of the visual cortex, rhythmic activities with about the same frequency range (in man, 8–13 Hz, in cat; 12–15 Hz) have been shown to occur in other cortical areas, namely in the somatosensory cortex (SI areas 1–3). These activities are known as "rolandic mu rhythms" or "wicket rhythms," named after the appearance of the records on the scalp in man, and they have a typical reactivity since they appear when the subject is at rest and they are blocked by movement. The mu rhythm is particularly pronounced in the hand area of the somatosensory cortex and it reacts typically to the movement of closing the fists. In the cat, there is no significant coherence between the mu rhythm of the SI cortex and the alpha rhythm of the visual cortex, which supports the general idea that these two types of rhythms are independent. Furthermore, mu rhythms of the SI area also differ from the alpha rhythms of the visual cortex recorded in the same animal in that the former have systematically higher frequencies than the latter, the difference being about 2 Hz. Mu rhythms were also recorded in thalamic nuclei, namely in the ventroposterior lateral nucleus. The mu rhythm has also been identified in MEG recordings over the rolandic sulcus, particularly over the somatomotor hand area. The reactivity of the EEG/MEG mu rhythm to movement and other behavioral conditions has been analyzed in detail in man using advanced computer analysis. In addition, another spontaneous MEG activity, the so-called tau rhythm, was detected over the auditory cortex. This rhythmic activity was reduced by sound stimuli. This MEG tau rhythm, first described by the group of Riitta Hari in Helsinki, is apparently similar to an EEG rhythm that was found using epidural electrodes over the midtemporal region by Ernst Niedermeyer in Baltimore.

C. EEG Activities of the Limbic Cortex

Two main types of rhythmic EEG activities can be recorded from limbic cortical areas characterized by different dominant rhythmic components, one in the theta and one in the beta/gamma frequency range. The former was first described by Green and Arduini in 1954, and in several species it may cover the frequency range between 4 and 12 Hz. It is common practice to call this activity theta rhythm since in most species it is dominant between 4 and 7.5 Hz; however, since in rodents it can extend to 12 Hz, it is preferentially called rhythmic slow activity (RSA). The brain areas in which RSA is most apparent are the hippocampus and parahippocampal gyri, although it also occurs in other parts of the limbic system. It has been questioned whether RSA also occurs in humans. However, RSA was incidentally recorded in the human hippocampus and was clearly demonstrated in the hippocampus of freely moving epileptic patients using spectral analysis. The relative difficulty in recording RSA in the human hippocampus may be related to the decrease in amplitude and regularity of RSA encountered in higher primates. Therefore, it can be concluded that the human hippocampus is no exception among mammals with respect to the occurrence of RSA. Using MEG imaging in normal human subjects, Claudia Tesche showed that the activity centered on the anterior hippocampus consisted of spectral components lower than 12 Hz that included task-dependent peaks.
